Abstract. The chemistry has reached its upper boundary, *i.e.*, the ability to detect, fix in space and identify a single molecule, measure almost any of its properties and observe its chemical transformations and functioning. At this frontier, procedures for manipulating single molecules are developed and the element base for nanooptics, nanomechanics and nanoelectronics is created. This is the prologue for a new technological civilisation, *viz.*, to molecular electronics which operates with electric voltages of the order of millivolts and electric currents of the order of nanoamperes. The bibliography includes 101 references.

I. Single molecules as investigation subjects

At the boundary of the 20 and 21 centuries, a quiet revolution almost unnoticed by the broad scientific community took place in chemistry and molecular physics, namely, a breakthrough in the experimental techniques for detection and identification of single molecules and manipulation of them. Luminescence, electrical conductivity, magnetism, non-linear optics, electron paramagnetic and nuclear magnetic resonances, atomic vibration frequencies, elasticity and strength, *i.e.*, all the parameters and properties that have been measured previously only for large ensembles of molecules are now measured also for a single molecule.

This review gives analysis of the key ideas and concepts in the chemistry, physics and mechanics of single molecules. Their significance for chemistry is formulated.

First, detection of a single molecule corresponds to the limit of detection in analytical chemistry. For 'readout' of one molecule on a $1\ \mu\text{m}^2$ surface from a $1\ \mu\text{m}$ -thick layer (nowadays, this is the normal 'operating' condition), the concentration detection limit is $10^{15}\ \text{litre}^{-1}$ or $10^{-9}\ \text{mol litre}^{-1}$. This boundary is meant in the design of detectors of single molecules and highest-sensitivity sensors.

Second, it becomes possible to establish the individual, 'personal' properties of a single molecule rather than averaged or

'hidden' in a large ensemble of similar molecules. Any spectroscopy of large ensembles exhibits non-uniform broadening of spectral lines, which are superpositions of a multitude of lines (differing in widths and frequencies) from the multitude of molecules occurring in different environments. 'Extracting' the spectrum of an individual molecule from the superposition of lines is a complicated and ambiguous task. The spectroscopy of single molecules normally does not face this problem. The spectrum of a single molecule is a reliable and sensitive test of its local environment (molecular site), *i.e.*, the place occupied by the molecule and its near surrounding.

Third, it is now possible to observe functioning of a single molecule and answer the question of how it works, either continuously or with 'rest' periods, in a time-correlated mode or its functioning is random, whether or not it retains the 'memory' of the preceding events of its 'life.' Actually, this is a new field of molecular knowledge which we are only starting to enter.

Fourth, while developing the techniques for manipulation of single molecules (their migration, joining, insertion and combination to form specified molecular ensembles), researchers acquire the experience in designing elements of nanoelectronics, nanomechanics, nanooptics — the future high technology. This is not just a declaration; this is real work on the route of research and discoveries.¹

II. Luminescence of single molecules

The principle of optical detection of single molecules is simple: laser irradiation of a surface containing luminescent molecules excites their luminescence and they can be detected as molecular 'glow-worms'. In Fig. 1a one can see signals from 'luminous' rhodamine B molecules dispersed on the surface of a poly(methyl methacrylate) film;² the site from which the radiation is collected is $4.5 \times 4.5\ \mu\text{m}$. Figure 1b shows the signals from single molecules of the enzyme cholesterol oxidase embedded into an agarose gel film.³ Flavin adenine dinucleotide is the emitter in the enzyme molecule. Light is collected from a $8 \times 8\ \mu\text{m}$ area which accommodates only several molecules. The flickering glow of one cholesterol oxidase molecule is shown in Fig. 1c.³

Since the first observations of the luminescence of single molecules (the late 1980s),⁴ the techniques and technology of optical detection have substantially progressed as regards both sensitivity and reliability.^{5,6} Scanning optical microscopes, high-sensitivity photoelectric detectors, and near-field microscopy

Figure 1. Image of the luminescence of single molecules: (a) rhodamine B on poly(methyl methacrylate) (the drawing was taken from Ref. 2); (b) cholesterol oxidase in the agarose gel (the drawing was taken from Ref. 3); (c) ‘flickering’ of one cholesterol oxidase molecule with time (n is the number of photons emitted per unit time).

opened up the access to detection of luminescent molecules and luminescent labels in solids and liquids, on surfaces and at interfaces, in monolayers and Langmuir–Blodgett films, in liquid crystals and gels, emulsions and porous media, membranes, proteins, nucleic acids, enzymes, chromosomes and molecular motors.^{7,8} A procedure has been developed for detecting luminescent molecules in microcapillaries and microdrops (hanging or dropping), during electrophoresis and in the tunnelling microscope cavity in which luminescence is excited by the tunnelling current.⁹ The range of luminophores (emitters having a high photostability and a great quantum yield) used for attachment to biomacromolecules as luminescent labels and suitable for being placed into any medium has been markedly extended.⁷

A two-quantum luminescence excitation process has been developed. In this case, a molecule is excited by a long-wavelength

radiation, the emission being detected in the short-wave region; this sharply decreases the scattered optical background in the luminescence band and increases the signal-to-noise ratio and, hence, the sensitivity.

Now we consider what new information useful for chemistry is provided by the optical detection of single molecules.

1. Testing of molecular sites

From classical luminescence measurements, one can derive information on averaged properties and interactions of a large ensemble of molecules (even when these are identical). The spectroscopy of a single molecule rules out the averaging. The data obtained by detecting a set of single molecules are much more valuable. The frequency, intensity, line width and polarisation of the luminescence of a single molecule depend on its local environment (local compression, crystal density, vacancies, the presence of quenchers) and on its interaction with the environment (through acoustic phonons and local vibrations). Actually, a single molecule is a ‘reporter’ providing information on the molecular site occupied by the molecule and on the events taking place in this site. An example of this ‘running commentary’ is shown in Fig. 2.¹⁰ Figure 2a shows a series of the fluorescence spectra of pentacene in a *p*-terphenyl crystal at 1.5 K; each spectrum was recorded for 2.5 s (at 0.25 s intervals). It can be seen that the radiation frequency of pentacene varies randomly and unpredictably (every time fluorescence is excited at a different laser frequency; the variation of this frequency is laid-off along the abscissa axis). This means that the energy state of the reporter molecule also varies randomly. The wandering of the molecule over its energy

Figure 2. Spectral diffusion of pentacene in *p*-terphenyl at 1.5 K. (a) successive fluorescence records showing random shifts of the excitation frequency (recording duration 2.5 s, spacing between the records 0.25 s); (b) path of the variation of the fluorescence frequency during the detection of the spectra (500 s).¹⁰

states (*i.e.*, over the luminescence spectrum) can be regarded as a random diffusion process, spectral diffusion.

Figure 2*b* presents the path of spectral diffusion. It can be seen from this path how the fluorescence spectral shift (it was taken from Fig. 2*a*) fluctuates with time.¹⁰ This is an example demonstrating how the environment influences a single reporter molecule. Note high resolution of the ‘running commentary’: at a luminescence wavelength of 592.546 nm (this corresponds to a zero in the abscissa axis in Fig. 2*a*), the molecule reports about energy changes of about 10 MHz; this corresponds to an energy resolution of 10^{-7} – 10^{-8} . A single molecule is the most sensitive sensor.

The spectral diffusion of a single terylene molecule in polyethylene at 0.03 K has been studied.¹¹ In this case, the excited molecule discharges the energy to high-energy phonons, which are partly used for reorganisation of the molecule environment. In turn, this reorganisation changes the orientation of the molecule, which is thus gets into a new environment. Thus, a single molecule is simultaneously a phonon generator and the detector of changes made by these phonons. Actually, we are dealing with spectral self-diffusion. The frequency of self-diffusion events (the probability of spectral jumps N) depends on the amplitude of energy jumps (Fig. 3): the greater the jump amplitude, the lower the probability. For example, a molecule experiences a 20 MHz jump 16 times, and a 40 MHz jump is made only once.

Figure 3. Probability (N) of the diffuse jumps over the spectrum as a function of the jump amplitude.¹¹

The spectral self-diffusion theory provides quantitative characteristics of host–guest interactions, namely the interaction constants and spectral self-diffusion coefficients. For example, the activation energy for the phonon interaction between a single luminescent molecule of dibenzanthanthrene (DBATT)[†] and a naphthalene crystal has been measured.¹² It was found to be 40 cm^{-1} , which corresponds to the local vibration mode in the environment of the guest molecule.

The sensitivity of the molecular sensor is so high that it is possible to measure the external pressure applied to the crystal from the shift of luminescence lines;¹³ this shift is directly proportional to the pressure, but the proportionality coefficients are different for different probe molecules. The linearity with respect to pressure describes the local compressibility of the matrix, different coefficients being indicative of the ‘individuality’ of the probe molecule with respect to the external pressure ‘violence’.

Using molecular sensors, one can reliably measure the linear and quadratic Stark effects (line shift in an electric field) even for

centrosymmetric molecules. Due to local defects in the molecular environment, the symmetry of the molecule is partially violated; as a result, an induced electric dipole equal to several millidebyes appears on the molecule;[‡] even this minor dipole moment on a single molecule suffices for detecting the Stark shift.¹⁴

A cubic Stark effect, indicative of substantial distortion of the geometry of the DBATT molecule in the n-hexadecane crystal, has been recently observed.¹⁵

2. Molecular dynamics

Procedures for direct observation of the migration of single luminescent molecules based on total internal reflection microscopy have been developed. Figure 4 shows the result of this observation for a single rhodamine 6G molecule in the polyacrylamide gel.¹⁶ Analysis of the path of the molecule may give a diffusion step, the distance distribution of the steps, the diffusion coefficient — actually, this is the visualisation of the Brownian motion of the single molecule.

Figure 4. Three-dimensional path of the diffusion walk of a single rhodamine 6G molecule at 20 °C. The gap between the points is 0.1 s.

In some cases, this motion is unexpected and even non-Brownian (non-isotropic). For example, diffusion of rhodamine 6G in a thin polyvinylbutyral film is non-uniform: some molecules remain still, while the other move randomly and isotropically, and some other move highly anisotropically and almost unidimensionally.¹⁷ These features can be attributed to different structures of the polymer local regions (molecular sites) in which the molecule is observed: each dictates the motion of its molecule. However, averaging of the independent paths of 97 molecules has shown¹⁷ that the averaged motion is simultaneously Brownian and isotropic with a diffusion coefficient of $2.6 \times 10^{-15}\text{ cm}^2\text{ s}^{-1}$.

Testing of the surface and surface regions at the level of single molecules is a promising line of research providing a lot of information. The dynamic probing of molecular sites is a complicated task; however the first steps have already been made. For instance, tetramethylrhodamine attached covalently through a flexible chain of atoms to a glass surface and immersed into ethylene glycol can occur in different conformation states — in some of them it moves freely, while in other it contacts with the surface. By measuring the luminescence intensity of single molecules as a function of time (in the nanosecond range and in the mode of single photon counting with time correlation analysis), it

[†] According to the IUPAC nomenclature, tetraceno[2,1,12,11-*opqra*]-tetracene.

[‡] In glasses, due to the chaos in the arrangement of host molecules around the guest, the induced dipole on the guest molecule may be as high as 1 D.

was found that the contact of the luminophore with the surface restricts the lifetime of the excited molecule; the presence of a quencher, an azulene molecule, also shortens this time.

The distribution of single molecules (for arrays composed of 300–500 molecules) over the fluorescence times has been obtained. It was found that fluorescence times are different in the absence and in the presence of the quencher. A theory needed for the analysis of a complicated motion dynamics modulated by conformational transitions has been developed.¹⁸

Optical methods are especially attractive for investigating fluorescence-labelled lipids and their motion in lipid layers and on the surface of cells. The motion of molecular motors along protein threads (for example, myosin along actin) and the unidimensional motion of RNA polymerase bound non-specifically to DNA were visualised at the single molecule level. Thus the motion of tetramethylrhodamine-labelled kinesin along a protein nanotube labelled by the same luminophore at the cysteine groups has been traced. The motion takes place only in the presence of adenosine triphosphate and is physiologically ‘native’. In this case, as in the case of myosin on actin, the motion of the luminescent biomolecule along the luminescent protein nanotube resembles movement of a car with switched-on headlights along a night highway with a chain of lights (if this movement is observed from above).¹⁹

For detecting the rotational dynamics of single molecules, luminescence is excited by polarised light; after this, emission of the polarised quanta accompanied by the loss of polarisation due to reorientation of the molecule is observed. Actually each molecule is excited many times and every time its emission is readout as an elementary event. Then the time distribution of these events is determined and the characteristic time of reorientation of the molecule is found by averaging over the events.

In solutions, reorientation times of the molecule occur in the picosecond region. By rigidly linking the luminophore to a large molecule, one can study the slow orientational dynamics of these molecules. By observing the depolarisation of the fluorescence of the fluorophore-labelled lipid molecule, the fluidity of the lipid membrane was measured.²⁰ This technique is of special interest for investigating the motion of the molecular-biological motors. In particular, it was shown that myosin reorientation on actin occurs jumpwise rather than as continuous rotation.²¹ In some cases, motion of the fluorescent label itself is studied. The label is connected with the ‘principal’ molecule by a flexible bridge. This method was used to study the rotation of Texas Red attached to a DNA molecule *via* a (CH₂)₆ chain.²²

If the molecule contains several freely jointed fluorescent fragments, one can study its intramolecular dynamics. As an example, consider molecule **1** in which four fluorescent fragments, namely, chains of phenylenevinylene groups, are attached to a carbon atom. Luminescence depolarisation for these four chains (arms) allows one to measure the frequency at which the molecule ‘swings its arms’ and to determine the resting time.²³

The rotation dynamics of the rhodamine 6G molecule in supercooled *o*-terphenyl was measured based on luminescence dichroism. Rotation was detected by two sensors located at right angle to each other.²⁴ Each molecule was characterised by the same time of the Brownian rotation motion τ_c ; however, after 10–100 rotation periods, the τ_c values sharply changed. These jumps of the molecule over τ_c are indicative of its motion. The characteristic time for the position change by the molecule (τ_{ex}) is on average 15 times longer than τ_c , although the temperature dependences of τ_c and τ_{ex} are the same. This means that both the rotation and the local rearrangement are motions of the same

type, their temperature dependences being described by the Debye–Stokes–Einstein theory.²⁴

We have already mentioned that the main function of single molecules is the reporter function. It is significant that reporter molecules (luminophores) be characterised by high quantum yields of radiation and high photostability; the latter ensures a long ‘reporter’ lifetime. Rhodamine 6G, Nile Red and terylene-diimine are most popular in the optics of single molecules, and green fluorescent protein GFP (see below), flavin adenine dinucleotide, *etc.* are used most widely in biology. Since recently, dendrimers have been used as luminophores.⁸

The problems of photostability of single molecules, in particular, their lifetime as a function of luminescence excitation intensity have been discussed.²⁵ The lifetime of the molecule and the number of photons it emits were found to sharply increase at low excitation intensities; the sensitivity of the method decreases but its information content increases.

The luminescence of single molecules has already found practical application; in particular, the single-molecule optics has been used to study the influence of the moisture content and swelling of polymers on their physicochemical properties and molecular dynamics.²⁶

3. Electronic spectroscopy of single molecules

Fluorescence detection in the photon counting mode (with high time and wavelength resolutions) underlies the electronic spectroscopy of single molecules. The spectra of single molecules differ from each other in signal position (frequency shift) and width, and often also in luminescence times. This indicates that molecules occur in different environments and experience the action of different local force fields (*i.e.*, they occupy different molecular sites). As a rule, the lines in the emission spectra of single molecules are less broadened than those in usual spectra, which is indicative of the lack of non-uniform broadening caused by superposition of the spectra of various molecules; in other words, the spectrum of a single molecule rather than spectral distribution is recorded — this is a great benefit of single-molecule spectroscopy. Of particular interest is the near-field optical spectroscopy in which the emission from a molecule is collected by an optical-fibre probe.⁶

The high resolution of single-molecule spectroscopy opens up the way to direct detection of the transfer of the electron excitation energy between single donor and acceptor. The transfer efficiency is a function of the distance, the environment and the overlap of the spectra in the donor–acceptor pair; these functional dependences can be directly measured. Examples of such spectroscopic studies have been reported.^{5,8} Of particular interest is the spectroscopy of biological molecules, which provides data on the conformation, complex formation, enzyme–substrate interactions, functioning of cell elements, *etc.*

High resolution (about 10^{-4} cm⁻¹, or 10^{-8} in absolute frequency units) in the electronic spectra of single molecules can be obtained using the two-laser procedure; one laser saturates the electronic-vibrational transitions of a specified molecule, while the other (probing) one records the spectrum thus eliminating the saturation. This technique was used to detect four terylene molecules placed into a deuterionaphthalene crystal at 1.4 K.²⁷ The frequencies of the two lower vibration levels and the homogeneous (true) line width of the electronic-vibrational transition were measured. The measurements showed that spectra of the molecules are not identical, as the molecules occupy different positions in the host crystal.

The exciton fluorescence of a single poly(diacetylene) macromolecule in the host monomer crystal was measured at temperatures of about 6 and 60 K.²⁸ The macromolecule adequately simulates the semiconducting organic quantum wire. In the crystal, the fraction of the polymer chains was less than 10^{-8} and excitation was performed in the vibronic band at 501.7 nm. Both light absorption and luminescence were highly polarised

along the axis of the molecule (the linear dichroism was about 600).

A single macromolecule was represented by a single Lorentzian emission line at 2.282 eV with a half-width of 350 μeV . The line shifted somewhat to higher energies and the line width increased linearly with temperature due to the exciton–phonon interaction. The characteristic time of the loss of phase coherence by the exciton was about 2 ps. It was found that upon excitation of only one part of the macromolecule, both its parts emit, although the second part is spaced by a 10 μm distance. This means that exciton moves rather fast along the molecule by distance of $\sim 10 \mu\text{m}$ over a time period shorter than its lifetime (~ 110 ps). The mechanism of exciton movement has not been unambiguously established; however, irrespective of the mechanism (ballistic transport or diffusion migration), the motion velocity is high, $\sim 10^7 \text{ cm s}^{-1}$ for the former mechanism or $10^4 \text{ cm}^2 \text{ s}^{-1}$ for the latter.²⁸

Spectroscopy of single macromolecules has been applied to study the structure and properties of conductive polymers²⁹ and to study functioning of the single light-storing complex LH2.³⁰ The complex contains 27 bacteriochlorophyll *a* molecules and 18 carotenoids. Analysis of the luminescence spectra and their dependence on polarisation of the exciting light demonstrated that excitation is concentrated on a limited number (1–3) of bacteriochlorophyll molecules.³⁰

4. Quantum and non-linear optics

The key goal of quantum optics is to generate single photons ‘by request’. The optical detection of single molecules in a specified mode contributes to achieving this goal. A source of photons can serve as the main unit in cryptography and communication systems and in computer systems. A highly luminescent photostable single molecule in the crystal (for example, a terylene molecule in the *p*-terphenyl crystal) may be a new candidate for this role. The possibility of using such systems in quantum optics is under active discussion.⁸

The luminescence of single molecules is closely related to the non-linear optics of single molecules, *i.e.*, non-linear interaction of the molecules with the electromagnetic field of a light wave where optical properties are functions of the light intensity. A large number of non-linear effects known for large ensembles of molecules have already been detected and studied for single molecules, for example, optical saturation, four-wave mixing, photon echo.³¹

5. Functioning of single molecules

In order to answer the question of how one molecule functions, we will consider decomposition of hydrogen peroxide induced by oxidoreductase in the presence of hydrogen donors.³²

Horseshoe peroxidase is an enzyme containing protoporphyrin IX as the key structural element. The iron ion incorporated in protoporphyrin IX participates in the redox cycle that initiates decomposition of the H_2O_2 molecule and reduction of donor molecules. Dihydrorhodamine 6G was used as the hydrogen donor; this compound does not fluoresce itself but the product of its oxidation, rhodamine 6G, is a bright luminophore.

To monitor the functioning of a single enzyme molecule, the biotinylated enzyme was immobilised on streptavidin-modified glass and placed into a buffer solution of calcium phosphate containing dihydrorhodamine 6G and H_2O_2 ; after that, enzyme single molecules were exposed to laser radiation. Enzyme functioning resulted in generation of rhodamine 6G, whose luminescence was detected. According to experimental conditions, free rhodamine 6G molecules quickly departed from the laser-irradiated environment of the enzyme, so that the major contribution to the luminescence was made by the molecules that had no time to leave the enzyme where they had been formed.³²

Figure 5 shows the records of counting of the photons emitted by rhodamine 6G molecules resulting from functioning of three enzyme molecules (curves 1–3, respectively). It can be seen that

Figure 5. Number of photons n emitted by rhodamine 6G synthesised by three single horseradish peroxidase molecules as a function of the functioning time of these molecules (curves 1–3). Curve 4 is the luminescence background from the region containing no enzyme molecule.³²

over the observation period (10 s), the product yield varies, *i.e.*, periods of intensive functioning of the enzyme alternate with resting periods; moreover, the enzyme molecules ‘flicker’ in different ways, which is indicative of different activities of the three enzyme molecules. This difference is detected only in the case of short observation periods but disappears for longer periods. This means that the enzyme molecules behave as ergodic steady-state systems, for which time averaging is equivalent to ensemble averaging. The flickering (fluctuating) activity of the enzyme was attributed³² (and this was convincingly proved) to different conformational states of the molecule. The conformational conversions of the enzyme change its activity and, hence, the product yield.

The energy transfer between two luminophores has been used to study the conformational dynamics of the molecule of staphylococcal nuclease, a small globular enzyme.³³ Each enzyme molecule was labelled by two luminophores: tetramethylrhodamine acting as the energy donor (it was specifically attached to the cysteine residue in the 28-position) and the cyanine dye Cy5, which was the energy acceptor (it was attached to an amino group of the protein).

Laser irradiation of single enzyme molecules induced alternating flickering luminescence of both luminophores: when one luminophore was active, the other was at rest. The flickering frequency corresponded to the frequencies of the conformational transitions in the protein that were accompanied by luminophore movement either towards or away from each other. It is noteworthy that in the presence of an inhibitor (deoxythymidine phosphate), which is bound by the nuclease active site, the conformational dynamics greatly changes. This opens up an additional source of information about the enzyme active sites.³³

The same method was used to study the conformational behavior of α -tropomyosin in an aqueous solution.³⁴ This protein is a dimer composed of twisted identical chains. In both chains, luminophores were grafted on cysteine-190, in particular, Cy3-maleimide (energy donor) on one chain and Cy5-maleimide (energy acceptor) on the other chain. When two α -tropomyosin chains occurred in the twisted state, only the acceptor luminesced, while in the untwisted (denatured) state, only the donor exhibited

luminescence. The alternating flickering of the donor and acceptor luminescence observed for one α -tropomyosin molecule indicates that the two chains of this protein get twisted or untwisted at intervals. Obviously, this 'single-molecule' strategy can be used to study the association–dissociation dynamics of other biomolecules and their complexes.

The folding dynamics of the GCN4 peptide dimer has also been studied based on the label luminescence.³⁵ In the folded state, the peptide is a two-stranded helix. The researchers attached fluorescent labels to one ends of the strands: rhodamine 6G (energy donor) to one strand and Texas Red (energy acceptor) to the other. By the other ends (negatively charged glutamic acid residues), the dimer was immobilised, through electrostatic interaction, on the surface of glass modified by the aminopropylsiloxane groups.

In the folded dimer, both luminophores (the donor and the acceptor) are located close to each other. Therefore, on laser irradiation of the dimer and excitation of the donor, the excitation energy is transferred to the acceptor. Rhodamine 6G is thus quenched, while the Texas Red 'glows'. In the unfolded state where the donor and the acceptor are separated in space, no energy transfer from the donor to the acceptor takes place, and rhodamine 6G 'glows', while the Texas Red is quenched.

The peptide transitions from the folded to the unfolded conformation and back are detected as periodic switching-on of either donor or acceptor luminescence, which takes place in opposite phases: luminescence of one luminophore is inevitably accompanied by quenching of the other — this is clearly seen in Fig. 6. This approach is becoming popular as a general method for the study of proteins at the level of single molecules and complexes.

Figure 6. Luminescence, in opposite phase, of two luminophores, Texas Red (TxR) and rhodamine 6G (R6G), at functioning of a single peptide GCN4 dimer molecule.

Z is the counting rate of the emitted photons.³⁵

Enzymes are not always ergodic. The two-stranded oligonucleotide, 217 bp long, labelled by tetramethylrhodamine at one end and modified by biotin at the other end, was immobilised on a streptavidin-modified glass surface due to biotin binding to streptavidin. The DNA molecule fixed in this way fluctuated between two conformational states, in one of which the label occurred near guanosine and did not luminesce (being quenched by guanosine) and in the other, the label and guanosine were separated in space; therefore, the label luminesced. The residence periods of the molecule in these two states are 0.16 and 0.03 s.³⁶

Remarkably, on averaging the oscillation frequency over the time of observation of a single molecule (the lifetime of the luminophore label, which is determined by its photochemical stability), the oscillation frequencies of the light and dark periods did not depend on time, *i.e.*, each of the 37 DNA molecules studied was a time-ergodic system (this is called homogeneous ergodicity). However, the behaviour of each molecule is individual and, in this

sense, the ensemble of molecules is a non-ergodic system (heterogeneous ergodicity); thus, time average is not equivalent to ensemble averaging. The reason for the non-ergodicity is the individual character of every DNA position on the glass surface. A similar heterogeneous non-ergodicity was found in a study of the catalytic activity of a single molecule of lactate dehydrogenase.³⁷

Green fluorescent protein (GFP) is widely known in the molecular and cell biology;³⁸ it is used as a gene expression indicator and as a fluorescence label for proteins. A small (238 amino acid residues) GFP isolated from jellyfish contains, at the centre of the molecule, a strongly absorbing and luminescent chromophore, which is formed spontaneously from three amino acid residues in the presence of oxygen. The luminescence of a single GFP molecule is unique: it flickers spontaneously. The luminophore emission is excited at 488 nm and lasts for 0.4 s at low laser pumping powers. The higher the power, the shorter the emission, *i.e.*, luminescence is not only excited but also quenched by light. The dark state is stable for several minutes and returns spontaneously into the initial state capable of luminescence. Flickering is caused by the conformational transitions in the protein. The nature of flickering is still obscure; it is only known that it does not depend on the pH and is not related to GFP protonation.⁸

Single-molecule spectroscopy actively enters analytical biochemistry. The first example of the use of this method dates back to 1997.³⁹ The researchers obtained a chameleon protein complex consisting of the CFP and YFP proteins (CFP and YFP are mutants of the GFP with cyan and yellow fluorescence, respectively), combined by a calmodulin molecule (Ca^{2+} -binding protein).

In the absence of Ca^{2+} ions, calmodulin molecule occurs in the unfolded state; therefore, the CFP and YFP are remote from each other. Laser irradiation of CFP at a wavelength of 442 nm induces luminescence at 480 nm. After the addition of four Ca^{2+} ions, the calmodulin molecule becomes folded; as a result, the two luminophores, CFP and YFP, approach each other, and energy transfer from CFP to YFP takes place. In this case, irradiation of CFP results in YFP emission at about 530 nm. Actually, the protein complex is a highly sensitive sensor for Ca^{2+} ions: switching of the cyan fluorescence to yellow is a precise indicator for Ca^{2+} ions. Similar indicators for H^{+} ions have already been developed (single-molecule pH-meter). The good prospects of this line of research for highly sensitive analytical and ecological chemistry are quite obvious.

An important problem in the molecular biology (in particular, neurochemistry) is the mechanism of operation of molecular motors, which ensure substance and microbody transport in the living cells. Single-molecule optics helps to answer this question. For instance, it has been used to study the movement of the protein kinesin along the microtubules composed of tubulin. Kinesin functions as a molecular motor, thus carrying various cell 'goods'. For example, it delivers the vesicle with neuromediators from the Golgi apparatus to presynaptic membranes, collects the 'containers' (*i.e.*, vesicle lipids) after liberation of neuromediators and return them to the initial 'loading' site.⁸ The transport of this motor by a 8 nm distance requires hydrolysing one ATP molecule ($\text{ATP} \rightarrow \text{ADP}$). However, neither X-ray nor electronic spectroscopy could answer the question how two ends of the kinesin molecule can extend for 8 nm.

In order to answer this question, it is necessary to study the orientational mobility of a single kinesin molecule. A kinesin mutant was prepared, in which two cysteine groups were located at a fixed distance; a reporter molecule, rhodamine, was rigidly attached to these groups (a bifunctional iodoacetamide rhodamine derivative was used for this purpose). By exciting the rigidly fixed luminescent label by polarised light and detecting luminescence polarisation of a single kinesin molecule, one can draw conclusions concerning its behaviour: whether the molecule

rotates and whether the orientation of the optical dipole changes upon kinesin functioning.

The result was unusual. It was found that polarisation of the luminescence of ADP-bound kinesin does not depend on the polarisation of the exciting light. This means that the optical dipole of a single kinesin molecule is dynamically disordered on the time scale of polarisation measurements (0.1 s), *i.e.*, the molecule (motor) executes motion averaging the optical dipole orientations. At the same time, kinesin remains bound to the microtubule through both ends. This brings about the idea of a new type of motion, *viz.*, ‘rolling’ of kinesin along the microtubule; the details of this motion are unknown as yet.⁴⁰

Interestingly, this type of motion is characteristic only of kinesin bound to ADP, whereas ATP-bound kinesin is rigidly oriented and remains still. Thus, every ATP → ADP cycle is accompanied by movement of the ‘motor’ by a 8 nm distance. Undoubtedly, single-molecule optics is a brilliant tool for investigating the functioning of molecular motors.

III. Scanning tunnelling spectroscopy

The discovery of the scanning tunnelling microscopy has become a great breakthrough in the science of the nanoworld. Direct monitoring of the atomic and molecular relief of the surface has opened up the way to nanotechnology. The tip of the tunnelling microscope has become the tool for diverse operations with single atoms and molecules. The possibility of controlling tunnelling currents and atom migrations in molecules with high accuracy (0.1 Å across the surface and 0.01 Å along the height) ensures the reliability of manipulation with atoms and molecules.

Moreover, the control systems ensure a special mode of operation of the tunnelling microscope in which the tip hangs above a single atom or molecule for an arbitrarily long period.⁴¹ This fact has immediately transformed the tunnelling microscopy into tunnelling spectroscopy of single molecules, which provided the way to their electronic-vibrational spectra and to their relaxation and chemical dynamics.

1. Visualisation of molecules and their movements

The visualisation of molecules, their ‘pushing’ or ‘dragging’ by the tunnelling tip and combination of atoms and molecules into ensembles of a specified architecture is a well-developed field of science (nanoengineering).⁴² However, for chemistry, it is important to visualise chemical events (transformations and migrations of the reacting molecules and products) and monitor their evolution.

A vivid example is the discrete rotation of the O₂ molecule on the Pt(111) surface.⁴³ Figure 7*a* shows the topographic view of the O₂ molecule. The ‘pear-like’ shape of the molecule is due to the fact that one oxygen atom ‘sits’ on the Pt atom; it is ‘buried’ and, hence, the tunnelling current from this atom is low, and it ‘glows’ weakly. The other atom is somewhat elevated, being located closer to the tip; the tunnelling current from this atom is greater, and the atom ‘glows’ more brightly.

If the tip of a tunnelling microscope is mounted above an O₂ molecule and a voltage of 0.15 V is applied to the tip, a jumpwise, counter-clockwise rotation of the molecule by 120° will take place after 20 s (Fig. 7*b*); at the same instant, the tunnelling current will sharply diminish (Fig. 7*d*). This indicates that the oxygen atom partly ‘moves away’ from under the tip. A new voltage application is accompanied by a new rotation of the molecule by 120° (Fig. 7*c*), *etc.* This hindered oscillating rotation of the O₂ molecule between three equivalent positions on the Pt(111) surface[§] is induced by a low-voltage tunnelling current, the rotation velocity being proportional to the tunnelling current and the rotation

Figure 7. Topographic images of the O₂ molecule on the surface of the Pt(111) crystal during its successive angular rotations by 120° (*a, b, c*); (*d*) is the jumpwise decrease in the tunnelling current at the instant of rotation.⁴³

barrier being between 0.15 and 0.175 eV (at 8 K).⁴³ Note that O₂ molecules not subjected to the tunnelling current remain still.

Yet another example is the rotation of an acetylene molecule on the Cu(100) surface. An acetylene molecule placed on the Cu(100) atomic surface [$l(\text{Cu} - \text{Cu}) = 2.55$ Å] can occupy two equivalent orthogonal positions in which the centers of the two C–H bonds fall on neighbouring Cu atoms, *i.e.*, the acetylene molecule ‘lies’ on two Cu atoms (Fig. 8*a, b*).⁴⁴ When the tip to which the voltage is applied is located above one end of the C₂H₂ molecule (nearly above the C–H bond lying on the Cu atom), the tunnelling current jumps in a random mode between two values (Fig. 8*c*). The jumps correspond to the instants the C₂H₂ mole-

Figure 8. Topographic images of the C₂H₂ molecule in two orthogonal sites on the Cu(100) surface (*a, b*); (*c*) time dependence of the tunnelling current.⁴⁴

§ Three potential wells for the O₂ molecule on the Pt(111) surface shifted by 120° with respect to the centre are determined by the hexagonal symmetry of the arrangement of Pt atoms.

cule hops between two orthogonal positions identical in energy. This can be clearly seen when looking at the images of the C_2H_2 molecule before and after the rotation (see Fig. 8*a,b*) or from reversible fluctuations of the tunnelling current (see Fig. 8*c*).

The rotation frequency of the acetylene molecule depends on the tip position (it is maximum when the tip is located above the C–H bond) and on the tunnelling current. The latter dependence is linear. The dependence of the rotation frequency on the voltage on the tip is not monotonic, showing a sharp maximum at the voltage where the energy of the tunnelling electrons coincides with the energy of the vibrational excitation of the C–H bond. For example, the rotation frequency of the acetylene molecule increases by an order of magnitude at a voltage of 358 mV (the frequency of C–H stretching vibrations).[†] In the case of the C_2D_2 molecule, a sharp increase in the rotation frequency (by almost two orders of magnitude) takes place at a voltage of 266 mV, which corresponds to the C–D stretching frequency.

These data indicate that the first event caused by the tunnelling current is the excitation of the C–H (or C–D for C_2D_2) bond; this is followed by the intramolecular energy transfer from the C–H stretching vibrations to bending vibrations and to vibrations of the molecule as a whole, or directly to the complex vibrations composed of the bending and rotation frequencies. The final outcome is the molecule jump from one position to the other (orthogonal). The quantitative estimates are consistent with this pattern: the probability of the orientational jump of the C_2H_2 molecule per passing (tunnelling) electron is constant and equals $\sim 10^{-10}$. Since approximately every hundredth electron excites a stretching vibration, we obtain that the probability of transformation of the stretching excitation into the rotation of the molecule as a whole is $\sim 10^{-8}$. Note that all this information — topographic images, jump frequencies, stretching vibration frequencies and the probabilities of excitation of various types of vibrations — has been gained from a single molecule.

Unlike the O_2 and C_2H_2 molecules, which rotate on the crystal surface, while remaining on the spot, an ethylene molecule migrates chaotically over the Ni(110) surface.⁴⁵ Figure 9*a* shows that the C_2H_4 molecule jumps by arbitrary distances in an arbitrary direction in different atomic planes of the nickel single crystal, short jumps being most probable. Most of the points in Fig. 9*a* are grouped at the centre, near the starting position of the molecule, which is designated by zero displacement. Figure 9*b* shows the histogram of the number of jumps as a function of the jumps distance; most (almost 90%) of 112 events fall in the distance range of 0.1–2.0 Å.

The jumps of the ethylene molecule over the surface are in line with jumps of the tunnelling current: when the molecule moves away from under the tip, the tunnelling current sharply drops; when the molecule returns, the tunnelling current increases jumpwise to the initial value. The return of the molecule is not a rare event. Indeed, during the pulse of the tip voltage (10 s), the tunnelling current ‘switches on’ many times, *i.e.*, the molecule has time to move away and return back to the start hundreds of times.

The histogram of the time intervals during which the molecule is waiting for a jump from under the tip is exponential (the histograms were constructed based on observation of 300–1300 events with their subsequent averaging over 8–16 single molecules⁴⁵). Using these histograms, the rate constants for the ‘departure’ of a molecule from under the tip were determined. The constants were found to depend markedly on the mass of the isotopes that form the molecule, being equal to 196, 204, 42, 24, and 15 s^{-1} for $CH_2=CH_2$, *trans*-CHD=CHD, *cis*-CHD=CHD, $CD_2=CD_2$, and $CH_2=CD_2$, respectively. It should be noted, however, that this dependence is not regular: the *trans*-CHD=CHD molecule jumps faster than *cis*-CHD=CHD and much faster than $CH_2=CD_2$ having the same mass. It has been

Figure 9. Distribution of the jump amplitudes of single ethylene molecules on the Ni(110) surface (*a*) and column diagram of the jumps (*b*) (N is the number of jumps with a given amplitude).⁴⁵

noted⁴⁵ that for stimulation of vibrations of the molecule as a whole by the tunnelling current, it is important whether the geometric centre of the molecule (to which the tunnelling current is directed from the tip) coincides with its centre of mass. This has a crucial influence on the efficiency of pumping of the vibrational energy of the molecule by tunnelling electrons.

The rate constants for the return of the ethylene molecule under the tip were measured in a similar way. For the same series of isotope-substituted ethylene molecules, they were 74, 65, 22, 21 and 6 s^{-1} . It is clear that lower constants correspond to weaker tunnelling currents. The dependence of the jump frequency on the mass of the molecule attests unambiguously to an inelastic interaction of the tunnelling electrons with the molecule, *i.e.*, to the vibrational excitation of the adsorbed molecule.

Note that the dynamic behaviour of each molecule is unique and is detected independently. There is no need to describe it by the rate constant. This value is useful only for the statistical, probabilistic characteristics of the molecule and is obtained by time averaging (over the number of migration events for one molecule) and ensemble averaging (averaging of these events over 8–16 individual molecules).

The migrations of the C_{60} molecule chemisorbed on silicon are also induced by the tunnelling current of about 1 nA at a voltage of 2–3 V.⁴⁶ It is remarkable that in this case, it is possible both to push and to pull the molecule, *i.e.*, the tip interaction with C_{60} takes place at both types of potential, namely, attraction and repulsion. The C_{60} molecule moves by steps, the step length being equal to two silicon lattice spacings. In the case where C_{60}

[†] 1 mV corresponds to 8.0655 cm^{-1} .

chemisorption implies the formation of the C–Si bond, the migration of the C_{60} molecule can be regarded as rolling conjugated with valence migration.

The conformational dynamics of individual pyrrolidine and deuterated pyrrolidine molecules on the Cu(001) surface at 9 K has been studied.⁴⁷ These molecules are attached fairly strongly to the crystal surface due to the nitrogen lone pair and occupy two positions, being arranged either at right angle to the crystal surface (position I in Fig. 10a) or parallel to the surface (position II in Fig. 10a). The tip mounted at a constant height above the molecule records two levels of the tunnelling current, high (0.15 nA) and low (0.03 nA) (see Fig. 10b), which correspond to these two positions. The random current ‘flickerings’ mark precisely the reversible jumps of the molecule, while the position of the molecule on the surface remains fixed (this follows from the topographic images of the molecule).

Figure 10. Arrangement of a single pyrrolidine molecule on the Cu(001) surface in two conformations I and II (a) and jumps of the tunnelling current upon the $I \leftrightarrow II$ conformation transitions (b).⁴⁷

By comparing the durations of two currents, one can estimate the populations of the two positions (orientations), *i.e.*, their statistical weight. Both the populations and the rate of transitions between the ‘standing’ and ‘lying’ positions (*i.e.*, the frequency of current flickering) depend on the tip voltage. It is clear that the populations are not thermodynamically equilibrated, as the molecule is exposed to the tunnelling current, which stimulates the orientational transitions.

When the transition rate is low, both orientations can be seen (see Fig. 10b), while in the case of fast transitions, the tunnelling current between them is averaged. This is observed at a tip potential of 376 mV for pyrrolidine and at 283 mV for d_8 -pyrrolidine. These potentials correspond to the excitation of the vibrational levels of the CH_2 and CD_2 fragments, respectively. The vibrational excitation induces fast transitions between two conformations and levelling of their populations. When the tip moves away from these resonance potentials, the slow orientation dynamics is again restored.

Two states of rigid molecules, thiophene and pyrrole, can also be clearly detected in their topographic images: in one state, molecules ‘lie’ on the Cu(001) surface (adsorption through the π -orbitals of the aromatic ring), while in the other one, they are arranged perpendicular to the surface (‘stand’), being strongly attached to the Cu atoms by the S or N lone electron pair, respectively. Conversely, the furan molecule is weakly bound to the Cu atom; it is too labile to stay under the tunnelling current.⁴⁸ It is of interest that tetrahydrothiophene similar in structure to pyrrolidine did not show any orientational transitions under the tip current; the topographic images of tetrahydrothiophene indicate that the molecule ‘stands’ on the Cu atom.⁴⁸

A special type of migration of single molecules is the controlled transfer from the surface to the tip and back; it is attained by variations of the voltage and tunnelling currents.⁴⁹ Thus the transfer of ethylene molecules is accomplished in the following way. A tungsten tip is mounted above the C_2H_4 molecule located on the Ag(110) surface. For a tunnelling current of 0.1 nA, a voltage of +70 mV is applied to the tip. While the current is maintained constant, the voltage is changed jumpwise by –70 mV and then brought gradually to –140 mV. The tunnelling current thus increases from 0.1 to 10 nA and the C_2H_4 molecule is transferred on the tip end. The back transfer takes place when the tip bearing the C_2H_4 molecule is mounted above the Ag atom and a +390 mV voltage is applied.⁴⁹ The reversible transfer of CO occurs in a similar way but at different tip potentials. Note that the physical mechanism of the transfer under these conditions is not entirely clear.

More definite considerations on the mechanism of molecular transfer were reported in another study⁵⁰ where high voltage was used to transfer the CO molecule from the Cu(111) surface to a Cu tip. When the voltage was > 2 V and the distance between the tip and the surface was ~ 7 Å, the current was several nanoamperes. The transfer of a CO molecule to the tip mounted above this molecule or along the surface took place at a voltage exceeding the threshold value of 2.4 V. In this case, the derivative dI/dV increased. This increase coincided with the occupation of the excited $2\pi^*$ -state of the CO molecule (this was determined by two-photon photoemission spectroscopy). The relaxation time of this electronically excited state was found to be very short (0.5–5.0 fs). The fast energy relaxation from the antibonding π^* -orbital of the CO molecule was the reason for the low quantum yield of carbon monoxide desorption (2.7×10^{-11} at 2.7 V or 3.0×10^{-11} at 3.0 V) and for its transfer to a new position (including the tip).

The average residence time of the CO molecule after voltage application (*i.e.*, the transfer waiting time) depended on the voltage and the current. The transfer rate (the reciprocal of the residence time) is proportional to the tunnelling current; this means that the transfer of the molecule is a single-electron process.

The isotope effect in the transfer rate has also been measured:⁵⁰ the heavy $^{13}C^{18}O$ molecules jumped to a new position under current 2.7 times more rarely than the light $^{12}C^{16}O$ molecules. The isotope effect attests to a key role of the relaxation of the electronic excitation to vibrations of the molecule as a whole. Quantitative analysis of the effect lead to an important conclusion: only 0.5% of all the tunnelling electrons excite the CO molecule to the $2\pi^*$ state and, hence, the probability of the ‘jump’ per excitation event is $\sim 5 \times 10^{-9}$. This is a low value but it is consistent with the low probability of electron energy relaxation to low-frequency vibrations of the molecule as a whole.

2. Tunnelling spectroscopy

The topographic images of the atomic-and-molecular surface relief are formed due to the elastic interaction of the tunnelling electrons with the surface atoms. However, probing of the energy levels of the surface atoms and molecules requires inelastic electron interaction; only inelastic interaction does involve the exchange of energy between the tunnelling electrons and surface particles. The presence of energy exchange (inelastic tunnelling)

can be detected from the current–voltage dependences the study of which constitutes the subject of tunnelling spectroscopy.

In chemistry, two versions of tunnelling spectroscopy are used most efficiently: threshold spectroscopy and resonance spectroscopy. The former was mainly developed by Ho and co-workers⁵¹ and the latter, by Dalidchik and co-workers.^{52,53}

The threshold spectroscopy uses low potentials $V \ll \varphi$ (φ is the electron work function in the tip–surface nanocontact). The scheme of tunnelling transitions for this case is shown in Fig. 11.

The inelastic tunnelling channel opens only at a voltage exceeding the critical (threshold) value, which corresponds to the energy level of the molecule in the nanocontact. At lower voltages, the inelastic tunnelling is forbidden, as an electron cannot lose energy by sinking below the Fermi level where all electronic states are occupied and there is no room for new electrons.

Figure 11. Scheme of tunnelling in a nanocontact at voltages $V \ll \varphi$. ε_F is the Fermi level, φ is the electron work function, I_e and I_i are elastic and inelastic tunnelling.

The threshold voltage V at which an additional inelastic tunnelling appears is recorded based on the jump in the tunnelling current $I(V)$. On excitation of the vibration frequencies of the molecule, the probability (cross-section) of the inelastic process is very low, because the probability of energy exchange between the ‘light’ electron and vibrations of ‘heavy’ atoms is low. In order to detect the vibration frequencies of single molecules based on small current $I(V)$ jumps, Ho and co-workers⁵¹ have developed highly sensitive equipment in which they attained a high stability of the tip position above the selected molecule (the tip could stay for hours); during this period, the potential on the tip varied periodically from $-V$ to $+V$, passing a multitude (hundreds or even thousands) of times the threshold value where the jump of the tunnelling current took place. The smoothly varying and controlled voltage on the tip was modulated at a frequency of hundreds of Herz, so that the current jump was detected based on the second derivative d^2I/dV^2 ; the peak position in the d^2I/dV^2 vs. voltage V dependence corresponds to the potential V_k , which is equal to a frequency in the vibrational spectrum of the molecule.⁴⁸

An example of such dependences for single C_2H_2 and C_2D_2 molecules on the Cu(110) surface is shown in Fig. 12. For the C_2H_2 molecule, the peak is clearly seen at 358 mV, while for C_2D_2 , the peak is at 266 mV. On an energy scale, these peaks coincide with the C–H and C–D stretching frequencies, respectively. Thus, the isotope shift in the potentials corresponds to a shift in the C–H and C–D vibration frequency.^{44, 51}

Threshold spectroscopy was used to obtain the spectra of diverse molecules: the $^{12}C^{16}O$ and $^{13}C^{18}O$ isotope forms,⁴⁹ ethylene and its isotope forms,⁴⁵ pyridine, benzene,⁵⁴ pyrrole, pyrrolidine, thiophene, tetrahydrothiophene and their deuterated analogues.⁴⁸ Recording of the vibrational spectrum of molecules, especially ‘light ones’ (for example, the spectrum of the O_2 molecule on the silver surface⁴⁹) is far from being always possible. This is due to the fact that molecules ‘run away’ from under the tip earlier than a relatively reliable spectrum can be accumulated from the d^2I/dV^2 vs. V dependence. Possible physical reasons are

Figure 12. Second derivative of the current with respect to the voltage as a function of voltage for single C_2H_2 and C_2D_2 molecules. The voltages of 358 mV and 266 mV correspond to C–H and C–D vibration frequencies, respectively.⁴⁴

either direct pumping, by tunnelling electrons, of the low-frequency vibrations of the molecule as a whole or the transfer of the vibrational energy from the stretching vibrations excited by inelastically tunnelling electrons to the vibrations of the whole molecule.

The resonance tunnelling spectroscopy of single molecules developed by Dalidchik *et al.*^{52,53} operates in the field-emission mode, *i.e.*, at tip voltages exceeding the electron work function. Under these conditions, the tunnelling electrons overcome two barriers, while leaving the tip and while entering the surface (Fig. 13); therefore, they become ‘captured’ in the space between the tip and the molecule for about 10^{-13} – 10^{-14} s. The space between the tip and the surface functions as a ‘nano-scale resonator’ in which stationary waves (field-emission resonances) are established at a certain value of energy. Since the energy of the resonances depends on the tip potential, the tunnelling current as a function of the voltage applied has clear-cut peaks corresponding to the electronic-vibrational (resonance) levels of the adsorbed molecule, which interacts with the electron captured by the resonator. This is a manifestation of the fundamental quantum effect, *i.e.*, the resonance clearing of the double potential barriers, which become absolutely transparent when the energy of the tunnelling electrons coincides with the vibration energies. At these resonance potentials, the tunnelling current sharply increases, thus recording the vibrational spectrum of the molecule under the tip (this is shown schematically in Fig. 13).

The resonance tunnelling spectroscopy is being actively developed by Dalidchik and co-workers since 1997.^{52,53,55,56} An example of the vibrational spectra of single H_2O and D_2O

Figure 13. Scheme of a nanoresonator confined by two barriers (a) and schematic dependence of the tunnelling current on the voltage (b).

Figure 14. Tunnelling current vs. voltage for a clean oxidised titanium surface (a) and for single H_2O (b) and D_2O (c) molecules adsorbed on the oxidised titanium surface. Resonance lines (1–5) correspond to the vibration frequencies of the molecule (see the text).^{53, 56}

molecules adsorbed on oxidised titanium is shown in Fig. 14. Here one can see the following resonance lines: $\omega_1 = e(V_3 - V_1) = 0.5$ eV and $\omega_2 = e(V_2 - V_1) = 0.2$ eV (one-quantum stretching and bending vibrations), $\omega_3 = e(V_5 - V_1) = 2\omega_1$ (two-quantum stretching vibrations) and $\omega_4 = e(V_4 - V_1) = \omega_1 + \omega_2$ (complex vibrations), where the subscripts n correspond to the numbers of resonance lines shown in Fig. 14 (V_n are the corresponding voltages).^{53, 56} For the D_2O molecule, ω_1 and ω_2 are 0.35 and 0.15 eV, *i.e.*, the isotope shift corresponds almost exactly to the isotope frequency ratio $[\omega(\text{H}_2\text{O})/\omega(\text{D}_2\text{O}) \approx \sqrt{2}]$.⁵⁶

Figure 15 presents the vibrational spectra of molecular oxygen adsorbed on different sections of the iron oxide surface.⁵⁷ Note that the scope of resonance tunnelling spectroscopy is unlimited. This method can be used to detect and measure the frequencies of individual vibrations and their combinations; measure the vibrational relaxation rates by controlling the tunnelling current (*i.e.*, the vibrational pumping rate). The difficulties and limitations of the resonance spectroscopy are also evident: it is far from being always possible to interpret the spectrum and assign the peaks in the tunnelling current to definite vibrations; interpretation of the spectra is a difficult task, especially for polyatomic molecules. In the interpretation, it is expedient to use related molecules, isotope forms, *etc.*

Figure 15. Vibrational spectra of oxygen molecules on different (non-identified) Fe_xO_y sites.⁵⁷

3. The chemistry of single molecules

The inelastic interaction of the tunnelling electrons with a molecule is accompanied by pumping the molecule with vibrational energy, which stimulates its chemical transformations. These events are detected based on the images of the reactant and product, on the tunnelling current jump at the instant of reaction and on the vibrational spectra of the reactant and the products.

The simplest example is the dissociation of the O_2 molecule, physically adsorbed on the Pt(111) surface, at 40–150 K.⁵⁸ When the voltage on the tip is 0.3 V and the tunnelling current is 22 nA, dissociation of the O_2 molecule into atoms takes place in 30 s, the atoms being dispersed by three Pt(111) lattice spacings. Simultaneously, atom images and a tunnelling current jump at the instant of the reaction are observed. The rate constant for dissociation measured by statistical averaging over many molecules increases with current according to the power law I^n , where the power exponent n depends on the voltage, being equal to 0.8, 1.8 or 2.9 for voltages of 0.4, 0.3 or 0.2 V, respectively. It is of interest that the behaviour of the O_2 molecules depends on their position on the surface of a Pt crystal, in particular, they only dissociate on a *fcc* face, desorb without dissociation on the terrace steps and both dissociate and desorb on the transition bridges. It is clear that the energy pumping to the inner (reaction) vibrations competes with that to the outer vibrations of the molecule as a whole.

Yet another example is the dissociation of the C_2H_2 and C_2D_2 molecules to C_2H and C_2D on the Cu(001) surface at potentials of 2.8 and 3.9 V, respectively.⁵⁹ The resulting C_2H and C_2D species then dissociate to C_2 at potentials of 2.1 and 2.7 V, respectively. The great isotope effects are due to not only isotopy of the C–H and C–D bonds but rather by the difference in the cross-sections of excitation of the isotope molecules by tunnelling electrons. As noted above, the excitation cross-section is determined by the probability of energy transfer (inelastic process) from the ‘light’ electron to the ‘heavy’ molecule. This probability is usually very low and proportional to $(a_0/R_0)^{2\Delta v}$, where a_0 is the amplitude of the zero-point vibrations of the molecule (or atoms in it), R_0 is the equilibrium position of the oscillator simulating the vibrational subsystem, Δv is the change in the vibrational quantum number upon excitation. Thus the large isotope effect in the excitation cross-section is obvious.

The whole sequence of reactions of the single C_2H_2 and C_2D_2 molecules is reliably recorded based on images (topographic), the tunnelling current (it changes jumpwise at the instant of $\text{C}_2\text{H}_2 \rightarrow \text{C}_2\text{H} \rightarrow \text{C}_2$ transformations), vibrational spectra and isotope frequency shifts.⁵⁹

The dehydrogenation of five isotope forms of ethylenes on the Ni(110) surface (they were considered in Section III.1) to acetylene by the tunnelling current has been studied. The process was

monitored by images and vibrational spectra of the reactant and the product. The dehydrogenation started at voltages exceeding the threshold values, the threshold voltages being different for each isotope molecule.⁴⁵ In this case, as in the case of acetylene (see above), the isotope effect is the result of competition between the energetic pumping on the internal and external vibrations of the molecule.

The single-molecule chemistry of pyridine and benzene (and their deuterated analogues) on the Cu(001) surface has been studied by spectroscopy and topography.⁶⁰ The main reaction is the dissociation of the C_5H_5N and C_6H_6 molecules to C_5H_4N and C_6H_4 , respectively. For pyridine, the dissociation threshold amounts to 3.0 V; for the deuterio analogue, this is 3.2 V. The data on the molecule topography are ambiguous; only a tentative conclusion has been drawn according to which benzene 'lies' on the crystal surface, while the dissociation product, the C_6H_4 molecule, stands on the edge.⁶⁰

The transformation of two iodobenzene molecules into biphenyl on the Cu(111) surface includes their dissociation, removal of the iodine atoms and coming together of the phenyl radicals until they are combined to form biphenyl. Each step of this process was controlled topographically and induced by the tunnelling current of the tip.⁶¹

Recently, Japanese researchers have published a reliable and convincing study dealing with dehydrogenation of *trans*-but-2-ene on Pd(110).⁶² First, they obtained topographic images of the initial molecules (Fig. 16a) and the dehydrogenation product, buta-1,3-diene (Fig. 16b): the former looked like dumb-bells (the methyl groups at the ends of the molecule are elevated and provide a substantial elevation of the tip), while the latter looked like ellipses with their principal axes parallel to the row of Pd atoms. The arrangement of the *trans*- C_4H_8 and C_4H_6 molecules relative to the lattice Pd atoms is shown in Fig. 16c,d.

Figure 16. Topographic images of single *trans*-but-2-ene (a) and buta-1,3-diene (b) molecules, their arrangement on Pd(110) (c, d) and images of the *trans*-but-2-ene (T) molecule before the reaction (e) and after its transformation into buta-1,3-diene (P) (f). B is the initial buta-1,3-diene molecule.

Figure 16e shows the initial state of the surface on which two *trans*-but-2-ene molecules (T) and one buta-1,3-diene molecule (B) are co-adsorbed. The tip of the tunnelling microscope was mounted above one of the *trans*-butene molecules (designated by the arrow in Fig. 16e). At a 7 nA current and a 450 mV voltage, this molecule is converted after 1 s into the product molecule (P), which is identical to the initial buta-1,3-diene molecule (B, Fig. 16f). Thus, the researchers were able to observe how *trans*-butene is dehydrogenated under the action of the tunnelling current. Probably, the hydrogen atoms are removed non-simultaneously from the methyl groups of *trans*-butene, but the inter-

mediate structure with one removed hydrogen atom is unstable and gives off the second hydrogen atom so rapidly that its image cannot be recorded.

Spectroscopic evidence for dehydrogenation of *trans*-butene and its deuterated analogue has been derived from analysis of the $I(V)$ dependence: the second derivative d^2I/dV^2 has maxima corresponding to the C–H vibrations of the methyl group, 366 mV for *trans*-butene and 268 mV for the deuterated molecule. In the reaction product, butadiene, these frequencies are missing. Moreover, the transformation of *trans*-butene into butadiene starts at threshold voltages that exactly coincide with the frequencies of the C–H and C–D stretching vibrations.

The dependence of the reaction rate W , measured statistically for a number of molecules, on the current is a power function: $W \approx I^n$, where the power exponent n depends on the voltage and the isotope composition of the molecule and varies in the range from 1.5 to 3.0. All these features indicate unambiguously that the chemical transformation is stimulated by the vibrational excitation of the C–H (or C–D) bonds by tunnelling electrons.

A remarkable feature of the *trans*-butene molecule as an experimental object is the fact that the molecule remains motionless under the tip tunnelling current, *i.e.*, it does not move across the surface (unlike other light molecules such as O_2 or C_2H_2 , considered in Sections III.1). This means that the high-frequency vibrations of the CH_3 groups interact weakly with the low-frequency vibrations of the weighty *trans*-butene molecule as a whole; therefore, the vibrational excitation of the CH_3 groups is eliminated by dissociation of the C–H (or C–D) bonds.

At the end of the discussion of studies dealing with the single-molecule chemistry, it is necessary to consider its limitations. The major one is the lack of information on the chemical transformation itself. All information on the physics of the chemical process is included in the reaction rate *vs.* current dependence ($W \approx I^n$) and in the dependence of n on V (this bears the rate of the tunnelling electrons) and on the isotope composition of the molecule. In order to extract this information, theoretical analysis of these dependences is required in terms of the theory of inelastic interaction of electrons with adsorbed molecules and energy relaxation of the molecule. This theory is well developed for gas molecules; however its extension to adsorbed molecules is an independent task. Moreover, to compare the theory with the experiment, one should know what portion of the tunnelling electrons interacts with the molecule in the inelastic mode, *i.e.*, makes a contribution to the vibrational excitation. Some estimates of this parameter for specific cases have been given above, but generally this problem is still to be solved.

IV. A single high-spin molecule as a nanomagnet

Classical nanomagnets are particles with sizes of about hundreds of nanometres. They are usually produced by dispersion or deposition of ferromagnetic materials; therefore, they are non-uniform (have particle size and magnetic moment distributions). The new class of nanomagnets, namely, single-molecule magnets, are free from these limitations. They are obtained by classical methods of chemistry and isolated and purified as pure chemical substances.⁶³ Like chemical 'cloning' products, single-molecule magnets are absolutely identical in size, structure and magnetism. As a rule, they are represented by high-spin metal clusters, which have a magnetic core made of transition metal atoms containing tens (or sometimes hundreds) of unpaired electrons (spin carriers) and a diamagnetic shell (coat) of organic ligands. The ligands eliminate the intermolecular exchange interaction of electrons and make the nucleus magnetically isolated (Fig. 17).

Each of these molecules is a nanomagnet, which shows all properties of a real magnet, in particular, spontaneous magnetisation, magnetisation anisotropy and hysteresis, domain structure, dynamic hysteresis (the imaginary part of the magnetisation detected based on the frequency dependence of the magnetisation in alternating fields). The exchange interaction of electrons and

Figure 17. Three-dimensional atomic image of the molecular magnet $\text{Mn}_{30}\text{O}_{24}(\text{OH})_8(\text{O}_2\text{CCH}_2\text{Bu})_{32}(\text{H}_2\text{O})_2(\text{MeNO}_2)_4$.⁶⁴ All atoms except hydrogen are shown.

the dipole interaction of the electron spins within a molecule is a source of magnetism in these molecules. The exchange interactions (J) between the unpaired electrons in the core of the molecule usually have different magnitudes and signs: for some electrons they are positive and align the electron spins parallel (ferromagnetism), while for other electrons this interaction is negative and the spins become antiparallel (antiferromagnetism). As a result, the total spin of the molecule does not correspond to the number of unpaired electrons in it. For example, the number of unpaired electrons (N) in the $\text{Mn}_{12}\text{O}_{12}(\text{O}_2\text{CMe})_{16}(\text{H}_2\text{O})_4$ molecule is 44 while the total spin (S) is only 10 (see Ref. 63). The $\text{Mn}_9\text{W}_6(\text{CN})_6$ and $\text{Mn}_9\text{Mo}_6(\text{CN})_6$ molecules have the same numbers of unpaired electrons ($N = 51$) but different total spins: $S = 39/2$ and $51/2$. The total spin $S = 51/2$ implies that in the molybdenum cluster $\text{Mn}_9\text{Mo}_6(\text{CN})_6$ all electrons are coupled ferromagnetically. In the $\text{Fe}_{11}\text{O}_6(\text{OH})_6(\text{O}_2\text{CPh})_{15}$ molecule, $N = 55$ and $S = 1/2$. Even for the record large molecule, $\text{Mn}_{30}\text{O}_{24}(\text{OH})_8(\text{O}_2\text{CCH}_2\text{Bu})_{32}(\text{H}_2\text{O})_2(\text{MeNO}_2)_4$ (see Fig. 17), in which the number of unpaired electrons is 143, $S = 5$.⁶⁴

The dipole interaction (D) of the electron spins in the $\{\text{Mn}_{30}\}$ molecule also has different signs and forms groups of spins that compose nanodomains inside the molecule. The energy of dipole interactions (normally about 1 cm^{-1}) creates a barrier to re-orientation of nanodomains and is a source of dynamic and static hysteresis.

Unlike macroscopic ferromagnets, in the molecular magnets, nanodomains change the magnetisation direction by the tunnelling mechanism; therefore, a quantum hysteresis loop appears in these molecules, the discrete magnetisation steps being its typical feature (Figs 18 and 19).^{63, 65}

The interest in the nanomagnet molecules is determined by the following facts:

- they are individual, identical and have a clear and exact atomic and molecular architecture;
- they are soluble and, therefore, can be easily and controllably assembled into molecular ensembles (including two-dimensional lattices on the surface);
- they have a large magnetic moment and can be reliably detected and controlled by ‘point’ methods, namely, atomic force and tunnelling scanning spectroscopy.

The molecular magnets attract enormous attention as elements of high-density magnetic memories and quantum computers and as materials for spintronics. About 20–30 such molecules with Mn, Fe, V, Cr, W, Tb and Dy cores have been synthesised to date.

The theory of these molecules is now under vigorous development; the conditions to be satisfied by multispin molecules for their functioning as nanomagnets have been summarised; they

Figure 18. Atomic structure of the $\text{Mn}_{12}\text{O}_{12}(\text{O}_2\text{CC}_6\text{H}_4\text{Cl}-2)(\text{H}_2\text{O})_4$ molecule (a) (the 2-chlorobenzene rings are not shown for simplicity) and quantum hysteresis loops (b) for the molecular nanomagnets $\text{Mn}_{12}\text{O}_{12}(\text{O}_2\text{CMe})_{16}(\text{H}_2\text{O})_4$ (1) and $\text{Mn}_{12}\text{O}_{12}(\text{O}_2\text{CC}_6\text{H}_4\text{X}-2)(\text{H}_2\text{O})_4$ (2, 3) [X = Br (2) and Cl (3)] at 20 K.⁶³

include spin non-equivalence in the J and D values, the anisotropy of spin–orbit (λLS) and exchange (J) interactions. These conditions are practically implemented by combination of atoms of different metals within one molecule (in some cases, with the addition of paramagnetic organic ligands)⁶⁶ and chemical design.

In the tunnelling spectroscopy, the molecular magnets exhibit a remarkable feature, namely, spin selectivity of the inelastic interaction of the molecule with the tunnelling electrons coming out of the tip. This feature was first discovered by Dalidchik and co-workers⁵⁵ in relation to the low-spin O_2^- molecule. The spin of the unpaired electron in the O_2^- radical anion and the spin of the tunnelling electron create either a singlet (the total spin is equal to zero) or triplet (the total spin is equal to unity) state through the exchange interaction. These states differ energetically by the value of exchange energy; the difference results in the line splitting in the vibrational spectrum of the O_2^- radical anions into pairs corresponding to the singlet and triplet channels of the tunnelling current (Fig. 20).

This feature opens up new opportunities for the use of molecular magnets as spin filters (for filtering the tunnelling electrons according to the spin). This is a remarkable result of the single-molecule spin chemistry, which will be undoubtedly included into the spintronics. Kozhushner and co-workers⁶⁷ proposed using a ferromagnetic tip (a source of polarised electrons) for the same purpose and developed a theory of this spin filter. An increase in the sensitivity of optical detection by micro-

wave treatment of the spin molecule and the use of electron paramagnetic resonance in the tunnelling spectroscopy have been discussed.^{68, 69}

V. Raman spectroscopy of single molecules

Raman spectroscopy is based on inelastic light scattering on molecular vibrations. The photons that fall on the molecule lose an energy quantum, which is spent for the excitation of molecular vibrations; this loss is detected as a shift of the exciting light frequency (Stokes shift). If the molecular vibrations have been excited, the photons falling on the molecule acquire an additional energy of molecular vibrations; as a consequence, the scattered light frequency increases (the anti-Stokes shift).

Raman spectroscopy has found wide application in the chemistry and physics of gases, liquids and solids and has become a serious supplement to the usual vibrational spectroscopy. Currently, this method is a powerful tool in the study of the molecular structure. However, the probability of inelastic photon–vibration (Raman) interaction (with generation of a Stokes or anti-Stokes line) is very low (the cross-section of this interaction does not exceed 10^{-30} cm² per molecule); therefore, the sensitivity of the method is low, which makes it applicable only to large ensembles of molecules.

In 1977, it was found that the probability of the inelastic light scattering by molecules sharply increases if these molecules are adsorbed on metallic surfaces,^{70, 71} in particular, on metallic electrodes with an extensive surface or nanoparticles. This immobilisation results in an essential increase (10^{14} – 10^{15} , sometimes 10^{20} -fold) in the intensities of the Stokes and anti-Stokes lines, which allows one to reach the threshold of the photon–vibrational interaction cross-section, needed to detect a single molecule (about 4×10^{-18} cm² per molecule) and often even to exceed the threshold.⁷² The best results as regards the sensitivity were obtained on adsorption of the detected molecules on Ag or Au nanoparticles with 10–100 nm size.

Two causes (two mechanisms) for the sharp increase in the probability of Raman scattering are discussed. The first one ('physical' mechanism) involves the enhancement of the local, light wave-induced electric field on the metallic surface due to the collective excitation of the conduction electrons (surface plasmon excitation). This field stimulates a strong non-linear polarisability of the molecule occurring in the vicinity of the plasmon excitation and increases sharply the probability of the photon–vibrational transition.

The second reason ('chemical' mechanism) is the specific interaction of the molecule with the metallic surface. Unlike the plasmon interaction, which is purely physical, this interaction is often called 'chemical'. The 'chemical' interaction is considered to include electron exchange between the adsorbed molecule and the surface metal atoms to yield states of the charge-transfer complex type. The electron exchange mechanism is supported by direct observations: for example, the Raman lines of the pyridine and bipyridine molecules adsorbed on silver clusters are shifted to higher frequencies, which approach those of the pyridinium cations.⁷¹ Thus, charge transfer in the surface–adsorbed molecule system is the key element of the 'chemical' mechanism of the stimulation of Raman scattering. The reversibly generated and destroyed short-lived states are characterised by high polarisability, which is accompanied by a sharp increase in the probability of the Raman vibration transitions in the adsorbed molecule.

Both mechanisms co-exist but the contribution of each of them depends on the particular chemical systems. It is noteworthy that the predominant contribution belongs to the 'physical' mechanism. The plasmons and plasmon resonances are excited on the scale of the exciting light wavelength; this can be called a large-scale process. Conversely, the 'chemical' mechanism acts locally on a molecular scale; it refers to the local electronic interaction of the molecule with the surface.

A contribution of the ‘chemical’ mechanism to the enhancement of surface-induced Raman scattering has been detected.⁷³ Using rhodamine 6G immobilised on colloid silver clusters as an example, the researchers not only detected the contribution of the ‘chemical’ mechanism to the Raman scattering but also separated the contributions of the ‘physical’ and ‘chemical’ mechanisms. The solution containing colloid silver particles was placed into a chamber and a solution containing rhodamine 6G (in order to stabilise the adsorption–desorption equilibrium on the clusters) and various anions, F^- , Cl^- , Br^- , I^- , $S_2O_3^{2-}$, SO_4^{2-} , etc., was passed through the chamber. Measurement of the Raman scattering intensity showed that the citrate, F^- or SO_4^{2-} anions do not influence the intensity of the Raman scattering lines, Cl^- , Br^- and I^- ions enhance the Raman scattering, and the thiosulfate anions decrease scattering by 2–3 orders of magnitude. It was also found that the plasmon spectrum of Ag clusters does not depend on their treatment with anions. These results indicate unambiguously that both mechanisms, ‘physical’ and ‘chemical’, exist almost independently from each other, the former being universal and the other depending on the chemical pre-history of the clusters and their surface chemistry.

Rhodamine 6G is the first molecule for which the vibrational spectrum was recorded under conditions where each individual molecule was arranged above a separate silver nanocluster.⁷⁴

The spectra of adenine and adenosine monophosphate single molecules have also been recorded on silver clusters.⁷⁵ From comparison of the Stokes and anti-Stokes line intensities for these molecules, the cross-section of the photon–vibrational interaction was calculated to be $\sim 10^{-16}$ cm² per molecule (this is an enormous value compared with the value of 10^{-30} cm², typical of the usual Raman process); it was also shown that the cross-section does not depend on the cluster size. Moreover, the spectra of both molecules were identical, *i.e.*, chemical binding of adenine with the carbohydrate does not affect the Raman excitation of adenine.

For the dye Crystal Violet adsorbed on Ag and Au colloid clusters, the enhancement coefficients of the photon–vibrational interaction reach record values of 10^{20} (see Ref. 76).

The Stokes lines arise upon direct interaction of the light field with molecular vibrations; therefore, they are one-quantum. Their intensity is proportional to the intensity of the exciting light. The anti-Stokes lines result from a two-quantum process: one quantum excites a molecular vibration, while the other one induces its stimulated emission, *i.e.*, takes this vibrational quantum away from the molecule. The intensity of the anti-Stokes lines is proportional to the squared intensity of the exciting light. This dependence allows one to characterise quantitatively the Raman inelastic interaction of light with molecular vibrations.

The most interesting and fruitful studies of the single-molecule Raman scattering were carried out by Sweden scientists using biologically important molecules, namely, haemoglobin⁷⁷ and horseradish peroxidase.⁷⁸ Thus comparison of the structure of Ag colloid particles bearing haemoglobin molecules, determined by scanning tunnelling spectroscopy and atomic-force microscopy, with the intensity of Raman lines of the haemoglobin molecules showed that the haemoglobin molecules confined between pairs or groups of three Ag clusters scatter the light most actively. These molecules make the major contribution to the intensities of both Stokes and anti-Stokes lines; the haemoglobin molecules fixed on dimeric clusters whose axis is parallel to the electric field vector of the exciting light being the most active. This allowed the researchers⁷⁷ to conclude (which was also confirmed by theoretical estimates) that the major contribution to the enhancement of Raman scattering on haemoglobin is made by the electric-field plasmon (‘physical’) mechanism but a contribution from the ‘chemical’ mechanism cannot be ruled out either.

Yet another biomolecule studied by this method is horseradish peroxidase immobilised on colloid silver (90 nm size).⁷⁸ In this case, the protein macromolecule becomes ‘captured’ by the clusters, which enhances the plasmon mechanism and increases

the Raman scattering intensity. The intensity growth is so pronounced that the researchers cited⁷⁸ were able to record the Raman spectrum from a sole peroxidase molecule. Measurement of the enzymatic activity of the peroxidase demonstrated that immobilised peroxidase molecules are less active. However, if the silver clusters are pre-treated with hydrogen peroxide, the activity of the immobilised enzyme is retained at the level of the initial (non-immobilised) compound but the intensity of Raman scattering decreases.

This type of behaviour of biomolecules, in particular, enzymes, can be used as an indicator of their functioning at the single-molecule level. In some cases, it is necessary to retain also the ‘native’ activity of the enzyme and its high detectability by Raman spectroscopy; to this end, special techniques are used (see, for example, solution of this problem in Ref. 78).

One important fact deserves attention. To date, there is only one example where the Raman spectrum actually detects a single molecule, *viz.*, peroxidase.⁷⁸ In most cases, the spectra from ensembles of single molecules are recorded, *i.e.*, ensembles of isolated molecules distributed among different clusters. However, this circumstance does not depreciate in any way the chemical information and the advantages of surface-activated Raman spectroscopy.

Like the fluorescence of single molecules (see Section II), the Raman scattering (‘flickering’) of single molecules on the surface of metal clusters depends on time in a random manner: the spectra vary with time as regards both intensities and frequencies. This phenomenon is typical of all molecules studied including biomolecules. The random fluctuation dynamics indicates unambiguously that ‘flickering’ is due to the local surface–molecule interactions. The formation and decomposition of charge transfer states is accompanied by the migration of molecule across the surface. This migration changes both the intensities and frequencies of lines in the Raman spectrum of the analysed molecule.

The fluctuations are of a non-thermal nature; they are initiated by the exciting light, which generates Raman scattering. Direct experimental evidence for this statement was obtained.⁷⁹ For an ensemble of molecules (30 to 50), the frequencies (ν) and intensities (I_ν) of the Raman lines were measured and the fluctuation correlation functions were calculated

$$c(\tau) = \sum_{\nu} [\langle I_{\nu}(t)I_{\nu}(t+\tau) \rangle - \langle I_{\nu}(t) \rangle^2]$$

(the angular brackets mean averaging over τ).

The dependence $c(\tau)$ was used to obtain the fluctuation rate k . These measurements were carried out for various intensities of the light exciting the Raman spectrum. The fluctuation rate was found to increase linearly with an increase in the exciting light power. The thermal heating was minor and did not exceed 0.1 K,⁷⁹ *i.e.*, the spectral fluctuations are non-thermal. This remarkable feature allows single molecules as a local dynamic surface probe.

VI. Electrical conductivity of single molecules

The particular interest in the electrical conductivity of single molecules is due to two factors. First, in chemistry (and especially in biochemistry), determination of charge conductivity of a molecule is subject to many uncertainties. For example, depending on the procedure used to determine the charge conductivity, the DNA molecule was assigned either to dielectrics, or to semiconductors, or to metallic conductors, or even to superconductors.⁸⁰ Second, a molecule as an object of molecular electronics and as an element of nanoelectronic devices (molecular resistors, diodes, single-electron transistors) requires accurate electro-physical characteristics.

The electrical conductivity of single molecules is measured using two procedures. The first one is based on a combination of atomic-force and tunnelling spectroscopy: using one of them, a single molecule is ‘found’, while using the other, the electrical current is applied to the molecule and measured. The second

procedure is based on direct electrochemical synthesis of the molecule (between two electrodes) and measurement of the resistance.

The first electrical conductivity measurement of a single C_{60} molecule placed between two electrodes, one being the surface of the Ag(110) crystal and the other being the tip of a tunnelling microscope, was carried out in 1995.⁸¹ At large distances (S) from the surface of the molecule to the tunnelling tip mounted above C_{60} , the current increased exponentially with a decrease in S . When the van der Waals mechanical contact of the tip with the C_{60} molecule has been established, the current reaches a maximum value, the total resistance (R_{ef}) being 54.807 M Ω .

By substituting this R_{ef} value into the expression

$$V = R_{\text{ef}}I = R_0 \left(1 + \frac{r}{t} \right) I$$

(R_0 is the electrical resistance of the C_{60} molecule, r and t are the reflection and transmission at the Fermi level[†]) representing Ohm's law for the molecular electrical contact, the researchers calculated the resistance (R_0) of the C_{60} molecule, which turned out to be 54.794 M Ω . After the distance from the surface of C_{60} molecule to the tip becomes smaller than the van der Waals mechanical contact, the exponential pattern of the $I(S)$ dependence is violated due to the deformation of the C_{60} molecule under the action of the tip.

The conductivity of molecules depends appreciably on their compression. For example, the compression of C_{60} by 1 Å changes the current strength that passes through the molecule by two orders of magnitude.⁴² For a C_{60} molecule applied onto a dielectric, Coulomb blockade is observed at 4.2 K. The ability of the C_{60} molecule to lock the current can be used in the design of one-electron devices in which the molecule is an ideal quantum dot.⁴²

The main problem in the conductivity measurement for single molecules is to create a reliable and controllable electrical contact of one molecule with two electrodes. Convenient objects are molecules containing reactive SH groups (for example, alkanedithiols); by means of these groups, molecules can be arranged as a wire between two electrodes.

An elegant and reliable experimental technique has been developed to measure the electrical conductivity of hydrocarbon $(CH_2)_n$ chains.⁸⁰ An alkanethiol monolayer with built-in alkanedithiol molecules are applied on the surface of an Au(111) single crystal from a solution. All monolayer molecules had an electrical contact with the Au surface due to S–Au covalent bonds. The upper boundary of the monolayer is formed by the terminal methyl groups of alkanethiol and (at the sites of the admixed dithiol molecules) the alkanedithiol SH groups (these groups can be single or form islets of two, three or four SH groups).

On the alkanethiol monolayer, triphenylphosphine-stabilised gold clusters were applied from a solution. The PPh_3 ligands are known to be easily exchanged with the SH groups; hence, the positions of the alkanedithiol molecules become labelled by gold clusters. Thus Au clusters are connected to the electrical contacts on the Au(111) surface through the $-S(CH_2)_nS-$ bridges. The tip of an atomic force microscope has found an Au cluster on the surface and the voltage was applied to the cluster through the $-S(CH_2)_nS-$ chain. By measuring the tunnelling current between the tip and the Au surface, the electrical conductivity of single $-S(CH_2)_nS-$ chains (Fig. 21) was found to be $0.97 \times 10^9 \Omega$ for $n = 8$, $2.89 \times 10^9 \Omega$ for $n = 9$ and $8.26 \times 10^9 \Omega$ for $n = 10$. From this it follows that the variation of R vs. n is exponential: $R \approx \exp(\beta n)$, where $\beta = 0.6$.⁸⁰

The dependences $I(V)$ at low voltages (50 mV) proved to be linear and symmetric with respect to the sign of V . The slope of the

Figure 21. Scheme of the addition of electrical contacts (Au surface below and Au clusters above) to one alkanedithiol molecule incorporated in the alkanethiol monolayer.⁸⁰

I – V straight line to the abscissa axis (axis I) corresponds to the ohmic resistance. It was found that all the R values can be divided into four groups related by the ratio 1.00 : 0.50 : 0.33 : 0.25. These values correspond to four cases of current passage, namely, through one molecule and through clusters consisting of two, three and four molecules, respectively. In the clusters, the ohmic resistance is made up from the ohmic resistances of each molecule, as in an electric circuit consisting of parallel resistors. Each molecule is an independent conductor, *i.e.*, its resistance does not depend on the neighbours in the clusters. This is a remarkable result, indicative of the reliability of the experimental technique used in the study cited.⁸⁰

Note that the electrical resistance of the $-S(CH_2)_nS-$ chain ($R \approx 10^9 \Omega$) is greater by two orders of magnitude than the resistance of the C_{60} cluster ($5 \times 10^7 \Omega$). It can be concluded that the conductivity of the molecule is mainly determined by the molecular orbitals, their energies and occupancies. Theoretical calculations⁸² of the conductance (G) of molecular wires are consistent with this conclusion. The researchers studied the dependence of the tunnelling current in a channel (wire) on the length and on the chemical structure of molecular wires using oligo(thiophene-2,5-diylalkynediyls), oligo(phenylenealkynediyls), polyenes, *etc.*, as the wires. The conductance in the metal–wire–metal channel was calculated using the formula

$$G = G_0 \exp(-\gamma L),$$

where γ is the damping factor, L is the length of the molecular wire. The G_0 and γ values depend on the chemical structure of the molecular wire.

As another example, one can consider the measurement of the conductivity of the single molecules of 9,10-bis(*p*-mercaptophenylethynyl)anthracene (**2**) and related asymmetrically substituted benzene **3**.

For 'laying' molecules **2** and **3** between electrodes made of Au atoms, an electrode pair with one movable electrode was produced by lithography. The distance between the electrodes was 'adjusted' mechanically to the length of the molecule placed between them.

[†] t is the transmission coefficient corresponding to the elastic passage of the electron Bloch wave through the C_{60} molecule from one electrode to the other, r is the coefficient of reflection of this wave from the molecule.⁸¹

The SH groups in molecules **2** and **3** were protected by acetate groups, which were substituted by Au atoms upon incorporation of the molecules between the electrodes.⁸³

The $I(V)$ plots for such molecular conductors were symmetric with respect to the sign of V . The application of a 1 V voltage to metallic surfaces gives rise to tunnelling currents of about 0.2–1.0 μA , which remain stable during long periods of time (up to 100 min). The electrical resistance of these molecular ‘wires’ was $\sim 2\text{ M}\Omega$ [almost 20 times lower than that of C_{60} and by three orders of magnitude lower than that of the aliphatic $-\text{S}(\text{CH}_2)_n\text{S}-$ chain]. It is clear that molecules **2** and **3** containing systems of highly conjugated bonds are better conductors than the C_{60} or $\text{HS}(\text{CH}_2)_n\text{SH}$ molecules; carbon nanotubes are even better conductors (their resistance is $\sim 100\text{ k}\Omega$).

Undoubtedly, the methods for the design of molecular nanowires and nanodevices based on them will be further developed; this is a route to nanoelectronics.

VII. Mechanics and mechanochemistry of single molecules

Atomic force microscopy measures the attraction force between the microscope tip and the surface of the molecule as a function of the distance between them, unlike tunnelling scanning microscopy, which measures the current between the tip and the molecule surface. In the classical version, atomic force microscopy is contactless: the tip slides along the surface without touching it. Atomic force microscopy is also capable of visualising monoatomic vacancies on the semiconductor and dielectric surface or adsorbed molecules. This allows drawing some approximate conclusions concerning the sizes and the shapes of the molecules, their densities and arrangement on the surface. However, it should be admitted that due to the low spatial resolution, this method provides more information about the surface than about the adsorbed molecules.

The situation changes fundamentally if the atomic force microscopy is made contact, *i.e.*, one end of the molecule is attached to the tip, and the other is on the surface. Then, as the tip moves away from the surface and the molecule is being stretched, one can measure the force as a function of stretching of the molecule, *i.e.*, to study the mechanics of a single molecule. In this case, the atomic force microscopy becomes force spectroscopy.

Figure 22 shows the experimental scheme used to measure the extension (x) of a molecule and the dependence of the force (F) on drawing. The function $F(x)$ is usually non-linear (non-Hookean). The curve $F(x)$ has small local peaks, rises and dips, which are indicative of the change in the conformation of the macromolecule upon drawing. The folded conformations are replaced by extended ones under the action of drawing. Finally, at some

critical elongation, the completely stretched molecule is torn; the tear strength is the strength of the chemical bond.

Force spectroscopy has reached high sensitivity for the strength and high resolution as regards deformation and operates in a broad range of deformations and strengths: 0.01–100 N m^{-1} and 10^{-13} – 10^{-8} N .

The main processes in the nanomechanical technology include ‘picking up’ of a single molecule from a solution, a gel or a solid by the microscope tip and its drawing. During drawing, the force and deformation of the molecule are measured. This technology combines science and art: usually, the tip is immersed into a solution (or film) applied on a substrate and kept there for some period using a force of several nanonewton, and then lifted, thus drawing the molecule. By changing the functional groups at the ends of the molecule, the material of the tip and the substrate from which the molecules are taken, by varying their concentration, the amplification and the type of contact between the cantilever tip and the molecule container and using the trial-and-error method, one can attain the goal, *i.e.*, pick up the required molecule and analyse its mechanics (or mechanochemistry).

Using the new technology, it is possible to measure the binding strength of molecules and complexes (for example, DNA strands or an antigen with an antibody) and the cleavage strength of chemical bonds, to observe the conformations of molecules, to measure their elasticity and to move atoms and molecules (pull or push them over the surface).

1. Nanomechanics of macromolecules

The first outstanding success in the mechanics of single molecules was achieved in a study of natural and synthetic macromolecules. In experiments with single polysaccharide molecules, the first stage was modification of the polysaccharide terminal groups in such a way that one end could be attached to a glass surface (*via* the Si–C covalent bond) or a gold surface (Au–S bond),⁸⁴ while the other end could be grafted to the cantilever. After that, the polysaccharide molecule was drawn, while measuring the force spent for deformation. The resulting $F(x)$ dependence for these molecules was similar to that shown in Fig. 22; the Si–C bond was cleaved at a force of 2 nN, while the Au–S bond, at 1.4 nN.

The nanomechanical properties of poly(*N*-isopropylacrylamide) and poly(acrylamide) in aqueous solutions have been studied.⁸⁵ For these flexible-chain macromolecules which fold into a statistical coil, back in 1942 Kuhn derived from the freely jointed chain model the $x(F)$ dependence, which is described by the Langevin function

$$x(F) = \left[\text{cth} \left(\frac{Fl}{kT} \right) - \frac{kT}{Fl} \right] L, \quad (1)$$

where l is the length of the statistically independent Kuhn segment, L is the contour length of the macromolecule (the distance between the ends of the fully drawn molecule). Within the framework of this model, the Kuhn segments are considered inelastic and non-stretchable. Direct measurements of $x(F)$ for single macromolecules have shown that the function $x(F)$ is described by this model only at very low forces F ($\sim 10\text{ pN}$), where the elasticity of the macromolecule is of purely entropic nature (the chemical bonds and angles are not strained), the elongation of the molecule being due only to the unfolding of folded conformations.

However, at $F > 10\text{ pN}$, this model does not comply with the experimental $F(x)$ dependence. If one assumes that the Kuhn segment is elastic and stretchable, the $x(F)$ dependence should be described by the generalised Langevin equation

$$x(F) = \left[\text{cth} \left(\frac{Fl}{kT} \right) - \frac{kT}{Fl} \right] \left(L + \frac{nF}{K} \right), \quad (2)$$

where n is the number of Kuhn segments ($n = L/l$), K is the elastic modulus of the Kuhn segment. The experimental data obtained

Figure 22. Scheme of the experiment with drawing of a single molecule in the atomic force microscopy (a) and schematic dependence $F(x)$ derived from this experiment (b).

for poly(acrylamide) and poly(*N*-isopropylacrylamide) are adequately described by this function up to $F = 1000$ pN.⁸⁵

Macromolecule	l /nm	L /nm	K /N m ⁻¹
Poly(<i>N</i> -isopropylacrylamide)	0.68	460	26
Poly(acrylamide)	0.625		20

If a Kuhn segment is represented as an elastic structure, the value $K = 26$ N m⁻¹ (or 26 000 dyne cm⁻¹) is indicative of a very high strength.

Note that the generalised Langevin equation (2) properly describes the elasticity of macromolecules under conditions where the intramolecular hydrogen bonds involving side groups have been destroyed (for example, in the presence of urea). However, in deionised water containing intramolecular bonds in a coil, the function $x(F)$ is no longer of the Langevin type, indicating intramolecular association.

The new atomic-force techniques have rushed like an avalanche into molecular biology.⁸⁶ Of the large number of studies,

Figure 23. Force (F) vs. extension (x) related to the chemical bond length (l_c) for dextran [(1 $\rightarrow$ 6)- α -D-glycan, *a*], amylose [(1 $\rightarrow$ 4)- α -D-glucan, *b*] and pullulan [(1 $\rightarrow$ 4,1 $\rightarrow$ 6)- α -D-glucan, *c*] before (dashed lines) and after (continuous lines) periodate oxidation (5 mM solution of NaIO₄); (*d*) dependence of $F(x)$ for the same polysaccharides with the pyranose rings destroyed by periodate oxidation.⁸⁷

we consider below only those related to biochemistry and biophysics. Figure 23 shows the $F(x)$ dependences for single polysaccharide molecules, namely, dextran (*a*), amylose (*b*) and pullulan (*c*).⁸⁷ These dependences are described by Langevin equation (2) only at low forces and deformations.

For dextran, Eqn (2) holds for $l = 0.44$ nm (the size of a monomer unit) and $K = 14.6$ N m⁻¹. At greater deformations, the enthalpic component appears in the elasticity of the dextran molecule (a plateau on the dashed curves): the pyranose rings pass from the chair conformation to the boat conformation. The modified polymer chain is described again by the Langevin equation with the parameters $l = 0.2$ nm and $K = 34.2$ N m⁻¹, i.e., the Kuhn segment becomes more elastic. In this new state, the enthalpic component of the elasticity disappears, while the entropic component is retained. The same result can be attained if the pyranose rings are destroyed by periodate oxidation: for dextran, this is attained in 180 min, for amylose, in 50 min and for pullulan, in 120 min (see Fig. 23 *a–c*).

Amylose and pullulan behave in a similar way. Only the entropic elasticity remains in the polymer chains formed upon destruction of pyranose rings (see Fig. 23 *d*).

The dependence $F(x)$ obtained upon drawing of the molecule of the protein titin responsible for the passive muscle elasticity is shown in Fig. 24. It can be seen from the Figure that this dependence is periodic (the curve resembles the saw teeth). The tooth period amounts to ~ 25 nm, while the restoring force in each tooth is 0.15–0.30 nN.⁸⁸ The periodicity is in good agreement with unfolding of the immunoglobulin titin domains. In order to verify this idea, the I8 and I4 fragments containing 8 and 4 immunoglobulin domains, respectively, were tested. The $F(x)$ curves thus obtained contained eight and four teeth, respectively, which is in full agreement with the expected result.⁸⁸ Similar dependences are also typical of another protein tenascin, a component of a territorial matrix.⁸⁹

A serious drawback of the atomic-force spectroscopy of single molecules is ambiguity of the $F(x)$ function measured experimen-

Figure 24. Force vs. extension of single titin molecules with various immunoglobulin domains. Domains I27–I34 (*a*), I28_n (*b*), I27_n (*c*).⁸⁸

tally, which is due to the difficulty or even impracticability of determining what molecular processes and atomic rearrangements are hidden therein. Therefore, the experiment is often accompanied by molecular dynamics calculations. An example of such calculation is shown in Fig. 25. The researchers obtained the dynamic drawing curves as a function of time for one titin domain, namely, for immunoglobulin I27, with a constant force applied to it [four curves are presented, for $F = 500$ (curve 1), 750 (2), 900 (3), and 1000 pN (4)]. In all cases, the initial elongation to 100–120 nm was followed by structure stabilisation (the molecule was not deformed for a certain period of time τ ; the lower the force applied, the longer the time). However, after the period τ had elapsed, further fast deformation of the domain took place due to untangling of the protein chains.⁹⁰

Figure 25. Dynamic (time) extensions of the domain I27 of titin at a constant force: $F = 500$ (1), 750 (2), 900 (3), 1000 pN (4). State A corresponds to the molecule with hydrogen bonds and state B corresponds to the molecule in which these bonds have been cleaved.⁹⁰

The stable state is confined between two states A and B. In the molecule occurring in state A, all hydrogen bonds function and hold the chain structure; in the molecule in state B, six hydrogen bonds have been cleaved. A sort of plastic yielding takes place between states A and B; during this period, the molecule, while resisting deformation, sacrifices six hydrogen bonds. These results are in good agreement with experimental data and provide a clearer understanding of the molecular unfolding process (including a functioning muscle) stimulated by mechanical deformation.⁹⁰

Considerable attention is attracted by the study of non-valence contacts in the host–guest, ligand–receptor, *etc.* systems. For a complex multipoint biotin–avidin contact, even the temperature dependence of $F(x)$ was measured. From analysis of the Poisson force distribution of the ruptures, the average strength of one contact was found to be 0.26 nN; the temperature dependence of the strength was found; in particular, as the temperature increases by 1 K, the strength decreases by 12.6 pN.⁹¹

Using the human serum albumin complex with a polyclonal antibody (1 : 1) as an example, the antigen–antibody interaction force was measured to be 0.244 nN.⁹² The interaction of ferritin with antiferritin is described by a low adhesion force of ~ 0.05 nN.⁹³ The adhesion of proteoglycans, which ensure cell recognition and aggregation, has also been studied.⁹⁴

2. Optical tweezers and biomechanics

Recently, a new mechano-optical technology for measurement of molecule deformation has appeared. The principal working tool is an optical trap (or optical tweezer). The optical tweezer is a set of polystyrene or quartz beads of about 1 μm size. On exposure to a focussed laser beam, the bead is drawn into the focus with a force depending on the light intensity. This trap attached to the end of a

molecule draws and deforms the molecule; actually, the optical trap acts as a cantilever in an atomic force microscope.

This technique is already widely used to study the structure and functioning of molecular motors.⁹⁵ ATPase, kinesin, myosin, immunoglobulin proteins — this is far from being the full list of biomolecules studied by this method.^{96,97} An impressive example is the study of operation of RNA polymerase (this enzyme accomplishes RNA transcription).⁹⁶ The researchers have fixed the RNA polymerase molecule on glass and connected it to one end of the DNA double strand, while the other end of DNA was equipped with an optical trap. It is known that RNA polymerase captures the DNA double strand and drags it through itself, while generating simultaneously the RNA thread. By exposing the optical trap to laser radiation, the researchers counterbalanced the force of DNA drawing-in by the enzyme at one end with the retention force of the DNA by the optical trap at the other end of DNA. After this balance of forces has been established, the enzyme stops operating. The balance is attained at 25 pN; this is the force at which RNA polymerase drags the DNA double helix through itself. It is believed that RNA polymerase is the most powerful known molecular motor: it is 5–6-fold more powerful than kinesin. Presumably, the major energy of this motor is spent for untwisting the DNA strands.

One more molecular (protein) motor, λ -exonuclease, is a component of a bacterial virus. Unlike RNA polymerase, which is energised from ATP, λ -exonuclease operates on the DNA energy: by dragging the two-stranded DNA helix through itself, it ‘swallows’ one of the strands. It is a weaker motor than RNA polymerase and develops only a 5 pN force.⁹⁸

An attempt has been undertaken to use the mechano-optical technology to study topoisomerase, a remarkable enzyme, which undoes the knots on the DNA, when DNA is unpacked in a nucleus during cell division. If one understood how this enzyme operates and its operation could be terminated, it would be possible to stop the division of the malignant cells.

3. Surface nanomechanics

The controlled migration and orientation of molecules on the surface is the major route to the combination of molecules into specified ensembles, to the creation of electrical contacts, electrical circuits and integrated nanocircuits. The procedures for manipulation of single molecules on a surface rely on atomic force microscopy and tunnelling electron spectroscopy.

The force microscopy has substantially advanced in manipulating nanotubes on the surface: the microscope tip is used not only for moving nanotubes and arranging them into diverse figures and ensembles, but also for measurement of the adhesion forces between the nanotubes and the surface.⁹⁹ Various versions of this technique have been described in a review.¹ Even greater opportunities for manipulating nanoobjects are provided by tunnelling spectroscopy. In this case, the force of the tip acting on the molecule being moved is controlled by both mechanics and the electric potential of the tip. Below we present two vivid examples of operation of the nanomechanical technology.

On the (100) face of a silicon single crystal, Si_2 pairs of atoms are aligned in rows; between the rows, a gutter is formed, which accommodates the C_{60} molecules applied on the surface.⁴⁶ In the tunnelling current, the images of the C_{60} molecule look like bright domes about 2.5 nm in diameter and with a height of 0.65 nm. The potential on the tip of the tunnelling microscope, the tunnelling current and the tip elevation above the crystal surface are related in such a way that the potential and the current are maintained constant, while the distance S between the tip and the surface is variable.

The tip, which moves along the gutter, comes across the C_{60} molecule, rises and moves above the molecule (this process is described by curve 1 in Fig. 26a). However, as the tip moves along the slope of C_{60} , this molecule jumps after the tip and lifts it again (this instant is shown by the arrow). These events are repeated several times, *i.e.*, the C_{60} molecule jumps after the tip moving

Figure 26. Vertical displacement (S) of the tip vs. horizontal displacement x (a) and horizontal displacement in the pushing mode (b).⁴⁶

away. Each jump covers a discrete distance, namely, two lattice spacings of silicon. The C_{60} molecule can behave in a different way, namely, as the tip approaches the molecule, the molecule may jump towards the tip; the tip would be sharply lifted (this type of behaviour of C_{60} is described by curve 2 in Fig. 26 a). In both cases, the molecule and the tip interact in the attraction regime: the molecule moves either to meet or to follow the tip.

By varying the tip potential, one can also implement the repulsion regime where the moving tip pushes the molecule in front of itself. This regime is clearly illustrated in Fig. 26 b. In this case, the tip meets the molecule at the instant indicated by the first arrow and repels it, and the molecule jumps away by 70–80 nm (this instant is indicated by the second arrow). Then the events are repeated. Actually, the tip ‘rolls’ the C_{60} molecule along the gutter, each migration of the molecule being accompanied by cleavage of its chemical bond with a silicon atom and the formation of a new bond in the new position. This conclusion is based on the fact that the molecule travels every time the same distance, namely, two lattice spacings. Other distances can also be detected but their probability is much lower.⁴⁶

Yet another example is the design of metallic monoatomic wires made of Au and Pd atoms on the NiAl(110) surface.¹⁰⁰ The Al atoms elevated above the (110) surface form parallel rows along the [001] direction; these rows alternate with rows of buried Ni atoms forming gutters along the same [001] direction. The Au and Pd atoms are sputtered onto the surface and then are driven together into the nickel gutters by means of a tip of a tunnelling microscope. The migration of the Au and Pd atoms starts when the distance between the atom and the tip corresponds to resistances of 150 and 50 k Ω , respectively. This means that Pd atoms are more strongly attached to the surface than the Au atoms; they migrate at tighter contacts with the tip (a smaller distance between the tip and the atom corresponds to a lower resistance).

Using this procedure, monoatomic Au and Pd nanowires and mixed wires with alternating Au and Pd atoms have been successfully obtained and their electronic properties (energy levels and

densities of the electronic states, standing waves of the electron density in the atomic chains) have been studied.¹⁰⁰ This study opens up enormous prospects for the understanding of the electronic interactions and properties of the metal alloys through the electronic properties of ‘one-dimensional’ alloys, *i.e.*, metallic nanowires.

VIII. Conclusion

By the early 21st century, chemistry has reached the limit of spatial resolution. Researchers learned to detect, locate in space and recognise a single molecule and to measure almost all of its properties, to study chemical transformations and functioning of single molecules. This gave rise to a new field of chemistry: the chemistry of single molecules.

What does this new field bring to chemistry and related sciences and what findings may be expected of the further development of this discipline?

In the general chemical sense, one should hardly expect any surprises from the study of single molecules or the appearance of new, in principle, information differing from the information obtained in the studies of large ensembles of molecules.[‡] Nevertheless, it is necessary to mention absolutely new information provided by single-molecule electrical conductivity measurements (for the theory of electron movement in a molecule) and by analysis of the energy fluxes in the molecule and on the surface (electronic-vibrational pumping and energy relaxation over vibrational oscillators).

One can hardly expect unusual results from the studies of functioning of single molecules. As shown by a known experiment, molecules are ergodic systems in which time averaging of the functioning of one molecule is equivalent to the ensemble averaging of instantaneous data; deviations from the ergodicity are due most often to artificial reasons (see Section II.5).

However, there is a field of chemistry for which studies of single molecules are of an inestimable value; this is the ‘biological wing’. Luminescence, mechanics and mechanochemistry of single biomolecules (enzymes, proteins, nucleic acids, molecular motors, antigen–antibody type complexes, *etc.*) open almost infinite prospects in the biochemistry and biophysics.

The work with single molecules stimulates the creation of the element base for molecular electronics, nanooptics and nanomechanics. Experience in the design of high-tech devices — nanoelectronic circuits, spin filters and transistors, molecular quantum dots, nanocomputer elements, optoelectronic switches, *etc.*, is being acquired. This aspect of the chemistry and physics of single molecules is infinite. The problem of creation and functioning of logical electronic circuits on a single molecule is already discussed.¹⁰¹

Abstract. The results of theoretical and experimental studies of the graphite surface by scanning tunnelling and atomic force microscopy are considered. The attention is focused on the mechanisms of formation of atomic resolution images. The reasons for the lack of coincidence between the graphite surface images obtained by these methods and its real topography are discussed. The bibliography includes 99 references.

I. Introduction

Graphite has an extremely wide range of applications. It is employed as a material for inert electrodes, neutron moderators, X-ray monochromators, strong and thermally stable coatings for spacecrafts. Technical progress has stimulated the development of new technologies of graphite production, as well as massive studies of its chemical and physical properties. In the early 1970's, it was believed that graphite is studied comprehensively. The known data were generalised in a number of reviews (see, for example, Refs 1–3).

In the 1980's, new instruments for surface studies were invented, such as scanning tunnelling microscope (STM)⁴ and atomic force microscope (AFM).⁵ Studies of graphite by these novel probe methods gave amazing results: its STM and AFM images were inconsistent with the real topography. Only one of each two carbon atoms was visible on the image. During the next decades a lot of studies were conducted in order to explain this fact. Despite the great amount of experimental data collected, there is still no consensus on the mechanism of the formation of STM images with atomic resolution.

Graphite crystals are convenient objects for the rapidly developing probe microscopy, as they have layered structure and form air-stable, atomic-smooth extended surfaces upon cleavage. Therefore they can be used as substrates in the studies of clusters, molecules and thin films. Graphite is one of a few materials for

which atomic resolution was reached under normal conditions in air.

At present, probe methods play a leading role in studies of surfaces. The portion of surface atoms in nanostructures is comparable to their volume content, therefore probe microscopy is an indispensable method in nanotechnology. Probe microscopes allow one to obtain images in liquid media, which is especially valuable in the studies of biological objects. However, STM and AFM images can differ from the topography of surfaces of the objects under study. Difficulties in the interpretation of graphite surface images suggest that one may expect serious errors in the studies of more complex systems.

In this review, the graphite atomic structure images observed with the use of STM and AFM in a contact or dynamic mode are analysed in detail. (In the contact mode, the probe is constantly in touch with the surface, while in the dynamic mode it oscillates in resonance and touches the surface periodically, thus minimising the friction force.) The mechanisms of formation of such images are discussed. A separate section is devoted to the visualisation of defects on the graphite surface and studies of their properties by probe methods.

II. Crystal structure of graphite

Among the carbon allotropic modifications, graphite is the most stable under normal conditions. Graphite consists of flat carbon layers that are shifted relative to each other to form hexagonal close packing of carbon atoms (Fig. 1 *a*). The space group is $P6_3/mmc$ and the unit cell parameters are: $a = 2.4612$, $c = 6.7078$ Å.⁶ The unit cell contains four atoms. Two adjacent carbon atoms in the layer are non-equivalent (see Fig. 1 *b*). Three of the six atoms have neighbours in the lower layer (site A), while

Figure 1. Graphite crystal structure. The unit cell parameters are given in Ångströms; for (*a*) and (*b*) see the text.

other three are located above the holes, *i.e.* in the centres of hexagons (site B). Weak van der Waals forces act between layers, causing substantial anisotropy of the graphite properties. Thermal and electrical conductivities in the direction parallel to the layers are much higher than in the perpendicular direction (Table 1). Due to the weakness of the interlayer bonds, graphite is easy to cleave.

Table 1. Electric resistance and thermal conductivity of highly oriented pyrolytic graphite (HOPG) and single-crystal graphite.²

Parameter	HOPG	Single crystal
Resistance / Ω m		
along the layers	$3.5 \times 10^{-7} - 4.5 \times 10^{-7}$	4×10^{-7}
perpendicular to the layers	$1.5 \times 10^{-3} - 2.5 \times 10^{-3}$	$1 \times 10^{-4} - 1.0 \times 10^{-2}$
Thermal conductivity / $\text{W m}^{-1} \text{K}^{-1}$		
along the layers	1600–2000	200–500
perpendicular to the layers	7–9	40–80

Graphite crystals of high quality are rarely found in nature. At present, most of the studies are carried out on highly oriented pyrolytic graphite, which is obtained by pyrolysis of gaseous hydrocarbons at temperatures above 2000 °C.^{2,7,8} Graphite obtained by this method is polycrystalline; however the directions of *c* axes for all crystallites virtually coincide (mosaic spread of high quality pyrolytic graphite is 0.4°, the dimensions of crystallites reach several tens of micrometers).

III. Visualisation of the atomic structure of graphite surface

1. Scanning tunnelling microscopy

Atomic resolution STM images of the graphite surface were obtained under different conditions: in high vacuum^{9–11} (Fig. 2, the real image size is not given in the original paper), in air^{12–15} and in water.^{13,16} The resolution is atomic that indeed is supported by the possibility to visualise defects in the atomic structure of the graphite surface by STM (Fig. 3).

Two main peculiarities of the graphite surface STM images are as follows:^{18–21} considerable corrugation of the surface (from 0.8^{22,23} to 24 Å²⁴) and asymmetry of the maxima corresponding to the carbon atoms in sites A and B.

Figure 2. Topographic graphite image obtained by STM in ultrahigh vacuum at 4.2 K.¹¹

Figure 3. A defect on the graphite surface induced by its bombardment with Ar⁺ at 60 eV.¹⁷

The image was obtained in the constant-current mode, $U = -36$ mV, $I = 0.5$ nA, scanning frequency, 10 Hz.

According to the helium scattering experiments, no surface reconstruction occurs and its corrugation is 0.2 Å. The over-estimated corrugation obtained by the scanning tunnelling microscopy is due to the features of graphite electronic structure,^{13,25} as well as to the effect of the microscope tip on the surface during scanning.^{24,26,27} An increase in the tip voltage leads to decrease in the corrugation.^{9,28}

A very interesting feature of the graphite surface STM images is the non-equivalence of the maxima corresponding to the adjacent carbon atoms.^{14,29} In some experiments, the asymmetry is so great that only three of the six atoms can be seen (a triangular array in Fig. 4a), in other cases all six atoms are observed with equal intensities (carbon hexagons in Fig. 4b).

There are several concepts of this asymmetry.

1. According to the theory of Tomanek *et al.*,^{15,30} asymmetry of the tunnelling current at low voltages is related to the difference in the local density of states, which, in the case of graphite, is determined by the interlayer interaction and the structural non-equivalence of the atomic positions. The calculations have shown³¹ that the maxima in the STM images correspond to the atoms in the sites B. According to this theory, the tunnelling current asymmetry should decrease with the increase in voltage, but should not be sensitive to its polarity. This was proven experimentally.^{15,30} For alkali metal intercalates, where carbon layers are arranged exactly one over the other and therefore all carbon atoms are equivalent, this theory predicts the absence of asymmetry.

In the STM image of alkali metal intercalates (Li, K, Rb, Cs), different lattices were revealed. Their periods are determined by the arrangement of the intercalated atoms (Fig. 5).^{23,31} This feature complicates the analysis of the carbon atom asymmetry.

The graphite lattice was successfully visualised for acceptor intercalation compounds.³² For example, different lattices were observed for MoCl₅-intercalated graphite within one image, namely, a trigonal lattice of maxima in non-intercalated areas and a honeycomb network of hexagons in the areas containing molybden pentachloride molecules in the first interlayer space (Fig. 6).³³

Within the framework of Tomanek's theory, the absence of the asymmetry can be explained by the shift of the top layer with

Figure 4. HOPG images with atomic resolution obtained by STM ($U = 20$ mV, $I = 1$ nA).¹⁴ Scanning frequency /Hz: 61 (a) and 122 (b).

respect to the lower layers during scanning. Indeed, the change in the character of image in the majority of cases was caused by passage to more ‘drastic’¹⁴ scanning conditions, viz. an increase in the tunnelling current or a decrease in the voltage between the tip and the sample. Moreover, in one experiment¹⁴ a change in the image type was observed with the change in the scanning speed in the constant height mode (see Fig. 4).

Evolution of the graphite surface image during scanning was described.³⁴ First scans have shown the asymmetry of maxima (A : B = 4 : 7). During the next scans, the image gradually changed until complete disappearance of asymmetry. However, on further measurements, the maxima became asymmetric again with a minimum A : B ratio. Probably, changes in the image during scanning are caused by sliding of the top layer relative to the lower layers. This sliding should occur easier in the area near to a defect, such as dislocation or vacancy. Since scanning covers a very small area, the probability of its position in the vicinity of the defect is rather low. This explains the rare appearance of the honeycomb structure.¹⁴

2. The main point of an alternative theory is that the A and B sites differ in their rigidities.³⁵ In other words, the perpendicular shift of a carbon atom in the site B requires more energy than similar shift of an atom in the site A; thus the site B is more ‘rigid’. Mechanical pressure of the STM tip on the graphite surface can result in the deformation of the layer and local changes in the

Figure 5. Images of the intercalate C_8K surface obtained by STM.³⁰ (a) constant-height mode (5×5 nm², $I = 3.5$ nA, $U = -20$ mV), a hexagonal 2×2 superlattice is visible; (b) constant-current mode (5×5 nm², $I = 5$ nA, $U = -50$ mV), a hexagonal $\sqrt{3} \times \sqrt{3}$ superlattice is visible; (c) constant-current mode (20×20 nm², $I = 10$ nA, $U = -19$ mV), a superlattice with the period of 3.3 nm is visible; (d) constant-height mode (5×5 nm², $I = 3.5$ nA, $U = -20$ mV), an orthorhombic superlattice with the period of 0.95 nm is visible.

Figure 6. Surface image of the HOPG intercalated with $MoCl_5$ obtained by STM in the constant-height mode.³³

tunnelling threshold. Therefore, in the case of repulsion forces the maxima on the image should correspond to the positions of the greatest rigidity. Because of the relatively large radii of the tip material atoms (W, Pt, Ir), which are comparable to the side of the carbon hexagon, it is necessary to take into account the interaction of probe not only with the carbon atom located directly below it, but also with the neighbouring atoms. In this case, the position of the maximum rigidity can be located in the hexagon centre and the maxima of the detected value in the image correspond to the holes.²²

Whereas the difference in the tunnelling current is determined in general by the ‘rigidity’ of positions, the appearance of all six atoms in the STM image with equal intensities can be explained by the selection of ‘soft’ scanning conditions where the surface

deformation is minimal. For example, a tiny particle of graphite can become attached to the tip, or the tip-to-sample distance is fairly large.²²

3. The asymmetry of carbon atoms is caused by the formation of charge density waves.³⁶ However, according to this theory, the asymmetry value should depend on the polarity of the tunnelling voltage, which contradicts the experimental data.

4. Tunnelling can occur through the local surface states. In this case, the change in the image depending on the variation of the tunnelling current by several tenth of nanoamperes can be explained by the presence of an adsorbate on the graphite surface.³⁷

Based on the theories 1 and 2, the difference in the intensities of maxima corresponding to the carbon atoms in A and B sites is determined by the influence of lower layers. According to theory 2, this influence is manifested in the deformation of the surface by the probe. Taking this into account, it can be predicted that in the case of scanning of a graphene (single graphite layer) the asymmetry should be absent. However, such a conclusion contradicts the available data³⁸ on the observation of only three of the six atoms in an STM image of a single graphene layer on the Pt(111) surface with atomic resolution. The isolated single graphene layer is extremely difficult to obtain,³⁹ therefore the graphene properties remain almost unknown so far. It is still possible that the STM image of the graphite surface is determined solely by the properties of one layer.

2. Atomic force microscopy

Graphite atomic structure images obtained in contact and dynamic modes of AFM differ substantially. In the contact mode, it is possible to detect only the graphite unit cell as a whole (Fig. 7), but at the same time, measurements can be carried out at ambient conditions.^{41–43} In the contact mode, the friction forces dominate, therefore this variant of AFM is an indispensable tool for nanotribology.

A different situation takes place in the case of dynamic AFM. This allows visualisation of separate atoms on the graphite surface. However, the atomic resolutions can be reached only under ultrahigh vacuum at helium temperatures and using perfect vibroisolation.^{44,45} This is due to the fact that the graphite surface is relatively inert in comparison with the ionic surfaces or to the surfaces with ‘dangling’ bonds. The forces applied to the tip near the graphite surface are of about ~ 100 pN.

Let us discuss the main mechanisms of formation of AFM images of the graphite surface obtained in the contact mode, *viz.* in the stick-slip motion of the tip^{43,46,47} and in scanning with a modified tip (when a graphite flake is attached to the tip).^{48–50} In a

number of theoretical works, the influence of probe geometry on the scanning process is considered.^{46,51–53}

Now let us analyse the reasons why the tip moves with sticking while it is in the contact with the graphite surface. According to published data,⁴⁶ we will consider the dependence of the potential energy of a single-atom tip – a single graphite layer system versus the tip position relative to the sample. The virtual scanning takes place in the constant height mode at -6 Å, therefore the normal component of the force acting between the surface and the tip is repulsive. In the scanning with the sufficiently rigid cantilever (the rigidity constant for this model was 1.3 N m^{-1}), the potential energy of the system has one minimum. In the case of a soft cantilever, an additional local minimum appears. Transition from the local to the global minimum is accompanied by a drastic change in the friction force. The tip sticks in hexagon centres and its move from one hexagon centre to another occurs in jumps.^{43,46} Continuous motion is possible in the case of more rigid cantilever or more ‘flat’ potential of the tip-to-surface interaction, but these conditions are not met in the experiment.^{40,46}

Calculations have shown⁵⁴ that a single-atom tip pressed against the graphite surface with a force of *ca.* ~ 1 nN bends it by 1 Å. The deformation extends only to the first three layers. Surface curvature disappears at a characteristic length of ~ 10 Å. The influence of a many-atomic tip should span the larger area of the graphite surface.⁵⁵ In some situations, the tip as a whole is attracted to the surface, but its topmost atom is in the area of repulsive force, thus causing plastic deformation of the graphite surface.⁵²

Measurements carried out in liquid media allow a decrease in the contribution of long-distance macroscopic forces acting between the peripheric atoms of the tip and the graphite surface. Presumably,⁵⁶ under such conditions one can obtain more stable images, although the contrast for the images obtained in the liquid is lower than for those obtained in vacuum (the difference in maximum heights is 0.39 and 0.6 Å, respectively).

Periodic changes in the friction forces during scanning can also be explained by modification of the tip as a result of sticking of a graphite flake to the tip. The friction force of ~ 1 nN, which appears at the shift of a modified probe to the new equilibrium position, is due to the interaction of the sample surface with the cluster (flake) consisting of *ca.* ~ 100 carbon atoms. The radius of the contact area does not exceed 1 nm.⁵⁰ When moved along the direction $\langle 12\bar{3}0 \rangle$, the graphite flake moves rectilinearly together with the probe, while in the scanning in other directions, the tip with the particle moves in a zigzag manner⁵⁰ or the flake is reoriented according to the direction of the tip rectilinear motion.⁴⁹ In these cases, from the AFM images it is possible to determine whether the tip has been modified.⁵⁰ For example, an AFM image of the graphite surface in the widely cited work by Mate *et al.*⁴¹ should be classified as the one obtained with modified cantilever.

In the dynamic mode, features of the AFM image are determined by the character of forces acting between the probe and the sample.⁵¹ An AFM image of the graphite surface obtained in the dynamic mode while detecting the repulsion forces is presented in Fig. 8. Two forces applied to the probe from the two adjacent carbon atoms are measured to be 248 and 250 pN. Obviously, the structural non-equivalence of the carbon atoms in graphite is manifested in the atomic force microscopy as well.

A substantial asymmetry between the atoms can be seen in the graphite surface image obtained by detection of the attractive forces.⁵⁸ According to the theory by Chen,⁵⁹ the attractive force acting on the tip should unequivocally determine the tunnelling current. In this case, the attraction force is a minimum for the tip position above the hexagon centre, and hence such a position corresponds to the maximum in the AFM image.⁶⁰ Atoms in the site A give weak local maxima, while atoms in the site B correspond to minima. Thus, the contrast in AFM images of graphite surface is inverted with respect to the STM images.

Figure 7. Image of the HOPG surface obtained by AFM in the contact mode with the friction force detection.⁴⁰ The normal force component is 40 nN, scanning frequency is 30 Hz.

Figure 8. Graphite surface image obtained by AFM in the dynamic mode.⁵⁷ Probe oscillation amplitude is 300 pm, scanning speed is 0.2 nm s⁻¹; white and black circles denote carbon atoms in A and B sites, respectively.

For the verification of Chen's theory, scanning was performed in the constant-height mode. The tunnelling current, the force acting on the tip and the dissipated energy were detected simultaneously (Fig. 9).¹⁰ It was expected that the maxima of the tunnelling current should correspond to the carbon atoms in the B sites, while the dissipated energy should be maximum upon the holes. It was established that in the case of repulsive forces (see Fig. 9c,†f) the asymmetry is a minimum, the maximum of the force corresponds to the atoms in sites A and the minimum corresponds to the holes. In the case of scanning in the attractive forces zone (see Fig. 9a,d), the force depended on the voltage applied to the tip. At negative bias voltage of -60 mV, images based on the measurement of tunnelling current and the attractive force were inverted, in qualitative accordance with the Chen theory. However, no inversion occurred in the case of scanning at positive potential of +160 mV (see Fig. 9a).

IV. Defects on the graphite surface

Probe methods allow studying of not only the composition of defects and their electronic structures, but also their reactivities. By means of scanning tunnelling microscopy, it is possible to determine the electron energy spectra or to establish the nature of an admixture atom.⁵⁹

First let us consider point defects, *i.e.*, vacancies and admixture atoms. The concentration of point defects on the HOPG surface of different quality under normal conditions is 0.1–20 μm⁻² (Refs 61 and 62). Defects appear in the STM images as bright spots (see Fig. 3).^{19,20} When the tip approaches the surface, the defects become invisible, as the volume states of graphite make the main contribution to the tunnelling process under these conditions. Judging by the dependence of the defect height from the tip-to-sample distance, one can determine the type of the incorporated atom.^{19,20}

In the majority of works, the point defects for their subsequent study are created artificially, usually by means of graphite surface bombardment with different ions.^{17,63–66} Such a process can lead to the vacancy formation on the surface layer, as well as to the implantation of ions. Local density of states at the vicinity of the vacancy increases, making them visible in STM images, but not in AFM images.¹⁷ Structure relaxation around the point defect can lead to the formation of new bonds, including those between atoms from adjacent layers.⁶⁷ But changes in the surface topography are too subtle to be detected by AFM working in the

Figure 9. HOPG surface images obtained in the constant-height mode.¹⁰ The tunnelling current (pA) was measured for the images to the left; a normalised shift of the resonance frequency (fN m^{1/2}) in the middle, and the dissipated energy (eV) to the right.

U /mV: 160 (a–c), -60 (d–f); z /pm: -100 (a, d), -350 (b, e), -750 (c, f).

contact mode. The increase in the charge density occurring around the vacancy¹⁷ explains the increased reactivity of the defect area.^{68–70}

Ion implantation leads to the formation of dome-shaped structures⁶⁵ and craters on the surface.⁶³ After heating of the ion-implanted samples at 500 °C, the height of the defect area

† The insert in Fig. 9c on the left shows a higher harmonic image.

Figure 10. Atomic resolution images of the HOPG surface with implanted tungsten ions obtained by STM.⁶³ Switch of the polarity of the tunnelling voltage did not reveal any new features in the image.

increases, which can be explained by the migration of the implanted ions closer to the surface.⁶³

In STM images of graphite around point defects, as well as at step edges, the formation of $\sqrt{3} \times \sqrt{3} R 30^\circ$ structure was observed (Fig. 10). This is not due to surface reconstruction,^{71,72} but can be explained by the Friedel oscillations.⁷³ Analysis of their symmetry allows one to establish the nature of point defects and the adsorbate state.^{19,20} For example, with account of the enhancement of the Friedel oscillation amplitude, the formation of covalent C–F bond on the graphite surface was concluded.⁷⁴

Possible line defects in cleaved HOPG include steps,⁷⁵ domain borders⁷⁶ and dislocations. The steps could be of two forms, *viz.* zigzag-like and chair-like. For zigzag-like steps, the formation of edge states was predicted.⁷⁵ According to the data from scanning tunnelling microscopy studies, the energy of such states exceeds the Fermi energy by 0.02–0.15 eV.⁷⁷ STM images of zigzag-like steps show bright dots at the points of broken bonds.^{78,79}

The activation energy of graphite oxidation at single-layer steps is somewhat higher than that at multilayer ones.⁸⁰ This fact can be explained by the bend of single-layer steps upon cleavage or under the pressure of the tip.⁸¹ The stability of such structures has been analysed.⁸²

The domain borders in STM images of HOPG are visible as wide helical structures.^{76,83} The domain border for two crystallites with disorientation angle of 39° is shown in Fig. 11 *a*. A model proposed for this structure includes five- and seven-membered carbon rings. (Fig. 11 *b*).

The 2D defects observed in STM images of a HOPG surface include different superlattices. Hexagonal superlattices arising from the disorientation of the topmost graphite layers are described in the review⁸⁴ in great detail (Fig. 12), so we will just briefly concern this problem. Such superlattices are observed around dislocations^{85,86} or can occur in the rotation of the

Figure 11. Image of the domain border obtained by STM (*a*), and its model (*b*).⁸³

Figure 12. Images of superlattices on the HOPG surface (*a*) and superstructure area (*b*) obtained by STM.⁸⁵

(*a*): $787 \times 787 \text{ \AA}^2$, $U = 480 \text{ mV}$, $I = 0.6 \text{ nA}$, the superstructure area is embraced by clear borders. The distance between the borders is $440 \text{ \AA}$, the dimension of the area $> 1 \text{ nm}$;
(*b*): $104 \times 104 \text{ \AA}^2$, $U = 210 \text{ mV}$, $I = 0.6 \text{ nA}$, superlattice period is $40 \pm 1 \text{ \AA}$ and the angle of its rotation with respect to the graphite lattice is $28 \pm 1^\circ$.

topmost graphite layer.^{85,87} Superlattices with periods from 1.7 up to 44 nm and height from 0.5 to 20 Å have been visualised. The reason for appearance of such defects is analogous to the Moire patterns in optics, which appear upon rotation of one periodic structure relative to another.^{88,89} Due to the disturbance of layer packing, the asymmetry of maxima corresponding to the atoms in the A and B sites can differ within one superlattice unit cell.⁹⁰ Defects in the graphite lattice can lead to the vacancy formation in the superlattice.⁹¹

Lattices with different periods can be created on the surface of HOPG.⁸⁴ Such lattices can be applied in nanotechnology for the production of templates. For example, cobalt particles (1–5 nm) are adsorbed mainly on the nodes of the superlattice with the period of 3.8 nm.⁹²

The appearance of periodic structures in STM images is not necessarily caused by the layer displacement. A superlattice with changing period was observed on the nanometer-size graphite sheet consisting of two layers.⁹³ The placement of a small graphite particle on the surface of the sheet resulted in the change in the lattice (Fig. 13). The appearance of this superstructure can be explained by the dimensional quantisation in a two-dimensional system. The change in the lattice parameter is due to the presence of a potential gradient in the system, which in turn is caused by the inclination of the sheet with respect to the bulk graphite. Dimensional quantisation was revealed in studies of etching pits with

Figure 13. Images of superstructures on the nanometre-size graphite sheet obtained by STM before (*a*) and after (*b*) a graphite particle was placed on the sheet.⁹³

(*a*): $U = 0.2 \text{ B}$, $I = 0.7 \text{ nA}$ ($400 \times 250 \text{ nm}^2$); layer height measured by STM image is $\sim 0.8 \text{ nm}$ in the top corner and $\sim 0.9 \text{ nm}$ for the bottom.

small diameter (< 10 nm) by scanning tunnelling microscopy.⁹⁴ The spectra of the pits located at a distance of 1–2 nm from each other have shown the splitting of the respective energy levels.

Finally, let us discuss superlattices arising due to the dislocation networks near the graphite surface. Most often, the dislocation networks observed in the STM images consist of triangular areas with sides of 100–300 nm.^{95–98} Examination of triangle borders in the images with atomic resolution revealed a distortion of the hexagonal graphite lattice.⁹⁶ The surface corrugation increases on the borders.

On variation of the STM scanning parameters, images of the dislocation networks undergo certain changes. An increase in the tunnelling voltage leads to weakening of the contrast between the adjacent triangles.^{96,98} As the interlayer distances in hexagonal and rhombohedral graphite are similar and the Burgers vector of the network-forming dislocation lies in the [0001] plane, the contrast revealed in the STM images between the domains is not due to the surface topography. The presence of the step within the dislocation network area does not lead to its disruption or distortion. However the contrast between the perfect areas and the stacking fault areas changes (and can even be inverted) upon motion over the step.⁹⁸ For the explanation of this effect, a model has been proposed considering propagation of the electron wave along the graphite *c* axis together with the presence of defect areas below the surface. According to the proposed model, the STM scanning should reveal not only dislocations with the Burgers vector perpendicular to the base plane (screw dislocations^{85,86} and dislocation loops⁹⁹), but also other types of dislocations.

Intensive mechanical pressure by the tip on the surface causes motion of the dislocations. Data are available indicating that the superlattices generated by the rotation of the topmost layer by less than 0.5° with respect to the substrate can transform to dislocation networks under the influence of the tip.⁹⁵ A triangular net presented in the STM image (Fig. 14*a*) has transformed to the star-like structure (Fig. 14*b*) after the change in the tunnelling voltage by 0.14 V.

Figure 14. Dislocation network on the graphite surface (*a*) and a star-like structure (*b*).⁹⁶

(*a*): $U = 0.24$ V, $I = 0.37$ nA, scanning frequency is 26 Hz;

(*b*): $U = 0.1$ V, $I = 2.4$ nA, scanning frequency is 26 Hz.

V. Conclusion

Though the first STM image of atoms of the graphite surface was observed some 20 years ago, a consistent theory explaining why in some experiments only three atoms of the hexagonal cell are observed, and sometimes all six of them, has yet to be built. The existing theories on the nature of this effect still do not have the necessary experimental support.

Despite the obvious progress in the development of atomic force microscopy in the last 10 years, there are still only few AFM images of the defect areas of graphite. This is due to substantial difficulties of registration of extremely weak forces acting on the tip.

Methods of probe microscopy allow visualisation of the defects. However, the mechanisms of images formation sometimes remain obscure, for example, in the case of dislocations in the graphite. By the probe methods, the reactivities of different defect areas on the graphite surface were determined. With the use of STM and AFM microscopy, one can find preferable sorption sites for nanoparticles, as well as the state of adsorbates on the graphite surface.

Modelling of the dynamic state of disperse systems

N B Uriev, I V Kuchin

Contents

I. Introduction	31
II. Fundamentals of the flow theory of disperse systems	32
III. Computer simulation of disperse systems	44
IV. Conclusion	53

Abstract. The review covers main theories and models of shear flow of suspensions and results of computer simulation of the properties of disperse systems under dynamic conditions. Emphasis is given to the state of aggregated and non-aggregated suspensions. The microstructure of disperse systems is demonstrated to play a crucial role in their bulk rheological properties. The causes and conditions of the appearance of macroscopic inhomogeneity, *i.e.*, discontinuity in highly concentrated systems are analysed and the specific features of microrheology of low-concentrated fractal colloidal gels are reviewed. The review describes the possibilities of the use of surfactants and vibration treatment for controlling the rheological properties of dispersions. The advantages and disadvantages of computer simulation of disperse systems are discussed and examples of application of these methods to the description of the dynamic state of suspensions are given. The bibliography includes 147 references.

I. Introduction

Many natural phenomena and various chemical engineering processes involve disperse systems under non-equilibrium conditions. Hence, both theoretical and applied studies of these systems are of considerable interest. In the present review, different aspects of the behaviour of dispersions under dynamic conditions are considered in terms of physicochemical dynamics of disperse systems.^{1–3} This new field supplements and extends the traditional approach to investigation of the properties of such systems predominantly under static conditions.

The physicochemical dynamics of disperse systems deals with dynamic processes taking place in ensembles of dispersed-phase particles held together by dispersion forces to form three-dimensional structural networks. Besides, it is concerned with the mechanisms of destruction of such systems under dynamic force conditions giving rise to particle aggregates (their evolution and interactions with each other and with a dispersion medium) and the reverse processes (structure formation under these conditions).¹ These problems are directly related to physicochemical hydrodynamics, including hydrodynamics of capillary systems.⁴

The ultimate aim of research in the area of physicochemical dynamics of disperse systems is to substantiate ways and procedures for achieving the maximum fluidity, which is necessary for intensification of various chemical engineering processes.¹ The control of the properties of suspensions, *viz.*, disperse systems, which are widely used in all fields of human activity, is of particular importance.

Theoretical analysis in physicochemical dynamics is based primarily on the construction of microrheological models that describe processes of interactions between particles, microstructure formation, microstructure transformations and degradation under external forces. These microprocesses determine the structural-rheological properties of suspensions characterising their response to mechanical forces.

Theoretical views of the features of microprocesses provide the basis for developing new procedures for controlling the properties of disperse systems under dynamic conditions and improving the available methods. Some rheological theories of suspensions and powders were analysed in the monograph.⁵

The continuing progress in computer technology offers opportunities to solve problems (in particular, to describe a microstructure of a medium), which are impossible to solve by analytical methods. Computer simulation occupies an intermediate place between theoretical and experimental studies. Computer experiments are based on theoretical models and are performed by numerical calculations. The models can become more complicated (to achieve better correspondence with experimental conditions) with progress in computer technology. Therefore, on the one hand, areas of theoretical research are expanded, and, on the other hand, it becomes possible to perform numerous repeated expensive experiments. Consequently, computer simulation is an important bridge between the theory and experiment.⁶

The efficiency of application of computer simulation to the dynamics of disperse systems is determined by several factors. First, theoretical models are often based on phenomenological equations, which describe phenomena at the macrolevel and ignore many microscopic features of the system. As a rule, this problem can be solved by numerical methods (in particular, a detailed view of the dynamics of structuring and microstructure transformations can be obtained). Second, computer simulation can be used as a rather efficient procedure for validating analytical theories of structures and properties of disperse systems. Third, computer simulation allows one to examine the behaviour of systems under conditions that are difficult to observe in practice (high flow rates, vibration treatment, *etc.*). In addition, this method provides information on parameters that are impossible to measure (the number of coagulation contacts between particles and the rate at which they are broken, shear stresses separately in

the liquid and solid phases, *etc.*). In some cases, the difficulties can be associated with hazardous experimental conditions and high cost of experiments. Because of this, computer simulation is a convenient and efficient tool for investigating the structures and properties of disperse systems. However, data obtained by this method should be compared with theoretical and experimental estimates because the results of numerical calculations may contain uncertainty due to specific features of the system under study and limitations of a particular simulation method.

The present review covers analytical and computer models used for describing the behaviour of an important class of disperse systems, *viz.*, suspensions, under dynamic conditions and predicting their structural-rheological properties.

II. Fundamentals of the flow theory of disperse systems

1. Non-structured disperse systems

The dependence of the effective suspension viscosity on the concentration of the solid phase is most simply described by the Einstein equation

$$\eta = \eta_0 \left(1 + \frac{5}{2} \varphi \right), \quad (1)$$

where η_0 is the viscosity of a pure liquid (dispersion medium) and φ is the concentration of the solid phase.

This equation is valid for highly dilute non-structured suspensions where interactions between particles can be ignored. The equation reflects an increase in the suspension viscosity due to hydrodynamic effects caused by solid particles introduced into the flow and takes into account the energy dissipation for rotation of particles in a shear flow.

If the concentration of solid particles increases so that interactions between the particles become significant, Eqn (1) provides poor agreement with experimental data. Hydrodynamic interactions can be taken into account, to some extent, by introducing higher-order terms with respect to φ (φ^2 , φ^3 , *etc.*). If only pair interactions are considered,⁷ the dependence of the suspension viscosity on the concentration of the solid phase can be described by the equation:

$$\eta = \eta_0 \left(1 + \frac{5}{2} \varphi + a\varphi^2 \right). \quad (2)$$

The coefficient a is a function of the concentration φ and the particle sizes and coordinates. This coefficient is calculated by complex statistical methods. The following dependence $a(\varphi)$ was obtained⁹ with the use of the Percus–Yevick equation:⁸

φ	0.0	0.1	0.2	0.3	0.4	0.5	0.6
a	5.00	5.38	5.81	6.31	6.91	7.65	8.66

The results of calculations according to Eqn (2) taking into consideration the dependence $a(\varphi)$ are in satisfactory agreement with experimental data at $\varphi \leq 0.25$. At higher concentrations, calculations by Eqn (2) underestimate the viscosity η , which indicates that it is necessary to take into account perturbations of the velocity fields about the particle caused by the influence of adjacent particles. Evidently, these calculations present considerable mathematical difficulties. However, there is a number of models and approximate methods that enable one to find the dependence $\eta(\varphi)$ up to the highest concentrations.

Of semiphenomenological equations describing the dependence of the suspension viscosity of spherical particles on their concentration throughout the range of φ , the Mooney equation¹⁰

$$\frac{\eta}{\eta_0} = \exp \left(\frac{\alpha \varphi}{1 - \varphi/\varphi_m} \right) \quad (3)$$

and the Krieger–Dougherty equation^{11,12}

$$\frac{\eta}{\eta_0} = \left(1 - \frac{\varphi}{\varphi_m} \right)^{-\alpha \varphi_m} \quad (4)$$

have gained wide acceptance. Here φ_m can be identified with the volume fraction of closely-packed particles (random packings of particles with φ_m varying from 0.59 to 0.65 are most typical of suspensions). The coefficient α is chosen such as to provide the agreement of Eqns (3) and (4) with the Einstein equation ($\alpha = 2.5$).

The results of calculations according to Eqn (4) are in somewhat better agreement with experimental data as compared to the Mooney equation. As mentioned above, the common drawback of these equations is their semiphenomenological character. The derivation of these equations was not based on theoretically supported microrheological views of the character of flow of concentrated disperse systems. In this respect, a more correct approach is based on the use of various cellular models that have been proposed for the first time in the publications.^{13–15} Within these models, it is generally assumed that the cell consists of a rigid spherical shell whose centre is occupied by the spherical particle under consideration. The velocity of the liquid within a circular layer between the particle and the sphere is estimated by the Stokes equation¹⁶ taking into account certain boundary conditions. With a knowledge of the velocities and mechanical stresses at the cell boundary, it is possible to calculate the energy dissipated in the cell containing a particle (E_1) and without this particle (E_0). The suspension viscosity is determined from the equation¹⁴

$$\frac{\eta}{\eta_0} = \frac{E_1}{E_0}. \quad (5)$$

One of the most perfect cellular models, which is sometimes called the free surface model, was proposed by Happel.^{14,15} Within this model, the viscosity is calculated according to the equation

$$\frac{\eta}{\eta_0} = 1 + 5.5\varphi \frac{4\varphi^{7/3} + 10 - (84/11)\varphi^{2/3}}{10(1 - \varphi^{10/3}) - 25\varphi(1 - \varphi^{4/3})}. \quad (6)$$

A substantial drawback of cellular models is that the cell shape is chosen arbitrarily. A spherical cell is simple for analysis. However, the results obtained with the use of this model at high concentrations of the solid phase are in poor agreement with experimental data. This is associated with the fact that with $\varphi \rightarrow \varphi_m$ the distance between the particles decreases to an extent that it becomes necessary to consider the liquid flow in microchannels between the particle surfaces.

This model has been considered for the first time by Frankel and Acrivos.¹⁷ This model is sometimes called the lubrication model because it is based on the lubrication theory. The model treats a test particle surrounded by z adjacent particles equidistant from the test particle. The cell consists of a sphere with a radius $r + h/2$ (r is the radius of the test particle and h is the distance between the particle surfaces). The test particle lies in the centre of the cell coinciding with the origin of coordinates. At $z = 6$ (which corresponds to a random close packing¹⁸), the centres of the adjacent particles lie on the Cartesian axes (x, y, z) (Fig. 1). It is hypothesised that an elongational flow occurs in suspensions. The hydrodynamic resistance to motion of each adjacent particle relative to the central particle is calculated according to the equations of the lubrication theory.⁷ It is assumed that the energy dissipation velocity is determined by both the perturbation of the velocity field with a single sphere and the sum of flows in microchannels between particle pairs. This model gives quantitative results for $\varphi \rightarrow \varphi_m$ when $h/2r \rightarrow 0$. The following equation for the suspension viscosity was derived from Eqn (5):¹⁷

Figure 1. Arrangement of particles in the lubrication model. The shaded particle is surrounded by 6 particles.

$$\frac{\eta}{\eta_0} = \frac{3z}{16} \frac{1}{(\varphi_m/\varphi)^{1/3} - 1}. \quad (7)$$

Frankel–Acrivos’s model was criticised many times. In particular, it was noted¹⁹ that it is incorrect to extend the results, which were obtained for an elongational flow under the assumption of a special arrangement of particles, to a shear flow. It was demonstrated²⁰ that the application of the lubrication theory to the particle motion performed by parallel layers in a shear flow gives only the logarithmic dependence of the suspension viscosity on $2r/h$ when $h \rightarrow 0$, whereas experiments showed that η more sharply increases with $\varphi \rightarrow \varphi_m$. The inclusion of other factors influencing the viscosity (for example, rotation of adjacent particles) does not change the logarithmic character of the dependence $\eta(\varphi)$. This led to the conclusion⁵ that particles of a suspension in a shear flow move chaotically rather than are arranged in layers. In this case, the lubrication model becomes more correct, because particles inevitably approach each other during chaotic motion, the liquid serving as a lubricant between the particle surfaces. Assuming that particles move chaotically, the equation analogous to Eqn (7) was derived²¹ with the use of the dense gas kinetic theory.

Another way of describing the configuration of particles surrounding the test particle is based on an effective medium model.²² Within this model, the configuration of particles is considered as a particular effective homogeneous medium containing the test particle. The viscosity of the medium η^* is equal to the viscosity of a pure liquid η_0 on the surface of the test particle, increases with increasing distance from this surface and is identified with the viscosity of the suspension as a whole at infinity

$$\eta^* = \eta_0 + (\eta - \eta_0)\psi(x, \varphi), \quad (8)$$

where $\psi(x, \varphi)$ is a function of the particle coordinates and concentration.

The field of velocity perturbations (u) induced by the test particle in the medium is determined by the Stokes equations,¹⁶ which are written for this model taking into account the dependence $\eta^*(x)$

$$\nabla p = \nabla(\eta^* \nabla u), \quad \nabla u = 0$$

The simplest assumption about the change in η^* can be made by identifying the effective medium with a suspension as a whole, *i.e.*, taking $\psi = 1$. This assumption,²³ which corresponds to the mean-field model widely accepted in physics, gives the following equation for the average stress tensor:

$$\langle \hat{\sigma} \rangle = 2\hat{E}\eta_0 + 5\varphi\eta\hat{E}, \quad (9)$$

where $\hat{E}$ is the strain rate tensor.

From Eqn (9), the following equation for the relative suspension viscosity was derived:^{23–25}

$$\frac{\eta}{\eta_0} = \frac{1}{1 - (5/2)\varphi}. \quad (10)$$

At small φ , this equation turns into Eqn (2). At high concentrations, the viscosities calculated according to Eqn (10) are overestimated. Evidently, this is associated with an arbitrary choice of the function $\psi(x, \varphi)$. To obtain more accurate results, a more realistic function ψ should be used in the effective medium model. However, in this case, it is impossible to derive analytical equations for the suspension viscosity due to mathematical difficulties.

The results of calculations according to Eqns (4), (6), (7) and (10) and experimental dependences of the viscosity of poly(methyl methacrylate) (PMMA) in decalin are presented in Fig. 2. A comparison of the curves shows that the results obtained with the use of the effective medium model and the free surface model agree with experimental data at low concentrations ($\varphi < 0.4$), whereas the results obtained with the use of the lubrication model are in agreement with experimental data at high concentrations ($\varphi > 0.4$). In the calculations, φ_m was taken to be 0.61, which corresponds to conditions of many experiments. Detailed analysis of the possibilities of using the above-considered models for the description of the viscosity of non-aggregated and aggregated suspensions was performed in the study.²⁶

Figure 2. The relative suspension viscosity vs. the volume fraction of particles.²⁶

Curves (1–4) were calculated according to Eqns (4), (6), (7 at $z = 6$) and (10), respectively; the points correspond to the experimental data²⁷ for PMMA particles ($d = 0.5 \mu\text{m}$) in decalin (the viscosity for $\dot{\epsilon} \rightarrow \infty$).

The influence of Brownian motion of particles on the viscosity of suspensions formed by these particles can be taken into consideration with the use of the Peclet number

$$\text{Pe} = \frac{d^2 \dot{\epsilon}}{D},$$

where d is the particle size, $\dot{\epsilon}$ is the shear rate and D is the particle diffusion coefficient.

The suspension viscosity can be represented as a function of the only parameter, *viz.*, the Peclet number²⁸

$$\frac{\eta - \eta_\infty}{\eta_1 - \eta_\infty} = \frac{1}{1 + \text{Pe}/\text{Pe}_c}, \quad (11)$$

where η_1 and η_∞ are the suspension viscosities at $\text{Pe} \ll \text{Pe}_c$ and $\text{Pe} \gg \text{Pe}_c$, respectively, and $\text{Pe}_c \approx 1$ is the critical value of the Peclet number.

Brownian suspensions of spherical particles were studied experimentally in broad ranges of particle concentrations and sizes.^{29–31} The results of these studies agree well with the results of calculations according to Eqn (11), Pe_c being dependent on φ . It

was found that $Pe_c = 1.5$ at $\varphi = 0.2$ and $Pe_c \rightarrow 0$ at $\varphi \rightarrow \varphi_m = 0.6$, *i.e.*, the influence of the Brownian motion on the suspension viscosity decreases as the packing of particles approaches the close-packing density. At the same time, as was demonstrated in the studies,^{9,32} the Brownian motion in dilute suspensions, for which the function $\eta(\varphi)$ can be expanded in a power series of φ , has an effect only on the quadratic term accounting for particle-pair interactions. The linear term in Eqn (2) is independent of the Peclet number.

Therefore, the Brownian motion influences most substantially the rheological properties of suspensions at a concentration $\varphi \approx 0.1-0.2$. However, this conclusion is true only for suspensions composed of strictly spherical particles. If the Brownian motion is taken into account in the case of anisometric particles, it is the linear term in Eqn (2) that becomes dependent on the Peclet number due to reorientation of the particles in a flow.

The development of a unified two-phase model for suspensions and powders^{5,21} has assisted in developing the rheological theory of disperse systems. The use of this model made it possible to derive the general equation, which is valid at low and high viscosities of a medium for powders and suspensions, respectively. This model was based on the lubrication model,¹⁷ which treats the test particle moving among z surrounding stationary particles. The following equation for the viscosity of a system of rigid spheres in a viscous medium was derived with the use of the Eyring equation of state:³³

$$\eta \approx 0.16\varphi_m\alpha \frac{\rho dv}{[(\varphi_m/\varphi)^{1/3} - 1][1 - \exp(-v/v_c)]}, \quad (12)$$

where α is the coefficient that depends on the parameters of particle collisions, ρ is the particle density, v is the velocity at which particles approach each other and $v_c = (9/4)z\eta_0/\rho d$ is the value identified with the minimum velocity v , which must be imparted to particles in order that they overcome the hydrodynamic resistance on collisions.

For two limiting flow types, the following equations were derived for the viscosity of a system when $\varphi \rightarrow \varphi_m$:⁵

$$\eta \approx \frac{c_1\eta_0}{(\varphi_m/\varphi)^{1/3} - 1} \text{ at } v \ll v_c, \quad (13)$$

$$\eta \approx \frac{c_2\rho dv}{(\varphi_m/\varphi)^{1/3} - 1} \text{ at } v \gg v_c. \quad (14)$$

Here $c_1 \approx 0.1$ and $c_2 \approx 0.05$.

For particle collisions, the hydrodynamic factor plays the determining role in the former case [Eqn (13)], *i.e.*, the viscosity of the system is determined by the energy dissipation in a flow in the space between the particles. This is typical of suspensions. Equation (14) is valid for low-viscosity media, where the viscosity is determined by the energy dissipation due to inelasticity of particle collisions, which is characteristic of powders. The advantage of Eqn (12) is that it is universal and describes both limiting flow types. Equation (13) corresponding to suspensions is equivalent to Eqn (7), which was derived in another way, by comparing the energy dissipated in a unit volume of a suspension with the energy supplied to the system upon its shear deformation. The drawbacks of Eqns (12)–(14) are that they are based on two-particle collisions, which, in the case of concentrated systems, is unlikely to be justified.

2. Structured disperse systems

The above-considered rheological models describe the viscosity of non-structured systems. However, it is known that the structure formation in disperse systems leads to a drastic change in their rheological properties.³⁴ The rheological properties of structured disperse systems under conditions of their continuous shear deformation are most often described with the use of the overall rheological flow curve, *e.g.*, the plot of the effective shear viscosity

vs. the shear rate $\dot{\epsilon}$ (or the shear stress σ) on condition that destruction is isotropic. The overall flow curve with a viscosity drop of up to 8–10 orders of magnitude was described for the first time in the study.³⁵ In this study, the authors introduced the concepts of ‘the highest viscosity of a virtually non-destroyed structure’ corresponding to the upper plateau in the flow curve and ‘the lowest Newtonian’ viscosity of a maximum destroyed structure. More recently, it has been demonstrated^{1–3} that the true maximum destruction can be achieved only under shear deformation used along with other external mechanical forces (for example, vibration), as well as by lyophilisation of the particle surface with surfactants.

To estimate the fluidity of structured systems, certain assumptions about the character of structuring should be made. There are two types of such assumptions and the corresponding structural models of disperse systems. Models of one type treat particles that are held together to form a continuous structure. Its homogeneity is retained, under deformation, at distances much larger than the particle diameter. Parameters having the dimensionality of length are not used for the description of the structure. In another type of models, the structures are composed of particle aggregates. The parameter characterising inhomogeneity of the structure is generally identified with the aggregate size.⁵

Thus, simulation is the main method of theoretical studies of structured systems. This is associated with the lack of experimental methods that would allow one to study in-depth the structures of disperse systems and their changes in flow. The available methods have been insufficiently developed. Only rheological experiments provide reliable data on the structures, the construction of alternative microrheological models being a necessary step in these investigations.

In the study,²¹ the rheological properties of a system were related to its structural characteristics, such as the diameter of spherical aggregates and the distance between their centres. It was assumed that deaggregation in flow occurs due to detachment of particles from the aggregate surface until an equilibrium state is established at a given shear rate $\dot{\epsilon}$, at which further detachment of particles becomes impossible. The space between the aggregates is filled with a suspension of particles detached from the aggregate surface. The viscosity of this suspension is equal to that of completely deaggregated system of spheres at the same concentration, *i.e.*, to the viscosity of this system after its complete destruction.

Under the assumptions used for deriving Eqns (13) and (14), the following equation was obtained²¹ for the dependence of the viscosity of a weakly aggregated suspension on the shear rate:

$$\frac{\eta}{\eta_\infty} = \left(\frac{\dot{\epsilon}_c}{\dot{\epsilon}} \right)^{1/2}, \quad (15)$$

where η_∞ is the viscosity when $\dot{\epsilon} \rightarrow \infty$, $\dot{\epsilon}_c = 6.4F/(\eta_\infty d^2) = 6.4k'/(\eta_\infty d)$ is the critical shear rate $\dot{\epsilon}$ corresponding to the complete deaggregation, F is the strength of bonding between the particles and k' is the coefficient that depends on the nature of the surface forces.

Equation (15) can be used at shear rates $\dot{\epsilon}_c(L_1/L_2)^2 \ll \dot{\epsilon} \ll \dot{\epsilon}_c$, where L_1 is the average distance between the particles and L_2 is the average distance between the centres of aggregates. At $\dot{\epsilon} < \dot{\epsilon}_c(L_1/L_2)^2$, the distance between the aggregate surfaces is comparable to the particle diameter and this equation is inapplicable. Equation (15) does not include the aggregate diameter and contains only parameters having a precise physical meaning, such as the viscosity of the completely destructured system η_∞ , which can be interpreted as the minimum viscosity at high $\dot{\epsilon}$ until dilatancy appears, and the coefficient k' . The latter is expressed in terms of the Hamaker constant A (see Refs 36 and 37) and the distance between the particle surfaces. Hence, with a knowledge of A , it is possible to determine the shape of the rheological curve. If the constant A is unknown, the order of A in this system can be estimated by measuring η_∞ and $\dot{\epsilon}_c$.

Figure 3. Calculated curve and experimental data (points) for a PMMA suspension in decalin ($\varphi = 60.1\%$, $d = 0.47 \mu\text{m}$, $\eta_0 = 2.8 \text{ mPa s}$ at $T = 293 \text{ K}$).²¹

In spite of a good agreement between the experimental data and the results of calculations according to Eqn (15) for a monodisperse suspension of PMMA particles in decalin (Fig. 3), this equation is of limited application. Actually, the dependence of the suspension viscosity on the shear rate

$$\eta \sim \dot{\epsilon}^{-1/2}$$

describes well the region of intermediate gradients for a model system considered in the study.²¹ However, for many other systems, even if this dependence at intermediate gradients is searched in the form

$$\eta \sim \dot{\epsilon}^{-n},$$

n can vary from $1/2$ to 1 .³⁸ In addition, at small $\dot{\epsilon}$ the dependence $\eta(\dot{\epsilon})$ generally becomes sharper, including that for the model system described in the study.²¹ The way of generalising Eqn (15), according to which n can assume the values $> 1/2$, and the relationship between n and the structural characteristics were discussed.³⁸ The authors believed that aggregates can form higher-order structures, *viz.*, superaggregates. The motion of superaggregates is treated in a non-aggregated suspension serving as a non-Newtonian medium, and the viscosity is determined according to Eqn (15). Under these assumptions, the following equation was obtained for the viscosity of strongly aggregated suspensions:

$$\frac{\eta}{\eta_\infty} = B\left(\frac{3k+1}{2k}, \frac{3-k}{2k}\right) \frac{3 \times 2^{1/k} (2+k)^{1/k}}{4} \times \left[\frac{p \dot{\epsilon}_c^{2(k+1)/(3-k)}}{(2+k)^{1/k} 2^{1/k} \eta_\infty \dot{\epsilon}^{(k+1)/(3-k)}} \times \frac{1}{B((k+1)/2k, (3+k)/2k)} \right]^{(3-k)/(3+k)}. \quad (16)$$

Here $B(\dots, \dots)$ is the β function, $k = 1/(1-n)$ and p is the strength of the superaggregates.

In particular, at $n = 0$ and $k = 1$, Eqn (16) can be represented as Eqn (15).

At concentrations $\varphi < 60\%$, the rheological curves, which were constructed with the use of the notions of the aggregation mechanism, agree well with experimental data throughout the range in which the shear stress σ was varied (Fig. 4). However, at $\varphi > 60\%$ and low σ , a substantial deviation from this dependence was observed, and the curve has a plateau, which can be attributed to discontinuity of structure. This phenomenon, its possible manifestations and factors responsible for its occurrence both in well-characterised disperse systems and systems formed by poly-dispersed (in some cases, anisometric) particles of dispersed phases in liquid media were analysed in-depth.^{39,40} The conditions

Figure 4. Effective viscosity η vs. the shear stress for a PMMA suspension in decalin at $\varphi = 60.1$ (1) and 59.5% (2).³⁸

determining the possibility of discontinuities under deformation of concentrated disperse systems were formulated in the study.⁴¹

In real systems with a non-uniform packing of particles in a quasi-crystal lattice, accumulations of vacancies, *i.e.*, cavities free from dispersed particles, are present. As in the crystalline substances, these cavities can be transformed into discontinuities (cracks) under shear stresses. The possibility of an increase in the cavity size is determined by the ratio of the relaxation times of the following processes that occur in the vicinity of this cavity under deformation of the system:⁴¹

elastic energy release due to the development of discontinuity

$$\tau_1 \sim l \frac{(\rho G)^{1/2}}{\sigma};$$

the formation of a new surface due to the development of a macroscopic crack

$$\tau_2 \sim l \left(\rho \frac{l}{\gamma} \right)^{1/2};$$

the mass transfer to the discontinuity zone as a result of vacancy drift

$$\tau_3 \sim \frac{l}{a} \sqrt{\frac{m \Delta^2}{U_0}} \exp\left(\frac{U_0}{k_B T}\right) \times \left[\sqrt{1 + \frac{m \Delta^2}{U_0} \left(\frac{\eta_0}{\rho a h} \right)^2} - \sqrt{\frac{m \Delta^2}{U_0} \frac{\eta_0}{\rho a h}} \right]^{-1} \times \left[\exp\left(\frac{\sigma a^2 \Delta}{k_B T}\right) - \exp\left(-\frac{\sigma a^3}{k_B T}\right) \right]^{-1}.$$

Here l is the linear size of the cavity in the quasi-crystal lattice, $G \sim F/\Delta a$ is the shear modulus, ρ is the density of the solid phase, $\gamma \sim U_0/a^2 \sim F\Delta/a^2$ is the specific surface energy, a is the quasi-crystal lattice spacing, Δ and U_0 are the half-height and half-width of the potential well, respectively, h is the distance between the particle surfaces and m is the particle mass.

The equations for the relaxation times of the first two processes were derived based on the dimensionalities of the physical parameters. The latter equation was obtained based on the Frenkel and Eyring hole theories assuming that the motion of dispersed particles is analogous to that of molecules of the liquid.

The development of discontinuity occurs if the relaxation time of elastic energy release (τ_1) is shorter than the relaxation times of processes, which can hinder the appearance of discontinuities (τ_2 and τ_3), *i.e.*, on the condition⁴¹

$$\frac{1}{\tau_1} \gg \frac{1}{\tau_2} + \frac{1}{\tau_3} \quad (17)$$

or

$$\sigma \gg \frac{F_c}{a^2} \sqrt{\frac{a}{l}} + G \left[\exp\left(\frac{\sigma a^2 \Delta}{k_B T}\right) - \exp\left(-\frac{\sigma a^3}{k_B T}\right) \right] \times \\ \times \exp\left(-\frac{U_0}{k_B T}\right) \times \left[\sqrt{1 + \frac{m \Delta^2}{U_0} \left(\frac{\eta_0}{\rho a h}\right)^2} - \sqrt{\frac{m \Delta^2}{U_0} \frac{\eta_0}{\rho a h}} \right].$$

This condition is fulfilled at

$$\sigma_1 \ll \sigma \ll \sigma_2, \quad (18)$$

where σ_1 and σ_2 are determined from the equations

$$\sigma_1 \sim p_h \left(\frac{a}{l}\right)^{1/2}, \quad (19)$$

$$\sigma_2 \sim p_h - \frac{k_B T}{a^2 \Delta} \times \\ \times \ln \left\{ \frac{G}{\sigma_2} \left[\sqrt{1 + \frac{m \Delta^2}{U_0} \left(\frac{\eta_0}{\rho a h}\right)^2} - \sqrt{\frac{m \Delta^2}{U_0} \frac{\eta_0}{\rho a h}} \right] \right\}, \quad (20)$$

where $p_h \sim F/a^2$ is the shear strength of an ideal (homogeneous) structure.

The development of discontinuity as a result of deformation occurs only at σ corresponding to the range (18), if the packing of particles was inhomogeneous before deformation. Under lower or higher shear stresses, a homogeneous viscous flow occurs. The structure inhomogeneity (regions with a closer packing) serve as nucleation sites for discontinuities. The parameters σ_1 and σ_2 calculated according to Eqns (19) and (20), respectively,⁴¹ are in satisfactory agreement with experimental data.

Some models of structured systems are based on the Eyring viscosity theory. This theory was used for deriving the equation for the viscosity of flocculated colloidal dispersions⁴²

$$\eta = (\eta_1 - \eta_\infty) \frac{[\text{sh}(\beta \dot{\epsilon})]^{-1}}{\beta \dot{\epsilon}} + \eta_\infty, \quad (21)$$

where η_1 and η_∞ are the limiting viscosities of the suspension when $\dot{\epsilon} \rightarrow 0$ and $\dot{\epsilon} \rightarrow \infty$, respectively;

$$\beta = k \frac{d^2}{D} \left(\frac{U}{k_B T}\right)^{-1} \exp\left(\frac{U}{k_B T}\right),$$

k is the proportionality coefficient that depends on the properties of the structure and U is the activation energy (potential barrier to particle shear migration).

The activation energies U were calculated by Churaev on the assumption that particles are fixed in the sites of a body-centred cubic lattice.⁴³ The migration of the particle A to the vacant site B through the potential barrier due to its interaction with the adjacent particles was considered. The potential barrier was calculated by summarising the energies of pair interactions between the particle A and the nearest neighbours. As a result, the forces acting on the transferred particle were determined taking into consideration the viscous resistance of interlayers of the liquid between particles. The time dependence of the deformation rate determined from the migration rates of the particle A is similar to that found within the limits of the well-known Calvin rheological model with a variable viscosity. Using these calculation methods, an attempt was made to establish the functional relationship between the potential curves of particle pair interactions in a disperse system, on the one hand, and its structural-mechanical properties, on the other hand. It became possible to reveal changes in the structural-rheological parameters of a

dispersion caused by changes in the electrolyte concentration, the surface charge, hydrophilicity of the particle surfaces and adsorption of surfactants and polymers on the particle surface. The drawback of the approach proposed⁴³ is that the properties of dispersions can be predicted only qualitatively.

In a model developed by Ogawa *et al.*,⁴⁴ the shear stress σ in colloidal suspensions can be divided into two components: the viscous stress and strain associated with interactions between particles. The first term can be determined from the Krieger–Dougherty equation (4). The second term depends on the inter-particle potential and was determined based on a knowledge about activation processes. Hence, the equation for the relative viscosity can be written as follows

$$\frac{\eta}{\eta_0} = \left(1 - \frac{\varphi}{\varphi_m}\right)^{-2.5\varphi_m} + c_1 \varphi \exp\left(\frac{U}{k_B T} - \frac{c_2 d^3 \sigma}{\varphi k_B T}\right), \quad (22)$$

where c_1 and c_2 are numerical constants (theoretically equal to $\pi/6$). The height of the energy barrier U is taken to be proportional to the particle pair potential at the midpoint between the particles. The parameter φ_m is chosen so as to achieve an agreement with experimental data at $\eta_\infty = \eta(\sigma \rightarrow \infty)$ for a suspension of solid spheres.^{29,45} With $\sigma \rightarrow 0$, Eqn (22) is identical to the equation corresponding to the model proposed earlier.⁴⁶ However, the author⁴⁶ considered U as the difference between the total potentials for the particles in the initial and final positions. The potentials were calculated taking into consideration the nearest neighbours under the assumption of a face-centred cubic lattice.

In the case of strong repulsions between the particles, the yield stress is described by the equation⁴⁴

$$\sigma_y = \frac{\varphi U}{c_1 d^3}. \quad (23)$$

This equation is equivalent to the equation for σ_y reported in the study.⁴⁷ Equation (23) can be easily obtained with the use of an effective medium model and assuming that $c_1 = 1/3$ rather than $\pi/6$. For systems characterised by a considerable attraction between the particles, several equations relating the yield stress to the energy required for deaggregation were proposed. These models were reviewed in detail in the publication.⁴⁸

In the study,⁴⁹ another class of models describing the viscosity of structured suspensions was considered. These models are based on approach including the following sequence of operations:

- a variable S that characterises the structure is introduced;
- the equation for the change in S under forces, which cause microstructure degradation (viscous friction forces in a shear flow) and assist in restoring the initial state (Brownian and dispersion forces) is written;
- the relationship between the viscosity and S is derived.

Let us consider one of the possible definition of the structural variable and its relationship with the suspension viscosity.^{50,51} Dispersions are represented as mixtures of individual particles and groups of particles (structural units, aggregates) suspended in a liquid. Particles comprising a structural unit move together as a rigid cluster thus transferring the liquid immobilised in this cluster. Therefore, a decrease in the viscosity with increasing shear rate is considered as a result of rapid degradation of structural units, which is accompanied by an increase in both the concentration of individual particles and the free liquid volume. An increase in the viscosity is, on the contrary, related to the formation of new structural units in a shear flow. The characteristics of the structural units (the size, shape and the possibility of the appearance or destruction in a shear flow) depend substantially on the type of interactions between the particles. If attractive forces between the particles prevail, the structural units can exist as flakes, aggregates or clusters of aggregates. In some systems, small aggregates are held together so tightly that deaggregation does not occur under shear forces. Hence, such aggregates can be considered as individual particles.⁵² If interactions are weak, the

structural units are merely groups of particles in a suspension of more or less free individual particles.

Let us denote the volume fractions of the structural units and individual particles by φ_s and $\varphi_p = \varphi - \varphi_s$, respectively. The structural variable can be given⁵⁰ as $S = \varphi_s/\varphi$. The effective volume fraction of the dispersed phase is

$$\varphi_{\text{ef}} = \frac{\varphi_s}{\varphi} + \varphi_p = \varphi(1 + CS),$$

where $C = 1/\varphi - 1$ is the compactness factor.

The equation specifying the change in S with time can be written as follows:

$$\frac{dS}{dt} = \frac{1}{\tau_1}(S_1 - S) - \frac{1}{\tau_2}(S - S_\infty), \quad (24)$$

where τ_1 and τ_2 are the characteristic relaxation times of the Brownian and hydrodynamic forces, respectively, and S_1 and S_∞ are the limiting values of the variable S when $\sigma \rightarrow 0$ and $\sigma \rightarrow \infty$, respectively. Under conditions of dynamic equilibrium, the variable S reaches a particular stationary value. In this case,

$$\frac{S_1 - S}{S - S_\infty} = \frac{\tau_1}{\tau_2} = \theta,$$

where θ is the kinetic ratio. For dilute suspensions of solid spheres, the time $\tau_1 \sim d^2/D$, which corresponds to the diffusion time of a particle to a distance comparable to its size. The characteristic time of hydrodynamic interactions in a shear flow τ_2 is similar in order of magnitude to $\dot{\epsilon}^{-1}$. Consequently, θ in dilute systems is equal to the Peclet number $\text{Pe} = d^2\dot{\epsilon}/D$, which can be considered as the ratio of the viscous friction work to the energy of thermal motion of the particles. In concentrated suspensions, the diffusion motion of the particles is strongly hindered and the suspension viscosity is substituted into the equations for the characteristic times instead of the viscosity of a medium. Then

$$\theta \sim \frac{\sigma d^3}{k_B T}.$$

Assuming that $\theta = \sigma/\sigma_c$, the critical shear stress can be determined as

$$\sigma_c = \frac{k_B T}{d^3}.$$

This relationship is the known Krieger correction (for Brownian motion) for colloidal suspensions.¹²

In the last step, the relationship between the viscosity and the shear stress is determined. In the study,⁵⁰ the following equation, which describes the non-Newtonian behaviour of suspensions under conditions of shear stress, is derived:

$$\eta(\sigma) = \eta_\infty \left(\frac{1 + \sigma/\sigma_c}{R_r + \sigma/\sigma_c} \right)^2. \quad (25)$$

Here, the rheological index R_r is expressed by the equation

$$R_r = \frac{1 - \varphi/\varphi_1}{1 - \varphi/\varphi_\infty} = \begin{cases} (\eta_\infty/\eta_1)^{1/2} & \text{if } \varphi < \varphi_1, \\ -\sigma_y/\sigma_c & \text{if } \varphi \geq \varphi_1, \end{cases} \quad (26)$$

where

$$\varphi_1 = \frac{\varphi_m}{1 + CS_1},$$

$$\varphi_\infty = \frac{\varphi_m}{1 + CS_\infty}.$$

At $\varphi < \varphi_1$, the calculated function $\eta(\sigma)$ represents a curve consisting of two regions, which correspond to the Newtonian

viscosity at low and high shear stresses, and an intermediate region in which the viscosity decreases. The plateau corresponding to low shear stresses disappears as the concentration φ increases and approaches φ_1 , i.e., the yield point σ_y is achieved. At $\varphi > \varphi_1$, the system exhibits the plastic properties.⁵³ In addition, at $R_r > 1$ the model can reflect the dilatant properties of suspensions.^{54,55}

Let us consider the differential method used for calculating the effective properties of disperse systems. The method consists of the following. A dispersed phase is added portionwise to the system under study. In each step, the effective properties of the disperse system are calculated with the use of the effective properties of the system determined in the previous step. In the zeroth step, the disperse system does not contain a dispersed phase and consists completely of a dispersion medium. The effective coefficients are determined in each step using a linear approximation, which was obtained from solving the problem at a low concentration of the dispersed phase. This approach allows one to derive differential equations or related differential equation systems, which describe the dependence of the desired characteristics on the concentration of the dispersed phase. The effective constants of the disperse system can be determined by solving the differential equation system. In the studies,^{56,57} this method was used to calculate the effective characteristics of porous media, in particular, to evaluate the viscosity of a dilute suspension containing porous particles.

A porous particle is modelled by a system consisting of N spherical liquid-impermeable particles with a given packing density. It is assumed that the liquid flow inside the porous particle obeys the Brinkman equations

$$\nabla p = \eta \Delta \mathbf{u} - K \mathbf{u},$$

where p is the pressure, $\mathbf{u}$ is the fluid velocity vector, η and K are the viscosity and the resistance coefficient of a porous medium, respectively.

The solution of this equation gives the following differential equations for the effective suspension viscosity and the resistance coefficient:⁵⁷

$$\frac{d\eta}{d\varphi} = \frac{5}{2} \frac{\eta}{1 - \varphi}, \quad \frac{dK}{d\varphi} = \frac{9\pi}{2R^2} \frac{\eta}{1 - \varphi}.$$

The boundary conditions: $\varphi = 0$, $\eta = \eta_0$ and $K = K_0$, where R is the radius of the porous particles, η_0 and K_0 are the viscosity and the resistance coefficient of the Brinkman fluid free of additional inclusions.

This differential equation system has the following solution:

$$\eta = \eta_0(1 - \varphi)^{-5/2}, \quad K = K_0 + \frac{9}{7} \frac{\pi \eta_0}{R^2} [(1 - \varphi)^{-5/2} - 1].$$

These equations determine the dependence of the effective suspension viscosity and the flow resistance coefficient taking into account the particle permeability to a dispersion medium.

An important class of rheological models includes models that are based on analysis of the processes of formation and cleavage of bonds between the particles. These models are called kinetic models because they are described by kinetic equations that characterise the changes in the bond numbers. The best known model of this type was developed in the study.⁵⁸ The kinetic equation for this model is as follows

$$\frac{dN_1}{dt} = -k_1 N_1^n + k_2 N_2^m, \quad (27)$$

where N_1 and N_2 are the concentrations of non-broken and broken bonds, and k_1 , k_2 , n and m are the constants characterising the rates of destruction and regeneration of the system.

An analogous model was proposed by Stolin *et al.*⁵⁹ The authors used a rheological system consisting of the structures A and B and identified the destruction and regeneration of the system with the forward and reverse chemical reactions

The constants k_1 and k_2 are similar in meaning to the analogous parameters in Eqn (27). Their dependence on the shear rate was taken into consideration under the following assumptions:

- (i) an increase in the deformation intensity leads to stronger structural changes (up to destruction);
- (ii) noticeable structural changes occur after elastic deformation (development of high-elastic deformations).

It is taken that

$$k_1 = k_{10} \exp\left(\frac{\omega}{2k_B T}\right),$$

$$k_2 = k_{20} \exp\left(-\frac{\omega}{2k_B T}\right),$$

where $\omega = (G/\tau)\dot{\epsilon}^2$ is the energy accumulated during elastic deformation τ .

The equation relating the dimensionless stress $\bar{\sigma}$ and the shear rate $\bar{\epsilon}$ was written in the following form⁵⁹

$$\bar{\sigma} = \frac{\bar{\epsilon}(1 + \kappa \exp \bar{\epsilon}^2)}{\lambda + \kappa \exp \bar{\epsilon}^2} \quad (28)$$

Here $\bar{\sigma} = F_A \alpha^{1/2} \sigma$, $\alpha = G/\tau$, $\bar{\epsilon} = \alpha^{1/2} \dot{\epsilon}$, $\kappa = k_{10}/k_{20}$, $\lambda = F_A/F_B$, F_A and F_B are the fluidities of the structures A and B, respectively.

Therefore, the viscosity of a system in the kinetic models is related to the concentrations of broken and non-broken structures (bonds) and it can be estimated from the corresponding kinetic equations.

Equation (28) describes the viscosity superanomaly, *viz.*, a decrease in the deformation resistance with increasing shear rate in stationary flows, characteristic of tixotropic structured systems. In this case, the flow curve (the shear rate vs. the shear stress) is a multivalued function. Its plot has a lower and upper branches, jumps from one branch to another being possible. This dependence was observed experimentally for various disperse systems and it is associated with the above-discussed discontinuity effect.⁴¹ It should also be noted that an agreement between the experiment and Stolin's model is evidently due to a free choice of a large number of independent parameters.

The kinetic model of aggregation–fragmentation of particles in a hydrodynamic shear flow of a coagulated suspension was developed by Dolgonosov.^{60, 61} In the equilibrium state, where the rates of attachment of the particles to aggregates is equal to the detachment rate, a dispersed phase was demonstrated to be separated into two fractions. One fraction consists of large aggregates, whereas another fraction is composed of small particles (initial particles and small aggregates). The formation of a two-fraction pattern was attributed to the fact that the growth of small and larger aggregates occurs by different mechanisms (Brownian and gradient). Within this model, the particles of the small and larger fractions are characterised by continuous spectra of masses $f(\mu)$ and $F(m)$ (μ and m are the particle masses of the corresponding fractions). The functions f and F were each normalised to the number of particles in the corresponding fraction. Under the assumptions used for the description of coagulation of small particles and their uptake by aggregates, as well as of the growth and degradation of aggregates, the following kinetic equations were derived:

$$\frac{\partial f(\mu)}{\partial t} = \int_0^{\mu/2} \beta(\mu - \mu', \mu') f(\mu - \mu') f(\mu') d\mu' - \int_0^\infty \beta(\mu, \mu') f(\mu) f(\mu') d\mu' - \int_0^\infty \beta(m, \mu) F(m) f(\mu) dm +$$

$$+ \int_\mu^\infty \gamma(m - \mu, \mu) F(m) dm,$$

$$\frac{\partial F(m)}{\partial t} = \int_0^{m/2} \beta(m - \mu, \mu) F(m - \mu) f(\mu) d\mu - \int_0^\infty \beta(m, \mu) F(m) f(\mu) d\mu + \int_0^\infty \gamma(m, \mu) F(m + \mu) d\mu - \int_\mu^{m/2} \gamma(m - \mu, \mu) F(m) d\mu. \quad (30)$$

Here $\beta(x, y)$ is the kernel of coagulation (the specific rate of coagulation of the particles x and y into the aggregate $x + y$) and $\gamma(x, y)$ is the kernel of degradation (the specific rate of degradation of the aggregate $x + y$ into the fractions x and y). The functional type of the sites of coagulation and degradation is written with consideration for the mechanism of aggregate growth with the use of approaches developed in the studies.^{62–65}

Calculations within this model allow one to reveal the changes in the spectrum of particles of a dispersed phase with time (Fig. 5). Analysis of the results of calculations showed that the evolution of the dispersed phase involves three steps: 1) the initial step: as a result of coagulation of aggregates, a coarse fraction manifests itself as several modes in the spectrum, which are transformed into one resulting asymmetric mode upon coalescence; 2) the intermediate step: aggregate coagulation continues, resulting in a decrease in asymmetry of the mode; 3) the final step: aggregation ceases, and ageing of the dispersed phase occurs due to capture of particles of the fine fraction by aggregates and detachment of fragments from aggregates under hydrodynamic stresses.

Calculations demonstrated that the peak in the spectrum of the fine fraction decreases in height and is broadened with time. In the studies,^{60, 61} it was demonstrated that the fine and coarse fractions do not overlap throughout the process, which is a condition for the applicability of the two-fraction model of a dispersed phase. The cited studies dealt with low-concentration disperse systems, in which the possibility of structuring is excluded, and only the kinetics of the formation of a dispersed phase was calculated taking into account coagulation and fragmentation of the particles. Apparently, the proposed model can be used also in calculations of the rheological characteristics of such systems.

Of the processes that substantially influence the rheological properties of dispersions, immobilisation of a liquid with aggregates and particles deserves notice. A liquid can be immobilised both on the particle surface and within aggregates. The immobilised liquid is not a true component of the liquid phase because it is bound to particles, and this liquid would be more properly considered as a supplement to solid particles, which increase the effective volume concentration of the dispersed phase

$$\varphi_{ef} = \varphi + \varphi_s + \varphi_v,$$

where φ_s and φ_v are the fractions of the liquid immobilised on the particle surface and in the bulk of aggregates, respectively.

The influence of immobilisation of the liquid on the rheological characteristics of suspensions was discussed by Windhab.⁶⁶ The volume of the immobilised liquid depends substantially on the degree of aggregation of the system, the particle surface roughness, the viscosity of the liquid, the porosity of aggregates, their density (Fig. 6) and other factors. Deaggregation of the system leads to release of the liquid located between the particles in the aggregate, resulting in a decrease in the volume of the immobilised liquid (φ_{ef}). However, further deaggregation leads to immobilisation of the liquid on the newly formed particle surface resulting in an increase in φ_{ef} . The effective concentration φ_{ef} directly affects the suspension viscosity. Therefore, the viscosity of the system

Figure 5. Mass distribution density of large aggregates vs. the time (t).⁶¹ $t = 0.1$ (a), 0.2 (b), 0.3 (c), 0.4 (d), 0.6 (e), 1.1 (f), 1.5 (g, curve 1); 7.0 (g, curve 2); 3, the Gaussian approximation of the equilibrium distribution; t is a dimensionless value.

changes with a change in the shear rate resulting in the aggregation or deaggregation and immobilisation or release of the liquid.

The following equation for the effective volume concentration was obtained:⁶⁶

$$\varphi_{\text{ef}} = \varphi \left\{ 1 + \frac{1 - \varphi_m}{\varphi_m} \left[1 + (\psi - 1) \frac{3}{4} n^{-1/3} \varphi_m^{1/3} \right] \right\}. \quad (31)$$

Figure 6. Degree of immobilisation of the liquid on the surface and in the bulk of particles or aggregates as a function of aggregability of the system.⁶⁶

Here $\psi = \Delta V_s / \Delta V_v$ is the ratio of the volume increments of the liquid immobilised on the surface (ΔV_s) and in the bulk (ΔV_v) of aggregates due to aggregation (deaggregation) of the system and n is the number of particles in the aggregate. Aggregation can lead to either a decrease or increase in the viscosity depending on ψ (at $\psi > 1$ and $\psi < 1$, respectively).

The number of the particles in the aggregate is calculated according to the equation

$$n = n(0) \left\{ \frac{k_a + k_d \exp[-(k_a + k_d)t]}{k_a + k_d} \right\}, \quad (32)$$

where $n(0)$ is the number of particles at the initial point of time and k_a and k_d are the rate constants of aggregation and deaggregation, respectively.

In the study,⁶⁶ it was suggested that Eqns (31) and (32) combined with the Krieger–Dougherty equation (4) be used for the estimation of the suspension viscosity:

$$\eta(\varphi, \dot{\epsilon}, t, \delta) = \eta_0 \left[1 - \frac{\varphi_{\text{ef}}(\varphi, \dot{\epsilon}, t, \delta)}{\varphi_m} \right]^{-\alpha(\delta)\varphi_m}. \quad (33)$$

The additional parameter δ takes into account the influence of the orientation of aspherical particles in a flow.

A comparison of the results of calculations according to Eqn (33) with experimental data showed that the model gives underestimated viscosities (Fig. 7). Apparently, this can be attributed to the fact that this model does not take into consideration the microstructure formation, which affects the viscosity of disperse systems.

The microrheology of low-concentration fractal colloidal gels was documented in several publications.^{67–74} If the shear stress applied to such gels is small, the gels exhibit ‘solid-like’ properties, viz., a high viscosity and the modulus of elasticity at low frequencies. If the stress is higher than the threshold value, the viscosity and, in some cases, the modulus of elasticity fall by several orders of magnitude and the system exhibits ‘liquid-like’ properties. An explanation of the nature of solid- and liquid-like states was given in the studies.^{67, 68} It was assumed that, at stresses higher than the threshold value ($\sigma > \sigma_c$), the structure consists of fractal aggregates, which are in contact with each other but are not linked in a network, and the system exhibits liquid-like properties. At $\sigma < \sigma_c$, the system occurs in the gel state, i.e., it consists of aggregates linked in a network and exhibits solid-like properties.

For the solid-like state, the viscosity can be estimated according to the equation^{67, 73}

Figure 7. Calculated (solid curves) and experimental (points) dependences of the shear viscosity of a sugar dispersion in silicon oil.⁶⁶ The results of approximation of experimental points by polynomials are indicated by dashed curves.

(1) φ_{ef} at $n_0 = 1000$; (2) φ_{ef} at $n_0 = 5000$; (3) η at $n_0 = 1000$; (4) η at $n_0 = 5000$; (n_0 is the number of particles in the aggregate in the absence of shear).

$$\eta_s \cong \alpha G_0 \tau_0 \exp\left(\frac{E}{k_B T}\right) c^{(3+2f_r)/(3-f_a)}. \quad (34)$$

Here $\alpha < 1$ is the coefficient that takes into consideration a decrease in the shear modulus in the space between the particles, G_0 is the shear modulus of the material of colloidal particles, τ_0 is the period of thermal oscillations of a pair of bound particles, E is the bond energy of the particles, c is the volume concentration of the particles in the system $c = c_N d^3$ (c_N is the numerical concentration of colloidal particles), f_r is the fractal dimensionality of unreplicated bonds in the backbone of the aggregate and f_a is the fractal dimensionality of the aggregates.

The viscosity of a gel in the liquid-like state is

$$\eta_l \cong B \pi \eta_0, \quad (35)$$

where $B > 1$ is the coefficient that takes into account the asphericity of the aggregate.

The critical (threshold) stress is

$$\sigma_c = K \frac{p_c E}{\xi^3}, \quad (36)$$

where $K \approx 1$ is the coefficient, p_c is the critical fraction of broken bonds, which is determined based on the percolation concepts, for a three-dimensional problems $p_c \approx 0.6-0.8$, and ξ is the linear size of the aggregate.

In the study,⁶⁷ it was concluded that at $\sigma = \sigma_c$, the system is inhomogeneous and stratifies into two phases, which are characterised by the viscosities η_s and η_l and the shear rates σ_c/η_s and σ_c/η_l . The shear rate changes stepwise with height. In regions corresponding to solid-like layers, the shear rate is lower than the average rate, whereas it is higher than the average rate between the layers.⁷⁴

The possibility of the co-existence of solid-like and liquid-like layers in a shear flow of low-concentration colloidal gels was considered in detail.^{72,74} In those studies, the co-existence of the layers in a shear flow in the shear rate range $\sigma_c/\eta_s \leq \dot{\epsilon} \leq \sigma_c/\eta_l$ was demonstrated to be responsible for the minimum energy dissipation rate, *i.e.*, the presence of these layers is energetically favorable. The fraction of the cross-section, which is perpendicular to the sample flow and is occupied by liquid-like layers, is determined by the equation

$$\varphi_l = \frac{\dot{\epsilon}/\sigma_c - 1/\eta_s}{1/\eta_l - 1/\eta_s}. \quad (37)$$

An idea of the co-existence of solid- and liquid-like phases was extended to gels under periodic shear deformation.⁶⁸ In the publication,⁷¹ the theoretical views about the structures of low-concentration gels were used for the description of the state of such gels under shear compression. In particular, it was noted that compression can lead to contacts between the branches (formed by particles) attached to the backbones of fractal cells and their gluing, on the one hand, and the cleavage of the most burdened branches, on the other hand.

The criterion formulated in the study⁶⁹ allows one to predict whether aggregates can fill the volume of the system and form a gel. This criterion is based on parameters of dilute colloidal systems in which fast coagulation of particles occurs and non-equilibrium fractal aggregates are formed. If the gel formation does not occur, aggregates fill a small volume fraction of the system, and their average sizes remain virtually unchanged with time because aggregation is compensated by fragmentation of aggregates (a stationary state). The volume concentration of the particles in the system was taken to be small, the aggregates were considered as consisting of a large number of particles, and the scaling solution of the Smoluchowski equations for large stationary aggregates, which was obtained earlier,⁷⁵ was used. The Smoluchowski equations include only pair collisions of aggregates and these equations are approximate, when the volume fraction occupied by aggregates φ_a is large.

In the case of formation of stationary fractal aggregates, their characteristics are described by the following expressions: the weighted-average mass of aggregates

$$M \cong \left(c_N \frac{k}{f}\right)^{1/(2+\beta-\alpha)}; \quad (38)$$

the average aggregate size

$$R \cong d M^{1/f_a} \cong d (c A n)^{(1/f_a)/(2+\beta-\alpha)}; \quad (39)$$

the number of aggregates per volume unit

$$n \cong \frac{c_N}{M} \cong d^{-3} c (c A n)^{-1/(2+\beta-\alpha)}; \quad (40)$$

the volume fraction occupied by aggregates

$$\varphi_a \cong n R^3 \cong c (c A n)^{(1/f_a)/(2+\beta-\alpha)}; \quad (41)$$

the time of establishment of a stationary state

$$\tau \cong \frac{d^3}{c k} (c A n)^{(1-\alpha)/(2+\beta-\alpha)} \cong \frac{1}{f} (c A n)^{-(1+\beta)/(2+\beta-\alpha)}. \quad (42)$$

Here k and f are the coagulation and fragmentation constants, respectively, α and β are the parameters that characterise the homogeneity upon coagulation and fragmentation, respectively, d is the particle size, f_a is the fractal dimensionality of the aggregates and $A n = d^{-3} k/f$ is the dimensionless parameter that characterises the ability of the system to undergo aggregation.

In the case of fast Brownian aggregation in the absence of cyclic (closed) fragments in the structure of fractal aggregates, the parameters α and β are equal to zero. Taking $f_a = 2$, the criterion of the existence of a gel can be obtained from Eqn (41) as the condition $\varphi_a \cong 1$ (aggregates fill the total volume).

$$c^{5/4} (A n)^{1/4} \cong 1. \quad (43)$$

The region of the parameters c and $A n$, at which the aggregates are not linked to each other and exist in a stationary state, is shown in Fig. 8. This region is limited by the weighted-average mass of the aggregates $10^2 < M < 10^6$. The requirement of large aggregate masses is associated with the fact that fractal models are

Figure 8. Region of the existence of stationary aggregates (without cyclic fragments) on the coordinates particle volume concentration – aggregability of the system.⁶⁹

The region is bounded by the straight lines $M = 10^2$ and 10^6 . The region of the existence of a gel is on the right from the wavy line.

adequate only in this case. However, the mass of real fractal aggregates cannot be much larger than 10^6 , because their structure will be substantially deformed under gravitation and thermal fluctuations. The wavy line in the Figure corresponds to the boundary of the gel formation $\phi_a \sim 1$.

It should be noted that aggregates occupy virtually the whole volume of the system at $\phi_a \sim 1$. In this case, the gel formation is beyond doubt. At the same time, the gel formation can occur at lower concentrations as well. The approximate character of the above criterion is associated also with the fact that the Smoluchowski equation that lies at the basis of this criterion is valid (as mentioned above) only at low ϕ_a .

3. Suspension dynamics under vibration in the presence of surfactants

A decrease in the viscosity of disperse systems (an increase in their fluidity) is one of the main conditions of optimisation of many heterogeneous chemical engineering processes. This problem is of particular importance for highly disperse systems with a high concentration of a solid phase, which are used in virtually all important industrial processes. The viscosity can be decreased by increasing the shear rate, which leads to decoagulation. However, high fluidity of disperse systems can be achieved also at low shear rates, if the dynamic state is created under other external forces, for example, under vibration, particularly, in the presence of surfactants.

The results of vibration treatment are in many aspects similar to the effect of Brownian motion, which hinders the formation of a coagulation structure from particles, thus providing aggregation stability of disperse systems. Vibration induces dispersion of structures. Hence, the vibration effect is analogous to lyophilisation of the system. However, it differs from the Brownian motion in that its parameters can be changed by many orders of magnitude, whereas the only controlled parameter of the Brownian motion, *viz.*, the temperature, can be varied only within an order of magnitude.

Experimental vibrorheological curves represent plots of the effective suspension viscosity *vs.* the vibration intensity³⁹ analogous to usual rheological curves $\eta_{ef}(\dot{\epsilon})$. Approaches to the theoretical analysis of vibrorheological curves were covered in the monograph.⁵

Within the model of a homogeneous structure, the effective viscosity of a disperse system is calculated according to the equation⁵

$$\frac{\eta_{ef}}{\eta_0} \sim \frac{(\xi \tau_i / \tau_f)^{1/2} \exp(U_a / \theta)}{(1 + \tau_f / \tau_i)^{1/2} - (\tau_f / \xi \tau_i)^{1/2}}, \quad (44)$$

where $\xi = h_1/d$, h_1 is the effective range of surface forces, τ_i and τ_f are the characteristic relaxation times of inertial motion of particles and their interaction due to the surface forces, U_a is the potential energy of particle interactions and θ is the parameter that characterises the kinetic energy of chaotic motion of particles.

For the suspensions considered in the monograph,⁵ $\tau_f \gg \tau_i$. In this case, Eqn (44) takes a simple form

$$\frac{\eta_{ef}}{\eta_0} \sim \exp\left(\frac{U_a}{\theta}\right). \quad (45)$$

When Eqns (44) and (45) are applied to suspensions under vibration conditions, the parameter θ includes, along with the energy of thermal motion of particles, the energy imparted to the particles under vibration,

$$\theta = k_B T + m(A\omega)^2,$$

where A and ω are the vibration amplitude and frequency, respectively.

At rather high θ (high vibration intensity), destruction occurs to give aggregates. In this case, models of aggregated suspensions can be used in the vibrorheological analysis of disperse systems.

The equations for the viscosity of low-concentrated aggregated suspensions with a fractal structure can be derived based on the concepts of sedimentation stability of suspensions by replacing the acceleration of gravity g by the acceleration produced by vibration $A\omega^2$. The following equations for the viscosity under vibration were thus obtained:⁵

within the mean-field model

$$\frac{\eta_{ef}}{\eta_0} = \left[1 - \frac{\phi}{\phi_m^2} \left(\frac{1.1}{\xi_v} \right)^{\sigma(3-f)/(f-1)} \right]^{-1.5}; \quad (46)$$

within the lubrication model

$$\frac{\eta_{ef}}{\eta_0} = \frac{6.2}{\xi_v} \left(\frac{\phi}{\phi_m^2} \right)^{\gamma_1[(3-f)+(f-2)]/(3-f)}. \quad (47)$$

Here

$$\xi_v = \frac{2}{9} \frac{|\rho - \rho_0| d A \omega^2}{\sigma_{0v}},$$

σ_{0v} is the resistance to vibration $\sigma_{0v} = \kappa \sigma_0$, $\kappa \ll 1$, f is the fractal dimensionality, σ_0 is the stability of the structure in the absence of vibration

$$\sigma = \frac{f-1}{(3-f)\gamma_1 + (f-2)} = \frac{f-1}{1+f(1+1/f_r)},$$

$f_r = f/f_c$, f_c is the chemical dimensionality;^{76,77}

$$\gamma_1 = \frac{2\alpha}{(3-f)(f-1)},$$

α is the parameter that depends on the degree of anisometry of the cluster, $0 \leq \alpha \leq f-1$.

The viscosity of highly concentrated suspensions can be estimated from the equation

$$\eta_{ef} \approx 17\eta_{ext} \left[\frac{\phi_m - \phi}{1 - \phi_m} \frac{|\rho - \rho_0| R A \omega^2}{\kappa \sigma_0} + \left(\frac{\eta_{ext} \dot{\epsilon}}{\sigma_0} \right)^{1/2} \right]^{-1}, \quad (48)$$

where

$$\eta_{\text{ext}} \equiv \frac{9}{8} \frac{\eta_0}{(\varphi_m/\varphi_{\text{ext}})^{1/3} - 1},$$

η_{ext} and φ_{ext} are, respectively, the viscosity and concentration of the suspension that fills the space between aggregates.

At low shear rates $\dot{\epsilon}$, Eqn (48) takes the form

$$\frac{\eta_{\text{ef}}}{\eta_{\text{ext}}} \approx 17 \frac{1 - \varphi_m}{\varphi_m - \varphi} \frac{\kappa \sigma_0}{|\rho - \rho_0| R A \omega^2}. \quad (49)$$

The influence of the particle surface modification with surfactants can be taken into account by varying the parameters U_a , h_1 and κ in Eqns (44)–(49).

Analysis of the resulting equations and their comparison with experimental data showed that the plot of the viscosity η_{ef} vs. the vibration intensity $I = A^2 \omega^3$ is characterised by the presence of the following two regions. At small values, the viscosity is calculated according to Eqns (44) and (45). At large values, the viscosity is calculated from to Eqns (48) and (49). These regions are associated with different flow mechanisms: a flow with a continuous structure (a model of a homogeneous structure) and degradation of the structure into aggregates and individual particles (a model of finite aggregates). In the former case, the viscosity decreases exponentially with increasing vibration intensity due to destruction of a homogeneous system. In the latter case, a weaker (power) dependence is observed, which corresponds to the aggregation mechanism of destruction. Since the viscosity depends on $A\omega$ and $A\omega^2$ in the first and second segments of the curve, respectively, it is reasonable to use relatively low-frequency vibrations to perform destruction in the initial step, whereas higher-frequency vibration must be used to achieve deeper destruction giving rise to aggregates. Vibration makes it possible to eliminate the segment of abnormally high viscosities at low shear rates in the rheological curve, in particular, to provide fluidity at shear stresses much lower than the effective yield point.

The influence of orthogonal oscillations on a disperse system (chocolate, $T = 32^\circ\text{C}$) under shear is shown in Fig. 9.⁷⁸ Measure-

ments were performed on a MCR-500 rotational rheometer. The experimental data showed that the viscosity substantially decreases in a wide range of shear rates.

The addition of surfactants to disperse systems reduces the lyophilic–lyophobic surface mosaicity of particles and favours a decrease in the viscosity in all regions, the general view of the rheological curve remaining unchanged (Fig. 10). Analysis of the dependences presented in Figs 9 and 10 revealed the effect of vibro-dilatancy consisting of the increase in the viscosity with increasing shear rate under vibration. The mechanism of this effect associated with the change in the structure of the flow remains unclear.

A high degree of deformation homogeneity can be achieved using vibration along with a decrease in the viscosity of a structured suspension due to ‘healing’ of discontinuities.⁴¹ Hence, vibration (particularly, combined with the addition of surfactants) can be considered as a universal tool for controlling the rheological properties of disperse systems.

An interesting synergism was observed under the combined action of different types of vibrations and surfactants on disperse systems. It was demonstrated⁷⁹ that low-frequency mechanical vibrations combined with high-frequency ultrasonic vibrations (60 Hz and 22 kHz, respectively) provide a higher degree of microstructure homogeneity of experimental samples (epoxy-based composite materials were examined as the samples). The possibilities of controlling the properties of disperse systems with the use of surfactant mixtures are much wider than those with individual surfactants. The colloid-chemical properties of aqueous solutions of high- and low-molecular-weight surfactants, viz., propanol 228 and sodium alkylbenzenesulfonate, respectively, and their 1 : 1 mixture were investigated.⁸⁰ The surfactant properties of the mixture were demonstrated to be more pronounced than the properties of the individual surfactants. Besides, the use of the mixture ensures higher aggregation stability of the system. Therefore, a combination of high- and low-molecular-weight surfactants results in the effect that is not observed in the case of individual surfactants.

Figure 9. Changes in the shear viscosity (1, 2) and the normal force (3, 4) (chocolate, $T = 32^\circ\text{C}$, a MCR-500 rotational rheometer) under orthogonal oscillations.⁷⁸

(1, 3) Without vibration; (2, 4) under vibration ($\nu = 60\text{ Hz}$, $A = 0.5\text{ mm}$).

Figure 10. Changes in the rheological curves of water–coal suspensions in the presence of surfactants and under vibration based on brown coal from the Moscow Coal Basin with $\phi = 41\%$ (a) and thermal coal from the Belovskii deposit with $\phi = 72.5\%$ (b).³

(1, 4) In the absence of surfactants; (2) in the presence of potassium lignosulfonate (0.4%); (3) in the presence of potassium lignosulfonate combined with vibration, $\nu = 50$ Hz, $A\omega^2 = 10g$; (5) in the presence of the condensation product of naphthalenesulfonic acid and formaldehyde (1%); (6) with the same additive as that used in 5 combined with vibration, $\nu = 50$ Hz, $A\omega^2 = 2.5g$.

The resistance of structured disperse systems to vibration and the knowledge of conditions under which destruction becomes impossible are of considerable importance. These problems were examined⁸¹ by analysing vibrations of a particle caused by oscillations of the fluid in a potential well in the vicinity of an equilibrium state. The equation for forced vibrations of a particle oscillator near equilibrium takes the form⁸²

$$\frac{\partial^2 x_{ij}}{\partial t^2} + 2\lambda_i \frac{\partial x_{ij}}{\partial t} + \omega_i^2 x_{ij} = \frac{F_j}{m} \sin \omega t, \quad (50)$$

where x_{ij} is the displacement of the particle from the equilibrium position, $i = 1$ and 2 correspond to the long- and short-range coagulation, respectively, $j = 1$ and 2 correspond to different calculation methods of the force F_j , $\lambda_i \sim z\eta_0 r^2/(H_i m)$, z is the coordination number, r is the particle radius, H_i is the distance which corresponds to the long- and short-range coagulation, m is the particle mass and ω_i is the eigenfrequency of vibrations of the particle.

The law of forced vibrations of a particle was derived from the equation of motion (50)⁸²

$$x_{ij}(t) = b_{ij} \sin(\omega t + \psi_i),$$

where

$$b_{ij} = \frac{F_j}{m[(\omega^2 - \omega_i^2)^2 + \lambda_i^2 \omega^2]^{1/2}},$$

ψ_i is the phase difference between the vibrations of the particle and the fluid.

The particle can escape from a potential well when exposed to the force F_j , if one of the following inequalities is fulfilled:⁸¹

$$b_{ij} \gg H_i, \quad (51)$$

$$mb_{ij}^2 \omega^2 \gg U_i. \quad (52)$$

If inequality (51) is fulfilled, the particle will be displaced from the equilibrium position to a distance larger than the potential well width, *i.e.*, will go beyond the range of action of the surface forces. If inequality (52) is fulfilled, the particle will acquire an energy higher than the potential well depth U_i and move as though there were no surface forces, $\omega_i = 0$. In both cases, the particle breaks free of the bonds that hold it in the structure, *i.e.*, destruction occurs. Detailed analysis of the particular form of conditions (51) and (52) for various modes of estimation of the force F_j as applied to long- and short-range coagulation, respectively, was performed in the study.⁸¹

In the case of destruction of structured systems that hinder high fluidity of dispersions the inertial effects are of importance in achieving the isotropic dynamic state of solid/liquid (S/L) disperse systems. When moving in an oscillating fluid, the vibration amplitude of the particle does not necessarily coincide with the vibration amplitude of the fluid. This effect becomes more pronounced as the particle mass increases, the oscillation frequency of the fluid increases or the viscosity of the fluid decreases. Under steady-state vibration mode, the proportionality coefficient β between the vibration amplitudes of the fluid (A) and the particle (A_p)

$$A_p = \beta A$$

is calculated according to the equation⁸³

$$\beta = \frac{\lambda}{(1 + \lambda^2)^{1/2}},$$

where

$$\lambda = \frac{9\eta_0}{\pi d^2 \rho \nu},$$

ν is the vibrational frequency of the liquid in Hz.

The coefficient β is essentially the criterion that indicates whether destruction and deaggregation can occur in a suspension. Destruction can take place if the particles that form the system are characterised by different values of coefficient β . The wider is the range of variations in β , the faster and more efficient is destruction. This condition means that only polydisperse systems with a wide range of variations in the particle size can undergo destruction in a suspension of rigid spheres under vibration. In this case, particles with different masses oscillate with different amplitudes due to which the particles are displaced with respect to each other resulting in destruction.

It should be noted that A_p are the amplitudes of free (*i.e.*, non-interacting) particles. The real amplitudes can be lower than A_p if there are interactions between the particles. This means that the above criterion provides evidence only for the possibility of destruction of structured components. Structural stability determined by interparticle forces is responsible for whether or not destruction will occur. To overcome these forces, it is necessary that the energy supplied under vibration be sufficient for cleavage of coagulation contacts [see Eqns (51) and (52)]. In other words,

this criterion describes the conditions necessary but insufficient for destruction of S/L disperse systems.

Undoubtedly, destruction and deaggregation under vibration depend on the degree of anisometry of the particles involved in the structures and aggregates. The value and character of the hydrodynamic forces acting on the particles depend substantially on their shape. At high anisometry, not only relative displacements of particles but also their more complicated translational-rotational motions take place resulting in faster deaggregation.

It is known that the presence of a surfactant layer on the particle surface leads to an increase in aggregation stability of disperse systems due to high viscosity, mechanical strength of the absorption layer and lyophilicity of its outer surface. Based on these facts, the structural-mechanical barrier is considered as one of factors stabilising disperse systems under static conditions.^{34, 84} However, stability of systems under dynamic conditions is of particular importance and there is a need for a theoretical description of the parameters and prerequisites for the appearance of the structural-mechanical barrier in the dynamic state. The processes that occur in adsorption layers on the surface of the particles during their high-speed collisions were analysed.⁸⁵ The layers are characterised by the viscosity coefficient η_l and the modulus of elasticity E_l . It was noted that the breakdown of an adsorption layer can take place at a rather high velocity of approach of particles to each other V_s . The breakdown occurs if the mechanical stress in the layer is comparable to the strength of the layer p_l . The inertial breakdown, *i.e.*, the breakdown due to the kinetic energy of particles received from an external source, was considered. Under these conditions, the viscous properties of the layer at particle velocities close to breakdown values can be ignored because the collision time is much shorter than the relaxation time (the time of elastic after-effect) $\tau_r \sim \eta_l/E_l$. In this case, the layer behaves as a purely elastic layer.

A quantitative expression for the criterion for the layer breakdown can be derived by comparing the kinetic energy $\Delta\epsilon_k$, which is received by particles from an external source, with the sum of the elastic energy $\Delta\epsilon_{ei}$, which can be accumulated in the layer without destruction, and the energy $\Delta\epsilon_{hi}$ dissipated for viscous friction as the surfaces approach each other.

The breakdown criterion is determined by the inequality

$$\Delta\epsilon_k > \Delta\epsilon_{ei} + \Delta\epsilon_{hi}. \quad (53)$$

According to the results of the study,⁸⁵ the terms in this inequality can be estimated according to the formulas

$$\begin{aligned} \Delta\epsilon_k &\sim \frac{2\pi}{3} r^3 \rho V_s^2, \\ \Delta\epsilon_{e1} &\sim E_l L^2 r_1 \left(\frac{p_l}{E_l}\right)^3, \\ \Delta\epsilon_{e2} &\sim E_l L^2 r_2 \left(\frac{p_l}{E_l}\right)^3 \left(\frac{r}{r_2}\right)^{3/2}, \\ \Delta\epsilon_{hi} &\sim \int_L^{h_{0i}} F_i dh. \end{aligned} \quad (54)$$

Here $r = [3m/(4\pi\rho)]^{1/3}$ is the linear size of anisometric particles (m is the particle mass and ρ is the particle density), L is the thickness of the adsorption layer, r_1 is the local curvature radius of the particle surface for angular collisions ($i = 1$), r_2 is the curvature radius of the lateral surface of disk-like particles ($i = 2$), h_0 is the initial distance between the particles and F_i is the hydrodynamic drag force when the particles approach each other

$$F_i \approx 6\pi\lambda_i\eta_l \frac{V r_i^2}{h}, \quad (55)$$

where $\lambda_1 = 1$, $\lambda_2 = 2(r/r_2)^{3/4}$.

Using relations (54) and (55), let us rewrite the criterion (53) as follows

$$V_s^2 - 9 \frac{\eta_l}{\rho r} \left(\frac{r_i}{r}\right)^2 \lambda_i \ln\left(\frac{h_{0i}}{L}\right) V_s - \frac{E_l}{2\rho} \left(\frac{L}{r}\right)^2 \frac{r_i}{r} \lambda_i^2 \left(\frac{p_l}{E_l}\right)^3 > 0. \quad (56)$$

This expression corresponds to the general criterion for the loss of aggregation stability under dynamic conditions. The structural-mechanical barrier is an essential factor of stability of dynamic systems, if the thickness of the layer and its modulus of elasticity are rather large. At low values of these parameters, particles are prevented from approaching each other only by hydrodynamic forces, and the minimum breakdown velocity of the layer is independent of the thickness and the modulus of elasticity of the layer.

Inertial coagulation is most probable for anisometric particles, *i.e.*, the creation of a structural-mechanical barrier in dynamics can be used as an efficient way of stabilising real disperse systems. It should be noted that the electrostatic factor is of lesser importance in dynamic systems compared to static systems.⁸⁶

In Section II, we have reviewed the most widely used rheological models of S/L disperse systems and some conclusions and criteria that are based on theoretical analysis of these models. However, the dynamic properties of disperse systems cannot be studied only by analytical methods because of their complexity. It is necessary to use calculation methods and computer simulation to understand the true mechanisms of many phenomena under particular conditions. Below we consider such methods, discuss the possibilities of computer simulation of disperse systems and summarise most characteristic results obtained with the use of these methods.

III. Computer simulation of disperse systems

1. Computer simulation methods for disperse systems

Let us consider approaches to computer simulation of disperse systems at different length scales and the corresponding numerical methods.

Three most important length scales are used in studies of colloidal suspensions (Fig. 11): the microscopic or atomic-molecular level, the mesoscopic level characterised by lengths of the order of colloidal particle size and the macroscopic level where suspensions are considered as a homogeneous fluid. Since the length scales corresponding to these levels differ by several orders of magnitude, it is impossible to perform simultaneous simulation of a suspension at all levels. Each simulation method is, as a rule, intended for the use at a particular level.

Simulations at the atomic-molecular level are carried out with the use of the molecular dynamics method (non-equilibrium molecular dynamics), in which the trajectories of the motion of molecules are calculated taking into account intermolecular forces based on Newton's laws. This method was developed about 50 years ago and was considered in numerous publications (for example, the description of this method has been given in the publications^{88–95}). However, the molecular dynamics method is very time consuming. To perform relatively reliable calculations of the fluid bulk properties with the use of this method, it is necessary to simulate systems containing more than 10^9 particles.⁹¹

The Monte Carlo method can serve as an alternative to the molecular dynamics method in simulations of equilibrium states of systems. The characteristic feature of the Monte Carlo method is its stochastic nature (strictly deterministic equations are used in the molecular dynamics method). In simulations of multiparticle systems, various modifications of the Monte Carlo method are used.^{95–100} The essence of the simplest modification is that all particles of the system are alternately subjected to random displacements. After each displacement, the system is tested to ensure whether the whole system satisfies a particular criterion and, if not, a new random displacement is done. After a rather large number of steps, the method gives an equilibrium configuration of particles, which best satisfies the desired criterion (the total energy of the system is generally used as this criterion).

Figure 11. Scheme illustrating the applicability of different approaches to computer simulation of disperse systems at different length scales and the numerical methods used.⁸⁷

Although the Monte Carlo method works faster than the molecular dynamics method, it is unlikely that this method can be used for the description of dispersion flows because it completely ignores the dynamics of the system under consideration.

It is difficult to simulate the behaviour of dispersed particles suspended in a medium of fluid molecules by the molecular dynamics method because it requires a large volume of calculations. To calculate the motion of even one dispersed particle, it is necessary to take into consideration collisions of this particle with at least several thousand 'background' molecules. Moreover, the time of particle–molecule collisions τ_{pm} ($\sim 10^{-9}$ s) is several orders of magnitude shorter than the time of particle–particle collisions τ_{pp} ($\sim 10^{-4}$ s). This means that detailed simulation of a suspension consisting of at least 1000 particles for a time much longer than τ_{pp} requires the use of a giant number of model units and an unrealistic number of iterations.

Brady has demonstrated¹⁰¹ that the time required for calculations of particles suspended in a fluid with the use of this method increases proportionally to the sixth power of the ratio of the particle size to the molecule size. Even for nanoparticles the sizes of which are larger than those of the fluid molecules by only a factor of 10, the time consumed for calculations increases billion-fold. Nevertheless, if simulations are performed for a period of time comparable to τ_{pp} , the use of this method, though being time consuming, is practically possible. However, in most cases, information on the motion of each fluid molecule seems to be excessive in simulation of suspensions because the parameters of the behaviour of particles in suspensions are determined primarily

by the macroscopic characteristics of the medium (viscosity, density, flow rates, *etc.*). In this connection, simulations are performed with the use of a continuous homogenous medium with specified macroproperties instead of the fluid molecules. In this case, interactions between particles are determined not only by molecular attraction and electrostatic repulsion but also by hydrodynamic forces transmitted through the fluid.

For small particle sizes ($< 1 \mu\text{m}$), thermal fluctuations of fluid molecules cause Brownian motion, which, after the replacement of fluid molecules by a continuous medium, can be represented as the result of action of a random force that obeys particular statistical regularities (Brownian dynamics^{102–104}). Since the motion of particles generally occurs at low Reynolds numbers ($\text{Re} = \rho v / \eta_0 \ll 1$, where v is the velocity of particles), hydrodynamic interactions are described by the linearised Navier–Stokes equations known simply as the Stokes equations. The corresponding simulation method is called the Stokesian dynamics.^{105–107} This method is used for suspensions of particles with a wide range of sizes ($10^{-8} - 10^{-3}$ m). The only limitation is that the sizes of dispersed particles should be larger than the sizes of fluid molecules to an extent that the medium can be considered as continuous, and the Reynolds number should be low.¹⁰¹

A family of methods, which treat fluids neither at the molecular level nor as a continuous medium but as a medium consisting of particles with sizes larger than the sizes of individual molecules, occupies an intermediate place between molecular and Stokesian dynamics. In these methods, the motion of particles obeys the law of momentum conservation. This law is at the basis

of the Navier–Stokes equations. As a result, the hydrodynamically plausible motion of the fluid is provided without the direct solution of these equations. Of these methods, dissipative particle dynamics^{108–112} and the lattice Boltzmann method^{113–122} are most widely used. The advantage of these methods is that they are less time consuming than the molecular dynamics method (in some cases, than the Stokesian dynamics as well) and yet adequately reproduce hydrodynamic effects. It should be noted that these methods are based on continual equations of a continuous medium, fluid particles serving as discrete elements, due to which the equation in terms of partial derivatives can be reduced to the difference system of ordinary differential equations. These methods are essentially continual and their discreteness is purely computational. To the contrary, the molecular dynamics method is based on the equations of motion of particles/molecules (ordinary differential equations) determined by the balance between the quantity of motion and the interaction potential between particles, *i.e.*, it is the true discrete method.⁶

One of the modern approaches to simulation at the macro-level, the so-called computational fluid dynamics (CFD), reproduces the behaviour of gas flows, Newtonian fluids and non-Newtonian fluids under different conditions. This extensively developed method was considered in numerous papers and monographs (see, for example, Refs 123–128), specialised journals and conferences. The detailed description of this method is beyond the scope of the present review. Let us only note that it is based on macroscopic equations (Navier–Stokes, *etc.*), whose solutions are sensitive to the boundary conditions. The available CFD program packages that implement numerical methods provide wide possibilities for solving problems of the dynamics of single-phase fluids, which are used in various fields of science and technology.¹²⁹ However, the application of these methods to simulation of suspensions presents difficulties because the boundaries move together with particles. These methods can be applied to systems composed of a small number of particles^{130, 131} having simple and symmetrical geometry.^{132, 133}

For this reason and also because the present review is devoted primarily to microrheological simulation, emphasis is given to methods oriented to simulation of suspension dynamics at micro- and mesoscopic levels. Let us briefly consider the mathematical backgrounds of some these methods.

a. Molecular dynamics method

The molecular dynamics method treats molecules and atoms as moving Newtonian particles. The equations of motion of classical mechanics for systems of interacting particles take the form

$$m_i \frac{d^2}{dt^2} x_i^{(\alpha)} = - \frac{\partial}{\partial x_i^{(\alpha)}} U(x_1^{(1)}, \dots, x_n^{(3)}), \quad (57)$$

where $\alpha = 1-3$; $i = 1, 2, \dots, n$, $x_i^{(\alpha)}$ is the α -component of the vector x_i of the position of the i th particle from the set n , $U(x_1^{(1)}, \dots, x_n^{(3)})$ is the potential energy of the system, which is calculated by summing the energies of interparticle interactions, which depend on the distances between pairs of interacting particles

$$U(x_1^{(1)}, \dots, x_n^{(3)}) = \frac{1}{2} \sum_{i \neq j} u(|x_i - x_j|).$$

An integration of the system of $3n$ equations of motion (57) with certain initial conditions gives the trajectories of particle motion. Particular (in the general case, arbitrary) coordinates and velocities of molecules are used as the initial conditions. In many cases, the velocities are chosen so that the total kinetic energy of the system corresponds to the given temperature. The density determined by the number of particles per unit volume can be used as another macroparameter. As a result of evolution, the system reaches an equilibrium state that depends on the temperature and the density, as well as on the interparticle interaction potential. The choice of the latter is of considerable importance because the

properties of the system strongly depend on this parameter. On the one hand, the potential should correspond well to the physical meaning of the model and, on the one hand, it should be convenient for calculations. The surface effects at the boundaries of the system can, to a certain degree, be compensated with the use of the so-called periodic boundary conditions: if the particle moves outside the computational space through the right boundary, it simultaneously enters the space through its left boundary. As a result, the density and energy of the system are retained. To eliminate interactions of the particle ‘with itself’, the pair interaction potential is cut at a particular distance from the particle.

b. Stokesian dynamics method

The Stokesian dynamics method has been proposed for the first time by Brady and Bossis.¹⁰⁵ According to this method, the motion of n undeformable particles suspended in incompressible Newtonian fluid is described in a vector form by the equation

$$\mathbf{m} \frac{d\mathbf{V}}{dt} = \mathbf{F}^h + \mathbf{F}^c. \quad (58)$$

Here $\mathbf{m}$ is the generalised mass tensor (the moment of inertia tensor) of particles, $\mathbf{V}$ is the vector of dimensionality $6n$ of the translational and rotational velocities of particles, $\mathbf{F}$ are the vectors of forces acting on the particles (moments of force) of dimensionality $6n$: $\mathbf{F}^h$ are the hydrodynamic dissipative forces caused by the motion of particles relative to the fluid and $\mathbf{F}^c$ are the conservative forces, which can be dispersion interaction forces of colloidal particles or external forces (for example, the gravity force).

At low Reynolds numbers ($Re \ll 1$), it is assumed that the hydrodynamic forces linearly depend on the velocities of particles

$$\mathbf{F}^h = \mathbf{R}\mathbf{V}, \quad (59)$$

where $\mathbf{R}$ is the resistance tensor the elements of which characterise the influence of the medium on the particle.

In disperse systems consisting of particles with sizes of about 10^{-6} m (or smaller), the characteristic times of inertial displacements are very short. Hence, in some cases, the left-hand side of Eqn (58) can be ignored. Then the equation for the velocities of particles can be written as follows:

$$\mathbf{V} = -\mathbf{R}^{-1}\mathbf{F}^c. \quad (60)$$

To calculate the velocities (and positions) of particles, a matrix inverse to $\mathbf{R}$ must be calculated in each step. Since the time consumed for the inversion of the resistance tensor increases proportionally to n^3 , this operation is one of the main limitations in simulations of systems with a large number of hydrodynamically interacting particles. A simplified modification of the Stokesian dynamics can be used¹⁰⁷ to increase the efficiency of calculations. This method allows simulations of motion of highly concentrated suspensions in a shear flow. At high concentrations, the components in the resistance tensor responsible for long-range hydrodynamic interactions can be ignored due to a small gap between the particles. As a result, the matrix $\mathbf{R}$ becomes sparse and contains only components of short-range hydrodynamic interactions, which are calculated from the lubrication theory. This substantially simplifies the inversion of the matrix and results in proportionality between the calculation time and the square of the number of particles, due to which calculations of systems with much larger n become possible. To reveal the nearest neighbours of the particle, Voronoi and Delaunay tessellations were used.¹⁰⁷ In this approach, the space is partitioned into regions within which all points are closer to a particular point than to any of the other points (Fig. 12). This region is called the Voronoi region and it represents a convex polyhedron and a convex polygon in a three- and two-dimensional space, respectively. The Voronoi and Delaunay tessellations are widely used in simulations of ensembles of discrete particles arbitrarily arranged in the space. A detailed description of this geometric method was presented and the

Figure 12. Voronoi tessellations of a point centre system in the plane.¹³⁴

possibility of its application to the solution of particular physicochemical problems was considered in a monograph.¹³⁴

In other modifications of the Stokesian dynamics, the Stokes law for an individual particle is used. It should be noted that this is valid only for low-concentrated suspensions.

The thermal motion of particles is described by the Brownian dynamics method. The stochastic force $\mathbf{F}^B$ responsible for the Brownian motion is added to the right-hand side of Eqn (58). In this case, the equation for the velocity of particles (60) takes the form

$$\mathbf{V} = -\mathbf{R}^{-1}(\mathbf{F}^c + \mathbf{F}^B). \quad (61)$$

The force $\mathbf{F}^B$ is chosen so as to fulfill the following conditions:

$$\langle \mathbf{F}^B \rangle = 0, \quad (62)$$

$$\langle \mathbf{F}^B(0)\mathbf{F}^B(t) \rangle = 2k_B T \delta(t) \mathbf{R},$$

where the angular brackets indicate the averaging over the total ensemble of particles and δ is the Dirac delta function.

The first condition means that the total result of the random Brownian forces is equal to zero. The second condition reflects the correlation between the random force at points of time 0 and t , which follows from the fluctuation-dissipative theorem of statistical physics. This condition is also indicative of the relationship between the Brownian and hydrodynamic forces, thus underlining their common nature.

The colloidal component of the force $\mathbf{F}^c$ in Eqn (58) is a combination of the molecular attractive and electrostatic repulsive forces. At moderate concentrations of particles and at their moderate velocities, this component can be determined by summing the pair interaction potentials of particles based on the Deryaguin–Landau–Verwey–Overbeek (DLVO) theory.^{36, 37}

c. Dissipative particle dynamics

The dissipative particle dynamics method has been proposed in the studies.^{108, 109} As mentioned above, this method is based on the representation of a fluid as a combination of hypothetical particles at a supramolecular level (dissipative particles), the motion of which occurs according to the laws of classical mechanics under the action of conservative, dissipative and random forces⁹⁵

$$\mathbf{F}_i = \sum_{j \neq i} [\mathbf{f}^c(\mathbf{r}_{ij}) + \mathbf{f}^d(\mathbf{r}_{ij}, \mathbf{V}_{ij}) + \mathbf{f}^r(\mathbf{r}_{ij})], \quad (63)$$

where $\mathbf{F}_i$ is the total force acting on the i th particle.

At first glance, this method is similar to the Brownian dynamics method. The radical difference is that Eqn (63) corresponds to forces acting on fluid particles rather than on dispersed particles.

The conservative force $\mathbf{f}_{ij}^c$ can be obtained, for example, from the interaction potential between the particles i and j . The dissipative force $\mathbf{f}_{ij}^d$ corresponds to the friction force that depends on the relative velocities of particles,

$$\mathbf{f}_{ij}^d(\mathbf{r}_{ij}, \mathbf{V}_{ij}) = -\gamma \omega^d(\mathbf{r}_{ij})(\mathbf{V}_{ij} \mathbf{e}_{ij}) \mathbf{e}_{ij},$$

where $\mathbf{r}_{ij} = \mathbf{r}_i - \mathbf{r}_j$, $\mathbf{V}_{ij} = \mathbf{V}_i - \mathbf{V}_j$, γ is the coefficient that controls the friction force, the function $\omega^d(\mathbf{r}_{ij})$ describes the change in the friction coefficient with distance and $\mathbf{e}_{ij}$ is the unit direction vector $\mathbf{r}_{ij}$. The random force $\mathbf{f}_{ij}^r$ is described by the equation

$$\mathbf{f}_{ij}^r(\mathbf{r}_{ij}) = \sigma \omega^r(\mathbf{r}_{ij}) \xi_{ij} \mathbf{e}_{ij}.$$

Here σ determines a random pair interaction force, the function $\omega^r(\mathbf{r}_{ij})$ describes the change in the random force with distance, ξ_{ij} is a random value characterised by the normal distribution law and the unit variance, $\xi_{ij} = \xi_{ji}$.

The parameters γ and σ and the functions $\omega^d(\mathbf{r}_{ij})$ and $\omega^r(\mathbf{r}_{ij})$ are specified so as to fulfill the following conditions:⁹⁵

$$\omega^d(\mathbf{r}_{ij}) = [\omega^r(\mathbf{r}_{ij})]^2,$$

$$\sigma^2 = 2k_B T \gamma.$$

Dissipative particles that move under the action of these forces interact with colloidal particles according to the mechanics laws thus providing their displacement and simulating the hydrodynamic and Brownian effects. Another essential difference between this method and the Brownian dynamics is that calculations according to the method under consideration ignore the momentum conservation in the system. In this case, the number of particles in the system is virtually the only unchangeable parameter. The equations of dissipative particle dynamics are written so as to provide the automatic fulfillment of the momentum conservation law, thus imparting the hydrodynamically realistic (satisfying the Navier–Stokes equation) behaviour to the system over rather wide time and space scales.

Consequently, the dissipative particle dynamics method makes it possible to go to the macroscopic level of pure fluids due to which certain properties of fluids (for example, the viscosity^{110, 111}) can be calculated. Usually, dissipative particles are considered as spheres with fixed diameters and masses. However, Flekkoy and Coveney¹¹² suggested that the dissipative particle dynamics method be extended to the microscopic level by identifying dissipative particles with the Voronoi polyhedra of different sizes (Fig. 13). The Voronoi tessellation of dissipative particles based on the configuration of a system makes it possible to allocate computational burden depending on the required degree of detailing (a higher degree is required in narrow channels between colloidal particles than in the fluid bulk). This increases the flexibility and efficiency of the method and makes it possible to

Figure 13. Scheme illustrating the applicability of the Voronoi tessellation in the dissipative particle dynamics method.¹¹²

Dissipative particles are identified with Voronoi regions. Four different length scales are presented: the scale of large colloidal particles, two scales of dissipative particles (between colloidal particles and in the fluid bulk) and the particle scale of the molecular dynamics method (solid points); the boundaries between dissipative particles are calculated depending on the arrangement of these scales.

apply this method to simulations of systems of concentrated suspensions, polymer solutions and flows in porous media with complex geometry on different length scales.

d. Lattice Boltzmann method

Among methods that are also based on the representation of fluids as discrete particles, the lattice Boltzmann method is worthy of note. In recent years, this method has been widely used for simulating hydrodynamic interactions in colloidal dispersions¹¹³ and was described, for example, in the publications.^{114–116} It belongs to the family of lattice methods and is based on the lattice gas model,¹¹⁷ in which the space filled with a gas or fluid is divided into regions using a regular lattice. The motion of a fluid is described by the dynamics of hypothetical particles of unit mass, which are transferred, with certain probability, to the adjacent sites along the links of a fixed lattice (Fig. 14). In the sites, particle collisions take place. The collisions are considered taking into account the conservation laws. The time and space averages satisfy the Navier–Stokes equation. The advantage of the lattice gas method is its stochastic nature, which, however, is responsible for its main drawback, *viz.*, a high noise level.

Figure 14. Possible displacements of a particle to the adjacent sites of two-dimensional (a) and three-dimensional (b) lattices. (1–18) are the numbers of the positions. The diagonal directions are indicated by empty arrows. The vertical and horizontal directions are marked by solid arrows.

This method can be improved by using the Boltzmann equation for the description of lattice gases. In the relaxation time approximation, this equation takes the form

$$\frac{\partial}{\partial t} f(\mathbf{r}, \mathbf{v}, t) + \mathbf{v} \cdot \nabla f(\mathbf{r}, \mathbf{v}, t) = -\frac{1}{\tau} [f(\mathbf{r}, \mathbf{v}, t) - f^{\text{eq}}(\mathbf{r}, \mathbf{v}, t)]. \quad (64)$$

Here $f(\mathbf{r}, \mathbf{v}, t)$ is the Maxwell–Boltzmann distribution function, $f^{\text{eq}}(\mathbf{r}, \mathbf{v}, t)$ is the equilibrium distribution function and τ is the relaxation time of the system due to particle collisions.

The Boltzmann equation can be transformed into the Navier–Stokes equations using the Chapman–Enskog expansion of Eqn (64). The Boltzmann equation for an incompressible Newtonian fluid can be solved in different ways with the use of lattice partitions. In the simplest modification of the lattice Boltzmann method, the summation in the lattice gas model is over particles, resulting in the replacement of this parameter with the density $f_i(\mathbf{r}, t)$ of particles with velocities $\mathbf{c}_i$ in this region of the lattice. The velocities $\mathbf{c}_i$ are chosen so that a particle can either move to the adjacent lattice site during the time Δt or stay in its initial position. The mass and momentum conservation laws must be fulfilled. In this case, the main hydrodynamic parameters, by analogy with the parameters of the kinetic gas theory, are the moments of different orders of a random value $\mathbf{c}_i$. For example, the local fluid density is the zero-order moment

$$\rho(\mathbf{r}, t) = \sum_i f_i(\mathbf{r}, t);$$

the local momentum density is the first-order moment

$$\rho \mathbf{v} = \sum_i f_i(\mathbf{r}, t) \mathbf{c}_i;$$

the momentum flux is the second-order moment

$$\Pi = \sum_i f_i(\mathbf{r}, t) \mathbf{c}_i \mathbf{c}_i.$$

Calculations of the displacements of particles can be substantially simplified by linearising the collision operator (the function that relates the state of the lattice node before a collision to its state after the collision) in the deviation of the particle density from its equilibrium value. The best form of the operator for this type of collision was proposed by Bhatnagar, Gross and Krook (BGK)¹¹⁸ and it provided the basis of the corresponding BGK models:¹¹⁹

$$f_i(\mathbf{r} + \mathbf{c}_i, t + 1) = f_i(\mathbf{r}, t) + \frac{1}{\tau} [f_i^{\text{eq}}(\mathbf{r}, t) - f_i(\mathbf{r}, t)] + \mathbf{F}. \quad (65)$$

Here $\mathbf{F}$ is an external force acting on a fluid (the mechanical force, the force of gravity, *etc.*). In Eqn (65), the unit time step was accepted, $\Delta t = 1$.

One of the possible ways of describing solid particles suspended in a fluid in terms of the lattice Boltzmann method is as follows.^{120, 121} In a particle placed on a lattice, internal and boundary nodes are distinguished (Fig. 15). The node is considered as a boundary node if it shares at least on edge with nodes surrounding the fluid particle. For simplicity of calculations, it is sometimes assumed that the particle is filled with a hypothetical fluid. The collision operator is used for each node, including the boundary and internal nodes of the particle. The condition of the absence of sliding at the L/S interface in this method is generally fulfilled due to ‘bounce-back’ of fluid particles from the surface of colloidal particles with momentum conservation. The concept of the bounce-back of particles can be extended to the moving colloidal particles^{120, 121}

$$f_i(\mathbf{r} + \mathbf{c}_i, t + 1) = f_{i'}(\mathbf{r} + \mathbf{c}_i, t_+) + 2\rho_f B_i (\mathbf{v}_w \mathbf{c}_i), \quad (66)$$

where t_+ is the time immediately after a collision, i' is the lattice link, which is a direction of bounce-back, B_i are the coefficients that depend on the lattice partition, ρ_f is the fluid density, $\mathbf{v}_w$ is the velocity of the wall (the surface of a colloidal particle) at a point $\mathbf{r}_w$, and the latter term characterises the momentum transfer between the fluid and the solid wall.

The velocity $\mathbf{v}_w$ is determined by the position of the centre of mass of the particle $\mathbf{r}_c$ and its linear ($\mathbf{V}$) and angular ($\boldsymbol{\omega}$) velocities.

$$\mathbf{v}_w = \mathbf{V} + (\mathbf{r}_w - \mathbf{r}_c) \times \boldsymbol{\omega}.$$

Figure 15. Schematic representation of a colloidal particle on a regular lattice.¹³⁵ (1–3) are the boundary, internal and external (with respect to the particle) lattice nodes, respectively.

The overall hydrodynamic forces and moments of forces acting on a solid particle from the fluid can be determined by summation of the effects calculated according to Eqn (66) over all boundary nodes of a solid particle in each time step. The result is the movement of this particle under the action of the above-mentioned forces according to Newton's laws.

Since the density of particles, unlike their number, is not a discrete parameter, solutions obtained by the lattice Boltzmann method are not exposed to fluctuations associated with discreteness of the number of particles. This is often an advantage of the method. However, in simulations of the Brownian motion, it is necessary to specify statistical deviations from the calculated positions. This can be done by introducing an additional random force into Eqn (65).¹²² On the whole, the lattice Boltzmann method provides a detailed description of the behaviour of a fluid and is efficient from a computational standpoint, due to which this can be successfully used in simulations of flows with complex geometry, *i.e.*, flows in porous materials, the dynamics of colloidal suspensions, *etc.*

In the next Section, we consider selected results of computer simulation of the dynamics of S/L disperse systems obtained with the use of the above-mentioned methods.

2. Results of computer simulation of dynamics of disperse systems

In Russia, computer simulation of the suspension dynamics has been performed for the first time in 1999.¹³⁶ Dispersions of spherical quartz particles in water consisting of 100, 400 and 900 particles were examined. Only pair interactions of particles were taken into account. The interaction potential curve was constructed based on the DLVO theory. The simulation was performed by a simplified method of the Stokesian dynamics based on the Stokes law for a single particle. Under shear conditions, the formation of a region with a low concentration of a dispersed phase was observed. This was attributed to the formation of layers oriented along the shear direction in a suspension flow. Earlier, this phenomenon has been observed and studied experimentally. In subsequent studies, computer simulations of disperse systems under dynamic conditions were carried out by the authors of the present paper using simplified Stokesian dynamics method.

The behaviour of dispersions in a shear flow was simulated by specifying a constant shear gradient at which the velocity of a fluid increases in the vertical direction. Particles in a fluid flow experience the Stokes force (viscous friction) exhibited by the fluid due to which they move together with the flow. The inertia component of the resistance force caused by the fluid was taken into account through the particle effective mass including, along with the particle mass, the added fluid mass, which is equal (in the case of spherical particles) to one-half of the mass of the displaced fluid,

$$m_{\text{ef}} = m + \frac{\pi d^3 \rho_0}{12}.$$

The characteristics of the systems were as follows: $\eta_0 = 10^{-3}$ Pa s, $\rho_0 = 10^3$ kg m⁻³, $\rho = 2.6 \times 10^3$ kg m⁻³, $\phi = 20\% - 40\%$, $d = 5 - 100$ μm . The particle interactions were calculated by specifying a potential curve with two energy minima corresponding to long- and short-range coagulation. Since the particle sizes of the systems under consideration differ by at most two times, the interaction energy was taken to be equal for each pair of particles regardless of their sizes.

In simulations of the influence of the physicochemical inhomogeneity of the particle surface (its lyophilic–lyophobic mosaicity) on the character of flow of a disperse system, it was assumed that the lyophilic and lyophobic regions are uniformly distributed over the particle surfaces. The probability of the formation of a contact in a lyophilic region, which is proportional to the fraction of the lyophilic particle surface γ , was determined using a random number generator. Each time, interactions between two particles were calculated assuming the parameters

Figure 16. Flow of a disperse system with different degrees of lyophilicity (γ) of the particle surface (a–c) and the interaction curve of two lyophobic particles (d).

Parameters of the system: $n = 200$ particles; $\dot{\epsilon} = 40$ s⁻¹, $\phi = 40\%$; $d = 5 - 10$ μm ; $\gamma = 0$ (a), 50 (b), 100% (c).

of the potential curve corresponding to a lyophilic or lyophobic contact. Since the presence of lyophilic regions results in weakening of attractions between particles, an increase in the degree of lyophilicity of the surface leads to an increase in the aggregation stability of the system (Fig. 16).

Computer simulations of disperse systems under dynamic conditions revealed many features of their behaviour characteristic of this state. The formation of layers and particle aggregates in flows of disperse systems was confirmed. Destruction and deaggregation of such systems can be performed by supplying additional energy as external mechanical forces (for example, vibration). Orthogonal oscillations of particles of disperse systems occur through vibrations of a dispersion medium in the direction perpendicular to the flow direction. This type of vibration effects causes a sharp increase in the fluidity of dispersions by promoting degradation of structured components in a disperse system, thus noticeably increasing its shear viscosity.^{1–3}

All characteristic steps of formation of a layered structure in a dispersion flow are presented in Fig. 17. In the formation of layers oriented along the shear direction, long-range attractive forces that act on particles are of considerable importance. Numerical experiments showed that layered structures are not formed in systems consisting of particles with a weak force field effective at a

Figure 17. Sequence of the formation of a layered structure in a shear flow of a polydisperse system.

Parameters of the system: $n = 800$ particles; $\dot{\epsilon} = 85$ s⁻¹, $\phi = 35\%$; $d = 50 - 100$ μm ; the time after the start of flow /s: (a) 0, (b) 0.05, (c) 0.3, (d) 0.5.

Figure 18. Illustration of the formation of aggregates in a dispersion flow due to dynamic coagulation of particles (a–c) and the interaction curve of two particles (d).

Parameters of the system: $n = 200$ particles; $\dot{\epsilon} = 50 \text{ s}^{-1}$, $\phi = 20\%$; $d = 50\text{--}100 \text{ }\mu\text{m}$; the time after the start of flow /s: (a) 0, (b) 0.1, (c) 0.2.

short distance; instead, a nearly isotropic dynamic state is reached in a flow or (in the case of a deeper short-range potential well) aggregation occurs due to dynamic coagulation of particles (Fig. 18). The formation of a layered structure is responsible for anisotropy of the viscosity along and across the shear flow (in the latter case, the viscosity can be substantially higher).

Computer simulations of destruction under vibration were performed for a disperse system with particle sizes from 50 to 100 μm . Such large particles (which are nevertheless able to form coagulation structures due to cohesion^{1,39}) were chosen because of the necessity to develop inertial effects under vibration, which cause displacements of particles relative to each other and lead to destruction. The results of calculations of inertial displacements of particles relative to the medium depending on the particle size and the vibrational frequency are given in Table 1.³⁹ It can be seen that the larger the particle size and the higher the vibrational frequency, the larger the difference in the vibrational amplitudes of the particles and the medium. This means that destruction of systems formed by particles of colloidal sizes can occur only under ultrasonic vibrations.

Table 1. Relative inertial displacements of solid-phase particles in a liquid dispersion medium depending on harmonic vibrational frequency and the particle size.³⁹

ν/Hz	Relative displacement at particle radii /m				
	10^{-5}	5×10^{-5}	10^{-4}	5×10^{-4}	10^{-3}
50	0.9999	0.9611	0.7933	0.4977	0.4869
100	0.9995	0.9002	0.6760	0.4903	0.4853
200	0.9982	0.7953	0.5849	0.4869	0.4846
300	0.9963	0.7240	0.5501	0.4859	0.4843
400	0.9938	0.6760	0.5325	0.4853	0.4842
500	0.9910	0.6423	0.5219	0.4850	0.4841
1000	0.9723	0.5642	0.5016	0.4844	0.4840

The harmonic oscillations of the fluid along the y direction were specified according to the law

$$y_f = A \sin \omega t,$$

where A is the vibrational amplitude, ω is the circular vibrational frequency and $\omega = 2\pi\nu$ (ν is the frequency in Hz).

In vibrations, the vibrational amplitude of a dispersion medium was 0.1 mm and the frequency was 100–200 Hz. The

choice of these parameters ensures a change in the ratio of the vibrational amplitudes of the particles and the medium for these vibrational frequencies in the ranges of approximately 1.0–0.7 and 0.9–0.5, respectively, thus providing conditions necessary for destruction.⁸³ However, the colloidal (surface) interaction forces of particles can be so large that the energy supplied by vibrations will be insufficient for destruction of structured ensembles in the dispersion.

As an example, the results of computer simulation of vibration effects on a disperse system under shear are presented in Fig. 19. It can be seen that the layered structure that is formed in a dispersion flow cannot be completely destroyed under vibrations of the medium. Moreover, in this case vibrations lead to coalescence of layers, *i.e.*, to the formation of larger structural inhomogeneities, which can apparently be accompanied by an increase in the shear viscosity of the disperse system. Presumably, this is one of the mechanisms of vibro-dilatancy, *viz.*, an increase in the dispersion viscosity under vibration.

Figure 19. Changes in the layered structure under vibration.

Parameters of the system: $n = 800$ particles; $\dot{\epsilon} = 85 \text{ s}^{-1}$, $\phi = 35\%$; $d = 50\text{--}100 \text{ }\mu\text{m}$; the time after the start of vibration /s: (a) 0, (b) 0.05, (c) 0.1, (d) 0.2.

Vibrations also cause ‘grading’ of particles according to sizes (see Fig. 19). This phenomenon is easy to explain as follows. Large particles are grouped predominantly with large particles; small particles, with small. This is due to the fact that particles are characterised by different vibrational amplitudes: small particles go ahead, whereas large particles go behind, resulting in the separation of the dispersion into fractions. At the same time, the possibility of adhering the smallest particles to the surface of large particles cannot be ruled out, which follows from the DLVO theory.^{36,37}

As mentioned above, the surface modification with surfactants facilitates destruction of coagulation structures because it eliminates the lyophilic–lyophobic mosaicity of the surface. As a result, virtually complete lyophilisation is achieved and, as a consequence, interactions between particles are weakened. In addition, coating of the surface with a surfactant layer creates a structural-mechanical barrier, which hinders dynamic coagulation.^{1,34}

Simulations of surfactant-modified systems were carried out under the assumption that neither surfactant desorption from the surface nor mechanochemical destruction of surfactants under dynamic forces take place. It was assumed that uniform coating of the particle surface is provided by surfactant molecules with short hydrocarbon radicals or with the use of a mixture of low- and high-molecular-weight surfactants.

The changes in the microstructure of surfactant-modified disperse systems in a shear flow can be seen from Fig. 20. The formation of a surfactant layer on the surface and its lyophilisation are accompanied by changes in the shape of the potential

Figure 20. Formation (*a–c*) of an internal microstructure of a dispersion modified by treating the particle surface with surfactants and its destruction under vibration (*d–f*). Parameters of the system: $n = 800$ particles; $\dot{\epsilon} = 85 \text{ s}^{-1}$, $\varphi = 35\%$; $d = 50\text{--}100 \text{ }\mu\text{m}$.

curve of particle interactions, for example, by a decrease in the depth of potential wells. Besides, the presence of a structural-mechanical barrier can prevent particles from approaching each other to a distance at which a short-range potential energy minimum exist. In this case, we can say that the short-range potential well is absent. Under these conditions, coagulation structures can be formed only due to long-range coagulation contacts, resulting in a lower density and a larger looseness of layers and other structured components in the dispersion (see Fig. 20). Under external vibrations, coagulation structures in such systems are rapidly destroyed (see Fig. 20 *d–f*) and a nearly isotropic dynamic state is achieved.

The data presented in Fig. 20 (and partially in Fig. 19) suggest also that discontinuities, which accompany the formation of a layered structure, are healed due to vibrations.^{1,41}

The results of computer simulation of disperse systems under dynamic conditions confirm the above conclusion that surfactants combined with vibration create the desired synergetic effect. The use of the latter allows one to control the rheological properties of dispersions. This procedure can be used to perform isotropic destruction of coagulation systems accompanied by a decrease in the viscosity (an increase in the fluidity) of dispersions by several orders of magnitude.

Let us consider the results of computer simulation that demonstrate other possibilities of this method. Of a large number of publications on computer simulations of disperse systems, we discuss here studies most closely related to the problems under consideration.

The use of the full form of the Stokesian dynamics method in simulations of disperse systems provides a highly accurate description of the hydrodynamic effects, which however sharply increases the volume of calculations. In the studies,^{101,106} the behaviour of a system consisting of 27 solid particles in a fluid was described by the Stokesian dynamics. The authors compared the results of these calculations with the data obtained by Brownian dynamics simulations, where the hydrodynamic effects are ignored, and demonstrated that it is important to take into consideration hydrodynamic interactions. In both cases, calculations were carried out for suspensions of solid spheres at a concentration $\varphi = 45\%$ in a simple shear flow. The plots of the equilibrium shear

Figure 21. Computer simulation of changes in the viscosity (*a*) and the pair distribution function that characterises the microstructure of a suspension under shear (*b*).¹⁰¹ (1) Stokes dynamics, $n = 27$; (2) Brownian dynamics, $n = 1331$; $\varphi = 45\%$.

viscosity vs. the Peclet number are shown in Fig. 21 *a*. The viscosities were calculated by non-equilibrium statistical mechanics methods with the use of the Green–Kubo equation.^{92,137} It can be seen from Fig. 21 that the quantitative contribution of hydrodynamic interactions consists of an increase in the suspension viscosity. However, the qualitative difference, *viz.*, an increase in the viscosity at high shear rates (the dilatancy effect), is more important. The qualitative difference in the behaviour is associated with the shear-induced microstructure. The pair distribution functions of particles for three different shear rates (different Peclet numbers) are shown in Fig. 21 *b*. At small Peclet numbers, the microstructures formed in the presence of hydrodynamic interactions are similar to those formed in the absence of these interactions and are also similar to microstructures characteristic of fluids. Dark regions correspond to high probabilities of the presence of particles; light regions, to low probabilities. Rings corresponding to the nearest neighbours of the particle under consideration are clearly seen in the figure. The time necessary for calculations of a system consisting of 1331 Brownian particles is approximately equal to that necessary for calculations of a system consisting of 27 Stokesian particles. At $Pe = 10$, patterns that are calculated taking into account the hydrodynamics are also analogous to those, where the hydrodynamic effects are ignored, and demonstrate a shear-deformed microstructure.

The results obtained by the Stokesian and Brownian dynamics simulations, are qualitatively different at $Pe = 1000$. In the former case, a shear-deformed microstructure typical of fluids is seen but it is characterised by the more thinner nearest ring. In the studies,^{101,138} the dilatancy effect was demonstrated to be directly related to this feature of the pair distribution function. In the absence of hydrodynamic interactions, the particles are arranged

Figure 22. Brownian dynamics simulations of the arrangement of the particles in the plane perpendicular to the flow direction.¹⁰¹

in chains one after another, and the chains are located in hexagonal order in the plane perpendicular to the flow (Fig. 22). These chains are formed at high shear rates (when Brownian motion is of little importance): particles collide, rebound and adhere to other particles, again collide, rebound and so on until an ordered structure is formed. In the presence of hydrodynamic interactions, particles that are transferred by a flow do not rebound after collision and are held close to each other due to short-range hydrodynamic lubrication forces. Two particles rotating together in a flow hinder the formation of ordered chains. Therefore, the hydrodynamic effects influence both quantitatively and qualitatively the rheology and microstructure of colloidal dispersions. A detailed review of shear-induced microstructures in colloidal suspensions and analysis of the conditions of their formation and the role of hydrodynamic interactions between particles were given in the recent paper.¹³⁹

It is particularly important to take into account the dilatancy effect under shear deformation and vibration accompanied by a spontaneous increase in the viscosity and shear stress because it inevitably influences the character of dispersion flows and the possibility of achieving the maximum fluidity.

In the study,¹³⁵ simulations of the dilatant properties of suspensions were carried out by the lattice Boltzmann method. The Couette flow of a suspension between two planar plates, which are located at a distance H from each other and move at a velocity u_w in opposite directions, was considered. The lattice partitions of dimensions 128×128 and 256×256 points were used. The particle diameter was 10 lattice nodes. The concentration of the solid phase was varied from 12% to 52%.

In the absence of the Brownian forces, the Reynolds number was used instead of the Peclet number for characterisation of shear flows

$$Re = \frac{\rho_0 d^2 u_w}{\eta_0 H}.$$

The suspension viscosity was determined from the equation

$$\eta = \frac{\sigma_t}{\dot{\epsilon}},$$

where σ_t is the total shear stress on the walls and $\dot{\epsilon} = 2u_w/H$ is the shear rate.

Plots of the relative suspension viscosity vs. the Reynolds number determined by computer simulations are given in Fig. 23 *a*. It can be seen that the higher is the suspension concentration, the earlier (*i.e.*, at lower shear rates) the dilatancy is observed. In the study,¹³⁵ these effects were related to the changes in the components of the total shear stress σ_t and σ_s corresponding to the liquid and solid phases. The changes in the relative contributions of σ_t/σ_t and σ_s/σ_t to the total shear stress depending on the Reynolds number at two suspension concentrations are

Figure 23. Suspension viscosity (*a*) and the shear stress corresponding to the fluid and solid phases (*b*) vs. the Reynolds number.¹³⁵

(*a*): $\phi = 52$ (1), 48 (2), 44 (3), 36 (4), 24 (5), 12% (6);

(*b*): σ_t/σ_t (1, 3); σ_s/σ_t (2, 4); $\phi = 12$ (2, 3) and 52% (1, 4).

shown in Fig. 23 *b*. It can be seen that the components of the total shear stress are independent of the Reynolds number in the initial region and begin to change only at a particular value that depends on the concentration of the solid phase. This change consists of the increase in the contribution of the shear stress corresponding to solid-phase particles. A comparison of the curves presented in Fig. 23 *a, b* demonstrated that an increase in the suspension viscosity and an increase in the shear stresses in the solid phase are observed at the same Reynolds number, which is indicative of the relationship between these phenomena.

The shear stress corresponding to solid particles is an important parameter. Figure 24 shows the plot of the relative suspension viscosity vs. σ_s/σ_t . The points in the figure were determined for Re varying from 0.1 to 11.7. All calculated points corresponding to different Re and the concentrations of the solid phase fall in a single curve, *i.e.*, the suspension viscosity is a mere function of σ_s/σ_t and does not directly depend on either the concentration or the shear rate.

In the study,¹³⁵ the simple equation was derived for the dependence of the viscosity on the contribution of the solid phase to the total shear stress:

$$\frac{\eta}{\eta_0} = \frac{1}{1 - \sigma_s/\sigma_t}. \quad (67)$$

However, the author of this work did not analyse the obtained results.

The results of computer simulations of the viscosity of a suspension consisting of solid spheres that were performed by different research groups using different methods^{135, 140–145} agree well with the results of calculations according to the Krieger–Dougherty equation (4) and the experimental data (Fig. 25). This demonstrates the efficiency of computer simulations in studies of

Figure 24. Relative suspension viscosity vs. the ratio σ_s/σ_t .¹³⁵ Points correspond to different concentrations and different Reynolds numbers. The solid line represents calculations according to Eqn (67). $\varphi = 52$ (1), 48 (2), 36 (3), 24 (4), 12 (5), 6% (6).

Figure 25. Theoretical data (curve) and data from computer simulations (points) of the suspension viscosity vs. the concentration. (1, 2) Lattice Boltzman method (2D);^{135, 145} (3, 4) Stokes dynamics (2D);^{140, 141} (5) lattice gas method;¹⁴⁴ (6) experiment;³⁰ (7, 8) Stokes dynamics (3D);^{142, 143} (9) lattice Boltzman method (3D).¹³⁵

the properties of disperse systems. The results of computer simulations were obtained at $Re = 0.1$ by the Stokesian dynamics,^{140–143} the lattice gas method¹⁴⁴ and the lattice Boltzmann method^{135, 145} for two- (2D) and three-dimensional (3D) systems. The maximum particle concentrations were taken equal to 0.785 and 0.605 for 2D and 3D systems, respectively.

The results of computer simulation of a system of ellipsoidal particles by dissipative particle dynamics are presented in Fig. 26.¹⁴⁶ The particles with the aspect ratio $f = 5$ were considered. The suspension viscosity was calculated from the equation

$$\eta = -\frac{\sigma_{xy}}{\dot{\epsilon}},$$

where σ_{xy} is the xy -component of the stress tensor, which is calculated in each time step. For dilute suspensions, the effective viscosity can be written as a first-order power series expansion in terms of the concentration of the solid phase φ

Figure 26. Relative viscosity of a suspension of ellipsoidal particles with the shape coefficient $f = 5$ vs. the concentration of the solid phase at dimensionless shear rates of 10^{-4} (1) and 10^{-5} (2).¹⁴⁶ Results of computer simulation were obtained by dissipative particle dynamics.

$$\frac{\eta}{\eta_0} = 1 + [\eta]\varphi.$$

According to the results of the investigation,¹⁴⁷ the degree of entanglement of rod-like particles increases with increasing concentration of a suspension, and the viscosity becomes proportional to the third power of the parameter φ . The results of simulations were approximated by third-order polynomials (see Fig. 26). The coefficient at the linear term $[\eta]$, which was obtained by approximation and interpreted as the ‘intrinsic’ viscosity of the system (5.67), is similar to the calculated value (5.78¹⁴⁶) for ellipsoids with $f = 5$.

The results of computer simulations of disperse systems considered in the present review confirm many experimentally observed and theoretically substantiated data on the dynamic and rheological properties of dispersions. Analysis of these results shows the ‘history’ of the appearance and development of some phenomena and provides an insight into their mechanisms, which is not only of theoretical interest but also of practical importance because it offers additional possibilities for searching new ways of controlling the properties of disperse systems.

IV. Conclusion

The development of procedures for controlling the dynamic state of disperse systems is tightly associated with the development of theories and models that describe the behaviour of disperse systems under dynamic conditions. The main rheological theories of solid phase–liquid disperse systems in flows are reviewed. Emphasis is given to the problems associated with the description of the properties of aggregated and non-aggregated suspensions, because the degree and character of structure formation are responsible for the bulk rheological properties of disperse systems. The theoretical views on the causes and conditions of the appearance of discontinuities, *viz.*, macroscopic inhomogeneities under structural deformation, are covered. The mechanism of the appearance of microinhomogeneities as discontinuities and the conditions of their healing were characterised for the first time by computer simulation methods. In a wide range of deformation rates, the evolution and elimination of inhomogeneities under vibrations are considered. The results of computer simulations of dynamics of disperse systems confirm many experimentally observed and theoretically substantiated features of the behaviour of disperse systems under dynamic conditions. Studies of these

features are of considerable importance not only because they provide the basis for the determination of the fundamental macroscopic and microrheological characteristics of these systems and elucidation of the relationship between these characteristics, but also because it is the controlled fluidity that is the most important factor for performing various heterogeneous chemical engineering processes (stirring, hydrotransport, catalysis, etc.).

Investigations of the dynamic state of disperse systems can help in revealing ways for providing dynamic aggregation stability and complete deaggregation of particles as the main condition for achieving the maximum fluidity of disperse systems with a decrease in the viscosity up to 8–11 orders of magnitude.

In studies of the ways and procedures for creating the maximum fluidity, it is necessary to use a combination of macro- and microrheological simulations taking into account intermolecular interactions, inertial and hydrodynamic effects under conditions of both continuous shear stress and a combination of this deformation with orthogonal oscillations and the addition of surfactants creating a structural-mechanical barrier on the particle surface. The parameters and conditions of the appearance of the latter require a theoretical description.

We thank E A Naumenko for help in performing computer simulations of disperse systems.

Abstract. Recent publications on the structures of crystalline water ices are surveyed. Interconversions of crystalline and amorphous ices are considered. Some hypotheses concerning the occurrence of high-pressure ices in nature are outlined. The bibliography includes 149 references.

I. Introduction

The properties of crystalline and amorphous water ices have been attracting steady interest of researchers for several reasons. First, water plays the most important role in biological processes and thus the knowledge of typical structures formed by water molecules may help elucidating the structures of water bound to proteins or other biological macromolecules. Second, water is one of the most abundant substances in the universe and thus investigations into potential states that can be adopted by water in the interstellar space or other orbs are of great interest. Third, studies of water are of general theoretical importance since they give insights into the common regularities of structure and polymorphism of various substances featuring tetrahedral coordination of molecules or atoms, the reasons underlying the existence of several amorphous forms of a substance and the regularities of phase transitions between them, the nature of pressure-induced amorphisation of crystals and solid-state crystallisation from an amorphous state and many other issues.

The present review concerns structural studies of crystalline water ices. We survey the data on the structures of crystalline forms of ice and transitions between them published over the last 10–15 years and consider related topics, in particular, amorphisation of crystalline ices and their crystallisation from amorphous phases. Some earlier papers are cited where appropriate. A comprehensive review of studies published before 1974 can be found elsewhere.¹

II. General remarks

At present, thirteen reliably established crystalline modifications of water ices are known (Fig. 1 and Appendix, numbering of the crystalline phases reflects the order of their discovery). These

Figure 1. The low-temperature part of the water phase diagram at pressures up to 2.5 GPa.

(1) The experimentally determined lines of stable phase equilibria, (2) the calculated and extrapolated lines of stable phase equilibria, (3) the experimentally determined and calculated lines of metastable phase equilibria, (4) the experimental curve² for the maximum rate of the transformation of ice III into ice IX within the region of stability of ice II and the curve for the transformation³ of metastable ice XII into stable ice VI, (5) the experimentally determined melting curves of metastable ices IV⁴ and XII,⁵ the bold dot indicates the region where ice XII was prepared for the first time⁶ by crystallisation from liquid, the second area of the existence³ of ice XII prepared by crystallisation of high-density amorphous ice (HDA, see Section III.6) is marked grey.

forms of ice can be reproducibly prepared using *ad hoc* techniques, they have been thoroughly characterised by spectroscopy and their crystal structures have been determined using X-ray or neutron diffraction. Some of the known crystalline modifications of ice are characterised by specific regions of the stability in the water phase diagram, whereas others (*viz.*, Ic, IV, IX and XII) occur exclusively as metastable states. It is of note that the recently discovered metastable ice XII can occur in two separate regions of the phase diagram.

In the structures of all known crystalline ices, each water molecule forms four hydrogen bonds directed towards vertices of an ideal or slightly distorted tetrahedron with neighbouring molecules. In all cases except for ice X, the H₂O molecules retain their integrity and act as donors of hydrogen atoms for two out of the four hydrogen bonds and as acceptors for two other bonds.

The normal-pressure crystalline phases (Ih, Ic and XI) are characterised by nearly ideal tetrahedral closest environment of water molecules. Meanwhile, in high-pressure phases (II, III, IX, V, IV, XII and VI), the oxygen atoms of neighbouring molecules occupy vertices of a distorted tetrahedron. The framework of hydrogen bonds becomes self-entangled starting from a pressure of ~ 0.5 GPa (ices IV and V), which means that it represents an integral network where at least some elementary H-bond cycles appear hooked to each other. At higher pressure, phases composed of two independent interpenetrating frameworks of hydrogen bonds are formed (crystalline ices VI, VII and VIII). Unlike self-entangled frameworks, these ices contain two interpenetrating non-linked H-bond networks. At a pressure of the order of 2 GPa or higher, nearly ideal tetrahedral coordination of water molecules is recovered (ices VII and VIII). Finally, at even higher pressures, the oxygen sublattice of ices VII and VIII is preserved but the hydrogen atoms are shifted towards the centres of the O—H $\cdots$ O bonds. Consequently, starting from ~ 50 GPa, the hydrogen atoms become evenly shared between the two neighbouring oxygen atoms and the molecular structure is transformed in a framework structure in crystalline ice X. Such a structure is maintained at pressures of up to 200 GPa, which is the highest value explored to date.

Protons in the crystalline water ices occupy the respective positions near the oxygen atoms in a regular or random way. In proton-ordered ices, the two neighbouring molecules involved in donor-type H-bonding and those two involved in acceptor-type H-bonding are defined unambiguously (in other words, the orientation of water molecules with respect to their closest neighbours is known). Two of the four possible positions of the H atoms near an O atom have occupancies close to unity (they are equal to unity in the case of complete ordering), whereas two other positions have occupancies close to zero (they are equal to zero in the case of complete ordering). In the case of proton-disordered ices, each of the four hydrogen bonds formed by a water molecule can serve simultaneously as both the donor and the acceptor such that four possible hydrogen positions around the respective oxygen atom have equal occupancies of 0.5. In a sense, water molecules in these proton-disordered ice modifications adopt arbitrary orientations with respect to their closest neighbours in the crystal structure. The situation with the occupancies of some hydrogen positions significantly differing from 0, 0.5 or 1 is referred to as a partial (dis)order. Ices II and VIII are completely proton-ordered; ice IX is partially proton-ordered; the proton-ordered ice XI has been obtained only as nanocrystallites embedded into a matrix of ice Ih, thus the extent of its proton-ordering cannot be reliably analysed; other ices are completely or partially proton-disordered.

Since water molecules preserve their integrity and form exactly two donor and two acceptor H-bonds with neighbouring water molecules in all but ice X water ices, the disordering of proton positions in the crystal structures of proton-disordered ices obeys the so-called Bernal–Fowler rules:⁷ (i) exactly two H atoms are located around each oxygen atom at a distance of the covalent bond; (ii) each hydrogen bond accommodates exactly one hydrogen

atom. A violation of the first rule gives rise to ionic defects (*i.e.*, the occurrence of H₃O⁺ or OH[−] ions instead of H₂O molecules); a violation of the second rule results in the Bjerrum defects (*i.e.*, the coexistence of two hydrogen atoms or a hydrogen vacancy along a hydrogen bond, also referred to as D- and L-defects, respectively).

Among the known ice polymorphs, several pairs of crystalline modifications having identical oxygen sublattices but differing from each other in the extent of the proton ordering can be distinguished. These include proton-disordered ices Ih, III and VII with their proton-ordered counterparts, ices XI, IX and VIII, respectively. Since orientations of water molecules relative to their closest neighbours within these pairs are different, these phases have different dynamical characteristics and, as a consequence, vibrational spectra. These differences are manifested in the IR, Raman and inelastic neutron scattering (INS) spectra.

Several water ices have close structural analogues among other crystalline substances built up of tetrahedrally coordinated atoms. In particular, lonsdalite (hexagonal diamond modification), wurtzite (ZnS) and high-temperature tridymite (SiO₂) are isostructural to ice Ih; diamond, silicon, germanium, grey tin, high-temperature cristobalite (SiO₂) and sphalerite (ZnS) are isostructural to ice Ic; high-pressure germanium and keatite (SiO₂) are isostructural to ices III and IX; the aluminosilicate framework of edingtonite Ba(Al₂Si₃O₁₀) is isostructural to one of two identical independent interpenetrating frameworks of ice VI. Note that Zn and S atoms in the frameworks of wurtzite and sphalerite alternate in positions occupied by the oxygen atoms in the corresponding ices Ih and Ic. In SiO₂ polymorphs isostructural to crystalline ices, H-bonded oxygen sublattice is replaced by similar frameworks of silicon atoms linked by covalent Si—O—Si bonds.

The discovery of a new crystalline phase of water, namely, the metastable ice XII, is probably the most outstanding recent achievement in the studies of crystalline water ices. The crystal structure of this phase, which has no analogues among substances with the tetrahedral coordination of atoms, has been determined; two regions of its stability in the water phase diagram have been established and the parallel crystallisation of ices IV and XII from amorphous high-density ice has been observed. In addition, the presence and extent of proton ordering in various water ices, the boundaries of their stability and metastability in the phase diagram as well as their thermodynamical parameters were specified in studies of the last decade. Phase transitions between ice polymorphs have been investigated. IR, Raman and INS spectra have been collected for all known ice phases. In parallel, vibrational spectra of various ices have been calculated theoretically using the lattice dynamics method. Finally, the molecular dynamics has been applied to simulate the existing and hypothetical crystalline water ices. The results of these studies are considered below.

III. Recent data on the structures and proton ordering of crystalline water ices. Phase transitions between crystalline ices

1. Ices Ih, Ic and XI

Hexagonal ice Ih, its proton-ordered low-temperature analogue, ice XI, and metastable cubic ice Ic constitute the group of normal-pressure (1 bar) crystalline water ices. Among these modifications, ice Ih, which is formed upon freezing of water at a pressure from 0 to ~ 0.2 GPa, is studied the best. Metastable ice Ic with the structure relating to that of ice Ih in the same way as the structure of diamond relates to that of lonsdalite can be prepared by deposition of water vapour on a cold ($163 < T < 183$ K) metal support,⁸ rapid cooling of emulsions composed of water microdroplets down to $150 < T < 190$ K (at a cooling rate of 10^6 – 10^7 K s^{−1}),⁹ freezing of water in capillaries^{10,11} (see below in this Section) and heating of quenched high-pressure crystalline^{12–18} (see Section III.8) or amorphous^{19–21} (see Sec-

tion III.6) water ices at a pressure of 1 bar. Irrespective of the preparation method, annealing of ice Ic initiates its irreversible conversion into ice Ih. The temperature of this transition depends on the heating rate and prehistory of the sample and lies in the range from 140 to 230 K.

The unit cell parameters a and c of ices Ih(H₂O) and Ih(D₂O) were measured²² by powder X-ray diffraction using synchrotron radiation in a wide temperature range from 10 to 265 K at a constant pressure of 100 Torr. The unit cell parameters of ice Ih(D₂O) were slightly larger than those of ice Ih(H₂O) in the whole temperature range. The a/c ratio was virtually independent of temperature indicating that the thermal expansion of ice Ih can be considered isotropic. The linear thermal expansion coefficients (α) of both ices Ih(H₂O) and Ih(D₂O) are negative below 75 K, which means that these phases expand upon cooling. Such a behaviour is also typical of other substances with the tetrahedral coordination of atoms.²² Below 100 K, the coefficients $\alpha_{\text{H}_2\text{O}}$ and $\alpha_{\text{D}_2\text{O}}$ are the same but the increase in $\alpha_{\text{D}_2\text{O}}$ above 100 K occurs faster than that of $\alpha_{\text{H}_2\text{O}}$.

The linear thermal expansion coefficients of ices Ih and Ic were also calculated theoretically using the TIP4P intermolecular interaction potential²³ with averaging over a large ensemble of possible proton configurations.²⁴ These calculations confirmed that the coefficients α for both ices Ic and Ih should become negative at low temperature. Similar calculations²⁵ for ices Ic and VII based on the Carravetta–Clementi potential²⁶ showed that $\alpha < 0$ for ice Ic at low temperature, whereas the linear thermal expansion coefficient is always positive for ice VII, which represents two independent interposed frameworks of ice Ic.

It is known that ice Ih is proton-disordered and this positional proton disorder persists upon cooling down to 0 K.⁷ Meanwhile, according to the third law of thermodynamics, only one thermodynamically stable structure with a specific arrangement of protons should exist at 0 K at any given pressure. Such a transition to the equilibrium structure cannot be realised for chemically pure water due to the vanishingly low orientational mobility of H₂O molecules in the crystal structure of ice Ih. Introduction of a minute amount of hydroxide anions into water results in the formation of defects distorting the framework of H-bonds, which facilitates the phase transition of the crystalline ice Ih to the proton-ordered state. Such a transition has indeed been observed at 72 K in calorimetric experiments and measurements of dielectric properties.²⁷ This new phase representing a proton-ordered low-temperature analogue of ice Ih was entitled²⁷ ice XI, since phases II–X had already been known to that moment.

The crystal structure of heavy ice XI(D₂O) doped with KOD was investigated using powder neutron diffraction.²⁸ High-resolution powder neutron diffraction was also applied to elucidate the structure of normal ice XI(H₂O) doped with KOH.²⁹ The results obtained were consistent with the orthorhombic structure corresponding to the space group $Cmc2_1$ with the protons ordered into a ferroelectric phase. It has to be mentioned that the same structure was predicted earlier based on a theoretical analysis.^{28,29} Nevertheless, the fraction of the ordered phase as revealed in the neutron diffraction studies^{28,29} was low, and the major structural information in these measurements related to disordered ice Ih. Thus, the cited studies left open the question on the structure of ice XI. Furthermore, a series of theoretical studies of the ordered structures with a framework of water molecules based on ice Ih^{30–32} claimed a structure corresponding to the space group $Pna2_1$ with the antiferroelectric ordering of protons and eight water molecules per unit cell to be the most stable. Therefore, the results of neutron diffraction studies^{28,29} were contested and thus the character of the proton ordering in the crystal structure of ice XI remained a subject of debate for a long time.

Recently, Jackson and Whitworth,^{33,34} using a newly developed method of temperature-stimulated depolarisation, which is based on the generation of an electric current pulse in the transition of a polarised ice into the disordered state upon heating,

have shown that the proton ordering in the structure of ice XI corresponds to a ferroelectric with a non-zero dipole moment along the c axis and the zero dipole moment in the ab plane. Further investigations into the structure of ice XI(D₂O) using high-resolution powder neutron diffraction³⁵ and of ice XI(H₂O) using neutron diffraction on a quasi-single crystal³⁶ obtained from ice Ih that underwent the phase transition Ih $\rightarrow$ XI and contained about 37% of ice XI, also confirmed the orthorhombic structure of ice XI with the space group $Cmc2_1$. Neighbouring hexagonal layers in this structure are somewhat shifted with respect to each other, which probably plays the decisive role in the stabilisation of the ferroelectric structure. It has been shown that the diffraction pattern of ice XI manifests the (131) reflection, which is forbidden for ice Ih (in the corresponding orthorhombic setting).

The formation of ice XI from a single crystal of Ih(D₂O) grown from a 0.1 M KOD solution kept for 520 h at 62 K and for 88 h at 68 K was also studied by neutron diffraction.³⁷ [The temperature of transition to ice XI for KOD-doped Ih(D₂O) was 76 K.] The extent of conversion was monitored by the intensity of the (131) reflection, which first increased and then reached a plateau. The degree of conversion of ice as a function of time and the ultimate degree of conversion at $t \rightarrow \infty$ (i.e., 38.2% at 62 K and 47.9% at 68 K for the 0.1 M KOD solution in D₂O used to grow the single crystal of Ih) were determined. The results obtained can be explained by the emergence of numerous nucleation sites of ice XI inside the single crystal of Ih (most probably, around the OD[−] ions) followed by growth of ordered domains of ice XI around these sites. The characteristic size of ice XI domains depending on temperature, duration of storage and KOD concentration in the solution did not exceed³⁷ 60 Å under the conditions used. However, it remains unclear, why the transition stopped very far from the complete conversion of the samples into ice XI with randomly oriented contacting domains. It is of note that storage of the KOD-doped ice Ih for 40 h at 51 K yielded no detectable amounts of ice XI.

The crystal structure of ice Ih has two different mutual orientations of H-bonded water molecules lying in adjacent hexagonal layers (Fig. 2*a,b*) and two different orientations of H-bonded water molecules within the same hexagonal layer (Fig. 2*c,d*). Due to the electrostatic repulsion, the energy of the molecular pairs depicted in Figs 2*b* and 2*d* is higher than that of the pairs depicted in Figs 2*a* and 2*c*, respectively. Within a model³⁸ proposed for ices Ih and Ic, the latter type of bonds is

Figure 2. Types of hydrogen bonds in ices Ih and Ic: strong (*a*) and weak (*b*) hydrogen bonds between the hexagonal layers of ice Ih; strong (*c*) and weak (*d*) hydrogen bonds within a hexagonal layer in ices Ih and Ic.³⁸

referred to as strong bonds, whereas the former type of bonds is referred to as weak bonds with the respective difference in the force constants used for their description. The application of this model to the interpretation of INS spectra of various crystalline ices is discussed in Section IV.

Within the model of two force constants, a structure with the maximum fraction of strong H-bonds has to be the most stable at a given geometry of the oxygen framework. Kirov³⁹ suggested a proton distribution over the structure of ice Ih containing only strong H-bonds. In this structure, the positions of protons are disordered in the hexagonal layer but are ordered along the *c* axis.³⁹ Analogous models comprising only strong H-bonds have also been suggested for ice Ic.^{40, 41} One of them is disordered along the direction [111] of the cubic lattice but contains ordered layers; another represents a defectless axial twin with a step-like proton ordering. However, it has to be noted that the proton-ordered ice Ic, even if observed, existed only as partially polarised thin films⁴² on a support inducing this polarisation (see below in this Section), and the real proton-ordered crystal structure of ice XI comprises three weak H-bonds per strong H-bond. Thus, as mentioned above, it is the change in the geometrical parameters, in particular, relative shifts of hexagonal layers, that plays the decisive role in the stabilisation of the proton-ordered structure of ice XI rather than the fraction of strong bonds (calculated within the model of two force constants).^{35, 36}

It has been shown that partial proton ordering in an ice structure leading to its polarisation can be caused by surface effects. In particular, proton ordering resulting in a polarised structure was observed in thin films of ice Ih (1–80 monolayers) prepared by vacuum deposition of water vapour on a Pt(111) support at 137 K.⁴³ The strains occurring in the first monolayer due to mismatch between the cell parameters of platinum and ice Ih are relieved already at the fifth monolayer. The preferred orientation of the first H₂O monolayer lying on the Pt(111) crystal face induces the polarised ordering in subsequent layers. The extent of the orientation order decreases with an increase in the distance to the platinum surface (by a factor of ~ 2.7 at a distance of 30 monolayers).

Iedema *et al.*⁴² reported partial polarisation of thin films of ice Ic (with thicknesses of 2000 to 100 000 monolayers) prepared similarly by the deposition of water vapour on a Pt(111) support at temperatures from 135 to 145 K. The degree of ordering in the films was 0.2% but it was independent of the distance to the support, in contrast to the data cited above.⁴³ The oxygen atoms of the H₂O molecules were directed away from the support. In both studies^{42, 43} it was considered that the partial ordering during ice crystal growth emerged due to interactions between the water molecules at the interface with the support or with the surface of the growing crystal.

Recently, the process of water freezing in narrow pores of glassy silicates, which is strongly affected by hydrophilic pore walls, has been elucidated. It was found¹⁰ that water can be overcooled down to –18 and –27 °C in completely filled pores with diameter of 50 Å and in half-filled pores (which corresponded roughly to three molecular layers adsorbed on the pore walls), respectively. Remarkably, no indication of crystallisation down to –196 °C was observed in quarter-filled pores, which corresponded to an H₂O monolayer on the wall. The temperature of nucleation of the crystalline phase depends on both the degree of pore coverage with water and the pore size: it decreases with a decrease in the pore size, *i.e.*, water can be overcooled to a lower temperature in a narrower pore.¹¹ In addition, in sufficiently narrow pores, ice Ih crystallises in the case of partial filling, whereas ice Ic crystallises in the case of complete filling.^{10, 11}

2. Ice II. Phase transition Ih → II

The formation of crystalline water ices II–X and XII requires elevated pressures, therefore, these phases are referred to as high-pressure ices.

Many of the high-pressure ices can be retained in the metastable state even at 1 bar. To this end, an ice sample prepared at the corresponding high pressure should be cooled to liquid nitrogen temperature and this temperature should be kept during the pressure release down to atmospheric pressure. Such metastable states of water are referred to as quenched ices. It is for recovered forms at atmospheric pressure that the crystal structures of various high-pressure ices have been determined. However, these measurements give no information on the changes in structural parameters (such as the extent of proton ordering, volume compressibility, tensor of elasticity constants, *etc.*) as a function of pressure and temperature. Recently, the structures of various crystalline ice phases have been studied at different pressures and temperatures within the regions of their thermodynamic stability and/or metastability.

The crystal structure of ice II was determined for the first time by Kamb⁴⁴ in 1964 using single-crystal X-ray diffraction on a recovered sample at atmospheric pressure. Ice II possesses a rhombohedral structure with hexagonal columns composed of alternating six-membered rings in the chair conformation differing from each other in the degree of flattening (Fig. 3) along the *c* axis of the hexagonal unit cell or along the direction [111] in the rhombohedral unit cell as the main structural elements. The more corrugated rings comprise water molecules with the O(1) atoms, whereas more flattened rings are composed of the water molecules with the O(2) atoms. Each column is surrounded by six other columns of the same type going parallel but shifted by 1/3 translation along the *c* axis. The cavity inside the columns has a diameter of about 3 Å, which thus can accommodate helium or neon atoms or hydrogen molecules.⁴⁵ The resultant non-stoichiometric solid solutions of inert gases or hydrogen in ice II matrix can also be considered as host–guest hydrates with the framework of ice II as the host and gas molecules as guests.

The presence of a dissolved gas changes substantially the thermodynamic parameters of ice. For instance, crystallisation of ice from water at a hydrostatic pressure of 0.28–0.50 GPa in an atmosphere of helium upon cooling to the freezing point of 250–270 K gives rise to ice II-based helium hydrates rather than to ices III and V, which are thermodynamically stable in this region of the phase diagram (see Fig. 1).^{45–47} The crystal structure of the helium hydrate with ice II-derived water framework, which

Figure 3. A hexagonal layer in ice II (the projection perpendicular to the *c* axis). Helium atoms that can penetrate into the hexagonal channels in ice II structure are also shown.

is formed under the above conditions, has been determined using powder neutron diffraction.⁴⁷ Like ice II, this helium hydrate is proton-ordered and this is the only known case when a proton-ordered crystalline framework of water molecules is formed directly from the liquid phase. The crystal structure of the gas-free ice II in the region of its thermodynamical stability has been determined for the first time by Lobban *et al.*⁴⁸ also using powder neutron diffraction; the results obtained made it possible to analyse the influence of absorbed gas on the geometry of the water framework of ice II.

Helium atoms in the hexagonal channels of ice II experience repulsion from the deuterium atoms D(4) at the oxygen atoms O(1) constituting the corrugated rings (see Fig. 3). As a result, helium atoms occupy positions closer to the flattened ring rather than exactly in the centre between the flattened and the corrugated rings within the unit cell of the respective hydrate (see Fig. 3).⁴⁷ The repulsion of the He atoms from the O(2) atoms of the flattened rings results in the increase in the diameter of these rings as compared to the structure of helium-free ice II.⁴⁸ Meanwhile, the diameter of the corrugated rings remains virtually unchanged. The inclusion of helium atoms into ice II structure results in the opposite changes in the unit cell parameters a and c .⁴⁸ The distance between walls of adjacent channels in the structure of the hydrate decreases due to the increase in the diameter of the flattened rings. Meanwhile, the distance between the axes of the channels somewhat increases upon inclusion of He, which results in the increase in the parameter a . In contrast, the parameter c somewhat decreases since the increase in the diameter of channels should be accompanied by the reduction in their lengths.

Upon an increase in pressure, the diameter of the flattened hexagonal rings changes insignificantly, whereas that of the corrugated rings decreases in both the structures of helium-free ice II and ice II-derived helium hydrate.⁴⁸ Upon an increase in pressure from 0.28 GPa to 0.48 GPa, the distance between the axes of the channels decreases. As anticipated, the volume compressibility of He-containing ice II is smaller than that of its helium-free prototype. An estimate⁴⁸ of the isothermal volume compressibility of pure ice (D_2O) at 200 K (14.8 GPa) is in good agreement with the value of 14.4 GPa obtained earlier⁴⁹ based on acoustic measurements for ice II(H_2O) at 237.5 K.

The structure of the water framework in ice II (free of dissolved helium) was simulated within the density functional theory using the PW91 functional at different temperatures and pressures.⁵⁰ The calculated values of density, volume compressibility, unit cell parameters and atomic coordinates were in good agreement with the experimental results.^{44, 48, 49} The same simulations showed that the decrease in the density of ice II upon an increase in pressure is due to a decrease in the distance between the axes of the hexagonal channels, which is also in accord with the experimental observations.⁴⁸

In an earlier study on the structure determination of quenched ice II, Kamb⁴⁴ noted that this structure can be derived from that of ice Ih by preserving some of the hexagonal channels of ice Ih while rearranging the system of H-bonds between them. This is accompanied by certain increase in the diameter of the hexagonal rings with a concomitant decrease in the distance between the axes of these channels, which gives rise to an increase in the density of the resultant framework. A scheme of such a conversion from the structure of ice Ih to that of ice II is depicted in Fig. 4.⁵¹

The transition of ice Ih to ice II under hydrostatic compression in an atmosphere of helium was studied experimentally using neutron diffraction.⁵² The incorporation of helium atoms into ice Ih starts at 120 K at a pressure interval from 0.25 GPa to 0.31 GPa. This results in an expansion of the crystal lattice around the inserted helium atoms, which manifests itself in an increase in the distance between the (h h 0) planes. Heating of the sample to 180 K at 0.31 GPa is accompanied by an abrupt phase transition of ice Ih with dissolved helium into ice II-based helium hydrate. Due to the large difference in densities of ices Ih and II, a single crystal of Ih converts into polycrystalline powder of ice II-based

Figure 4. Rearrangement of the framework of hydrogen bonds of ice Ih (a) to ice II (b). In both cases, projections along the c axes of the hexagonal lattices are given. The hexagonal channels in ice Ih that are retained upon the transition Ih $\rightarrow$ II are marked grey.

helium hydrate. It is of note that the positional proton disorder in the structure of ice Ih is preserved until completion of the transition into He-containing ice II.

3. Ices III and IX. Transition III $\rightarrow$ IX

The structures of ices III and IX at pressures from 0.28 to 0.30 were first determined by Londono *et al.*⁵³ using powder neutron diffraction. Later, powder neutron diffraction was applied to refine the structure of ice III in different points in the region of its thermodynamical stability.⁵⁴ Ices III and IX possess identical oxygen frameworks but differ from each other in the extent of proton ordering (Fig. 5). Gradual ordering of proton positions upon cooling of ice III compressed to 0.23 GPa in a temperature range from 208.0 to 164.5 K was established back in 1968 by dielectric susceptibility measurements.² The maximum change in the dielectric susceptibility as a function of temperature (which corresponded to the maximum ordering) was observed at ~ 173 K. Meanwhile, there was no indication of any changes in the oxygen framework. Thus, ice IX represents a low-temperature proton-ordered analogue of ice III.² It is of note that quenched ice III cannot be recovered at atmospheric pressure using the standard method since it always undergoes a phase transition to ice IX upon cooling. In the crystal structure of recovered ice IX determined⁵⁵ at atmospheric pressure using single-crystal neutron diffraction, the mean occupancy of the least occupied hydrogen position was as low as 4%. The change in entropy due to the phase transition III $\rightarrow$ IX was found⁵⁶ to be $1.34 \pm 0.29 \text{ J K}^{-1} \text{ mol}^{-1}$. Meanwhile, the theoretical value of the entropy change assuming the complete proton disorder in ice III and complete order in ice

Figure 5. The structures of proton-disordered ice III (a) and its proton-ordered analogue, ice IX (b). The projection is along the c axis. All possible positions of the hydrogen atoms in ice III are shown; their occupancies are close to 0.5. The atoms O(1) forming helices along the c axis are marked black, whereas the atoms O(2) linking the helices into a united framework are marked grey.

IX should be $3.37 \text{ J K}^{-1} \text{ mol}^{-1}$ (Ref. 54), which is 2.5 times larger than the above experimental value (see Ref. 56). This large discrepancy cannot be explained solely by a partial proton disorder of ice IX, therefore, it was suggested that the structure of ice III is partially proton-ordered. The correctness of this suggestion was confirmed experimentally by crystallographic studies of ice III.^{53, 54}

The mean occupancies of the least occupied proton position in the crystal structure of ice IX at 0.28 GPa and at atmospheric pressure are nearly the same (4%).⁵³ No substantial changes in the extent of positional proton order of ice III within the region of its thermodynamical stability were observed (the occupancy of the least occupied position was slightly larger than 40%).⁵⁴ However, the change in the configurational entropy due to the transition III $\rightarrow$ IX estimated from the occupancies of the proton positions in ices III and IX also exceeds the experimental value. Therefore, ΔS corresponding to this phase transition is not governed exclusively by the change in the configurational entropy due to different proton ordering in these phases, some other factors are also involved.⁵⁴

In addition to the proton ordering, cooling of ice III is accompanied by changes in the unit cell parameters a and c and, consequently, the unit volume. It is of note that the relative decrease in the volume of ice due to the transition III $\rightarrow$ IX is an order of magnitude larger than that due to analogous transitions into proton-ordered phases with the conservation of the oxygen framework, *i.e.*, Ih $\rightarrow$ XI and VII $\rightarrow$ VIII.⁵³ The c/a ratio in ice III is larger than that in ice IX.^{53, 54} Although the unit cell parameters a and c do not depend on the sample prehistory, both a decrease in temperature and an increase in pressure, on the whole, result in the anisotropic compression of ices III and IX with the parameter c decreasing faster than a . In addition, ice IX anisotropically expands upon pressure release to atmospheric pressure. In the crystal structures of ices III and IX, water molecules with the oxygen atoms O(1) form helices along the c axis, whereas water molecules with the oxygen atoms O(2) link the adjacent helices into a united framework (see Fig. 5). The ease of compression and stretching of the helices along their axes explains the lower rigidity of the parameter c .⁵⁴

4. Ice V

In contrast to the transition of proton-disordered ice III into nearly completely proton-ordered ice IX, which does not violate any symmetry operations and thus preserves the space group $P4_12_12$, the proton ordering in the structure of ice V has to result in lower space symmetry of the crystal structure. According to structural studies of ice V at different temperatures and pressures (in particular, within the region of its thermodynamical stability)

performed for the first time by Lobban *et al.*,⁵⁴ the degree of proton ordering in ice V generally increases upon cooling or compression. Nevertheless, no complete ordering is achieved. Thus, neither the aforementioned lowering of the space symmetry occurs, nor consequently changes in the space group are observed.⁵⁴ The crystal structure of recovered ice V at atmospheric pressure⁵⁷ corresponds to the same space group $A2/a$ as at 0.4–0.5 GPa.⁵⁴

The $\text{O} \cdots \text{O} \cdots \text{O}$ angles in the crystal structure of ice V (from 86° to 132°) deviate strongly from the bond angle $\text{H} - \text{O} - \text{H}$ of a free water molecule (*ca.* 105°), which results in bending of the $\text{O} - \text{H} \cdots \text{O}$ hydrogen bonds. Straight hydrogen bonds are energetically more favourable than bent ones. Therefore, the fraction of H_2O molecules occupying unfavourable positions with strongly bent H-bonds in the crystal should decrease upon cooling thus increasing the degree of the orientational order of the structure.

On the one hand, an increase in pressure deforms the water framework (further distortion of the hydrogen bonds), while, on the other hand, the density of the phase increases, *i.e.*, the volume per water molecule in the crystal structure diminishes. The latter factor enhances the contribution of van der Waals repulsion, which tends to orient adjacent molecules that are not linked through H-bonds. Apparently, this factor is responsible for the proton ordering upon an increase in pressure, since the energy change due to the former factor is insignificant, as evidenced by theoretical estimates.⁵⁴

The dielectric relaxation spectra⁵⁸ of ice V agree well with the observed proton ordering. The increase in the dielectric susceptibility of ice V upon cooling from 266 to 133 K amounts to 77% of the value calculated from the decrease in both volume and internal energy. Johari and Whalley⁵⁸ assign this difference to partial orientational ordering of H_2O molecules upon cooling.

Specific endothermic effects observed in the differential scanning calorimetry (DSC) curves (heating rate, 30 K min^{-1} at atmospheric pressure) for samples of metastable ice V subjected and not subjected to annealing at sufficiently high temperature can also be interpreted as a kinetic activation of the orientational transition proton order–disorder.⁵⁹ When ice V is cooled at a certain rate (say, 30 K min^{-1}), the orientational relaxation time required to achieve the equilibrium state becomes, starting from a specific threshold temperature, longer than the duration of the experiment. This results in kinetic freezing of the excessive proton positional disorder at low temperature. In subsequent heating at the same rate, the response of the system to heating is somewhat delayed since the orientational mobility of water molecules is initially too low, *i.e.*, at any given temperature T , the extent of proton disorder in the system is higher than the equilibrium value. With a further increase in temperature, the orientational mobility of molecules increases and, starting from a certain temperature, becomes sufficient to enable complete relaxation to the equilibrium degree of disorder. This is equivalent to the reactivation of the transition order–disorder related to the positions of protons in the structure of ice V.

The actuation of the orientational relaxation to the thermodynamic equilibrium is manifested in the DSC curves⁵⁹ registered at a heating rate of 30 K min^{-1} as an endothermic effect with a leading edge at 130 K and a width of 20 K for samples of ice V not subjected to annealing at sufficiently high temperature or with a leading edge at 125 K and a width of also around 20 K for preannealed samples or samples being heated for the second time. The orientational relaxation times τ for the structure of ice V at atmospheric pressure estimated from the DSC curves⁵⁹ are about 70 s and 7 s at 130 K and 140 K, respectively. These values are in accord with other estimates of τ for ice V at pressures of 0.50 GPa⁵⁴ and 0.61 GPa.⁵⁸

5. Ices VI, VII, VIII and X and transitions between them

General features of the crystal structures of ices VI, VII and VIII (including the extents of the proton ordering therein) in the

Figure 6. The structure of one of two identical independent interpenetrating frameworks of ice VI.

(a) The chain of water molecules stretched along the c axis representing the main structural unit in ice VI, (b) the pattern of assembly of the chains into the united framework.

Chains forming the second framework (not shown here) pass through the cavities of the first framework. All possible positions of the hydrogen atoms are shown; the occupancies are equal to 0.5.

regions of their thermodynamical stabilities were determined in the mid-1980s.^{60–62} Ice VI is composed of two identical independent interpenetrating water frameworks that represent structural analogues of the aluminosilicate framework $(\text{Al},\text{Si})\text{O}_2$ found in the mineral eddingtonite (Fig. 6).^{60,63} According to the available data,⁶⁰ the structure of ice VI is completely proton-disordered throughout the region of its thermodynamical stability, no indication of any proton ordering has been revealed upon cooling. The crystal structures of ices VII and VIII can be described as two interposed frameworks of ice Ic. As a first approximation, one can consider that the oxygen atoms occupy the sites of a body-centred cubic (bcc) lattice of ice VII. Ice VII is completely proton-disordered,^{60,61} whereas, in contrast, ice VIII is completely proton-ordered.^{60,62} In the structure of ice VIII, the dipole moments of all molecules of the two independent frameworks of ice Ic are oriented along the directions $[001]$ and $[00\bar{1}]$ of the tetragonal lattice. This results in the compensation of the dipole moments of both the independent frameworks in any unit cell of ice VIII. The interaction of molecules with oppositely oriented dipole moments gives rise to a relative shift of the frameworks along the c axis by $0.27 \text{ \AA}$, which slightly distorts the bcc packing of oxygen atoms. Due to the shift, two distances between any oxygen atom and its four non-H-bonded neighbours appear longer ($3.32 \text{ \AA}$) and two appear shorter ($2.74 \text{ \AA}$) than the other four distances with the H-bonded O atoms ($2.89 \text{ \AA}$).^{60,62} Ices VI, VII and VIII can be considered as self-clathrates owing to the presence of two interpenetrating water frameworks with no common hydrogen bonds in their structures.

In contrast to the transition III $\rightarrow$ IX (see Section III.3), the transition between ices VII and VIII is clear and reversible, the conversion VII $\rightarrow$ VIII occurring at a temperature about 10 K lower than the reverse conversion VIII $\rightarrow$ VII.^{60,64} Densities of ices VII and VIII at identical temperatures in the region of the transition are very similar.⁶⁰

According to data from powder neutron diffraction,^{60,62} the O–D covalent bond lengths and D–O–D bond angles in water molecules constituting ice VIII ($0.97 \text{ \AA}$ and $\sim 105^\circ$, respectively) are close to those in a free molecule¹ ($0.958 \text{ \AA}$ and 104.5° , respectively). At the same time, refinement of the structure of ice VII using the neutron diffraction data under assumption of oxygen atoms occupying sites of the bcc lattice yields unrealisti-

cally short O–D distances of 0.89 or $0.943 \text{ \AA}$ (see Refs 60, 61) and unrealistically large D–O–D angles of 109.5° . This was rationalised as disordering of the equilibrium positions of either oxygen atoms around the sites of the bcc lattice with a deviation $\delta(\text{O})$ ⁶⁰ or deuterium atoms around the positions (x,x,x) ⁶¹ with a deviation $\gamma(\text{D})$. Refinement of these models afforded more realistic O–D bond lengths and D–O–D bond angles; however the best-fit deviations $\delta(\text{O})$ and $\gamma(\text{D})$ did not exceed the respective thermal vibration amplitudes.^{60,61} Therefore, several new attempts aimed at the redetermination of the crystal structures of ices VII and VIII have been undertaken.

Nelmes *et al.*⁶⁵ elucidated the structures of ices VII and VIII at identical P and T with pressures ranging from 3.3 to 20.6 GPa and in temperature intervals lying between the transitions VII $\rightarrow$ VIII and VIII $\rightarrow$ VII (*i.e.*, under the conditions admitting the coexistence of both phases) using neutron diffraction. For ice VII, the atomic parameters were refined within three different models of deviations of O atoms from the sites of the bcc lattice: (i) six possible positions for a deviation along the family of symmetrically related directions $\langle 100 \rangle$, (ii) twelve positions for a deviation along the family of directions $\langle 110 \rangle$ and (iii) two sets of four positions forming a regular tetrahedron for a family of directions $\langle 111 \rangle$ or $\langle \bar{1}\bar{1}\bar{1} \rangle$. For the D atoms, three different models of deviations from the equilibrium positions perpendicular to the directions $\langle 111 \rangle$ were also considered: (i) three positions $(x+u, x, x)$, $(x, x+u, x)$ and $(x, x, x+u)$, where $u = \gamma/\sqrt{2}a$; (ii) three positions $(x-u, x, x)$, *etc.* and (iii) six positions $(x+v, x-v, x)$, *etc.*, where $v = \gamma/\sqrt{6}a$, a is the cubic lattice parameter. After the refinement of atomic positions, those combinations of possible O and D sites were chosen that gave the O–D distance and D–O–D angle closest to the mean values for ice VIII at the same P and T . The model of disordering of O atoms around the sites of the bcc lattice along the directions $\langle 111 \rangle$ and of D atoms over three positions $(x+u, x, x)$, *etc.* provided the maximum likelihood. Within this model, the mean O–D bond length [$0.977(7) \text{ \AA}$] and the D–O–D bond angle [$107(1)^\circ$] in the structure of ice VII at 5.1 GPa appeared very similar to the respective values in the structure of ice VIII ($0.97 \text{ \AA}$ and 107.3° , respectively). Due to the deviations of O positions from the sites of the bcc lattice, the structure of ice VII reveals two types of hydrogen bonds with lengths of ~ 2.75 and $\sim 2.93 \text{ \AA}$.⁶⁵ With an increase in pressure to 20.6 GPa , the O–D bond lengthens to $0.98 \text{ \AA}$ (ice VIII, $230\text{--}250 \text{ K}$) and $0.99 \text{ \AA}$ (ice VII, $260\text{--}280 \text{ K}$).⁶⁵

Systematic investigations into the structure of ice VIII using powder neutron diffraction at a pressure ranged from 2 GPa to 10 GPa at 265 K confirmed^{66,67} the tetragonal crystal structure with one independent oxygen and one deuterium atoms in the positions $(0, 1/4, z)$ and $(0, y, z)$, respectively. Furthermore, it was found that the O–D covalent bond linearly elongates with an increase in pressure and the relative shift ε between the two independent frameworks of hydrogen bonds decreases with an increase in pressure (rapidly and non-linearly in the range from 2 GPa to 3 GPa and linearly in the range from 3 GPa to 10 GPa).

Ice VIII is thermodynamically stable above 2 GPa . However, at temperatures below 125 K , the ice VIII structure is retained with pressure release. It was established that many properties of this phase (in particular, positions of bands in the Raman spectra⁶⁸) change non-linearly in the pressure range from 2 GPa to atmospheric pressure. The same is true for the frequencies of translational vibrations revealed in INS⁶⁸ and IR spectra.^{68,69} Neutron diffraction studies of ice VIII at 85 K at a pressure from 7 GPa to 0 GPa demonstrated⁶⁸ that this non-linearity was due to a drastic increase in the relative shift ε between the independent water frameworks in the structure of ice VIII with a decrease in pressure owing to a weakening of the electrostatic interaction between them. For a constant temperature of 85 K , the non-linear increase in ε with an increase in pressure starts at 7 GPa and ceases at $\sim 1 \text{ GPa}$.⁶⁸ As mentioned above, at 265 K , this transition starts

between 3 GPa and 2 GPa but is interrupted at a lower pressure by the subsequent transition VIII $\rightarrow$ VI.^{66, 67} Besson *et al.*⁶⁸ explained this abrupt weakening of the electrostatic interactions between the independent water frameworks in the structure of ice VIII with a decrease in pressure by a respective drastic change in the charges on the O and D atoms, which should give rise to strengthening of the covalent O–D bond and, respectively, to its shortening. Indeed, according to the available experimental data, the O–D bond length in the structure of ice VIII decreases with a reduction of pressure.⁶⁸

In contrast to ice VIII, the quenched form of ice VII (like that of ice III) cannot be recovered at atmospheric pressure by the standard methods, since it always transforms into the ordered ice VIII upon cooling. This transition occurs at about 273 K at a pressure from 2 GPa to 15 GPa. Notwithstanding, a new low-temperature metastable form of ice VII existing within the region of stability of ice VIII has recently been discovered; this can be prepared by isothermal compression of various crystalline ices or high-density amorphous ice (HDA) below 150 K. Quenched ice VII can be recovered at atmospheric pressure from this form by pressure release at low temperature.

This low-temperature metastable form of ice VII is often referred to as ice VII'. This form has been prepared for the first time by isothermal compression of ice Ih at 77 K (see Ref. 70). First, the transition Ih $\rightarrow$ HDA occurs at 1.0 GPa (it is considered in detail below in Section III.6 devoted to amorphous ices), then HDA converts into ice VII' at $\sim$ 4 GPa. Ice VII' transforms into ice VIII upon isobaric heating. Different ice phases were identified by Raman spectroscopy.

A transition of ice VI(D₂O) into ice VII' was also observed.¹² Ice VI was prepared by cooling liquid D₂O down to 300 K at 1.5 GPa. Then the temperature was further lowered to 95 K and ice VI was compressed to 5.4 GPa. During compression, an abrupt increase in pressure was observed at $P = 3.8$ GPa, which can be interpreted as a transition into a new phase. According to neutron diffraction data, this phase has a structure of ice VII, which is conserved after the isothermal (at 100 K) release of pressure down to atmospheric pressure. A neutron diffraction study of recovered ice VII' at $P = 1$ bar confirmed that this is identical with ice VII. Storage of ice sample at atmospheric pressure at 77 K did not result in any structural changes, as was also evidenced by neutron diffraction.¹²

The compression of ice II at low temperatures also affords a metastable phase with the structure of ice VII.⁷¹ In contrast to ice VII' prepared from ice VI, diffraction patterns of ice VII' samples prepared from other ices revealed some features not typical of pure ice VII. Meanwhile, the IR and Raman spectra of the differently prepared ice VII' samples were identical.^{70, 71}

Song *et al.*⁷¹ determined the boundaries of the metastability region of the low-temperature phase VII'. In that study, ice VII' was produced by isothermal compression of ices II and VI to 4–10 GPa below 120 K. Ice phases were identified by IR spectroscopy. The compression of ice VI in the temperature range of 200–273 K leads to a transition into ice VIII at 1.9–2.1 GPa. On the other hand, no conversion into ice VIII is observed upon isothermal compression of ice VI at $T < 150$ K, which is near the boundary between the stability regions of ices VI and VIII as estimated by the extrapolation of its experimentally established high-temperature part. Further increase in pressure induces the transition into ice VII'. The pressure of the transition VI $\rightarrow$ VII' increases with a decrease in temperature: from 2.8 GPa at 120 K to 7.9 GPa at 40 K. Similar trends were also reported for the compression of ice II (see Ref. 71) and HDA.⁷⁰ Further increase in pressure at a temperature below 100 K results in the transformation of ice VII' prepared by the method described above into ice VIII at 30 GPa irrespective of temperature. The isobaric heating of ice VII' also induces the transition into ice VIII, the temperature range of this transition is from 10 to 20 K, and the temperatures of

the start and completion of this transition decrease with an increase in pressure. Thus, metastable ice VII' exists in the pressure range from 2.8 GPa to 30 GPa at temperatures below 180 K.

The temperature-induced transition of ice VII' into the ordered state proceeds⁷¹ due to the activation of the orientational mobility, which allows rearrangement of water molecules into ice VIII, *i.e.*, the phase with a higher thermodynamical stability. The VII' $\rightarrow$ VIII transition upon isothermal compression at temperatures below 100 K is due to rotational tunneling of water molecules, because their rotational mobility is frozen under the conditions indicated. The probability of a tunnelling jump is determined by the lengths of the hydrogen bonds, which strongly depend on pressure and are virtually independent of temperature under the conditions considered. Thus, the pressure of the transition VII' $\rightarrow$ VIII initiated by the isothermal compression at $T < 100$ K is also virtually independent of temperature.⁷¹

With an increase in pressure, the structures of ices VII and VIII gradually change, which finally results in the formation of a new crystalline framework phase, *viz.*, ice X, where the oxygen atoms form a bcc lattice (as in the structure of ice VII) with hydrogen atoms residing exactly in the middle between the respective oxygen atoms.

In the structures of ices VII and VIII, the distances between oxygen atoms both connected and not connected by H-bonds decrease with an increase in pressure. This impedes rotation of water molecules due to, first, strengthening of the H-bonds and, second, steric repulsion of non-H-bonded adjacent oxygen atoms. Therefore, an increase in pressure suppresses orientational mobility of water molecules as regards their rotation around the oxygen atoms. In parallel, another mechanism of proton positional disordering is becoming increasingly important. The approach of the oxygen atoms linked by the O–H $\cdots$ O bonds decreases the distance between two minima of the potential energy corresponding to two possible positions of an H atom along this bond. Simultaneously, the barrier height between them is decreased thus increasing the frequency of proton tunnelling transitions between these two minima. In the case of proton-ordered ice VIII, this should bring about disordering of proton positions, *i.e.*, to a transition into ice VII. In addition, such transitions lead to the dissociation of water molecules to form defects, such as H₃O⁺ and OH[–]. When the probability of occurrence of a proton exactly in the centre of the respective O $\cdots$ O bond becomes equal to those in the minima of the potential energy along this hydrogen bond, ice VII transforms into a new form with symmetric hydrogen bonds, *viz.*, ice X. With further shortening of the distance between the oxygen atoms, the probability density of the proton localisation in a given point will have a single maximum at the centre of the bond. Furthermore, the two potential energy minima along the O–H–O bond coalesce, which all the more retains the symmetry of the H-bond.

The idea that the O–H $\cdots$ O hydrogen bond should become symmetric with a single potential energy minimum at an elevated pressure was proposed more than 30 years ago.⁷² An alternative definition of the symmetric hydrogen bond was suggested: a hydrogen bond is considered symmetric provided that the distribution function of proton positions along the hydrogen bond has the only maximum exactly at its centre.⁷³ The structures with two potential energy minima but one maximum of the proton distribution function exactly at the centre of the O $\cdots$ O bond are referred to as proton-disordered symmetric ices, whereas those with the single potential energy minimum at the centre of the hydrogen bond are referred to as proton-ordered symmetric ice.⁷⁴

The sequence of structural changes occurring with ices VII and VIII with an increase in pressure described above was fully supported by quantum-chemical calculations.^{74–76} In the calculations, the molecular dynamics method was used with atomic nuclei treated within the quantum mechanical approximation.

The simulation box contained sixteen water molecules. The simulation was performed in the *NPT* ensemble.[†] No dimensionality reduction or other approximations, including quasiclassical and quasiharmonical, apart from the neglect of exchange between identical species were applied in the calculation of the path integrals. For each specific configuration, the forces experienced by nuclei were calculated within the Born–Oppenheimer approximation based on the electronic structures determined within the density functional theory. The simulation admitted cleavage and reformation of chemical bonds.

The following sequence of transitions as a function of increasing pressure was revealed for 100 K: ice VIII–ice VII (owing to tunnelling translational transitions of protons along the hydrogen bonds)–proton-disordered ice X–proton-ordered ice X.⁷⁴ The pressure required for the transition of ice VII(H₂O) into the structure with two potential energy minima for a proton along the hydrogen bond and a single maximum of the proton distribution function located in the centre of the bond was estimated⁷⁶ to be 55 GPa at 300 K. The pressure of the next transition into ice with a single potential energy minimum in the centre of the hydrogen bond was estimated to be 110 GPa at the same temperature.⁷⁶

The implementation of diamond anvil cells over the last decades has made it possible to generate ultrahigh pressures and characterise samples subjected to extreme conditions by various spectroscopic techniques and X-ray diffraction. In particular, Hemley *et al.*⁷⁷ used X-ray diffraction with synchrotron radiation (SR) to show that oxygen atoms still occupy the sites of the bcc lattice up to a pressure as high as at least 128 GPa. A more recent SR-based single-crystal X-ray diffraction study of ice VII(H₂O) at 300 K and pressures up to 170 GPa demonstrated⁷⁸ that the oxygen framework of ice VII is preserved under these conditions and the hydrogen bonds become symmetric in the pressure range from 60 GPa to 150 GPa. Although the localisation of hydrogen atoms based on X-ray data is challenging, the proton ordering in the cited study was monitored by the intensity of reflection (111) and its symmetry equivalents, which are forbidden in the ideal bcc structure with fully disordered proton positions. With an increase in pressure, the intensities of these reflections first increased, then reached a plateau at 60 GPa and then again started to increase rapidly after 150 GPa. This is in agreement with two theoretically predicted^{74–76} transitions of ice VII first to the proton-disordered and then to the proton-ordered ice X, for which these reflections are allowed.

More direct evidence for the symmetrisation of the hydrogen bonds can in principle be provided by neutron diffraction, which can reliably locate positions of deuterium atoms. However, these experiments under ultrahigh pressures are presently not feasible since they require relatively bulky samples taking into account the low neutron-scattering cross-section. As mentioned above, neutron diffraction studies on the structures of heavy ices VII(D₂O) and VIII(D₂O) in the pressure range up to 20 GPa revealed some increase in the length of the O–D covalent bonds.^{66,67} This experimental observation is also supported by the results of quantum-chemical calculations.⁷⁶

The transitions of ices VII and VIII into the form with the symmetric hydrogen bonds can also be monitored by means of vibrational spectroscopy, since three types of bands corresponding to the three types of vibrations of a water molecule in a molecular crystal should be transformed into two types of bands typical of a framework crystal. According to the IR studies of ice VII(H₂O) at room temperature in the pressure range up to

110 GPa, the symmetrisation of the hydrogen bonds occurs between 59.5 GPa and 64.7 GPa.⁷⁹ In a more detailed IR study⁸⁰ of ices VII and VIII (both H₂O and D₂O) at temperatures between 85 K and 300 K in the pressure range up to 210 GPa, the transition to the symmetrically H-bonded structure was found to occur at 60 GPa (H₂O) and 70 GPa (D₂O). In both cases, the transitions afforded proton-disordered ice X and the experimentally measured transition pressures agreed well with the respective theoretical estimates.⁷⁶ In addition, Goncharov *et al.*⁸⁰ reported changes in the IR spectra at a pressure between 150 GPa to 160 GPa, which suggests the subsequent structural transition to the proton-ordered ice X devoid of proton tunnelling transitions between the two potential energy minima.

According to Raman studies⁸¹ of ices VII, VIII and X at pressures up to 100 GPa, the transition from ice VII to ice VIII occurs at 273 K at pressures lower than 12 GPa, and the transition temperature rapidly decreases with an increase in pressure approaching 0 K at about 60 GPa. In another Raman study by Goncharov *et al.*,⁸² the phase diagram of H₂O was determined in the regions of the transitions VII–VIII–X. The authors found that the transition into the proton-ordered ice X with the symmetric H-bonds occurs at $P > 100$ GPa.

The phase diagrams of ices H₂O and D₂O in the regions of the transitions VII–VIII, VII–X and VIII–X were also systematically elucidated by Song *et al.*⁸³ using IR spectroscopy. The transition to the proton-disordered ice X with the symmetric H-bonds was monitored in the temperature range of 12–298 K and pressure range of 2–100 GPa. The transition VII–VIII occurred at about 273 K for H₂O (at 277 K for D₂O) at a pressure of ~ 15 GPa, and the transition temperature decreased nearly linearly as a function of pressure down to ~ 100 K at 62 GPa (H₂O) and 75 GPa (D₂O). The values of pressure where the transitions VII–X and VIII–X occurred depended little on temperature: in the case of H₂O, the transition pressure increased only from 60 GPa to 62 GPa on going from 300 K down to 12 K; in the case of D₂O, the transition pressure increased from 72 GPa to 77 GPa on going from 298 K down to 16 K. The determined⁸³ temperatures and pressures of the transitions VII–VIII–X were in good agreement with the respective values obtained earlier using IR^{79,80} and Raman^{81,82} spectroscopy. The triple point VII–VIII–X was located at 100 K and 62 GPa for H₂O and at 100 K and 75 GPa for D₂O.⁸³ According to theoretical predictions,^{74–76} the isothermal compression of ice VIII between 100 K and 273 K should first initiate the transition to ice VII and then to ice X.

Schwager *et al.*⁸⁴ determined the melting curve of ices VII(H₂O) and X(H₂O) in the pressure range from 20 GPa to 90 GPa. The curve revealed a kink around 43 GPa supposedly attributed to the triple point VII–X–liquid (at 43 GPa and 1600 K). The dissociation of H₂O molecules in the liquid phase became significant only at temperatures above the melting point by 200–400 K.⁸⁴

It is of note that the symmetrisation of hydrogen bonds upon the transition VII $\rightarrow$ X switches the mechanism of proton diffusion in the crystal. In the structure of ordinary ice, the diffusion proceeds in two steps (a proton can move to the adjacent energy minimum along the H-bond or jump to a different bond) but in the case of ice with the symmetric H-bonds, the diffusion can be accomplished only by jumps between the bonds. Thus, it might be expected that the proton diffusion coefficient of ice X is higher than that of ice VII. Furthermore, compression of ice VII increases the concentration of ionic defects, which should also lead to an increase in the proton diffusion coefficient with an increase in pressure. However, direct measurements of the proton diffusion coefficient for ice VII at pressures ranged from 10.2 GPa to 63 GPa at 400 K (which lies in the region of its thermodynamic stability) showed⁸⁵ that under these conditions the proton diffusion coefficient decreases from $10^{-15} \text{ m}^2 \text{ s}^{-1}$ to $10^{-17} \text{ m}^2 \text{ s}^{-1}$ with an increase in pressure.

[†] *NPT* ensemble is a thermodynamical ensemble in which the total number of particles N , pressure P and temperature T remain constant; other thermodynamical ensembles, *e.g.*, *NVE* (with the constant total number of particles N , volume V and total energy E) and *NVT* (with the constant total number of particles N , volume V and temperature T) will be referred further in the text.

6. Kinds of amorphous ices. Pressure-induced amorphisation of crystalline ices and crystallisation of different ices from amorphous water phases on heating

As has been mentioned above, the isothermal compression of ice Ih affords HDA, which in turn transforms into crystalline ice VII' upon further compression. This example of interconversions of amorphous and crystalline ices is not unique. The kinds of amorphous ice known to date are considered in this section in their relation to crystalline ices.

Amorphous ice has been prepared for the first time by deposition of water vapour onto a copper support cooled to a temperature below 163 K (see Ref. 8). The density of amorphous ice produced in this way⁸⁶ was 0.94 g cm^{-3} . Sometimes, this type of amorphous ice is referred to as amorphous solid water (ASW). Rapid cooling of water emulsions composed of water droplets with sizes of the order of a few micrometers at a rate of more than 10^5 K s^{-1} affords amorphous ice of a similar density.¹⁹ This form is typically referred to as hyperquenched glassy water (HGW). The thermodynamical properties of ASW and HGW are much alike and thus they can be considered as the same phase.⁵⁹ Upon heating, ASW and HGW convert into ice Ic, which in turn converts into ice Ih at higher temperature.

A detailed study of phases prepared by deposition of water vapour on a cold metal support has shown⁸⁶ that the type of the phase formed depended on the temperature and deposition rate. In particular, the deposition at a rate of 10 mg h^{-1} onto a support kept at 77 K affords amorphous ice with a density of 0.94 g cm^{-3} , whereas the deposition at a rate of 4 mg h^{-1} onto a support at 10 K yields another form of amorphous ice with a density of 1.1 g cm^{-3} . For the former case, according to wide-angle X-ray scattering, the local structure is characterised by nearly ideal tetrahedral environment of water molecules with the $\text{O}\cdots\text{O}\cdots\text{O}$ angle close to 109° and the mean distance between the oxygen atoms of $2.76 \text{ \AA}$. In the latter case, the mean closest distance between the oxygen atoms is also about $2.76 \text{ \AA}$; however the overall local structure is more complicated than in the former phase. Therefore, the very slow deposition onto a very cold support (kept at a temperature below 55 K) affords amorphous ice other than ASW, which is characterised by higher density and distinct structural and thermodynamical characteristics.⁸⁶

Mishima *et al.*²⁰ developed another method for the preparation of amorphous ice by isothermal (at 77 K) compression of ice Ih. Upon compression to $\sim 1.0 \text{ GPa}$, the volume of the samples gradually decreased, the decrease became abrupt in the pressure range from 1.0 GPa to 1.5 GPa and again smooth with a further increase in pressure to 1.6 GPa . When the pressure was isothermally (at 77 K) released to the atmospheric value, the sample expanded elastically, this was accompanied by a gradual increase in its volume. The densities of the sample were 1.31 g cm^{-3} and 1.17 g cm^{-3} at 1.0 GPa and atmospheric pressure, respectively. Ice sample prepared in this way proved amorphous, as evidenced by powder X-ray diffraction. Subsequent annealing of the sample at atmospheric pressure afforded another amorphous phase with a density of 0.94 g cm^{-3} . The heavier amorphous phase was referred to as HDA (see previous Section) and the lighter one to as low-density amorphous ice (LDA). Thermodynamical properties of LDA differ from those of ASW and HGW.^{20, 59} LDA transforms into cubic ice Ic upon annealing, similar to ASW and HGW. Presently, there is no consensus on the equivalency of ASW and HGW on the one hand and LDA on the other.^{59, 87} The relation of HDA to amorphous ice with a density of 1.1 g cm^{-3} produced⁸⁶ by the slow deposition on a cold support also remains a subject of debate.

Like ice Ih, LDA converts into HDA upon isothermal compression at 77 K, albeit the transition $\text{LDA} \rightarrow \text{HDA}$ starts at lower pressure (*ca.* 0.6 GPa)²¹ than the transition $\text{Ih} \rightarrow \text{HDA}$. It is of note that the transitions $\text{Ih} \rightarrow \text{HDA}$ and $\text{LDA} \rightarrow \text{HDA}$ are irreversible but have some common features with first-order phase transitions as regards stepwise changes in certain parameters.^{20, 21}

The compression of ice Ic also yields HDA.⁸⁸ Therefore, the following closed loop of transitions can be realised: (i) $\text{Ic} \rightarrow \text{HDA}$ upon isothermal (at 77 K) compression to 0.8 GPa , (ii) elastic expansion of HDA by isothermal (77 K) pressure release down to atmospheric pressure, (iii) $\text{HDA} \rightarrow \text{LDA}$ by annealing at atmospheric pressure, (iv) $\text{LDA} \rightarrow \text{Ic}$ by annealing at higher temperature at atmospheric pressure.⁸⁸

As has been mentioned in the previous section, HDA transforms into ice VII' upon isothermal (at 77 K) compression to 4 GPa .⁷⁰ Meanwhile, the isothermal compression at higher temperature (*ca.* 140 K) initiates the transition of HDA into ice VIII. Upon isobaric heating, HDA can convert into various crystalline ices, depending on the pressure and heating rate. For instance, the transition of HDA into ices Ih (through the intermediate steps of LDA and Ic), VI and VIII at $T \leq 160 \text{ K}$ was reported.⁷⁰ Systematic studies of conversions of HDA in the course of isobaric heating at different pressures revealed that HDA transforms into LDA at $P \approx 0.2 \text{ GPa}$ ⁸⁹ and, at higher pressures, subsequently into crystalline ice III' ($\sim 0.2\text{--}0.3 \text{ GPa}$), a mixture of ices IV, V and XII ($\sim 0.4\text{--}0.7 \text{ GPa}$) and a mixture of ices VI and XII ($\sim 1.0\text{--}1.2 \text{ GPa}$).⁹⁰ The aforementioned crystalline ice III' represents ice III with a higher degree of proton ordering, which transforms first into ice IX and then to ice II upon isobaric heating at $\sim 0.2\text{--}0.3 \text{ GPa}$. Some features of the transition⁹¹ of HDA to ices IV and XII upon isobaric heating are discussed in more detail below.

The density of HDA increases in the course of isobaric heating at 1.1 or 1.9 GPa . If the heating of HDA is stopped before the start of crystallisation of ices IV or XII, a new amorphous ice phase with a density of 1.25 g cm^{-3} different from the phases described above can be recovered at atmospheric pressure by cooling the sample down to 77 K followed by pressure release at this temperature.⁹² This phase is referred to as very high-density amorphous ice (VHDA). Upon heating at atmospheric pressure, VHDA is transformed directly to LDA without intermediate formation of HDA.⁹² It is of note that the structures of HDA and VHDA determined at similar densities are very similar, therefore, VHDA probably should not be considered as an independent amorphous phase.⁹³

Section III.8 considers yet another type of transitions between crystalline and amorphous ices, *viz.*, temperature-induced transformation of quenched ices VII' and VIII into LDA.¹²

At present, the investigations into amorphous ices are focused on the following issues.

1. How different are the known amorphous water phases and what properties are the most indicative of this difference? In particular, what is the difference between the local structures of amorphous ices? What is the fundamental reason for water polyamorphism?

2. Which of the aforementioned amorphous phases can be considered as a thermodynamic extension of supercooled liquid water to the region of lower temperatures?

3. What are the thermodynamic characteristics of the transitions between amorphous ices? In particular, does the second critical point of water exist, which corresponds to the experimentally observed first-order $\text{LDA} \rightarrow \text{HDA}$ transition, and what are its P , T coordinates?

4. What is the mechanism of the pressure-induced amorphisation of ices Ih and Ic and whether such amorphisation is possible for other crystalline ices?

5. What is the mechanism of the solid-state crystallisation of amorphous ices upon annealing at $150\text{--}170 \text{ K}$?

A discussion of the above issues can be found elsewhere.^{87, 94, 95} Ponyatovsky *et al.*⁹⁶ proposed a new method (alternative to the adopted method by Mishima and Stanley⁹⁴) for the determination of the coordinates of the second critical point of water and applied it⁹⁷ to elucidate non-equilibrium phase diagrams of substances other than water. Non-equilibrium transitions between crystalline and amorphous water phases in the low-temperature part of the phase diagram were studied in detail

by Gromnitskaya *et al.*⁹⁸ and by Lyapin *et al.*⁹⁹ Very recently, Brazhkin and Lyapin¹⁰⁰ surveyed the experimental data on the transitions between disordered condensed phases (either liquid or solid) of various compounds and modern theoretical approaches to their description.

7. Ices IV and XII

Let us resume the discussion of properties of crystalline ices and transitions between them.

Some properties of ices Ic and IX, which have no specific regions of thermodynamic stability in the water phase diagram, have already been discussed above. In addition to these two forms, two more modifications, *viz.*, ices IV and XII, are also known to exist only in metastable state within the regions of stability of other ices.

The existence of metastable crystalline ice IV has already been mentioned in the very first studies^{101, 102} of the water phase diagram. It was established that ice IV exists within the region of stability of ice V and can be prepared by overcooling liquid water in a certain pressure range.^{4, 102} The structure of quenched ice IV recovered at atmospheric pressure at 10 K was determined by Engelhardt and Kamb¹⁰³ (Fig. 7). Structural parameters of ice IV were also reported for 210 K and 0.7 GPa, which lies within the region of its metastable existence.⁹⁰

Figure 7. Two identical fragments of the structural motif of ice IV linked to each other. All possible positions of the H atoms (with the occupancies of 0.5) are shown.

Note that ice IV persisted at 248 K only for a short period from a few seconds to several minutes before spontaneous transformation into a more stable phase in a study⁴ aimed at determining transition lines IV–VI and liquid–ice IV and the triple point liquid–IV–VI. In the study of the transition liquid–ice IV within the region of stability of ice V, the formation of other metastable crystalline ices was detected as well but it appeared impossible to reliably characterise them since the probability of their formation was even lower and their conversion into the stable phase proceeded even faster than for ice IV.⁴

A reproducible method for the preparation of one of these metastable crystalline phases, ice XII, was developed quite recently.⁶ It consists of slow cooling of liquid D₂O in an argon atmosphere at 0.55 GPa and 260 K, *i.e.*, again within the region of stability of ice V. Under these conditions, the crystal structure of ice XII was determined (Fig. 8) and its density was measured, which appeared rather close to that of ice IV and somewhat higher than that of ice V.

Later on, the same phase was prepared¹⁰⁴ in a totally different region of the water phase diagram by isothermal compression of ice Ih to 1.8 GPa at $T < 150$ K, albeit it is HDA rather than crystalline ice that was produced under nearly the same conditions in previous studies.^{20, 70} The reasons for the formation of ice XII instead of HDA remained unclear. Further investigations revealed¹⁰⁵ that the compression of Ih yields ice XII always through the intermediate formation of HDA. Ice XII crystallises only from LDA rather than directly from ice Ih and only at a

Figure 8. The structure of ice XII (the projection along the *c* axis). The occupancies of H positions are close to 0.5.

sufficiently high pressure and temperature. In particular, Koza *et al.*¹⁰⁴ found that ice XII was produced by the compression of ice Ih to $P > 1.1$ GPa at 77 K only in the case of imperfect mechanics operation giving rise to pressure drops, whereas no ice XII was formed in the case of smooth pressure trends. Likely, pressure drops result in acoustic pulses and consequent local heating of the sample up to 260 K, which actuates nucleation and growth of ice XII crystallites.¹⁰⁵ From the standpoint of these results, boundaries of the region of existence of ice XII determined by Koza *et al.*¹⁰⁴ required verification accounting for the pressure drops.

According to the study³ of the transition HDA → XII → stable crystalline ice upon isobaric heating of HDA prepared by smooth compression of ice Ih at various pressures, the refined second region of existence of metastable ice XII lies within the region of stability of ice VI and extends from 158 to 212 K and from 0.7 to 1.5 GPa. Interestingly, the two regions of metastability of ice XII are disconnected, *i.e.*, there is no direct path to pass from one region to another avoiding phase transitions. In particular, ice XII prepared from liquid water at 260 K transforms⁶ into stable ice V upon cooling, whereas ice XII prepared from HDA transforms³ into ice VI upon heating above 212 K. It is of note that the temperature-induced transition of HDA to ice XII is much faster than the subsequent transition of ice XII to ice VI. Presumably,³ the structure of HDA intrinsically contains crystallisation nuclei of ice XII.

Further analysis of properties of ice XII in comparison with those of ice V using DSC suggested⁵⁹ that some features of the DSC curves of ices XII and V can be explained by kinetic activation of the proton transition order–disorder resulting in partial proton ordering therein due to prolonged storage at 110–115 K. At the same time, the available neutron diffraction data^{6, 104} strongly suggest the complete proton disorder in the structure of ice XII. Salzmann *et al.*⁵⁹ proposed the following explanation of this discrepancy. In one of the neutron diffraction studies,⁶ the structure of ice XII was determined at 260 K, which is above the suggested transition order–disorder. In the second study,¹⁰⁴ ice XII was prepared at low temperature under the action of pressure drops. Rapid quenching of the sample heated by an acoustic pulse can in this case be responsible for the freezing of the positional proton disorder.

The measured³ lower boundary of the region of existence of ice XII prepared from HDA is determined by kinetics of the transition HDA → XII and this type of ice XII can in principle be cooled down to extremely low temperatures. In particular, the structure of ice XII was determined at 1.5 K and atmospheric pressure.¹⁰⁴ (Those samples were produced from HDA at different

pressures; then the pressure was released to atmospheric pressure while the samples were cooled to 77 K, and finally the samples were cooled down to 1.5 K.) It was even suggested³ that ice XII prepared by heating of HDA and existing within the region of stability of ice VI can become thermodynamically more stable than ice VI at low temperature. However, Johari¹⁰⁶ showed that the Gibbs free energy of ice XII at 1.1 GPa and 100 K is higher than that of ice VI thus confirming that ice VI is the stable phase.

In several cases, some amounts of ice IV formed upon annealing of HDA in addition to ice XII.³ A more detailed study⁹¹ of the crystallisation of HDA upon isobaric heating at $P = 0.81$ GPa up to 195 K at variable rates confirmed the possibility of the formation of ice IV. Under the conditions used, HDA converted into ices XII and IV simultaneously with the relative yields depending on the heating rate.⁹¹ Pure D₂O ice IV and nearly pure H₂O ice IV were formed on slow heating at a rate of 15 K min⁻¹. Mixtures of ices IV and XII were obtained at intermediate heating rates. This means that both entirely metastable high-pressure ice phases, ices IV and XII, exist within approximately identical regions of the phase diagram and can be prepared by either crystallisation of supercooled liquid or temperature-induced crystallisation of metastable LDA.

It is of note that very soon after the publication of the neutron diffraction study of ice XII,⁶ an independent report on the preparation of a new ice phase, unknown for that moment and crystallising from liquid water within the regions of stability of ices V and VI, appeared.⁵ The authors determined the melting curve of the phase, described typical crystal morphology and measured Raman spectra but failed to assign it to ice XII, since very limited information on this modification was then available. Recently measured¹⁰⁷ Raman spectra of ice XII manifest pronounced similarity to the spectra of that unidentified phase⁵ thus strongly suggesting that it was indeed ice XII.

Salzmann *et al.*¹⁰⁸ performed a comparative analysis of the thermodynamical properties of metastable ices IV and XII. In particular, the triple point for the metastable equilibria IV–XII–liquid were located at 0.5–0.6 GPa and ~267 K in the intersection of melting curves of ices IV (see Ref. 4) and XII (see Ref. 5). Since both ices IV and XII are completely proton-disordered,^{6,90,103,104} they should be characterised by a nearly zero entropy difference. Based on the Clapeyron–Clausius equilibrium, this means that the boundary between the phases IV and XII should be nearly parallel to the temperature axis. Ice IV is more stable at $P < 0.5–0.6$ GPa, since its melting curve lies above that of ice XII under these conditions.¹⁰⁸ In contrast, ice XII becomes more stable above this threshold pressure. Surprisingly, the temperature-induced transition XII → IV was observed experimentally⁹⁰ at 0.6–0.7 GPa, *i.e.*, in the region of the higher stability of ice XII according to the above thermodynamic arguments. Salzmann *et al.*¹⁰⁸ noted that the accuracy of the experimental measurement of pressure⁹⁰ was of the order of 0.1 GPa, which can explain the apparent discrepancy: likely, the pressure of the transition XII → IV was actually lower than the reported value⁹⁰ of 0.6–0.7 GPa, *i.e.*, it lied in the region of higher stability of ice IV.

8. Transformations of quenched high-pressure ices upon heating at atmospheric pressure

As was established quite a long time ago, many high-pressure ices recovered at atmospheric pressure in their metastable quenched forms readily transform into ice Ic upon annealing. In particular, annealing of quenched ices II, IX, V and VI at $P = 1$ bar yields metastable ice Ic, which converts into thermodynamically stable ice Ih at higher temperature.^{13,14,109} The rates of these transitions depend on temperature and thermal prehistory of the sample under study. These processes can be utilised for the production of ice Ic in large quantities.¹³

However, not all quenched high-pressure ices transform into ice Ic upon annealing at atmospheric pressure. For instance, quenched ice VIII first converts into LDA and only then the

subsequent transitions LDA → Ic and further Ic → Ih occur.¹⁵ Like in the previous case, the temperature and rate of the transition depend on the heating rate. In particular, at a heating rate of 10 K h⁻¹, the transitions VIII → LDA, LDA → Ic and Ic → Ih are revealed in thermograms as peaks centred at 136 K, 148 K and 210 K, respectively.¹⁵

Quenched ice VII' prepared by compression of ice VI first to 3.8 GPa and then to 5.4 GPa at 95 K followed by pressure release to atmospheric pressure at a temperature of 100 K undergoes similar thermal transformations.¹² In this case, a slow temperature increase to 115 K initiates gradual ordering of ice VII' into ice VIII, then the transformation of ices VII' and VIII into LDA starts at $T = 125$ K, which is completed after annealing of the sample at 138 K for 1.5 h. The neutron diffraction pattern of the sample heated to 152 K is fully consistent with that of Ic.¹²

There have been several reports^{16,17} that quenched ice VIII converts into LDA and HDA simultaneously upon heating to 130–135 K at a rate of 1 K min⁻¹. This conclusion was derived on the basis of neutron diffraction data. In a more recent study,¹² similar neutron diffraction patterns were obtained but the conclusion^{16,17} on the formation of HDA was questioned. Klotz *et al.*¹² argued that the peak observed in the neutron diffraction patterns previously attributed^{16,17} to HDA was too narrow for an amorphous phase and thus its appearance should rather be explained by an admixture of an unidentified crystalline phase. Furthermore, it is known²¹ that HDA irreversibly converts into LDA above 125 K. Therefore, we may conclude with a high level of confidence that the temperature-induced conversion of quenched ice VIII into LDA is not accompanied by the concomitant formation of HDA.

In summary, heating of quenched ices VII' and VIII brings about their transformation into LDA, which in turn converts into Ic and further to Ih. Although both phases VII' and VIII behave similarly, ice VII' undergoes partial ordering to ice VIII and the transition VII' → LDA starts at lower temperature than the respective transition VIII → LDA.

According to the most recent data,^{18,104,107} quenched ice XII also transforms into ice Ic upon heating at atmospheric pressure. We would like to remind that it is ice XII, which is crystallised within its low-temperature metastability region from HDA during heating, that can be quenched. The conversion of quenched ice XII first prepared at atmospheric pressure by Koza *et al.*¹⁰⁴ into ice Ic upon heating to $T > 135$ K was reported. More recently, the thermal transition of quenched ice XII into ice Ic at $P = 1$ bar was studied in more detail.¹⁸ In this study, samples of ice XII were repeatedly heated to a specific (ever increasing) temperature ranged from 113 K to 183 K, maintained at this temperature for 5 min and cooled down to 93 K to register the X-ray diffraction pattern.¹⁸ The diffraction pattern obtained fully corresponded to the transition XII → Ic revealing no evidence of any amorphous phase.

Based on the high rate of the crystallisation of ice XII from HDA, a close relation between the structures of these two phases was suggested³ (see Section III.7). With this respect, Tulk and Klug¹¹⁰ proposed, disregarding the X-ray diffraction results,¹⁸ that quenched ice XII should behave in a way similar to HDA upon heating, *i.e.*, transform first into LDA and only then into ice Ic. They recorded Raman spectra¹¹⁰ of a sample of ice XII maintained at 12 K, heated to 120 K at a rate of 10 K min⁻¹, maintained at this temperature for several minutes, heated to 130 K at the same rate and maintained at this temperature for 15 min. The spectra registered at 12 and 130 K were ascribed to the crystalline phases XII and Ic, respectively, whereas a broad peak revealed in the spectrum measured at 120 K was attributed¹¹⁰ to LDA. Thus, based on the Raman spectra they concluded that quenched ice XII indeed behaves analogously to ices VII' and VIII: upon annealing at atmospheric pressure it transforms first into LDA, which in turn converts further into ice Ic.

Salzmann *et al.*¹⁰⁷ also recorded Raman spectra in ice XII during heating from 80 K to 150 K at a rate of 2 K min⁻¹. They observed that the positions of bands typical of ice XII drifted slightly with an increase in temperature; new bands typical of ice Ic emerged at 140 K, the bands of ice XII disappeared at about 150 K indicating that the transition XII → Ic was complete. No evidence of the intermediate formation of an amorphous phase was observed in agreement with the X-ray diffraction study cited above.¹⁸ Rationalising the discrepancy with the previous Raman study,¹¹⁰ Salzmann *et al.*¹⁰⁷ speculated that the initial sample in the study by Tulk *et al.*¹¹⁰ could be some phase other than ice XII. At least, that sample was not attested with diffraction methods, while its reported Raman spectrum¹¹⁰ differed from that of crystallographically characterised ice XII.¹⁰⁷

We may thus state with a high level of confidence that ice XII, like ices II, IX, V and VI transforms upon heating at atmospheric pressure directly to ice Ic, which in turn converts into ice Ih with a further increase in temperature. For ice IV, this sequence of transitions was also confirmed¹¹¹ using Raman spectroscopy for the temperature range of 80 < *T* < 145 K (at a heating rate of 2 K min⁻¹). It is of note that ices Ic and Ih cannot be distinguished by their Raman spectra and thus the formation of Ic was suggested^{107,111} only by analogy with the behaviour of other quenched ices.

Summarising all the experimental evidence discussed above, the annealing of quenched high-pressure ices II, IX, V, VI, IV and XII at *P* = 1 bar induces their transformation directly to Ic, whereas ice VII' and VIII first convert into LDA and only then the subsequent transition LDA → Ic occurs. Ice Ic converts into ice Ih upon further heating. Ice XI is stable at atmospheric pressure, it converts into ice Ih upon heating to 72–74 K.^{33,34} Ice III cannot be recovered at atmospheric pressure in the quenched form by the standard cooling at high pressure due to the inevitable transition III → IX. At the same time, no information is available on the thermal transformations at *P* = 1 bar of quenched low-temperature ice III' prepared⁹⁰ by the isobaric heating of HDA at 0.2–0.3 GPa. Ice X has not yet been obtained in the quenched form due to its transition into ice VIII upon pressure release.

IV. Inelastic neutron scattering spectroscopy of water ices

Vibrational spectroscopy can provide valuable information on the potential of the interactions between water molecules in various condensed phases since vibrational frequencies of a molecule are determined by the shape of the corresponding potential well. However, the interpretation of low-frequency part of conventional IR and Raman spectra of water phases is challenging due to the complex pattern of vibrational motions of H-bonded water molecules including acoustic, translational optical and libration modes. The parameters of molecular vibrations can be retrieved in the most straightforward way from inelastic neutron scattering, since INS spectra relate to the density of vibrational states of water molecules in a relatively simple manner.^{38,112} The INS spectra of quenched ices Ih, Ic, II, IX, V, VI, VII, VIII and XI, as well as of LDA and HDA (for both H₂O and D₂O) measured at atmospheric pressure at 15 K have been comprehensively analysed.¹¹²

The INS spectra of ices Ih and Ic are virtually identical.¹¹² This can be explained by the fact that vibrational spectra of condensed water phases are primarily determined by the interactions of water molecules with their proximate rather than long-range environment and the local environments of H₂O molecules in these two proton-disordered ices are identical: the closest oxygen neighbours reside in the vertices of a nearly ideal tetrahedron at distances of ~2.75–2.76 Å. The INS spectrum of LDA that features a local structure very similar to the structures of Ih and Ic (see Section III.6) also looks similar to those of Ih and Ic.

The INS spectra of ices Ih and Ic reveal two peaks at 28 meV[‡] and 37 meV with an integral intensity ratio of ~1 : 2 in the region of translational optical vibrations. These two peaks are located at nearly the same positions for H₂O and D₂O; they are observed in the spectra of both polycrystalline powders and single crystals (irrespective of their orientation).¹¹² Lattice dynamics and molecular dynamics simulations using traditional interaction potentials for water molecules failed to reproduce these two features in the low-frequency region.^{38,112} In 1993, Li and Ross suggested³⁸ that the split band of translational vibrations can be due to the presence of two types of hydrogen bonds (*viz.*, strong and weak one) in the structures of these ices, which become inequivalent due to different mutual orientations of adjacent molecules (see Fig. 2).

Since only bonding configurations depicted in Figs 2*c* and 2*d* are possible in the crystal structure of Ic, the number of former configurations should be twice as that of latter configurations in the case of a random distribution of protons obeying the Bernal–Fowler rules. With this respect, a model for the simulation of vibrational spectra of ices Ic and Ih was developed,³⁸ which assumed that two types of H-bonds, *viz.*, strong and weak ones, described by different force constants are present in the crystal structures of ices Ih and Ic in a ratio of 2 : 1.

It is of note that the above ratio of strong and weak H-bonds valid for the structure of Ic should be different in the case of ice Ih, since only one third of the hydrogen bonds between the hexagonal layers can adopt the configuration depicted in Fig. 2*a* from mere geometrical considerations. Nevertheless, the model assumed^{38,112} that the structure of Ih also features two strong H-bonds per weak one. A simulation within the lattice dynamics approach for a simulation box composed of eight unit cells of ice Ih with a random distribution of strong and weak bonds (in a ratio of 2 : 1) with the optimised force constants provided good agreement between the theoretical and experimental spectra; in particular, the peaks at 28 and 37 meV were quantitatively reproduced.^{38,112} The best-fit values for the force constants were 2.1 and 1.1 eV Å⁻² for the strong and weak H-bonds, respectively. It is of note that the empirically optimised ratio between the force constants, *i.e.*, 2.1 : 1.1, significantly exceeds the value that can be estimated based on the electrostatic repulsion of protons. In order to explain this discrepancy, the authors of the model^{38,112} speculated that the electron density distribution for a specific water molecule is highly sensitive to the orientations of surrounding molecules.

For the crystal structure of proton-ordered ice VIII, this model predicts the presence of only weak H-bonds (see Fig. 2*b*). The feature corresponding to strong bonds should thus be absent in the vibrational spectra of ice VIII. This fully agrees with the experimental INS spectrum of ice VIII.¹¹² Furthermore, the spectrum of proton-disordered ice VII should reveal the band of strong H-bonds, which again agrees with the experiment.¹¹² Meanwhile, the INS spectrum of proton-disordered ice XI (which includes both strong and weak H-bonds in a ratio of 3 : 1) simulated within the model of two force constants appeared drastically different from the experimental spectrum in the region of translational vibrations, which was rather similar to the spectrum of ice Ih.^{112,113} Likely, the model of two force constants for the hydrogen bonds represents merely a convenient empirical model, which well reproduces the spectra of ices Ih and Ic, since it was parametrised (as regards the values of force constants and the relative number of strong and weak bonds) just for this case but is not always applicable to the description of spectra of other water ices.

A comparison of INS spectra of ices Ih and XI, on the one hand, and of ices VII and VIII, on the other hand, demonstrates¹¹² that the spectra of proton-ordered phases reveal distinct narrow peaks, whereas the spectra of related proton-disordered phases are significantly smoother. The same is also true for IR and

[‡] 1 meV = 8.066 cm⁻¹.

Raman spectra. This is due to the fact that water molecules in the structures of proton-ordered ices with only one crystallographic type of oxygen atoms have identical environments thus occupying potential wells with identical shapes. Meanwhile, the shapes of potential wells, which depend on both local and long-range environment, in the proton-disordered ices somewhat differ even for identically oriented water molecules with the oxygen atoms of the same crystallographic type. This gives rise to broadening of peaks in the vibrational spectra of proton-disordered ices and their general smoothing as compared to the respective spectra of proton-ordered ices.

The model of two force constants^{38,112} was extended to the case of ice II.¹¹⁴ The translational region of its INS spectrum was reproduced to a high accuracy within a model that considered water molecules as points. Five force constants were introduced for the description of intermolecular interactions, two of them were selected to be identical and equal to that of the strong H-bond ($2.1 \text{ eV } \text{\AA}^{-2}$) from the respective model^{38,112} of ice Ih. The representation of molecules as points becomes insufficient for the calculation of librations, which required introduction of nine force constants. The simulations enabled an assignment of the peaks observed in the low-frequency part of the experimental INS spectrum to specific types of translational vibrations of water molecules in the crystal structure of ice II. A splitting of the libration band to a well-resolved sharp maximum at 68 meV and two broader bands, which resembles the respective region in the spectra of ice Ih, is characteristic of the INS spectrum of ice II.¹¹⁴

The lower-frequency boundary of the libration region in the INS spectra shifts towards lower energies in the series Ih–IX–II–V–VI–VIII.¹¹² This shift reaches the maximum value of about 12 meV for ices VI and VIII. The spectrum of LDA (H_2O) is characterised by a similar shift (13 meV). The INS spectrum of ice VI has other common features with that of HDA (both for H_2O ¹¹⁵ and D_2O ¹¹⁶), which allowed Kolesnikov *et al.*^{115,116} to suggest that similar dynamical properties of water molecules in HDA and ice VI are due to similar local environments of water molecules in these structures, which gives rise to potential wells with similar shapes. In particular, they proposed^{115,116} that domains of two interpenetrating but not interlinked frameworks of hydrogen bonds observed in the structure of ice VI are also characteristic of HDA. Note that the libration band in the INS spectrum of ice VI, like that of ice II, can be subdivided into three regions, including a well-resolved peak, which is however somewhat broader than the corresponding peak at *ca.* 60 meV in the spectrum of proton-ordered ice II. No similar peak was observed in the libration band of the INS spectrum of HDA.

The shift in the libration band boundary in INS spectra towards lower energies correlates with an elongation of mean $\text{O}\cdots\text{O}$ distances along the series I–IX–II–V–VI–VIII.¹¹⁷ This regularity is of common character. For instance, according to pressure-dependent INS spectroscopy of ice II, the lower-frequency boundary of the libration band shifts towards higher frequencies with an increase in pressure, which results in shortening of mean $\text{O}\cdots\text{O}$ distances.¹¹⁷ Furthermore, the lower-frequency boundary of the libration band in the INS spectrum of ice II-based helium clathrate hydrate (which is, in overall, quite similar to that of helium-free ice II) is shifted towards lower frequencies in agreement with somewhat elongated mean $\text{O}\cdots\text{O}$ distances.⁴⁶

An introduction of a small amount of H_2O into D_2O results in the incorporation of HOD molecules into the crystal structure, which violates periodicity. Vibrations of such impurity molecules give rise to narrow localised defect modes at frequencies differing from the vibrations of the whole lattice. Three defect modes characteristic of an HOD molecule can be attributed to different shifts of its H atom within the D_2O lattice. The μ_3 mode corresponds to shifts of the H atom along the hydrogen bond; the μ_2 mode emerges due to vibrations within the HOD plane perpendicular to the hydrogen bond; and the third defect mode, μ_1 , corresponds to vibrations in the direction orthogonal to the

first two. This type of vibrations of H atoms within HOD molecules was elucidated for quenched D_2O ices Ih, II, VIII and HDA at atmospheric pressure using INS.¹¹⁸

The peak corresponding to the low-frequency μ_1 mode shifts towards lower frequencies in the series Ih–II–VIII–HDA. The μ_1 band of ice VIII has a regular Gaussian profile, whereas in the case of ice Ih, it can be well approximated only with two Gaussians, which is in agreement with the model of two force constants. The peak corresponding to the high-frequency μ_3 mode shifts towards higher frequencies along the same series. Meanwhile, there is virtually no difference between frequencies corresponding to the μ_2 mode for various ice phases. It is of note that the shape of the μ_1 band can be also explained without recourse to the model of two force constants.¹¹⁹

Therefore, inelastic neutron scattering provides essential information on the vibrational spectrum of water molecules constituting various ice phases, which makes it possible to analyse the character of the intermolecular interactions therein.

V. Computer simulations of crystalline ices

Molecular dynamics (MD) represents yet another powerful tool that makes it possible to evaluate dynamical properties of water molecules in various condensed phases.¹²⁰ This is a general method for the numerical simulation of possible states adopted by a many-particle system, which is based on the integration of the Newton equations for all atoms constituting the system under study. The MD method can be applied to water systems only provided that the potentials of interactions between all atoms from both the same and different water molecules are known. Presently, a number of different potentials applicable to the simulation of water systems have been elaborated, however their comprehensive survey lies beyond the scope of the present review. Some advantages and disadvantages of several most common potentials are discussed elsewhere.^{121–123}

Molecular dynamics can be applied to direct computational problems aimed at the prediction of specific numerical values of desired parameters and to model problems pursuing the exploration of possible qualitative trends in the system behaviour irrespective of exact values. The first type of problems include, for instance, calculations of the equations of states for various ice phases. In this case, the resultant numerical values usually strongly depend on the potential selected. The second type of problems are diverse and numerous; among them, the following can be mentioned: verification of the stability of a real or hypothetical crystalline phase at a given interaction potential, elucidation of the character of motion of separate atoms or the whole molecule, monitoring of structural transitions at the molecular or atomic level, *etc.* In contrast to the first type of problems, specific parameters of the interparticle interactions are often not essential in such simulations, since in the case of a reasonably selected potential, the qualitative simulation results much less depend on its exact parameters. Below we consider some recent works on MD simulation of condensed water phases, including the problems of both types.

Borzsák and Cummings¹²⁴ elucidated the structural stability of a hypothetical proton-ordered analogue of ice XII as a function of proton configuration. The model structure had the same oxygen sublattice and unit cell as ice XII. For such a unit cell, ninety different proton configurations conserving the periodicity of the structure are possible with exactly one proton on every hydrogen bond and exactly two protons covalently bound to every oxygen atom.¹²⁴ All these possible configurations were simulated using molecular dynamics with the TIP4P potential²³ for a runtime of 100 ps. Only twenty-one configurations proved stable, whereas the remaining structures (both polarised and non-polarised) collapsed during the simulation. The most stable proton configuration in the proton-ordered ice XII analogue corresponded to a structure polarised along the *c* axis.¹²⁴ Note that after publication of these computational results, partial proton

ordering in ice XII upon prolonged storage at 110–115 K was suggested based on the experimental DSC data, although the character of this ordering was not clarified⁵⁹ (see Section III.7).

Ayala and Tchijov¹²⁵ calculated specific volumes v of ices III and V as a function of pressure at a specific temperature (246 K for ice III and 238 K for ice V) and as a function of temperature at a specific pressure (0.25 GPa for ice III and 0.5 GPa for ice V). They used molecular dynamics within the NPT ensemble with the TIP4P and TIP5P interaction potentials (see Ref. 126). In this computer experiment, the studied ice phases did not melt at pressures and temperatures lying within their regions of stability. Nevertheless, ice V did melt around the point $T = 268$ K, $P = 0.5$ GPa with the TIP4P potential, whereas the TIP5P showed no melting. For both ice phases, the two potentials afforded differently looking functions $v_T(P)$, *i.e.*, specific volume *vs.* pressure at constant temperature. More specifically, the curve $v_T(P)$ obtained with the TIP5P potential was located lower than that obtained with the TIP4P potential and both curves were lower than the respective curve $v_T(P)$ estimated from the experimental data.⁴⁹ As for the function $v_P(T)$, the TIP5P potential again yielded lower values of specific volume for both ice phases considered.

Báez and Clancy¹²⁷ calculated various parameters of the transitions liquid–crystal for a number of real and hypothetical ices at atmospheric pressure. The simulation was performed using the non-equilibrium molecular dynamics with the SPC/E potential (see Ref. 128). In contrast to the case of real water, the SPC/E-based simulation predicted that it is ice B,¹²⁷ a novel phase with a density higher than that of ice Ih, which was not observed experimentally, rather than ice Ih that should be the most stable crystalline phase at 100 Pa. The authors also attempted to grow various crystalline ices from the melt (*i.e.*, liquid water) at the respective ice–melt interface in the course of the simulation. In the case of ice II–melt interface, they observed a growth of ice II on some parts of the interface and partial melting on other areas in the same computer experiment, thus it was impossible to decisively conclude on the possibility of growth of ice II crystals in the model system. Meanwhile, in the case of the hypothetical ice B–melt interface, stable growth of ice B crystals was clearly observed. Furthermore, the phase B spontaneously formed from another hypothetical ice A (which has the structure of ice IX with a modified proton arrangement) in a simulation of ice A–liquid interface.¹²⁷ It is of note however that since the SPC/E potential rather poorly reproduces experimental properties of water and water ices, these results are mainly of methodical significance.

Zheligovskaya *et al.*¹²⁹ utilised MD to elucidate the dynamical properties of H₂O molecules in ices II and IX. The interactions between water molecules was described using the Poltev–Malenkov (PM) potential;^{130,131} the simulation was performed within the NVE ensemble for two values of the total energy of the system corresponding to temperatures of 82 and 201 K for ice II and of 87 and 203 K for ice IX. According to the direct visual control and a hydrogen bond analysis, the structures of these ices survived the simulation at the temperatures used.

The crystal structures of ices II and IX are proton-ordered and include two crystallographically different H₂O molecules. The following characteristics were calculated for the whole system: the mean-square displacement of the centre of gravity of water molecules as a function of time

$$\langle r^2(t) \rangle = \frac{1}{N} \sum_{i=1}^N [r_i(t) - r_i(0)]^2$$

[$r_i(t)$ is the radius-vector to the centre of gravity of the i th molecule at a time moment t ; the summation is performed over all N molecules in the system], the autocorrelation function of velocities of centres of gravity of water molecules

$$c(t) = \frac{\frac{1}{N} \sum_{i=1}^N [v_i(t)v_i(0)]}{\frac{1}{N} \sum_{i=1}^N [v_i(0)v_i(0)]}$$

[$v_i(t)$ is the velocity vector of the gravity centre of the i th water molecule at a time moment t] and the autocorrelation function of velocities of hydrogen atoms $c_H(t)$ (given by a similar formula). These parameters were also calculated separately for each of the two subsystems of crystallographically equivalent water molecules.

Different local environments of crystallographically non-equivalent water molecules lead to the respective difference in their dynamical characteristics. In particular, the amplitude of translational vibrations of the water molecules H₂O(1) constituting corrugated six-membered rings in the crystal structure of ice II appeared somewhat larger than that of the molecules H₂O(2) that constitute flattened rings (see Fig. 3). Similarly, in the case of ice IX, the amplitude of translational vibrations of the water molecules H₂O(1) constituting helices was smaller than that of the water molecules H₂O(2) that link the helices into the united framework (see Fig. 5b). Based on the autocorrelation function of velocities of centres of gravity of water molecules, the density of translational vibrational states was calculated, whereas the density of librational vibrational states was derived from the autocorrelation function of velocities of hydrogen atoms. The derived densities of librational and translational vibrational states were slightly different for crystallographically non-equivalent water molecules for the structures of both ices II and IX. A comparison of the theoretical density of librational vibrational states with the experimental INS spectra indicates¹³² that the use of the PM potential underestimates the position of the libration band with respect to that in the experimental spectrum.

As has been mentioned above, in the case of proton-disordered ices, dynamical characteristics differ even for both crystallographically independent molecules and molecules with crystallographically identical O atoms even those possessing O–H bonds with the same orientation. The effects of the proton order on the dynamical characteristics of water molecules in crystalline ices were elucidated with proton-disordered ice III and its proton-ordered counterpart, ice IX, as examples.¹³³ As in the previous case,¹²⁹ ices III and IX were simulated using MD with the PM potential within the NVE ensemble. The same parameters as listed above¹²⁹ were calculated for all water molecules in the model, separately for the crystallographically non-equivalent molecules H₂O(1) and H₂O(2) and, in the case of ice III, additionally for all water molecules with specifically oriented protons. According to the results obtained, the difference between the dynamical characteristics of the molecules H₂O(1) and H₂O(2) was significantly larger in ice IX than in its proton-disordered analogue, ice III. Furthermore, the theoretical spectrum of librational vibrations of ice III was more smeared as compared to that of ice IX. This is due to the presence of ten different types of orientations of water molecules [six orientation for H₂O(1) and four more orientations for H₂O(2)] in ice III instead of only two possible orientations in ice IX. Moreover, both local and long-range environments of water molecules can be different even for identically oriented molecules. Therefore, the spectrum of ice IX formally represents a superposition of two spectra, whereas the spectrum of ice III represents a superposition of a significantly larger number of spectra corresponding to molecules in different environments, which gives rise to its apparent smoothing.

The PM potential was also employed¹³⁴ in simulations of proton-disordered metastable ices IV and XII. As in the two studies cited above,^{129,133} the MD simulation was performed within the NVE ensemble. The mean temperature was fixed at about 70 K. The structure of ice IV partially collapsed during the simulation, whereas ice XII survived the simulation and preserved its integrity. The self-entangled framework of hydrogen bonds in ice IV contains, as the main structural unit, rings built up of six

water molecules with the oxygen atom O(1) pierced by a ‘needle’ composed of two H-bonded water molecules with the oxygen atom O(2) (see Fig. 7). The O(2)⋯O(2) hydrogen bonds in ice IV are elongated to 2.916 Å; each oxygen atom O(2) has short contacts of only 3.14–3.29 Å with six O(1) atoms forming no H-bonds with it.¹⁰³ Therefore, the collapse of the structure of ice IV started with the cleavage of the long O(2)⋯O(2) hydrogen bond followed by the formation of initially absent O(2)⋯O(1) hydrogen bonds.

The six-membered rings initially present in ice IV were mainly preserved after such a transformation and thus they survived the simulation. The metastable ice XII survived the simulation, which made it possible to calculate dynamical characteristics (the same as discussed above^{129,133} for ices II, IX and III) of the constituent water molecules. As expected, the theoretical parameters of the crystallographically non-equivalent water molecules H₂O(1) and H₂O(2) in the structure of ice XII proved somewhat different.

According to the recent calculations by Henry¹³⁵ using the DFT-based method PACHA (Partial Atomic Charges and Hardnesses Analysis), ice IV is indeed characterised by the most strained structure among all known water ices. Based on the computational results obtained, Henry proposed¹³⁵ a corrected structural model for ice IV without the elongated O(2)⋯O(2) hydrogen bonds. (It has to be however stressed that the reported¹⁰³ crystal structure of ice IV is correct since it was confirmed in a more recent study.⁹⁰) Difficulties in the experimental preparation of ice IV and its rapid spontaneous conversion into more stable phases at 250 K consistently indicate the relatively low stability of this structure.⁴ From this standpoint, its collapse during the computer experiment¹³⁴ does not look surprising.

The diffusion of noble-gas atoms and surplus water molecules not incorporated into the crystal structure through the frameworks of crystalline water ices was a subject of several studies. For example, an MD study on the diffusion of water molecules and helium atoms through the crystals of Ih showed¹³⁶ that the mechanisms of the diffusion of He atoms and surplus H₂O molecules through the framework of Ih are different in principle. Helium atoms migrate by jumps from one stable position in a cavity of the framework of Ih to another cavity, which makes virtually no effects on vibrations of water molecules forming the framework. In contrast, surplus water molecules not incorporated into the crystalline framework form short-lived hydrogen bonds with the molecules of the framework and thus their diffusion should be accompanied by cleavage and formation of new H-bonds.

Another MD study¹³⁷ of dynamical characteristics of Ar and He atoms in the water framework of ice II showed that Ar atoms diffuse in ice II neither along the hexagonal channels, nor through their walls. At the same time, in the case of He atoms filling a part of cavities inside the channels, single jumps of helium atoms to adjacent cavities within the same channel were detected.

Finally, Matsumoto *et al.*¹³⁸ reported the first observation of crystallisation of ice from the bulk of liquid water in a molecular dynamics experiment. They simulated a system composed of 512 water molecules within the *NVT* ensemble using the TIP4P potential. The crystallisation process in the system was initiated at a time moment $t = 0$ by an abrupt temperature decrease to 230 K after a prolonged preliminary thermalisation at 400 K.

The process of crystallisation of ice from the bulk of liquid water in this simulation proceeded in four distinct steps. In the first step, there were no stable nuclei of a crystalline phase in the system. This step was characterised by a relatively high and nearly constant potential energy of the system. The fluctuating network of hydrogen bonds involved five-, six- and seven-membered rings in nearly constant proportions. The first step completed at a time moment $t \approx 256$ ns with the spontaneous generation of a local stable polyhedral structure of long-lived hydrogen bonds with strengths above the system average.

In the second step of the crystallisation process, the polyhedral structure was slowly growing up while migrating through the system with gradual decrease in the potential energy. The nucleus of a crystalline phase settled at a certain place to a time moment $t \approx 290$ ns and its rapid growth started, which corresponded to the third crystallisation step. The network of hydrogen bonds within the growing nucleus included predominantly six-membered rings. The energy of the system was rapidly decreasing. At the end of the process, *i.e.*, at the moment of about $t \approx 320$ ns, the nucleus already encompassed the entire volume of the model system. This started the fourth crystallisation step. During this step, the network of hydrogen bonds was gradually approaching the regular structure of ice Ih, which gave only insignificant gain in the potential energy.

Matsumoto *et al.*¹³⁸ did not specify the overall duration of the computer experiment (*i.e.*, the CPU runtime expended), but it is evident that the experiment lasted for many months. This fact together with the stochastic nature of the wait time before the generation of a crystalline nucleus make this study unique and difficult to reproduce.

We would like to emphasise that this was the very first MD-based computer experiment¹³⁸ that clearly tracked the spontaneous crystallisation from the bulk of liquid at the molecular level. Previously, the crystallisation from a liquid phase was observed in computer experiments only in the presence of a predefined crystalline surface¹²⁷ or under external electric field (see Ref. 139).

Computer experiments related to water crystallisation under an external impact or boundary conditions can be illustrated by another example, *viz.*, an MD simulation of the crystallisation of water in a narrow slit between two hydrophobic walls.¹⁴⁰ The model included 960 water molecules confined between two planar hydrophobic walls at a distance adjusted to < 1 nm so as to accommodate two molecular layers. The interactions between water molecules were described with the TIP4P potential, whereas the interactions between water molecules and the walls were described with the 9-3 Lennard-Jones-type potential. The simulation was performed within the *NPT* ensemble. According to the simulation, a bilayer amorphous phase was gradually formed from the initial confined liquid water volume upon a decrease in temperature. The layers constituting the amorphous phase were nearly planar and included five-, six- and seven-membered rings. The two layers were related to each other to within a high accuracy by a symmetry plane going in the middle of the gap parallel to the walls. Each water molecule in the bilayer amorphous phase formed four hydrogen bonds (three bonds with the molecules from the same layer and an additional bond with its mirror image from the second layer). Upon further decrease in temperature, this amorphous phase started to crystallise into a bilayer crystalline phase composed of two hexagonal layers arranged one above another and linked by vertical hydrogen bonds. In contrast to the Ih structure comprised of corrugated hexagonal layers with one hydrogen bond to the upper layer and one to the lower layer per a six-membered ring, the resultant bilayer structure¹⁴⁰ consists of nearly flat hexagonal layers with two hydrogen bonds to the bottom layer per a six-membered ring of the upper layer. This result implies that the confinement effects can give rise to the formation of water structures non-typical of bulk phases, *e.g.*, in hydrophobic nanopores.

The formation of unusual structures upon cooling of water incorporated in nanopores even in the case of wettable walls was observed in yet another computer experiment.¹⁴¹ It is known that carbon nanotubes are wetted with water and thus water can penetrate inside due to the capillary effect. According to the MD simulation¹⁴¹ of the behaviour of water inside carbon nanotubes with an internal diameter ranged from 1.1 nm to 1.4 nm, water molecules can assemble at sufficiently low temperatures into nanotubes with square, pentagonal, hexagonal or heptagonal cross-sections, depending on the diameter of the carbon nanotube. Note that experimental investigations^{10,11} into the crystallisation

of water within small pores of silicate materials also demonstrated that this process differs from bulk water crystallisation and thus can lead to another outcome.

VI. Occurrence of high-pressure ices in nature

Under terrestrial conditions, the pressure in ice strata never exceeds a few hundred atmospheres and the temperature never goes below 180 K. Therefore, high-pressure ices do not occur on Earth. Typically, frozen water occurs on Earth as hexagonal ice Ih or as a component of gas hydrates, a detailed consideration of which is beyond the scope of the present review.

Ice strata in Antarctica and Greenland have been maintained at low temperature for a long period. Fukazawa *et al.*¹⁴² suggested that this could have resulted in at least partial positional proton ordering, *i.e.*, the transition to proton-ordered ice XI could have started. In order to verify this hypothesis, several ice probes retrieved from depths of 200 m (temperature of 213 K and age of 8000 years) and 350 m (temperature of 214 K and age of 15000 years) of an Antarctica's ice shelf were studied by means of INS.¹⁴² The spectra obtained manifested some features typical of the INS spectra of ice XI, which suggested that the studied samples of ice from the Antarctica's ice shelves have indeed transformed into ice XI.¹⁴² However, the INS spectra of analogous ices retrieved from depths ranged from 200 m (age of 1000 years) to 5500 m (age of more than 10⁶ years) of Greenland's ice shelves were fully consistent¹⁴³ with the respective spectra of ordinary ice Ih. The authors of the latter study¹⁴³ argued that ice samples analysed in the former study¹⁴² also represented ordinary ice Ih and the INS features were misinterpreted due to the insufficient signal-to-noise ratio and low resolution.

Bina and Navrotsky proposed a model¹⁴⁴ of geological processes proceeding upon subduction of the oceanic lithosphere that considered the formation and accumulation of ice VII in large quantities as a possible consequence of the oceanic bed lowering. It is of note however that this is only one of many hypotheses concerning geological processes in the Earth's mantle.

Water ices can also occur in the Earth's atmosphere. Many types of halos around Moon and Sun and other related optical

phenomena can be explained by refraction of light upon propagation through crystals of ice Ih suspended in atmosphere. A rare type of such a halo due to the light deflection by 28° have been observed several times, which cannot be explained by the refraction in crystals of ice Ih.¹⁴⁵ This halo can be rationalised under the assumption of emergence of small octahedral crystals of ice Ic in the atmosphere, since light refraction in such crystals can result in the deflection exactly by 27.4° (see Ref. 145). The shape of several types of snow-flakes with ice Ih crystals twinned at 70° is another evidence of the formation of small crystals of ice Ic in the Earth's atmosphere. Such a twinning can be explained by the epitaxy of the (0001) planes of hexagonal ice Ih on the family of symmetry related {111} planes of octahedral crystallites of ice Ic acting as nuclei for the growth of the snow-flake.¹⁴⁶

Therefore, only occurrence of Ih in the Earth's mantle is reliably established, although there is serious experimental evidence that both ice Ih and Ic can form in the Earth's atmosphere as small crystals.

There are 18 orbs with radii more than 100 km composed to a large extent of water ices within the Solar system.¹⁴⁷ These are the largest Jupiter's satellites, *viz.*, Europa, Io, Ganymede and Callisto, Saturn's satellites, *viz.*, Mimas, Enceladus, Tethys, Dione, Rhea, Titan, Hyperion and Iapetus, Uranus' satellites, *viz.*, Ariel, Umbriel, Titania and Oberon, a Neptune's satellite, Triton, and the Pluto–Charon system. Observations of these orbs were performed from the Earth and, in some cases, from the spacecrafts passing by. Among them, the Jupiter's and Saturn's satellites are the best studied.

The presence of water ices on a surface of an orb can be suggested based on the results of IR photometry or reflectometry. A low mean density of an orb is another indicator of a large water fraction in its interior. The densities of the orbs listed above except for Europa (with $\rho = 3.0 \text{ g cm}^{-3}$) do not exceed 2 g cm^{-3} , whereas all known rocks have densities more than 2.5 g cm^{-3} .

For the four largest Jupiter's satellites, Ganymede, Europa, Callisto and Io, spherically symmetrical density distributions were simulated to be consistent with the available data on their radii, mean densities and moments of inertia.¹⁴⁸ Based on the densities obtained, the composition of mantle-forming rocks and the

VII. Appendix

Table. Crystallographic parameters of the structures of crystalline ices.

Ice	Space group	T, P^a	Unit cell parameters	Z^b	$\rho / \text{g cm}^{-3}$	Degree of proton ordering	Ref.
Ih(H ₂ O)	$P6_3/mmc$	98 K, 1 bar	$a = 4.48 \text{ \AA}, c = 7.31 \text{ \AA}$	4	0.92	completely disordered	63

^a Temperature and pressure at which the structure was determined; ^b the number of water molecules (the number of formula units for ice X) per unit cell.

possible thicknesses of the outer crusts from water ices were estimated. For Ganymede and Callisto, the models were further refined according to the data on the surface heat radiation, presumed intensity of heat generation in their cores due to the radioactive decay, heat conductivity of mantle components and of the outer ice crust to predict the depth distributions of densities, temperatures and pressures. Based on these data altogether, the occurrence of high-pressure ices therein was concluded. The results of measurements of the magnetic fields around the satellites were also utilised, which can support either the presence or absence of an iron core creating an own magnetic field around the satellite or the presence of an internal conductive ocean from liquid water with dissolved salts, which affects the magnetic field induced by Jupiter.

The following conclusions were derived based on these calculations.¹⁴⁸ Io is composed of a core (mostly from Fe and FeS) with a radius of 38% to 53% of its total radius (1821.6 km) surrounded by an outer shell of olivine rocks. No water is present in Io. The radius of the central core of Europa (composed of pure or FeS-contaminated iron) amounts 10% to 45% of the total radius of this satellite (1565 km), its mantle is composed of olivine rocks, the outermost shell represents a crust from water ices with a thickness from 120 to 170 km. Ganymede has a core with a radius of 1/4 to 1/3 of its total radius (2634 km), the mantle is also dominantly composed of olivine rocks, whereas its outer ice crust with a thickness of 900 km is subdivided into concentric shells of ices VI, V, III and I. Water ices and rocks are probably at least partly spatially separated also in Callisto (with a radius of 2410.3 km); among ice forms, ices VI, V, III and I can occur there.

As for the investigated Saturn's satellites, the density of Titan is 1.9 g cm^{-3} , densities of other satellites range from 1.4 g cm^{-3} to 1.0 g cm^{-3} . This strongly suggests that the composition of all the investigated Saturn's satellites but Titan is dominated by water ices. According to simulations of the structure of Titan's interior, the Titan's core is either composed of only silicate rocks or represents a core-shell structure with a central core from molten iron and an outer shell of silicate rocks.¹⁴⁹ The core is surrounded by a mantle composed of several layers, including ice VI, other high-pressure ices and clathrate hydrates, then liquid water and the outermost layer of ice Ih.¹⁴⁹

Therefore, there is serious evidence that crystalline high-pressure ices indeed occur in some satellites of larger planets in the Solar system.

* * *

Solid water phases have remained in the focus of interest of researchers over the last 15 years. A new crystalline modification, ice XII, has been discovered; transitions between crystalline ices, amorphisation of crystalline ices and crystallisation of amorphous ices have been elucidated in detail. The data obtained clearly demonstrate that water polymorphism is truly multi-faceted and no other substance can compete with water in the diversity of forms. We believe that the nearest future will witness more striking investigations into water, especially, its non-equilibrium forms and transitions between them.

The present review has been written with a partial financial support of the Russian Foundation for Basic Research (Project No. 03-03-32227).

Abstract. Nuclear quadrupole resonance and SQUID-magneto-metric studies on magnetic properties of bismuth(III) oxy compounds comprising neither d- nor f-elements are surveyed and systematised. The magnetic properties, not conventionally expected in the Main Group element substances, were found to exist in most of the compounds discussed. The results of the analysis of the zero-field ^{209}Bi NQR line shapes, the Zeeman-perturbed patterns in external fields of various orientations with respect to the crystal axes, and the spin-echo envelopes suggest the existence in $\alpha\text{-Bi}_2\text{O}_3$, $\text{Bi}_3\text{O}_4\text{Br}$, $\text{Bi}_2\text{Al}_4\text{O}_9$, $\text{Bi}_2\text{Ge}_3\text{O}_9$, $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ and BaBiO_2Cl , of ordered magnetic fields ranging from 30 to 250 G, which notably exceed the dipole nuclear magnetic fields. The magnetoelectric effect was observed in the $\alpha\text{-Bi}_2\text{O}_3$ single crystal, and the paramagnetism depending on the thermal prehistory of the crystal was found using a SQUID-technique. The questions concerning the origin of unusual magnetic and electronic properties of the title compounds are discussed. The bibliography includes 49 references.

I. Introduction

Bismuth oxide $\alpha\text{-Bi}_2\text{O}_3$ and related compounds are parent substances for the preparation of high-temperature superconductors and ferroelectrics, and some of them are materials exhibiting valuable electroacoustic, piezoelectric and nonlinear optical properties. However, in spite of the interest of researchers, the magnetic properties of these compounds have not been explored adequately. The ^{209}Bi nuclear quadrupole resonance (NQR) spectra suggest that $\alpha\text{-Bi}_2\text{O}_3$, $\text{Bi}_3\text{O}_4\text{Br}$, $\text{Bi}_2\text{Al}_4\text{O}_9$, $\text{Bi}_2\text{Ge}_3\text{O}_9$, $\text{Bi}_4\text{Ge}_3\text{O}_{12}$, BaBiO_2Cl and $\text{Bi}_3\text{B}_5\text{O}_{12}$ comprising no magnetism

carriers, *i.e.*, atoms of d- or f-elements, are not diamagnets in the conventional sense. Local ordered magnetic fields (H_{loc}) up to 250 G in these compounds cause, in some of them, typical Zeeman splittings of the ^{209}Bi NQR lines in the absence of external magnetic fields (see Refs 1–4 and references cited therein). Their NQR spectra reveal an extraordinarily high sensitivity of the electronic characteristics to weak ($H_e < 500$ Oe) external magnetic fields, which suggests a strong coupling between the magnetic and electronic subsystems of the substances. This, in principle, points to a possibility of governing the functional properties of the corresponding materials by applying weak magnetic fields. For instance, a dramatic increase in the line intensity was observed in the ^{209}Bi NQR spectrum of $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ upon applying an external magnetic field, which is not described within the conventional theory of the Zeeman NQR spectroscopy.

The NQR spectroscopy is recognised as a direct, most efficient and precise method of detecting and studying the nuclear quadrupole interactions, because the quadrupolar Hamiltonian is determined by interactions between the nuclear electric quadrupole moment Q (all the nuclei with spin $I > 1/2$ have such a moment) and the electric field gradient (EFG)

$$q_{ij} = \frac{\partial E_i}{\partial j} = -\frac{\partial^2 U}{\partial ij},$$

where E is the strength of the electrostatic field, U is the electrostatic potential at the nuclear site and $i, j = x, y, z$. The quadrupole coupling constant

$$QCC = \frac{eQq_{zz}}{h}$$

and the EFG asymmetry parameter

$$\eta = \frac{q_{xx} - q_{yy}}{q_{zz}}$$

are the parameters that are measured.

Their values are directly related to the electron density distribution around the nucleus studied. As a result, any weak disturbance of the electron density is clearly and adequately reflected in the NQR spectra. The NQR spectroscopy may be used for studies of a wide variety of phenomena accompanied by changes in the electric fields in the vicinity of the resonance nuclei, and NQR was used as the basic method of investigating the problems discussed. The physical principles of the NQR phenom-

enon, the scope and limitations of NQR spectroscopy in application to problems of inorganic chemistry have been reviewed.^{5,6}

The results of investigations showed that the methods based on measurement of nuclear quadrupole interactions are highly sensitive to the presence of a magnetic field in a substance. The experiments discussed in the present review involved studies of the zero-field ^{209}Bi NQR line shapes in crystalline powders and single crystals, analysis of splittings in the spectra of single crystals in external magnetic fields (H_e) of various orientations with respect to the crystal axes (the Zeeman experiment) and examination of the shapes of the quadrupole spin-echo envelopes (SEE). The experiments recording the SEE in the spectra of crystalline powders enable one to detect small (within the line width) splittings observed as modulations of the SEE curves. Subsequent mathematical processing and computer simulation of either the Zeeman splittings or the SEE shape give the quantitative characteristics of the internal source of splittings, namely, the strength and orientation of the local magnetic field.

The ^{209}Bi NQR Zeeman spectra of the majority of compounds discussed in this review displayed multiplicities, which points to the magnetic non-equivalence of bismuth positions. Therefore, the computer simulation required analysis of the symmetry properties of the EFG tensor. This analysis was based on the crystal-field potential model developed by Orlov.⁷

II. Splitting of the ^{209}Bi NQR spectra of bismuth(III) oxy compounds in internal magnetic fields

The zero-field ^{209}Bi NQR spectrum (the ^{209}Bi nuclear spin is $9/2$) comprises a set of four transitions between five doubly degenerate energy levels $|\pm m\rangle$; their frequencies, assuming the simplest case of magnetic equivalence of the bismuth sites and $\eta = 0$, are determined as

$$\nu_k = \frac{3keQq_{zz}}{2I(2I-1)h},$$

where $k = 1, \dots, 4$.

Figure 1 shows the diagram of the ^{209}Bi NQR spectra of a single crystal in zero and non-zero external magnetic field of arbitrary orientation with respect to the EFG axes. A perturbing static magnetic field H_e removes the double degeneracy $\pm m$ of the quadrupole energy levels, because the energy of interaction of the nuclear magnetic moment with this field becomes different for the orientations of the nuclear spin projection along and opposite the H_e direction. In this case, each singlet, assigned to the resonance transition $\pm m \rightarrow \pm(m+1)$, at $m > 1/2$ is split into a doublet with the separation between the components

Figure 1. Diagrams of quadrupole energy levels and transitions between them for the ^{209}Bi nucleus (spin $9/2$) in zero (a) and Zeeman (b) magnetic fields.

$$\Delta\nu = 2\gamma H_e \cos\theta, \quad (1)$$

where γ is the gyromagnetic ratio for the quadrupole nucleus and θ is the angle between the EFG q_{zz} axis and H_e . The doublet components are symmetrical about the original non-split NQR frequency ν_m , and their total intensity is equal to that of the initial non-split line.⁸ The lowest levels $m = \pm 1/2$ mix in external magnetic field to produce new states ψ_+ and ψ_- and hence a quadruplet, centred at the frequency of the unperturbed transition $\nu_{\pm 1/2} \rightarrow \nu_{\pm 3/2}$

$$\nu_\alpha = \frac{6A}{h} - \frac{1}{2}(3-f)\gamma H_e \cos\theta, \quad (2)$$

$$\nu_\beta = \frac{6A}{h} - \frac{1}{2}(3+f)\gamma H_e \cos\theta,$$

$$\nu'_\alpha = \frac{6A}{h} + \frac{1}{2}(3-f)\gamma H_e \cos\theta,$$

$$\nu'_\beta = \frac{6A}{h} + \frac{1}{2}(3+f)\gamma H_e \cos\theta,$$

where

$$A = \frac{eQq_{zz}}{4I(2I-1)},$$

$$f = \left[1 + \left(I + \frac{1}{2} \right)^2 \tan^2\theta \right]^{1/2}.$$

The quadruplet components are also symmetrical about the frequency of the unperturbed transition.⁸

Thus, the presence in the spectrum of a quartet of lines assigned to the lowest transition ν_1 ($\Delta m = 1/2 - 3/2$) and doublets to the remaining transitions ($\nu_2, \dots, \nu_n$) points to the magnetic nature of the splittings, hence excluding the crystallographic non-equivalence of atomic positions as the cause for the splittings. The separations between the doublet components $\nu_\alpha(\nu'_\alpha)$ and $\nu_\beta(\nu'_\beta)$ are evidently determined by equations

$$\Delta\nu_\alpha = (3-f)\gamma H_e \cos\theta, \quad (3)$$

$$\Delta\nu_\beta = (3+f)\gamma H_e \cos\theta.$$

which show that the number of components (multiplicity) and their frequencies depend on the strength and orientation of the Zeeman field H_e with respect to the EFG axes of a single crystal.

Figure 2 demonstrates the ^{209}Bi NQR line shapes recorded in zero applied field for $\alpha\text{-Bi}_2\text{O}_3$ and $\text{Bi}_3\text{O}_4\text{Br}$. One can see that both

splitting patterns appear as typical Zeeman-perturbed NQR patterns for nuclei having spin $I > 3/2$: the lowest line ν_1 ($\Delta m = 1/2 - 3/2$) is split into a quadruplet, and the lines of higher frequency transitions ν_2, ν_3 , into doublets. This evidences that an internal source of the line splittings exists in these compounds, namely, a local ordered magnetic field H_{loc} , which has a fixed orientation with respect to the nuclear spin direction. This is supported by the observation of the zero-field splittings not only in single crystals, but also in powders. Each crystallite in a powder sample is a single crystal for the local magnetic field, so the observation of the zero-field Zeeman splittings in powder samples rules out the suggestion that an impurity may be the cause for the splittings.

The zero-field splittings were later observed in the ^{209}Bi NQR spectra of several other bismuth oxy compounds, $\text{Bi}_2\text{Al}_4\text{O}_9$, $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ and $\text{Bi}_2\text{Ge}_3\text{O}_9$,^{3,4} although the X-ray data^{9–11} show that the bismuth sites are crystallographically equivalent in their structures. This also excludes the crystallographic non-equivalence as the cause for the spectroscopic splittings. Analysis of the splittings showed that they are consistent with local ordered magnetic fields of 25–250 G notably exceeding the dipole nuclear magnetic fields (about several G). Therefore, the electronic system solely can be the source of the fields in the compounds in question. On the other hand, the values of H_{loc} are several orders of magnitude smaller than those in conventional ferro- and anti-ferromagnets, which is indicative of a new phenomenon. The ^{209}Bi NQR spectra of the compounds mentioned and the values of H_{loc} estimated from the zero-field splittings are listed in Table 1.

III. ^{209}Bi NQR experiments on $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ and $\text{Bi}_3\text{B}_5\text{O}_{12}$ single crystals in external magnetic fields

Small values of splittings and low intensities of some of the transitions made difficult further studies of magnetic properties in the zero field. They were continued in weak external magnetic fields with a view to study the Zeeman splittings in the ^{209}Bi NQR spectra of single crystals. This approach appeared to be efficient because the Zeeman spectra of single crystals exhibited some specific features most clearly revealed on the change in the orientation of external magnetic fields with respect to the crystal axes. The single crystals of $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ and $\text{Bi}_3\text{B}_5\text{O}_{12}$ were studied extensively.^{12–15}

The Zeeman fields H_e from 0 to 500 Oe were applied either parallel or perpendicularly to the direction of the radiofrequency field (H_{rf}). The crystals were turned in the rf-coil about the H_{rf} direction at a definite angle α , which changed the orientation of H_e with respect to the crystallographic axes of the samples. This procedure allowed detailed studies on the shapes, intensities and multiplicities of the resonance lines as functions of mutual orientation of the fields disturbing the bismuth nuclear magnetic moments. A pulse NQR spectrometer, which enabled continuous

scanning through the frequency range required, was used for the experiments.

The $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ single crystal had a shape of parallelepiped ($6 \times 9 \times 25$ mm) with a (100) crystallographic plane perpendicular to the radiofrequency coil axis that coincided with the H_{rf} direction. On successive variation of the strength and orientation of H_e during the experiment, the ^{209}Bi NQR lines of the $\nu_1 - \nu_3$ transitions were recorded at several positions of the crystal in the coil.¹²

If the spin system is simultaneously disturbed by both local and external magnetic fields, the Zeeman spectrum shown in Fig. 1b is expected to become more complicated. As was mentioned above, this is chiefly determined by the crystal symmetry of the compound studied. The number of components (multiplicity), their frequencies and intensities depend also on the strength and orientation of the fields H_e and H_{loc} . Therefore, a theoretical modelling that takes into account the crystal symmetry is necessary for the interpretation of the spectra.

The package of programs¹² for the modelling of the Zeeman splittings in the ^{209}Bi NQR spectra of single crystal included no approximate analytical expressions for the nuclear spin energy levels or transition probabilities. The calculation of these parameters by diagonalisation of the quadrupolar Hamiltonian was carried out numerically with any desired accuracy. After that, the evolution of the spectroscopic splittings was simulated for the given strength and orientation of H_e with respect to the crystal axes. By comparing the simulated and observed splittings, the strength of H_{loc} and angular parameters specifying the field orientation with respect to the EFG axes at the bismuth sites, were derived. The basic stages of the simulation of the ^{209}Bi NQR Zeeman spectra of the $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ single crystal¹² are briefly described below and summarised in the Appendix.

According to X-ray diffraction data,^{9,10} all the sixteen bismuth atoms in the unit cell of the eulitine-type structure (space group $I\bar{4}3d$), to which $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ belongs, occupy the c -type sites in the threefold rotation axis. These positions are characterised by four magnetically non-equivalent EFG tensors. The direction of the maximum component $q_{zz'}$ for each EFG tensor (x', y', z' are the EFG principal axes) with respect to the crystallographic system (x, y, z) is found by diagonalisation of the tensors. This direction is determined by the Euler angles θ and φ connecting the co-ordinate systems (x, y, z) and (x', y', z') (Fig. 3). The third Euler angle ψ , which specifies the direction of the axes x' and y' in the plane perpendicular to the z' -axis, remains arbitrary in consistence with the zero EFG asymmetry parameter at the bismuth sites in the eulitine structure. The angle ψ does not affect line splittings in the NQR spectra in a magnetic field, influencing only line intensity. With the symmetry properties of the lattice contribution to the EFG tensor taken into account, the relationship between the angular parameters of the principal axes $q_{zz'}$ was derived for all the four EFG tensors.¹²

Figure 3. Mutual orientation of the Cartesian coordinate systems: the laboratory frame ($\tilde{x}, \tilde{y}, \tilde{z}$) and the system referred to the crystallographic axes (x, y, z) (a); the system referred to the crystallographic axes and to the EFG principal axes (x', y', z') (b).

$$\theta, \varphi; \pi - \theta, \varphi; \theta, \pi - \varphi; \pi - \theta, \pi - \varphi. \quad (4)$$

Hence, one has to find the angular parameters θ and φ for the principal axes of only one EFG tensor, those for three remaining ones being determined by the relationships (4).

In the absence of local and external magnetic fields and at $\eta = 0$, the energy of the nuclear spin levels E_j ($j = 1, 2, \dots, 10$) and the appropriate eigenfunctions Y_j are calculated by diagonalisation of the simplest quadrupolar Hamiltonian:

$$\hat{H}_Q = \frac{eQq}{4I(2I-1)} [3I_z^2 - I(I+1)], \quad (5)$$

where $eQq/h = 490.3$ MHz (see Table 1). The frequencies of transitions between the appropriate quadrupole levels are the same for all the four EFG tensors, because the Hamiltonian (5) does not depend on the parameters (4). In other words, in the absence of magnetic fields, all the bismuth sites in the eulitine structure are equivalent and the NQR spectra are indistinguishable. The observed singlets assigned to each of the four transitions ($k = 1, \dots, 4$, see Fig. 1a) represent superposition of four lines with identical frequencies and intensities. An external magnetic field directed at different angles to the four EFG principal axes systems makes the bismuth positions in the eulitine structure magnetically non-equivalent. In general, the NQR line can split into a maximum of 16 components (four quadruplets) for the transition $\Delta m = 1/2 - 3/2$ and 8 (4 doublets), for all the remaining transitions, the EFG symmetry properties (4) being taken into account. The angles θ and φ can be determined from the measured splittings of the Zeeman spectra of the oriented single crystal. The orientation of the laboratory system ($\tilde{x}, \tilde{y}, \tilde{z}$) is determined by the field directions as $\tilde{x} \parallel \mathbf{H}_{rf}$ and $\tilde{z} \parallel \mathbf{H}_e$ (see Fig. 3). Because the quadrupole Hamiltonian (5) was determined in the system of the EFG principal axes, a projection of vector $\mathbf{H}_e$ onto the axes (x', y', z') is to be used in the Hamiltonian of interaction of the nuclear magnetic moment with external magnetic field $\hat{H}_e$. This procedure is performed using a rotation matrix D , whose particular form is determined by orientation of the single crystal axes with respect to the laboratory system. Hence, the matrix D depends on the angle of sample turn in the rf-coil from the initial position ($\alpha = -45^\circ$) and from the Euler angles θ, φ and ψ . It is to be reminded that in the reported experiments,¹² the $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ single crystal was placed in the rf-coil so that its longer axis [100] was parallel to the coil axis. The direction of $\mathbf{H}_e$ in the initial position of the crystal was perpendicular to the plane (011).

If the spin system of a quadrupole nucleus is simultaneously disturbed by both local and external magnetic fields, the nuclear spin energy levels and their eigenfunctions are evaluated by diagonalisation of the Hamiltonian¹²

$$\hat{H} = \hat{H}_Q + \hat{H}_{loc} + \hat{H}_e, \quad (6)$$

where $\hat{H}_{loc}$ is the Hamiltonian of interaction of local magnetic field with the bismuth nuclear magnetic moment, $\hat{H}_e$ is the Hamiltonian of interaction of external magnetic field with the bismuth nuclear magnetic moment

$$\hat{H}_{loc} = -g_{\text{Bi}}\mu_{\text{B}}\mathbf{H}_{loc}\mathbf{I} = \quad (7)$$

$$= -g_{\text{Bi}}\mu_{\text{B}}H_{loc}(\sin\theta_{loc}\cos\varphi_{loc}I_{x'} + \sin\theta_{loc}\sin\varphi_{loc}I_{y'} + \cos\theta_{loc}I_{z'}),$$

$$\hat{H}_e = -g_{\text{Bi}}\mu_{\text{B}}\mathbf{H}_e\mathbf{I} = -g_{\text{Bi}}\mu_{\text{B}}H_e(D_{13}I_{x'} + D_{23}I_{y'} + D_{33}I_{z'}). \quad (8)$$

Here $g_{\text{Bi}} = \mu_{\text{Bi}}/I\mu_{\text{B}}$, $\mu_{\text{Bi}} = 4.0797\mu_{\text{B}}$ is the magnetic moment of the bismuth nucleus and angles θ_{loc} and φ_{loc} determine the direction of $\mathbf{H}_{loc}$ with respect to the EFG principal axes.¹²

In $\mathbf{H}_e \perp \mathbf{H}_{rf}$, the components of the matrix D are

$$\begin{aligned} D_{13} &= \cos\psi \sin\varphi \sin\alpha + \sin\psi (\cos\theta \cos\varphi \sin\alpha + \sin\theta \cos\alpha), \\ D_{23} &= -\sin\psi \sin\varphi \sin\alpha + \cos\psi (\cos\theta \cos\varphi \sin\alpha + \sin\theta \cos\alpha), \\ D_{33} &= -\sin\theta \cos\varphi \sin\alpha + \cos\theta \cos\alpha. \end{aligned} \quad (9)$$

Hence, in this case, the nuclear spin energy levels E_j ($j = 1, 2, \dots, 10$) are determined by the parameters eQq/h , H_{loc} , θ_{loc} , φ_{loc} , H_e , θ , φ and α .

In $H_{loc} = 0$ and $\eta = 0$, the typical Zeeman spectrum consists of a quadruplet assigned to the transition v_1 ($\Delta m = 1/2 - 3/2$) and doublets for the remaining transitions, provided that all the EFG tensors are magnetically equivalent (see, for instance, Fig. 4 in Ref. 12). As follows from Eqns (6), (8) and (9), the contribution of the external magnetic field ($\mathbf{H}_e \perp \mathbf{H}_{rf}$) to the splitting of the doublet components is determined as

$$\Delta_e = \frac{2g_{\text{Bi}}\mu_{\text{B}}}{h} H_e (-\sin\theta \cos\varphi \sin\alpha + \cos\theta \cos\alpha). \quad (10)$$

It can be shown that in $\mathbf{H}_e \parallel \mathbf{H}_{rf}$, the matrix D does not depend on α , and the above expression becomes

$$\Delta_e = \frac{2g_{\text{Bi}}\mu_{\text{B}}}{h} H_e \sin\theta \sin\varphi. \quad (11)$$

Using Eqns (10), (11) with relationships (4) taken into account, one can simulate the Zeeman-perturbed ^{208}Bi NQR spectra for the $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ single crystal. The splittings of the selected lines in the Zeeman spectrum of this crystal are shown in Fig. 4. As follows from Eqn (11), the Zeeman-perturbed patterns assigned to the transition $\Delta m = 3/2 - 5/2$ and other higher transitions in $\mathbf{H}_e \parallel \mathbf{H}_{rf}$ are expected to be unit doublets, because the separations between the doublet components are identical according to relationships (4) for all the four EFG tensors. Meanwhile, it is clearly seen in Fig. 4c that each doublet component displays a weak additional splitting, which can be explained by the presence of H_{loc} in the compound $\text{Bi}_4\text{Ge}_3\text{O}_{12}$. The contribution of H_{loc} to the Zeeman splitting of the NQR spectra is described by the formula

$$\Delta_{loc} = \frac{2g_{\text{Bi}}\mu_{\text{B}}H_{loc}\cos\theta_{loc}}{h}. \quad (12)$$

The net splitting observed between the doublet components for the transitions $v_2 - v_4$ is evidently constituted by a superposition of the contributions described by Eqns (11) and (12):

$$\Delta = |\Delta_e + \Delta_{loc}|. \quad (13)$$

Analysis of the Zeeman-perturbed pattern for the line v_2 , carried out using Eqns (11)–(13), showed that the simulated pattern gives the best fit to the observed one (compare Figs 4c and f) if the local magnetic fields are added to relationships (4) for the angular parameters of the EFG principal axes as follows:

Figure 4. Recorded (*a–c*) and simulated (*d–f*) Zeeman-perturbed patterns in the ^{209}Bi NQR spectrum of the $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ single crystal; (*a, d*) are the lines assigned to the transition ν_3 ($\Delta m = 5/2 - 7/2$) in the field $\mathbf{H}_e \perp \mathbf{H}_{\text{rf}}$ at the orientation of the crystal $\alpha = 0^\circ$ (see text); (*b, e*) $\alpha = 45^\circ$; (*c, f*) are the lines assigned to the transition ν_2 ($\Delta m = 3/2 - 5/2$) in the field $\mathbf{H}_e \parallel \mathbf{H}_{\text{rf}}$. H_e / G : (*a, b*) 0 (1), 300 (2), 480 (3); (*c, f*) 450; (*d, e*) 480.

$$\theta, \varphi, H_{\text{loc}} \cos \theta_{\text{loc}}; \quad \pi - \theta, \varphi, -H_{\text{loc}} \cos \theta_{\text{loc}}; \quad (14)$$

$$\theta, \pi - \varphi, H_{\text{loc}} \cos \theta_{\text{loc}}; \quad \pi - \theta, \pi - \varphi, -H_{\text{loc}} \cos \theta_{\text{loc}}.$$

This means that the local magnetic fields in the compound $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ are ordered antiferromagnetically. The magnitude of projection $H_{\text{loc}} \cos \theta_{\text{loc}}$ of the local field vector onto the EFG principal axis z' , estimated from the additional splittings of the doublet components in $\mathbf{H}_e \parallel \mathbf{H}_{\text{rf}}$ (Fig. 4 *c*), was found to amount to 30 ± 3 G.

The angular parameters θ and φ can be found using Eqn (10) from the analysis of the Zeeman-perturbed line shapes observed upon rotation of the single crystal in the radiofrequency coil ($\mathbf{H}_e \perp \mathbf{H}_{\text{rf}}$) through various angles α . Thus, it follows from this equation that the Zeeman-perturbed pattern at $\alpha = 0^\circ$ is a doublet, which was confirmed experimentally (Fig. 4 *a*). Using Eqn (10) and the experimental data, the angle θ was found to amount to $61 \pm 3^\circ$.

It also follows from equation (10) that the Zeeman patterns should be identical at α equal to $+45^\circ$, -45° and -135° . The coincidence of the appropriate splittings has earlier been observed experimentally as well.¹² The angle $\varphi = 54 \pm 3^\circ$ was determined using Eqn (10) from the measured separation between the outer pair of lines in the Zeeman spectra (see Figs. 4 *a, b*). A more complicated modelling procedure¹² had to be performed because of slight deviation of the crystallographic axis of the sample from the $\mathbf{H}_{\text{rf}}$ direction due to the imperfect shape of the single crystal used for the experiment.

The probability of transitions between the nuclear spin energy levels Y_i is proportional to the squared matrix element

$$\Omega_{ij} = |\langle Y_i | \mathbf{H}_{\text{rf}} \mathbf{I} | Y_j \rangle|^2 = H_{\text{rf}}^2 \omega_{ij}, \quad (15)$$

where for both cases, $\mathbf{H}_e \parallel \mathbf{H}_{\text{rf}}$ and $\mathbf{H}_e \perp \mathbf{H}_{\text{rf}}$ the relationships

$$\omega_{ij} = |\langle Y_i | D_{11} I_x + D_{21} I_y + D_{31} I_z | Y_j \rangle|^2, \quad (16)$$

$$D_{11} = \cos \psi \cos \varphi - \sin \psi \cos \theta \sin \varphi,$$

$$D_{21} = -\sin \psi \cos \varphi - \cos \psi \cos \theta \sin \varphi,$$

$$D_{31} = \sin \theta \sin \varphi$$

hold true.

The line shape was modelled by a procedure described earlier⁴:

$$F_{ij} \propto v_{ij}^2 \omega_{ij} \int_{\tilde{\nu}_1}^{\tilde{\nu}_2} g(v - v_{ij}) dv. \quad (17)$$

Here $v_{ij} = (E_j - E_i)/h$ is transition frequency, ω_{ij} is defined by Eqn (16) and Gaussian $g(v - v_{ij})$ is described as

$$g(v - v_{ij}) = \frac{\sqrt{4 \ln 2}}{\sqrt{\pi} \sigma} \exp \left[-\frac{4 \ln 2 (v - v_{ij})^2}{\sigma^2} \right], \quad (18)$$

where σ denotes a line width at half maximum and simulates the effect of broadening due to EFG inhomogeneity.

The entire spectrum was simulated by summing the functions (17) over all the transitions with non-zero ω_{ij}

$$F = \sum_{i,j} F_{ij}. \quad (19)$$

As was said above, the observed splittings in Fig. 4 (see also Figs 1 and 2 in Ref. 12) represent a superposition of the Zeeman splittings giving rise to a complicated pattern that depends on the orientation of $\mathbf{H}_e$ with respect to the crystal axes (angle α) and direction of $\mathbf{H}_{\text{rf}}$. In $\mathbf{H}_e \parallel \mathbf{H}_{\text{rf}}$, the spectral pattern is independent of the position of a sample in a probe head and remains unchanged upon rotation of the crystal. In $\mathbf{H}_e \perp \mathbf{H}_{\text{rf}}$, the spectral patterns recorded at α equal to -135° and $\pm 45^\circ$ were similar to each other as well as those at 0 and -90° [here $(-)$ means clockwise and $(+)$, counterclockwise rotation].¹²

Therefore, based on the results of computer simulation of the Zeeman splittings in the ^{209}Bi NQR spectra of the $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ single crystal, the conclusion was made that antiferromagnetically ordered local magnetic fields of the order of 30 G exist in the unit cell of this compound.¹²

Apart from the additional splittings caused by the local magnetic fields, the Zeeman spectra of $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ exhibited yet another specific feature: a dramatic increase in the resonance intensity occurred in an external magnetic field (see Fig. 4). The resonance line intensity is known to be proportional to

$$I \approx \nu_{ij}^2 \omega_{ij},$$

where ν_{ij} is the frequency of transition between the quadrupole levels i and j , and ω_{ij} is the term that defines the angular dependence of the transition probability [see Eqn (16)]. This term seems to be the only factor that can vary considerably upon applying $\mathbf{H}_e$. Therefore, the angular dependence of the resonance intensity for the ν_2 – ν_4 transitions was analysed.¹² This is determined by the sum of the squared coefficients of I_x and I_y in Eqn (16) as

$$S = \cos^2\theta + \sin^2\theta \cos^2\varphi. \quad (20)$$

Assuming the angular dependence of the function S to be responsible for the observed increase in intensity, one has to admit that $\mathbf{H}_e$ is capable of influencing the spatial orientation of the EFG axes with respect to the crystallographic ones.¹²

As distinct from $\text{Bi}_4\text{Ge}_3\text{O}_{12}$, no splittings were observed in the zero-field ^{209}Bi NQR spectrum of the $\text{Bi}_3\text{B}_5\text{O}_{12}$ single crystal. However, the anomalies found in the intensity ratio of the spectroscopic lines suggested the presence of unusual magnetic properties in this compound as well.¹³ The $\text{Bi}_3\text{B}_5\text{O}_{12}$ single crystal used in the experiment was grown by the Czochralski method from a stoichiometric melt to have a long side (20 mm) parallel to the b -axis of the unit cell and a hexagonal cross-section ($D \cong 10$ mm). The plane parallel to the ab -plane of the crystal was polished. According to the X-ray data,^{16,17} the orthorhombic (space group $Pnma$) lattice of bismuth borate comprises two crystallographically independent bismuth sites [Bi(1) and Bi(2)] that form a triangle centred at the oxygen atom not bonded to boron atoms (Fig. 5). The occupancy of the Bi(2) position of the general type is evidently twice as high as that of Bi(1) lying in the symmetry element (the mirror plane). In agreement with the X-ray diffraction data, the ^{209}Bi NQR spectrum of $\text{Bi}_3\text{B}_5\text{O}_{12}$ also points to the presence of two crystallographically independent bismuth positions. The Bi(1) atom, located in the mirror plane, is characterised by lesser magnitude of the EFG asymmetry parameter than Bi(2) due to its higher local symmetry (Table 2). The double occupancy of the Bi(2) sites is expected to give, in the NQR spectrum, the line ν_2 of nearly double intensity as compared to ν_2 of Bi(1).

However, the experiment on a single crystal showed the inverse resonance intensity ratio: the intensity of the ν_2 line of Bi(1) lying in the mirror plane was at least twice as high as that assigned to Bi(2) in the general position (Fig. 6).

In order to calculate the dependence of the resonance intensities in a pure NQR spectrum of a single crystal on the orientation of the EFG axes with respect to the $\mathbf{H}_{\text{rf}}$ direction one has to find the orientation of these axes at both bismuth sites with respect to the crystal axes. For this, the zero-field resonance intensities were

Figure 6. Zero-filed ν_2 resonances assigned to the sites Bi(2) (1) and Bi(1) (2) in the ^{209}Bi NQR spectrum of the $\text{Bi}_3\text{B}_5\text{O}_{12}$ single crystal ($\mathbf{H}_{\text{rf}} \parallel b$).

first analysed on rotation of the crystal about the b -axis in $\mathbf{H}_{\text{rf}} \perp b$ (Fig. 7) and then the Zeeman-perturbed NQR spectra were examined in the external magnetic field optimum for modelling

Figure 7. Zero-field ν_2 resonances assigned to the sites Bi(1) and Bi(2) in the ^{209}Bi NQR spectrum of the $\text{Bi}_3\text{B}_5\text{O}_{12}$ single crystal for the crystal orientation $\mathbf{H}_{\text{rf}} \perp b$, $\mathbf{H}_{\text{rf}} \parallel a$ (1) and $\mathbf{H}_{\text{rf}} \perp b$, $\mathbf{H}_{\text{rf}} \parallel c$ (2) (a) and the amplitude changes of these resonances over one-period rotation of the crystal about the crystallographic axis b ($\mathbf{H}_{\text{rf}} \perp b$) (b).

Figure 8. Zeeman-perturbed ($H_c \perp H_{rf}$, $H_c = 300$ G) ν_2 resonances (see Table 2) in the ^{209}Bi NQR spectrum of the $\text{Bi}_3\text{B}_5\text{O}_{12}$ single crystal (solid lines) as compared to those in zero magnetic field (dotted lines) for the crystal orientations $H_{rf} \parallel b$, $H_c \parallel q_{zz} \parallel a$ (a) and $H_{rf} \parallel b$, $H_c \parallel c$ (b). The orientations of the crystallographic and EFG principal axes of the single crystal as well as the directions of the H_c and H_{rf} fields are given for the Bi(1) and Bi(2) sites.

($H_c = 300$ G) at two orientations of the crystal with respect to the H_c direction (Fig. 8).¹³ In zero field, the rotation of the sample in the rf-coil about the b -axis was accompanied by a simultaneous amplitude change for both resonances: they practically vanished in $H_{rf} \parallel a$ and reached their maxima in $H_{rf} \parallel c$, whereas the intensity ratio

$$r = \frac{I_{\text{Bi}(1)}}{I_{\text{Bi}(2)}} \quad (21)$$

at its maximum remained the same ($r > 2$, see Fig. 7b). This means that on both bismuth sites, the EFG q_{zz} axes are parallel to the crystallographic axis a . The orientations of the q_{xx} and q_{yy} axes with respect to the crystal axes were found from the Zeeman experiment in $H_c = 300$ G ($H_c \perp H_{rf}$; $H_{rf} \parallel b$). The splittings ($\Delta\nu$) between the Zeeman components for both Bi(1) and Bi(2) atoms at various positions of the crystal in the probe head (see Fig. 8) are given by the formula

$$\Delta\nu = 2\gamma H_c \left\{ \left[A_m \cos^2\theta + \frac{1}{4} \sin^2\theta (B_m + 2C_m \cos 2\varphi) \right]^{1/2} - \left[A_{m'} \cos^2\theta + \frac{1}{4} \sin^2\theta (B_{m'} + 2C_{m'} \cos 2\varphi) \right]^{1/2} \right\}, \quad (22)$$

where $\pm m$ and $\pm m'$ denote the degenerate states $\pm 3/2$ and $\pm 5/2$, respectively, and the coefficients $A_m(m')$, $B_m(m')$, $C_m(m')$ are tabulated by Cohen for certain values of η .¹⁹ Good agreement of the observed and calculated splittings (Table 3) is reached assuming that at Bi(1), the EFG $q_{xx}(q_{yy})$ axis is parallel to the b -axis and

Table 3. The observed ($\Delta\nu_{\text{exp}}$) and calculated ($\Delta\nu_{\text{calc}}$) splittings of the ν_2 resonances in the ^{209}Bi NQR spectrum of the $\text{Bi}_3\text{B}_5\text{O}_{12}$ single crystal in $H_c = 300$ G (see Fig. 8).¹³

Atom	ν_2 / MHz	$\Delta\nu_{\text{exp}}$ / kHz	$\Delta\nu_{\text{calc}}$ / kHz
$H_c \parallel a$			
Bi(1)	53.03	466.0	487.0
Bi(2)	52.20	548.0	566.0
$H_c \parallel c$			
Bi(1)	53.03	548.0 (av.)	554.5 (av.)
Bi(2)	52.20	342.0	389.0

$q_{yy}(q_{xx})$, to the c -axis of the crystal. At Bi(2), q_{xx} lies in the bc -plane at an angle of 45° to the b -axis and q_{yy} , in the same plane at an angle of -45° to the b -axis. The additional splitting of the ν_2 Bi(1) line (see Fig. 8b) is caused by the magnetically non-equivalent Bi(1) positions in the lattice. With the orientation of the EFG principal axes found, one can calculate the expected resonance intensity ratio r in zero field, i.e., in a pure quadrupole spectrum of a single crystal. The transition probability W (and hence the line intensity) in a pure NQR spectrum is known to depend on the orientation of the EFG axes with respect to the H_{rf} direction as

$$W = 2D \cos^2\theta + \frac{1}{2} \sin^2\theta (G + 2J \cos 2\varphi). \quad (23)$$

Here θ and φ are the angles between the H_{rf} direction and the EFG principal axes; D , G and J are the coefficients depending on η and m .¹⁹ As the results of the calculation showed, the resonance intensity ratio r in a pure NQR spectrum is less than unity being different in the crystal orientations $H_{rf} \perp b$ and $H_{rf} \parallel b$. However, the experimental intensity ratio r exceeded 2 and was the same in both crystal orientations (see Figs 6 and 7). Hence, the observed zero-field NQR spectrum of the $\text{Bi}_3\text{B}_5\text{O}_{12}$ single crystal is not a pure quadrupole spectrum, which gives indirect evidence for the existence of unusual magnetism-related properties in this compound, in particular, local magnetic fields found earlier in $\alpha\text{-Bi}_2\text{O}_3$ and $\text{Bi}_4\text{Ge}_3\text{O}_{12}$. These fields are most likely weak, so that the appropriate zero-field splittings are masked by the effect of inhomogeneous line broadening and cannot be observed directly. The Zeeman fields $H_c = 300$ G optimal for modelling completely suppressed the spectroscopic manifestation of the local field ($H_c \gg H_{\text{loc}}$), resulting in no anomalies in the Zeeman splittings. Therefore, the evaluation of the local field strength and orientation with respect to the crystal axes from the Zeeman experiments appeared impossible.¹³

IV. Studies of local magnetic fields by analysis of the quadrupole spin echo envelope

A study of the problem was continued using an approach enabling detection of weak (within an inhomogeneous line broadening) spectroscopic splittings. Such splittings are known to be registered as low-frequency modulations of the spin echo envelope. The registering of SEE involves accumulation of the NQR signals upon continuous increase in pulse separation followed by data processing. A preliminary experiment showed that the SEE for the ν_2 Bi(1) line was modulated in zero field, pointing to the presence of line splitting. A detailed examination of this SEE curve revealed its distinctive modulation in both single crystal and powder samples of $\text{Bi}_3\text{B}_5\text{O}_{12}$ (Fig. 9).¹³ The strength and orientation of H_{loc} had to be further evaluated from the SEE shape using the mathematical model. However, due to the low-symmetry structure of $\text{Bi}_3\text{B}_5\text{O}_{12}$, an increased multiplicity of the spectrum occurs in external magnetic field, thus revealing the magnetic non-equivalence of the bismuth sites. In order to avoid computational difficulties, a model¹³ was first elaborated for $\text{Bi}_2\text{Ge}_3\text{O}_9$ [benitoite-type structure, space group $P6_3/m$ (see Ref. 11)], the

Figure 9. Zero-field spin echo envelopes assigned to the v_2 transition of Bi(1) (see Table 2) recorded for the $\text{Bi}_3\text{B}_5\text{O}_{12}$ single crystal at ambient temperature (a) and for a powder sample at 77 K (b).¹³

^{209}Bi NQR spectrum of which is given in Table 1. In agreement with the X-ray diffraction data, the spectrum reveals an axial symmetry of the crystallographically equivalent bismuth sites ($\eta = 0$, see Table 1). Earlier, the existence of local magnetic field in this compound has been suggested based on the analysis of the zero-field line shape (Fig. 10).⁴

As follows from the symmetry properties of the EFG tensor at the ^{209}Bi sites, the lattice charge contribution to the EFG tensor is the same for all the bismuth atoms in the unit cell of $\text{Bi}_2\text{Ge}_3\text{O}_9$, i.e., all the bismuth positions are crystallographically and magnetically equivalent. Hence, its ^{209}Bi NQR spectrum gives a single set of splittings in a magnetic field.¹³ In addition, the EFG principal axis q_{zz} is parallel to the sixfold axis of the hexagonal lattice, which is the z -axis of the crystal.

The zero-field SEE curves were recorded at room temperature for the lines assigned to the v_1 and v_2 transitions¹³ (see Table 1) using a powder sample of $\text{Bi}_2\text{Ge}_3\text{O}_9$ prepared as described in Ref. 3 (see Fig. 11). In zero external field, the SEE curve assigned

Figure 10. A zero-field line assigned to the transition v_1 ($\Delta m = 1/2 - 3/2$) in the ^{209}Bi NQR spectrum of a powder sample of $\text{Bi}_2\text{Ge}_3\text{O}_9$.

Figure 11. Observed (1) and calculated (2) zero-field spin echo envelopes assigned to the transitions v_1 ($\Delta m = 1/2 - 3/2$) (a) and v_2 ($\Delta m = 3/2 - 5/2$) (b) for a powder sample of $\text{Bi}_2\text{Ge}_3\text{O}_9$.¹³

to the v_2 transition exhibits apparently regular oscillations, whereas the modulation pattern of the SEE curve assigned to the v_1 line is more complicated, both indicating the presence of a local magnetic field in this compound. The evaluation of the local field characteristics was performed by modelling of the SEE that took into account the presence of local and external magnetic fields.¹³ Like the model described earlier²⁰ where the SEE was analysed for nuclei with the spin $3/2$, this approach was based on the density matrix formalism with the difference consisting in the consideration of the symmetry properties of the EFG and local magnetic field that substantially influence the SEE shape.¹³ The basic stages of the modelling¹³ as well as the algorithm for the SEE calculation in the presence of H_e and H_{loc} are given in the Appendix.

The simulated SEE curves are also shown in Fig. 11. It was found that the shape of the simulated curve assigned to the v_1 transition was in fairly good agreement with the experimental one assuming that the local magnetic field in $\text{Bi}_2\text{Ge}_3\text{O}_9$ amounts to 65 ± 5 G and directed at an angle $83 \pm 1^\circ$ to the EFG q_{zz} -axis. As to the transitions higher than v_1 , their line shapes are expected to be featureless in the external magnetic field, if $\eta = 0$ (Refs 20 and 21). In agreement with the results of studies,²¹ the simulated lines uniformly broadened to the Larmor frequency value. However, the results of modelling¹³ showed that, assuming even negligibly small deviation of the EFG symmetry from the axial ($\eta \sim 0.005$), the modulations of the SEE curve assigned to the v_2 transition are closely reproduced at the same characteristics of H_{loc} that have been found from the modelling of the SEE assigned to the v_1 transition (see Fig. 11). Naturally, such a small value of η is beyond the accuracy of NQR measurements. The question on whether the appropriate deviation of the electron density distribution from axial symmetry might be detected in an X-ray experiment seems to be interesting. The anomalies found in the magnetic properties of $\text{Bi}_2\text{Ge}_3\text{O}_9$ make the experiments on a single crystal very attractive. Unfortunately, all efforts to grow a single crystal of suitable size failed.¹³

The modelling of the SEE for $\text{Bi}_3\text{B}_5\text{O}_{12}$ having more complicated structure was carried out in a similar way (Fig. 12). As was mentioned above, the unit cell of $\text{Bi}_3\text{B}_5\text{O}_{12}$ is orthorhombic [space group $Pnma$ (D_{2h}^{16}), $Z = 2$] with four Bi(1) atoms occupying the c -sites in the symmetry plane and eight Bi(2) atoms, the d -positions of the general type.^{16,17} The analysis of the EFG symmetry at the c -sites showed that two types of the EFG tensors are available for the Bi(1), Bi(2) and Bi(3), Bi(4) atoms, respectively:

$$\begin{pmatrix} a & 0 & d \\ 0 & b & 0 \\ d & 0 & c \end{pmatrix} \text{ (I) and } \begin{pmatrix} a & 0 & -d \\ 0 & b & 0 \\ -d & 0 & c \end{pmatrix} \text{ (II),}$$

where a, b, c, d are the lattice sums of products of the atomic coordinates by derivatives of the crystal-field potentials at the atomic sites.⁷ The roots of the characteristic equations associated with the tensors (I) and (II) are equal to each other

$$\lambda_1 = b, \quad (24)$$

$$\lambda_{2,3} = \frac{a+c}{2} \pm \frac{1}{2} \sqrt{(a-c)^2 + 4d^2}.$$

The fact that one of the roots is equal to the diagonal element of the EFG tensor ($\lambda_1 = b$) complicates the procedure of finding the direction cosines for the principal axes of the tensors (I) and (II). However, one can show that the following symmetry relationships hold true:

$$\sigma_{21}^{(I)} = \sigma_{31}^{(II)}, \quad \sigma_{31}^{(I)} = \sigma_{21}^{(II)}, \quad \sigma_{23}^{(I)} = -\sigma_{33}^{(II)}, \quad \sigma_{33}^{(I)} = -\sigma_{23}^{(II)},$$

Figure 12. Observed (a) and simulated (b) SEE curves of the transition v_2 of the Bi(1) site in the ^{209}Bi NQR spectrum of the $\text{Bi}_3\text{B}_5\text{O}_{12}$ single crystal for the various parameters of local magnetic field ($H_{\text{loc}i} = H_{\text{loc}} \cos \theta_i$). $H_{\text{loc}i}/\text{G}$: 0 (1), 2 (2–4), 2.5 (5), 2.25 (6); θ_i/deg : 0 (1), 15 (2), 20 (3, 5), 25 (4), 22.5 (6).

$$\sigma_{12}^{(I)} = \sigma_{12}^{(II)} = 1 \quad (25)$$

$$\sigma_{11}^{(I)} = \sigma_{11}^{(II)} = \sigma_{22}^{(I)} = \sigma_{22}^{(II)} = \sigma_{33}^{(I)} = \sigma_{33}^{(II)} = \sigma_{23}^{(I)} = \sigma_{23}^{(II)} = 0.$$

These relationships enable one to determine the two of three Euler angles connecting the crystallographic coordinate system with those of the EFG principal axes (see Fig. 3b).

$$\theta_1, \varphi_1 = \frac{3\pi}{2}, \quad \psi_1 = \frac{\pi}{2}, \quad (26)$$

$$\theta_2 = \theta_1 + \frac{\pi}{2}, \quad \varphi_2 = \frac{\pi}{2}, \quad \psi_2 = \frac{3\pi}{2}.$$

The θ_1 -value for the Bi(1) positions in the $\text{Bi}_3\text{B}_5\text{O}_{12}$ lattice can be found from a comparison of the simulated and observed NQR Zeeman spectra.¹³ The modelling of the Zeeman spectra was performed as described above (see Part III). For the $\text{Bi}_3\text{B}_5\text{O}_{12}$ single crystal used in the experiments, the components of the rotation matrix D in the Hamiltonian $\hat{H}_e$ [see Eqn (8)] are

$$\begin{aligned} D_{13} &= -\cos \psi \cos \varphi \sin \alpha + \\ &+ \sin \psi (\cos \theta \sin \varphi \sin \alpha + \sin \theta \cos \alpha), \\ D_{23} &= \sin \psi \cos \varphi \sin \alpha + \\ &+ \cos \psi (\cos \theta \sin \varphi \sin \alpha + \sin \theta \cos \alpha), \\ D_{33} &= -\sin \theta \sin \varphi \sin \alpha + \cos \theta \cos \alpha, \end{aligned} \quad (27)$$

where θ, φ and ψ are the Euler angles [see Eqn (26)]. It is to be reminded that the field $\mathbf{H}_{\text{rf}}$ was parallel to the axis b of the single crystal, and the crystal was turned through the angle α about the coil axis coinciding with the $\mathbf{H}_{\text{rf}}$ direction. At $\alpha = 0^\circ$, the external field $\mathbf{H}_e$ was directed along the c -axis, and at $\alpha = -90^\circ$, along the a -axis of the crystal. In $\mathbf{H}_e \parallel c$ ($\alpha = 0^\circ$), the components of the rotation matrices in Eqn (27) referring to the two sets of the Euler angles (26) are described as

$$\begin{aligned} D_{13}^{(1)} &= \sin \theta_1, \quad D_{23}^{(1)} = 0, \quad D_{33}^{(1)} = \cos \theta_1, \\ D_{13}^{(2)} &= -\cos \theta_1, \quad D_{23}^{(2)} = 0, \quad D_{33}^{(2)} = -\sin \theta_1. \end{aligned} \quad (28)$$

In these expressions, the upper index corresponds to the set of the angular parameters in Eqn (26). In $\mathbf{H}_e \parallel a$ ($\alpha = -90^\circ$), the components of the rotation matrices become

$$\begin{aligned} D_{23}^{(1)} &= 0, \quad D_{33}^{(1)} = -\sin \theta_1, \\ D_{13}^{(2)} &= -\sin \theta_1, \quad D_{23}^{(2)} = 0, \quad D_{33}^{(2)} = \cos \theta_1. \end{aligned} \quad (29)$$

The angle $\theta_1 = 0 \pm 5^\circ$ was found from the comparison of the observed (Fig. 8) and simulated spectra of the $\text{Bi}_3\text{B}_5\text{O}_{12}$ single crystal in $H_e = 300$ G.

The calculation of the SEE shape by the program based on the density matrix formalism¹³ (see Appendix) enabled one to derive the value of local magnetic field in this compound (~ 2.5 G, see Fig. 12).

Thus, the above results showed that a weak local magnetic field exists in $\text{Bi}_3\text{B}_5\text{O}_{12}$. Assuming that the presence of these fields is related to the anomalies observed for the resonance intensity ratio [for instance, the local field unequally influences the intensities assigned to the v_2 resonances assigned to the Bi(1) and Bi(2) sites characterised by the EFG of presumably different symmetry¹³], one has to admit the existence of a strong coupling between the electronic and magnetic subsystems in $\text{Bi}_3\text{B}_5\text{O}_{12}$.

The zero-field modulations of the ^{209}Bi SEE curves were naturally observed in the compounds where $\mathbf{H}_{\text{loc}}$ has earlier been revealed from either Zeeman-perturbed or zero-field spectroscopic splittings.¹³ Distinctive modulations were also observed for BaBiO_2Cl (Fig. 13) the crystallochemical properties of which have much in common with those of the above described $\text{Bi}_3\text{O}_4\text{Br}$. In the structures of both compounds, the layers of bismuth oxide polyhedra alternate with those of halide anions.^{22,23} The

Nearly all the compounds discussed here featured extraordinary sensitivity of the NQR spectroscopic parameters to weak magnetic fields. For most of them, a considerable increase in the

Figure 14. Line of the ν_2 transition of Bi(2) (see Table 2) in the ^{209}Bi NQR Zeeman spectra of $\text{Bi}_3\text{B}_5\text{O}_{12}$ (a) and spin-echo envelopes recorded for the same line in various magnetic fields (b).

resonance intensity depending on the ^{209}Bi EFG symmetry properties and mutual orientation of the fields disturbing the spin system was observed upon applying magnetic field (see, for instance, Figs 4 and 8). This phenomenon could explain the deviation of the $\nu_2\text{Bi}(1)$ -to- $\nu_2\text{Bi}(2)$ intensity ratio in $\text{Bi}_3\text{B}_5\text{O}_{12}$ from that in a pure quadrupole spectrum.¹³

A strong increase in the line intensity observed in the Zeeman spectrum of $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ was suggested to result from the effect of external magnetic field on the spatial orientation of the EFG axes.¹² Recent experiments showed that H_e also strongly affects the spin–spin relaxation time and hence the resonance intensity (Fig. 14).²⁴ This problem for the high-spin systems with non-equidistant energy levels is, however, virtually unstudied.

It is important to note that no intensity increase in the ^{115}In NQR lines in a magnetic field was observed for crystallographically related indium compounds In_xB_y ($B = \text{O}, \text{Se}, \text{Te}$) where the valence electron shell of the central atom (the ^{115}In nuclear spin is $9/2$) has, unlike bismuth, no unshared pair of electrons (Table 4, Fig. 15).²⁴

V. The results of magnetisation measurements and magnetoelectric effect in the $\alpha\text{-Bi}_2\text{O}_3$ single crystal

Studies of magnetic properties of the compounds by complementary methods included an examination of a powdered $\alpha\text{-Bi}_2\text{O}_3$ sample using a muon spin relaxation (μSR) technique^{25–27} and SQUID measurements of the $\alpha\text{-Bi}_2\text{O}_3$ single crystal.^{28,29} The results of the experiments were understood as indicative of previously unknown magnetic properties in the compound. The μSR experiments within 10–300 K revealed no pronounced precession of the muon spin, hence ruling out the existence of a long-range order in $\alpha\text{-Bi}_2\text{O}_3$. However, fast depolarisation of the muon spin was distinctly observed for short time intervals, which was interpreted as manifestation of local magnetic fields in interstices of the α -bismuth oxide crystal lattice.^{25–27}

In the experiments using a SQUID magnetometer with the sensitivity of about 10^{-7} G cm^3 , the magnetisation of the $\alpha\text{-Bi}_2\text{O}_3$ single crystal was measured as a function of the magnetic field and temperature to find the paramagnetic character of magnetisation at low temperatures ($\sim 4.2 \text{ K}$) in magnetic fields up to 3–5 kG (Figs 16 and 17).²⁸ The magnetisation of the single crystal was highly anisotropic, which makes groundless a suggestion of paramagnetic impurities as the cause of magnetisation: because of disordered distribution in a diamagnetic crystal, they can produce the isotropic magnetisation only.³⁰

As the temperature and external magnetic field increased, the magnetisation of $\alpha\text{-Bi}_2\text{O}_3$ passed from the para- to the diamagnetic region where it conformed to the conventional classification of this substance as diamagnetic. It is to be noted that this classification is based on the results of measurements of the magnetisation by the Faraday method using a magnetic balance at room temperature in magnetic fields of the order of 10 kG.

A strong dependence of the $\alpha\text{-Bi}_2\text{O}_3$ single crystal magnetisation (M) on the magnetic prehistory of the sample was observed.²⁹ Figure 18 demonstrates the $M(H)$ curves measured along the crystallographic c -axis of the sample at 4.2 K. The sample was cooled either in the zero external field (Zero-Field

H_c/G : (a) 0 (1), 21 (2), 60 (3), 150 (4), 225 (5), 300 (6), 480 (7); (b) 0 (1), 30 (2), 60 (3), 90 (4), 120 (5), 225 (6), 300 (7), 480 (8); (c) 0 (1), 30 (2), 90 (3), 150 (4), 225 (5), 300 (6), 480 (7).

Cooling, ZFC; the strength of H_c inside a magnetic screen containing the sample was several mG, or in the fields of the order of several hundred Oersted (Field Cooling, FC). The dependence $M(H)$ under the ZFC conditions was linear in weak fields and rapidly came to a saturation in the fields above 2.5 kG. However, the magnetisation dramatically increased upon cooling the crystal in the external magnetic field. Thus, it increased by an order of magnitude in the fields $H_c \sim 3\text{--}4$ kG for the sample

precooled in the field of 580 G, the tendency for saturation weakening as the field in which the sample was cooled increased.²⁹

The temperature dependence of the magnetisation also strongly depended on the magnetic prehistory of the sample.²⁹ Both curves in Fig. 19 were measured in the external field of 4850 G applied along the axis a of the crystal. The curve 1 was measured after ZFC, whereas the other one, after the crystal was stored for ~ 10 hours in a residual field of a solenoid ($H_c \sim 10$ G) at liquid nitrogen temperature.

The mechanism of this phenomenon is not yet clear, the suggestion being made of its magnetoelectric nature, because the magnetoelectric effect (electric polarisation in an applied magnetic field) linear with respect to the field was observed in $\alpha\text{-Bi}_2\text{O}_3$ at 4.2 K.^{28,29} In addition, α -bismuth oxide is similar to ferro- and antiferroelectrics in electric properties. This is supported by

Figure 16. Magnetisation of the $\alpha\text{-Bi}_2\text{O}_3$ single crystal in external magnetic fields.²⁸

Measuring conditions: (1) $T = 4.2$ K, $H_c \parallel a$; (2) $T = 4.2$ K, $H_c \parallel b$; (3) $T = 4.2$ K, $H_c \parallel c$; (4) $T = 77$ K, $H_c \parallel a$; (5) $T = 77$ K, $H_c \parallel c$; (6) $T = 200$ K, $H_c \parallel c$. Dashed line is M_{dia} (see text). In the inset, the initial parts of some curves are shown.

several anomalies in its physical properties found between 450–570 K, for instance, a maximum displayed by the real part of the dielectric permeability.^{31, 32} These anomalies were however accompanied by neither distortions of monoclinic symmetry of the α -Bi₂O₃ lattice, nor sharp changes in the lattice parameters over 300–570 K. The monoclinic lattice of α -bismuth oxide remained stable also at low temperatures: the IR³³ and Raman³⁴ spectra of the single crystal were qualitatively very similar to those measured at room temperature.

Based on the results of measurements of the field and temperature dependences of the α -Bi₂O₃ magnetisation, the authors²⁹ evaluated the effective magnetic moment per unit cell of the crystal, assuming several contributions to the magnetisation:

$$M = M_{\text{dia}} + M_{\text{VV}} + M_{\text{para}}, \quad (30)$$

where $M_{\text{dia}} = \chi_{\text{dia}} H$ is the temperature-independent diamagnetic contribution of the ionic cores (the magnitude of $\chi_{\text{dia}} = -1.85 \times 10^{-7} \text{ cm}^3 \text{ g}^{-1}$ was estimated assuming additive contributions of the ion diamagnetic susceptibilities to the total diamagnetic susceptibility of α -Bi₂O₃³⁵); M_{VV} is the temperature-independent positive Van Vleck-type contribution; M_{para} is the paramagnetic Curie-type contribution. Both latter contributions depend on the magnetic prehistory of a sample (see Figs 18 and 19). The known formulae were used to evaluate M_{VV} and M_{para} :

$$M_{\text{VV}} = \chi_{\text{VV}} H, \\ \chi_{\text{VV}} \approx \frac{N_A \mu_B^2}{A} \frac{\alpha^2}{\Delta},$$

$$M_{\text{para}} = \chi_{\text{para}} H,$$

$$\chi_{\text{para}} = \frac{N_A \mu_B^2}{A} \frac{\mu_{\text{ef}}^2}{3kT},$$

(31)

where N_A is the Avogadro number, $A = 466 \text{ g mol}^{-1}$ is the molecular weight of α -Bi₂O₃, α^2 is the squared matrix element of the magnetic moment operator, Δ is the energy difference between the ground and excited states of the electronic subsystem, μ_{ef} is the effective magnetic moment of the unit cell of the crystal.

The parameters α^2/Δ and μ_{ef} were estimated at 4.2 and 77 K based on the results of ZFC magnetisation measurements²⁸ (Figs 16 and 17) in weak fields ($H_e < 500$ Oe) where M linearly depends on H_e directed along the axis a of the crystal. They were found to amount to $\alpha^2/\Delta \approx 4 \times 10^{-4} \text{ K}^{-1}$ and $\mu_{\text{ef}} \approx 0.06 \mu_B$ (per formula unit). Although the estimated value of the α -Bi₂O₃ magnetic moment appeared to be small compared to those in conventional ferro- and antiferromagnets, it unambiguously points to the electronic origin of the paramagnetism in this compound. Moreover, the magnetisation of the sample precooled in a constant magnetic field (the FC experiment) increased by factors 5–10 compared to that of the sample measured after ZFC (see Fig. 18). It is clear that if Eqns (31) hold true under the FC conditions, a similar analysis of the magnetisation will give the values of α^2/Δ and μ_{ef} increased accordingly.

As was mentioned above, the magnetoelectric effect was observed in the α -Bi₂O₃ single crystal.^{28, 29} This effect was studied for a plate $\sim 0.03 \text{ cm}^2$ in area and 0.13 cm thick that was cut in the bc plane of the crystal. A highly sensitive electrometer Kythley 642 was used for the measurements. The experiment was carried out at 4.2 K in a superconducting solenoid capable of producing magnetic field up to 150 kOe. The magnetic field $H \parallel E$ was applied perpendicularly to the plate surface, i.e., close to the axis a of the crystal. The results are shown in Fig. 20. As one can see, the polarisation linearly increased (the slope is 1.6×10^{-7}) in the fields up to 50 kOe showing a tendency for saturation in higher fields.

The crystal structure of α -Bi₂O₃ is known to be monoclinic.³⁶ There are four magnetic classes in the point group C_{2h} ,³⁷ from which C_{2h} and $C_{2h}(C_i)$ allow ferromagnetism, whereas $C_{2h}(C_2)$ and $C_{2h}(C_s)$, antiferromagnetism. An inversion (I) is present among the symmetry elements of the two former classes. This means that the linear magnetoelectric effect described by the magnetoelectric component of the thermodynamic potential³⁷

Figure 20. The magnetoelectric effect in the α -Bi₂O₃ single crystal measured at 4.2 K.²⁹ P is polarisation. Arrows show the direction of field change.

$$\Phi_{me} = -\alpha_{ij}E_iH_j \quad (32)$$

is forbidden for the C_{2h} and $C_{2h}(C_i)$ classes (α_{ij} is the magnetoelectric tensor) and allowed for $C_{2h}(C_2)$ and $C_{2h}(C_s)$. Based on the symmetry properties, it was shown²⁹ that the magnetoelectric tensor for the class $C_{2h}(C_2)$ is

$$\alpha_{ij} = \begin{pmatrix} \alpha_{xx} & 0 & \alpha_{xz} \\ 0 & \alpha_{yy} & 0 \\ \alpha_{zx} & 0 & \alpha_{zz} \end{pmatrix}. \quad (33)$$

For the class $C_{2h}(C_s)$, the components complementary to those of matrix (33) differ from zero:

$$\alpha_{ij} = \begin{pmatrix} 0 & \alpha_{xy} & 0 \\ \alpha_{yx} & 0 & \alpha_{yz} \\ 0 & \alpha_{zy} & 0 \end{pmatrix}. \quad (34)$$

Attempts to explain the origin of the linear magnetoelectric effect in α -bismuth oxide faced however several difficulties.

According to Landau and Lifshitz, who predicted the existence of the effect in magnetically ordered substances,³⁷ the tensor α_{ij} is an odd function with respect to time inversion. After theoretical prediction by Dzyaloshinskii³⁸ followed by observation of the magnetoelectric effect in antiferromagnetic Cr_2O_3 ,^{39,40} the systematic classification of magnetoelectric materials was performed.⁴¹ It was noted that the linear magnetoelectric effect described by Eqn (32) can exist only in substances characterised by the long-range ferro- or antiferro-magnetic ordering. However, the analysis of the α - Bi_2O_3 magnetisation carried out using Eqn (30) showed that the existence of the long-range magnetic ordering in α -bismuth oxide is unlikely.²⁹

The suggestion that the paramagnetoelectric effect, similar to that found in piezoelectric paramagnetic crystals,⁴² may exist also in α - Bi_2O_3 comes into conflict with several facts. This effect is described by a contribution into the thermodynamic potential of the type

$$\Phi_{\text{PME}} = -\zeta_{ijk}E_iH_jH_k,$$

where ζ_{ijk} is the magnetoelectric tensor of the third rank.

Hence, this is forbidden for the point group C_{2h} , because the inversion I is available among its symmetry elements. In addition, the electric polarisation is a function of H but not H^2 over a wide range of fields, as demonstrated in Fig. 20.

As to the existence of the magnetoelectric effect in diamagnetic dielectric crystals, the observation of this effect in crystals with paramagnetic defects was documented. Using EPR, a notable increase in magnetisation of α -quartz comprising the $\text{Al}-\text{O}^-$ centres was found in an alternating electric field.⁴³ The magnetic and electric characteristics are coupled in such systems by spin-orbit interaction. A tunnelling of the charged electron holes between the equilibrium positions, if available, enhances the effect considerably. The hole is known to carry the magnetic moment because it possesses both spin and orbital magnetic moments. Such a paramagnetic centre carries also the electric dipole moment. If a coupling exists between the electric and magnetic moment, one can observe the magnetoelectric effect.

The existence of a system of paramagnetic centres in α - Bi_2O_3 is quite probable. The holes in the p-electron shell of the oxygen atoms may presumably serve as such centres, whereas the $\text{Al}-\text{O}^-$ centres in α -quartz result from the Al^{3+} substitution for Si^{4+} . Considering the low symmetry of the electric field of the crystal at the oxygen sites and weak spin-orbit interaction (the spin-orbit coupling constant for the oxygen atom is ~ 10 meV) one can admit the presence of several low-lying crystal field levels, which are responsible for the observed field and temperature dependences of the paramagnetic contribution into the α - Bi_2O_3 magnetisation. Thus for the p^4 atomic configuration, the multiplets $^3P_2$ (ground) and excited $^3P_1$ and $^3P_0$ (lying, accordingly, 20 and 30 meV above the ground level in a free oxygen atom⁴⁴) must split into nine

crystal-field levels. To verify the hypothesis for the presence of the paramagnetic centres in α -bismuth oxide, a detailed examination of its electron structure is necessary.

VI. On the probable origin of anomalies in magnetic properties of bismuth oxy compounds

No information on the electron structure of α - Bi_2O_3 is available in the literature, so that the calculation of its electron band structure was found to be expedient. The program package used for the calculations was a version of the FP-LMTO (Full-Potential Linear-Muffin-Tin-Orbital) approach⁴⁵ based on the electron density functional theory.⁴⁶ This approach belongs to the so-called 'first principle' methods of calculating the electron structure, which require only the nuclear charges, lattice parameters and atomic coordinates to be given as the initials. Based on the electron density functional theory, the electron density is further computed by a self-consistence procedure, after which the full energy and electron band structure of the compound are evaluated. The calculated electron band structure of α - Bi_2O_3 appeared however too cumbersome, therefore the density of states only is shown in Fig. 21, which nevertheless carries a sufficient amount of information on the electronic properties of this compound.

Figure 21. Density of states for α - Bi_2O_3 . Dashed line shows the Fermi level.

According to the results of the calculation, a peak of the density of states exists near the Fermi level, the ground state of the electron structure of α - Bi_2O_3 being metallic, whereas it is actually dielectric. A similar inconsistency results from the electron structure calculations of copper oxy compounds that served as the initial reagents for the preparation of high-temperature superconductors. This inconsistency can be removed, for instance, by the introduction of the Hubbard Hamiltonian, which takes into account the electron correlations. Examples are provided by transition or rare earth element compounds that exhibit sharp peaks of the density of states near the Fermi surface (Kondo-insulators).⁴⁷ Unlike the known systems with strong electron correlations, α - Bi_2O_3 comprises no atoms with unfilled d- or f-electron shells. Hence, the revealed features of the α - Bi_2O_3 electron structure allow one to raise the question about the existence of strong electron correlations in systems with valence s- and p-electrons also.

The analysis of the partial densities of states suggested that the $\text{Bi}6s$ - and $\text{O}2s$ -electrons make the predominant contribution to the peaks located in the energy range from -16 to -12 eV, the high density of states at -5.0 and -3.0 eV resulting largely from

the Bi6p- and O2p-electrons. The unoccupied states above the Fermi level are due mostly to the Bi6p-electronic states. Based on the results of the calculations, the conduction band width ($\sim 4-5$ eV) involving the hybridised O2p- and Bi6p-electronic states was evaluated as well as the band width for the O2p-states in the Fermi level ($2-3$ eV). As follows from the results obtained, the correlations between the O2p-electrons may be responsible for the semiconducting (close to dielectric) type of the α -Bi₂O₃ electron band structure as well as for the unusual magnetic properties: the existence of local magnetic fields, paramagnetism depending on the thermomagnetic prehistory of a sample and magnetoelectric effect. The Bi6s- and O2s-electronic states in α -bismuth oxide can hardly be the strongly correlated subsystem, if the high bonding energy and the Pauli principle are taken into account. The dominant role played by the Bi6p-electrons seems to be the participation in the superexchange O2p – Bi6p – O2p interactions accompanied with the electron spin-flip hoppings, which may result in the antiferromagnetic correlations and magnetoelectric effect.⁴⁸ This suggestion is supported by low (monoclinic) crystal symmetry of α -bismuth oxide removing the spin – orbit degeneracy of the 6p-electron levels, a gain in energy caused by the half-filled bismuth 6p-electron shell (the $6s^2 6p^3$ configuration), and high, as the calculation showed, density of the vacant 6p-states above the Fermi level. It is to be noted that the ferromagnetic correlations in systems comprising only p-electrons are forbidden by the Pauli principle.

VII. Conclusion

This review summarises the results of investigation of some unusual magnetic and electronic properties of bismuth oxy compounds comprising the Main Group elements only. The results were obtained using mainly the ²⁰⁹Bi NQR spectroscopy and SQUID-magnetometry. The quantitative analysis of both the complicated Zeeman NQR spectra of high multiplicity and quadrupole spin echo envelopes, measured on mono- and polycrystalline samples, became possible due to development of new approaches in the NQR theory, *viz.*, elaboration of the computer model of the quadrupole spin echo based on the density matrix formalism and account of the EFG symmetry properties. As a result, the high sensitivity of the NQR spectroscopy to the presence in substances of weak magnetic fields compared to the terrestrial field was demonstrated. Because of this superior sensitivity, the NQR method (along with NMR) may become a promising tool for the solution of topical problems concerned with the reading of an information stored by nuclear spin systems.

A variety of unusual magnetic properties revealed in the bismuth oxy compounds, which have been traditionally considered as diamagnets, namely,

- the existence of local magnetic fields,
- the paramagnetism depending on the magnetic prehistory of a sample,
- magnetoelectric effect linear in magnetic field

give, along with the calculated peaks of the density states near the Fermi surface, grounds to believe that the electron correlations may exist also in substances with valence s- and p-electrons.

The electronic and magnetic properties of the discussed bismuth oxy compounds, as well as those of extensively studied transition and rare earth element oxides, result from an interplay of a number of contributions, such as specific features of crystal structure, electron correlations, exchange and superexchange interactions and orbital degrees of freedom.

An extension and analysis of the experimental basis aimed at clarifying the origin and mechanism of the coupling between the electronic and magnetic subsystems in non-magnetic compounds make a valuable contribution to our knowledge of magnetism. Thus the material surveyed in this review suggests the important role of the matrix (of gallium arsenide-type) for the explanation of unconventional properties displayed by highly dilute magnetic

semiconductors recognised as promising materials for spintronics technology.

The authors also appreciate the support of The Department of Chemistry and Materials Sciences of the RAS (the program ‘Elaboration of new efficient methods of chemical analysis and structural studies of substances and materials’, Project OKh-2.14) (E A Kravchenko); Federal Program for the Support of Leading Scientific Schools of the Russian Federation (Grant NSh-15722.2003.2) and The Foundation for the support of basic research in RSC ‘Kurchatov Institute’ (Project No. 17) (V G Orlov and M P Shlykov).

VIII. Appendix. The calculation of the nuclear quadrupole spin echo

The numerical modelling of the quadrupole spin echo was carried out for a two pulse spin echo sequence. The radiofrequency field H_{rf} was supposed to act during the time intervals $0 \leq t \leq t_1$ (the first pulse) and $\tau \leq t \leq \tau + t_2$ (the second pulse) and be switched off between the pulses ($t_1 \leq t \leq \tau$) and after the second pulse ($t \geq \tau + t_2$). The spin echo signal was expected to appear at the moment $t \cong 2\tau$. The duration of both pulses was assumed to be short compared to the interval between the pulses ($t_1, t_2 \ll \tau$). The interval τ is usually restricted to $\tau < T_2$ where T_2 is the spin – spin (transverse) relaxation time. In the modelling of the spin echo envelope, the magnitude of τ was varied in consistence with the time of measuring the SEE.

A distinctive feature of this model of the quadrupole spin echo consists of the presence of local and external magnetic fields. Both fields were assumed to be small: $\gamma H_{loc}, \gamma H_e \ll \omega_Q$, where $\gamma/2\pi = g_{Bi}\mu_B/h = 6.9 \times 10^{-4}$ MHz (G⁻¹) is the gyromagnetic ratio for the bismuth nucleus, ω_Q is the quadrupole transition frequency. The radiofrequency field H_{rf} was also assumed to be small: $\omega_1 = \gamma H_{rf} \ll \omega_Q$.

In the NQR experiments on the bismuth oxy compounds, the magnetic fields do fulfil the above requirements. Thus in the ²⁰⁹Bi NQR spectrum of Bi₂Ge₃O₉, the frequency ω_Q of transition between the nuclear spin levels $1/2 \rightarrow 3/2$ is ~ 160 MHz, the quadrupole coupling constant eQq_{zz}/h amounting to 605.9 MHz. One can easily find that the magnetic field strength H , derived from the relationship $\gamma H \sim \omega_Q$, is of the order of $(3-4) \times 10^4$ G, which is much larger than the local magnetic fields detected using NQR in the bismuth oxy compounds (30–250 G). In the NQR Zeeman experiments discussed here, the external magnetic fields up to 500 G were applied. The strength of H_{rf} in the coils of pulse NQR spectrometers also did not exceed several hundred Oersted, because the spin echo signal is observed if $\omega_1 t_{1,2} \sim 1$, the radiofrequency pulse widths $t_{1,2}$ being of the order of 1–10 μ s. Under the optimum observation conditions, the spin echo frequency ω_1 must be of the order of 1×10^6 s⁻¹, which gives $H_{rf} \sim 200$ G. In addition, the condition $\omega_Q t_{1,2} \gg 1$ is also satisfied.

In order to observe the nuclear quadrupole resonance signal, one has not to place a sample in a constant external magnetic field, because the nuclear spin levels are split due to the interaction of the nuclear electric quadrupole moment with a non-uniform electric field inherent in the sample. The level spacing can be found by the calculation of the energy levels of the quadrupole Hamiltonian. In the system of the EFG principal axes (x', y', z'), the quadrupole Hamiltonian is

$$\hat{H}_Q = \frac{eQq_{zz}}{4I(2I-1)} \left[3I_z'^2 - I(I+1) + \frac{\eta}{2}(I_+^2 + I_-^2) \right], \quad (A.1)$$

where $I_{\pm} = I_{x'} \pm iI_{y'}$.

In the presence of external and local magnetic fields, the term describing the interaction of the nuclear magnetic moment with these fields should be added to Eqn (A.1) to give the time-independent Hamiltonian

$$\hat{H}_0 = \hat{H}_Q - \gamma \hbar \mathbf{H}_{\text{loc}} \hat{\mathbf{I}} - \gamma \hbar \mathbf{H}_e \hat{\mathbf{I}}. \quad (\text{A.2})$$

The interaction of the nuclear magnetic moment with radio-frequency field $\mathbf{H}_{\text{rf}}$ is described as follows:

$$\hat{H}_1 = -\gamma \hbar 2 \mathbf{H}_{\text{rf}} \hat{\mathbf{I}} \cos \omega t. \quad (\text{A.3})$$

The total Hamiltonian is the sum of the Hamiltonians (A.2) and (A.3):

$$\hat{H} = \hat{H}_0 + \hat{H}_1. \quad (\text{A.4})$$

Under the action of pulsed radiofrequency field, the nuclear spin operators will evolve in time, so it is convenient to model the quadrupole spin echo using the time dependent density matrix^{20,49} with the elements

$$\rho_{mm'} = \langle m | \rho | m' \rangle, \quad (\text{A.5})$$

where m, m' are the state numbers. The time dependence of ρ can be found from the Liouville quantum equation (the Neumann equation)⁴⁹

$$i\hbar \frac{\partial \rho}{\partial t} = [\hat{H}, \rho] = \hat{H}\rho - \rho\hat{H}, \quad (\text{A.6})$$

where $\hat{H}$ is the total Hamiltonian (A.4).

Thus, the calculation of the quadrupole spin echo deals with the response of the nuclear spin system described by the Hamiltonian (A.2), the Hamiltonian (A.3) being taken into account.

At the initial moment, the density matrix $\rho(0)$ is given by the normalised Boltzmann distribution

$$\rho(0) = \frac{N}{2I+1} \exp\left(-\frac{H_0}{kT}\right), \quad (\text{A.7})$$

where N is the number of nuclei in a sample. In the high-temperature approximation ($eQq_{zz} \ll kT$) this formula becomes

$$\rho(0) \approx \frac{N}{2I+1} \left(1 - \frac{H_0}{kT}\right). \quad (\text{A.8})$$

The solution of Eqn (A.6) using an evolution operator S ⁴⁹ is described as follows:

$$\rho(t) = S\rho(0)S^{-1}. \quad (\text{A.9})$$

The evolution operator S obeys the Schrödinger equation, the unit matrix E satisfying the initial condition

$$i\hbar \frac{\partial S}{\partial t} = \hat{H}S, \text{ at } S(0) = E. \quad (\text{A.10})$$

In the earlier publications on the quadrupole spin echo theory that made use of the density matrix formalism (see, for instance, Ref. 20), the evolution operator S was used as the product of transformation matrices R and D , referring, respectively, to the duration of the radiofrequency field action and intervals between the pulses:

$$S = D_n R_n \dots D_2 R_2 D_1 R_1. \quad (\text{A.11})$$

Here

$$D_n(t, t_{n0} + t_n) = \exp\left[-\left(\frac{i}{\hbar}\right) H_0(t - t_{n0} - t_n)\right]$$

is the solution of the Schrödinger equation in the interval between the n th and $(n+1)$ th pulses ($H_1 = 0$); $R_n(t, t_{n0})$ is the solution of the Schrödinger equation at the moment t of the n th pulse duration ($t_{n0} \leq t \leq t_{n0} + t_n$)

$$i\hbar \frac{\partial R_n(t, t_{n0})}{\partial t} = (H_0 + H_1) R_n(t, t_{n0}), \quad (\text{A.12})$$

where t_{n0} is the time of switching the n th pulse on and t_n is its duration (the first pulse is assumed to be switched on at the moment $t_{10} = 0$).

The Schrödinger equation was solved with the unit matrix E satisfying the initial condition for all the matrices R and D in (A.11) (see Ref. 20). Using the interaction representation,⁴⁹ Eqn (A.12) can be rewritten as follows:

$$R_n(t, t_{n0}) = \exp\left[-\frac{i}{\hbar} H_0(t - t_{n0})\right] \tilde{R}_n(t, t_{n0}), \quad (\text{A.13})$$

$$i\hbar \frac{\partial \tilde{R}_n}{\partial t} = \tilde{H}_1 \tilde{R}_n,$$

where

$$\tilde{H}_1(t) = \exp\left[\frac{i}{\hbar} H_0(t - t_{n0})\right] H_1(t) \exp\left[-\frac{i}{\hbar} H_0(t - t_{n0})\right].$$

The solution of (A.13) was given in Ref. 20 as

$$\tilde{R}_n(t, t_{n0}) = \exp\left[-\frac{i}{\hbar} \int_{t_{n0}}^t \tilde{H}_1(t') dt'\right]. \quad (\text{A.14})$$

Formula (A.14) as well as the presentation of the evolution matrix as a chain of products of matrices $S = D_n R_n \dots D_2 R_2 D_1 R_1$, each being a solution of the Schrödinger equation with the unit matrix E satisfying the initial condition, are valid, provided the Hamiltonian $\tilde{H}_1(t)$ in (A.13) is independent of time. Since in the latter case $\tilde{H}_1(t)$ is a function of time, the procedure of finding S should be modified, the changes concerning the calculation of matrices $R_n(t, t_{n0})$. Generally, when the condition $\omega_Q t_{1,2} \gg 1$ is ignored and magnetic fields are not small, these matrices can be found by Eqn (A.13). Upon solving this equation, it is not E that should be taken to satisfy the initial condition but rather the evolution matrix value at the preceding stage $D_{n-1} R_{n-1}$.

As before, the matrix D_n in the interval between the n th and $(n+1)$ th pulses may be presented in the form

$$D_n(t, t_{n0} + t_n) = \exp\left[-\frac{i}{\hbar} H_0(t - t_{n0} - t_n)\right],$$

which follows from the solution of the Schrödinger equation, the unit matrix E satisfying the initial condition. In this case, the evolution matrix at the moment of switching the $(n+1)$ th pulse on is calculated by multiplying the matrices $S = D_n R_n$. For instance, the procedure of calculating the evolution matrix for the two-pulse method of spin echo registration may be presented as follows:

$$S(t, 0) = D_2(t, \tau + t_2) R_2(\tau + t_2, \tau) \Big|_{D_1(\tau, t_1) R_1(t_1, 0)} \Big|_E \quad (\text{A.15})$$

A shorthand notation was introduced in order to avoid a cumbersome description of the initial conditions:

$$S = D_2 R_2 \times D_1 R_1, \quad (\text{A.16})$$

where $\times$ denotes a procedure of calculating matrix R_2 , the initial condition being $D_1 R_1$. A multipulse chain can be presented similarly:

$$S = D_n R_n \times D_{n-1} R_{n-1} \times \dots \times D_2 R_2 \times D_1 R_1, \quad (\text{A.17})$$

where $\times$ denotes the operation specified by Eqns (A.15) and (A.16).

One can show that equation (A.17) is transformed to (A.11), which was used in the earlier publications on the quadrupole spin echo theory,²⁰ if, along with the above mentioned conditions ($\gamma H_e \ll \omega_Q$, $\gamma H_{\text{loc}} \ll \omega_Q$, $\omega_Q t_{1,2} \gg 1$), the following condition is also satisfied:

$$\gamma H_{e, \text{loc}} t_{1,2} \ll 1. \quad (\text{A.18})$$

The condition (A.18) imposes the restriction $H_{e, \text{loc}} \ll 200$ $\text{\AA}$ on the external (or local) magnetic field strength in the bismuth

compounds. If Eqn (A.18) holds true, Eqn (A.13) for the matrix $\tilde{R}_n$ is reduced to

$$\frac{\partial \tilde{R}_n}{\partial t} = A \tilde{R}_n, \quad (\text{A.19})$$

where A is a time-independent matrix. An explicit expression for the matrix $\tilde{R}_n$ can further be found by a cumbersome computation. If the condition (A.18) is not satisfied, the matrix $\tilde{R}_n$ can be found by a numerical solution of Eqn (A.13).

Assuming the condition (A.18) is satisfied and Eqn (A.11) holds true, one can derive the formula for the average value of nuclear spin projection onto the rf-coil axis $\langle I \rangle$, and use it as the basic formula for further elaborating a scheme of modelling of the SEE in $H_{e,loc} \ll 200$ G (the latter restriction was undoubtedly satisfied in the experiments discussed). If the time dependence of $\langle I \rangle$ is known, one can find a derivative $d\langle M \rangle/dt$ of the nuclear magnetic moment projection ($\langle M \rangle = g_{\text{Bi}} \mu_B \langle I \rangle$), to which the intensity of the spin echo signal is proportional.

According to the density matrix formalism, the average spin of a nuclear subsystem is evaluated by the formula

$$\langle I \rangle = \text{Sp}(\rho \hat{I}). \quad (\text{A.20})$$

In the high-temperature approximation, the density matrix at the initial moment is determined by formula (A.8). At any subsequent moment, the value of the matrix can be found by Eqn (A.9). Since $\text{Sp}(\hat{I}) = 0$, the expression for the average moment is

$$\langle I \rangle = C \text{Sp}(S H_0 S^{-1} I), \quad (\text{A.21})$$

where

$$C = -\frac{N}{(2I+1)kT}.$$

Using Eqn (A.11) for the evolution operator S , one can derive an expression for calculating the average nuclear spin after the action of the first

$$\langle I \rangle = C \text{Sp}(D_1 R_1 H_0 R_1^{-1} D_1^{-1} I) \quad (\text{A.22})$$

and second

$$\langle I \rangle = C \text{Sp}(D_2 R_2 D_1 R_1 H_0 R_1^{-1} D_1^{-1} R_2^{-1} D_2^{-1} I) \quad (\text{A.23})$$

radiofrequency pulses.

Substituting D_1 and D_2 into Eqns (A.22) and (A.23) and using the interaction representation, one obtains

$$\langle I \rangle = C \text{Sp} \left[\left(-\frac{i}{\hbar} H_0 t \right) \tilde{R}_1 H_0 \tilde{R}_1^{-1} \exp \left(\frac{i}{\hbar} H_0 t \right) I \right], \quad (\text{A.24})$$

$$\langle I \rangle = C \text{Sp} \left[\exp \left(-\frac{i}{\hbar} H_0 (t - \tau) \right) \times \quad (\text{A.25}) \right.$$

$$\times \tilde{R}_2 \exp \left(-\frac{i}{\hbar} H_0 \tau \right) \tilde{R}_1 H_0 \tilde{R}_1^{-1} \exp \left(\frac{i}{\hbar} H_0 \tau \right) \tilde{R}_2^{-1} \times$$

$$\times \exp \left(\frac{i}{\hbar} H_0 (t - \tau) \right) I \left. \right].$$

Using further the representation of operators in the basis of eigenfunctions for the operator H_0 (A.2) and denoting $\omega_{ij} = \lambda_i - \lambda_j$ (where $\lambda_i = E_i/\hbar$ and E_i are the eigenvalues of the Hamiltonian H_0), one can derive the expressions for calculating the average nuclear spin at instants after the first [formula (A.26)] and second [formula (A.28)] radiofrequency pulses

$$\langle I \rangle = C \sum_{m,s} A_{ms}(t) I_{sm}, \quad (\text{A.26})$$

where

$$A_{ms}(t) = e^{i\omega_{sm}t} \sum_n \lambda_n (\tilde{R}_1)_{mn} (\tilde{R}_1^*)_{sn}, \quad (\text{A.27})$$

$$\langle I \rangle = C \sum_{m,s} B_{ms}(t, \tau) I_{sm}, \quad (\text{A.28})$$

$$B_{ms}(t, \tau) = \sum_{n,k,p} \left\{ \exp i\omega_{sm} \left[t - \left(1 + \frac{\omega_{np}}{\omega_{sm}} \right) \tau \right] \right\} \times \quad (\text{A.29})$$

$$\times \lambda_k (\tilde{R}_2)_{mn} (\tilde{R}_1)_{nk} (\tilde{R}_1^*)_{pk} (\tilde{R}_2^*)_{sp}.$$

Since the operator $\hat{I}$ is Hermitian and the eigenfunctions of the Hamiltonian H_0 are real, the following relationships hold true: $A_{sm}^* = A_{ms}$, $B_{sm}^* = B_{ms}$. As a result, the average spin values calculated by formulae (A.26) and (A.28) are real.

The formula (A.29) clearly indicates when the spin echo signal appears. It is important that the Hamiltonian (A.2), which determines the scale of energy levels spacing [in this case, the quadrupole Hamiltonian (A.1)], be independent of time in the absence of radiofrequency field. The spin echo signal appears at the instants

$$t = \left(1 + \frac{\omega_{np}}{\omega_{sm}} \right) \tau,$$

defined by the ratio of various frequencies in the Hamiltonian (A.2). Among them, the spin echo appearing at the moment $t = 2\tau$ is always present. The signal intensity is determined by coefficients B_{ms} (A.29), which reach their maxima when the frequency of H_{rf} is close to the frequencies ω_{sm} and ω_{np} .

The free induction decay signals appearing after the first and second pulses ($t = t_1$ and $t = \tau + t_2$) can also be modelled using expression (A.28). As formulae (A.28) and (A.29) show, one can observe the spin echo signals for nuclei with spin $I > 3/2$ not only at the moment 2τ , but, for instance, also at $t = 3\tau$. For nuclei with spin $I = 3/2$, the spin echo is observed at $t = 2\tau$ solely, because only one quadrupole transition frequency is available. Whether the spin echo at $t = 3\tau$ is observable, depends on the signal intensity, which is defined by Eqn (A.29).

Formulae (A.26) and (A.28) can be conveniently used for calculating the average nuclear spin in an external magnetic field. Upon varying a pulse separation τ [see Eqns (A.28) and (A.29)] in the presence of static external or local magnetic fields, one can observe modulations (beats) on the SEE curve.²⁰ Their frequencies are proportional to the Zeeman-perturbed splittings of the nuclear spin levels described by the Hamiltonian (A.2). For the calculation of SEE, the absolute maximum of expression (A.29) at $t \sim 2\tau$ should be found for each τ .

Since the relaxation effects (a decay of the spin echo signal) were ignored in the Hamiltonian (A.4), on simulation they can be incorporated by simple multiplying the spin echo amplitude by a factor $\exp[-(1/2T_2^2)\tau^2]$, the value of T_2 being taken from the experiment.

The procedure of modelling the quadrupole spin echo signals should also take account of a mutual orientation of the laboratory $(\tilde{x}, \tilde{y}, \tilde{z})$ and crystallographic (x, y, z) coordinate systems. The appropriate relationships involve the Euler angles α, β and γ . The system of the EFG principal axes (x', y', z') is related to the crystallographic system by another set of the Euler angles θ, φ and ψ . The orientation of the local magnetic field vector H_{loc} with respect to the EFG principal axes is determined by angles θ_{loc} and φ_{loc} . Thus, the direction of the fields H_e , H_{loc} and H_{rf} with respect to the principal axes system (x', y', z') of the quadrupole Hamiltonian (A.2) is completely determined by the angles $\alpha, \beta, \gamma, \theta, \varphi, \psi, \theta_{\text{loc}}$ and φ_{loc} . All the scalar products $H_e J$, $H_{\text{loc}} J$ and $H_{\text{rf}} J$ in the Hamiltonians (A.2) and (A.3) have to be determined in the same coordinate system. For this purpose, the matrix D determined by angles $\theta, \varphi, \psi, \alpha, \beta$ and γ , which projects the vectors H_e and H_{rf}

onto the EFG principal axes, is involved into the calculation scheme. The crystallographically equivalent bismuth sites may appear to be magnetically non-equivalent. In such a case, each type of the EFG tensors is specified in external magnetic field by its own principal axes system (see Section III), so that the average nuclear spin is calculated for each orientation of the EFG tensors. The net average spin of the nuclear subsystem will evidently be the sum of the contributions from all the magnetically nonequivalent EFG tensors.

For a polycrystalline (powdered) specimen, the calculation procedure is similar. It differs in that the calculated spin is averaged over all the orientations of the crystallites with respect to the laboratory system, *i.e.*, over the Euler angles α , β and γ .

Thus, the procedure of calculation of the spin-echo amplitude as a function of radiofrequency pulse separation τ in weak ($\ll 200$ G) magnetic field involves the following stages:

1) the analysis of the EFG tensor symmetry; the evaluation of the matrix D : the calculation is performed for each magnetically non-equivalent EFG tensor;

2) the calculation of the eigenvalues and eigenfunctions of the Hamiltonian $\hat{H}_0$ (see A.2);

3) the calculation of matrix elements for operators using the representation in the eigenfunctions basis of the operator $\hat{H}_0$;

4) the evaluation of the matrix $\hat{R}$ with the unit initial condition by solving the Schrödinger equation (A.13);

5) the computation of coefficients A_{ms} and B_{ms} in equations (A.27) and (A.29);

6) the evaluation of the absolute maximum of expression (A.29);

7) the incorporation of the spin echo relaxation effect by multiplying by a factor $\exp[-(1/2T_2^2)\tau^2]$.

IV. Ion-molecular reactions of silylium ions	103

Abstract. The history and state of the art of research on silylium ions are summarised. Achievements of the last two decades in the preparation of silylium ions as individual species in solutions and crystals and as intermediates in reactions of organosilicon compounds are considered. Attention is focused on ion-molecular reactions of silylium ions with nucleophilic reagents in the gas and condensed phases. The bibliography includes 164 references.

I. Introduction

For more than five decades, scientists have debated whether silicon compounds can exhibit chemical properties characteristic of their carbon analogues. Since silicon and carbon are both Group 14 elements, attempts were made to find features of organosilicon chemistry characteristic of organic chemistry, *e.g.*, the ability of Si atoms to be involved in formation of Si=E double bonds (E = Si, C, O, N, *etc.*), long-chain silicon polymers and intermediates analogous to carbon compounds (for example, to carbenes and carbocations). Available experimental data show that the chemical properties of carbon are very different from those of silicon. First and foremost, silicon compounds containing multiple bonds are very unstable (unlike carbon analogues). Up to the mid-twentieth century, the existence of such compounds has been doubted.¹ First publications on the synthesis of unstable silicon compounds containing Si=Si, Si=C, *etc.* bonds date back to 1967.^{2–7} Nowadays, the opinion that silicon cannot form multiple bonds is completely disproved.^{8,9} The formation of polysilanes, whose properties have long been poorly known, was also proved.^{10,11} However, the existence of silicon intermediates analogous to carbon intermediates is still an open question. In recent years, silylenes,^{12–14} which are silicon analogues of well-known carbenes,¹⁵ have been synthesised and their properties

have been studied. However, it appeared to be very difficult to obtain (particularly, in the condensed phase) the tricoordinate organosilicon cations R_3Si^+ analogous to the carbocations R_3C^+ and prove their existence. Earlier, silylium ions in the gas phase have been studied primarily by ion cyclotron resonance and conventional mass spectrometry.¹⁶ However, the applicability of these methods is limited to observations of charged particles in a rarefied-gas atmosphere.

The present review deals with silylium ions and summarises both the history and state of the art of research in this field. The review covers the achievements of the last two decades in the synthesis of silylium ions as individual species both in solutions and crystals and as intermediates in reactions of organosilicon compounds. Emphasis is given to the reactivity of silylium ions and their ion-molecular reactions with nucleophilic reagents in the gas and condensed phases, which have remained virtually unknown until recently. It should be noted that in Russia the latest review of research into silylium ions was published by Nefedov *et al.*¹⁷ in 1986. Data on the synthesis and results of studies of silylium ions in the gas and condensed phases have been partially systematised.^{18–20} In addition, certain aspects of this problem have been summarised in short publications.^{21,22} The aim of the present review is to provide a deep insight into the development of chemistry of silylium ions.

II. History of investigations into silylium ions

The discovery of carbenium ions R_3C^+ isoelectronic with the silylium ions R_3Si^+ has played a great role in the development of organic chemistry because most organic reactions proceed *via* these reactive intermediates.²³ Their existence was established in the early twentieth century (see, for example, Ref. 24). For almost a century, these intermediates have attracted the most attention in studies of mechanisms of various chemical processes. In the 1990s, researchers have shifted their interest to the related species, *viz.*, silylium ions.

The ways of development of the chemistry of organosilicon cations R_3Si^+ and their carbon analogues R_3C^+ are substantially different. Even the name of the R_3Si^+ cation has long been debated. At different times, this cation was referred to as the siliconium,²⁵ silycenium²⁶ or silylenium²⁷ cation. Nowadays, it is called the silylium ion.²⁸ Taking into account that the carbenium ions are of tremendous importance in organic chemistry, the formation of silylium ions as intermediates in many organosilicon

Received 6 July 2005

Uspekhi Khimii 75 (2) 107–124 (2006); translated by T N Safonova

[†] According to the latest IUPAC recommendations, the tricoordinate R_3Si^+ cation is called the silylium ion.

reactions was often postulated without proof. However, alternative mechanisms can, as a rule, be suggested for such reactions.

The possible involvement of silylium ions as intermediates in reactions has been reported for the first time by Whitmore and Sommer,²⁵ who studied the rearrangement of chloromethyltrimethylsilane under the action of AlCl_3 .

The formation of silylium ions as reactive intermediates was also postulated in the rearrangement of (1-haloalkyl)trimethylsilanes in the presence of SbF_5 (see Ref. 29) and in the rearrangement of (1-hydroxyalkyl)trimethylsilanes in the presence of BF_3 .³⁰ The ionic mechanism was proposed without proof to account for the so-called β -cleavage of trialkyl(2-haloethyl)silanes **1** in the presence of AlCl_3 ³¹ or in an aqueous ethanolic medium.³² These reactions afford trialkylchlorosilanes **2** or trialkylethoxysilanes **3**.

$$R = \text{Alk.}$$

Dolgov *et al.*^{33,34} studied disproportionation of dialkylchlorosilanes **4** and also suggested that this reaction proceeds by the ionic mechanism.

In this case, no experimental evidence for the proposed reaction mechanism was reported as well.

Alternative mechanisms of the above-considered reactions involve the intermediate formation of a four- (structure **5a**) or six-centred (**5b**) activated complex³⁵ and a non-classical carbenium ion **5c**.³⁶

It is noteworthy that the rearrangement of fluorodiethylsilane occurs spontaneously in the absence of catalysts,³⁷ which suggests that this reaction proceeds through a cyclic transition state of type **5c**.

Many researchers attempted to prepare and characterise stable silylium ions isostructural with carbenium ions in the condensed phase. A silicon analogue of ionic tris(*p*-dimethylaminophenyl)chloromethane, *viz.*, silyl chloride **6**, was synthesised.^{38, 39}

However, studies by physicochemical methods (conductometry, IR and UV spectroscopy, X-ray diffraction analysis, *etc.*) demonstrated that compound **6** is covalent. Silicon perchlorates R_3SiClO_4 ($R = \text{Alk}$) were demonstrated⁴⁰ to be covalent, unlike ionic crystalline triarylmethyl perchlorates.

Olah *et al.*^{20,41} attempted to synthesise classical silylium ions in a superacidic medium ($\text{FSO}_3\text{H}-\text{SbF}_5-\text{SO}_2$ system) of extremely low nucleophilicity. Under these conditions, non-primary carbenium cations are stable and are generated from various organic compounds.⁴² In this medium, the behaviour of trialkylalkoxysilanes **3** was studied by low-temperature NMR spectroscopy. It was found that these compounds initially undergo protonation followed by the replacement giving rise to trialkylfluorosilane.

In this process, no R_3Si^+ ions were detected. The formation of trialkylfluorosilanes was accounted for by the formation of a pentacovalent intermediate **7** (for $\text{R} = \text{Me}$).⁴¹

Analogous results were obtained upon storage of hexaalkyldisiloxanes in a superacidic medium.⁴¹

One of the main problems in preparing silylium ions in the condensed phase is associated with the nature of the leaving group. In organic chemistry, carbenium ions are traditionally generated by the S_N1 or $E1$ mechanisms, a halogen- (I^- , Cl^- , *etc.*) or oxygen-containing anion serving, as a rule, as the leaving group. Taking into account high strength of the silicon bonds with halogens and oxygen, the latter cannot be used as the leaving groups for generation of silylium ions. Corey⁴³ described the synthesis of silylium ions by reaction (1) with the use of the hydride ion as the leaving group.

Actually, the Si—H bond is weaker than the C—H bond and, consequently, reaction (1) is thermodynamically favourable. This reaction is named after Corey and it has been used for years to prove the formation of silylium ions as stable species and short-lived intermediates in various transformations.

In 1975, the synthesis of stable silylium ions as a result of hydride ion abstraction from compound **8** was documented.^{44,45}

However, these results were later rejected.^{27, 46} These studies ended in failure apparently because the researchers assumed that the properties of silicon are completely analogous to those of carbon.

In the study,⁴⁷ the authors succeeded in preparing positively charged organosilicon ions by coordination of silicon with compounds having a basic character. For example, the reaction of iodotriphenylsilane with 2,2'-bipyridine gave salt **9** with a penta-covalent silicon ion.

More recently, other analogous pentacoordinate cations were prepared.^{48, 49}

In the review,¹⁸ which summarises the results of research on silylium ions obtained by that time, a conclusion was drawn that positively charged organosilicon ions can be generated only as a result of the nucleophilic attack on the Si atom.

R = Alk, Ar; X is a halogen; Nu is a nucleophile.

However, it should be emphasised that the pentacoordinate ion thus produced differs in principle from the trivalent silylium ion R_3Si^+ . The latter, like the carbenium ion, could be formed upon the heterolytic cleavage of the Si–X bond.

Although the attempts to detect the silylium ions R_3Si^+ in condensed phases failed, these species were reliably identified in rarefied gases. Taking into account that the physical properties of silicon (thermodynamic, electronic, *etc.*) should make the generation of silylium ions easier compared to the structurally similar carbenium ions, the reasonable question arises as to why this process is hindered in the condensed phase?

The answer to this question can be found by analysing the results of quantum-chemical studies,⁵⁰ which confirm a substantial difference in the chemical properties of carbon and silicon. First and foremost, this refers to the unique ability of the silicon atom to increase its coordination number. For example, compounds with the hypercoordinate silicon atom (for example, the SiF_6^{2-} anion) are well known, whereas analogous carbon compounds are absent. Due to the ability of silicon to have high coordination numbers, silylium ions, unlike carbocations, are more prone to complexation with various nucleophiles, including counterions and solvents used in the synthesis of organosilicon compounds. Apparently, this is responsible for the fact that all attempts to observe silylium ions in solution failed.

The above facts argue against the conclusion¹⁸ that it is impossible to prepare the trivalent silylium ions R_3Si^+ in the condensed state; that is, a different in principle strategy is required for their generation.

III. State of the art of research on silylium ions

1. Silylium ions in the gas phase

The existence of silylium ions in the gas phase is beyond doubt. These ions are easily generated in rarefied gases by various methods, including electron impact, photoionisation and chemical ionisation. The appearance potentials of silylium ions are substantially lower than those of carbenium ions.⁵¹ Taking into account that, until recently, virtually all attempts to generate and characterise silylium ions in the condensed phase failed, any information on these ions obtained in gas-phase studies is of

considerable importance and is very useful. Not only thermodynamic but also certain physical characteristics of silylium ions were determined. In particular, studies of the H_3Si^+ ion by gas-phase infrared laser spectroscopy demonstrated⁵² that this cation (like the H_3C^+ ion) is planar, the Si–H bond length is 1.462 Å, and the fundamental stretching band is at 838.0674 cm^{-1} .

The gas-phase chemistry of silylium ions is versatile and includes unusual rearrangements, which differ substantially from the rearrangements of carbenium ions. The rearrangements of silylium ions require activation,^{53, 54} whereas the rearrangements of carbenium ions can occur at very low temperatures and even in the solid phase.^{55, 56}

The mechanism of rearrangements of silylium ions differs from that of rearrangements of carbenium ions proceeding under the same conditions.^{57–59} For example, dissociation of the *tert*-butyl cation in a mass-spectrometer chamber occurs primarily with elimination of methane⁵⁹

whereas dissociation of the trimethylsilyl cation results in elimination of an ethylene molecule^{57–59}

The mechanism of the latter rearrangement has been extensively studied over many years. Bakhtiar *et al.*,⁵⁷ who were the first to observe this rearrangement, described a mechanism involving isomerisation of the activated trimethylsilylium ion to give $EtMeHSi^+$ followed by elimination of ethylene. However, more recently it has been demonstrated⁵⁸ that these ions can undergo interconversions before elimination of ethylene.

Consequently, a less stable isomeric form of the silylium ion can be transformed into a more stable form if the activation energy is sufficiently high and the isomerisation barrier is lower than the dissociation threshold. Analogous isomerisation of the $C_2H_7Si^+$ ion was also studied:^{53, 57–60}

Since the Me_2HSi^+ ion is more stable than the EtH_2Si^+ ion by $22.5\text{ kcal mol}^{-1}$,⁵³ the amount of the Me_2HSi^+ ions increases with increasing kinetic energy of the EtH_2Si^+ ions⁶⁰ (Fig. 1). At

Figure 1. Yields of the Me_2HSi^+ (1) and EtH_2Si^+ (2) ions vs. the activation energy.⁵⁸

higher energies, dissociation of the EtH_2Si^+ ion with elimination of ethylene occurs.

According to the results of mass-spectrometric studies,^{57, 58} 90% of the EtH_2Si^+ ions are isomerised into the thermodynamically more stable Me_2HSi^+ ions. Evidently, in this case the isomerisation barrier is lower than the energy required for elimination of ethylene. A totally different situation is observed for the EtMeHSi^+ ion. The isomerisation and dissociation barriers of this ion have similar heights,⁵⁴ due to which its isomerisation to the trimethylsilylium ion proceeds by only 5%.⁶¹

Only 28% of the $\text{C}_2\text{H}_7\text{Si}^+$ ions decompose to form ethylene.⁶² Dissociation of $\text{C}_2\text{H}_7\text{Si}^+$ affords hydrogen molecules as the major product (72%). It appeared that the composition and the kinetic energy of the reaction products are independent of the isomer type of this ion, *viz.*, Me_2HSi^+ or EtH_2Si^+ . This suggests that the equilibrium between the isomers is established prior to dissociation. By contrast, the isomers of the $\text{C}_3\text{H}_9\text{Si}^+$ ion, *viz.*, Me_3Si^+ and EtMeHSi^+ , decompose to give primarily ethylene (89% and 97%, respectively) and differ substantially in the kinetic energy.

Structural isomers of silylium ions, unlike those of carbenium ions, can be distinguished by qualitative reactions.^{60, 61} Isomerisation of the ethylsilylium ion to the dimethylsilylium ion was confirmed by the isotope exchange between this ion and perdeuterated ethylene. In the disubstituted R_2HSi^+ ion ($\text{R} = \text{Me}$ or Et), only the silicon-bound ^1H atom can be exchanged for deuterium, whereas all hydrogen atoms in the monoalkyl-substituted RH_2Si^+ ion can be involved in the isotope exchange.⁶⁰

The theoretical explanation of this phenomenon was given in the study.⁵³ The proposed mechanism of the reaction of MeH_2Si^+ with C_2D_4 involves the formation of the $[\text{MeH}_2\text{Si}^+ \cdot \text{C}_2\text{D}_4]$ complex (**10**) as an intermediate followed by the migration of the hydrogen atoms from the silicon atom to the ethylene moiety to give the asymmetrical $\text{Me}(\text{CD}_2\text{H})_2\text{Si}^+$ cation (**11**) *via* a transition state **TS1** with a minimum energy.

The reverse transformation of ion **11** into the starting complex can involve the unlabelled methyl group. In this case, complex **12** is, for example, formed *via* a transition state **TS2**. Its subsequent dissociation affords the $(\text{CD}_2\text{H})\text{HDSi}^+$ ion and the $\text{H}_2\text{C}=\text{CDH}$ molecule. The perdeuterated methylsilylium ion can be obtained

by repeating these processes many times. The reaction of Me_2HSi^+ with $\text{CD}_2=\text{CD}_2$ produces the $\text{Me}_2(\text{CD}_2\text{CD}_2\text{H})\text{Si}^+$ ion as the most stable isomer. Its transformation can afford only Me_2DSi^+ and $\text{HDC}=\text{CD}_2$, *i.e.*, only the hydrogen atom bound to silicon can be replaced by the deuterium atom. The hydrogen exchange between the methyl and silyl groups does not occur due to a high energy barrier.

Wojtyniak and Stone⁶³ made a substantial contribution to investigations of the reactivity of silylium ions with respect to nucleophilic reagents. They studied the gas-phase reactions of the Me_3Si^+ ion with alcohols, ethers, esters and aromatic hydrocarbons at a pressure of 3–5 mm Hg and a temperature from 298 to 600 K by mass spectrometry. The reactions gave the $[\text{Me}_3\text{Si}^+ \cdot \text{B}]$ adducts ($\text{B} = \text{AlkOH}$, $\text{AlkOAlk}'$, $\text{AlkCO}_2\text{Alk}'$ or ArH). The equilibrium constants of the reactions of the Me_3Si^+ cation with the oxygen-containing bases B_1 and B_2

were measured and the relative basicities of these compounds towards Me_3Si^+ were determined from these constants. The change in the free energy of this reaction served as a measure of the basicity.

The basicity of various alcohols and water was demonstrated to increase in the same order as the proton affinity: butanol > propanol > ethanol > methanol > water.

It should be noted that the energy of association of alcohols with the Me_3Si^+ ion is higher than that with the Me_3C^+ and Me_3Sn^+ ions by ~20 and 7 kcal mol⁻¹, respectively (Table 1). For all cations, the energy of association increases with increasing basicity of alcohol ROH, *i.e.*, with increasing length of the alkyl substituent.

Table 1. Changes in the enthalpy ΔH_0 (kcal mol⁻¹) of the reaction $[\text{Me}_3\text{E}^+ \cdot \text{B}] \rightarrow [\text{Me}_3\text{E}]^+ + \text{B}$.⁶³

B	E			
	C	Si	Sn	
H ₂ O	11.7	30.1	25.7	
MeOH	22.8	39.2	32.6	
EtOH	26.9	42.0	34.8	
Pr ⁱ OH	24.9	43.9	—	

The difference in the energies of association of the Me_3Si^+ and Me_3C^+ ions with alcohols can be attributed to a higher positive charge density on the silicon atom compared to that on the carbon atom due primarily to the different degree of interaction between the unoccupied orbital of these cations and the orbitals of the methyl substituents.⁶⁴ For example, analysis of the populations of the unoccupied p_z orbitals demonstrated⁶⁵ that the population in the H_3Si^+ and H_3C^+ ions is virtually equal to zero (the orbital is actually unoccupied), whereas the population in the Me_2HC^+ and Me_2HSi^+ ions increases to 0.37 and 0.1, respectively. The electron density transfer to the carbon atom is much more substantial than that to the silicon atom. The inductive effect of the methyl substituents in the Me_3C^+ ion also leads to certain delocalisation of the positive charge on the cationic centre. In the Me_3Si^+ cation, the positive charge delocalisation due to the presence of the alkyl substituents is virtually absent because the electronegativity of silicon is lower than that of carbon.

The higher energy of association of the Me_3Si^+ ion with alcohols compared to that of the Me_3Sn^+ ions is apparently attributed to the larger volume of the tin atom and, consequently, the larger Sn—O bond length in the adduct.

The energy of association of the above-considered Me_3E^+ ions ($\text{E} = \text{C}$, Si and Sn) changes in the same order as that observed for other oxygen-containing compounds (for example, for ethers and esters).⁶³ Consequently, due to the larger positive charge

density on the silicon atom compared to that on the carbon atom and the smaller volume of silicon compared to tin, the trimethylsilylium ion is the most reactive species in this series with respect to oxygen-containing compounds in spite of the fact that the position of silicon in the Periodic table is between a typical non-metal (C) and a metal (Sn).

The basicity of different classes of oxygen-containing compounds towards the Me_3Si^+ cation changes in the following series: water < alcohols < ethers < esters.⁶³

The energies of association of the Me_3Si^+ and Me_3Sn^+ ions with aromatic hydrocarbons (ArH), such as mesitylene and *o*-xylene, have similar values, which are slightly smaller than the energies of association with oxygen-containing compounds. Below are given the changes in the enthalpy (kcal mol^{-1}) of the reactions

E	ArH		Ref.
	mesitylene	<i>o</i> -xylene	
Si	31.1	29.2	63
Sn	32.0	29.9	66

A decrease in the difference between the energies of association of the Me_3Si^+ and Me_3Sn^+ ions with aromatic hydrocarbons can be explained in terms of hard and soft acids and bases.⁶⁷ For example, less polarisable silicon in the Me_3Si^+ ion more readily reacts with hard oxygen-containing bases, whereas the reaction of the Me_3Sn^+ ion becomes more preferable in the case of soft aromatic bases.

Amines are stronger bases than oxygen-containing compounds towards the trimethylsilylium ion. This is evident from the fact that the energies of association of the Me_3Si^+ ion with amines are substantially higher than those with alcohols. Table 2 gives the affinities (*i.e.*, the energies of association) of various amines to the Me_3Si^+ ion and the proton. As can be seen from Table 2, the affinity of amines to the Me_3Si^+ ion increases in the same order as the proton affinity: $\text{NH}_3 < \text{MeNH}_2 < \text{EtNH}_2 < \text{Bu}^n\text{NH}_2$, and it is determined by the increase in polarisability of the alkyl substituent in the amine.

Table 2. Affinities of amines to the Me_3Si^+ ion and the proton (kcal mol^{-1}).

Amine	Me_3Si^+ (see ⁶⁸)	H^+ (see ⁶⁹)
NH_3	46.5	204
MeNH_2	55.4	214.1
EtNH_2	57.4	217.0
Bu^nNH_2	59.5	218.4
Bu^sNH_2	57.9	220.5
Bu^tNH_2	58.0	220.8
Me_2NH	60.0	220.6

The basicities towards the Me_3Si^+ ion and the proton affinities of selected aromatic oxygen- and nitrogen-containing compounds were determined (Table 3).⁷⁰ As can be seen from

Table 3. Relative basicities of aromatic compounds towards the Me_3Si^+ ion and the proton affinities (kcal mol^{-1}).

Compound	Me_3Si^+	H^+
PhC(O)H	36.2	191.7
PhC(O)Me	37.8	198.2
PhNH_2	35.5	203.3
PhNMe_2	39.5	217.3
Py	47.1	214.7

Table 3, the characteristics of these compounds can be arranged in different series of increasing values because they are determined by different factors. For example, the basicities of compounds towards Me_3Si^+ can be influenced by steric factors, which have no effect on the proton affinity.⁶³ Nevertheless, these two characteristics equally depend on the nature of the substituents in the aromatic ring. In addition, as in the case of protonated organic compounds, the bonds between the Me_3Si^+ ions and the O (or N) atoms in adducts are essentially covalent in character.

Therefore, the above-described studies showed that silylium ions not only are readily generated in the gas phase but also exhibit substantially higher affinity to π - and n -electron-donating compounds than carbenium ions.

2. Silylium ions in the condensed phase

The proof of the existence of silylium ions in the condensed phase is still a challenging problem of organosilicon chemistry. As we demonstrated above, conventional methods, which are generally used in organic chemistry for the generation of carbenium ions, are unsuitable for the synthesis of silicon analogues. Evidently, non-conventional approaches are required for the generation of silylium ions and investigation of their chemical behaviour in the condensed phase.

Studies by Lambert and co-workers (see, for example, Ref. 71) have opened a new stage in solving the problem of the synthesis of silylium ions in the condensed phase. Lambert proposed that silylium ions should be generated with the use of

- substituents at the silicon atom that enhance thermodynamic stability of silylium ions;
- counterions and solvents of low nucleophilicity;
- substituents creating steric hindrance to the approach of nucleophiles to the silicon centre.

All subsequent studies on the generation of silylium ions in the condensed phase were carried out taking into account these ideas.

In the chemistry of carbenium ions, the positive charge on the cation is stabilised primarily through $\pi-\pi$ and $n-\pi$ resonance interactions (for example, in the benzyl PhCH_2^+ , allyl $\text{CH}_2=\text{CHCH}_2^+$ and methoxymethyl MeOCH_2^+ cations) and $\sigma-\pi$ resonance interactions (in the *tert*-butyl cation Me_3C^+). By contrast, the electron-withdrawing inductive effect of such substituents as Ph, $\text{CH}=\text{CH}_2$ or OMe destabilises the carbenium ion. Consequently, the positive charge can be stabilised only if the $\pi-\pi$ and $n-\pi$ interactions not only compensate but are stronger than the undesired inductive effect, which is observed in the chemistry of carbenium ions. In the case of the silicon atom, resonance interactions with electronegative elements (N, O or F) are very weak and cannot compete with the destabilising inductive effect of the latter, due to which these elements are inefficient for stabilisation of silylium ions.

According to Lambert and Sun,⁷¹ the positive charge in silylium ions can be stabilised by organosilicon substituents directly bound to the cation centre [for example, in the $\text{Me}_3\text{SiMe}_2\text{Si}^+$ or $(\text{Me}_3\text{Si})_3\text{Si}^+$ ions]. Since the silicon atom is less electronegative and more polarisable than the carbon atom, the inductive effect of a silicon-containing substituent will stabilise the cation centre.

Quantum-chemical calculations demonstrated⁷² that silylium ions can be efficiently stabilised by resonance $3p-3p$ interactions in the $(\text{RX})_3\text{Si}^+$ or $(\text{R}_2\text{X})_3\text{Si}^+$ cations, where X are third-period elements (X = S or P). Actually, the bond between the sulfur and silicon atoms is rather highly polarisable. In addition, the sulfur atom has $3p$ lone pairs and its electronegativity is approximately equal to that of the carbon atom (~ 2.5). For this reason, its inductive effect is expected to be smaller than that in the case of phenyl or oxygen-containing substituents.

Taking into account the above facts, the silylium ion $(\text{Pr}^i\text{S})_3\text{Si}^+$ was prepared⁷³ by the Corey reaction. The hydride ion abstraction was performed with the use of triphenylmethyl perchlorate in dichloromethane or sulfolane. The conductivity of the resulting tris(isopropylthio)silyl perchlorate in both solvents

355 ppm (Ref. 79)] and Et_3Si^+ [371.2 ppm (Ref. 81)], whereas it is similar to the chemical shift calculated for the $[\text{Me}_3\text{SiC}_6\text{H}_6]^+$ complex [80.9 ppm (Ref. 75)]. In traditional organic chemistry, the structures of carbenium ions are, as a rule, beyond doubt due to a good agreement between ^{13}C NMR spectroscopic data and the results of quantum-chemical calculations.

Another important question was whether the compound synthesised by Lambert is σ complex **13a** or π complex **13b**.

It was hypothesised⁹⁵ that the $[\text{Et}_3\text{Si} \cdot \text{PhMe}]^+$ cation is neither a pure σ complex nor a pure π complex but is a particular hybrid. The argument was that the $\text{Et}_3\text{Si}-\text{C}-\text{C}(\text{para})$ angle in the complex synthesised by Lambert (104°) is intermediate between the values of this angle in the ideal π complex (90°) and the ideal σ complex (125°).

In 1995, Reed and co-workers⁹⁶ synthesised crystalline trialkylsilyl(hexachloro)carboranes containing the silyl group structurally similar to the silyl cation. Halocarborane $(\text{CB}_{11}\text{H}_6\text{Cl}_6)^-$ was used as the anion of low nucleophilicity. In all the complexes under study, the cation and the anion were coordinated through the halogen atom involved in the anion. However, the distance between the silicon and chlorine atoms was rather large (2.23 Å).

The structure most similar to that of the silylium ion was observed in the $\text{Pr}^i_3\text{Si}(\text{CB}_{11}\text{H}_6\text{Cl}_6)$ (**14**), where the average angle $\text{C}(\text{Pr}^i)-\text{Si}-\text{C}(\text{Pr}^i)$ is 117.7° .

$\text{Si}-\text{Y}$ $\text{Y} = \text{CB}_{11}\text{H}_6\text{Cl}_6$.

bond type: covalent ionic-like ionic

The angle, the rather large $\text{Si}-\text{Cl}(\text{CB}_{11}\text{H}_6\text{Cl}_6)$ bond length (2.23 Å) and the fact that the $\text{Si}-\text{C}(\text{Pr}^i)$ bond length remains unchanged (1.85 Å) led the authors to conclude that the charges in this compound are sufficiently separated, which is an indication of the formation of silylium ions. Unlike the carbon chemistry, where the covalent compounds R_3CX are clearly distinguished from the carbenium ions $\text{R}_3\text{C}^+\text{X}^-$, trialkyl-substituted derivatives of silicon R_3SiX have a geometry characteristic of bonds intermediate between covalent (sp^3 -hybridisation) and ionic (sp^2 -hybridisation).

According to calculations⁹⁶ of the total energy for the model compound $\text{Me}_3\text{Si}^+\text{Cl}^{6-}$, the degree of ionicity of compound **14** with the $\text{C}(\text{Pr}^i)-\text{Si}-\text{C}(\text{Pr}^i)$ angle of 117.7° is 60%.

However, the chemical shift of the silicon atom in the ^{29}Si NMR spectrum of compound **14** ($\delta = 115$) differs substantially from that calculated for the Pr^i_3Si^+ cation [$\delta = 342.3$ (calculations by the GIAO method) and 371.0 (calculations by the SOS-DFPT method)⁷⁹].

High-level calculations performed in 1996 (see Ref. 97) demonstrated that silylium ions can form complexes with weak Lewis bases, such as ethylene, benzene, bromomethane and fluoromethane, and even with methane and noble gases. This

fact suggests that in none of the solvents the silylium ion can be isolated in the 'free state'. Hence, the problem is not to generate silylium ions but to estimate the degree to which the silylium ion in a complex with a solvent is cationic.

However, the final conclusion drawn by theorists has stimulated the research teams headed by Lambert and Reed to examine the possibility of introducing other substituents at the silicon atom with the aim of solving the problem of silylium ions. These substituents should not only stabilise the positive charge on the silicon atom but also cause steric hindrance to the approach of the anion or solvent molecules to the cation centre, thus preventing complexation. Since the *tert*-butyl and hexyl groups^{21, 89} are unsuitable for this purpose, 1,3,5-trimethylphenyl (mesityl, Mes) was chosen as the substituent. In this case, the charge can be stabilised by a resonance interaction between the silicon and the aromatic ring with the simultaneous protection of the cationic centre by steric hindrance due to the presence of the *ortho*-methyl substituents.

However, bulky substituents, in turn, make it impossible to generate silylium ions by the Corey reaction based on bimolecular[‡] hydride ion abstraction from R_3SiH because such substituents hinder the approach of the carbocation to the hydrogen atom of the $\text{Si}-\text{H}$ bond. Because of this, the hydride ion was replaced with the bulkier allyl (All) group (the chemical behaviour of All with respect to nucleophiles is similar to that of H).

As a result, the following reaction scheme was proposed for the synthesis of silylium ions:⁹⁸

$\text{R} = \text{Mes}$, E is an electrophile.

In this case, the allyl group interacts with an electrophile, thus facilitating release of the silylium ion containing bulky substituents. Lambert *et al.*⁹⁸ applied this approach to the synthesis of the $[\text{Mes}_3\text{Si}^+][\text{B}(\text{C}_6\text{F}_5)_4^-]$ salt (**15**).

The chemical shift of the silicon atom ($\delta = 225.5$) in the ^{29}Si NMR spectrum of compound **15** is similar to the calculated chemical shift for the Ph_3Si^+ cation ($\delta = 208.9$). This suggests that at least the major portion of the positive charge is localised on the silicon atom. However, the question whether the silylium ion is 'free' can ultimately be answered only by demonstrating that the position of this signal is independent of the nature of both the solvent and anion. It was found that the silicon atom has similar chemical shifts in the ^{29}Si NMR spectra of trimesitylsilyl tetrakis(pentafluorophenyl)borate (**15**) in aromatic hydrocarbons: δ 225.5 in benzene, 225.7 in a 1 : 3 benzene-toluene mixture and 225.6 in a 1 : 1 benzene-*p*-xylene mixture. However, in acetonitrile this signal in the spectrum was observed at δ 37.0. Apparently, the acetonitrile molecule is so small that it can reach the cationic centre even in the presence of three bulky substituents at the silicon atom.

[‡] Unlike carbenium ions, which are readily generated by the $\text{S}_{\text{N}}1$ mechanism, silylium ions can be generated only in bimolecular reactions due to high affinity of silicon to the leaving group.

After the replacement of the $[\text{B}(\text{C}_6\text{F}_5)_4]^-$ anion with the carborane derivative $(\text{CB}_{11}\text{H}_6\text{Cl}_6)^-$, the chemical shift in the ^{29}Si NMR spectrum remains virtually unchanged (225.9 ppm), which confirms the absence of complexation of the Me_3Si^+ cation with these anions.⁹⁹ The calculated ^{29}Si chemical shift for the trimesitylsilylium ion in the equilibrium geometry is 230.1 ppm,^{100, 101} which is in good agreement with the experimental value (225 ppm).

Therefore, in spite of tremendous difficulties associated with the choice of the anion, the leaving group, substituents at the silicon atom and the solvent, the research teams headed by Lambert and Reed succeeded in demonstrating the possibility of the existence of the free silylium ion in the condensed phase.

The use of substituents containing electronegative heteroatoms with lone pairs (N or O) is yet another interesting way of stabilising the positive charge on the silicon atom. In this case, the so-called intramolecular stabilisation of the cationic centre can occur. Corriu and co-workers¹⁰² was the first to synthesise this type of nitrogen-containing cations.

The ^{29}Si NMR spectrum of compound **16** confirms the structure of the pentacoordinate ion both in solution and in the solid state.

In the $[\text{R}_2\text{SiC}_6\text{H}_3(\text{CH}_2\text{NMe}_2)_2\cdot 2,6]^+$ cations ($\text{R} = \text{H}$ or Me), the intramolecular coordination of silicon by the nitrogen atom is so strong that it prevents solvation with solvent molecules.¹⁰³

Baukov and co-workers^{104–106} synthesised silylium ions **17**, in which the positive charge is stabilised by the coordination interaction $\text{O} \rightarrow \text{Si}$.

However, in spite of the fact that the positive charge on the silicon atom in these cations is stabilised, such structures can hardly be considered as classical free trivalent silylium ions.

A non-traditional radiochemical approach to solving the problem of the generation of silylium ions in the condensed phase was developed by a research group from St Petersburg.^{17, 107–111} This approach is based on the use of β -decay of tritium (incorporated in substituted silanes), which is independent of external conditions.

$\text{R} = \text{Me}, \text{Et}, \text{Ph}; n = 1-3.$

The uniqueness of this nuclear-chemical method is that it allows one to generate free (without a counterion and an equilibrium solvent shell) silylium ions with a desired charge localisation both in the gas phase in a wide pressure range and in the condensed phase. This method was used for the generation of the silylium ions Me_2TSi^+ , Et_2TSi^+ , Et_2TSi^+ and PhT_2Si^+ , and the properties of these ions were studied (for details see Section IV.2).

3. Silylium ions as short-lived reaction intermediates

In spite of all difficulties associated with the generation of stable silylium ions in the condensed phase, their formation as short-

lived intermediates was not ruled out; moreover, their formation in many reactions was postulated by analogy with carbenium ions. Comprehensive kinetic studies of the reaction mechanisms of organosilicon compounds are presently underway. Charged silylium species are assumed to be involved in these reactions. The hydride ion abstraction from the R_3SiH molecule with the use of carbenium ion resulting in the generation of the silylium ion R_3Si^+ (the above-considered Corey reaction) is one of such reactions.

Chojnowski *et al.*^{112, 113} studied the kinetics of this reaction in detail for silanes R_3SiH ($\text{R} = \text{Et}, \text{Bu}, \text{Ph}, \text{etc.}$) and the salts $[\text{Ph}_3\text{C}]^+\text{BF}_4^-$ and $[\text{Ph}_3\text{C}]^+\text{SbF}_6^-$. Investigation of the influence of the steric and electronic effects of the substituents at the Si atom on the reaction rate and the use of isotopic indicators led the authors to conclude that the electron transfer is the rate-determining step of the reaction. The second (fast) step gives silylium ions.

However, according to calculations,¹¹⁴ the reaction mechanism involving electron transfer is energetically unfavourable, and the synchronous barrierless hydride transfer is the rate-determining step.

Studies on the influence of the steric and electronic effects of the substituents at the silicon atom on the reaction pathway of R_3SiH with the diarylcarbenium ions Ar_2CH^+ ($\text{Ar} = \text{Ph}, p\text{-Tol}, p\text{-MeOC}_6\text{H}_4$ and $p\text{-PhOC}_6\text{H}_4$) and investigation of the reaction mechanism demonstrated¹¹⁵ that the formation of silylium ions is the rate-determining step of the process.

In the study of dimethyl(trimethylelementomethyl)silanes $(\text{Me}_3\text{ECH}_2)\text{Me}_2\text{SiH}$ ($\text{E} = \text{C}, \text{Si}, \text{Ge}$ or Sn),¹¹⁶ it was demonstrated that the steric and electronic effects, as well as the conjugation effects, which can stabilise the positive charge on the silicon atom, substantially influence the rate of reactions of these compounds with carbenium ions. This fact suggests that silylium ions are formed as reaction intermediates.

The formation of solvolysis products of 2-chloro- or 2-benzyloxy-2-(trimethylsilyl)adamantanes (**19a,b**) in aqueous hexafluoropropan-2-ol was accounted for by the rearrangement of the initially formed carbenium ions **20a,b** into silylium ions **21a,b** through the 1,2-methyl shift.¹¹⁷

$\text{X} = \text{Cl}$ (**a**), $\text{O}_2\text{CC}_6\text{H}_4\text{NO}_2\text{-4}$ (**b**); $\text{Y} = \text{OH}, \text{OCH}(\text{CF}_3)_2$.

The possibility of this rearrangement was confirmed by gas-phase studies and calculations, which provided evidence that silylium ions are thermodynamically more stable than carbenium ions. Alternatively, this reaction can be explained by the involvement of a non-classical bridged cationic intermediate **22** in this process.

Eaborn¹¹⁸ reasoned that bridged silylium ions of type **22** are formed as intermediate species in some reactions of organosilicon compounds containing bulky substituents, for example, $(\text{Me}_3\text{Si})_3\text{C}$. In particular, Eaborn and co-workers demonstrated¹¹⁹ that the reactions of compounds of the type $(\text{Me}_3\text{Si})_3\text{CSiR}^1\text{R}^2\text{X}$ and $(\text{Me}_3\text{Si})_2\text{C}(\text{SiMe}_2\text{X})(\text{SiR}^1\text{R}^2\text{X})$ with some electrophiles, including silver salts AgY ($\text{Y} = \text{AcO}$, CF_3CO_2 , ClO_4 , etc.), $\text{CF}_3\text{CO}_2\text{H}$ and ICl_3 , afford mixtures of rearranged and non-rearranged $\text{Si}-\text{X}$ -bond cleavage products.

$\text{R}^1, \text{R}^2 = \text{Me}, \text{Et}, \text{Ph}, \text{etc.}; \text{X} = \text{Hal}, \text{H}, \text{etc.}$

These results can most adequately be explained by the formation of a non-classical bridged ion **23**. In this process, the attack of the nucleophile on one end (path *a*) affords non-rearranged products, whereas the attack on another end (path *b*) gives rise to rearranged products.

Dihalosilylenes SiX_2 ($\text{X} = \text{F}, \text{Cl}, \text{Br}$ or I) generated in the gas phase and concentrated in a toluene solution in the presence of I_2 or ICl at -90°C give mixtures of *ortho*, *meta* and *para* isomers of $\text{MeC}_6\text{H}_4\text{SiX}_2\text{I}$.¹²⁰ The authors attributed the formation of these compounds to the electrophilic attack of the short-lived cations X_2ISi^+ on the aromatic ring. The isomer ratio for $\text{X} = \text{Cl}$ in the presence of I_2 was *ortho*:*para*:*meta* = 10:4:3, i.e., the *ortho*-substituted isomer was the major product. When ethylbenzene was used as the solvent, the yield of the *ortho* isomer sharply decreased and the isomer ratio was 4:2:3. These results are attributed to the influence of the steric effects of the alkyl group and are consistent with the data obtained by Lambert.⁹²

It was hypothesised^{121, 122} that silylium ions are intermediates of radiation-induced polymerisation of permethylcyclorosiloxanes $(\text{Me}_2\text{SiO})_n$, where $n = 3-5$. The initial ionisation of the molecule occurs as a result of elimination of the methyl anion from cyclorosiloxane. The authors postulated that the resulting silylium ions

contain either a coordinated (**24**) or non-coordinated (**25**) cationic centre.

The above-considered published data are conclusive proof of the formation of silylium ions postulated earlier as short-lived intermediates in organosilicon reactions.

IV. Ion-molecular reactions of silylium ions

1. Reactivity

The concepts 'reactivity' and 'thermodynamic stability' are closely related to each other. To estimate the reactivity of silylium ions, it is necessary to consider the factors responsible for stability of these ions.

The physicochemical properties of silicon suggest that silylium ions are thermodynamically more stable than isostructural carbenium ions. This is associated with both lower electronegativity of the silicon atom and its larger radius compared to those of the carbon atom (1.8 and 2.5,¹²³ 1.17 and 0.77 Å,¹²⁴ respectively). The ionisation potentials of the alkyl and silyl radicals, the enthalpies of formation of the silylium and carbenium ions and their hydride ion affinities are also indicative of higher thermodynamic stability of silylium ions compared to carbenium ions (Table 4).

Quantum-chemical calculations showed that the silylium cation H_3Si^+ is at least 54 kcal mol⁻¹ more stable than the methyl cation H_3C^+ .¹³¹ However, this difference becomes substantially smaller in the presence of alkyl substituents, as well as π - and n -electron-donating substituents, in the cationic centre.^{50, 132}

The relative stabilities of silylium ions can be estimated from the enthalpies of isodesmic⁸ reactions (2)–(4).⁵⁰

$n = 0-3$.

The stabilisation energies of the $\text{R}_n\text{H}_{3-n}\text{Si}^+$ and $\text{R}_n\text{H}_{3-n}\text{C}^+$ ions calculated for these reactions are given in Table 5.

All the above-considered substituents, except for F, stabilise silylium ions. However, the stabilisation effect is substantially

§ Isodesmic reactions are reactions that involve only charge transfer, whereas the chemical bond configuration remains unchanged.¹³³

smaller than that in the case of carbenium ions. Silylium ions in the gas phase are always more stable than the corresponding carbenium ions. An increase in the number of substituents at the cationic centre stabilises silylium ions to a lesser extent than carbenium ions (see Table 5).

Substituents that cause steric hindrance to the approach of a nucleophile to the cationic centre, thus increasing stability of the latter, stabilise silylium ions to a lesser degree than carbenium ions. This is explained by a substantially larger atomic radius of silicon compared to that of carbon. The stereo projections of the Me_3C^+ and Me_3Si^+ ions calculated by the MP2(fc)/6-31G* method⁵⁰ are given below.

Therefore, in spite of the fact that the introduction of substituents of different nature and an increase in their number diminish the difference between stabilities of carbenium and silylium ions, the latter remain thermodynamically more stable.

The high positive enthalpies of formation (ΔH°) (and, correspondingly, high free energies ΔG°) are indicative of the high reactivity of silylium ions, because the reactions can follow several pathways resulting in a decrease in the free energy of the system. Reactions of silylium ions are fast due to the presence of the unoccupied 3p orbital in these ions and the positive charge on the silicon atom. This leads to the appearance of a long-range polarisation interaction whose energy can be even higher than the activation energies of various transformations of a complex formed from the ion. The above-mentioned thermodynamic and kinetic requirements for ion-molecular interactions are equally characteristic of silylium and carbenium ions. However, as mentioned above, silylium ions are highly prone to expansion of the coordination sphere. As a result, these ions become even more electrophilic and can react with any nucleophile, including counterions and solvent molecules. That is why silylium ions, which are thermodynamically more stable in the gas phase than carbenium ions, remain virtually undetectable in the condensed phase.

Because of the difficulties in generating silylium ions in the condensed phase, their chemical behaviour in solution have remained unknown for many years. In the first studies dealing with this problem, ion-molecular reactions of the Et_2HSi^+ ions with benzene, dibutyl ether and (*tert*-butylamino)trimethylsilane were investigated by a radiochemical method.^{108–111}

2. Ion-molecular reactions of silylium ions with π - and n -electron-donor compounds

Among chemical transformations of silylium ions, ionic silylation of nucleophilic reagents in the condensed phase is of particular interest.

Benzene is a classical representative of π -electron-donor compounds. The importance of electrophilic ionic alkylation of benzene in organic chemistry is difficult to overestimate. A different situation arises with electrophilic ionic silylation of aromatic compounds. First attempts to perform electrophilic silylation of benzene^{63, 134} in the gas phase led only to the identification of an adduct to which the structure of π complex **26a** was assigned.

More recently, experimental^{135–138} and theoretical⁷⁵ studies demonstrated that the reactions of silylium ions with aromatic compounds yield σ complex **26b**. Actually, the energies of association of silylium ions with aromatic compounds are even higher than those with their carbenium analogues (Table 6), and the role of the σ complex in electrophilic alkylation is well known.

In spite of the fact that the formation of σ complexes in the reactions of the H_3Si^+ and Me_3Si^+ cations with benzene and toluene was proved, silylation products of these aromatic compounds were not detected.¹³⁶ This can be attributed to the fact that, under the experimental conditions used, desilylation of σ complexes occurs much faster than their deprotonation ($k_2 \gg k_1$).

B is a Lewis base.

More recently, it has been demonstrated^{136–138} that electrophilic silylation of benzene and toluene in the gas phase occurs only in the presence of strong proton acceptors (for example, of amines). Oxygen-containing bases induce predominantly desilylation.

A comprehensive insight into reactions of these species with nucleophilic compounds under different conditions was obtained for the first time with the use of the nuclear-chemical method of generation of silylium ions and a radiochemical approach to investigation of their reactions.^{17, 107–111, 139–146}

Ion-molecular reactions of the ethyl- (see Ref. 139) and diethylsilylium ions^{108, 109} with benzene in the gas and condensed phases in the absence of additives were studied by the radiochemical method. In the case of tritium-labelled ions, silylation products were identified for both cations. However, the ethylsilylium cation gives not the expected silane $PhSiH_2Et$ but its isomer $PhSiHMe_2$ in very low yield (4%); this reaction affords labelled benzene as the major product (96%). These data agree well with the mass spectrometric data and results of quantum-chemical calculations for the $C_2H_7Si^+$ ion.^{54, 57, 58}

In the case of diethylsilylium ion, the reactions afford predominantly silylation products (>95%), whereas the yield of labelled benzene is 2%–5% (Table. 7).

The reaction products contain both the starting (Et_2HSi) and rearranged (EtH_2Si and Me_2HSi) silyl groups. Ethyl(dimethyl)-

phenylsilane resulting from the reaction with the most stable tertiary silylium ion Me_2EtSi^+ , was not detected.

Quantum-chemical calculations of the potential energy surface of the $\text{C}_4\text{H}_{11}\text{Si}^+$ cation by the B3LYP/6-31G** method demonstrated¹⁰⁹ that isomerisation of the diethylsilylium cation giving rise to the most stable ethyl(dimethyl)silylium ion has to overcome two activation barriers. One of these processes gives the intermediate complex $[\text{EtH}_2\text{Si}^+ \cdot \text{C}_2\text{H}_4]$, whereas another process leads to the rearrangement into the most stable isomeric form Me_2EtSi^+ (Fig. 2). The dissociation threshold of the initially formed $[\text{EtH}_2\text{Si}^+ \cdot \text{C}_2\text{H}_4]$ complex (63.2 kcal mol^{−1}) is 5.3 kcal mol^{−1} lower than the isomerisation barrier (68.5 kcal mol^{−1}), which provides dissociation of the complex to form ethylene and the ethylsilylium ion. Consequently, even having the required energy, the Et_2HSi^+ ion does not undergo isomerisation to form the most stable tertiary cation Me_2EtSi^+ , which is confirmed by the absence of ethyl(dimethyl)phenylsilane among the reaction products.

In spite of the fact that the ratios of the silylation products of benzene with ethyl- and diethylsilylium ions are substantially different, there is no reason to assume that these reactions proceed by different mechanisms. This is evidenced by the similar energies of complexation of the ethyl- and diethylsilylium ions with benzene (−39.7 and −31.2 kcal mol^{−1}, respectively, calculated by the B3LYP/6-31G** method) and the structure of a model intermediate **27**.¹⁴⁷

The Si—C(1)—C(4) angle in the complex **27** ($\sim 105^\circ$) is similar to the corresponding angle in classical π complexes (90°).

The charge distribution in the complex **27** was calculated by the NBO (Natural Bond Orbital analysis) method.¹⁴⁷ It appeared that the major positive charge (+0.99) is localised on the silicon atom. The positive charge on the hydrogen atom in the *ipso*

**Figure 2.** Potential energy surface for the transformations of the $\text{C}_4\text{H}_{11}\text{Si}^+$ cation.¹⁰⁹

position (+0.33) is virtually equal to that on the other hydrogen atoms of the benzene ring (+0.28). Alkylation of aromatic compounds is known¹⁴⁸ to give covalently bonded σ complex **28** as an intermediate. In this complex, the angle between the alkyl group and the plane of the ring is $\sim 136^\circ$. The positive charge is transferred from the carbenoid carbon atom to the hydrogen atoms of the benzene ring, the charge being most substantially transferred to the *ipso* position (+0.36). The charge of the C(7) atom in the complex **28** is −0.65.

Evidently, the structure and the charge distribution in the σ complex formed by the reaction of silylium ions with benzene favour desilylation rather than deprotonation. The difference in

the experimental yields of the silylation products of benzene with ethyl- and diethylsilylium ions is associated with the difference in the ability of these species to be involved in the isotope exchange with the hydrogen atom in the *ipso* position. As a result, monomolecular decomposition of the σ complex with diethylsilylium ion affords tritium-free benzene as the major product.¹⁰⁸ The interconversions of the $\text{C}_2\text{H}_7\text{Si}^+$ and $\text{C}_4\text{H}_{11}\text{Si}^+$ ions proceed *via* ethylene complexes and can be accompanied by migration of silicon-bound tritium to the ethyl group.¹⁰⁹ Since only the silicon-bound tritium can be exchanged with the aromatic hydrogen atom, it is evident that the probability of this process in the case of diethylsilylium ions is substantially lower. Larger lability of the hydrogen atom in the monosubstituted ethylsilylium ion also leads to an increase in the rate of isotope exchange.

Therefore, desilylation occurs as the major process in the case of both the Et_2HSi^+ and EtH_2Si^+ cations, as in the case of Me_3Si^+ .^{135–138}

High isomerisation barriers compared to the energy acquired by the silylium ion, which is generated by the nuclear-chemical method, upon the rearrangement of the tetrahedral structure into the planar structure [$\sim 22\text{--}24\text{ kcal mol}^{-1}$ (see Ref. 149)] suggest that isomerisation of silylium ions in the reaction with the benzene molecule occurs in an intermediate complex. The difference in the lifetime of the intermediate complex in the gas and condensed phases is responsible for the difference in the degree of isomerisation of the diethylsilylium ion. As a result, the percentage of products containing the rearranged silyl fragment is lower in the condensed phase.^{108, 109}

The $[\text{R}_3\text{Si}^+ \cdot \text{alkene}]$ adduct [reaction product of alkenes with the R_3Si^+ ions ($\text{R} = \text{Me}, \text{Et}$)] and its subsequent transformations were studied¹⁵⁰ in the gas phase by the radiolytic method. A high concentration of the adduct is provided by a high pressure of a dilutant gas. It was found that this rather stable ionic adduct can decompose only in the presence of strong bases, *viz.*, by deprotonation in the presence of amines (for example, Et_3N) or desilylation in the presence of oxygen-containing nucleophiles (for example, H_2O , MeOH , *etc.*).

The direct reaction of the ethylsilylium ion generated by the nuclear-chemical method with ethylene affords dimethylvinylsilane in low yield ($\sim 10\%$).¹³⁹

The structures of the adducts of silylium ions with alkenes have been debated for many years. Both the bridged (**29a**)¹⁵¹ and open (**29b**)¹⁵² structures were considered.

Quantum-chemical calculations demonstrated¹⁰⁹ that the resulting adduct is the bridged ethene complex, for example, $[\text{EtH}_2\text{Si}^+ \cdot \text{C}_2\text{H}_4]$, located in a local minimum on the potential energy surface (see Fig. 2), which is $28.6\text{ kcal mol}^{-1}$ higher than the global minimum. Another local minimum, which is only 13 kcal mol^{-1} higher than the global minimum, corresponds to the ethene complex of the isomeric dimethylsilylium ion $[\text{Me}_2\text{HSi}^+ \cdot \text{C}_2\text{H}_4]$. A minimum corresponding to the open structure was not found.

Unlike π -electron-donor compounds, n-electron-donor compounds readily undergo silylation under the action of silylium ions. The reactions of the silylium ions $\text{R}_{3-n}\text{T}_n\text{Si}^+$ ($\text{R} = \text{Me}$ or Et ; $n = 1$ or 2) with alcohols^{141–144} in the gas phase afford primarily silylation products, *viz.*, the corresponding alkoxy-silanes. These reactions give rather strong covalently bonded oxonium ions of type **30** (calculations by the B3LYP/6-31G** method for the adduct of H_3Si^+ and methanol) as intermediates. In the latter, the positive charge ($+0.58$, estimated by NBO) is localised to a large extent on the proton of the hydroxy group.

This proton is readily abstracted (for example, is transferred to substrate molecules), resulting in the formation of alkylalkoxy-silanes from complexes of type **30**.

The oxonium complex can also undergo monomolecular decomposition with elimination of the carbenium or silylium ion to give the corresponding disiloxane or tritium-labelled alcohol.^{141–144} The formation of the latter is attributed to isotope exchange between the hydrogen atom of the alcoholic hydroxy group and the tritium atom in the silylium ion. As with benzene, this exchange occurs much more easily in the case of the EtT_2Si^+ ion.^{141–144}

The reaction of the diethylsilylium ions Et_2TSi^+ with yet another representative of n-electron-donor oxygen-containing compounds, *viz.*, dibutyl ether, also proceeds *via* an oxonium complex **31**.¹¹⁰ The exothermicity of the reaction is $72.7\text{ kcal mol}^{-1}$.

Taking into account the relaxation energy of the silylium ion,¹⁴⁹ the total excitation energy of the oxonium complex appears to be rather high, which facilitates its monomolecular decomposition with elimination of the diethylsilylium or the butyl cation.¹¹⁰ Since there are no labile hydrogen atoms in this complex, its reactions with substrate molecules can lead only to energy transfer. Because of the absence of labile hydrogen atoms in the ether molecule, the isotope exchange, *i.e.*, the formation of tritium-labelled dibutyl ether, becomes impossible. Consequently, the formation of silylation products (Et_2TSiOBu , EtT_2SiOBu and Me_2TSiOBu ; the yield was 80%) in the gas and condensed phases is attributed to monomolecular dissociation of complex **31** with elimination of the butyl cation.¹¹⁰

The reaction of the Et_2TSi^+ ions with hexamethyldisiloxane gives an intermediate adduct **32** which decomposes according to the following scheme:

Along with the main reaction product, *viz.*, unsymmetrical disiloxane **33**, a series of disiloxanes containing rearranged terminal silyl substituents were identified.¹⁴⁵ Unlike the reaction with dibutyl ether, the reaction of the diethylsilylium ion with hexamethyldisiloxane affords, among other products, labelled substrate **34**. Hexamethyldisiloxane is an organosilicon ether. It contains no labile hydrogen atoms and, at first glance, would not form a labelled substrate. According to quantum-chemical calculations [the HF/4-21(O*)G method]¹⁵³ for the model $\text{H}_3\text{C}^+-\text{Me}_2\text{O}$ and $\text{H}_3\text{C}^+-(\text{H}_3\text{Si})_2\text{O}$ systems, the ether methyl group in the oxonium complex retains the tetrahedral structure, whereas the silyl group in the $[\text{H}_3\text{C}(\text{H}_3\text{Si})_2\text{O}]^+$ complex is virtually planar. Apparently, the trimethylsilyl substituent in oxonium complex **32** is substantially ionic in character and can undergo isomerisation to give the EtMeHSi substituent containing the labile hydrogen atom. As a result, the isotope exchange between the hydrogen atom of the silyl fragment of the substrate and the tritium label in the diethylsilylium ion in the reaction (5) becomes possible.¹⁴⁵

According to the results of mass spectrometry,⁶⁸ the reaction of the trimethylsilylium ion with *n*-butylamine gives the $[\text{Me}_3\text{SiNH}_2\text{Bu}]^+$ adduct as the major product, whereas the reaction of this cation with tributylamine involves two competitive processes. One process affords the $[\text{Me}_3\text{SiNBu}_3]^+$ adduct, whereas another process is accompanied by the hydride ion abstraction from the butyl substituent of the amine molecule under the action of the Me_3Si^+ ion to form the carbenium ion $[\text{C}_{12}\text{H}_{26}\text{N}]^+$. It should be noted that, in spite of the fact that the proton affinity of the Bu_3N molecule is higher than that of $\text{Me}_2\text{Si}=\text{CH}_2$, the reaction of the Me_3Si^+ ion with a mixture of Bu_3N and BuNH_2 gives the protonated tributylamine in insignificant amount. The authors hypothesised that this compound, unlike alkyl cations,^{154–163} is formed in the reaction of the $[\text{Me}_3\text{SiNBuH}_2]^+$ adduct with tributylamine rather than due to the proton transfer from the trimethylsilylium ion to the tributylamine molecule.

The reactions of ethyl- and diethylsilylium ions with trimethyl(*tert*-butylamino)silane in the gas and condensed phases were studied by the radiochemical method.^{111, 146}

It is known^{154–163} that reactions of carbenium ions with organic and organosilicon amines follow two competitive pathways, *e.g.*, occur as condensation (6) and proton transfer (7). In the former reaction, amine reacts as a nucleophile, whereas it acts as a base in the latter reaction. Silylium ions and amines are involved only in condensation (8), in spite of the fact that the proton transfer is not energetically forbidden.^{111, 164}

$\text{R} = \text{Me}_3\text{C}, \text{Me}_3\text{Si}.$

This difference is associated with the difference in the electron density distribution in carbenium and silylium ions. According to quantum-chemical calculations,¹⁴⁷ the positive charge in the H_3Si^+ cations is virtually completely localised on the silicon

atom, and the hydrogen atoms are hydride in character, whereas the positive charge in carbenium ions is uniformly distributed between the carbon atom and the hydrogen atoms.

In the condensed phase, the qualitative composition of the reaction mixture remains unchanged, and only the component ratio becomes different: the mixture contains a higher percentage of the products formed by bimolecular reactions whose efficiency increases in the condensed phase.¹¹¹

Therefore, products containing the starting Et_2HSi group and the EtH_2Si and Me_2HSi groups as the silyl fragment were obtained in radiochemical studies of ion-molecular reactions of diethylsilylium ions with π - and n -electron-donor compounds (Table 8). Consequently, the rearrangement into ethyl- and dimethylsilylium ions takes place; this rearrangement is characteristic of diethylsilylium ions.^{110, 111, 143–145}

Table 8. The ratio of silylation products of oxygen-containing organic compounds and benzene with diethylsilylium ions.

Silyl substituent in the product	Ratio of silylation products (%) ^a			
	Bu_2O	BuOH	$(\text{Me}_3\text{Si})_2\text{O}$	PhH
Et_2HSi	90	62	29	13
$\text{EtH}_2\text{Si} + \text{Me}_2\text{HSi}$	10	38	71	87

^a The ratio was calculated from the relative yields of the corresponding silylation products.

The degree of this conversion is determined to a large extent by the nature of the electron-donor substrate. For example, for all studied oxygen-containing compounds and benzene, the percentage of products containing non-rearranged silyl substituents sharply decreases in benzene compared to that in dibutyl ether (see Table 8).¹⁶⁴ The activity series of the compounds inducing this rearrangement $\text{Bu}_2\text{O} < \text{BuOH} < (\text{Me}_3\text{Si})_2\text{O} < \text{PhH}$ correlates with their nucleophilicities and is determined by the excitation energy of the intermediate complex and the possibilities of its transfer to the substrate molecules. The association energies calculated by a quantum-chemical method¹⁶⁴ for the H_3Si^+ ion and related model compounds increase in the following series (kcal mol^{-1}): $\text{PhH} (47.6) < (\text{H}_3\text{Si})_2\text{O} (65.0) < \text{MeOH} (69.7) < \text{Me}_2\text{O} (72.7)$.

The minimum energy of association of the silylium ion with benzene ensures a longer lifetime of the complex and, as a consequence, the maximum degree of conversion. The opposite situation is observed for dibutyl ether. In this case, the degree of conversion is 10%, whereas the association energy of the similar model $\text{H}_3\text{Si}^+-\text{Me}_2\text{O}$ system is the highest in this series of compounds ($72.7 \text{ kcal mol}^{-1}$).

Although the calculated energies of association of the silylium ion with MeOH and Me_2O have similar values, the experimentally determined degree of conversion of the diethylsilylium ion in the reaction with butanol differs from that in the reaction with dibutyl ether. This is attributed to the different mechanisms of excitation energy transfer. In the case of alcohols, the complex undergoes both mono- and bimolecular decomposition, whereas only monomolecular decomposition can occur in the case of ethers.

From the above, it is clear that studies of ion-molecular reactions of silylium ions with nucleophilic reagents are in their infancy. The mechanisms of these transformations cannot be reliably established based on the results of mass-spectrometric

studies performed so far in the gas phase. The nuclear-chemical method of generation of silylium ions provides exhaustive information on their reactions with nucleophiles both in the gas and condensed phases. This method allows one to observe not only usual reaction products but also their isomeric forms, due to which more reliable conclusions about the mechanisms of reactions of silylium ions with nucleophilic compounds can be drawn.

* * *

Based on the above-considered data, the following conclusions can be drawn.

First, in spite of the fact that silylium ions have long been considered as analogues of carbenium ions, studies of the reactivity of the former ions have rejected this statement. The differences in the chemical behaviour are associated primarily with the difference in the electron density distribution in these cations. Second, the unique ability of the silicon atom to expand its coordination sphere results in higher electrophilicity of silylium ions compared to carbon analogues. Silylium ions can react with all types of nucleophiles, including counterions and solvent molecules, which make them undetectable in the condensed phase. Third, the existence of silylium ions as both reactive intermediates and individual species was unambiguously established with the use of non-traditional approaches to the generation of these ions in various media described in the present review. Nevertheless, it should be noted that further investigations of the properties of silylium ions will allow these species to play an important role in silicon chemistry.

Abstract. The published data on metal-mediated reactions of oximes are described systematically. The attention is focused on the reactions that serve as convenient methods for the synthesis of various organic compounds or models for the interpretation of the mechanisms of catalytic processes and the reactions resulting in new ligand systems. The bibliography includes 182 references.

I. Introduction

The permanent interest in ligand reactivity is caused, first of all, by the necessity of interpretation of the mechanisms of homogeneous metal-catalysed processes (including industrially important ones) in which a substrate is activated upon its coordination to a metal site. Usually it results in drastic changes in the substrate properties, particularly its electrophilicity (or nucleophilicity), acidity or redox properties. This alters the reactivity of the ligands to such an extent that the chemical reactions, impossible for a free ligand, become achievable. Books and reviews^{1–25} concerning ligands' reactions are mainly focused on complexes with 'simple' (containing only one reaction site) ligands: hydrides,¹¹ carbonyls,¹² alkenes,¹³ dinitrogen,¹⁴ azides,¹⁵ cyanides,¹⁶ nitrosyls,¹⁷ nitriles,^{18,19} isonitriles,²⁰ amines,²¹ sulfoxides,²² sulfides and thiols,²³ pseudohalides²⁴ and phosphines.²⁵ Their chemical transformations mimic some catalytic processes and organic reactions taking place in the presence of metal complexes.

In contrast to the above-mentioned ligands, a coordinated oxime contains three active sites (C, N and O atoms) and an OH group the acidity of which increases drastically upon coordination.²⁶ Virtually all types of metal-mediated transformations are possible for the coordinated oximes, *viz.*, nucleophilic and electrophilic reactions, intramolecular redox reactions, template synthesis,^{27,28} metal-induced Beckmann rearrangement, *etc.*

Abundant experimental material on these transformations and on the metal-catalysed reactions of oximes and their complexes was considered in several reviews.^{29–37} However, the

problem is still topical, which is circumstantially proved by quite a number of recent papers on the subject. New reports together with previously non-reviewed results lead to a new insight into reactions of metal-activated oximes.

Retention or loss of integrity of the oxime fragment C=NOH during the coordination was the main characteristic used for our systematisation of metal-mediated reactions of oximes. According to this feature, all reactions are divided into two large groups.

The first group comprises transformations occurring with the cleavage of the O–N, O–H and C=N bonds. Two sub-groups within this first group involve non-redox reactions (first of all, addition or elimination of water molecules) and redox reactions.

Metal-mediated reactions of oximes with retention of the C=NOH fragment involve mostly the oxygen atom (less common, N and C atoms) of the oximes, they are represented by the nucleophilic addition reactions to substrates containing multiple bonds. Reactions involving peripheral groups in oxime and oximate complexes also belong to this category.

II. Reactions with loss of integrity of the C=NOH fragment

1. Metal-mediated hydrolysis of oximes

Examples of metal-mediated hydrolytic cleavage of oximes occurring without change in the oxidation state of the nitrogen atom are discussed below.

A study of a catalytic process of acetone oxime hydrolysis in the presence of *cis*-[Pd(en)(Solv)₂]²⁺ or *cis*-[Pd(dtod)(Solv)₂]²⁺ (**1**) [en is ethylenediamine, dtod is 3,6-dithiaoctane-1,8-diol, Solv is H₂O or (CD₃)₂CO], including its kinetics, was reported.³⁸ A mechanism of the Pd-catalysed hydrolysis of acetone oxime has been proposed.

Palladium centre coordinates both the oxime and the hydroxide ion in the first step of the process yielding complex **2**. In the second step the C=N bond activated due to metal coordination is subject to intramolecular nucleophilic attack by the hydroxyl

ligand. As a result, the bond is hydrolytically cleaved to form acetone. The last and the rate determining step of the process is release of hydroxylamine upon dissociation of its Pd(II) complex. This step significantly reduces the efficiency of the catalytic process (the turnover number of the catalyst does not exceed 4). The presence of acetone and hydroxylamine (both free and coordinated) was confirmed by NMR spectroscopy.

Treatment of the complex $[\text{Bu}_4\text{N}][\text{PtCl}_3(\text{Me}_2\text{C}=\text{NOH})]$ with concentrated hydrochloric acid for 30 days at room temperature leads to two products, *viz.*, $[\text{NH}_4]_2[\text{PtCl}_6]$ and $[\text{Bu}_4\text{N}]_2[\text{PtCl}_6]$,³⁹ which presumably result from consecutive redox and hydrolytic processes. Two alternative pathways of the process are presented in Scheme 1: acid hydrolysis of the oxime in the starting complex followed by intramolecular oxidation of Pt(II) to Pt(IV) by the eliminated $[\text{NH}_3\text{OH}]^+$ cation (path *a*), or oxidative deoxygenation of the oxime followed by hydrolysis of the produced iminium fragment (path *b*).

Scheme 1

However, no solid evidence in favour of one or another mechanism has been obtained. Nevertheless, it has to be stressed that both hydrolysis and oxidative deoxygenation of acetone oxime in this case are mediated by platinum(II).

Study on the reactivity of rhodium imino complexes formed in the nucleophilic addition of acetone oxime to rhodium(III) nitrile complexes reveals⁴⁰ that it is the oxime fragment of the imino-ligand that undergoes hydrolysis at pH 1 and 80 °C, while the imine fragment[†] manifests enormous stability under the same conditions. This implies that Rh(III) selectively activates the C=N bond of the oxime fragment.

¹H NMR study of this reaction has shown that the starting complex **3** completely transforms into a mixed-ligand product **4** in

[†] It is known that non-coordinated imines are readily hydrolysed at low pH values.

36 h; the formation of acetone was also observed. When complex **4** was treated under the same conditions for 4 weeks, hydrolysis of the second imino-ligand occurred to give new bis-chelate complex **5**, which was isolated and structurally characterised. It is of note that the reaction proceeds faster in the absence of HCl, however the selectivity decreases substantially. In this case, considerable amount of by-products prevents isolation of compounds **4** and **5** in individual state.

Technetium imine-oxime complexes behave similarly.⁴¹

2. Dehydration of oximes

Synthesis of nitriles by dehydration of the corresponding aldoximes is long known and successfully employed in organic chemistry.^{42,43} However, there are few examples of metal-mediated conversions of $\text{R(H)C}=\text{NOH}$ into RCN .

Thus synthesis of two osmium nitrile complexes $[(\eta^6\text{-C}_6\text{H}_6)\text{OsH}(\text{NCR})(\text{PMeBu}_2)]^+$ ($\text{R} = \text{Me}, \text{Ph}$) by reactions of $[(\eta^6\text{-C}_6\text{H}_6)\text{OsHI}(\text{PMeBu}_2)]$ with aldoximes $\text{RCH}=\text{NOH}$ in the presence of AgPF_6 used for abstraction of the iodide ligand was described.⁴⁴ Tungsten nitrile complexes $[\text{W}(\text{NCR})(\text{CO})_5]$ ($\text{R} = \text{Me}, \text{Ph}, \text{C}_6\text{H}_4\text{OMe-}p$) were obtained from the corresponding aldoximes and $[\text{W}(\text{THF})(\text{CO})_5]$.⁴⁵

The reaction of RuBr_3 with benzaldoxime in 6 M aqueous HBr furnishes the mixed-valence ruthenium complex $[\text{RuBr}(\text{NCPH})_5][\text{RuBr}_4(\text{NCPH})_2]$.⁴⁶ Refluxing of the osmium acetonitrile trinuclear cluster $[\text{Os}_3(\text{CO})_{11}(\text{NCMe})]$ with anthracene-9-carbaldoxime in chloroform for 5 h resulted in the anthracene-carbonitrile complex $[\text{Os}_3(\text{CO})_{11}(\text{NCC}_{14}\text{H}_9)]$ in 46% yield.⁴⁷ The formation of N-coordinated oxime intermediates in the initial stages of the above-mentioned reactions was suggested.^{44–47} The electron density on the aldoxime nitrogen atom increases as a result of coordination to the metal (due to dative interaction of the occupied d-orbitals of a metal with the unoccupied π^* -orbitals of a ligand), which facilitates cleavage of the N–O bond followed by dehydration and formation of a nitrile.

A number of studies on the dehydration of oximes assisted by Ru and Os complexes were reported. It is known that these metal sites possess strong affinities for nitriles. Obviously, the formation of highly stable nitrile complexes is one of the main driving forces of the reaction. This suggestion was indirectly supported by the results of a study⁴⁸ where it was shown that the reaction of the ruthenium complex $[\text{Ru}(\text{NH}_3)_5(\text{H}_2\text{O})]^{2+}$ with the ketoximes $\text{Me(R)C}=\text{NOH}$ [$\text{R} = \text{C}(\text{O})\text{Me}, \text{C}(\text{O})\text{Ph}$ and $\text{CH}(\text{OH})\text{Ph}$] leads to the acetonitrile complex $[\text{Ru}(\text{NH}_3)_5(\text{NCMe})]^{2+}$ and elimination of ROH. The affinity of Ru(II) to nitrile is so high that even the cleavage of the ketoxime C–C bond becomes favourable.

Attanasi *et al.*⁴⁹ have shown that refluxing of aldoximes in acetonitrile in the presence of catalytic amounts of $\text{Cu}(\text{OAc})_2 \cdot \text{H}_2\text{O}$ produces the corresponding nitriles in good yield (85%–98%). Refluxing of benzaldoxime with AlI_3 (molar ratio 1:2) in acetonitrile for 2 h resulted in benzonitrile (92%).⁵⁰ Aldoximes undergo dehydration under mild conditions in the presence of titanium and indium trifluoromethanesulfonates $[\text{TiCl}_3(\text{OTf})]$ ⁵¹ and $[\text{In}(\text{OTf})_3]$ ⁵² affording the corresponding nitriles. Heterogeneous ruthenium catalysts obtained by adsorption of $[\text{RuCl}_2\text{L}_2]$ (L is *p*-cymene) on activated charcoal⁵³ or molecular sieves⁵⁴ are also used for conversion of aldoximes into nitriles.

Various aldoximes are converted into the corresponding nitriles in less than 1 h in more than 95% yields by azeotropic distillation with toluene or mesitylene in the presence of catalytic amounts of perhenic acid HOREO_3 (1 mol.%, an aqueous solution).⁵⁵ A plausible reaction mechanism consists of nucleophilic addition of aldoximes to rhenium with formation of six-membered M,H-cyclic intermediates **A** which are split to give the corresponding nitriles:

Solid-phase dehydration of oxime ligands is also known.^{56–58} The formation of PhCN as a result of thermal decomposition of the copper complex $[\text{Cu}\{2\text{-OC}_6\text{H}_4\text{C(Ph)=NOH}\}_2]$ was proved by combination of TGA and mass spectrometry.⁵⁶ Pyrolysis of Co(II) dimethylglyoximate and cyclohexanedione-1,2-dioximate complexes afforded acetonitrile and hexanedinitrile, respectively.⁵⁷ Lead(II) bis(salicylaldoximate) decomposes in the temperature range from 160 to 200 °C yielding the nitrile complex $[\text{NCC}_6\text{H}_4\text{OPb}]_2\text{O}$ with elimination of water.⁵⁸ Unfortunately, the formation of this product was confirmed only by elemental analysis.

An example of promotion of aldoxime dehydration by a coordinated ligand is known.⁵⁹ Thus the nucleophilic addition of aldoximes R(H)C=NOH to the platinum(IV) nitrile complex *trans*- $[\text{PtCl}_4(\text{NCEt})_2]$ results in iminoacyl (imide) derivatives *trans*- $[\text{PtCl}_4\{\text{HN}=\text{C(Et)ON}=\text{CHR}\}_2]$ (**6**).

R = Me, Ph, C(O)Ph.

Complexes **6**, when stored in a solution, decompose yielding a Pt(IV) propionamide complex **7** (where the amide is stabilised in the imidic form) and the corresponding nitriles. This was confirmed by ¹H and ¹³C NMR spectroscopy, thin layer chromatography and mass spectrometry. Comparison of the results presented in two papers (Refs 47 and 59) suggests that the reaction of the Os cluster (Ref. 47) also proceeds *via* an osmium iminoacyl intermediate, its decomposition results in anthracene-9-carbonitrile, which further reacts with Os.

3. Metal-mediated Beckmann rearrangement

The Beckmann rearrangement is still the simplest and the most convenient method of oxime conversion^{60,61} into the corresponding amides both in laboratory and industry.[‡] Strong Brønsted or Lewis acids are normally used as catalysts of this conversion.

The mechanism of the reaction was studied for borophosphates as Lewis acids.⁶² In the first step, oximes react with borophosphates to form intermediate **8** (Scheme 2) stabilised by a hydrogen bond. Decomposition of the latter yields nitrilium cation **9**, which is converted into an amide **10** upon the reaction with the hydroxide ion.

Scheme 2

The rearrangement of oximes into amides is also catalysed by metal ions. For instance, benzamide was obtained from benzaldoxime in the presence of CuCl_2 .⁶³ Later, it was shown⁶⁴ that monosaccharide oximes are converted into the corresponding aldonamides upon refluxing in 1,4-dioxane in the presence of $\text{Cu(OAc)}_2 \cdot \text{H}_2\text{O}$. Presumably,⁶⁴ copper(II) oximate complexes isolated from the reaction mixture are intermediates of this conversion. Unfortunately, no other experimental data on the reaction mechanism have been obtained.

Studies on the Beckmann rearrangement of various aldoximes into the corresponding amides catalysed by nickel(II) salts were carried out.^{65–67} In particular, in the presence of catalytic amounts of $\text{Ni(OAc)}_2 \cdot 4\text{H}_2\text{O}$, aldoximes isomerise into amides in xylene or water in high yields. The role of the metal in this process was studied in detail^{68,69} using rearrangement of a number of aldoximes into the corresponding amides in the presence of catalytic amounts of the complexes $[\text{M}(\text{acac})_2]$ (M = Pd, Ni) or $[\text{Pd}(\text{CH}_2\text{NO}_2)(\text{acac})(\text{PPh}_3)]$ as a model reaction. The reaction mixtures contained aldoxime and $[\text{Pd}(\text{acac})_2]$, the presence of small amounts of acetonitrile was revealed by GLC and ¹H NMR spectroscopy. Heating of a three-component mixture $\text{Me(H)C=NOH} - \text{PhCH}_2\text{CN} - [\text{Pd}(\text{acac})_2]$ results in the conversion of acetaldoxime into acetonitrile and of phenylacetonitrile into phenylacetamide. Thus, a stepwise mechanism was suggested,^{68,69} which includes dehydration of the aldoxime into the corresponding nitrile and hydrolysis of the latter into the amide.

Similar mechanism was suggested for the conversion of aldoximes into amides in the presence of catalytic amounts of the Wilkinson complex $[\text{RhCl}(\text{PPh}_3)_3]$ (DMF, 150 °C).⁷⁰ In this case, the formation of small (~8%) amounts of nitriles was also observed. Unsuccessful attempts of rearrangements of ketoximes and *O*-alkylaldoximes into amides were yet another evidence in favour of the suggested stepwise mechanism of this reaction.

It was shown^{71,72} that various ketoximes were converted in high yields into amides upon refluxing in nitromethane as the result of the Beckmann rearrangement catalysed by a mixture of $[\text{Bu}_4\text{N}][\text{ReO}_4]$ and $\text{CF}_3\text{SO}_3\text{H}$. No reaction occurs in the absence of $[\text{Bu}_4\text{N}][\text{ReO}_4]$. It was suggested that oxime perchrenate **11** (Scheme 3) is an intermediate of this process in the case of cyclohexanone oxime. This intermediate **11** decomposes yielding a seven-membered cation **12** and HReO_4 . Hydrolysis of the cation **12** yields ω -caprolactam (**13**).

To increase the yield of ω -caprolactam, $\text{NH}_2\text{OH} \cdot \text{HCl}$ was added to the reaction mixture in order to bind the ketone formed as a by-product. The use of MeNO_2 as a solvent also increases the yields of amides, which is explained by possible formation of

‡ This is an industrial method for the manufacture of ω -caprolactam.

Scheme 3

intermediate **14**, *i.e.*, an adduct of nitromethane (in aci-nitro form) to the cation **12**, which is easily hydrolysed to give ω -caprolactam.

$[\text{Yb}(\text{OTf})_3]^{73}$ and $[\text{La}(\text{OTf})_3]^{74}$ appeared to be very efficient catalysts of the Beckmann rearrangement of some ketoximes. Unfortunately, the role of metal in this process was not discussed.

Analysis of the published data shows that the role of the metal in the metal-mediated Beckmann rearrangement is reduced to the dehydration of aldoximes, on one hand, and, on the other hand, to activation of the nitriles formed with respect to hydrolysis, which affords amides (for metal-mediated hydrolysis of nitriles, see a review ⁷⁵).

4. Reductive and oxidative deoxygenation

Among the methods for conversion of oximes into carbonyl compounds, reductive and oxidative deoxygenation are of the greatest interest, particularly, the reactions occurring in the presence of various metal compounds. These reactions are accompanied by changes in the oxidation state of the oxime nitrogen atom followed by hydrolytic cleavage of the C–N bond resulting in carbonyl compounds.

For instance, oxidation of various aldoximes and ketoximes in the presence of activated MnO_2 in aprotic solvents (dichloromethane, chloroform) proceeds under mild conditions (room temperature) and produces the corresponding carbonyl compounds in very high yields.⁷⁶ A plausible reaction mechanism involving the metal site was suggested. In the first step of the process, addition of an oxime to MnO_2 occurs to yield intermediate **15**, which then undergoes a [2,3]-sigmatropic shift followed by decomposition of the complex and formation of the carbonyl compound:

Reaction of ferrous chloride FeCl_2 with salicylaldoxime in the presence of triethylamine leading to the formation of the trinuclear complex $[\text{Fe}_3^{\text{III}}(\mu_3\text{-O})(\mu_2\text{-OPh})]^{6+}$ is an example of oxidative deoxygenation (see Ref. 77). The reaction proceeds in methanol in an atmosphere of argon. The formation of 2-[bis(salicylideneimino)methyl]phenol (**16**) is explained by reductive deoxygenation of the starting oxime **17** into the corresponding imine **18**, hydrolysis of the imine **18** to salicylaldehyde **19** and condensation of the latter with the imine **18** (the ratio **18**:**19** = 2:1).

Numerous experimental papers on the subject in question published before 2001 were thoroughly analysed in a review.⁷⁸ Therefore, only the data published after 2000 are discussed in the present review with indication of the oxidising agents used.

Quaternary heterocyclic halochromates $[\text{HetH}](\text{CrO}_3\text{X})$ (Het is pyridine, methylpiperidine, quinoline; X = Cl, F),^{79–85} $\text{Mg}(\text{HSO}_4)_2$ in the presence of wet SiO_2 ,⁸⁶ MnO_2 ,⁸⁷ $[\text{Cu}(\text{NH}_3)_4](\text{MnO}_4)_2$,⁸⁸ LnCl_3 ⁸⁹ and KMnO_4 ⁹⁰ were used as oxidants in the oxidative deoxygenation.

Reductive deoxygenation of oximes to the corresponding carbonyl compounds proceeds in high yield using a suspension of zinc powder in non-dried MeCN in the presence of tungsten(VI) and molybdenum(VI) chlorides.⁹¹

Microwave irradiation was shown to effect oxidative deoxygenation. For example, oximes are cleaved in the presence of BiCl_3 in refluxing THF in 10 h (the yield of ketones is 40%). The same reactions under microwave irradiation are completed in a few minutes and in high yields, which allows smooth conversion of even such a sterically hindered substrate as camphor oxime into the corresponding ketone.⁹²

Thus, reductive and oxidative deoxygenation of oximes can be effected with various oxidants or reductive agents and can be used as a method of synthesis of carbonyl compounds.

5. Oxime-mediated nitrosylation of metals

In the previous Section, we discussed the method of synthesis of carbonyl compounds from oximes by reductive and oxidative cleavage of the oxime C=N bond with involvement of metal complexes. Nitroso complexes of metals formed upon oxidation of the oxime nitrogen atom are intermediates in these processes. In this Section, we present examples of obtaining stable metal nitroso complexes by splitting of oximes. We assume that these examples are complementary and, therefore, their discussion in one paper will provide more detailed understanding of the mechanism of the oxidative deoxygenation.

The possibility of application of oximes as nitrosylating agents was demonstrated by the synthesis of the molybdenum nitroso complex $[\text{Mo}(\text{acac})_2(\text{NO})\{\text{MeC}(\text{NH}_2)\text{NO}\}]$ by reaction of acetamideoxime $\text{MeC}(\text{NH}_2)=\text{NOH}$ with $[\text{MoO}_2(\text{acac})_2]$ in methanol at room temperature.⁹³ The structure of the complex was confirmed by X-ray diffraction analysis. Nitroso complexes were also obtained from acetone oxime and various Mo(VI) oxo complexes.⁹⁴ For instance, the complex $[\text{Mo}(\text{acac})_2(\text{NO})\{\text{Me}_2\text{C}=\text{NO}\}]$ was obtained by refluxing $[\text{MoO}_2(\text{acac})_2]$ with acetone oxime in methanol for 5.5 h. The formation of nitroso

complexes in these reactions is explained⁹⁴ by hydrolytic splitting of acetone oxime to hydroxylamine followed by reductive nitrosylation of Mo(VI). The mechanism of reductive nitrosylation of molybdenum oxo complexes with hydroxylamine in water was studied in detail⁹⁵ and may be illustrated as follows:

The ruthenium(III) nitroso complex $[\text{NH}_4]_2[\text{RuCl}_5(\text{NO})]$ was prepared by reaction of various oximes (acetaldoxime, acetone oxime, cyclohexanone and cyclopentanone oximes) with $\text{RuCl}_3 \cdot x\text{H}_2\text{O}$.^{96,97} The formation of the same product in all cases is explained by metal-mediated hydrolysis of oximes resulting in hydroxylamine and further disproportionation of the latter into nitrosyl and ammonium ion. High affinity of ruthenium to the nitrosyl ligand is yet another factor favouring the formation of the nitroso complexes.

6. Reductive deoxygenation

Alper and Edward⁹⁸ have shown that the reaction of *p*-nitrosophenol (a tautomeric form of *p*-quinone monooxime) with $\text{Fe}(\text{CO})_5$ results in 4,4'-dihydroxyazobenzene (**20**). However, 2-isopropyl-5-methyl-4-nitrosophenol is converted into 4-amino-2-isopropyl-5-methylphenol (**21**) under the same conditions.

Later, the process of metal-mediated reductive deoxygenation of quinone and benzoquinone oximes in the presence of $\text{Fe}(\text{CO})_5$ (Ref. 99) or the trinuclear ruthenium carbonyl cluster $\text{Ru}_3(\text{CO})_{12}$ (Ref. 100) was studied in detail. In both cases, the reactions of quinone oximes with metal carbonyls were carried out in refluxing THF under argon.

In the reaction of 1,2-naphthoquinone 2-oxime (**22**) with $\text{Fe}(\text{CO})_5$, 2-amino-*N*-(1-hydroxy-2-naphthyl)-1,4-naphthoquinone 4-imine (**23**) and 5-hydroxydibenzo[*b,i*]phenazin-12(6*H*)-one (**24**) were identified.

The formation of these products is explained⁹⁹ by conversion of the quinone oxime into a quinone imine **25** (as a result of deoxygenation) (Scheme 4) followed by possible formation of nitrene intermediate **26**, which is readily converted into aminonaphthol **26** (due to proton abstraction) or into dihydroxyphenazine derivative **28** (due to recombination).

Iron(II) quinone oximate complex **29** (the main product) and trace amounts of isomeric quinone imine complexes **31** and **31** are

Scheme 4

formed alongside with compounds **23** and **24** in the presence of aniline.

Mononuclear ruthenium naphthoquinone oximate complexes are the main products in similar reactions with $\text{Ru}_3(\text{CO})_{12}$.¹⁰⁰ In addition to these complexes, mixed-ligand cluster **32** was isolated in the case of 1,2-naphthoquinone 1-oxime.

Presumably,¹⁰⁰ two types of ligands in the cluster **32** are formed as a result of deoxygenation of 1,2-naphthoquinone 1-oxime in the presence of $\text{Ru}_3(\text{CO})_{12}$, which yields a nitrene intermediate of the type **26**, and its further conversions, similar to those shown in Scheme 4.

Reactions of quinone oximate complexes of 3d metals [Cu(II), Ni(II), Zn(II) and Fe(III)] with PPh_3 and RNH_2 afford compounds similar to those described previously (see Scheme 4).^{101–105} It has to be noted, that in reactions with Cu(II) and Fe(III) complexes,¹⁰¹ only mixtures of unidentified products with low oxidation states of the metal sites have been obtained. Reaction of a Ni(II) quinone oximate complex with PPh_3 ¹⁰⁵ yields a triphenyl(*o*-hydroxyphenylimino)phosphorane complex **33**.

Ketoximes unable to tautomerise into nitroso-derivatives yield either the corresponding imines in reactions with $\text{Fe}(\text{CO})_5$,¹⁰⁶ or ketones.¹⁰⁷

The reaction of $\text{RhCl}_3 \cdot 3\text{H}_2\text{O}$ with 1,2-naphthoquinone 2-oxime (**22**) in the presence of P- or N-donors (triphenylphosphine, pyridine or its 4-phenyl derivatives)¹⁰⁸ results in a mixture of Rh(III) complexes. Mixed-ligand complex **34** was isolated from this mixture and its structure was determined by X-ray crystallography.

Steinborn *et al.*⁴¹ have found that the rhodium glyoximate $[\text{Rh}(\text{dmgH})_2(\text{PPh}_3)_2]^-$ (hereinafter referred to as $[\text{Rh}]^-$) (dmgH_2 is dimethylglyoxime) reacts with dihalomethanes CH_2X_2 ($\text{X} = \text{Br}, \text{Cl}$) producing both previously known compounds of the $[\text{Rh}]-\text{CH}_2\text{X}$ type and the new imino-oximate complexes $[\text{Rh}(\text{CH}_2\text{X})\{\text{ON}=\text{C}(\text{Me})-\text{C}(\text{Me})=\text{NH}\}(\text{dmgH})(\text{PPh}_3)]$. The complex $[\text{RhCl}_2(\text{dmgH})(\text{dmgH}_2)]$ reacts with trialkylphosphines in the presence of NaBH_4 to afford an imino-oximate complex $[\text{Rh}(\text{dmgH})(\text{bdioH})(\text{PR}_3)_2]\text{Cl}$ (bdioH is butane-2,3-dione 2-imine-3-oximate).¹⁰⁹ Unusually high resistance of the newly formed imine bond against hydrolysis has been noted.³⁹ The boron–technetium imino-oximate binuclear complex obtained in the reaction of $[\text{ReCl}_3(\text{NCMe})(\text{PPh}_3)_2]$ with dmgH_2 and $\text{EtB}(\text{OH})_2$ appeared to be stable as well. This binuclear complex was isolated using 1 M HCl.¹¹⁰ Reactions of salicylaldoximes with $[\text{RuCl}_2(\text{PPh}_3)_3]$ ¹¹¹ and $[\text{ReOCl}_3(\text{PPh}_3)_3]$ ¹¹² demonstrated a possibility of synthesising imino-oximate complexes.

Deoxygenation of ketoximes in the presence of catalytic amounts of the complex $[\text{Ru}_2(\text{CO})_4(\mu_2-\eta^2-\text{Me}_2\text{C}=\text{NO})_2] \cdot (\text{Me}_2\text{C}=\text{NOH})_2$ resulting in imines has been studied.¹¹³ 2,3,4,5-Tetrahydro-2,2,4,4,6-pentamethylpyrimidine (**35**), CO_2 and NH_3 are formed upon deoxygenation of acetone oxime with CO . A plausible mechanism of this process includes carbonylation of acetone oxime followed by decarboxylation of an unstable intermediate $\text{Me}_2\text{C}=\text{NOC}(\text{O})\text{H}$ to yield the imine $\text{Me}_2\text{C}=\text{NH}$. This undergoes trimerisation with elimination of NH_3 .

It was shown¹¹⁴ that, in the presence of $\text{Ru}_3(\text{CO})_{12}$, various ketoximes are converted (CO , 20 atm) into the corresponding ketimines in virtually 100% yield:

The mechanism of this process was not studied in detail. Taking into account the fact that *o*-benzylpropiophenone oxime and *o*-acetylacetophenone oxime are inactive in this reaction, it was suggested that the initial stage of the process is the reductive cleavage of the N–O bond.

7. Oxidative addition of oximes

Oxidative addition of oximes to electron-rich metal sites may proceed with cleavage of both the O–H bond and the N–O bond resulting in complexes with bridging or monodentate ligands.

a. Oxidative addition of oximes as a result of the O–H bond cleavage

For the first time, the reaction of oxidative addition with cleavage of the O–H bond was performed by Beck and co-workers¹¹⁵ with heterocyclic oximes as examples. The platinum(0) complex $[\text{Pt}(\text{C}_2\text{H}_4)(\text{PPh}_3)_2]$ reacts with heterocyclic oxime **36** in toluene at room temperature yielding Pt(II) hydride-oximate complexes **37**. It has to be noted, that up to now this reaction is the only example of formation of monodentate N-coordinated oximate fragment in a complex formed as a result of the O–H bond cleavage.

It was shown by Floriani and co-workers¹¹⁶ that the reaction of benzophenone oxime with the complex $[\text{CpCo}(\text{C}_2\text{H}_4)_2]$ in toluene at room temperature leads to the formation of the μ_2 -imidooximate cobalt cluster $[\{\text{CpCo}\}_2(\mu_2-\text{N}=\text{CPh}_2) \cdot (\mu_2-\text{ON}=\text{CPh}_2)]$ (**38**). The suggested reaction mechanism includes the following steps: oxidative addition of oxime to $\text{Co}(\text{I})$ with cleavage of the O–H bond, intramolecular nucleophilic addition of the hydride ion to the carbon atom of the second N-coordinated oxime moiety and dehydration of the intermediate **39** with formation of the complex **38**.

The reaction of the cluster $[\text{Os}_3(\text{CO})_{10}(\text{NCMe})_2]$ (**40**) with 7-chloro-4-(hydroxyamino)quinoline (**41**) existing in two tautomeric forms **A** and **B**, in a mixture of dichloromethane and acetone at room temperature produces the clusters $[\text{Os}_3(\mu_2-\text{H})(\mu_2-\eta^1-\text{OC}_9\text{H}_6\text{N}_2\text{Cl})(\text{CO})_{10}]$ (**42**) and $[\text{Os}_3(\mu_2-\text{H})(\mu_2-\eta^2-\text{ONC}_9\text{H}_6\text{NCl})(\text{CO})_{10}]$ (**43**) in 37% and 23% yields, respectively.¹¹⁷ The complex **42** is completely converted into the complex **43** when kept in acetone for two days at room temperature.

Acetone oxime reacts with the cluster **40** in the same way.¹¹⁸ The formed hydride-oximate complex $[\text{Os}_3(\mu_2\text{-H})(\mu_2\text{-ON}=\text{CMe}_2)(\text{CO})_{10}]$ isomerises into the hydroxo-imide complex $[\text{Os}_3(\mu_2\text{-OH})(\mu_2\text{-N}=\text{CMe}_2)(\text{CO})_{10}]$ on refluxing in octane. It was suggested¹¹⁸ that isomerisation proceeds with formation of the oxime intermediate $[\text{Os}_3(\mu_2\text{-HON}=\text{CMe}_2)(\text{CO})_{10}]$ (of the type **43**) in which the N–O bond cleavage takes place as a result of oxidative addition. This type of oxidative addition of oximes will be discussed in detail in the next Section of the review.

2-Benzoylpyridine oxime reacts with another osmium cluster $[\text{Os}_3(\text{CO})_{11}(\text{NCMe})]$ in dichloromethane at 25 °C yielding the complex $[\text{Os}_3\text{H}(\text{CO})_{11}\{\eta^2\text{-ON}=\text{CPh}(\text{NC}_5\text{H}_4)\}]$ (**44**) (carbonyl groups in formulas **44** and **45** below are omitted). Another cluster $[\text{Os}_3(\mu_2\text{-H})(\text{CO})_9\{\mu_2\text{-}\eta^3\text{-ON}=\text{CPh}(\text{NC}_5\text{H}_4)\}]$ (**45**) was obtained by refluxing the complex **44** for 3 h in toluene under argon.¹¹⁹

Oximato-silane complexes were obtained by heating $(\pi\text{-C}_5\text{Me}_5)_2\text{Si}$ with $\text{R}^1\text{R}^2\text{C}=\text{NOH}$ in toluene for several hours at 60 °C:¹²⁰

b. Oxidative addition of oximes with cleavage of the N–O bond

The first example of oxidative addition of acetone oxime to the rhodium complex *trans*- $[\text{ReCl}(\text{N}_2)(\text{dppe})_2]$ with cleavage of the N–O bond was described in 1998.¹²¹ The reaction was carried out in THF in the presence of TiHSO_4 . The hydroxo-complex *trans*- $[\text{Re}(\text{OH})(\text{NCMe}_2)(\text{dppe})][\text{HSO}_4]$ was obtained upon addition of the oxime to the Re(I) complex. Later, other oximes $\text{R}^1\text{R}^2\text{C}=\text{NOH}$ [$\text{R}^1 = \text{H}; \text{R}^2 = \text{Me}, \text{Ph}; \text{R}^1\text{--R}^2 = (\text{CH}_2)_4, (\text{CH}_2)_5$] were introduced in reactions with this complex.¹²²

Afterwards, Tillack *et al.*¹²³ have shown that reactions of titanocene derivatives with *O*-silylated oximes $\text{R}^1\text{R}^2\text{C}=\text{NOSiMe}_3$ [$\text{R}^1 = \text{R}^2 = \text{Me}, \text{R}^1\text{--R}^2 = (\text{CH}_2)_5$] in refluxing hexane for 5 h resulted in complexes $[\text{Cp}_2\text{Ti}(\text{N}=\text{CR}^1\text{R}^2)(\text{OSiMe}_3)]$ in 45% and 50% yields, respectively.

The oxidative addition of oxime derivatives to palladium catalysts was used to synthesise key intermediates in the preparation of various heterocycles.^{124–127} Thus unsaturated *O*-substituted ketoximes are converted into various nitrogen heterocycles (pyrroles, pyridines, isoquinolines, spiroimines and azaazulenes) on heating in DMF (110 °C, 30 min) in the presence

of catalytic amounts of $\text{Pd}(\text{PPh}_3)_4$ and triethylamine. It was suggested that these reactions occur *via* alkylideneaminopalladium intermediate of the type **46** (as a result of oxidative addition of the oxime to Pd^0) followed by intramolecular amination (similar to the Heck reaction) of the alkene fragment of the molecule.^{124–127}

Thus, oxidative addition of oximes to a metal site, which occurs with cleavage of the O–H or N–O bond (depending on the character of the metal), may result in both hydride-oximate (N- or O-coordinated) and hydroxoalkylideneamine metal complexes.

III. Reaction with retention of the C = NOH fragment

1. Nucleophilic addition of oximes to multiple bonds

a. Metal-mediated addition reactions of oximes to nitriles

Vast amount of experimental data are known to date concerning metal-mediated nucleophilic addition of oximes to nitriles with formation of iminoacyl ligands.^{18, 19, 128} Reactions of nitrile complexes of metals in higher oxidation states $[\text{Pt}(\text{IV})]$,^{129–134} $[\text{Re}(\text{IV})]$ ¹³⁵ with various oximes in aprotic media (nitriles, chloroform, CH_2Cl_2) are highly selective and result in monodentate N-coordinated iminoacyl derivatives in high yields. *E*-Isomers of iminoacyl ligands are stabilised by an intramolecular hydrogen bond between the hydrogen atom of the imine and the nitrogen atom of the acyl fragment with formation of a 5-membered N–H–ring.

In these reactions, the metal centre activates the carbon atom of the nitrile ligand and then stabilises the coordinated imine formed.

In contrast to $\text{Pt}(\text{IV})$ and $\text{Re}(\text{IV})$ nitrile complexes, a $\text{Rh}(\text{III})$ nitrile complex, *viz.*, *mer*- $[\text{RhCl}_3(\text{NCR})_3]$, reacts with oximes (for example, with cyclopentanone oxime) yielding rhodium(III) *N,N*-mono- (**47**) and *N,N*-bis-chelate (**48**) iminoacyl complexes.¹³⁶

Bis-chelate complexes **48** were also obtained by a reaction of *mer*- $[\text{RhCl}_3\{\text{HON}=\text{C}(\text{CH}_2)_4\}_3]$ with acetonitrile in ethanol.³⁸ Previously, similar chelate iminoacyl compounds were formed on refluxing oxo-vanadium salicylaldoximate complex $[\text{VOL}_2]$

$$\text{PdCl}_2 + \text{R}^1\text{R}^2\text{C}=\text{NOH} \xrightarrow{\text{R}^3\text{CN}} \text{Product}$$

$$\begin{array}{ccc}
 \left[\begin{array}{c} \text{R}^3 \\ \diagup \\ \text{C} \equiv \text{N} \\ \diagdown \\ \text{OH} \end{array} \right] & \longrightarrow & \begin{array}{c} \text{H} \\ \diagup \\ \text{N} \\ \diagdown \\ \text{O} \end{array} \\
 \text{[M]} & & \text{[M]} \\
 \text{R}^1 \text{---} \text{C} \text{---} \text{R}^2 & & \text{R}^1 \text{---} \text{C} \text{---} \text{R}^2
 \end{array}$$

49 **50**

Platinum(II) cyanamide complexes, viz., *cis*-[PtCl(N≡CNR³)₂(PPh₃)₂][BF₄] and *cis*-[Pt(N≡CNR³)₂(PPh₃)₂].[BF₄]₂, react with oximes in the presence of Ag⁺ or Cu²⁺ salts (CH₂Cl₂, 20–25 °C) to form azametallacycles [Pt(NH=C(NR³)).ON=CR¹R²)(PPh₃)₂][BF₄]₂.¹⁴⁰ The oxime-cyanamide intermediate *cis*-[Pt(N≡CNET₂)(HON=CR¹R²)(PPh₃)₂][BF₄]₂ was isolated at R³ = Et, which serves as indirect evidence for the above-mentioned mechanism of formation of chelate iminoacyl complexes. It was suggested¹⁴⁰ that the Ag⁺ or Cu²⁺ ions favour additional electrophilic activation of the carbon atom of the cyanamide group and allow this reaction to take place even in the case of relatively inert Pt(II) complexes.

Complex **51** was obtained in the reaction of $\text{CoI}_2 \cdot 2\text{H}_2\text{O}$ with an excess of butan-2-one oxime in dry acetone in the presence of trimethyl orthoformate and its structure was determined by X-ray crystallography.¹⁴⁴

[illegible]

The intramolecular cyclisation of unsaturated alkenyl- and allenyl-oximes resulting in heterocyclic compounds (oxazoles and oxazines) and cyclic nitrones is one of the best studied and often employed reactions of this type. Thus it was shown^{146, 147} that α,β -unsaturated oximes $\text{HON}=\text{CR}^1-\text{CR}^2=\text{CR}^3\text{H}$ ($\text{R}^1 = \text{R}^3 = \text{Ph}$, $\text{R}^2 = \text{H}$; $\text{R}^1 = \text{Bu}^t$, $\text{R}^2 = \text{H}$, $\text{R}^3 = \text{Ph}$; $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{Me}$, $\text{R}^3 = \text{Pr}^i$) were converted into the corresponding isoxazoles by refluxing in benzene in the presence of equimolar amount of $[\text{PdCl}_2(\text{PPh}_3)_2]$ and a fivefold excess of NaOPh . Presumably,^{146, 147} a Pd σ,π -oxime complex, in which the palladium centre is linked to the nitrogen atom and the ethylene fragment, is formed in the initial stage of the reaction. The electrophilically activated $\text{C}=\text{C}$ bond then undergoes intramolecular nucleophilic attack by the oxygen atom of the oxime moiety resulting in closure of the isoxazole ring.

Depending on the configuration, γ -alkenyl oximes are converted into either 1,2-oxazines **56** or cyclic nitrones **57** in the presence of selenium compounds PhSeX (X = Cl, Br) at room temperature in acetonitrile or dichloromethane.^{148, 149}

The structure of the final products depends on the spatial configuration of the starting oximes. The O-nucleophilic attack on the carbon atom of the C=C bond takes place in the case of *E*-isomers; in the case of *Z*-isomers, N-nucleophilic attack occurs.

Cyclic nitrones are also formed from *Z*-isomers of γ -alkenyl oximes in the presence of mercury(II) acetate in THF at 25 °C¹⁵⁰ as well as from *E*-isomers of δ -unsaturated oximes upon refluxing in THF in the presence of PdCl₂ or [PdCl₂(NCMe)₂].¹⁵¹ Allenic oximes are converted into unsaturated cyclic nitrones in high yields at room temperature in dichloromethane in the presence of Ag⁺.¹⁵²

Various oximes are converted into oxime ethers or cyclic nitrones in the presence of catalytic amounts of the complex [Pd(PPh₃)₄] or a system of reagents Pd(NO₃)₂–PPh₃ (1 : 4) as a result of intermolecular nucleophilic addition (O- or N-) to butadiene.¹⁵³ Presumably,¹⁵³ electrophilic activation of butadiene is a result of formation of a palladium π -allyl intermediate.

The reaction product of coordinated allene in *cis*-[PtCl₂(C₃H₄)(PMe₂Ph)] (**58**) with acetone oxime is the only example known so far of a stable complex obtained upon nucleophilic addition of the oxime to the C=C bond.¹⁵⁴

Allene electrophilically activated by coordination to Pt undergoes intramolecular nucleophilic attack by the nitrogen atom of the O-coordinated oximate ligand, which is accompanied by 1,3 prototropic shift and closure of a five-membered C,O-chelate ring giving rise to complex **59**.

2. Reactions of peripheral groups in oxime- and oximate complexes

Peripheral groups of coordinated ligands may undergo different transformations; such reactions are well known in coordination chemistry. However, there are very few examples of such processes in the chemistry of oxime and oximate complexes. These will be discussed in this Section.

Chlorination of various platinum(II) salicylaldoximate complexes was studied in detail.^{155, 156} Thus chlorination of oxime-oximate complex **60** afforded the complex *trans*-(N,N)-[PtCl₃(3,5-Cl₂-2-OC₆H₂CH=NOH)(3,5-Cl₂-2-HOC₆H₄CH=NOH)] (**61**); its structure was determined by X-ray crystallography.

Other platinum(II) salicylaldoximate complexes, *e.g.*, the bis-chelate complex [Pt(*o*-OC₆H₄CH=NOH)₂]¹⁵⁷ and mixed-ligand complexes *trans*-(S,N)-[PtCl₂(*o*-HOC₆H₄CH=NOH)(Me₂SO)]·H₂O and *trans*-(S,N)-[PtCl(*o*-OC₆H₄CH=NOH)(Me₂SO)]¹⁵⁵ undergo similar transformations upon chlorination. The reactions of these complexes with an excess of Cl₂ are selective: the chlorine atoms in the products occupy *ortho*- and *para*-positions of the benzene ring relative to the OH group. Conversely, the chlorination of non-coordinated salicylaldoxime is non-selective and results in a large number of products.

Chlorination of complex **62** with an excess of Cl₂ in chloroform at room temperature yielded complex **63**. The same reaction in methanol afforded complex **64** in 24% yield.

Chlorination of non-coordinated 1,2-naphthoquinone 1-monoxime under the same conditions resulted in the corresponding methoxylated oxime in less than 3% yield. This suggests that the methoxylation is metal-mediated.¹⁵⁷ The following mechanism of formation of the complex **64** was suggested: oxidation of Pt(II) into Pt(IV), chlorination of the naphthalene fragment and subsequent methoxylation.

Chlorination of the platinum(II) bis-oximate chelate complex [Pt^{II}{C₈H₁₂(=NO)₂H₂}] (**65**) with PhICl₂ in CH₂Cl₂ produces the platinum(III) binuclear complex [Pt^{III}Cl{C₈H₁₂(=NO)₂H₂}]₂, which is converted into [Pt^{IV}Cl₂{C₈H₁₂(=NO)₂H₂}]₂ under the action of an excess of PhICl₂.¹⁵⁹

Oxidation of the platinum(II) *cis*- and *trans*-acetone oxime complexes [PtCl₂(Me₂C=NOH)₂] with excess chlorine in CHCl₃ yields [Pt(IV)Cl₄(Me₂C=NOH)₂].¹⁶⁰ In both cases,^{159, 160} chlorination affects only the platinum site with retention of the oxime and oximate ligands.

Thus, in spite of different chlorination conditions (different solvents and chlorinating agents) and various starting Pt(II) complexes, the oxime fragment was not changed upon chlorination. The metal site serves in all these reactions as a protecting group, which prevents the Piloty reaction¹⁵⁸ (chlorination of 'free' oximes) and/or oxidative deoxygenation (see Section II.4).

Voloshin *et al.*^{161–172} have shown that functionalisation (change of peripheral environment) of clathrochelate complexes with encapsulated metal ions (Fe^{2+} , Co^+ , Co^{2+} , Co^{3+} , Ru^{2+}) follows two principal pathways, *viz.*, incorporation of a substituent (*e.g.*, a chlorine atom) into chelating edge fragments of the cage (edge functionalisation) and substitution in tripod linking fragments. In the case of edge functionalisation of the macrobicyclic cage framework, the substituent and encapsulating metal site have substantial electronic and spatial impacts on each other, which are especially strong in the case of polyenic clathrochelate complexes of transition metals with a conjugated system of π -bonds in the chelating fragments. The presence of a system of σ - and π -bonds provides effective transfer of both inductive and mesomeric effects of functional substituents to the encapsulated metal ion. For instance, the presence of reactive chlorine atoms in molecules of tris-dioximate clathrochelates **66** enables their further functionalisation under mild conditions in the nucleophilic substitution with various H-nucleophiles (NuH) and synthesis of compounds with predetermined properties.

$M = \text{Fe}^{2+}$, Co^+ , Co^{2+} , Co^{3+} , Ru^{2+} ; $M' = \text{B}^{3+}$, Sn^{4+} ;
 $R = \text{Me}$; $A = \text{F}$, Bu^n , Ph ; NuH — O-, S- and N-nucleophiles.

Chemically stable cage structures with pendent substituents, highly biologically active materials,¹⁷³ new liquid-crystalline systems,¹⁷² luminescent labels¹⁷⁴ and selective reagents for sequencing of nucleic acids¹⁶⁸ have been synthesised by this method.

IV. Miscellaneous oxime reactions involving metal complexes

The reactions of oximes that do not comply with the classification used in the previous Sections are discussed in this Section.

Oxidation of platinum(II) oxime complexes *cis*-[PtCl₂·(R¹R²C=NOH)₂] with chlorine in CHCl₃ yields the platinum(IV) coordination compounds *cis*-[PtCl₄(R¹R²C=NOH)₂] (**67**), which are spontaneously converted into platinum(II) chelate derivatives [PtCl₂{N(=O)CR¹R²ON=CR¹R²}] (**68**) on storage in aqueous acetone for 3 h.

$R^1 = R^2 = \text{Me}$; $R^1 - R^2 = (\text{CH}_2)_4, (\text{CH}_2)_5$.

Complexes [PtX₂{N(=O)CR¹R²ON=CR¹R²}] isostructural to the complex **68** were obtained in the reaction of *trans*-[PtX₂(R¹R²C=NOH)₂] [X = Cl, Br; R¹ = R² = Me; R¹ - R² = (CH₂)₄, (CH₂)₅] with *m*-chloroperoxybenzoic acid in DMF at 40 °C.¹⁷⁵ While the formation of the chelate **68** is a result

of intramolecular two-electron redox interaction between Pt(IV) and the nitrogen atom of the oxime ligand, the formation of its isostructural analogue in DMF (see Ref. 175) occurs as an intermolecular oxidation of the nitrogen atom of the coordinated oxime with *m*-chloroperoxybenzoic acid.

Reactions of *O*-trialkylstannyl oximes with alkyl and aryl isocyanates, their thia analogues and aldehydes result in compounds that can formally be regarded as the insertion products into the Sn—O bond.¹⁷⁶

Refluxing of the palladium(II) dimeric bridged oxime complex [Pd(μ-Cl)(CH₂CMe₂CMe=NOH)]₂ (**69**) in acetic anhydride yields complex **70** with an *O*-acylated oxime.¹⁷⁷

A platinum(II) dimeric bridged complex **71**, *viz.*, [Pt(μ-Cl)·{*o*-C₆H₄C(Me)=NOAc}]₂ containing an *O*-acylated oxime fragment was obtained by refluxing [PtCl{*o*-C₆H₄C(Me)=NOH}·(HON=CPhMe)] in acetic anhydride for 1 h.¹⁷⁸

Reactions of nitriles with ketoximes in the presence of salts of 3d metals were studied.^{179–182} Thus nitriles R¹CN are converted into the corresponding amidines at 50 °C in 8 h on treatment with ketoximes R₂C=NOH in the presence of Co(NO₃)₂·6 H₂O in a molar ratio of 4:1. These amidines were isolated as nitrates [R¹C(=NH₂)NH₂](NO₃).¹⁷⁹ In the case of acetonitrile, a stable intermediate [Co(NCMe)₂(H₂O)₄](NO₃)₂ was isolated and structurally characterised. Acetic acid, which is a product of the two-step hydrolysis of the nitrile, was also detected. A suggested¹⁷⁹ reaction mechanism is based on iminoacylation of a nitrile (see Section III.1.a) coordinated to Co(II) followed by intermolecular nucleophilic attack of NH₃ on the imidate carbon atom (a product of two-step hydrolysis of R¹CN) and amidine formation.

$R^1 = \text{Me}$, Et , Pr^n , Bu^n ; $R_2 = \text{Me}_2$, $(\text{CH}_2)_5$.

Catalytic hydrolysis of nitriles into the corresponding carboxamides R¹C(O)NH₂ was performed in the presence of a system ZnX₂ - R₂C=NOH [X = Cl, NO₃, CF₃SO₃; R₂ = Me₂, (CH₂)₄, (CH₂)₅; the molar ratio of the zinc salt to oxime being equal to

1:4].¹⁸⁰ The highest efficiency was achieved in the hydrolysis of *p*-methoxyphenylacetone nitrile in the presence of a system $\text{Zn}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O} - \text{Me}_2\text{C}=\text{NOH}$. In this case, the turnover number of the catalyst was equal to 1000. A zinc(II) oxime complex $[\text{Zn}(\text{NO}_3)_2(\text{Me}_2\text{C}=\text{NOH})_2]$ was the only stable intermediate isolated in the process. Presumably,¹⁸⁰ the formation of an imine complex $[\text{Zn}] - \text{NH}=\text{C}(\text{R}^1)\text{ON}=\text{CR}_2^2$ is the first step of the putative mechanism of the process. Hydrolysis of the imino-ligand into carboxamide in the coordination sphere of zinc and recovery of the catalyst due to hydration of the complex complete the catalytic cycle.

The nickel(II) imidoamidinate complexes $[\text{Ni}\{\text{NH}=\text{C}(\text{R}).\text{NHC}(\text{R})=\text{NH}\}_2]^{2+}$ (see¹⁸¹) were obtained in high yields (65%–91%) by refluxing $\text{NiCl}_2 \cdot 2\text{H}_2\text{O}$ in nitrile solvents in the presence of acetone oxime. As in the two previously described cases (see^{179,180}), the plausible mechanism of the reaction includes the formation of an $[\text{Ni}] - \text{NH}=\text{C}(\text{R})\text{ON}=\text{CMe}_2$ intermediate, which hydrolyses later with elimination of NH_3 . Ammonia formed reacts with another coordinated nitrile to give amidine. Nucleophilic addition of this amidine to the ligand RCN results in nickel imidoamidinate complexes.

A novel efficient method for the synthesis of industrially important symmetrical (**72**) and asymmetrical phthalocyanines and their complexes with Ni(II), Cu(II), Zn(II) and Cd(II) by reactions of substituted phthalocyanines **73** with the corresponding metal chlorides in the presence of an oxime $\text{Me}(\text{R}^2)\text{C}=\text{NOH}$ (Scheme 5, path *a*) was proposed.¹⁸²

Chelate **74** was obtained by refluxing $\text{NiCl}_2 \cdot 2\text{H}_2\text{O}$ in acetone for 24 h in the presence of an oxime and various phthalonitrile derivatives (the molar ratio oxime:phthalonitrile = 2:1). Complex **74** is the nucleophilic addition product of two oxime

molecules to one nitrile group (Scheme 5, path *b*) and this is the first example of such type of metal-mediated reactions of oximes. Nickel phthalocyanines **72** ($\text{M} = \text{Ni}$) can be obtained under 'mild' conditions (refluxing in methanol, 24 h) and in high yields (~60%) when complex **74** is used as a phthalogen (Scheme 5, path *c*).

V. Conclusion

The data discussed in the present review on metal-mediated and metal-catalysed reactions of free and coordinated oximes and their derivatives show that nowadays the development of new methods of organic synthesis and design of new models for the interpretation of mechanisms of catalytic processes are in the focus of attention. Particularly, methods of dehydration and reductive deoxygenation of aldioximes in the presence of metal complexes giving nitriles in high yield have been developed; new reactions of oxidative and reductive deoxygenation resulting in carbonyl compounds have been discovered. The search for efficient catalysts of the Beckmann rearrangement is underway. It appeared that application of various rhenium(VII) derivatives allows smooth conversion of cyclohexanone oxime into industrially important ω -caprolactam. A new catalytic method of hydration of nitriles into amides in the presence of oximes and zinc nitrate as well as simple and inexpensive method of amidine synthesis from oximes and cobalt(II) nitrate in nitrile media were developed. A new efficient method for the synthesis of industrially important symmetrical and asymmetrical metal phthalocyanines by reactions of various phthalonitriles with an excess of oximes in the presence of Ni(II), Cu(II), Zn(II) and Cd(II) chlorides has been found.

Significant attention is still paid to metal-mediated reactions of oximes resulting in new ligand systems: loss of integrity of the $\text{C}=\text{NOH}$ fragment in reactions of reductive deoxygenation of oxime ligands leads to mixed-ligand imine-oxime complexes. New methods of synthesis of nitrile complexes of W, Ru and Os by dehydration of the starting oxime adducts as a result of cleavage of the $\text{N}-\text{O}$ bond of the oxime fragment are developed. Stable nitroso complexes of Mo(VI) and Ru(III) are obtained by hydrolytic and redox processes in aqueous media. Reactions of oxidative addition of oximes to electron-rich sites resulting in imide-oximate or hydride-oximate ligands have been studied. Hydroxo-alkylideneamine ligands, generated by oxidative cleavage of the $\text{N}-\text{O}$ bond, are regarded as the key intermediates of the palladium-catalysed Heck reaction in the synthesis of heterocycles. New types of imino-ligands have been synthesised by nucleophilic addition of oximes to coordinated nitriles. Depending on the character of the metal, either monodentate N-coordinated molecular complexes or N,N-chelate products are formed. Nickel(II) imidoamidinate chelates or phthalocyanines are obtained in oxime–nitrile template transformations in the presence of nickel(II) chloride.

III. Certain analytical applications of multisensor systems of the electronic tongue type	129
IV. Conclusion	131

Abstract. The main types of modern multisensor systems of the electronic tongue type as well as the sensitive materials and sensors (transducers) employed in such systems are considered. The most commonly used analytical applications of the electronic tongue including recognition and classification of various liquid media, quantitative analysis, process monitoring and taste assessment of foodstuffs are discussed. The bibliography includes 84 references.

I. Introduction

A challenge for the development of new analytical methods and instruments consists of the quest for the highest possible selectivity with respect to a given component or components. To meet this goal, a great number of electrochemical (particularly, potentiometric) sensors such as ion-selective electrodes (ISE), ion-selective field transistors (ISFT), *etc.* were developed. The first multisensor systems, as well as many systems of the electronic tongue type proposed to date, are based on the use of ISE or sensors of a similar nature.^{1,2} This is why the way from individual sensors to the electronic tongue is traced in the present review by the example of ISE, although many arguments are equally valid for other types of chemical sensors.³

The first potentiometric chemical sensor, *viz.*, the ion-selective electrode with an oxide glass membrane, was proposed for the determination of the activity of hydrogen ions in aqueous solutions.⁴ Later, a great number of various membrane materials for ISE were developed, *viz.*, oxide glass, single crystals, pressed polycrystalline blends of inorganic active components, liquid and plasticised organic polymeric compositions containing ion-exchange resins or neutral carriers, chalcogenide glass (for the determination of heavy metal ions). The membrane materials were used in both bulk sensors and various thin-film electrodes and microsenors. For the comprehensive description of the existing ISE and sensors of other types, see books and reviews.^{4–9}

Short time of analysis, the possibility of miniaturisation of instruments and automation of the procedure as well as the simplicity and rather low cost of sensors make them an attractive

tool for the analysis of solutions. The use of ISE for these purposes is limited, as a rule, to the cases where the concentrations of interfering ions are low and the electrode response is described by the Nernst equation. In addition, the use of ISE for the analysis of real objects is often hampered due to the insufficient selectivity with respect to the detected ion in the presence of other substances.

The most impressive progress in the field of sensor materials is associated with the synthesis of new organic substances employed as ionophores in polymeric plasticised membranes. However, it is the glass pH-electrode that still possesses the highest selectivity and is most popular, because the use of other sensors based on other detection principles often faces the same problem of insufficient selectivity in multicomponent media, which hinders their analytical application. The development and application of multisensor systems of the electronic tongue type offers a possible way towards the solution of this problem.

II. Multisensor systems

1. The role of biology and chemometrics in the development of multisensor systems

Two fields of knowledge had the greatest effect on the development of multisensor systems. These are, on the one hand, the new achievements in biology, namely, understanding of the structure and operation of the human sensory system, and, on the other hand, the new possibilities and approaches to the processing of multidimensional data that were proposed within the framework of chemometrics.

The development of chemical multisensor systems was largely an attempt to mimic the structure and properties of biological sensory systems, namely, the mammalian olfaction and taste systems.¹⁰ Initially, such an approach was realised in gas analysing systems, *i.e.*, electronic noses; later, similar principles were used for the development of liquid analysers — electronic tongues. In the course of evolution, olfaction became the most efficient sensory system due to the high sensitivity of the human nose with respect to certain substances (one can identify up to 10 thousands of substances in the amount of down to 40 molecules).¹¹ The detection limit of the human nose with respect to certain substances is several ppb, while that of animals' noses may be even lower. Such possibilities of olfaction are attributed to the large number of different types of poorly selective receptors in combination with the specific way the signals from the set of receptors are processed in the peripheral and central nervous systems. The sense of taste is organised in the same way as the olfaction, although the number of taste receptors in humans is smaller.¹¹ Traditionally, the following four basic taste sensations are distinguished: sweet, salty, sour and bitter. Recently, an

additional (fifth) taste characteristic, *viz.*, umami, was introduced, which is determined in particular by sodium glutamate and isocyanate.¹² Five major taste characteristics and their combinations are used to describe and quantitatively assess the taste of foodstuffs by additionally invoking such characteristics as taste sharpness, food texture, mouthfeel, taste duration, *etc.*

At present, the relationship between the structure (and chemical properties) of many substances and their taste is insufficiently studied, as well as many other interesting effects, *e.g.*, the interaction of substances with different taste kinds or the increase in the sensitivity limit (desensitising) due to the synergistic effect of substances with different taste kinds.¹¹ The detection limit is usually higher for tastes as compared with scents, with one exception of alkaloids (for instance, quinine). However, the differential sensitivity of biological sensory systems of tasting and smelling is comparable. Thus, the mechanisms of operation of the taste and olfaction sensory systems are similar, although olfaction is a more sophisticated sense in animate nature (for example, for mammals and people).

The potentials of biological sensory systems based on a great number of nonspecific receptors led to the idea of using their structural principles in the development of artificial sensory systems. The latter were initially intended for the analysis of gases and identification of scents.

The development of electronic noses, *i.e.*, multisensor systems for the gas analysis, was initiated by the studies by Moncrieff¹³ and Persaud and Dodd;¹⁴ later, different research teams all over the world made their contribution to the solution of this problem.¹⁰ A typical electronic nose consists of a set (array) of non-selective sensors (most often, semiconducting sensors based on tin dioxide with different additives) and a system for processing multivariate data (for instance, on the basis of artificial neural networks). Electronic noses are applied for the identification of various gas mixtures and/or individual gases (for example, in leakage of chemicals).

The same organisational principles (arrays of low-selective sensors and multidimensional methods of data processing) were used in the development of multisensor systems for the analysis of liquids, the so-called electronic tongues. Like its biological prototype, the electronic tongue operates in various liquid media. However, the sensitivity and detection limits of artificial 'tongues' may substantially surpass the parameters of biological prototypes, because the materials of these sensors are capable of far extending the analytical potential of the system.

A common typical feature of electronic noses and tongues consists of combining the arrays of low-selective sensors with the data processing that employs pattern recognition methods. However, the sensor materials used in noses and tongues have virtually nothing in common, the sensors used in tongues being more plentiful both in the number and type. This offers certain advantages, for example, the electronic tongues are used not only for recognition and identification but also for the multicomponent quantitative analysis. In contrast to its biological prototype, the electronic tongue can be employed in the measurements in any media including hazardous and even lethal for living organisms.

What is important is that despite the similar organisational principles one cannot draw parallels between the potentials of artificial and biological systems and must take into account the significant differences between the sensors used for electronic tongues and noses, which leads to different approaches to the development of new sensors and the methods of their application. In the present review, we consider the studies devoted to multisensor systems for the analysis of liquids, *viz.*, electronic tongues. The majority of such systems were developed on the basis of potentiometric sensors.

As was mentioned above, most ISE (and also most of sensors based on different principles) exhibit low selectivities in multicomponent solutions. In the case of ISE, the effect of interfering

ions on the electrode response is conventionally described by the Nikolsky equation (or similar equations)

$$E = E^\circ + \frac{RT}{z_i F} \ln \left(a_i + \sum_j K_{ij} (a_j)^{z_i/z_j} \right), \quad (1)$$

where E is the potential difference (emf) of the electrochemical cell that consists of a reference electrode and ISE; E° is the standard potential; R is the gas constant; T is the absolute temperature; F is the Faraday constant; z_i and z_j are the charges of the primary and interfering ions, respectively, a_i and a_j are the activities of the primary and interfering ions, respectively; K_{ij} is the coefficient of selectivity of ISE with respect to the primary ion i in the presence of an interfering ion j .

Thus, the response of a low-selective electrode is determined by the concentrations of the primary ion and the interfering ion (or ions). If two terms in parentheses in Eqn (1) are comparable, the electrode response becomes non-linear. A non-linear calibration curve, as long as it is reproducible, can also be used for analytical purposes; however, more than one electrode should be used for the determination of parameters in Eqn (1). Apparently, the number of electrodes should not be smaller than the number of ions to be determined. Within the framework of such an approach, it was proposed to use ISE arrays rather than separate sensors to overcome the insufficient selectivity of ISE in the presence of interfering ions. It was assumed that the response of each electrode in multicomponent solutions is described by the Nikolsky equation. Solving the system of such equations allows certain parameters of the electrode response in multicomponent solutions to be determined, namely, the standard potential, the selectivity coefficients and/or the slope. The mentioned parameters can further be used for the determination of concentrations of ions in solutions of unknown composition. It is well known that many parameters of the ISE response (for instance, the detection limit or the selectivity coefficient) depend on the conditions and methods of their determination. Numerous attempts to develop standard methods for their determination failed. Thus, the fact that all parameters of sensors are determined directly in multicomponent solutions with compositions close to those of analysed solutions pertains to advantages of the approach described above, in addition to the possibility of taking into account the effect of interfering ions. The calculated parameters of the response are more adequate than the theoretical parameters and make it possible to enhance the accuracy of the analysis, even being far from versatile. Various mathematical methods were proposed for solving the system of the Nikolsky equations, including different versions of regressions (Multi Linear Regression, Non-linear Regression, Partial Least Squares) and artificial neural networks.^{15–23}

The next step involved abandoning the Nikolsky equation in favour of the methods that do not require any *a priori* information on the functional dependences between the potentials of sensors and the activities (concentrations) of determined substances. Thus, a new direction in the application of chemical sensors, which substantially differs from the use of conventional ion-selective electrodes and is known as the 'electronic tongue', was developed.

The electronic tongue is an analytical instrument that comprises a set (array) of chemical sensors of relatively low selectivity, being simultaneously sensitive to several components in the analysed solution (cross-sensitivity), and employs a suitable method for the processing of multidimensional data from the array of sensors (*e.g.*, the methods of pattern recognition and multivariate calibration). A system that uses sensors with reproducible analytic response and employs, if necessary, an adequate calibration procedure (calibration as such, training) is capable of the recognition (identification, classification) of various liquid media and the multicomponent quantitative analysis of inorganic and organic constituents.

2. Requirements to sensors for electronic tongue-type systems

It is evident that the array of sensors forms the key part of the electronic tongue. Sensors with relatively low selectivity or cross-sensitivity rather than highly selective sensors are most promising candidates for these systems.^{18–20} Reproducibility of their characteristics is the necessary condition. Thus, an electronic tongue requires sensors with reproducible analytical characteristics and high cross-sensitivity. Although the term ‘cross-sensitivity’ is generally accepted for describing the properties of sensors in the literature devoted to multisensor systems, to date we have no its unambiguous definition. Quite a number of terms to describe the same phenomenon are used as synonyms (*e.g.*, non-selectivity, cross-reactivity, low selectivity, partial selectivity and even global selectivity). Hereinafter, we will use the term ‘cross-sensitivity’.

At present, there is no generally accepted method for the assessment of cross-sensitivity. The use of the selectivity coefficient [Eqn (1)] or its reciprocal value seems to be a poor choice, because it contains no information on the sensitivity itself and its value strongly depends on the determination procedure (there is no standard method). When determining the selectivity coefficient, it is assumed that the response of a sensor to both primary and interfering ions corresponds to the theoretically calculated value, which is rarely the case. Moreover, the selectivity coefficient is by definition a value that characterises a binary system (which consists of one primary and one interfering ion), whereas for the case of a complex solution that contains several interfering ions, the question of the primary ion remains open and the selectivity coefficient value is far from real.

The authors of this review have put forward²⁴ an empirical method for assessing the cross-sensitivity. For this purpose, the following three parameters were used: the average slope, the reproducibility factor and the non-selectivity factor, which describe the sensitivity and reproducibility of a sensor's response and also its selectivity with respect to the studied ions. These parameters were originally determined for sensors with chalcogenide glass membranes with respect to a group of transition metal cations.²⁴ Later, the proposed approach was applied for assessing the cross-sensitivity of other sensor materials (*e.g.*, polymeric) with respect to other groups of ions.²⁵

The calculation of the parameters mentioned above involves the use of experimental data obtained in calibration measurements in a solution of a selected set of substances (ions) using the previously determined sensor materials the cross-sensitivity of which is to be studied. Even the most ‘non-selective’ sensor materials are sensitive only to a certain group of substances rather than to all ions in the solution.

The first and most important parameter of the cross-sensitivity is the average slope (S), which is determined in individual solutions of a selected set of substances as follows:

$$S = \frac{1}{n} \sum_i S_i,$$

where S_i is the slope of the sensor electrode response in calibration solutions that contain individual substances, with respect to which the cross-sensitivity of the sensor is studied, n is the number of substances studied. Thus, this parameter represents the averaged sensitivity of a sensor material toward a certain group of substances (ions).

The second parameter is the stability factor (K), which represents the signal-to-noise ratio for the sensor material averaged over all studied substances

$$K = \frac{1}{n} \sum_i K_i = \frac{1}{n} \sum_i \frac{S_i}{s_i^2},$$

where S_i is the slope of the sensor electrode response in solutions of chosen substances, s_i is the standard deviation of the electrode response in solutions of chosen substances. Apparently, the standard deviation is calculated in parallel measurements and characterises the reproducibility of the electrode characteristics of the sensor material in the solutions under study.

The third parameter, *viz.*, the non-selectivity factor (F), characterises the uniformity of the distribution of sensitivity of a sensor material with respect to the set of substances chosen for studies

$$F = \frac{S}{s^2},$$

where S is the average slope, s is the standard deviation of the average slope, which is calculated based on the slopes of the electrode response in solutions of individual substances.

The larger is the average slope, the higher is sensitivity of a sensor to the studied set of substances. The optimum value of this parameter is estimated in each particular case. Assume that the cross-sensitivity of a sensor material with respect to a set of doubly charged ions is considered. In this case, the electrode response slope is most likely to vary from 0 (the absence of sensitivity) to 29 mV (pX)^{−1} (a response corresponding to the Nernst equation). Thus, the average slope close to 29 mV (pX)^{−1} suggests the equally high sensitivity with respect to all ions under study. In practice, the same sensitivity with respect to a wide set of ions is virtually unknown. Therefore, it can be assumed that sensor materials with an average slope > 25 mV (pX)^{−1} exhibit high cross-sensitivity and may be included into the multisensor system for determination of this set of ions. However, in certain cases the average slope of a material sensitive with respect to a set of doubly charged ions can exceed 30 mV (pX)^{−1}, which is associated with the supersensitivity with respect to one or several ions. In this situation, to assess whether the sensor has cross-sensitivity, one has to consider the non-selectivity factor, which describes the uniformity of distribution of sensitivity over ions. A factor of non-selectivity below 0.1 is typical of highly selective sensors that exhibit high sensitivity to only one primary ion. The factor equal to 0.1 points to the sensitivity with respect to several ions among those studied. For the materials with relatively uniform sensitivity with respect to all ions, this value should exceed unity. As a rule, it is assumed that the non-selectivity factor of 0.5 and higher suggests the presence of cross-sensitivity of a given sensor material with respect to the studied set of ions. It is evident that both parameters, the average slope and the non-selectivity factor, should be taken into account in practice. Thus a sensor that exhibits equally low sensitivity with respect to all studied ions will have a high factor of non-selectivity but a low average slope.

The stability factor is used for assessing the reproducibility of electrode characteristics of sensor materials. Although it is measured in solutions of individual substances, it is evident that the reproducibility of electrode characteristics of sensor materials in these solutions correlates with their reproducibility in mixed solutions containing these substances. The higher the stability factor the higher the reproducibility. It is shown that sensors with the stability factor ≥ 2 can be used in a multisensor system.^{24, 25}

This set of parameters is representative and suitable, although other sets exist.

Summarising, it is essential to note that within the framework of the proposed approach no *a priori* assumptions are drawn on the mechanism of the response of sensors; therefore, this approach can be applied for assessing the cross-sensitivity of not only potentiometric sensors but also chemical sensors of other types.

3. Sensors used in the electronic tongue systems

Systems of the electronic tongue type can comprise any chemical sensors for analysing liquids regardless of what physical principle they are based on.

The ‘taste sensor’ was the first multisensor system analogous to the electronic tongue.²⁶ It included eight potentiometric sensors with the so-called lipid membranes^{2, 27, 28} that exhibited cross-sensitivity with respect to substances of different tastes. The membranes had a polymeric (PVC) matrix. Thin-film sensors were also manufactured, with the aim of miniaturisation, by applying Langmuir–Blodgett films on semiconducting supports, based on the same sensor materials but using a different principle

of signal detection. Different authors used field effect transistors,²⁹ light-addressable potentiometric sensors (LAPS) and sensors based on the method of surface photovoltage (SPV)^{30,31} as the sensitive elements (transducers).

An electronic tongue based on arrays of various potentiometric sensors including inorganic membranes was developed;³² its measuring circuit and photograph are shown in Figs 1 and 2. It is the authors of this study who, together with their Italian colleagues from the University Tor Vergata (Rome), were the first to propose the term 'electronic tongue' as applied to cross-sensitive sensors in combination with the data processing based on pattern recognition methods.³³ The sensors were fabricated using a wide assortment of membrane materials, which included chalcogenide glass doped with different metals, plasticised polymers containing various active substances and also polycrystalline compositions.^{1,24,25,32} Several hundred different sensors were studied, from which the compositions with the highest cross-sensitivity were selected. As a rule, an electronic tongue comprises from 5 to 30 sensors depending on the analytical problem. Microsensors based on thin nanofilms of chalcogenide glasses were prepared using pulsed laser deposition (PLD).³⁴ The composition and properties of the film materials and systems differed little from those of the parent chalcogenide glasses.

A flow-injection version of the electronic tongue system with multisensor detection was developed, which included from 3 to 11 sensors.³⁵ The possibility of performing repeated measurements including those in the automatic mode (due to the multichannel actuator) and the small sample volume (as a rule, 150–500 μL , which can be decreased to 50 μL) are among the advantages of flow-injection multisensor systems.

It was proposed to use electronic tongues built of potentiometric sensors the preparation of which involved the application of metalloporphyrins with different central atoms [Mn(III), Fe(III), Co(II), Ni(II)], and also tetraphenylporphyrin onto glassy

carbon supports by means of the electropolymerisation technique.³⁶ An electronic tongue based on already existing and commercially available ISE was produced.^{37,38}

The measurements using arrays of potentiometric sensors are by and large similar to those using individual ISE. In both cases, the emf of electrochemical cells formed by sensors of the array taken in turn and the reference electrode is measured. In these measurements, multichannel voltmeters with high input impedance ($\geq 10^{12} \Omega$) are used. As a rule, a computer controls the measurements and data recording.

In addition to potentiometry, it was proposed to use voltammetry in multisensor systems,^{3,39–41} which is also based on a similar combination of measurements of non-specific electrochemical signals and their processing by pattern recognition methods. The polarographic wave becomes a non-selective analytical signal in those cases where several solution components are oxidised at the same or similar potentials. To resolve such a signal and retrieve certain analytical information, one has to use several working electrodes rather than one electrode, as in the classical scheme. Noble metals (platinum, gold, iridium, rhodium, rhenium) are used as the working electrodes.

A multisensor system based on electrodes modified with monophthalocyanine complexes of cobalt and copper, bis(phthalocyanine) complexes of europium, gadolinium, and lutetium and octakis(*tert*-butyl)-substituted bis(phthalocyanine) complex of praseodymium is described.⁴² The modified electrodes were prepared either by applying Langmuir–Blodgett films on glass supports or with the use of the graphite paste electrode technology (by mixing 15 vol.% phthalocyanine with a graphite paste). Measurements with such voltammetric multisensor systems are carried out using a classical three-electrode circuit, which contains a reference electrode, a steel counter electrode, an array of working electrodes and a commutator for switching from one electrode to another. Large amplitude pulse voltammetry (LAPV) was chosen for the measurements with an array of electrodes made of noble metals. The potential was scanned in the range from -0.4 to $+0.6$ V with 100-mV steps.³ Cyclic voltammetry with a scanning rate of 0.1 V s^{-1} was used⁴² in the measurements with an array of modified electrodes.

An electronic tongue design was proposed that mimicked the biological prototype despite being based on optical sensors.⁴³ Sensors that mimicked taste receptors consisted of grains of poly(ethylene glycol)–polystyrene resin (PEG-PS) with various indicator molecules. The latter represented fluorescein, *o*-cresolphthalein complexone, alizarin complexone and resorufin-substituted galactoside boronate. The response of sensors was measured with respect to a control sensor, which represented a grain of a resin with acetylated terminal amino groups. The grains were located in microcavities fabricated by the micromachining technology in silicon/silicon nitride plates, which mimicked the arrangement of taste buds on the tongue. The changes in the light absorption by the grains in different solutions were detected using CCD (Charge-coupled Devices). The study was aimed at merely demonstrating the possibilities; therefore, the analytical applications of this tongue are yet unknown.

Different conducting polymers such as polyaniline, polypyrrole, stearic acid and their mixtures are used in the preparation of sensors for electronic tongues.^{44,45} Langmuir–Blodgett polymeric films are applied on metal supports. Measurements are carried out using the method of impedance spectroscopy at room temperature (20 ± 3) °C in a frequency range from 20 to 10^5 Hz. The use of impedance spectroscopy is based on the fact that the low frequency range of such a spectrum describes the properties of the electrical double layer formed as a result of adsorption of substances from the analysed solution on the surface of a sensor.

Obviously, the possible sensor materials and detection methods are not limited to the versions mentioned above, and one can expect the appearance of reports on the use of other types of sensors.

Figure 1. The measuring circuit of an electronic tongue based on potentiometric chemical sensors.³²

Figure 2. A photograph of a laboratory prototype of the electronic tongue based of potentiometric chemical sensors.³²

4. Data processing

Although chemical sensors form the most important part of the multisensor system, the adequate methods of data processing also play an important role. The response of a cross-sensitive sensor in a multicomponent solution is complex and contains information on different components present in the medium. To gain this information, it is necessary to analyse the overall response of all sensors in the system. Under these conditions, the correct choice of the method of data processing and its application are of great importance. Different approaches including the methods of pattern recognition and multivariate calibration are used.

The choice of a particular method for the data processing depends on both the analytical problem and the parameters of sensitivity of sensors, *i.e.*, the non-linearity of the response, the degree of correlation between the responses of different sensors in the array, *etc.* The following three main problems are known in the data processing: the studies on the data structure and recognition; the classification and identification; the quantitative analysis (determination of concentrations of substances or other quantitative parameters).

The first stage of data processing always involves the data recognition and the studies on their structure, which allows one to initially assess the reproducibility and detect outliers, to visually study the data structure, detect data clusters, *etc.* For these purposes, the methods of unsupervised learning such as the principal component analysis and certain kinds of artificial neural networks are used.

The problems of classification and quantitative analysis are solved, as a rule, by the methods of supervised learning. For classification, such methods as (Soft Independent Modeling of Class Analogy) SIMCA, linear discrimination analysis, multi-dimensional regressions and artificial neural networks are used. In those cases where *a priori* information on the studied samples is absent, the classification can be accomplished by the methods of unsupervised learning. To obtain calibration curves for the determination of concentrations of solution components, multivariate calibrations are used, the most popular of which involve principal components regression and partial least squares as well as artificial neural networks. The detailed descriptions of the main methods of chemometrics, which are used to process the results of measurements with multisensor systems, are available in the literature.^{46–48}

5. Advantages of sensor systems over individual sensors

Even the first studies devoted to the use of sensor arrays have demonstrated that the use of chemometrics for processing the response of sensors makes it possible to compensate to a certain extent the insufficient selectivity of ISE and quantitatively determine the activities of ions in multicomponent solutions. Subsequent experimental data implied that sensors with moderate selectivities or cross-sensitivities should be preferred for constructing the arrays.¹⁹ Such arrays allow one to carry out quantitative measurements with smaller errors as compared with arrays including only highly selective sensors. Thus, there appears a possibility for extending the range of analysable substances or solution components.

In addition to the compensation of insufficient selectivity of sensors, the arrays of sensors with cross-sensitivity in relatively simple solutions make it possible to reduce the detection limit (with respect to concentration) by an order of magnitude.⁴⁹ In solutions of complex composition, this effect can even be more pronounced.

Yet another practically important feature of arrays of sensors is the possibility of carrying out potentiometric measurements without recourse to the reference electrode. In this case, the potential differences between all the pairs of sensors in the array are measured.⁵⁰ Evidently, some of potential differences obtained in this way will be excessive and should be rejected in the course of data processing. The analytical characteristics of the electronic

tongue are shown to be independent of the reference electrode during the measurements.

The capability of systems of the electronic tongue type to recognise and identify multicomponent solutions in almost the same way as people do is very promising. In the literature, this is usually referred to as the fingerprint technique. Such an analysis is totally untypical of not only ion-selective electrodes but also all other conventional analytical methods. As a result, a multisensor system may produce an integral estimate, a chemical pattern of the analysed liquid, *i.e.*, its 'fingerprint'. This pattern either coincides or differs for different analysed liquids. This allows a conclusion to be drawn on their identity or difference. What is most unusual is that the electronic tongue can recognise liquids of unknown composition without any preliminary information on the qualitative or quantitative composition of samples. Apparently, the classification and identification by means of an electronic tongue require preliminary calibration of the instrument with respect to a series of known samples. This is a new and promising approach to the analysis of the quality of many foodstuffs and determination of its compliance with a chosen quality standard.

The ability of multisensor systems to recognise and quantitatively assess tastes is their most unusual property, which is the reason for their title 'electronic tongue'. The system is calibrated (trained) over a series of standard solutions or food samples, which have been characterised by professional tasters as regards the taste type and intensity. If a system can detect the key substances and the features that determine the taste, then, after such a training, the electronic tongue acquires the capability to analyse unknown food samples, producing the type and intensity of their taste as the result. The demand for the determination of taste by means of an analytical tool is the highest in the food and drug industries, which probably represents one of the most interesting practical applications of electronic tongues in future.

III. Certain analytical applications of multisensor systems of the electronic tongue type

To date, a great number of studies devoted to various applications of the electronic tongue multisensor systems are documented.^{1,32,51} Many of them describe how to recognise different foodstuffs, determine the quality of one and the same foodstuff, confirm their correspondence to the quality standard and their authenticity and reveal counterfeit products. Currently, great attention is paid to the use of electronic tongues for monitoring industrial processes and the quality control, which involves the determination of concentrations of key components and the assessment of the correspondence of the overall quality of a process or a foodstuff to the standard. The taste of foodstuffs is assessed. For calibration of the system, the taste estimates made by professional tasters are used.

Electronic tongues are used most often in the analysis of foodstuffs. The performance of systems for the analysis of fruit juices,^{3,31,52,53} mineral water,^{54–56} soft drinks,⁵⁶ coffee,^{56,57} tea,^{58–60} milk and dairy products,^{3,39,61,62} wine,^{55,63,64} miso (Japanese soy paste),⁶⁵ sake,^{66,67} vegetable oils,⁶⁸ fruit,⁶⁹ vegetables,⁷⁰ meat,⁷¹ fish⁵⁶ is described. As a rule, the electronic tongue was used for recognition and classification of listed foodstuffs, less often, for their quantitative analysis. For instance, the use of the electronic tongue for recognition of different coffee brands was described.⁵⁶ Figure 3 shows the results of recognition for eight individual brands of coffee and three commercial mixtures. Data were processed by the Principal Component Analysis (PCA). As is seen, all the samples differ from one another except for samples 2 and 6, which represent one and the same coffee sample. This sample strongly differs from the rest samples in both the results of the analysis using the electronic tongue and its taste and scent.

The response of an electronic tongue towards the dilution of fruit juice with water or sugar solution was studied.⁵⁴ This problem was topical due to the appearance of faked foodstuffs obtained by excessive dilution of fruit juices with water, sugar

Figure 3. Results of measurements with an electronic tongue for eight individual brands of coffee (samples 1–8) and three commercial mixtures (sample 9–11). Data were processed using the principal component analysis.⁵⁶ PC1 and PC2 are the first and the second principal components.

solution, or similar solutions. Figure 4 shows the results of measurements with a multisensor system for two samples of orange juice (freshly squeezed and prepared from a concentrate). The data were processed using the principal component analysis technique. The points in the upper part of the plot correspond to pure juice, those in the bottom part correspond to diluted juice. It was found that the multisensor system allows determination of just 1% water added to orange juice.

The use of the electronic tongue for the determination of concentrations of inorganic cations and anions, organic acid anions, amino acids, polyphenols, and also such parameters as the total and titratable acidity^{55, 56, 64} and the number of bacteria in spoilt milk³⁹ is described. The electronic tongue can be used for the monitoring and determination of concentrations of key components in biotechnological processes for the synthesis of such substances as enzymes used in the production of cheese,⁷² miso⁶⁵ and sake.⁶⁷ To evaluate this method in assessing the taste, solutions of substances with typical tastes were tested both separately and in mixtures with different foodstuffs and drugs. As a rule, several parameters were assessed in the taste, which were important for a given foodstuff, for example, the flavour, acidity,

Figure 4. Monitoring of the dilution of orange juice with water carried out using a multisensor system.

The results of measurements with the electronic tongue for two orange juice samples: prepared from concentrate (juice A) and freshly squeezed (natural). Data were processed by the principal component analysis.⁵³ PC1 and PC2 are the first and the second principal components. Open circles represent projections of the experimental points on a plane.

and texture of coffee,⁵⁶ the taste richness and the baked-milk flavour in milk,⁶² 'dietness' (the difference between regular and light versions of beverages) of Pepsi-Cola,⁵⁶ *etc.* The main problem in the assessment of the taste of drugs was to measure the bitterness intensity in active substances and effectively mask it by different sweeteners and flavourings.^{73–75} An electronic tongue (e.t.) based on potentiometric chemical sensors was used for the determination of taste characteristics of eight brands of coffee (Table 1).⁵⁶ The calibration was carried out using organoleptic estimates of the flavour and scent of coffee, which were made by professional tasters and provided by the manufacturing company. Four parameters were assessed on a ten-point scale. The calibration model was calculated using a neural network with back propagation of errors. A part of samples were used for calibration, the other samples were used in the tests. Table 1 shows the organoleptic estimates made by tasters and the values obtained by applying the calibration model to the control samples. All the cases demonstrate good agreement. The possibility of drawing correlations between the response of an analytical tool and human perception can be of great practical importance.

Table 1. Organoleptic tests of coffee made by tasters and calculated by applying the calibration model to the test samples.

Parameter	Method of estimate	Sample			
		5	6	7	8
Flavour	e.t.	4.8±0.2	7.8±0.1	3.1±0.3	4.1±0.4
	tasters	3–7	7–9	1–2	2–4
Acidity	e.t.	4.8±0.1	3.6±0.3	5.7±0.3	5.4±0.3
	tasters	5–8	2–5	5–8	5–8
Body	e.t.	7.0±0.1	8.5±0.01	8.4±0.1	6.0±0.1
	tasters	5–9	8–9	8–9	5–7
Smell	e.t.	5.3±0.2	8.4±0.01	3.8±0.3	4.7±0.3
	tasters	4–7	8–9	2–3	3–5

The application field of the electronic tongue is not limited to foodstuffs. Multisensor systems were used for the monitoring and determination of the principal components in the growth media used for growing microorganisms,⁷⁶ for recognition of various growth media,⁷⁷ for monitoring of cleaning of drinking water,⁷⁸ for determination of the contents of inorganic anions and transition-metal cations in model ground, mine and sea water,^{24, 25, 79–83} and also in the smoke from incineration plants (after the absorption of smoke by a liquid);³⁵ for the quantitative analysis of the dialysis solutions used in the devices such as 'artificial kidney',⁸⁴ *etc.* The use of electronic tongues for simultaneous determination of iron and uranium in different oxidation states in model mine water is described.^{81, 82} The need for such tests is associated with the control over the composition of water in deserted uranium mines in order to undertake timely measures on the radiation safety. Uranium in different oxidation states exhibits different solubility and, hence, the different ability to migrate under natural conditions. This is why the determination of the contents of uranium(VI) and uranium(IV) and also of iron(II) and iron(III), which accompany uranium, is among the most important problems in the analysis of mine water. Table 2 shows the results obtained by means of an electronic tongue. The possibility of simultaneous determination of the contents of iron and uranium in different oxidation states was also demonstrated.

The idea of simultaneously using liquid and gas sensors for the analysis of foodstuffs was born in analogy to the fact that people simultaneously assess tastes and smells. The sensitivity and selectivity of sensors used in electronic noses and tongues substantially differ from the characteristics of biological receptors; therefore, the role of artificial sensory systems and their contribu-

Table 2. Results of determination of the contents of iron and uranium in different oxidation states in solutions that model mine water (the results shown correspond to test solutions only).

The form of the element	Found /mol litre ⁻¹	Added /mol litre ⁻¹	Standard deviation

	5.0×10^{-5}	5×10^{-5}	2×10^{-5}

tions to the final result can differ from those of their natural prototypes. Nonetheless, the hybrid systems 'electronic nose + electronic tongue' were used in recognition of wines,⁶³ fruit juices,⁴¹ milk and even urine samples.⁶¹ The idea of using hybrid systems looks interesting, although to date it demonstrated no real advantages over the use of electronic tongue alone.

IV. Conclusion

Multisensor systems of the electronic tongue type represent a rapidly developing and promising interdisciplinary scientific field. At present, there is a possibility of using such systems for the quantitative analysis, quality control, recognition and classification in the food and pharmaceutical industries, medicine and also for environmental control. The existence of a correlation between the response of an electronic tongue and the human perception of taste is both unusual and promising from the viewpoint of practice. Today, the first commercial systems of the electronic tongue type are available.

Unfortunately, the knowledge in this young scientific direction is still largely empiric. The use of only limited number of sensor materials is a significant drawback of multisensor systems. In many cases, only a single type of sensors is used. For example, in certain studies only metalloporphyrins³⁶ or phthalocyanine complexes⁴² or some other substances are used as the active components of sensor membranes. Naturally, the differences in the electrode characteristics of sensors containing homologues as the active substances are not great, and, in effect, such a multisensor system can be used for determination of only a limited group of substances and shows no serious promise for its extending. Consequently, the development of new sensor compositions and materials gains in importance. It is also necessary to extend

the range of substances detectable by electronic tongues. For example, there are numerous problems on the determination of organic substances in mixtures. Without solving these problems, the extension of the application fields of this method and its further development are impossible.

Insufficient attention is also paid to studying the mechanism of the response of sensor materials used in multisensor systems. As a rule, the studies devoted to sensors are descriptive and empirical. The in-depth, more fundamental knowledge of the mechanism of the sensor response is the second prerequisite for the development of new compositions and the extension of the range of detectable substances.

An important task yet insufficiently reflected in the literature is the development of the objective criteria of the formation of a multisensor system to solve a given analytical problem. In particular, no methods exist which would allow one to *a priori* determine how many sensors and what sensor characteristics are required for the analysis of a given mixture of substances. At present, two major approaches to the formation of multisensor systems are distinguished. It is possible to take a redundant set of sensors sensitive to the analysed substances and then, in the stage of data processing, select those sensors that provide the greatest body of information, *i.e.*, exhibit the highest sensitivity with respect to the analytes and good reproducibility. Here, the requirement for the wide initial set of sensors is the key problem. Another approach consists of the use of a standard set of sensors. The weight of information provided by them is also assessed in the stage of data processing. It is evident that this approach is not always the optimum one.

Insofar as the electronic tongue represents an analytical tool, a question arises on its complex application. Despite the appearance of the first commercial instruments, most analytical results obtained with the electronic-tongue multisensor systems merely demonstrate their potentials rather than their practical analytical applications. There is the demand for the thorough development of the methodical grounds, in particular, aimed at providing the reproducibility of the responses of sensors, on the methods of calibration, conditioning and washing of sensors, *etc.*

Summarising, note once again that serious efforts should be undertaken in the studies of the mechanism of the sensor response to different analysed substances, in the development of new sensor compositions and also in the elaboration of methods for practical application of electronic tongues to solving particular problems. It is probable that rapid progress will be observed in this field in the near future.

VII. Conclusion	142

Abstract. The published data on the degradation of natural and synthetic polymers in the environment are analysed. The use of polymer degradation in the most advanced biomedical technologies is considered. The bibliography includes 221 references.

I. Introduction

Degradation of polymers is a global process occurring in the biosphere of the Earth, which has an enormous impact on its formation and human activity. In nature, polymer degradation determines the material balance in the biosphere. It was estimated¹ that at least 10^{15} kg of cellulose, the most abundant plant polymer, is produced on Earth annually by photosynthesis. Multiple catabolic–anabolic conversions of cellulose yield a variety of other products. As a result, the major part of the cellulose formed undergoes degradation with the formation of low-molecular-mass (predominantly, gaseous) products, while the other part is stored in the uppermost layers of the Earth's crust where it makes the major contribution to the formation of the topsoil or undergoes partial mineralisation.

Considering the role of polymeric materials in the development of material and spiritual culture of Mankind, it may be conjectured that polymer degradation is a critical factor in this process. Polymeric materials constitute the basis of clothing, building, shipbuilding and, which is even more important, of recording, reproduction and storage of information (paper and book- printing, cine- and magnetic films, *etc.*). However, the degradation of polymeric articles that are vitally important for human life reduces critically their service lives. Therefore, since ancient times the Man considered polymer degradation as an inevitable evil and did his best to prevent or retard this process without even getting an insight into its physical meaning. It is not therefore surprising that degradation and stabilisation of polymers were among the first subjects of investigation in polymer chemistry. However, the discoveries made in the past few decades

enabled the utilisation of degradation processes in modern technologies.

The ecological equilibrium formed over the course of millenia was disturbed drastically in the past century as a result of anthropogenic activity, particularly due to conversions of natural substances (mineral oil, gas, carbon) into novel, non-natural materials, such as Teflon, polystyrene, polypropylene, *etc.* No efficient mechanisms of the degradation of these polymers exist in nature, therefore their stock on the Earth is steadily increasing, which threatens severe, hardly predictable changes in the environment. The ever increasing output of synthetic polymeric materials is a challenge to Mankind as regards the maintenance of the global equilibrium (sustainable development).

This review surveys the papers devoted to studies on the degradation of natural and synthetic polymers in the environment as well as the use of this process in modern technologies.

II. General concepts of polymer degradation

Deterioration of polymeric materials occurs much faster than that of other substances (metals, minerals, *etc.*) resulting in the loss of their strengths and elasticities up to spontaneous decomposition of polymeric articles even in the absence of external forces. Degradation of the constituent polymers is the reason for such behaviour of polymeric materials.

Degradation of polymers, *i.e.*, cleavage of chemical bonds in the main chain of a macromolecule, is usually classified according to two parameters, *viz.*, the mechanism of chain degradation and the type of energy that brings about the degradation. The former involves chain reactions (depolymerisation) where monomeric molecules are eliminated successively from the reactive site of the macromolecule under the action of energetic factors. An alternative mechanism consists of random degradation where those chemical bonds are cleaved under the action of energy factors, which experience the maximum strain by virtue of fluctuation.²

Virtually all energy types cause degradation of polymers. This can be induced by thermal, radiation-chemical (photochemical), chemical (hydrolysis, ammonolysis, oxidation), mechanochemical, *etc.*, factors. In most cases, the degradation is induced simultaneously by several factors and the contribution of each of them cannot always be established. One of the most common types of polymer degradation, *viz.*, biodegradation, occurs in polymers under the action of different enzymes. In a broad sense, biodegradation implies the destruction occurring under the influence of environmental factors, such as water, soil, bio-

logical fluids, *etc.* Many synthetic polymers, especially carbochain polymers, *i.e.*, those built exclusively of carbon atoms in the main chain, are not subject to biodegradation and remain in the environment over the course of years. In contrast, biopolymers (natural polymers and their synthetic analogues) undergo biodegradation being converted into low-molecular-mass compounds.

The degradation rate is an essential feature of the process. However, its true rate constant can seldom be established and this can be done only under model, strictly specific conditions. In real situations with numerous factors influencing the degradation, the rate of the overall process has to be determined by indirect methods.

The most popular methods for the estimation of the degradation rate are as follows:²

(1) Estimation of changes in masses and linear sizes of samples. This approach is used for determining the degree and rate of degradation by measuring the reduction of the mass per unit time. If the surface area is known, the reduction of the mass per unit area per unit time can easily be calculated and the corresponding rate constants can be determined. The dimensional characteristics of the samples can be established in a similar way.

(2) Estimation of changes in the average molecular mass and molecular-mass distribution of the polymer employed in the preparation of a sample. In this case, determination of molecular characteristics of the original sample (as a rule, by gel-permeation chromatography) is followed, after a definite period of time, by determination of molecular characteristics of the sample subjected to degradation. However, the heterogeneity of degradation over the bulk of the sample prevents correct interpretation of the results.

(3) Estimation of changes in the concentrations of the degradation products. This approach is used for the determination of diverse miscellaneous characteristics, *e.g.*, total volume of gaseous products, concentration of the monomer or the degradation products of a particular polymeric material, changes in pH, *etc.* This method usually gives reliable results provided that the degradation of the tested sample is complete.

(4) Estimation of changes in the concentrations of low-molecular-mass products included into the tested sample. Dyes and radiolabelled substances are used as the most reliable 'markers'; in practice, drugs can also be employed.

(5) Determination of the rates of changes in the mechanical characteristics of degradable polymeric articles. As a rule, these studies are confined to films or fibres.

(6) Determination of the rates of changes in the thermal characteristics of polymers used as starting materials for the preparation of tested articles (*e.g.*, melting and glass-transition temperatures).

The above-described methods are not absolute and the results obtained depend critically on the experimental conditions. Therefore, a comparison of experimental results obtained by different groups of researchers who employ different methods is not always justified. To make the experimental results comparable, the methods used for the study of polymer degradation should be standardised.

The methods for estimating the changes in the molecular masses or concentrations of degradation products in the tested samples provide the most reliable information about the rates of these reactions. Such characteristics can be used for the assessment of the average degree of degradation of the sample at large. However, taking into account the heterogeneous nature of the process the surface/volume ratio of the sample should be considered in each specific case

III. Natural polymers contributing the most to the formation of the biosphere

In nature, biopolymers are represented by several major classes which differ in the types of the chemical bonds in the main chains. These include hydrocarbons (rubber, gutta-percha), carbo-

hydrates (cellulose, starch, chitin, *etc.*), proteins, nucleic acids, aliphatic polyesters and polyphenols (lignin).

Structure-forming polymers of plants and animals constitute the major part of high-molecular-mass organic substances synthesised on the Earth annually. The structural function of biopolymers underlies the ability of the living beings (from bacteria to higher organisms) to take definite shapes which is changed depending on the situation. In plants, the structure-forming function is fulfilled by polysaccharides, first of all, by cellulose. In animal organisms, this role is played by both polysaccharides (*e.g.*, chitin, the main constituent of invertebrate's exoskeletons) and proteins (*e.g.*, collagen and keratin, the main structure-forming elements of vertebrates). Biochemical conversions of these polymers are crucial for the formation of the biosphere.

1. Polysaccharides

Cellulose (poly-1,4- β -D-glucopyranose) is the main constituent of algae, herb and shrub stalks and stems. Biosynthesis of cellulose seems to be among the most ancient biochemical processes on the Earth. Recent studies have shown that cyanobacteria (blue-green algae), one of the oldest life forms on our planet, synthesise cellulose.^{3,4} There is evidence⁵ that cellulose can also be synthesised by some animal organisms. It is interesting to note that cellulose underlying a vast array of food chains of higher animals is not digested by their organisms due to the absence of the corresponding enzymes (cellulases). In herbivores, its primary degradation to easily digestible oligo- and monosaccharides is effected by symbiotic microorganisms.⁶

From the chemical point of view, cellulose degradation represents hydrolysis of the polysaccharide to oligo- and monosaccharides. In nature, this reaction is predominantly catalysed by the enzyme cellulase.

Studies of cellulose degradation are of special importance for a number of reasons.

— Owing to its large-scale synthesis in nature, cellulose represents the main material factor responsible for the formation of soils and deposits (carbon, shale oils). As to the origin of oil fields, this is still open to question. These problems constitute the subject of an interdisciplinary science, biogeochemistry.

— The cellulose-based articles (*e.g.*, fabrics, wood) that came down to us from ancient times are of tremendous interest for archeochemistry, a science that evolved at the interfaces between archeology, history, chemistry, microbiology, mycology and some other sciences.

— Cellulose is a basic component of paper. Therefore, studies of cellulose degradation are underway on the (i) development of methods for conservation, protection and restoration of paper and articles thereof and (ii) determination of the rates and mechanisms of degradation of cellulose (including paper) under the action of external factors in compost, soil, river- and seawater, *etc.*

— Of particular importance is thermal degradation of cellulose concomitant with inflammation of degradation products. Studies in this area make the subject of thermochemistry and those branches of chemistry that are concerned with reduction in the combustibility of cellulose materials.

Among other polysaccharides, mention should be made of a structural isomer of cellulose, *viz.*, poly- α -D-glucopyranose (starch, glycogen and amylose). They are synthesised in plants and animals as reserve sources of carbon and energy and are easily hydrolysed by the corresponding enzymes. Of tremendous importance in this group of biopolymers is starch, which has been widely used since the 1990's for the preparation of biodegradable polymeric materials as a constituent of mixtures with polyethylene, polypropylene and other large-scale non-biodegradable synthetic polymers.

Chitin [poly(*N*-acetyl-1,4- β -D-glucosamine)] occupies a special place in polysaccharides. It is present in small amounts in fungi and some algae. In the biosphere, chitin is predominantly localised in the external skeletons of invertebrates, particularly of

Arthropoda. It was calculated⁷ that the total mass of chitin in the oceans amounts to 1.5×10^{12} kg. Its annual production by krill alone exceeds 10^8 kg. Enormous amount of chitin-containing waste products formed upon its processing is considered to be a valuable raw material for the commercial production of a vast array of chemical substances.⁸

A partly N-deacetylated chitin derivative chitosan presents particular interest for medicine. Chitosan is one of the few biopolymers that contain basic groups, which determines its ability to form interpolyelectrolyte complexes upon interaction with negatively charged biomacromolecules. The problems of biocompatibility, biodegradation and practical application of chitin and chitosan are considered in detail by Kumar.⁹

2. Proteins and polypeptides

This group includes both natural polymers (collagen, fibroin) and synthetic polypeptides based on one or several amino acids.

In mammalian tissues, collagen constitutes up to 30% of the protein mass. Collagen is an extracellular matrix protein and contains predominantly glycine, proline and hydroxyproline; three separate polypeptide chains form helical structures, which combine in more complex microfibrils. Being a constituent of connective tissues, cartilages and vascular walls, collagen plays the role of a structure-forming element in the organism. Besides, it is the main protein component of a bone tissue. More than 10 types of collagen can be distinguished depending on the type and function of the parent tissue.

3. Polyhydroxyalkanoates

Polymers pertaining to this group occur in nature as organelles of some fungi and bacterial cells and serve as the reserve energy and carbon sources.¹⁰ The first compound of this series, poly(3-hydroxybutyrate) (PHB), was discovered in 1927. In its properties, it is similar to synthetic thermoplastics, such as polyethylene or polypropylene, but, in contrast to the latter, it is decomposed in biological media into non-toxic products. This property attracted keen attention of investigators in PHB and its structural analogues as promising biodegradable plastic materials for medical purposes. In addition, these polymers present substantial interest as biodegradable packaging materials. Although PHB is itself a brittle material, its mechanical properties can significantly be improved if employed as a co-polymer with other monomers, *e.g.*, 4-hydroxyvaleric acid.^{11–14} The industrial production of PHB and a co-polymer of 3-hydroxybutyric and 4-hydroxyvaleric acids (PHBV) under the tradename Biopol by microbiological synthesis using the widespread soil bacteria *Alcaligenes eutrophus* began in the 1980's. Whereas in 1980 the cost of PHB was ~2000 USD per kilo, by 1995 it dropped to 10 USD per kilo (*cf.* the cost of ordinary polyethylene-type thermosets, 1 USD per kilo).¹⁵

The possibility to synthesise polyhydroxyalkanoates using transgenic plants was widely explored in the past decade. The first report on such a synthesis in a transgenic cruciferous plant (*Arabidopsis thaliana*) appeared in 1992.¹⁶ It is expected that the cost of natural polyhydroxyalkanoates will soon reach that of large-scale products, such as sugar or starch.

Degradation of PHB and PHBV *in vivo* occurs under the action of intracellular and extracellular enzymes (depolymerases) to yield digestable hydroxybutyric and hydroxyvaleric acids. Their further aerobic conversions yield water and carbon dioxide. Under anaerobic conditions, methane is also formed. The metabolic pathways in organisms that produce polyhydroxyalkanoates and prospects of their biotechnological manufacture are discussed in detail.^{17–19}

The problems related to environmental pollution by synthetic polymers and the increasing cost of crude oil the reserves of which will sooner or later be depleted have recently become especially acute. In this connection, special attention is given to the production of materials based on either natural polymers or polymers prepared from natural renewable raw materials. These include traditional natural polymers (wood, cotton, silk, wool, leather,

etc.) and their analogues or hitherto unknown polymeric materials prepared by genetically modified microorganisms in common biosynthetic routes.²⁰ So far, these polymeric materials are much more expensive than the synthetic polymers. Moreover, studies in this area come up against the resistance of oil-producing companies which supply raw materials for the production of synthetic polymers.

4. Polyphenols

Lignin is the most important representative of this class of polymers. In addition to cellulose, it is an essential component of wood; in soft woods, its content reaches 50%. This amorphous non-toxic polymer is widely available as a side product from paper-making; however, it has a limited market²¹ and it is mainly used as a fuel. Lignin macromolecules have complex structures: in softwoods, the main monomeric fragment of lignin is 2-methoxy-4-propylphenol (guaiacol), while that in hardwoods is 1,5-dimethoxy-4-propyl-phenol (syringol). In the environment, lignin is rapidly decomposed into low-molecular-mass phenols and is regarded as a very promising material for the preparation of biodegradable polyalkene-containing mixtures.

IV. Synthetic biodegradable polymers. Chemical structures and preparation features

The onrush of the field of polymer chemistry related to the synthesis and utilisation of biodegradable polymers is observed in the past decades. As a rule, it is the ester and amide bonds that undergo hydrolytic degradation under biotic and abiotic conditions. Other bond types, *e.g.*, anhydrides, also cleave easily. The stabilities of the corresponding chemical groups against hydrolysis increase in the following order:

The discovery of bacterial polyhydroxyalkanoates stimulated the search and synthesis of novel polymers related to this class.²² Polymers of glycolic and lactic acids (polyglycolides and polylactides, respectively) are the most known and most abundant representatives of synthetic polyhydroxyalkanoates. High-molecular-mass polymers were obtained for the first time in the 1950's.²³ They are usually synthesised by ionic polymerisation in a melt of a monomer under the action of organometallic catalysts, *e.g.*, tin octanoate.^{24–26} Properties of the polymers thus prepared strongly depend on the nature of the catalyst;^{27,28} therefore, a search for novel efficient catalysts is a topical trend in studies aimed at the synthesis of biodegradable polyhydroxyalkanoates.^{29–40}

Some examples of polyhydroxyalkanoates prepared by chemical synthesis are listed in Table 1.²²

Table 1. The main synthetic polyhydroxyalkanoates.

Name	Structure
Poly(oxymethylenecarbonyl) (polyglycolide, polyglycolic acid)	
Poly(oxyethylidenecarbonyl) (polylactide, polylactic acid)	
Poly(oxymethyleneoxyethylenecarbonyl) [poly(1,4-dioxanone)]	
Poly(oxypentamethylenecarbonyl) [poly(6-caprolactone)]	

Polyglycolide is a crystalline polymer with the melting temperature 225–230 °C.⁴¹ Its half-life varies from 60 to 90 days depending on the shape and size of the tested sample and the degradation conditions.^{42–49}

In contrast to polyglycolide, polylactides differ in structures and, correspondingly, in properties. The presence, in lactic acid, of a chiral carbon atom points to the existence of two stereoisomers (D and L); therefore, polylactide chains can be built of D- or L-isomers or of a racemic mixture of both. Poly-D-lactide and poly-L-lactide are crystalline polymers. Poly-D,L-lactide is an amorphous polymer; its properties are determined by the microstructures of its chains, namely, by the distribution of the D- and L-isomers,^{50–54} which varies from random to highly blockwise. This, in turn, determines physical (crystallisability) and chemical (degradation rate) properties of the polymer.⁵⁵

Both polyglycolide and polylactides can be regarded as the basic polymers of a family of polymeric products; in their hydrolysis, the $-O-C(O)-$ bond is cleaved. One of the groups of this family is represented by polyhydroxyalkanoates with a long-chain side alkyl substituent at the α -carbon atom.^{56–67} Yet another prominent group contains linear ω -polyesters among which poly(6-caprolactone) presents the greatest practical interest.^{68–73}

In addition to polyesters containing only ester hydrolysable groups, of great industrial importance are polymers containing other functional groups in the main chain, *e.g.*, ether groups, obtained by polymerisation of dioxanones.^{74–78} Such polymers are more hydrophilic than polyhydroxyalkanoates. Mention can be made of polymers containing alternating ester and amide bonds in their chains. They are prepared by polymerisation of morpholine-2,5-diones.^{79–83} Essentially, these compounds represent alternating copolymers of α -hydroxy and α -amino acids. They possess enhanced hydrophilicities; in addition, side functional groups that can undergo polymer-analogous transformations can be incorporated into the polymeric chains.

Synthesis of such polymers is rather complicated and labour-consuming; therefore, copolymers of lactide with the corresponding morpholinediones are prepared instead.^{84–91}

An interesting and efficient approach to the synthesis of copolymers of hydroxy and amino acids has been developed by Deng and co-workers.⁹² It is based on the copolymerisation of amino acid *N*-carboxy anhydrides with α -hydroxy acid anhydrosulfites.

The physical and chemical properties of polymers (including degradation rates) can be changed substantially by varying their chemical structures. The degradation rate depends critically on the nature of the monomers. Thus polyesters derived from oxalic acid are characterised by the highest degradation rates and are rapidly (within several hours) decomposed in weakly alkaline media (*e.g.*, in saturated solutions of sodium bicarbonate).^{93–95} Polyanhydrides^{94–104} prepared by polycondensation of aliphatic dicarboxylic acids in the presence of acetic anhydride¹⁰⁵ or by polymerisation of cyclic anhydrides^{106,107} undergo very fast hydrolytic degradation. However, polyoxalates and polyanhydrides have one common disadvantage: their degradation yields abiotic products.

Yet another type of biodegradable polymers is represented by polyamides including synthetic protein analogues, *viz.*, poly- α -amino acids (polypeptides). Their degradation rates in biological media are significantly lower than the degradation rates of structurally similar polyesters. As a rule, the degradation of polyamides requires the presence of the corresponding proteases in the reaction medium.^{108–112}

Polypeptides are prepared by various methods, among which polymerisation of *N*-carboxy anhydrides of α -amino acids has been studied in detail.

Recently, procedures for the polymerisation of these monomers have been developed that yield living polymers. This allowed preparation of polypeptides with a very narrow molecular-mass distribution.^{113,114}

The amino acid units in synthetic polymers based on natural amino acids can be linked into polymeric chains in both α - and other positions. Along with amino and carboxylic groups, other functional groups (*e.g.*, the hydroxy groups of serine, threonine or tyrosine) can be involved in the chain formation, which enables the access to polymers with predetermined properties.¹¹⁵

V. Degradation of natural and synthetic polymers in the environment

Studies of degradation of natural and synthetic polymers in the environment may conventionally be classified into several groups:

— ‘Archeochemical’ studies of polymeric articles dating back to ancient times. As a rule, such investigations are concerned with archeological finds. Thus the paper¹¹⁶ describes the results of an analysis of more than 6000-year-old wood specimens from some Egyptian tombs in comparison with other ancient specimens discovered in different parts of the world. Special attention is given to the dependence of the action of fungi and microorganisms on the specimens in the local environmental conditions (humidity, soil characteristics, *etc.*).

— ‘Full-scale’ studies of polymer degradation in soil, sea- and river water, compost, *etc.* Such studies usually have only limited, regional significance, since the factors responsible for the degradation of polymers are highly region-specific. The objects for such studies include newsprint paper, natural and synthetic packaging materials, *etc.*^{117–122}

— Laboratory studies where the effects of one or several quantitatively describable factors able to induce degradation of polymers in nature (light, oxygen, water, definite bacterial strains, *etc.*) are simulated.^{123–125}

Studies of polymer degradation *in vivo* occupy a prominent place.

The search for synthetic polymeric materials that are decomposed in the environment at fast rates without the formation of large amounts of harmful products are underway in many countries. A key trend is the increase in the degradation rates of materials based on carbochain polymers, such as polyethylene, polypropylene, poly(vinyl chloride), which contribute the most to the environmental pollution, since they are not very prone to oxidative and photochemical degradation, nor they are decomposed by enzymes, microorganisms or fungi. Polyethylene, which is especially dangerous for soils, is an example. It was calculated¹²⁰ that the decomposition of low-density 60 μ m-thick polyethylene films lasts 300 years! IR spectroscopic studies have shown that the main degradation mechanisms of this material include oxidative and photooxidative degradation, which is accompanied by the introduction of hydroxy groups and double bonds in the polymeric chain. Enhanced hydrophilicity of polymeric films favours their attack by microorganisms.

The main pathways to increase the decomposition rates of polyethylene and related polymeric compounds include the incorporation, into the polymeric chain, of units susceptible to degradation. This can be performed by copolymerisation of the basic monomer with a small amount of a 'degradable' co-monomer or by preparation of composite biodegradable materials from blends of carbochain polymers with natural biodegradable polymeric compounds, *e.g.*, starch.

2-Methylidene-1,3-dioxepane, which is easily homo- and copolymerised under various conditions, is a promising degradable co-monomer. Upon its incorporation into polyethylene¹²⁶ or other vinyl polymers,¹²⁷ the monomeric units are formed that contain an aliphatic ester bond which undergoes cleavage in the hydrolytic degradation of the copolymer macromolecule.

However, the majority of these studies are aimed at the production of blends of carbochain polymers with biodegradable (both natural or synthetic) polymers. A prominent position among natural polymers used as additives to polyethylene or polypropylene is occupied by starch. Blending of starch with polyethylene in certain proportions under various conditions affords thermoplastic polymeric materials. The articles prepared from them are only slightly inferior to those prepared from the free polymer in mechanical characteristics, but they decompose in the environment by factors of tens faster.¹¹⁹ A series of such polymeric materials (Mater-Bi) have been developed recently in Italy.¹²⁸ The interest in their manufacture is especially high in southern countries where the production of starch from various local sources, *e.g.*, rice, is especially well-established.¹²⁹ In some cases, hydrophilic polysaccharides are subjected to chemical modification in order to enhance their hydrophobic properties and to improve their compatibilities with hydrophobic polyolefins.¹³⁰

Composite degradable polymeric materials were also developed on the basis of other polymeric combinations, *e.g.*, poly(vinyl alcohol)–starch¹³¹ and polycaprolactone–lignin.¹³² The main advantages of this approach include relative simplicity, low cost and possibility to use basic polymers produced on a large scale and inexpensive degradable additives (starch, lignin). The disadvantage consists of low mechanical characteristics of ready articles, predominantly due to the poor compatibility of the components.

The manufacture of polymeric articles that preserve high mechanical characteristics throughout the operation period and undergo rapid degradation afterwards without release of harmful products is yet another promising trend in the design of environmentally friendly polymeric materials. As regards their functions, this group refers primarily to packaging materials. The aliphatic polyesters of synthetic and microbiological origin described above present the greatest practical interest in this respect. Such polymers can be used as such in single-component systems and as degradable components in blends with large-scale manufactured polymers.

VI. Biomedical technologies based on polymer degradation

Natural polymers (*e.g.*, cellulose and silk fibres) have been used in medicine as suture and dressing materials since the time of its origin by virtue of their high durability, flexibility and ability to absorb moisture. The advent of novel polymeric materials (natural rubber and gutta-percha) favoured the development of novel medical products. The discovery of the macromolecular origin of polymers and the subsequent explosive development of the synthetic polymer chemistry has led to closer interactions between

these areas of knowledge. Biodegradable polymers were also in great demand in clinical medicine. A variety of novel, in principle, biomedical technologies developed in the past decades are based on degradation of polymers in aqueous physiological media.

The biodegradable polymeric materials used in the medical practice differ in the phase states of their constituent polymers (solutions, gels, solids), shapes [*viz.*, one-dimensional (fibres, tubes), two-dimensional (films, fabrics), three-dimensional (large-size articles some of which have rather complex shapes)] and in decomposition rates in biological media. This Section deals with the description of three lines of research in this area, *viz.*, preparation of biodegradable suture and dressing materials, development of biodegradable polymers for the targeted delivery of medicinal drugs and the use of biodegradation in tissue engineering.

1. Biodegradable polymeric suture, fastening and dressing materials

The problem of bioresorbable (biodegradable) suture materials is as old as the surgery itself. Whereas suture removal after external wound healing does not present significant difficulties, in the case of intracavitary operations this procedure may require additional surgical intervention.

Traditionally, fibrous materials of cellulose fibres are used in the clinical practice as dressings due to their high moisture-absorbing properties. Filaments of cellulose and natural silk have been used as suture material; they do not induce rejection, but are resorbed in the organism for a time exceeding manifold that required for the regeneration of tissues. Therefore, practitioners in medicine are on a continuous search for bioresorbable suture materials. The catgut, *i.e.*, a filament prepared from dried intestinal membranes of young cattle, is now forbidden for use in the surgical practice in many countries of the world because of the problem of 'mad cow disease' (bovine spongiform encephalopathy).

Suture materials (fibres and filaments) prepared from polylactide, polyglycolide and their copolymers are currently widely used in intracavitary operations. These polymers are readily converted into fibres by extrusion at temperatures below their thermal degradation temperature, which excludes the presence of foreign degradation products in the extrudates. The time required for the complete decomposition of these materials in the human organism can be controlled by the composition of the copolymers. Commercial production of such suture materials (mono- and polyfilamentous fibres)¹³³ is currently underway in some European companies. Each type of filaments has advantages and disadvantages of its own. Monofilamentous threads have smoother surfaces and are sterilised more easily. Their main disadvantage is higher stiffness, which creates additional problems during the operation. Polyfilamentous threads are more convenient, however their less smooth surfaces create complications and do not always meet the requirements for high sterility.^{133–138} In Russia, surgical suture filaments based on biodegradable polymers (Vycril, Dexon) are mainly produced from imported raw materials.

The adequate use of ware for union and fastening of bone fragments in reconstructive surgery presents a serious problem. While metallic (titanium) staples, pins and screws are very convenient surgical tools, their removal after consolidation of fractured bones demands additional surgical operation. Therefore, leaving metallic fasteners in the patient's organism is considered admissible. Within the organism, these are gradually overgrown with connective tissue and after a while they are no longer recognised by the organism as foreign bodies. However, the difference in the deformation characteristics of the bone tissue and titanium may create serious problems for patients. Moreover, redistribution of load in favour of the metallic element increases the risk of osteoporosis.

Some manufacturers produce polylactide fasteners for bone fragments. The adequate choice of chemical structures of poly-

mers enables the synchronisation of the time of their degradation and that of bone consolidation, which varies from several weeks to several months. Such materials are usually made of poly-L-lactide, a polymer with a regular structure and high degree of crystallinity. Due to the regular crystalline structure, the diffusion coefficients of the destructive reagents inside the fasteners decrease, which makes the latter more stable than those made of amorphous materials. Of particular importance is the sizes invariability of polymeric fastenings in the earliest steps of bone consolidation, *i.e.*, these materials should not swell in biological media.¹³⁹

2. Biodegradable polymers for targeted delivery of medicinal drugs

The problem of drug formulations is one of the main challenges to modern pharmacology. On entering the organism (especially, upon oral administration) drugs are exposed to the action of highly active biological media containing enzymes. This results in partial or complete inactivation of the drug before it reaches the small intestine and is absorbed by blood. Therefore, one has to increase the drug dose, which increases the risk of side effects. Direct administration of medicinal drugs into the circulating blood is not always efficient due to functioning of protective mechanisms from drugs as foreign compounds. Therefore, the therapeutic effects of drugs administered in this way are short-lasting (Fig. 1).

In the 1950's, it has occurred to use polymers for the modification of medicinal drugs. Initially, biologically active substances were chemically immobilised on polymeric macromolecules as supports.¹⁴⁰ This approach was thought to prevent drug inactivation in the organism (especially, upon oral administration) and to prolong their therapeutic effects. Studies aimed at perfecting the functioning of drugs follow two major lines, *viz.*,

Figure 1. Time dependences of the concentration of a free drug (a) and of a drug included into biodegradable polymeric microgranules (b). The time of drug administration is marked by arrows.

(i) maintenance of constant drug levels over sufficiently long periods of time and (ii) efficient (without inactivation) delivery of drugs to damaged cells, tissues or organs with subsequent release of the active substance in the target organ or tissue (targeted drug delivery).

Various approaches are known to reach this goal, including the use of thermo- and pH-sensitive hydrogels¹⁴¹ and biodegradable polymers. Chemical and physicochemical aspects of drug design for targeted delivery of active substances based on the use of biodegradable polymers are considered below. The main principle in the design of such formulations consists of the encapsulation of medicinal drugs into matrices of biodegradable polymers and administration of these compositions. In the organism, the polymer undergoes gradual degradation with liberation of the active substance. Obviously, invariability of the drug upon the production of such compositions is a necessary condition.

Biodegradable films and macroscopic plates are among the simplest formulations of this kind where the active substance is dispersed more or less uniformly in the bulk. Such articles are implanted into the area of the injured tissue or organ and function as 'drug depots'. The controlled release of the drug from the polymeric matrix occurs continuously, in the course of its degradation.

The methods for the manufacture of such articles depend on the physicochemical properties of the constituents. If the drug and the polymer are soluble in the same solvent (*e.g.*, dichloromethane), films of required thickness are cast from a solution of the components and are cut into plates or rods. If the components have no common solvent, they are finely dispersed into a mechanical blend and thermal compacting affords films, plates or rods. In the case of thermal inactivation of a drug, an inert solvent is added to the dispersed blend until a thick paste is formed. This is dried to give plates of a biodegradable polymer–drug composite. This method was used¹⁴² to obtain composites of the antibiotics Sulperazone or Duocide with a copolymer of 3- and 4-hydroxybutyric acids employed in the therapy of osteomyelitis.

Microencapsulation is a more complex process for the production of compositions of biodegradable polymers with drugs. Usually, it includes emulsification of a solution of a biodegradable polymer in water in the presence of a surfactant or a stabiliser, *e.g.*, partly hydrolysed poly(vinyl acetate). In these technologies it is important that the polymer and the drug be soluble in the same solvent. In this case, the polymer and the drug are dissolved in this solvent (*e.g.*, dichloromethane) and are emulsified in water in the presence of a surfactant (an 'oil-in-water' emulsion) using vigorous stirring or sonication. On gentle heating, the solvent is evaporated from the emulsion droplets to afford a suspension of microgranules. Their sizes depend on the stirring rate, the surfactant concentration and other factors; they vary from 10 to 60 μm . Such granules represent homogeneous systems the active drug in which is evenly distributed in the bulk.

This method was used by Langer and co-workers¹⁴³ for the preparation of microgranules from copolymers of lactic acid with lysine containing side polypeptide chains grafted to the NH_2 groups of lysine. Rhodamine B was used as a model of the encapsulated drug. Such copolymers present considerable interest, since the presence of side amino acid functional groups and the active substance in the grafted polypeptide chains allows covalent binding of this or any other drug to the surface of the microgranules (in addition to encapsulation) or its binding through electrostatic forces.

The situation is more complex where the drug is water-soluble and the polymer is soluble in a low-polar solvent. In this case, microgranules are prepared by the double emulsion method ('water-in-oil' in water). The first step includes the preparation of an aqueous solution of the drug in a solution of the polymer in a low-polar solvent ('water-in-oil'). In the second step, the resulting emulsion is poured into an aqueous solution of a surfactant with vigorous stirring or sonication (Fig. 2) to yield a double emulsion ('water-in-oil' in water). The last step includes

Figure 2. A chart of manufacture of drug-loaded polymeric microgranules.

(a) Loading of the polymer with the drug; (b) preparation of a polymer dispersion; (c) removal of an organic solvent; (d) isolation of the microgranules.

removal of the low-polar solvent and solidification of the microgranules with the encapsulated droplets of the aqueous drug solution by evaporation of the solvent with constant stirring or by addition of a solvent that precipitates the polymer. The microgranules can be filtered off or isolated by centrifugation. If required, water can be removed from the frozen granules by lyophilisation. The product obtained represents a microheterogeneous system where the drug (as an aqueous solution or as such) is dispersed in the bulk of the degradable polymer. Surface erosion of such granules results in the release of the drug into the organism.

The features of the manufacture of microgranules based on a copolymer of D,L-lactide with glycolide by the double emulsion method is described in detail.¹⁴⁴ In this study, ¹⁴C-mannitol was used as the included compound; its content in the granules and the rate of its liberation upon polymer degradation were established by radioactivity measurements.

More sophisticated techniques for the manufacture of microgranules with drugs included have been developed. For example, according to the ProLease[®] technology,¹⁴⁵ a solution of a polymer in dichloromethane containing dissolved or dispersed additives is sonicated in a vessel with liquid nitrogen. On the vessel bottom, frozen ethanol is present meant for polymer precipitation. Thawing of ethanol as the temperature is increased results in extraction of the solvent from the granules. This approach was used¹⁴⁶ for the manufacture of polylactide microgranules containing human growth hormone; their degradation and the concomitant liberation of the hormone were studied both *in vitro* and *in vivo*.

Production of nanoparticles with included medicinal drugs was the next step in the miniaturisation of degradable polymer granules. These technologies are based on the formation of micelles of diphilic block-copolymers, one of the blocks being biodegradable. Immobilisation of lipophilic drugs is achieved by their solubilisation in micelle cores. The structures of micelles can be stabilised by polymerisation of the functional groups localised either in the micelle core or on its surface. A series of papers devoted to polymeric core-shell micelles were published by

Kataoka and co-workers.^{147, 148} One of the first reports on 'surface cross-linked' micelles was published by Wooley and co-workers.¹⁴⁹ Micellar 'nanodepots' for drug delivery are reviewed in detail.^{150, 151}

3. The use of biodegradable polymers in tissue engineering

Tissue engineering is a novel, rapidly developing trend in the biomedical science which is concerned with the methods for the growth of fragments of tissue or organ injured as a result of a disease or an accident, from patient's own cells and further implantation of the tissues into the organism. Quite naturally, the immunocompatibility problem is not critical in this case. This approach was developed in the 1980's by the American surgeon Vacanti in collaboration with the chemist Langer. The first publications on this subject appeared in the early 1990's.^{152, 153}

Currently, cell therapy is often used for the treatment of some severe diseases resulting from injuries of tissues of internal organs and including myocardial infarction. A suspension of living cells of the corresponding tissue are commonly administered to the patient, they find the target site themselves and favour fast healing of the injured tissue. Unfortunately, this approach is not always efficient; moreover, it demands the use of a large excess of cell cultures.

In the approach developed by Langer and Vacanti, the cell culture of the corresponding tissue is plated onto a special porous scaffold made of a biodegradable polymeric material. After adsorption on the inner surface of the scaffold pores, the cells begin to proliferate, which results in fusion of an integrated tissue. In a biological medium, the scaffold undergoes gradual degradation (Fig. 3). After a while, a fragment of the integrated tissue is formed instead of the polymeric scaffold with sown cells. Its shape is the same as the shape of the original scaffold and is not foreign for the organism.

Figure 3. Time dependences of the mass of an integrated cultured tissue (1) and the polymeric material of the scaffold (2).

At present, the muscle, bone and connective tissue engineering has reached the clinical level.^{154–159} Studies on culturing of skin,^{160, 161} nerve,^{162–165} parodontium^{166, 167} and eyeball (including crystalline lens) tissues^{168–170} are in the research stage. Needless to say, each tissue type has its own peculiarities and requires original approaches. Thousands of papers devoted to tissue engineering have appeared since the first publication (see, for example, Refs 171–187). The use of polymeric materials in tissue engineering has been reviewed^{188, 189} (the data are as of 2000).

Further progress in this area depends on the solution of a great number of diverse problems. Here we briefly discuss the major problems related to the use of biodegradable polymers in tissue engineering (for the design of scaffolds) and their interactions with the cellular material, *viz.*,

- chemical nature of the polymer;
- types of polymeric scaffolds and technologies for their manufacture;
- dependence of cell behaviour on chemical, energetic and morphological characteristics of the polymer surface;
- cell interaction with the polymeric surface of the scaffold and the principles for improving its efficiency by surface modification.

a. Chemical nature of polymers used in scaffold manufacture

Polymers used for the manufacture of scaffolds should meet a number of demands:

- (i) they should not be toxic, nor induce rejection, *i.e.*, be biologically compatible with body tissues;
- (ii) their degradation rates should correlate with the rates of formation of the integrated tissue;
- (iii) their degradation products should not be toxic; moreover, it is desirable that these products served as nutrients for the growing tissue cells;
- (iv) the chemical structures of the polymers should create the most favourable conditions for the cell growth on the scaffold surface.

A series of natural and synthetic biodegradable polymers meet these requirements. Among the natural polymers, various types of collagens, chitosan, hyaluronic acid, starch and some other polysaccharides can be distinguished. Being a matrix protein formed by living cells sown onto a foreign surface, collagen would be an ideal material for the scaffolds. However, its physicochemical properties do not always match the technology of scaffold manufacture. In addition, the rate of its degradation in the organism is often too low for the solution of many practical tasks of tissue engineering. Chitosan is a product of partial or complete deacetylation of chitin. Its physicochemical properties are determined by the degree of deacetylation, which allows their adaptation for the solution of specific tasks.^{9, 190} For this reason, chitosan and its derivatives can be regarded as promising polymeric materials for the manufacture of scaffolds.^{191–195}

However, the majority of studies aimed at the design of scaffolds deal with synthetic biodegradable polymers, predominantly polyhydroxyalkanoates and related materials. Poly-D,L-lactide, poly-L-lactide and their copolymers are used as the basic polymers; they are the most thoroughly studied as regards their synthesis, degradation and behaviour *in vivo*. The use of polylactides for the preparation of medicinal products is authorised in the majority of industrially developed countries. Non-toxicity of these polymers and their degradation products is their main advantage.

The degradation rate of poly-D,L-lactide meets the requirements for the polymeric materials used for the manufacture of scaffolds. These materials are easily processed by molding from

melts or casting from solutions in organic solvents.¹⁹⁶ The broad range of properties of lactide-based copolymers allow their extensive use in the design of macromolecular constructions.

A family of novel copolymers based on polylactide have been developed.¹⁹⁷ These include depsi-peptides with side groups containing ionogenic groups; comb-like and branched polylactides; polylactides grafted to polysaccharide chains. Polylactide copolymers grafted to dextran as the main chain have been described.¹⁹⁸

b. Types of polymeric scaffolds and technologies of their manufacture

A key problem in the construction of a tissue or an organ fragment is related to the structure of the polymeric scaffold used as a biodegradable matrix for cell seeding. As a rule, they are two- or three-dimensional constructions containing an array of interconnected pores of definite sizes and configurations. These may include truly porous (*e.g.*, foam-like or sponge-type) or quasi-porous objects made of woven or non-woven moulded materials with fibres of various diameters prepared from biodegradable polymers. The manufacture of the latter type of scaffolds utilises the most advanced technologies, such as, for instance, multilayer deposition of fused fibres with the help of a special programming device (Fusion Deposition Modelling). The approaches to the formation of such scaffolds are given in detail in a review.¹⁵⁵

Of particular interest are the technologies used for the manufacture of genuinely porous scaffolds where the cells are bound to the polymer on the inner surface of a pore rather than on the outer surface of a fibre or a disc. In contrast to foams where the pores are isolated from one another, sponges contain a well-developed system of interconnected pores. Sponge-like systems are the most suitable for tissue engineering, the bimodal pore size distribution being optimal, with large pores having diameters $\geq 100 \mu\text{m}$ and small ones having diameters of tens to hundreds nanometres. It is on the inner surface of large pores that the cells attach to the polymer, proliferate and then integrate into the tissue. The supply of nutrients and the removal of metabolites occur through the biological fluid that circulates through the system of small pores. Porosity, *i.e.*, the ratio of the pore volume to the total volume of the polymeric article, is an important characteristics of a scaffold. This is directly related to its mechanical properties including the ability to preserve its shape during the time required for the formation of an integrated tissue. In this situation, it is important to maintain the balance between the mechanical strength and the resistance of the scaffold to external factors, on the one hand, and the minimum content concentration of the structure-forming polymer in the total volume of the scaffold, on the other hand. The main methods for the manufacture of porous scaffolds and their characteristics are listed in Table 2.^{155, 199}

Table 2. The main approaches to the manufacture of polymeric scaffolds.

Method	Average pore size / μm	Degree of porosity (%)	Structural features
Foaming with a gas	0.1 – 1000	—	open and closed isotropic pores
Phase stratification in the system polymer – solvent induced by temperature changes with subsequent removal of the solvent (by lyophilisation or extraction)	< 200	97	open isotropic pores
Preparation of a 'water-in-oil' emulsion with subsequent freezing and lyophilisation (removal of water)	< 200	97	the same
Preparation of mechanical blends of a polymer and fractionated salt crystals with subsequent extraction of the latter with water	< 100	85	closed and open pores having the shapes of porogen particles (cubic in the case of NaCl crystals)
Construction of a pore system using a three-dimensional template with subsequent removal of the latter	45 – 150	60	open pores of any predetermined shape
Phase stratification of two incompatible polymers with subsequent removal of one of the polymers by selective solubilisation or degradation	200 – 300	80 – 90	open pores

A novel approach to the formation of porous structures based on the use of blends of two incompatible polymers and subsequent selective degradation of one of them has been developed by the authors of the present review.⁹⁵ Its essence is as follows:

(1) The degradation rates of two polymers one of which is a matrix-forming component and the other is a pore-forming component should be essentially different (by no less than 1 to 2 orders of magnitude).

(2) The polymers should undergo phase separation in solution or in a melt to form biphasic continuous systems.

(3) The heterogeneous structure formed is stabilised by precipitation of the polymer or by cooling of the melt.

(4) The pore-forming polymer should be selectively extracted.

The feasibility of this approach was demonstrated in experiments with blends of a polylactide (PLA) and polyoxalates [poly(phenolphthaleine oxalate), PPPO and poly(hexamethylene oxalate), PHMO], which possess high degradation rates in alkaline media.

Highly porous polylactide discs (the degree of porosity $\sim 90\%$) were prepared by sedimentation of a heterogeneous polymeric blend from a solution with subsequent compacting and degradative removal of the polyester.²⁰⁰ The micrographs show the general view of a porous disc (optical microscopy) (Fig. 4) and its microstructure (electron microscopy) (Fig. 5).

Porous films prepared by casting from both the melts and the solution with subsequent degradative polyester removal are shown in Fig. 6.²⁰¹ A similar approach to the formation of porous structures was developed recently by Favis and co-workers^{202, 203} and by Langer and co-workers.²⁰⁴

Other characteristics of inner surfaces of the scaffold pores including the character of the inner surface of pores and its topography, free surface energy, charge, the presence of func-

Figure 6. A porous film manufactured from the PLA–PHMO melt after the degradative removal of PHMO.

tional groups, hydrophobicity–hydrophilicity ratio, *etc.*, also play a prominent role.

c. Cell interactions with scaffold polymeric surfaces

The interactions of living cells with polymer surfaces present a serious problem in many areas of biology and medicine, particularly with respect to donor blood storage, organ and tissue prosthesis, *etc.* However, it is in tissue engineering that the interactions of cells designed for tissue growth with polymer surfaces are especially critical. These cells ought to manifest specific behaviour over the whole period of tissue growth beginning with the plating of the cells onto the scaffold up to the moment of their implantation into the organism. In the first step, the cells are to be adsorbed on the surfaces of polymeric articles. In this step, the forces that determine their adsorption should be strong enough to ensure their binding to the surface without causing their deformation. In subsequent steps, the cells begin to synthesise extracellular matrix proteins (collagen, fibronectin, *etc.*) and thus create convenient surfaces for subsequent active proliferation and formation of integrated tissues. These processes occur in parallel with the disintegration of the polymeric material of the scaffold.

The interactions that determine the adsorption of cells on the scaffold surface can be classified into several groups:

(1) non-specific weak non-covalent interactions that are largely determined by the free surface energy of the polymeric material (or, more exactly, by the free interphase energy at the polymer–physiological medium interface);

(2) electrostatic interactions of negatively charged cells with the polymer surface;

(3) highly specific interactions of cell receptors with binding chemical structures, most commonly, of the peptide nature, immobilised on the surface of the polymeric material.

In addition to physicochemical and biospecific factors, cell binding to polymeric surfaces strongly depends on their morphology.^{205–208} The majority of cell adsorption experiments were carried out with films, since three-dimensional samples present problems as regards formation of certain surface structures and their analysis. Polymeric materials with predetermined surface morphology can be obtained in different ways, *e.g.*, using various combinations of a polymer and a solvent (or solvent mixtures)²⁰⁹ or by preparing films from polymer blends followed by thermal or chemical treatment of the preformed films.^{210, 211} It was found²⁰⁷ that polyhydroxyalkanoate films prepared under special conditions had coral-like surfaces with low cell adsorption. The structures of such surfaces become smoother upon treatment of films with lipase, which increases cell adsorption 40-fold.

The free energy of a surface is largely determined by the nature of the polymeric material. The lowest values of this parameter are characteristic of perfluorinated polymers. For example, the free surface energy of Teflon is 18 mJ m^{-2} . The interactions of such surfaces with cells are negligibly weak, which allows their use for the storage of donor blood and for other similar purposes. Higher values of free energy are required for more efficient adsorption of cells on the scaffold surface.²¹² Surface hydrophilicity is yet another important related factor, since the majority of cells (with the exception of adipose tissue cells) function in aqueous media and possess high affinity for hydrophilic surfaces. Polyhydroxyalkanoates, the most popular scaffold material, have hydrophobic surfaces, which reduces cell adsorption on them.

The hydrophilicities of polyhydroxyalkanoate-based scaffold surfaces can be increased by different methods. One of the most popular techniques includes treatment of scaffold surfaces with solutions of extracellular matrix proteins. This procedure has a dual effect, since it increases both the hydrophilicity and the biocompatibility of the scaffold surface. The use of collagen-treated films for cell adsorption allows one to increase significantly the number of cells adsorbed per surface unit.^{213, 214} Moreover, these cells are able to proliferate spontaneously (without additional adaptation). The main disadvantage of this approach is that collagen and other matrix proteins are very quickly desorbed from the polymer surface in physiological media. To prevent desorption, these proteins are covalently bound to the polymer, *e.g.*, using glutaraldehyde (Scheme 1).¹⁸⁴

Scheme 1

However, the practical realisation of this approach requires the use of polymeric materials with surface amino groups, *e.g.* chitosan the number of amino groups in which is easily controlled by the extent of hydrolysis of the acetamido groups.²¹⁵ Lysine units can be introduced into polyhydroxyalkanoates, the most suitable material for the manufacture of scaffolds, by copolymerisation of the lactide with the corresponding morpholinedione.⁸⁸ Removal of the protective benzyloxycarbonyl groups in the side chains liberates amino groups.

The role of positively charged amino groups on the scaffold surface is not confined to the covalent binding of matrix proteins. These groups enhance cell adsorption due to electrostatic interactions with the negatively charged cell surface.²¹⁶ In order to further enhance this interaction, Langer and co-workers⁸⁹ employed the amino groups of lysine in the copolymer chains for graft-polymerisation of N^α -carboxy- N^ϵ -benzyloxycarbonyl lysine (Scheme 2).

Covalent attachment of the so-called binding peptides is one of the most interesting approaches to increasing the affinity of the scaffold surfaces to the cells to be adsorbed. The tripeptide arginyl-glycyl-aspartyl (RGD-peptide) able to interact with cell-binding receptors has been studied in most detail.^{217–221} The incorporation of even very small amounts of this peptide resulted in a significant increase in the surface adsorption of the cells. The works devoted to biospecific adsorption of cells on the surfaces of polymeric materials under the action of binding peptides were published quite recently. There is still no data on which of the methods for grafting of the peptide to the scaffold surface ensures the best results. However, further studies may culminate in significant achievements in the physicochemistry and biochemistry of interactions of living cells with various surfaces.

Obviously, very soon novel tissue engineering technologies will occupy a prominent place not only in reconstructive surgery, but also in treatment of diseases that are still beyond the control of modern medicine. The development of novel biodegradable polymeric materials will surely make a weighty contribution to the attainment of this goal.

VII. Conclusion

In the past few decades, the branch of chemistry of high-molecular-mass compounds concerned with the degradation and stabilisation of polymers has developed into a vast area of knowledge that involves diverse sciences and technologies — from chemistry to microelectronics, biogeochemistry, ecology, medicine and even archeology. The conventional views on the polymer degradation and its role in nature and in modern technologies also changed considerably. For a long time, the main efforts were focussed on the protection of polymeric articles from degradation;

however, more recent trends are towards investigation of the role of polymer degradation in sculpturing the appearance of our Planet and functions of living organisms, natural transformations of low-molecular-mass compounds into polymers and *vice versa* and the 'fate' of polymeric articles that have served their time in the environment. However, the most important result in studies of polymer degradation is that this phenomenon has found novel, quite unexpected applications in the most advanced technologies.

IV. Experimental results on the impedance of modified electrodes	154
V. Conclusion	159

Abstract. The available models of charge transfer processes in electroactive polymer films are considered. Examples of interpretation of the data of electrochemical measurements using model approaches are given. The emphasis is placed on the interpretation of the results on the impedance of modified electrodes. On this basis, conclusions concerning the most topical research problems and the description of the processes in question are drawn. The bibliography includes 122 references.

I. Introduction

The laws of electrode processes in electroactive polymer films have been the subject of intensive research in recent decades. At present, this is an individual investigation direction called electrochemistry of modified electrodes. Research in this field became particularly intensive since the discovery of the so-called 'synthetic metals' (conducting polymers with conjugated bonds) in the late 1970s.¹ Incessant interest in such polymers is due to prospects for their practical use as materials for power sources, various electrochromic and optoelectronic devices, *etc.*^{2–10} Until very recently, most studies in this field concerned the search for novel systems in order to fabricate films whose properties will fulfill practical demands. Studies on the laws of transport processes in such systems are scarce. The fact that the kinetics and mechanisms of charge transfer in electroactive polymer films have been poorly studied is due to the lack of information on their structural features. The stoichiometry and products of the electrode reactions are sometimes unclear. Often, it is unknown which proportion of potentially active film fragments is involved in the electrode process and whether or not are the film properties changed with the film thickness. The authors of the present review do not pretend to highlight all aspects of research in this field. Here, it is appropriate to place the emphasis on theoretical approaches to the description of charge transfer in various polymers and on generalisation of quantitative data on the kinetics of these processes.

A polymer-modified (from this point on, 'modified') electrode is a conducting substrate coated with an organic or inorganic electroactive polymer film contacting an electrolyte solution. Usually, two main classes of such films include electron-conducting (or simply conducting) polymers and redox polymers.^{8–10} The first class comprises organic polymers with a conjugated system of π -bonds. Here, the conductivity is due to delocalisation of electrons or 'holes' that appear upon the oxidation (doping) of the polymer. Typical conducting organic polymers with conjugated bonds include, *e.g.*, polymers based on aniline and its derivatives, polymers based on simple and substituted five-membered heterocycles (polythiophenes, polypyrroles), *etc.* A feature of this class of organic polymers is the ability to undergo reversible redox transitions involving the so-called dopants (anions, hydrogen ions). Redox transitions induce abrupt changes in the polymer conductivity, from quasi-metallic conductivity to semiconductor one.

The class of redox polymers comprises polymer structures containing immobilised redox active centres. Electron transfer between these centres determines relatively low electronic conductivity of such polymers. Electroactive centres can be constituents of the polymer chain or be bound to functional groups of the polymer. Typical redox polymers include polynuclear complexes based on metal hexacyanoferrates, polyoxotungstates and polyoxomolybdates as well as ion-exchange polymers with incorporated (electrostatically bound) redox active cations or anions.

In most cases electroactive polymer films are synthesised on the surface of electron-conducting substrates by electrochemical polymerisation of monomeric organic compounds or metal complexes.

Electrochemically active centres in the redox polymers are metal ions, which can change the oxidation state and thus participate in electron exchange processes. The conductivity of a redox polymer is governed by the product of the electron donor concentration by the electron acceptor concentration and reaches the maximum value at the formal potential of the redox system.

The electrochemically active fragment of conducting polymers is the double bond. Elimination of an electron from the double bond (oxidation) leads to the formation of a radical cation in the initial stage. Experimental EPR studies of conducting polymer films confirm the presence of unpaired electrons in the films.^{2,3}

A radical cation that formed is partially delocalised over a polymer chain fragment of size of a few (usually, 4–6) monomer units. This leads to deformation of the polymer structure and polarisation of the environment (this gave the name 'polaron' to the chain fragment containing the radical cation). Polarisation of the environment and interaction with counterions lead to stabi-

sation of the radical cation. If the next electron is removed from the same polymer chain fragment, a dication or bipolaron is formed. At present, the polaron theory of conductivity has been recognised as the main model for explanation of the electronic conductivity of polymers with conjugated bonds. According to this theory, the electronic conductivity is due to the motion of polarons and bipolarons along the polymer chain in an electric field and occurs by reorganisation of the double and single bonds and by electron hopping between chains.

In spite of some distinctions between these classes of polymers, common to both of them is a mixed electronic-ionic mechanism of conductivity. Indeed, a negative or positive charge injected into a film should be compensated by injection or removal of electrolyte ions absorbed in the film in order to meet the electrical neutrality condition for the entire film. Therefore, in both cases theoretical description of charge transfer has much in common; in essence, it uses the same model of electron hopping mechanism of charge exchange between adjacent redox centres (or delocalised holes and electrons in conducting polymers), accompanied by transfer of counterions.^{4–10} Considering the concepts underlying the interpretation of data on the electrochemical properties of electroactive polymer films, two approaches to construction of theoretical models of these systems should be pointed out. The first approach has been best developed and treats the film as a system possessing homogeneous properties.^{5, 11–19} Analysis of the response of a metallic electrode (conducting substrate) coated with such a film and contacting an electrolyte solution involves the division of the overall process into certain stages, namely, charge transfer in adjacent electrolyte and charge injection into and charge transfer inside the film. The second approach, which has been intensively developing recently, takes into account inhomogeneous structure of the film and, in particular, microcrystallite structure of the film, *i.e.*, the presence of pores filled with electrolyte.^{20–28} Apparently, electrolyte ions can be absorbed in (and removed from) such inhomogeneous film not only from the outer interface with the solution but also from the inner interfaces corresponding to pore–polymer interfaces.

From the aforesaid it follows that modified electrodes should be studied by various methods. Apparent correspondence between the electrochemical properties of the modified electrodes and the structure and morphology features of the modifier films requires the use of various structural-physical methods. At the same time it is desired that the structure and properties of films be changed in a target fashion using chemical techniques. Often an electrode process is accompanied by changes in the spectral characteristics of the films; this makes spectroelectrochemical methods of investigation necessary (see *e.g.*, reviews^{29, 30}). An important role is also played by the quartz microbalance method,^{31–36} which in many cases helps to reliably determine the nature of counterions incorporated into polymer film and the degree of changes in the viscoelastic properties of the film in the course of the electrode process. The most widely used electrochemical methods of investigation of modified electrodes include cyclic voltammetry (CV) and Electrochemical Impedance Spectroscopy (EIS). Chronoamperometry (CA) is somewhat more rarely used. Multistage character of electrode processes in such systems, the presence of at least two interfaces (film–solution and film–metallic electrode or another conducting substrate, *e.g.*, semiconductor, graphite, glassy carbon) complicate the interpretation of experimental data.

Both the use of methods of investigation of modified electrodes and processes occurring in them and the difficulties in the interpretation of measurement results require elaboration of relevant theoretical concepts. A broad spectrum of problems and methods make it impossible to correctly describe all aspects of research in the field of modified electrodes in the framework of a small review article. Therefore, in this work we will restrict ourselves to consideration of electrochemical aspects of this avenue of research (*i.e.*, the available models for the description of charge transport in the systems under study and illustration of

the use of such models in studies of electrode processes occurring in particular systems).

Electrochemical impedance spectroscopy is the most efficient method of studying charge transfer processes. However, the use of this technique often faces some difficulties³⁷ that are usually due to the need of taking into account a large number of factors responsible for charge transfer in real systems (*i.e.*, to multiparametric character of analysis). Studies on the impedance of the redox polymer and conducting polymer films carried out to 1989 were briefly outlined by Musiani.³⁸

The possibility of using different models of the systems under study and different transport schemes *a priori* makes the interpretation of the results obtained somewhat ambiguous. Therefore, often a particular interpretation is predetermined by the choice of a certain equivalent electric circuit as a model for the system under study or by introducing a number of additional elements corresponding to peculiar features of the impedance spectra into the available circuits. This manner of data interpretation is highly popular and can be treated as a specific approach involving the use of analogue electric circuits. Since the approach uses no particular model, it can be employed for analysing the electrical responses of modified electrodes in the case of both homogeneous and inhomogeneous films and, in particular, porous polymer films.

II. Method of equivalent circuits

As mentioned above, electroactive polymer films exhibit a mixed electronic-ionic conductivity, *i.e.*, electron transfer in a film is accompanied by transfer of counterions. To visualise this process, Albery *et al.*^{20–23} proposed an equivalent circuit (Fig. 1) comprised of transmission lines corresponding to the system's con-

Figure 1. Transmission lines for two particles (electron and ion) (a) and for three particles (electron, cation M^+ and anion X^-) (b).²²

ductivity with respect to each type of particles and connected by capacitors. The capacitors take into account the possibility of redox process in the film upon injection of a negative or positive charge and compensation of this charge due to incorporation (removal) of corresponding ions. Initially, this equivalent circuit was proposed for the description of porous electrodes. Albery *et al.* considered two phases of the film, namely, the polymer and pores. The film-related impedance is represented by a finite transmission line consisting of two resistors, R_1 and R_2 , and one capacitance (see Fig. 1a). Here, R_1 is the resistor describing the motion of electrons in the polymer and R_2 is the resistor describing ion transfer in pores. Consideration of this circuit shows that if $R_1 \ll R_2$ (electronic conductivity is much higher than ionic conductivity) the charge 'leaks' from the polymer with the higher conductivity towards the electrolyte surface. The exchange reaction begins at the film–solution interface and propagates through the film (porous coating) into the interior to the electrode. Otherwise, if $R_1 \gg R_2$ (ionic conductivity is much higher than electronic conductivity), the charge leaks along more conductive pores, and oxidation begins at the electrode–polymer interface and gradually propagates into the interior of the polymer coating. The Albery theory allows the pore-to-polymer volume ratio, diffusion coefficient and thickness of the coating to be determined. Qualitatively, the model of infinite or (in simplified form) finite transmission lines describes conducting polymer films irrespective of their structure (porous or not). However, this only indicates the correctness of representation of films by this equivalent electric circuit. Physical meaning of the model is still to be clarified, in particular in the cases of frequency-dependent elements of the circuit (see below). Often, for the sake of simplicity the transmission lines in the equivalent circuit shown in Fig. 1a are replaced by an element called the Warburg impedance (Z_W) or diffusion impedance (Z_d).

In addition to charge transfer in bulk film, which is characterised by the transmission lines, the EIS spectrum of modified electrodes is affected by the charge injection processes at the conducting substrate–film and film–solution interfaces. This effect is usually included by introducing the so-called RC-chain (element consisting of a resistor R_{ct} and capacitor C_{dl} connected in parallel) into corresponding equivalent circuit. The resistor describes hindered injection of charge carriers through a certain interface and the capacitor describes the need of charging the electric double layers for the injection to occur. The equivalent circuits often include a resistor R_s responsible for the resistance of the region of the bathing electrolyte solution from the film to the tip of the electrolytic salt bridge. Therefore, the simplest equivalent circuit of a homogeneous electroactive film, which takes into account the effect of one interface and charge transfer in bulk film, has the form shown in Fig. 2a.

Figure 2a also shows an ideal spectrum of this circuit in the complex coordinates ($-iZ_{Im}$, Z_{Re}) that are usually called the Nyquist coordinates. If the relaxation times characteristic of different stages of charge transfer differ appreciably, the overall impedance diagram reveals different frequency domains corresponding to each electrode process included. In the high-frequency limit one should expect the electrolyte solution resistance equal to R_s . At relatively lower frequencies, the impedance is due to a process at the electrode–film and/or film–electrolyte interface and the spectrum exhibits a semicircle (sometimes, two semicircles). The time constant τ (relaxation time or 'characteristic time') of the semicircle is governed by the product of the charge transfer resistance by the double layer capacitance

$$\tau = R_{ct}C_{dl}.$$

These two parameters can be determined using the diameter, D , and frequency, ω_{max} , at the maximum of the semicircle (see Fig. 2a).³⁷

$$D = R_{ct};$$

Figure 2. Simplest equivalent circuits for interpretation of the impedance of modified electrodes: conventional Randles circuit (a) and modified circuit (b) corresponding to the limiting effect of charge injection into film and the corresponding impedance spectra plotted in the complex coordinates (negative imaginary component of the impedance $-iZ_{Im}$ vs. real component Z_{Re}).

$$C_{dl} = \frac{1}{\omega_{max} R_{ct}}.$$

At lower frequencies, the major contribution to the frequency characteristic of the impedance comes from diffusion. Here, two regions can be considered, a linear region with a phase angle of $\pi/4$ corresponding to semi-infinite diffusion and treated as the Warburg impedance, Z_d , and a second linear region at more lower frequencies with a phase angle of $\pi/2$. Considering that the diffusion of ions in solution occurs much faster than in the film (*i.e.*, in the solid), it is reasonable to assume that mass transfer is governed by the diffusion of current carriers in the film. The region of very low frequencies with a phase angle of $\pi/2$ can be treated as a pure capacitive response of the system. In this region the diffusion is gradually limited by charge accumulation within the film as the frequency decreases, which leads to the limiting capacitance C_{lf} that can be calculated from the equation³⁷

$$C_{lf} = \frac{L^2}{3D_{eff}R_L},$$

where L is the film thickness, D_{eff} is the effective coefficient of diffusion in the film and R_L is the limiting resistance (intercept on the real axis of the impedance).

It should be noted that in practice the impedance spectra are often inconsistent with the simplest model mentioned above;^{39–43} sometimes they exhibit a bent semicircle centred below the real axis (see Fig. 2b). In addition, the pure capacitive behaviour predicted by the model (see above) is not observed even at very low frequencies. In many practically used models this deviation from the ideal behaviour is taken into account by replacing the capacitance by the so-called constant phase element (CPE)³⁷ whose impedance is given by

$$Z(\omega) = \frac{1}{T(i\omega)^\varphi},$$

where T is a constant measured in $\Omega^{-1} \text{ s}^\varphi$ and the exponent φ ($|\varphi| \leq 1$) determines the phase shift equal to $(\pi/2)\varphi$. The smaller the φ value ($0 < \varphi < 1$), the larger the shift of the semicircle. The CPE corresponds to a capacitor with the capacitance T at $\varphi = 1$, to an induction coil at $\varphi = -1$, to a resistor at $\varphi = 0$ and to the Warburg impedance Z_W at $\varphi = 1/2$ (see below).

The introduction of the CPE for the description of experimental data is a formal procedure, because the physical meaning of this element is still unclear, except for the particular cases mentioned above. The CPE is more likely introduced to simplify calculations rather than understand the actual nature of the processes occurring in the film. Nevertheless, the use of the CPE in equivalent circuits has been a routine step for many authors,^{41–43} in particular, in the description of the frequency-dependent capacitance of polymer films. The reasons for this dependence (frequency dispersion of capacitance) have been the subject of extensive literature based on the concepts of structural-chemical inhomogeneity in films, high roughness of interfaces and possible trapping effects (presence of mobile charge carrier traps in the form of certain film fragments). In these cases the frequency-dependent capacitance $C(\omega)$ is usually described by the semi-empirical relation

$$C(\omega) = \frac{C_0}{1 + (i\omega\tau)^{1-\alpha}}. \quad (1)$$

Here C_0 is a constant capacitance, τ is the characteristic time of the process responsible for the observed frequency dispersion of capacitance and α is an empirical exponent. It should be noted that as a rule the use of expression (1) is based on the De Levie theory for porous electrodes.⁴⁴ In this theory and its more recent versions the capacitance $C(\omega)$ does obey the relation of type (1). Experimental criteria for validation of the use of the porous film model include effects of film thickness and concentration of the bathing electrolyte, specific to these systems. Numerous investigations showed that variation of the film thickness usually leads to a change in the film morphology. As a rule, the degree of film porosity increases with the film thickness, thus affecting the magnitudes of the parameters to be determined. The contribution of ion transfer also changes, namely, increases on going to more porous films. Therefore, in such films one can expect an increase in the effective diffusion coefficient of current carriers with an increase in the concentration of the bathing electrolyte. Practical convenience of the use of the transmission line model lies in that it allows one to divide the impedance spectrum into characteristic regions [high-frequency semicircles and the diffusion (Warburg) impedance and low-frequency capacitance regions] responsible for different stages of charge transfer in films and thus to make qualitative conclusions about the mechanism of this process. At the same time quantitative interpretation of experimental data using the model mentioned above is impossible, because this requires the use of corresponding theoretical results.

Prior to going to a brief outline of the results for a homogeneous modifying polymer film a circumstance not discussed above

should be pointed out. The case in point is the choice of the fashion in which different elements of an equivalent circuit are connected to one another. Indeed, according to the Albery model, there are at least two transmission lines describing transfer of electrons and counterions in the film. Apparently, in the case of the substrate–film interface the RC -element corresponding to injection of electrons into the film (or *vice versa*) should be connected to the electron transmission line. But at the same interface, the transmission line for counterions should be connected to the substrate through a capacitor, because the charging of the interface will to a greater or lesser extent be determined by the dynamics of these ions in the electric double layer surrounding the substrate (see Ref. 45 and Fig. 3). A similar connection should also correspond to the film–solution interface (or polymer–pore interface in the case of porous film structure), but the difference is that now the RC -element is connected to the counterion transmission line and placed before the resistor R_s . In the absence of electron transfer at this interface the electron transmission line should terminate with a capacitor (see Fig. 3) or with the second RC -element in the presence of electron acceptors in the solution.

Figure 3. Equivalent circuit representing an electric model of polymer film with two charge carriers.

R_k is the bulk film resistance with respect to the k th current carrier, $R_k(z)$ and $C_k(z)$ are respectively the resistance and capacitance of the film interfaces at the coordinate z ($z = 0$ at the metal–film interface and $z = L$ at the film–solution interface); $k = i$ for electrons and $k = m$ for counterions; C_{if} is the low-frequency film capacitance; and R_s is the resistance of the bathing electrolyte.

Thus, detailing of the equivalent circuit of the modified electrode suggests the need of introducing at least three parameters (two capacitors and a resistor) for each interface in order to correctly describe its charging. Actually, yet another, fourth parameter should be added to the three ones, as was shown by Vorotyntsev *et al.*^{16,17} and will be considered below. Therefore, in the general case processing of experimental data using corresponding theoretical results can face certain problems. Even with a certain set of necessary parameters, the results of experimental data processing will cast some doubt. The reason is the lack, up to date, of a correct theory that would provide a basis for the interpretation of experimentally observed changes in such relatively simple parameters as the charge transfer resistance R_{ct} and interface capacitance C_d with the potential and other variable experimental parameters. To make no naked assertion, note that experimental C_{dl} values (usually, a few $\mu\text{F cm}^{-2}$, see below) have no comments. At best, mention is made that these values are small compared to the double layer capacitances in electrolyte solutions. The situation with interpretation of the R_{ct} values is somewhat different. They are often interpreted using the Butler–Volmer equation in order to write the expression for the rates of injection of current carriers into the film.¹² However, this equation does not include the effect of the electric double layer on the rates of heterogeneous charge transfer (the so-called Frumkin correction). Therefore, application of the Butler–Volmer equation to conducting polymers is at least a moot question. The expressions for injection currents used by Vorotyntsev *et al.*^{16,17} and Láng and Inzelt⁴⁶ were linearised with respect to small deviations of the concentrations and potential jumps. This representation of the injection currents is correct if small-amplitude methods (in partic-

ular, EIS) are used, but consideration of the shape of the R_{ct} -vs.-electrode potential plot (provided that relevant data are available) in this case is impossible. It seems obvious that correctness of data interpretation can only be confirmed by attaining agreement between the observed changes in the measured parameters of the impedance spectra as functions of the electrode potential and some theoretical concepts. Such an agreement is even more necessary in the case of multiparametric processing of impedance data, as often occurs in studies of modified electrodes (see below).

From the aforesaid it follows that research on charge transfer in the systems in question involves a particular investigation line, viz., elaboration of theoretical concepts appropriate for minimisation of the number of descriptor parameters.

III. Homogeneous film model

A correct formulation of the problem of the impedance of a modified electrode and its solution for homogeneous conducting polymer films were reported by Vorotyntsev¹⁶ and then extended¹⁷ to the case where the bathing electrolyte contains a redox pair that provides the possibility for electrons to leak from the film surface. The importance of these results is not limited to the case of homogeneous conducting films separating the substrate and solution (or two metallic substrates or two solutions, see Refs 16 and 17). We believe that they should be taken into account, in one form or another, when using the porous models of such films. However, up to date general character of the analysis performed in these studies prevents the use of the results obtained. In this connection it seems appropriate to dwell here on some important aspects of the analysis,¹⁶ restricting ourselves to the case of modified electrode. In contrast to the non-model approach¹⁶ in this review we will employ a model one in order to find out the possibility of obtaining analytical expressions for some parameters reported by Vorotyntsev *et al.*^{16,17}

For a homogeneous electroactive film containing only two types of current carriers the electron and counterion flux densities j_{im} and j_m , respectively, are given by the following equations:¹¹

$$\begin{aligned} j_{im} &= -D_{im} \left\{ \frac{\partial C_R}{\partial z} - C_R(1 - \theta_R) \left[\frac{\partial \Phi}{\partial z} - \alpha_0 \frac{\partial \theta_R}{\partial z} \right] \right\}, \\ j_m &= -D_m \left\{ \frac{\partial C_m}{\partial z} + z_m C_m \frac{\partial \Phi}{\partial z} \right\}, \end{aligned} \quad (2)$$

where D_{im} and D_m are the electron and counterion diffusion coefficients, respectively; C_R is the concentration of the reduced fragments (sites); z is the distance from the substrate–film interface; $\theta_R = C_R/C$ is the coverage of the film fragments involved in electron transfer following the reaction

with the reduced form. Here $C = C_R + C_{Ox} \neq f(z)$ is the total concentration of such fragments; C_{Ox} is the concentration of oxidised fragments (sites); α_0 is a dimensionless (in units of RT) attraction constant determined by the energies of the interactions between film fragments and the nearest environment; C_m and $z_m = \pm 1$ are respectively the concentration of counterions in the film and the charge of these mobile charge carriers; $\Phi(z) = F\varphi(z)/RT$ is the dimensionless electric potential (vs. adjacent bulk electrolyte) and $\varphi(z)$ is the dimension value of this potential (see also Ref. 19 and references cited therein). Conditions for conservation of current carriers (electrons localised on the reduced fragments and counterions) in the film are given by the equations

$$\begin{aligned} \frac{\partial C_R}{\partial t} + \frac{\partial j_{im}}{\partial z} &= 0, \\ \frac{\partial C_m}{\partial t} + \frac{\partial j_m}{\partial z} &= 0, \end{aligned} \quad (3)$$

which correspond to the absence of chemical reactions (e.g., binding of counterions to film fragments) in the bulk film under study. The expression for the resulting current density, $I(z,t)$, due to the electron and counterion fluxes (j_{im} and j_m , respectively) is obvious:

$$I(z,t) = F(z_m j_m - j_{im}). \quad (4)$$

Equations (2)–(4) are supplemented with the Poisson equation

$$\frac{\partial^2 \Phi(z)}{\partial z^2} = -\frac{4\pi F^2}{\epsilon_f RT} \{ z_m C_m(z) + (z_0 - 1) C_R(z) + z_0 C_{Ox}(z) \}, \quad (5)$$

where z_0 is the charge of the oxidised form and ϵ_f is the dielectric permittivity of the film. An analogous Poisson equation

$$\frac{\partial^2 \Phi(z)}{\partial z^2} = -\frac{4\pi F^2 C_s}{\epsilon_s RT} \{ \exp[-\Phi(z)] - \exp[\Phi(z)] \} \quad (6)$$

should also be written for the bathing electrolyte, *i.e.*, for the distances $z > L$, where L is the film thickness, C_s is the volume concentration of a solution of symmetric (1–1-charged) electrolyte and ϵ_s is the dielectric permittivity of the electrolyte. Writing Eqn (6) also implies zero concentration gradients in the bulk electrolyte during measurements.

Gabrielli *et al.*,¹² Deslouis *et al.*⁴⁷ and the Mathias and Haas¹¹ solved Eqns (2)–(5) ignoring the electric double layers at film interfaces. Lång and Inzelt⁴⁶ have found an approximate solution to the problem taking into account the deviation from electrical neutrality. In contrast to these studies the derivation^{16,17} of the expressions for the impedance seems to be very correct. In particular, it was assumed that the equilibrium potential and current carrier concentration distributions are retained within the diffuse parts of the electric double layers of the film even when the potential applied to the electrode is altered at relatively high frequencies. Indeed, relaxation of these distributions should occur almost instantaneously, because the Fourier parameters, $(1/\kappa_f)^2/D_{eff}$, of these layers are very small [$1/\kappa_f$ is the thickness of the diffuse part of the electric double layer (EDL) of the film at the left or right boundary, D_{eff} is the effective diffusion coefficient of charge carriers in the film]. Therefore changes in the concentration and potential in these layers should occur under quasi-stationary conditions. Grafov and Chernenko^{48,49} first showed that in this case the potential and concentration distributions within diffuse layers should be equilibrium in character. This allowed the thermodynamic theory of interfaces (in particular, the Gibbs adsorption equation) to be employed^{16,17} for the description of the charging of the EDL in electroactive polymer films. Some important aspects of this analysis will be considered in detail in the text below. At the same time we will show the possibility of decreasing the number of description parameters.

It is convenient to begin with the determination of the injection rates of current carriers into the film. Let us make some simplifications, namely, assume that injection of counterions into the film is limited by partial desolvation of the counterions at the film–solution physical border. With this assumption the equation for the injection rate $J_m(L,t)$ of these ions has the form

$$J_m(L,t) = z_m F [\sigma_m C_M(L,t) - \rho_m C_m^s(L,t)], \quad (7)$$

where $C_M(L,t)$ is the concentration of counterions at the film surface as viewed from the adjacent solution, $C_m^s(L,t)$ is the concentration of the same counterions at the film surface as viewed from the film and σ_m and ρ_m are respectively the rate constants for injection. Since this stage is assumed to be the limiting stage for the incorporation (removal) of ions into the film, the concentrations $C_M(L,t)$ and $C_m^s(L,t)$ should respectively be related to the concentration, C_0 , of injected ions at the end of the diffuse layer in the solution and the concentration, $C_m(L,t)$, at the end of the diffuse layer in the film on the same side of the film by some equilibrium relationships. Taking into account these interrelations, Eqn (7) can be rewritten in the form

$$\begin{aligned}
& \times \left\{ 1 + \exp \left[\frac{F\{\varphi_s(0) - \varphi(0)\}}{RT} + \alpha_0(\theta_R^0 - \theta_R^f) \right] \frac{\theta_R^0}{1 - \theta_R^0} \right\}^{-1} = \\
& = -F\rho_e^0 \exp \left[\frac{F\{\alpha\varphi_s(0) + \beta E - \varphi(0)\}}{RT} + \alpha_0\theta_R^0 - \alpha\alpha_0\theta_R^f \right] \times \\
& \quad \times \frac{\theta_R^0}{1 - \theta_R^0} \left\{ 1 + \exp \left[\frac{F\{\varphi_s(0) - \varphi(0)\}}{RT} + \right. \right. \\
& \quad \left. \left. + \alpha_0(\theta_R^0 - \theta_R^f) \right] \frac{\theta_R^0}{1 - \theta_R^0} \right\}^{-1}, \quad (15)
\end{aligned}$$

where the superscript '0' denotes the equilibrium values of corresponding variables (this is also indicated by the absence of the symbol 'δ'); besides, for the equilibrium state of the system, which is assumed in derivation of Eqns (14) and (15), one has $\varphi(0) = \varphi(L)$ and $\varphi_s = 0$.

Although the relations derived are in essence phenomenological (in the sense that they include the rate constants σ_e^0 and ρ_e^0 determined only from measurements), the dependences of the exchange currents on the electrode potential, E , and concentration, C_0 , following from Eqns (14) and (15) can be checked experimentally. By comparing this type of theoretical dependences with experimental results it is possible to assess the correctness of the models used in processing of corresponding data. As an example, it is appropriate to analyse the simplest situation, *viz.*, insignificance of short-range effects ($\alpha \approx 0$) and applicability of the Gouy model to the substrate–film interface. In this case one has $\varphi_s(0) = E$ and from two alternative definitions of the exchange current of electron injection (15) the expression follows:

$$\frac{\theta_R^0}{1 - \theta_R^0} = \frac{\sigma_e^0}{\rho_e^0} \exp \left\{ \frac{F[\varphi(0) - E]}{RT} \right\}, \quad (16)$$

where $\sigma_e^0/\rho_e^0 = k_e$ apparently has the sense of the partition coefficient of electron between the film under study and the substrate. As should be expected, Eqn (16) follows from the first equation of the system (2) at j_{im} and α_0 equal to zero. Substituting Eqn (16) into Eqn (15) suggests that for this model of the film–substrate interface the exchange current I_{im}^0 is independent of the electrode potential:

$$I_{im}^0 = -F\sigma_e^0 \text{ at } \varphi_s(0) = E \text{ and } \alpha_0 \approx 0.$$

We can also make certain that the exchange current I_{im}^0 depends on the potential E if the same interface can be described by the Stern model. The form of this dependence will be reported elsewhere. Seemingly, the possibility of deriving, in the framework of the model approach employed, relationships for other impedance parameters of the modified electrode, namely, the film interface capacitance, transference numbers for the diffuse layers and the asymmetry factors does not require special comments. We will only point to this possibility.

In describing the impedance of the systems considered by Vorotyntsev *et al.*^{16,17} an important role was played by the choice of convenient variables to be analysed, namely, the charges

$$\delta q_s(k) = Fz_s \int_{1/k_f(k)} \delta c_s dz$$

in the diffuse layers of the film [$1/k_f(k)$ is the thickness of the diffuse layer at the k th interface ($k = 0, L$), $s = m, R$ is the index of the charge carriers under consideration]. A local change in the concentration of the s th sort of current carriers, $\delta c_s(z)$, due to application of an ac voltage, δE , to the system corresponded to the division^{16,17} of the total concentration, C_s , of this sort of particles into two components, $C_s = \delta n_s + \delta c_s$. The first component corresponds to the concentration that fulfils the condition for local electrical neutrality, that is, $z_m \delta n_m(z) = \delta n_R(z)$, while the second component corresponds to the deviation of the concentration of these particles from the 'electrically neutral' value δn_s . Clearly, the second component differs from zero only within the bulk charge regions (diffuse layers of the film in the vicinity of the film–

substrate and film–electrolyte solution interfaces). If we know the dependence of the charges $\delta q_s(k)$ in the diffuse layers on the increments of the concentration $\delta n_R(k, t) = z_m \delta n_m(k, t)$ and the potential jump in the k th diffuse layer $\delta \Delta \varphi(k)$, Eqns (2)–(6) can be solved correctly.^{16,17} Eventually, this makes it possible to derive the expression for the impedance of the system under study. Without dwelling on details of the solution we will note that the $\delta q_s(k)$ values were determined^{16,17} owing to the use of the Gibbs equation at the film interfaces

$$d\sigma(k) = q(k)d\delta \Delta \varphi(k) + \sum_{s=R}^{s=m} \Gamma_s(k)d\mu_s(k).$$

Here, summation was performed over two components (electrons localised on the reduced fragments of the film and counterions) ignoring a possible contribution of solvent molecules incorporated into the film. Since, owing to the condition for electrical neutrality, the increments of the chemical potentials $d\mu_s(k)$ are interrelated

$$\delta n_R(k) = z_m \delta n_m(k),$$

the tension $\sigma(k)$ (at the k th interface) depends on only two variables [$\delta \Delta \varphi(k)$ and $\delta n_R(k)$]. Based on the fact that the derivative $\partial^2 \sigma(k)/\partial[\delta \Delta \varphi(k)]\partial[\delta n_R(k)]$ is independent of the order of differentiation with respect to the variables $\delta \Delta \varphi(k)$ and $\delta n_R(k)$, expressions relating the charges $\delta q_s(k)$ to the total charge increments $\delta q(k) = \delta q_m(k) + \delta q_R(k)$ and $\delta n_R(k)$ were obtained:^{16,17}

$$\delta q_m(k) = \eta_m(k)\delta q(k) - C_f^{(k)} \left[\frac{d\mu_m(k)}{z_m F} - \frac{(-1)^{z_m} d\mu_R(k)}{F} \right],$$

$$\delta q_R(k) = \eta_R(k)\delta q(k) - C_f^{(k)} \left[\frac{d\mu_m(k)}{z_m F} - \frac{(-1)^{z_m} d\mu_R(k)}{F} \right].$$

Derivation of these relations requires the introduction of the (i) transference numbers for the diffuse layers [$\eta_m(k)$, $\eta_R(k)$] with respect to corresponding current carriers and (ii) asymmetry factor $C_f^{(k)}$, which are generally different for different film interfaces. The introduction of the $\eta_m(k)$ and $\eta_R(k)$ numbers is due to the necessity of taking into account the contributions of the $C_i(k)$ and $C_m(k)$ capacitors (see circuit in Fig. 3) to the resulting capacitance, $C(k)$, of the k th interface, whereas the factor $C_f^{(k)}$ describes the effect of the concentrations of both types of current carriers [at $z = 1/\kappa_f(0)$ and $z = L - 1/\kappa_f(L)$] on the charging of this interface. Since the sum of the transference numbers for the diffuse layers with respect to electrons and counterions equals unity^{16,17} [$\eta_R(k) + \eta_m(k) = 1$], the total number of phenomenological parameters for the description of each interface appears to be equal to four (with inclusion of the interface capacitance and exchange current for one or another stage of injection). This means that in the general case the overall expression for the impedance of a modified electrode

$$\begin{aligned}
Z(\omega) = & R_f + R_s + Z(0, \omega) + Z(L, \omega) + \\
& + Z_f(t_m, D_{eff}, A_0, \eta_m(k), C_f^{(k)}, C(k), I_{im}^0, I_m^0, \omega) \quad (17)
\end{aligned}$$

should contain not only the parameters of transport in the bulk film, namely, t_m , D_{eff} and A_0 (where t_m is the transference number of counterions in the bulk film) but also additional eight parameters characterising the charging and injection at the film interfaces.

A salient feature of the impedance $Z(\omega)$ is as follows. Generally, the impedance is not an additive sum of the solution resistance R_s , instantaneous resistance of bulk film $R_f = RTL/\alpha F^2 D_{eff}$, and the impedances of both interfaces:

$$Z(0, \omega) = \left[\frac{F|I_{im}^0|}{RT} + i\omega C(0) \right]^{-1}$$

and

$$Z(L, \omega) = \left[\frac{F|z_m I_m^0|}{RT} + i\omega C(L) \right]^{-1},$$

and the diffusion impedance of the bulk film. The impedance component Z_f in expression (17) includes cross-effects that characterise both the direct effect of the current carrier concentration gradients that appear in the bulk on the charging of the diffuse layers and the reverse effect of the charging of these layers on transport in the bulk film. The necessity of these effects apparently follows from relations (13), according to which the rate of charge carrier injection into the film is determined by not only the potential jump at the k th interface but also the concentration shifts $\delta C_m(k, t) = \delta n_m(k, t)$ at the boundaries of the electrically neutral bulk film adjacent to the diffuse layers. Only for the frequencies at which the reactive components of the interface impedances are small compared to the active components of the interface impedances

$$\frac{F|I_{im}^0|}{RT} \gg \omega C(0) \text{ and } \frac{F|z_m I_m^0|}{RT} \gg \omega C(L),$$

expression (17) is transformed into the following relationships

$$Z(\omega) = R_f + R_s + \frac{RT}{F|I_{im}^0|} + \frac{RT}{F|z_m I_m^0|} + \frac{(t_{im}^2 + t_m^2)RT}{F^2 A (i\omega D_{eff})^{1/2}} \left\{ \frac{A_0}{C_R^0 (1 - \theta_R^0)} + \frac{1}{z_m^2 C_m} \right\}, \quad (18)$$

$$Z(\omega) = R_f + R_s + \frac{RT}{F|I_{im}^0|} + \frac{RT}{F|z_m I_m^0|} + (1 - 3t_m t_{im}) \left\{ \frac{A_0}{C_R^0 (1 - \theta_R^0)} + \frac{1}{z_m^2 C_m} \right\} \frac{LRT}{F^2 A (3D_{eff})}, \quad (19)$$

for the limiting cases of high ($\omega L^2/D_{eff} \gg 1$) and low ($\omega L^2/D_{eff} \ll 1$) frequencies, respectively. Expressions for the Warburg impedance components follow from Eqns (18) and (19) and have the form

$$\text{Re}Z_w(\omega) - \text{Re}Z_w(\infty) = -\text{Im}Z_w(\omega) = \frac{RT(t_{im}^2 + t_m^2)}{C_{eff} F^2 (2\omega D_{eff})^{1/2}}$$

at $\omega L^2/D_{eff} \gg 1$, where

$$\text{Re}Z_w(\infty) = R_f + R_s + \frac{RT}{F|I_{im}^0|} + \frac{RT}{F|z_m I_m^0|};$$

$$C_{eff} = \left[\frac{A_0}{C_R^0 (1 - \theta_R^0)} + \frac{1}{C_m^0} \right]^{-1},$$

and for the low-frequency limiting imaginary component of the impedance

$$-\text{Im}Z_w(\omega) = \frac{1}{\omega F^2 C_{eff} L} \text{ at } \omega L^2/D_{eff} \ll 1.$$

They are most widely used in processing the data on the impedance of modified electrodes. In the Gabrielli model,¹² the components of the interface impedances ($RT/F|I_{im}^0|$ and $RT/F|z_m I_m^0|$) from relations (18) and (19) are in essence formally replaced by the impedance

$$Z(0, \omega) = \left\{ \frac{F|I_{im}^0|}{RT} + i\omega C(0) \right\}^{-1}$$

and

$$Z(L, \omega) = \left\{ \frac{F|I_{im}^0|}{RT} + i\omega C(L) \right\}^{-1},$$

respectively. From consideration of Refs 16 and 17 given above it is clear that this replacement as well as representation of the

impedance by expressions (18) and (19) may appear to be quite incorrect. It should be noted again that in the framework of the model described all eight parameters (see above, except for the rate constants for injection σ_e^0 and ρ_e^0) characterising the charging of the film interfaces can be expressed through the bulk film properties, electrode potential and electrolyte concentration. This was demonstrated above taking the injection rate as an example. As to calculations of other parameters, relations¹⁶ between them and the electrode potential and electrolyte concentration exemplify the realisation of this possibility for a system consisting of two metallic electrodes and a binary electrolyte solution. Extension of these results to the modified electrode will be reported elsewhere. Here we can only mention that carrying out such an analysis (or similar analysis in the framework of other models) will indicate that only the parameters of charge transport in bulk polymer films should be taken into account.

IV. Experimental results on the impedance of modified electrodes

Among the best studied and at the same time simplest systems are inorganic redox polymer films, in particular, films based on various metal hexacyanoferrates. They belong to zeolite-type inorganic compounds with rigid crystal lattice and alkali metal cations can migrate into and out of the film structure. Since the lattice structure of such films has been well studied and the stoichiometry of corresponding compounds established reliably, they can be treated as convenient systems for experimental evaluation of the available concepts of charge transfer in electroactive polymer films.

The kinetics of electrode processes in Prussian blue (PB) films was studied by the EIS method.^{50–54} The EIS spectra of the PB films deposited on a platinum substrate exhibited no high-frequency semicircle and the major portion of the spectrum corresponded to the Warburg diffusion impedance.^{53, 54} Analysis of the EIS spectra obtained in the framework of the homogeneous film model showed⁵³ that the model correctly describes diffusion-controlled charge transport in the film. It was established^{53, 54} that a decrease in the film thickness leads to shortening of the Warburg region $Z_d(\omega^{-1/2})$, however, as should be expected from theoretical predictions [see Eqn (18)], this is not accompanied by significant changes in the slope. The diffusion coefficients D_{eff} , calculated for the first redox process, namely, recharging of outer-sphere ions $\text{Fe}^{3+}/\text{Fe}^{2+}$, were found to depend on the nature of the cation of the bathing electrolyte and decreases in the order $\text{K}^+ > \text{NH}_4^+ > \text{Cs}^+$. It was also found that for both redox processes the plots of the diffusion coefficients vs. the initial potential of the PB film exhibit maxima near the formal potentials. This is consistent with the published data.⁵¹

At the highest frequencies, the impedance spectra of the PB films synthesised on an oxide ($\text{SnO}_2 + \text{In}_2\text{O}_3$) conducting substrate in 1 M KCl solutions exhibited semicircles characteristic of retarded interfacial charge transfer.^{50–52} At lower frequencies, the Warburg impedance region was followed by a poorly pronounced initial part of the capacitive behaviour of the film. The resistance, R_{et} , of 'thick' PB films (film thickness $> 1 \mu\text{m}$) reached a value of 3.3Ω at the formal potential of the first redox process and was treated as the resistance of the electrode–film interface. This conclusion is consistent with the published data,^{53, 54} from which it follows that replacement of the oxide substrate by a platinum substrate should lead to disappearance of the semicircle in the spectrum. The coefficients of charge carrier diffusion in the film were calculated from analysis of the impedance response at medium frequencies⁴² assuming that the PB film consists of two layers with different transport characteristics, namely, a compact inner layer and a more porous outer layer. It is believed^{51, 52} that the diffusion coefficients calculated for these layers (4.6×10^{-10} and $1.1 \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$, respectively) correspond to slow motion of counterions.

The EIS spectra of cobalt hexacyanoferrate (CoHCF) films on a platinum electrode exhibit a Warburg portion at high frequencies and the capacitive behaviour of the film at low frequencies.^{55,56} Deviations from the major linear part of the Warburg plot at the highest frequencies were explained⁵⁶ by the bilayer character of the system comprising a relatively thin dense layer and a thicker porous layer.

The diffusion coefficients D_{eff} derived for the compact and porous layers from the slopes of the linear portions are respectively 2.4×10^{-12} and $1.1 \times 10^{-11} \text{ cm}^2 \text{ s}^{-1}$ at $E = 0.4 \text{ V}$ and 8.4×10^{-11} and $3.7 \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$ at $E = 0.8 \text{ V}$. The higher diffusion coefficients at 0.8 V can be a consequence of different nature of the redox processes occurring at 0.8 and at 0.4 V. The diffusion coefficients of the CoHCF films are in reasonable agreement with the published data for PB films.

The effect of the substrate material on the high-frequency semicircle in the EIS spectra was also established in studies of indium hexacyanoferrate (InHCF) films in potassium nitrate solutions.^{57–59} Replacement of platinum substrate by glassy carbon one as well as an increase in roughness of the platinum surface led to considerable increase in the charge transfer resistance R_{ct} (up to a factor of 7); however, the interfacial capacitance C_{dl} decreased to almost the same extent and the product, $R_{\text{ct}}C_{\text{dl}}$, remained nearly constant. Changes in the substrate roughness had no effect on the measured effective diffusion coefficient D_{eff} ; hence, the bulk film structure is independent of the substrate material. Based on these facts, it was concluded that the process is controlled by charge transfer across the interface between the InHCF films and the support electrode.^{58,59}

Another interpretation of the observed impedance spectra was reported⁵¹ in a CV and EIS study of charge transfer on composite electrodes (geometric surface area of 0.2 cm^2) fabricated from a mixture of powdered copper hexacyanoferrate (CuHCF) and impregnated graphite. The EIS spectra of these electrodes exhibited a distorted semicircle which was considered as consisting of two components. The first of them, contributing largely to the high-frequency spectral region, was attributed to electron transfer in the bulk film. The electron diffusion coefficient was estimated from parameters of this component at $D_e = 0.1 \text{ cm}^2 \text{ s}^{-1}$. The high D_e value was treated as an indication of the semiconductor conductivity mechanism involving the valence band instead of conventionally assumed hopping mechanism of charge transfer.⁶⁰ The second semicircle was ascribed to slow injection of counterions (K^+ ions) into the metal hexacyanoferrate crystallites. However, then the authors of Ref. 60 made a conclusion about the hopping mechanism of charge transfer in the metal hexacyanoferrate crystallites and calculated $D_{\text{eff}} = 1.5 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$ from the observed portion of the Warburg impedance. Large difference between the D_e and D_{eff} values indicates a slow diffusion of counterions in the metal hexacyanoferrate crystallites.

The charge transfer resistances R_{ct} , determined from the high-frequency semicircle in the impedance spectrum of poly-[NiMe₂Salen] films in 0.1 M solutions of tetraethylammonium tetrafluoroborate in acetonitrile, were ascribed to the film–electrolyte solution interface.⁵² The R_{ct} values were almost independent of the potential in the region of electrical activity of the film (0.8–1.1 V). Analysis of the impedance spectra at medium and low frequencies permitted the determination of the low-frequency capacitance C_{lf} and the effective diffusion coefficient D_{eff} . The D_{eff} values calculated from the slopes of the Warburg portions of the spectrum using the relationships for the homogeneous film model ($\approx 3 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$) are about two orders of magnitude higher than the D_{eff} value found from the CV current peaks using the Randles–Sevcik equation.⁶¹ It was assumed that this discrepancy is mainly due to the neglect of the short-range forces between film fragments in the calculations using the Randles–Sevcik equation. The observed large half-width of CV peaks points that this effect, which corresponds to large positive values of the attraction constant α_0 [see the system of equations (2)], should also be taken into account.

Among conducting polymers with conjugated bonds, polypyrrole, polythiophene and substituted polythiophene films exhibit a relatively simple electrochemical behaviour. When using non-aqueous solvents, these systems are free from problems that are due to protonation effects and certain redox processes, which is characteristic of, *e.g.*, polyaniline-based polymers.

In most cases the impedance of such systems can to a first approximation be correctly described by the circuit shown in Fig. 2a. A similar spectral pattern or certain characteristic parts of the spectrum were found for polypyrrole and its derivatives^{6,62–74} and for polythiophene-based polymers.^{13,75–93} For instance, the high-frequency semicircle (usually, it is distorted and more correctly, suppressed) and an extended (with respect to frequencies) capacitive response were observed for polypyrrole films on various substrates in solutions of LiClO_4 in propylene carbonate^{69–73} and in aqueous KCl solutions.^{6,74} Similar parts in the impedance spectra were observed for polythiophene derivatives, namely, poly(3-methylthiophene) (PMT),^{75–79,85,86} poly(3-octylthiophene) (POT),^{80,84,87} poly(3,4-ethylenedioxythiophene)^{90–93} and some other compounds.^{88,89} It was also reported that the impedance spectra of the reduced or weakly oxidised forms of polythiophenes exhibit not only the high-frequency semicircle regions and low-frequency capacitive responses at medium frequencies but also parts corresponding to the Warburg impedance with slopes approaching unity.^{82,83,87} The high-frequency semicircle was most pronounced for little doped polypyrrole.^{70,74} The presence of the high-frequency semicircle and noticeable capacitive response was also reported⁷¹ for polypyrrole, poly(3,6-dioxyheptylpyrrole) and poly(3-methylthiophene) films in 1 M LiClO_4 solutions in propylene carbonate [for poly(3-methylthiophene) and for solid electrolytes based on poly(ethylene oxide), (PEO)₂₀ LiClO_4].

Thus, the impedance spectra of polypyrrole- and polythiophene-based polymer films exhibit characteristic portions with well-separated frequency regions corresponding to the kinetics of different stages of charge transfer. This points to common nature of electrode processes in these polymers. Now we will dwell on the results obtained for particular systems in which the impedance parameters were analysed systematically.

From the impedance measurements of polypyrrole films at specified constant frequencies ($f > 10 \text{ Hz}$) it was found⁶² that the plots of the film capacitance, C_p , and conductivity, $1/R_p$, vs potential have maxima at the formal potential [$E = (E_{p,k} + E_{p,a})/2$]. Analysis of the frequency dependences of these parameters suggested⁶² that polypyrrole behaves as a porous material whose resistance is mainly due to the resistance of the electrolyte filling its pores. High film capacitances (a few mF cm^{-2}) were attributed to the double layer capacitance of the developed inner surface of the polymer. It should be noted that in most studies^{65–68} on polypyrrole it was concluded that in the conducting state the rate of charge transfer in the polypyrrole film is controlled by the diffusion of ClO_4^- anions.

Typical impedance spectra exhibiting three noticeable regions (capacitive, Warburg and high-frequency semicircle) were observed for polypyrrole films in various aqueous electrolyte solutions.⁷⁰ Using these data, the electron diffusion coefficient for polypyrrole films was calculated, $D_e \approx 10^{-3} \text{ cm}^2 \text{ s}^{-1}$. It was found⁶² that the ion diffusion coefficient D_m for the film ($L = 15 \mu\text{m}$) strongly depends on the nature of the anion in the electrolyte, namely, $D_m = 2.5 \times 10^{-6}$ (Cl^-), 6.2×10^{-7} (ClO_4^-), 8.2×10^{-8} (SO_4^{2-}) and $\sim 1 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$ (tosylate ion) and weakly depends on the nature of the cation in the electrolyte (H^+ , Na^+ , Me_4N^+). Particular attention was given^{63,64} to analysis of the capacitive regions of the impedance spectra of polypyrrole films. An attempt was made to separate the contributions of the capacitive and Faradaic currents to the overall impedance response. The capacitive component was attributed to the charging of the double layer at the film interface and the Faradaic component was attributed to the incorporation of the dopant anions, ClO_4^- , into compact film fragments.

The impedance spectra of polythiophene films were analysed as functions of the potential and film thickness for asymmetric configuration of the metal–polymer–solution system characteristic of modified electrode and for symmetric configuration (metal–polymer–metal) using air-dry film.¹³ The high-frequency semicircle in the spectrum obtained for the asymmetric configuration and the derived parameters of the RC -circuit ($R_{ct} \approx 30 \Omega \text{ cm}^2$ and $C_{dl} \approx 1\text{--}5 \mu\text{F cm}^{-2}$) were ascribed to the film interface. However, strictly speaking, no experimental facts for identification of this interface (substrate or solution) are available. The calculated¹³ diffusion coefficient D_- attributed to the motion of ClO_4^- anions in the film were of the order of $(0.05\text{--}1.2) \times 10^{-12} \text{ cm}^2 \text{ s}^{-1}$. The D_- value increased almost linearly with an increase in the polythiophene film thickness from 0.1 to 1.6 μm , which suggested an inhomogeneous film structure (in particular, formation of a more porous structure with an increase in the film thickness). The diffusion coefficients D_- were calculated with inclusion of the relations for the Warburg constant that follow from the classical electrochemistry. As was shown in a number of studies, these relations require redefinition of parameters which have a more complex sense in the case of modified electrode. Probably, so low D_- values are due to the calculation procedure employed, being not reliable.

The system platinum electrode–PMT film in a 0.2 M LiClO_4 solution in MeCN was studied by the electrochemical impedance method.⁷⁵ It was established that the impedance spectra of the films of the reduced form of PMT exhibit a semicircle which is gradually transformed into the capacitive response of the film as the frequency decreases. On going to the oxidised form of PMT the diameter of the semicircle noticeably decreases; the charge transfer resistance R_{ct} derived from the diameter of the semicircle was about $15\text{--}20 \Omega \text{ cm}^2$. This R_{ct} value was attributed to the bulk polymer resistance assuming the major contributions of the conductivity of the electrolyte in pores of the polymer for the oxidised form of the PMT film and the electron conductivity for the reduced form of the PMT film. However, this assumption was unsubstantiated.⁷⁵ The diffuse part of the spectrum, which is usually characterised by a unity slope of the $Z_{Re}(Z_{Im})$ plot, was almost not observed. At the same time, data analysis allowed the authors to find the diffusion impedance component and to determine the coefficient of charge carrier diffusion in the film (D varied from 1.5×10^{-14} to $1 \times 10^{-12} \text{ cm}^2 \text{ s}^{-1}$), which was attributed to diffusion of the dopant ions in the film. The lowest D values were obtained for thin (about 20 nm) polymer films. Since the coefficient D characterises diffusion of ions both in the compact polymer and in pores, the fact⁷⁵ that D values are independent of film thickness indicates that the average size of dense domains (aggregates) and the average pore size behave analogously. It should be noted that very low values of diffusion coefficients⁷⁵ are inconsistent with the assumptions of high film porosity and corresponding capacitive response. Besides, at such D values one would observe a large contribution of the diffusion resistance of the film; however, the impedance spectra in the frequency range $10^4\text{--}10^{-3} \text{ Hz}$ exhibited no Warburg response with a characteristic linear dependence with a slope approaching unity (see above).

The impedance of PMT films was also measured in 0.1 M $\text{NBu}_4^+\text{PF}_6^-$ solution in propylene carbonate⁷⁷ and in 0.05–0.5 M LiClO_4 solutions in acetonitrile.⁸⁶ Strongly suppressed, poorly pronounced high-frequency semicircles were observed in both cases. The mid-frequency parts of the spectra exhibited some indications of the Warburg impedance and transformed into abruptly rising curves associated with the capacitive response of the films. The charge transfer resistance determined from the diameter of the semicircle ($30\text{--}60 \Omega \text{ cm}^2$) was attributed to the film–electrolyte solution interface.⁷⁷ The estimates of the coefficients of charge carrier diffusion obtained from direct measurements of the electron and ionic components of the conductivity of the PMT film are $D_e = 5.6 \times 10^{-3}$ and $D_i = 1.6 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$. Thus, from the results obtained it follows that the mobilities of

electrons and counterions (PF_6^-) in the polymer phase differ by a factor of 10^6 and the overall charge transfer is controlled by the diffusion of counterions in bulk polymer. The dependence⁶⁹ of the impedance parameters on the PMT film thickness was explained with allowance for the porous structure of the polymer films. It should be noted that, in spite of considering a porous film, the authors⁷⁷ reported the possibility of interpreting the same results in the framework of the homogeneous film model. However, parameters obtained in such a fashion have different physical meaning.

It was found⁸⁶ that the high-frequency semicircle in the spectrum becomes more pronounced as the LiClO_4 concentration decreases by an order of magnitude; the diameter of the semicircle increases by about a factor of four. The authors⁸⁶ concluded that the appearance of the semicircle in the EIS spectra is due to predominant contribution of the impedance of the film–electrolyte solution interface in this frequency range. Slow charge transfer at this interface seems to be due to partial desolvation of dopant anions (ClO_4^-) during incorporation of these ions into the polymer matrix. This conclusion was confirmed by the results obtained in a study⁹⁴ on the effect of solvent viscosity and the size of the solvent molecules on the reversibility of the oxidation of poly(3,4-ethylenedioxythiophene) films. Seemingly, yet another argument in favour of this assignment is provided by a decrease in the resistance R_{ct} with an increase in the film thickness; here one can assume that the outer surface of the film becomes looser (see above). A decrease in R_{ct} with an increase in the electrode potential was explained⁸⁶ by additional solvation of the polymer molecules upon swelling of the film, which leads to a decrease in the energy barrier to incorporation of the dopant anions into the film. The effective diffusion coefficients, D_{eff} , of PMT films calculated using the homogeneous film model were almost independent of the potential in the range 0.6–1.2 V [$D_{\text{eff}} = (1.3\text{--}2.3) \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$].

Impedance measurements of PMT films deposited on platinum in aqueous electrolyte solutions containing different anions were reported.⁷⁸ It was concluded that the charge transfer resistance at the film–solution interface contributes largely to the measured impedance. The overall patterns of the impedance spectra of PMT films were also reported;^{80, 81} however, here the authors made only qualitative conclusions about the appearance of incomplete high-frequency semicircle and low-frequency pseudocapacitive response.

Significantly different impedance spectra of the neutral and oxidised forms of POT were obtained with the Pt/POT-electrode immersed in a 0.1 M solution of LiBF_4 in propylene carbonate.^{82–84} The spectra of the neutral form of POT (at potentials $E = 0.0\text{--}0.7 \text{ V}$) exhibited a semicircle corresponding to a rather high resistance R_{ct} (about 30 k Ω). The impedance spectrum of the neutral form of POT was explained⁸² by the effects of the double layer with $C_{dl} = 2 \mu\text{F cm}^{-2}$, which was attributed to the polymer–electrolyte solution interface. For the doped (oxidised) form of POT (at $E = 0.8\text{--}1.2 \text{ V}$) the semicircle becomes more pronounced and its diameter considerably decreases as the degree of film oxidation increases, namely, R_{ct} decreases to 980–790 Ω at a potential of 1.2 V. As the potential changes in the range 0.8–1.2 V, the capacitance C_{dl} increased by nearly a factor of 1.5 (from 2.8 to 4 $\mu\text{F cm}^{-2}$) and the low-frequency capacitance C_{lf} changed from 0.76 to 4.1 mF cm^{-2} . The coefficients of charge carrier diffusion, determined at different oxidation states of the POT film lie in the range $(1\text{--}8) \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$. Similar measurements for poly(3-octylthiophene) films were carried out in solutions of lithium perchlorate in acetonitrile.^{86, 87} The pattern of the impedance spectra is consistent with the data obtained for solutions of LiBF_4 in propylene carbonate. Three characteristic spectral features were revealed, *viz.*, the high-frequency semicircle, the transient spectral region and an abrupt increase in the imaginary impedance component, $-Z_{Im}$, with a decrease in frequency. As the degree of film oxidation increases, the diameter of the semicircle and the transient region at medium frequencies

decreases appreciably (for the neutral form of the polymer, the transient region exhibits the properties of the Warburg impedance). The diffusion impedance components are particularly pronounced when analysing the data in the $-Z_{\text{Im}}, Z_{\text{Re}}-f^{-0.5}$ coordinates. This analysis reveals parallel linear regions indicating diffusion-controlled charge transfer in the film. The diffusion coefficients, which apparently should be associated with the diffusion of counterions (ClO_4^-), depend on the potential and are as follows:

E/V	0.8	0.9	1.0	1.1	1.2
$10^7 D/\text{cm}^2 \text{ s}^{-1}$	0.29	0.68	1.5	6.3	17

Similar values of the diffusion coefficient of BF_4^- ions ($D_{\text{eff}} = 8 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$ for the potential of the anodic maximum in CV) were reported for POT films.⁸²

In contrast to the spectra considered above, in most cases the impedance spectra of polyaniline films and films based on polyaniline derivatives, *e.g.*, poly(*o*-phenylenediamine) (PPD) and poly(*o*-aminophenol) (PAP), have a more complex shape. This manifests itself in the absence of well-defined spectral regions which could be associated with particular processes. In other words, the impedance spectra of these systems cannot be described by simple theoretical relations.

The impedance of polyaniline films was studied in hydrochloric acid.⁹⁵ The dependences of the capacitance and conductivity on the potential measured at a constant frequency of 10 Hz exhibit maxima in the region of electrical activity of the film. The authors⁹⁶ reported a thorough analysis of the published data⁹⁵ and concluded that the properties of the polyaniline film can be explained with allowance for the porous film structure.

Based on the IR spectroscopy and quartz microbalance data for PPD and PAP films, it was established^{89,90} that the electrode process in acid aqueous solutions involves hydrogen ions as charge-compensating ions. In contrast to the processes in polyaniline, here anions are involved in the electrode process to a much lesser extent, although some researchers intensively elaborate anion-related concepts.

The EIS spectra of PPD films exhibit a region corresponding to the Warburg impedance and a poorly pronounced low-frequency capacitive response.⁹⁷ Analysis of the impedance spectra and estimation of parameters of the processes were carried out in the framework of the homogeneous film model. It was established that the low-frequency capacitance is proportional to the film thickness and the maximum capacitance is reached at the formal potential of the polymer. A minimum of the Warburg constant and the maximum width of the Warburg impedance region were also observed near the formal potential.

The effective diffusion coefficients are of the order of $(1-10) \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ depending on the film potential.⁹⁷ It was concluded that charge transfer is controlled by electron 'diffusion' and the 'electron diffusion coefficient' D was estimated at $D_e = 2 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$. At the same time it was reported that the model used is irrelevant to specific features of the processes occurring in the polymer, in particular, to protonation of the redox centers in the film.

A solution study⁹⁸ of the impedance spectra of PPD film on glassy carbon in a broad range of pH values allowed the dependence of the film parameters on the concentration of hydrogen ions to be analysed in detail. It was found that at low pH values the impedance spectra were slightly different from the published spectra^{97,99} and a high-frequency semicircle appeared in the spectra at $\text{pH} > 4$. The key parameters, *viz.*, interfacial charge transfer resistance R_{ct} , low-frequency capacitance C_{lf} and the effective diffusion coefficient D_{eff} were determined⁹⁸ using relations for the homogeneous film impedance. It was established that the capacitance C_{lf} and diffusion coefficient D_{eff} depend on potential and reach maximal values near the formal potential.

An increase in D_{eff} with a decrease in pH value was treated as an indication of the fact that electron transfer is accompanied by intermolecular proton transfer and the shape of this dependence

was explained by an increase in the rate constant for homogeneous electron transfer upon protonation of the polymer.

The electrochemical properties of PPD films in solutions of different anionic compositions at different pH values were also studied.⁹⁹ The impedance spectra of the PPD films exhibited a 'non-classical' shape, which was probably due to similar values of the characteristic relaxation frequencies corresponding to diffusion and pseudocapacitive charging of the film.

To describe these EIS spectra, the equivalent circuit (see Fig. 2a) was modified⁹⁹ by introducing an additional capacitance and a CPE element responsible for occurrence of certain reactions with solution components and for structural features of the film (namely, film porosity). Finally, processing of the spectra gave dependences of the effective diffusion coefficient D_{eff} on the potential E for PPD films. The D_{eff} values calculated using any of the three models employed by the authors vary by several orders of magnitude as the electrode potential increases by 400 mV. These changes in D_{eff} values were explained by strong interaction between electroactive centres in the polymer and counterions.

Analysis of the EIS spectra of PPD films was continued in the next study⁴⁶ reported by the same authors. To describe the EIS spectra, they elaborated a new model with inclusion of diffusion and migration of three charge carriers (proton, electron and anion) in bulk film. Expressions for the impedance were derived with allowance for the effects of two interfaces (electrode–film and film–solution). The equivalent circuit proposed for this model is shown in Fig. 5.

Figure 5. Equivalent circuit of PPD films.⁴⁶

Z_1 and Z_3 are the impedances of the interfaces; Z_2 is the bulk film impedance; C_1 and C_3 are the capacitances of the interfaces; R_t is the shunt resistance responsible for charge leakage; and R_u is the solution resistance.

Among quantitative results obtained,⁴⁶ the diffusion coefficients and the double layer capacitances deserve particular attention. Despite the fact that the diffusion coefficients vary by several orders of magnitude as the potential changes (this is similar to study⁹⁹), no comments were made. The interfacial capacitances ($C_1 = 80-200$ and $C_3 = 300-450 \mu\text{F cm}^{-2}$) exceed conventional values of the double layer capacitances. A possible explanation for this anomaly for the metal–film interface (C_1) is provided by roughness of the electrode surface, *i.e.*, larger actual surface area compared to the geometric surface area. However, the effect of adsorptive capacitance on C_1 and C_3 seems to be a more probable explanation.

Analysis of the results obtained in this study revealed some difficulties faced by the authors in constructing their own, 'improved' models of charge transfer in order to describe complex, 'non-classical' impedance spectra with poorly separated frequency regions corresponding to a certain process. As a rule, mathematical formalism employed is rather complicated and includes parameters that are often difficult to compare with real characteristics of the system under study. Besides, a large number of such parameters complicates processing of experimental data, which forces the authors to essentially simplify their models in order to decrease the number of independent variables. Sometimes, this leads to paradoxical consequences as in, *e.g.*, the study considered above. Having elaborated a rather complex model of

charge transfer involving three different current carriers, in processing experimental data the authors had to reduce the number of particles to two, thus returning, in essence, to the well-known formalism.

Dispersion of the low-frequency capacitance, which is characteristic of the impedance spectra of PPD films was investigated.^{100, 101} The authors concluded that this phenomenon is due to inhomogeneity of the polymer surface, whereas the surface structure of the conducting substrate and the binding of counterions in the film have no effect on the dispersion of the low-frequency capacitance. This is inconsistent with theoretical consequences reported in other studies,^{72, 73} according to which one should observe a noticeable effect of the binding of counterions on the low-frequency capacitance.

Poly(*o*-aminophenol) is one of the nearest analogues of PPD. As in the case of PPD films, studies of PAP films were accompanied by debates concerning the nature of counterions involved in the electrode process. Although a significant role of protons in charge transfer in these films is undoubtful,^{102–104} the authors of some studies (see, *e.g.*, Ref. 105) consider the involvement of anions of the bathing electrolyte as counterions. Nevertheless, the scheme^{102, 103} involving hydrogen ions as counterions should be considered as the most probable scheme of the redox processes occurring in such films.

The apparent diffusion coefficients of $(3.6 \pm 0.4) \times 10^{-10}$ and $(5.5 \pm 0.3) \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$ for the anodic and cathodic processes, respectively, are two orders of magnitude lower than the values obtained by the same authors for PPD.¹⁰²

PAP films were studied by the EIS method.¹⁰⁶ The EIS spectra were processed using the homogeneous film model.¹² The spectra obtained exhibited the high-frequency semicircle and a characteristic region corresponding to the low-frequency capacitance of the polymer. The following parameters of the semicircle were determined: the electrolyte resistance R_u ($2.8 \pm 0.5 \Omega$) and the charge transfer resistance θ attributed to the bulk film. Then the standard rate constant for charge transfer $k_{s,h} = (2.3 \pm 0.4) \times 10^{-6} \text{ cm s}^{-1}$ and the double layer capacitance $C_{dl} = (8 \pm 2) \times 10^{-6} \text{ F cm}^2$ were calculated. By analysing the pseudocapacitive spectral region the low-frequency capacitance, C_{lf} , of the polymer and the effective diffusion coefficient D_{eff} were determined. The latter parameter was almost independent of the potential and equal to $1.3 \times 10^{-11} \text{ cm}^2 \text{ s}^{-1}$, which, similarly to Ref. 102, is two orders of magnitude lower than the values obtained by the same method for PPD.^{97, 98} In spite of apparent simplicity and reliability of this 'classical' approach to processing of the EIS spectra, it casts some doubt when comparing the results obtained in different studies. For instance, the same authors studied¹⁰⁷ the dependence of charge transfer parameters in PAP films on the film thickness and ionic strength of the bathing electrolyte solution; the diffusion coefficients obtained under identical experimental conditions differed from the published data¹⁰⁶ by an order of magnitude. Even higher diffusion coefficients ($10^{-8} \text{ cm}^2 \text{ s}^{-1}$) were obtained¹⁰⁸ for PPD using the equations of the Mathias and Haas model.¹¹ In spite of different compositions of the bathing electrolytes used^{98–100} such a large discrepancy between the diffusion coefficients is hard to explain.

Unlike the Inzelt model, the charge transfer model developed in order to describe the EIS spectra of PAP¹⁰⁹ represents an attempt to allow for the effect of protonation on the EIS spectra. This model was based on the Gabrielli model¹² with inclusion of slow protonation in order to explain a strong effect of the pH values on the electrochemical properties of PAP and related polymers. The authors assumed that the proton concentration in the film is constant in time and independent of the electrode potential. Therefore, the distribution coefficient K_p was introduced, which determines the ratio of the concentrations of hydrogen ions in the film and in solution ($[H^+]_{film} = K_p \times [H^+]_{sol}$). Representing the reactions in the polymer by two consecutive stages (protonation and the redox process itself)

and assuming that the kinetics of the second stage at the electrode–film interface obeys the Butler–Volmer equation, the authors derived the final expression for the film impedance. Using this approach, experimental data were fitted quite correctly, reasonable values of diffusion coefficients were established (2.2×10^{-10} and $0.53 \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$ for pH values of 1 and 2, respectively) and the acidity constant K_a for the oxidised form of the polymer ($pK_a = 2.93$), consistent with the expected value for deprotonation of the amino group of polyaniline, was determined.¹¹⁰

It should be noted that the assumption of constant concentration of hydrogen ions in the film seems to be somewhat incorrect, because in this model protons are counterions and maintain electrical neutrality of the entire film. Mention should be made, also concerning other studies, that the results of approximation using different models for the same systems under study and similar experimental data often provide good agreement between experiment and theory. However, the physical meaning of the parameters obtained is often ambiguous.

The role of porosity in the charging of conducting polymer films has long been discussed in the context of the 'faradaic' and 'capacitive' components of the overall current.^{103–111} A number of methods for experimental separation of these contributions were proposed. Among them, the most important is spectroelectrochemical study of conducting polymer films in the UV and visible spectral regions.^{111–118} It was assumed that the capacitive current can be determined based on electrochemical measurements carried out along with optical spectral measurements, which contain information on changes in the concentration of the redox species (polarons, *etc.*) in bulk film. However, as was established to date, such a separation is impossible, because the surface and bulk film charging processes occur involving species of the same chemical nature. Therefore, the problem of interpreting the capacitive response is still to be solved.

Recently, spectroelectrochemical studies of conducting polymer films have been widely used to elucidate the nature of quasi-particles generated in films and the mechanism of the redox processes.^{119, 120}

When analysing the experimentally determined low-frequency capacitance C_{lf} of electroactive polymer films in the region of redox activity, in most cases C_{lf} is a parabolic function of the potential E with a maximum at an oxidation state θ of about 0.5. This is associated with the maximum value of the product of the concentrations of the oxidised and reduced fragments in the polymer near the formal potential. The experimentally observed dependence of C_{lf} on potential is in qualitative agreement with the theoretical ratio for the low-frequency capacitance, which follows from the homogeneous film model,

$$C_{lf} = \frac{AF^2L}{RT} \left\{ \frac{1 + \alpha_0 \theta_R^0 (1 - \theta_R^0)}{C_R^0 (1 - \theta_R^0)} + \frac{1}{z_m^2 C_m^0} \right\}^{-1}.$$

The C_{lf} – E curve calculated⁸⁷ for poly(3-octylthiophene) films is in good agreement with the experimental curve assuming a value of 6.8 for the fitting coefficient (interaction parameter α_0). According to the definition of the parameter α_0 , its sign and magnitude indicate a repulsive interaction between redox fragments in the film, with a rather high interaction energy. Similar character of the approximation of the experimental C_{lf} – E curve was established for PPD films.⁹⁷ Possible reasons for significant differences between theoretical and experimental curves include structural-chemical inhomogeneity of films leading to dispersion of the formal redox potentials and film swelling effects; both of them are ignored in the homogeneous film model.⁸⁷ It seems that these factors affecting the low-frequency capacitance cannot be formally 'included' by the fitting parameter of the model, α_0 .

An important feature of the capacitance C_{lf} experimentally observed for certain electroactive polymer films is the frequency dependence of this parameter. Up to now the nature of the frequency dispersion of the capacitance C_{lf} is a debated topic. Considerable attention to this issue was paid by Bisquert *et al.*^{72, 73, 121, 122} who reported detailed analysis^{72, 73} of the dependence of the low-frequency capacitance on the thickness of polypyrrole film and on the potential. The frequency dispersion of capacitance was explained⁷³ by film porosity and the experimental data were treated in the framework of the modified Albery model for charge transmission lines. However, from this analysis it follows that the specific low-frequency capacitance $C = C_{lf}/L = 100\text{--}200\text{ F cm}^{-3}$ is almost independent of film thickness. This points to a linear dependence of C_{lf} on the film thickness and, with allowance for the available data on noticeable changes in the morphology of polypyrrole films with an increase in the film thickness, suggests the volume character of the film charging rather than formation of charged double layers on the large inner surface of the porous film. In this case the dispersion of capacitance was associated⁷³ with effects of diffusion length (pore size and polymer grain size) distribution for charge carriers over the bulk polymer and with the binding of counterions in the film.

The data obtained in the impedance studies^{58, 59} of indium hexacyanoferrate films are of interest in the context of the problem of dispersion of the low-frequency capacitance. It was found that for potassium nitrate solutions the capacitive response fits well by a linear dependence of $-Z_{lm}$ on ω^{-1} , whereas a considerable change in the slope $\partial(-Z_{lm})/\partial(\omega^{-1})$ with frequency was observed for lithium nitrate solutions. These results were explained⁵⁹ by the binding of lithium ions to negatively charged film lattice fragments. The absence of dispersion of the capacitance of the InHCF film in the case of K^+ -containing solutions points that most of potassium ions in these films are in free state. As to the Li^+ -containing solutions, it seems likely that the contributions of the free and bound forms of counterions vary with frequency, thus being responsible for the observed frequency dependence of C_{lf} .

V. Conclusion

Analysis of electrochemical aspects of research on modified electrodes reveals that specific features of charge transfer in these systems due to mixed electron-ionic conductivity have, in principle, become understandable. Experiments showed that a large number of systems exhibit such features as simultaneous appearance of high-frequency semicircles and the presence of diffusion portions (Warburg impedance) in the EIS spectra and the absence of dispersion of the low-frequency capacitance, *i.e.*, behaves consistently with the homogeneous film model. However, quantitative agreement between experiment and theory is a long way in the future. The case in point consists in *a priori* uncertainty of the extent to which the charge transport parameters obtained correspond to real processes (in particular, processes at polymer film interfaces) rather than possible errors in determinations, which are usually performed using the simplified theory of homogeneous film impedance by Mathias and Haas. Therefore, the development of the theory of injection of current carriers into films and obtaining relevant experimental data are topical problems of investigations in the field of charge transport in modified electrodes.

A recent trend towards allowance for the structure of real polymer films and film morphology effects on the electrochemical properties indicates a new step in research on modified electrodes. Researchers have been refining their understanding of such systems. In this connection not only the problems considered above but also construction of correct models with inclusion of the film structure and their experimental evaluation seem to be important. And, as earlier, search for novel systems based on electroactive polymer films and fulfilling practical demands remains a task of paramount importance.

Abstract. The problems related to the synthesis of nanolayers of various classes of substances (inorganic, organic and hybrid, *i.e.*, inorganic/organic) by successive ionic, ionic–molecular and ionic–colloidal layer deposition are discussed. The experimental data are systematised in terms of the type of reaction occurring on the surface during the synthesis. The use of successive ionic layer deposition in nanotechnology for the preparation of practically valuable nanolayers is considered. These nanolayers include the layers in SnO₂-based conductometric gas sensors, passivating protective coatings on the metal surface, semiconductor cells for solar energy conversion, photo-, electrochromic and magnetic materials, pervaporation membranes, electrocatalysts, light diodes, and so on. The bibliography includes 201 references.

I. Introduction

The development of nanotechnology brings about new challenges for the preparative chemistry, in particular, the precision synthesis of nano- and multinano-layers and 2D and 3D-nanostructures based on inorganic, organic and hybrid (inorganic/organic) substances.

Among the procedures of such synthesis, ‘chemical assembly methods’,^{1,2} *i.e.*, layer-by-layer syntheses, occupy an important place. They are based on successive adsorption of low-dimensional precursors on the substrate surface with obligatory removal of an excess of non-consumed reagent. As a consequence, a layer of the substance being synthesised with a thickness of several nanometres or fractions of a nanometre (a nanolayer) is formed on the surface. Upon multiple repetition of the adsorption reactions, the layer thickness increases in proportion with the number of treatment cycles.

After the first publications by V B Aleskovskii and S I Kol'tsov,^{3,4} as well as T Suntola,⁵ the use of gaseous reagents for the thin-film synthesis began. This was believed to create

conditions for the complete irreversibility of the reactions. However, the design of these structures is faced with the problem of low volatility of the precursors at the relatively low temperatures used for this purpose (as a rule, lower than 400 °C).

In recent years, solutions of salts containing ions that react on the sorbent surface to give poorly soluble compounds have been used more and more often as reagents in the preparation of nanolayers.

Most of reactions of inorganic compounds are carried out in solutions. In particular, metal complexes are synthesised in solution and then isolated by crystallisation, extraction or another method. Solutions are also used for the preparation of thin films of inorganic compounds by chemical metallisation, alkaline oxidation, phosphatation or chromatation, which have found wide use in mechanical engineering for the protection of the surface of metal articles.

The key feature of these methods is the use of so-called mixing regime in which the final product is formed from a mixture of reactants as the equilibrium shifts towards the least soluble compound.

The first syntheses by the ‘layer-by-layer’ procedure using colloidal solutions were carried out by Iler.⁶ This procedure was further developed by using true solutions. The syntheses of ZnS and MnO₂ layers involving the cations and anions occurring in solutions were independently described in the patents by Nicolau⁷ and Tolstoy *et al.*⁸ The reaction conditions were found such that successive adsorption of cations and anions, which react to give the layer compound, takes place on the substrate surface in each stage of the synthesis.

This method of the synthesis has been called⁹ Successive Ionic Layer Deposition (SILD).[†] An obligatory condition for the layer synthesis by this method is removal of excess reagents and products, for example, by washing with a solvent after each stage of adsorption. If the excess of reagents is not removed, the synthesis of the layer will take place under ‘mixing’ conditions and it will be impossible to control precisely the thickness of the growing layer. This distinguishing feature of SILD is illustrated by Fig. 1, which shows the variation of the reagent concentration at the substrate–solution interface during the synthesis.

[†]Other names are Successive Ionic Layer Adsorption and Reaction (SILAR) or Layer-by-Layer (LbL) synthesis.

Figure 1. Variation of the reagent concentrations $C_{M_1A_1}$ and $C_{M_2A_2}$ in the layer at the solution–substrate interface during SILD synthesis (2 cycles).

τ_{res} is the residence time in solution of each reagent, τ_{rem} is the time of removal of excess reagent and reaction products by washing the substrate with the solvent.

The interest in these studies is increasing. Thus in the early 1990s several papers a year were published on this subject, in 2000 more than 200 papers appeared, while the number of publications in 2003 was ~ 400 . Reviews^{9,10} and a collective monograph¹¹ devoted to the synthesis of polyelectrolyte layers were published.

This study describes systematically the results of investigations on the nanolayer synthesis carried out during the last 10 years and considers the most promising fields of its application in nanotechnology for the solution of practically valuable problems.

II. Conditions for successive ionic layer deposition reactions

The SILD reactions on the substrate surface are carried out using two types of special automated equipment. Devices of the first type are designed for the synthesis of layers on the surface of block substrates. They consist of beakers with reagents, an electro-mechanical drive with a cartridge for samples and a PC-based control unit. The synthesis is performed by successive immersion of the specimen into solutions of reagents. It is assumed that in the beaker containing a solution of the cationic reagent, for example $Pb(NO_3)_2$ (the simplest case), adsorption of the Pb^{2+} cations on the substrate surface takes place and then excess reagent and reaction products are removed. During treatment with an anion-containing solution, for example Na_2S , in the other beaker, adsorption of the S^{2-} or HS^- anions takes place in a similar way. A SILD cycle gives rise to a single nanolayer of the compound being synthesised (in this case, PbS). When the cycle is repeated many times, the layer thickness is increased.

Layers on the surface of disperse substrates are prepared using a flow-type setup. In this case, the substance to which the nanolayer is applied is fastened in a chemical reactor and reagent solutions and washing liquids are added in succession. The order of treatment is specified by the control unit by opening and closing the appropriate electromagnetic valves.

As shown by experience, tens, hundreds or more cycles of layer deposition may give thin-layer structures according to a pre-specified pattern.

After the SILD, a layer with a thickness of about several nanometres or fractions of a nanometre, *i.e.*, a nanolayer, is formed on the surface. This definition of the ‘nanolayer’ does not imply any information concerning its morphology. Indeed, the reactions on the surface can yield either the continuous layer of new structural units (monolayer) or a discontinuous layer. In some cases, due to incomplete coverage of the surface by a reagent or incomplete removal of the reagent during washing, one can

expect an ‘islet’ mechanism of layer growth where the layer thickness in the growth area would exceed the monolayer thickness (but this would be still a ‘nanolayer’).

Even the first experiments have shown that for most compositions, washing after the adsorption results in the removal of not only excess reagents and reaction products but also a part of the (or entire) adsorbed layer. Thus, determination of the conditions of a SILD synthesis is a complicated task, as more than 10 parameters are to be controlled (including the pH values and concentrations of several solutions of reagents, pH of wash liquids, residence times, and so on). The monographs^{12,13} devoted to studies of ion exchange on the surface cover the results of numerous papers. However, they do not clarify the point concerning the choice of optimal conditions of synthesis, because the studies were aimed at elucidating the conditions of adsorption of cations (or anions) by ion exchange resins and their subsequent desorption needed for regeneration of the ion exchanger. However, the conditions for irreversible adsorption for most ion exchangers have not been described systematically and, in some cases, they are presented only as oblique results. As a rule, these studies are devoted to adsorption on a sorbent or ion exchange resin, whereas the SILD method requires information on irreversible adsorption conditions in each cycle.

Nevertheless, the optimal conditions for the SILD synthesis of nanolayers of most classes of inorganic solid compounds, in particular, metal sulfides,^{14–49} selenides,^{50–52} oxides,^{53–59} hydroxides,⁶⁰ peroxides^{61–68} and fluorides,^{69,70} have now been elucidated. An important phase in the development of this subject would be systematisation of the accumulated experimental data and classification of the SILD reactions and the approaches used.

In our opinion, SILD procedures can be divided into groups according to the main types of reactions of cations with anions in solutions.⁷¹ The major group comprises the surface reactions of an adsorbed cation (or anion) with an anion (or cation) situated in solution. The oxidation state of ions does not change. If the reaction gives a poorly soluble compound, a nanolayer is formed on the surface. The reaction of adsorbed Zn^{2+} aqua complexes with the HS^- anions to give a strong $Zn-S$ bond is an example. Water molecules are ‘squeezed out’ of the coordination sphere of zinc cations. Drying affords a layer of anhydrous ZnS .

Yet another group comprises redox reactions. Two types of such reactions are distinguished. The first type includes reactions where the adsorbed cation is oxidised ($Sn^{2+} \rightarrow Sn^{4+}$) (see Ref. 55) or reduced ($Ag^+ \rightarrow Ag^0$) (see Ref. 72), or the adsorbed anion is reduced ($Cr_2O_7^{2-} \rightarrow Cr^{3+}$) (see Ref. 73), and so on. In this case, the dissolved molecules or ions of the oxidising or reducing agent involved in the process are not incorporated in the resulting layer.

The second type comprises redox reactions where the oxidising or reducing agent and probably the product of its chemical transformation are incorporated in the layer, giving rise to a multi-component surface nanolayer (for example, $Sn^{2+} + MoO_4^{2-} \rightarrow Sn_xMoO_y$).⁵⁹

There exists a group of ‘conjugated’ SILD processes in which the redox reaction of one of the types indicated above taking place on the surface is accompanied by adsorption of other cations or anions to give a poorly soluble compound. For example, treatment of an adsorbed Ce^{3+} layer with a solution containing H_2O_2 and OH^- results in the $Ce^{3+} \rightarrow Ce^{4+}$ oxidation, accompanied by adsorption of H_2O_2 and OH^- to give a $Ce(OH)_2OOH$ nanolayer.

Apart from the reactions of cations and anions, numerous processes involving reagents as molecules or colloidal nanoparticles can also be referred to as SILD reactions. The set of these reactions is schematically shown in Fig. 2; the methods of synthesis with these reagents are defined as ionic–molecular and ionic–colloidal layer deposition, respectively.

Figure 2. Main types of SILD reactions with solutions containing ions, colloidal particles and molecules in the liquid and gas phase as reagents.

III. Ionic layer deposition reactions without changes in the oxidation states of ions

1. Nanolayers of inorganic compounds

a. Synthesis of ZnS and CdS layers

The ZnS and CdS layers attract keen attention of researchers due to the attempts to create efficient electroluminescent and cathodoluminescent panels, windows for solid-state solar energy converters, photoconductors, *etc.*; therefore, the largest number of publications was devoted to this topic.^{14–43}

A pioneering systematic study of the preparation of ZnS and CdS layers using solutions of metal chlorides and sulfates and a solution of Na₂S has been carried out by Nicolau.^{14,15} The reagent concentrations were 0.005–5.0 mol litre^{−1}; the residence time in solutions and in water was 20 s; the substrates used were glass with indium and tin oxide (ITO) layers, Si, Ge, GaAs, InP, CaF₂, Al₂O₃ and LiNbO₃ single crystals, polycrystalline Ti, Mo, and Ta. The growth rate of the nanolayer depended on the solution concentration; the highest rates for ZnS and CdS, equal to 0.31 and 0.14 nm, respectively, were attained at ZnCl₂ and CdCl₂ concentrations of 5 mol litre^{−1} and a Na₂S concentration of 2.8 mol litre^{−1}. All other factors being the same, a higher growth rate was observed with chloride rather than sulfate solution. The effect of pH on the adsorption of the cations and anions on the surface of zinc and cadmium sulfides was judged from the data on the ζ -potential. These studies allowed one to determine more precisely the region of specific adsorption of ions and to construct adequate models of the processes taking place on the surface. The ZnS and CdS layers prepared under the optimal conditions were uniform and polycrystalline and had a mirror surface. The ZnS layers possessed a cubic structure and CdS layers were hexagonal, their predominant orientation being dependent on the substrate used.

In addition to layers of individual ZnS and CdS, solid solutions Cd_xZn_{1−x}S were prepared.²³ Aqueous solutions (0.1 M) of Cd(NO₃)₂, ZnSO₄ and Na₂S were used as reagents and silicon and germanium plates were used as substrates. Solid solutions were obtained using a mixture of zinc and cadmium salts. The mole fraction of cadmium was varied from 0.0001 to 1.0. The thickness of the synthesised layers was estimated based on their interference colour. For CdS, the thickness was 0.32, while for ZnS, 0.29 nm per cycle. The ZnS layers synthesised on the silicon surface had a wurtzite type hexagonal lattice after the first 20 cycles and a sphalerite type cubic structure after 40 cycles. The subsequent cycles resulted in an increase in the crystallite size and gave rise to mosaic blocks whose (111) plane was oriented parallel to the substrate. The growth of CdS layers at the Ge (111) face started with the formation of a polycrystalline cubic phase, but as the layer thickness increased, some of the crystallites oriented themselves with the (111) plane. Solid solutions were formed if the mole fraction of cadmium was 0.0001–0.003, the most perfect ones were produced for a value of 0.0002. If the mole fraction of

cadmium exceeded 0.003, layers with a CdS cubic structure were formed.

The ZnS/CdS multilayers on a glass surface coated with ITO or GaAs were prepared³⁹ by alternating treatment of the substrate with solutions of ZnCl₂ and CdCl₂ according to the SILD procedure. The thickness of each layer in the multilayer was 1–6 nm (and larger) and the overall thickness was 100–120 nm. The interfaces in the multilayer were not sharp and contained the Cd_xZn_{1−x}S solid solution. The layer-by-layer identification was carried out by scanning electron microscopy (starting with 20 nm).

It has been shown²⁷ that ZnS layers on a poly(vinyl chloride) and polycarbonate surface can be synthesised under conditions similar to those used in the synthesis on the surface of inorganic solids. The difference lied in the special preparation of the polycarbonate surface. The poly(vinyl chloride) specimens were washed only with ethanol prior to the synthesis, while the polycarbonate specimens were treated with a 10% acidic solution of KMnO₄. The MnO₂ layer thus formed was etched with concentrated HCl to give surface carbonyl groups, which then participated in the sorption of reagents in SILD synthesis. The structure of these layers was polycrystalline in the case of poly(vinyl chloride) and amorphous in the case of polycarbonate. Apart from the zinc and sulfur atoms, the layers contained about 20% of oxygen [apparently, as a constituent of ZnO or Zn(OH)₂]. On the basis of these results, the researchers concluded that SILD can be used to obtain ZnS layers with good adhesion on a polymer surface.

The oxygen content in the ZnS layers synthesised on a glass surface with an ITO layer was determined by EXAFS.²⁸ Depending on the conditions of synthesis, this was 10%–30%. In non-heated samples, oxygen was incorporated in Zn(OH)₂, while in those heated at 500 °C, in ZnO. The crystal structure in the latter case was fully identical to the structure of the layers synthesised in the gas phase by molecular layer deposition at the same temperature.

The synthesis of ZnS layers was also performed on the polyether surface.³⁰ Prior to the synthesis, the polymer samples were kept for 12 h in a 0.1 M solution of SnCl₂ for the creation of the surface layer ensuring high adhesion. Then they were washed and dried in air. One SILD cycle gave, depending on the conditions, a 0.16–0.22-nm thick sulfide layer. The layers were amorphous, but at thicknesses of more than 250 nm, crystallite peaks were noted in the diffraction pattern.

b. Synthesis of Ag₇SbS₆ layers

The ways of synthesis of nanolayers containing two metals and an anion-forming element (S^{2−}, F[−], OH[−], *etc.*) have been considered.^{19,20} The authors were the first to show that not only simple anions like S^{2−} but also complex thio salts such as SbS₄^{3−} can be used for SILD. The synthesis was carried out using solutions of S^{2−} and AgNO₃ or Pb(NO₃)₂.

The growth kinetics of Ag–Sb–S-containing nanolayers on a fused quartz surface was studied by spectrophotometry. From the dependence of absorbance on the concentration of the silver salt solution, it was found that an increase in the concentration above 0.01 mol litre^{−1} does not induce a substantial change in the absorbance. This indicates that the compound is formed in the layer of ions adsorbed on the substrate surface rather than in the solution. In 0.01 M solutions of AgNO₃ and Na₃SbS₄, the absorbance increased linearly upon an increase in the number of SILD cycles. This was indicative of a stepwise layer synthesis. The X-ray photoelectron spectrum of the layer showed electron binding energies of 368.0, 529.3 and 161.4 eV, which were assigned to the Ag⁺, Sb⁵⁺ and S^{2−} ions, respectively. According to X-ray spectral microanalysis, the ratio of these elements in the layer prepared on silica gel over ten SILD cycles was Ag:Sb:S = 8.2:1.0:7.2. With allowance for the experimental error, this ratio corresponds most closely to Ag₇SbS₆. According to powder X-ray diffraction (CuK α radiation), the layer was X-ray

Note. Here Δd_1 is the layer thickness per SILD cycle; TEA is triethylamine; EDTA is *N,N,N',N'*-ethylenediaminetetraacetic acid.

amorphous; however, the X-ray diffraction pattern contained a small peak at $2\theta = 30.34^\circ$, typical of Ag₇SbS₆.

The conditions and the results of syntheses of layers of other metal sulfides, selenides, iodides and thiocyanates are summarised in Table 1.

c. Synthesis of LaF₃ · *n* H₂O layers

The conditions of synthesis of LaF₃ · *n* H₂O nanolayers have been elucidated.^{69,70} Aqueous solutions of lanthanum chloride or nitrate and gaseous HF were used as reagents. First, the substrate was immersed into solutions of a lanthanum salt and then into water. Then the specimen was dried in an air flow and placed for 10 min into a flow reactor through which an air–HF gas mixture was passed. A concentrated solution of hydrofluoric acid through which air was passed at a flow rate of 0.2–0.3 dm³ min^{−1} served as the source of hydrogen fluoride. This sequence formed one SILD cycle.

Solutions of NaF or NH₄F acidified with HF to pH ≈ 4.2 were other sources of fluoride ions used in the synthesis. These were used to obtain a sample of hydrofluoride complex in the solution and on the surface. The synthesis conditions were optimised by varying the concentration of metal salts, solution pH, residence times of the specimen in the liquid and gas phases and the number of SILD cycles. The change in the lanthanum salt concentration from 10^{−2} to 10^{−3} mol litre^{−1} barely influenced the increment of the LaF₃ layer thickness (~0.45 nm) per SILD cycle. It was found by electron diffraction that the layer prepared

using gaseous HF is polycrystalline and has a hexagonal LaF₃ structure with the unit cell parameters $a = 0.716$ and $c = 0.732$ Å.

d. Synthesis of BiVO₄ layers

In the synthesis of Bi–V–O-containing layers,^{75,76} 0.01 M aqueous solutions of BiOClO₄ and NaVO₃ were used as the reagents.

These layers were prepared at an equilibrium pH of the solution of BiOClO₄. The pH value of the solution of NaVO₃ varied, being 2.0, 3.0, 6.0 or 8.0. In a solution of NaVO₃ with pH 2, a light-yellow nanolayer with the ratio Bi : V = 1 : 0.79 was formed on the silica gel surface (according to X-ray spectral microanalysis of the specimen formed after ten SILD cycles). In a solution with pH 3.0, the layer was bright-yellow and the Bi : V ratio was 1 : 1. At pH 6.0 or 8.0, the colour was less bright, while the Bi : V ratio in the layer was 1 : 0.3.

These differences were attributed to different compositions of the vanadium(V) oxyhydroxide complexes in solutions at these pH values.⁷⁷

The layers synthesised were amorphous (X-ray analysis) but the X-ray diffraction pattern of the specimen obtained from a solution of NaVO₃ at pH 3 showed a number of peaks typical of BiVO₄. On heating in air (300 °C), the intensity of these peaks increased.

e. Synthesis of metal hydroxyperoxide layers

A number of syntheses based on the formation of poorly soluble metal peroxide or hydroxyperoxide layers on the substrate surface

have been proposed. According to one of these, a layer can be obtained by successive adsorption of metal cations, H_2O_2 molecules and hydroxide ions. The adsorption irreversibility is attained due to lower solubility of hydroxyperoxides of some metals with respect to the solubility of hydroxides. First of all, this refers to the hydroxyperoxides $\text{CuO}_{1+x} \cdot n\text{H}_2\text{O}$,⁶³ $\text{ZnO}_{1+x} \cdot n\text{H}_2\text{O}$,^{61, 68} $\text{NiO}_{1+x} \cdot n\text{H}_2\text{O}$ ⁶² and $\text{La}(\text{OH})_{3-x}(\text{OOH})_x$.⁶⁶ It is clear that after heating in air, metal hydroxyperoxides should be converted into hydroxides or oxides, although for some of them [in particular, for $\text{La}(\text{OH})_{3-x}(\text{OOH})_x$], the formation of relatively stable basic carbonates cannot be ruled out either.

In the synthesis of copper hydroxyperoxide $\text{CuO}_{1+x} \cdot n\text{H}_2\text{O}$, aqueous solutions of $\text{Cu}(\text{NO}_3)_2$, solutions of $\text{Cu}(\text{OAc})_2$ in aqueous ethanol, aqueous and aqueous-ethanolic solutions of H_2O_2 and ammonia were used as the reagents. The substrate was successively treated with ammoniacal copper, wash solution, a weakly alkaline solution of H_2O_2 and again with the wash solution. The optimisation of the synthesis conditions demonstrated the necessity of using solutions of ammoniacal copper with $\text{pH} \approx 8-9$ and concentrations of $0.01-0.1 \text{ mol litre}^{-1}$ and $0.1\%-3.0\%$ of hydrogen peroxide. Under these conditions, an increase in the number of SILD cycles induces a regular increase in the absorbance of the layer in the UV transmission spectrum (*i.e.*, layer thickness). According to ellipsometry data, depending on the synthesis conditions, one SILD cycle gives a 0.3- to 1.5-nm thick layer.

It should be borne in mind that in weakly alkaline media, ammoniacal copper cations are adsorbed on the silica surface, the removal of their excess affording a $\equiv \text{SiOCuOH}$ layer. When the specimen is put into a weakly alkaline solution of H_2O_2 , the $\equiv \text{SiOCuOOH}$ groups, which dissociate to give CuOO^- and H^+ ions, appear on the surface.

The surface acquires again a negative charge and, hence, ammoniacal copper ions can again be adsorbed, thus forming the next copper peroxide layer.

Poorly soluble compounds are also formed when some metal cations react with soluble peroxo complexes. This synthetic protocol was tested experimentally to prepare $\text{La}_x\text{NbO}_y \cdot n\text{H}_2\text{O}$ layers using solutions of $\text{La}(\text{OAc})_3$ and peroxyphosphoric acid.⁶⁴

f. Synthesis of hybrid iso- and heteropoly oxometallates

The difficulty of preparing polyoxometallate layers on various substrate surfaces is due to their relatively low thermal stability; therefore, thin layers cannot be applied by, for example, vapour deposition. The preparation of heteropoly compound (HPC) layers from reagent solutions is also faced with difficulties, as due to the 'cluster' structure of HPC, the energy of their adsorption on most substrates is too low to produce a dense monolayer. In addition, the adsorbed HPC layer has no sites for sorption of the subsequent layer. However, some heteropolyacids (HPA), for example, $\text{H}_3\text{PMo}_{12}\text{O}_{40} \cdot n\text{H}_2\text{O}$, can be reduced rather readily to $[\text{PMo}_{12}\text{O}_{40}]^{n-}$ (in particular, with a solution of SnCl_2).⁷⁸ The resulting species may prove more reactive toward SILD synthesis. It is known⁷⁹ that the least soluble compound is formed in the reaction of the reduced form of phosphomolybdic acid with Zr^{4+} cations.

The use of aqueous solutions of $\text{Zr}(\text{OAc})_4 \cdot n\text{H}_2\text{O}$, $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ and $\text{H}_3\text{PMo}_{12}\text{O}_{40} \cdot n\text{H}_2\text{O}$ as reagents gave a $\text{Zr}_{2.6}(\text{OH})_x\text{PMo}_{8.0}\text{Sn}_{1.9}\text{O}_y \cdot n\text{H}_2\text{O}$ layer on the surface.⁸⁰ It can be considered as a sort of 'hybrid' compound containing structural fragments of the initial HPA and zirconium polyhydroxy cations. Together with Sn^{4+} cations, the latter serve as a sort of bridges binding HPA anions to one another. Thus, a three-dimensional network of chemical bonds is formed on the surface.

2. Polyelectrolyte nanolayers

The first layer-by-layer synthesis of a polymer layer on a solid surface was reported by Nicolau *et al.*^{81, 82} This was done using solutions of pyrrole or aniline in ether, 3-methylthiophene in dichloromethane; and solutions of FeCl_3 in MeOH or MeCN were

used as oxidants. Repeated successive adsorption of organic molecules and their oxidation on the substrate surface gave a layer of the corresponding polymer. In essence, this was a molecular layer deposition reaction.

Aqueous solutions of polyelectrolytes in the cationic or anionic form have been proposed⁸³⁻⁸⁵ as reagents for precision synthesis of layers of organic compounds. Examples of such polyelectrolytes are poly(ethyleneimine) (PEI) with a molecular mass of 20–750 kDa (contains NH_2 groups and forms cations in the solution) and sodium poly(styrenesulfonate) (PSS) with a molecular mass of 70–500 kDa (contains SO_3^- groups and forms anions in solution). When the substrate whose surface has a charge opposite to the charge of the polyelectrolyte is immersed in the solution, the polyelectrolyte is adsorbed (Fig. 3). To produce a multilayer, the substrate is withdrawn from the solution, washed with water, placed into a polyelectrolyte solution (with the opposite charge of the macromolecule functional groups), kept in this solution, and once again withdrawn and washed with water (see Fig. 3). A distinctive feature of the process of synthesis of polyelectrolyte nanolayers compared to the synthesis of nanolayers of inorganic compounds is the necessity to dry the specimen in air after each cycle. This is required to remove water molecules from the layer and to enhance 'adhesion' of the long-chain polyelectrolyte molecules (to the substrate and to one another).

Figure 3. Schemes of SILD reactions involving polyelectrolyte solutions. (1) Initial substrate, (2) specimen with the layer of a cation-containing polyelectrolyte, (3) specimen with the layer of a cation- and anion-containing polyelectrolyte, (4) specimen after the adsorption of nanoparticles and a cationic polyelectrolyte layer, (5) specimen after the adsorption of metal cations.

The described method of synthesis has found a rather broad use.^{86, 87} The following compounds have now been studied as cationic polyelectrolytes: poly(diallyldimethylammonium chloride) (PDDA, 20–200 kDa), poly(allylamine hydrochloride) (PAH, 8–15 kDa), poly(L-lysine) (PLL) and poly(D-lysine) (PDL, 30–70 kDa), tetra(*p*-toluenesulfonate) 5,10,15,20-tetrakis(1-methyl-4-pyridinio)porphyrin (TMPyP), diazo resin (DR), poly(amidoamine) (PAMAM), (4-vinylbenzyl)dodecyltrimethylammonium chloride (VDAC), and 4,4'-bis(5-pyridylpentyl)-biphenyl (4,4'-BPPOBP).

Among anionic polyelectrolytes, one can mention albumin, heparin, PSS (70–500 kDa), hyaluronic acid (HA), poly(L-Glu) (PGA, 50–100 kDa), polyacrylic acid (PAA, 90 kDa), polymethacrylic acid (PMA, 100 kDa), DNA, poly(aniline-*N*-butylsulfonate) (PANBUS, 3500 Da) and poly(vinyl sulfate) (PVS, 170 kDa).

These polyelectrolytes have been used to prepare PDDA/PSS, PVS/PAH, PLL/HA, PSS/PAH, heparin/PAH, PAA/PAH and other layers.

Detailed description of the reactions with polyelectrolyte solutions can be found in a collective monograph.¹¹ Some examples of the use of these nanolayers for solving practical problems are considered below.

3. Multinanolayers of hybrid (organic and inorganic) substances

The most significant studies deal with the synthesis of hybrid layers containing polyelectrolyte macromolecules in the cationic form and HPA anions. The use of polyelectrolytes allows one to overcome the above-noted (see Section II) problems which arise in the synthesis of HPA layers, because polyelectrolytes function as a peculiar transition layer, which glues together the HPA anions. Examples are provided by the layers containing PAH and $[\text{Eu}(\text{P}_2\text{W}_{17}\text{O}_{61})_2]^{17-}$ or $[\text{Eu}(\text{SiW}_{11}\text{O}_{39})_2]^{13-}$ (see Refs 88, 89), PAH and $[\text{Eu}(\text{BW}_{11}\text{O}_{39})_2]^{15-}$ (see Ref. 90), $[\text{Eu}(\text{SiW}_{10}\text{VO}_{39})_2]^{15-}$ and PEI,⁹¹ $[\text{Eu}(\text{SiW}_{11}\text{O}_{39})_2]^{13-}$ and the poly(4-vinylpyridine)–Os(2,2'-bipy) complex,⁹² PEI, $[\text{PMo}_{12}\text{O}_{40}]^{3-}$ and the $[\text{Ru}(\text{bipy})_3]^{2+}$ complex,⁹³ $[\text{W}_{10}\text{O}_{32}]^{4-}$ or $[\text{NaP}_5\text{W}_{30}\text{O}_{110}]^{14-}$ and PEI,⁹⁴ PEI and $[\text{NaP}_5\text{W}_{30}\text{O}_{110}]^{14-}$ (see Ref. 95).

Anionic polyelectrolytes can form poorly soluble compounds and nanolayers with metal cations under the reaction conditions (see Fig. 3). The studies,^{96–98} devoted to the synthesis of Tb^{3+} –PSS, Y^{3+} –PSS and Gd^{3+} , Eu^{3+} or Nd^{3+} and PSS layers, deserve attention.

IV. Successive ionic layer deposition with a change in the oxidation states of adsorbed ions

1. Reactions accompanied by the oxidation or reduction of cations

The preparation of layers of poorly soluble metal hydroxides using successive adsorption of metal cations and OH^- anions is faced with some complications. This is due to the fact that after adsorption of cations and anions, it is necessary to treat the substrate with a salt solution containing a metal cation. The hydroxide layer formed may react with the protons formed upon hydrolysis of the salt, this may result in hydroxide dissolution, and the synthesis of a thick layer may become impossible.

A solution of SnF_2 and a weakly alkaline solution of H_2O_2 have been chosen as the reagents in order to attain conditions for irreversible synthesis of SnO_2 nanolayers.⁵⁵ Under the action of hydrogen peroxide, the adsorbed Sn^{2+} cations are oxidised to Sn^{4+} [in an alkaline medium, the Sn^{2+} cations are converted into $\text{Sn}(\text{OH})_4$]. The use of these reagents also appears justified based on the analysis of another publication,⁷⁷ which reports the precipitation conditions for Sn^{2+} and Sn^{4+} hydroxides from 0.001 M solutions. Complete precipitation of $\text{Sn}(\text{OH})_2$ is known to occur at $\text{pH} \approx 6$, and that of $\text{Sn}(\text{OH})_4$, at $\text{pH} \approx 3$, i.e., the $\text{SnO}_2 \cdot \text{H}_2\text{O}$ layer synthesised by treatment of an alkaline solution with an oxidant is not dissolved in the next cycle.

In aqueous solutions at $\text{pH} 2\text{--}3$, adsorption of SnOH^+ ions takes place on the silica surface; after the removal of excess salt, a nanolayer of adsorbed $\text{Sn}(\text{II})$ hydroxide is formed. Then treatment with a weakly alkaline solution of H_2O_2 induces the $\text{Sn}(\text{II}) \rightarrow \text{Sn}(\text{IV})$ transition.

In the second SILD cycle, the $\text{Sn}(\text{IV})$ hydroxide is not dissolved on treatment with SnF_2 , and SnOH^+ ions are adsorbed on the surface. After SILD cycles repeated many times, a layer of the $\text{Sn}(\text{OH})_4$ hydroxide is formed.

Similar redox reactions in the layer of adsorbed cations have been used in the synthesis of iron(III) hydroxide⁶⁰ and hydrated $\text{Ti}(\text{III})$ oxide layers.⁵⁴ A weakly alkaline solution of H_2O_2 is also an oxidant for the adsorbed Ce^{3+} cations. However, unlike SnO_2 , apart from participating in the redox reaction, this reagent tends to form a stable peroxide compound by the reaction

The $\equiv \text{SiOCe}(\text{OH})_{3-x}\text{OOH}_x$ fragment can dissociate to give the $\equiv \text{CeOO}^-$ groups, which function as adsorption sites for the Ce^{3+} ions in the subsequent SILD cycles.

For some cations, for example, Pb^{2+} , an alkaline solution of KMnO_4 is the most efficient oxidant.⁵⁶ On treatment of the substrate with a solution of $\text{Pb}(\text{NO}_3)_2$, the Pb^{2+} or PbOH^+ ions are adsorbed on the surface, while the subsequent treatment with a weakly alkaline solution of KMnO_4 results in $\text{Pb}^{2+} \rightarrow \text{Pb}^{4+}$ oxidation and reduction of Mn^{7+} , probably to Mn^{5+} . The latter reacts with excess solution of KMnO_4 to give MnO_4^{2-} ions. After washing, a $\text{PbO}_2 \cdot n\text{H}_2\text{O}$ layer is formed on the substrate surface. The layer has the structure of orthorhombic α - PbO_2 with the unit cell parameters: $a = 0.4038$, $b = 0.503$, $c = 0.5486$ nm; the c axis is perpendicular to the substrate surface.

The Ag^0 (see Ref. 72) and Cu^0 (see Ref. 99) nanolayers were synthesised by SILD by reduction of the cations adsorbed on the surface. The key problem of this synthesis (compared with the synthesis of, for example, metal sulfides or fluorides) is that the layer consists of only one sort of atoms and it is difficult to select conditions of irreversible layer-by-layer adsorption.

The reduction of Ag^+ in a weakly alkaline solution of H_2O_2 was chosen as a method for the synthesis of Ag^0 nanolayers. A metallic silver layer is formed in the mixing regime according to the following reaction

In the first cycle of SILD, the substrate was successively treated with a solution of $[\text{Ag}(\text{NH}_3)_2]\text{NO}_3$, washed with ammonia ($\text{pH} 9$) and with a weakly alkaline solution of H_2O_2 , and then washed with distilled water. In the subsequent cycles, a solution of AgNO_3 was used for Ag^+ sorption, water was used for washing and the reduction of Ag^+ ions was performed by a weakly alkaline solution of H_2O_2 . After treatment of the substrate with a solution of the silver ion and washing off the excess of the reagent with an ammonia solution, adsorption of ammoniacal silver takes place on the surface. Subsequently, after treatment with a solution of the reducing agent, only partial reduction of Ag^+ ions takes place to give known¹⁰⁰ compounds of the Ag_2^+ or Ag_4^{2+} type. They are characterised by a sharply lower intensity of the absorption bands of free and bound OH groups at 1370 and 1400 nm. Apparently, after treatment with a reducing agent, the Ag_2^+ , Ag_4^{2+} and other clusters form peculiar complexes of the $\equiv \text{Si}-\text{OAg}_2$, $\equiv \text{Si}-\text{OAg}_4^+$ type on the surface. When the substrate is treated with a solution of AgNO_3 , these complexes may function as adsorption sites for the Ag^+ ions, which are then (on treatment with a reducing agent) converted into Ag^0 to give a larger complex. As the number of SILD cycles increases, a layer of metallic silver is formed.

Layers of Cu^0 were prepared using solutions of $\text{Cu}(\text{II})$ salts and a highly alkaline ($\text{pH} 13\text{--}14$) solution of formaldehyde. Water served as the wash liquid. The nanolayers were characterised using scanning electron microscopy and atomic force microscopy (AFM). Unfortunately, the method used to check the completeness of reagent removal after reduction of the cations is not mentioned in the study cited.⁹⁹ Probably, alkali was not removed completely during washing, and treatment with a solution of the copper salt was accompanied by 'precipitation' of copper hydroxide, which was then reduced to the metal on multiple treatment with a solution of a reducing agent.

Metal cations can serve as oxidants for adsorbed cations. In the synthesis of $\text{Ag}^0 \cdot \text{MnO}_2$ layers,¹⁰¹ Mn^{2+} cations function as reducing agents and Ag^+ cations are the oxidants. It is important that, for these cations, a pH region exists in which the reaction products formed on the surface, namely, MnO_2 and Ag^0 , are poorly soluble. These underlay the choice of the reagents for the synthesis of so-called 'hybrid' metal–oxide layers.

For the synthesis of an $\text{Ag}^0\text{--Mn--O}$ -containing nanolayer,¹⁰¹ aqueous solutions of $\text{Mn}(\text{OAc})_2$ and AgNO_3 were used as the reagents. The growth of the layer was observed when 0.01 M aqueous solutions of $\text{Mn}(\text{OAc})_2$ ($\text{pH} 7.5$) and AgNO_3 ($\text{pH} 8.5\text{--}9$)

were used. To increase the pH in the solution of $\text{Mn}(\text{OAc})_2$, a solution of sodium acetate was used; in the case of AgNO_3 , this was attained by an ammonia solution. At the given pH values, the reagents were adsorbed on the surface, and irreversible Mn^{2+} oxidation and Ag^+ reduction took place. The X-ray photoelectron spectrum displayed a peak at 642.2 eV corresponding to Mn^{4+} ions ($2p_{3/2}$) in MnO_2 and a peak at 368.6 eV corresponding to Ag^0 ($3d_{5/2}$). The Ag^0 : MnO_2 ratio in the layer was determined from the peak intensities to be ~ 0.7 . The diffuse reflectance spectra of the layers on the silica gel surface exhibited broad bands at 400–500 nm, *i.e.*, in the absorption region of metallic silver clusters. In a powder X-ray diffraction study, the metallic silver in the layer exhibited a peak at $2\theta = 64.48^\circ$. This confirms its crystalline structure.

2. Reactions involving the oxidation of cations and the reduction of anions

If the SILD makes use of reactions involving the oxidation of cations and the reduction of anions, the oxidant reacts with the adsorbed cationic layer, thus passing to a lower oxidation state and forming a poorly soluble compound with the layer of the oxidised cation.

This synthetic strategy was first tested in the preparation of $\text{MnO}_2 \cdot n\text{H}_2\text{O}$ nanolayers on the silica surface.^{8,53} Solutions of MnCl_2 , MnSO_4 and $\text{Mn}(\text{OAc})_2$ served as the reducing agents and weakly alkaline solutions of KMnO_4 was used as the oxidant. When these compounds react in the mixing regime, a $\text{MnO}_2 \cdot n\text{H}_2\text{O}$ layer is produced on the surface, which is confirmed by X-ray fluorescence and IR spectroscopy. The layer is mechanically strong, its thickness being controlled by the number of SILD cycles.

If cations and anions of different elements are used in the redox reaction on the surface, the layer will be multicomponent, which was observed in the synthesis of layers containing $\text{Co}(\text{III})$ – $\text{Mn}(\text{IV})$ – O ,⁵⁷ $\text{Ce}(\text{IV})$ – $\text{Mn}(\text{III})$ – O ⁵⁸ and $\text{Fe}(\text{III})$ – $\text{Cr}(\text{III})$ – O .¹⁰² The compositions of the prepared layers were described as $\text{Co}_3\text{MnO}_x \cdot n\text{H}_2\text{O}$, $\text{Ce}_4\text{MnO}_x \cdot n\text{H}_2\text{O}$ and $\text{FeCr}_{0.7}\text{O}_x \cdot n\text{H}_2\text{O}$, respectively.

The Ce_xNbO_y nanolayers were synthesised in a similar way.¹⁰³ The Ce^{3+} cations served as the reducing species, while the NbO_8^{3-} anions were the oxidants. The layer composition can be described as $\text{Ce}_{0.7}\text{NbO}_x \cdot n\text{H}_2\text{O}$.

A similar strategy has been used⁵⁹ to prepare nanolayers $\text{Sn}(\text{IV})\text{Mo}(\text{VI},\text{V})_{0.6}\text{O}_y \cdot n\text{H}_2\text{O}$ using aqueous solutions of SnCl_2 and $(\text{NH}_4)_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$ or $(\text{NH}_4)_2\text{Mo}_7\text{O}_{24} \cdot 2\text{H}_2\text{O}$ as the reagents. Apart from the molybdate anions, heteropolyacid anions can also react with the reducing agent, a SnCl_2 solution. This was shown in a study¹⁰⁴ where $\text{H}_3\text{PW}_{12}\text{O}_{40} \cdot n\text{H}_2\text{O}$ was used to prepare the $\text{Sn}_{16}(\text{OH})_x\text{PW}_{19}\text{O}_y \cdot n\text{H}_2\text{O}$ nanolayer.

V. Conjugated ionic layer deposition reactions including oxidation or reduction of ions and adsorption

Using the SILD method, it is possible to prepare not only one- but also multi-component layers, in particular, multilayers of different composition. A necessary condition for the synthesis of multilayers is the insolubility of the peroxide nanolayer already formed in the reagent solutions used to form the subsequent layers. The $\text{CeO}_{2+x} \cdot z\text{H}_2\text{O}$ and $\text{LaO}_{1.5+x} \cdot z\text{H}_2\text{O}$ multilayers have been obtained.⁶⁶ The synthesis was carried out on a silicon surface in the following way: one SILD cycle gave a $\text{CeO}_{2+x} \cdot z\text{H}_2\text{O}$ nanolayer; this was followed by the cycle giving a $\text{LaO}_{1.5+x} \cdot z\text{H}_2\text{O}$ layer; and then these cycles alternated many times (up to 60). The resulting multilayer was studied by X-ray photoelectron spectroscopy. The results showed the presence of both $\text{La}(\text{III})$ and $\text{Ce}(\text{IV})$. Their relative concentration equal to $\sim 1:1$ was determined based on the band intensities.

In the synthesis of multicomponent layers, metal ions can be introduced into the layer using mixtures of solutions of their salts. Thus for the synthesis of a two-component Ce- and La-containing layer, $\text{La}(\text{NO}_3)_3$ was added in different proportions to a solution of $\text{Ce}(\text{OAc})_3$. The overall solution concentration was $0.01 \text{ mol litre}^{-1}$, while the mole fractions of lanthanum were 10%, 20% and 40%. However, the lanthanum concentrations in the resulting layer (according to X-ray photoelectron spectroscopy) were 9%, 15% and 22%, respectively. The decrease in the lanthanum content in the layer with respect to its concentration in the solution is due to lower sorbability of the $\text{La}_{\text{aq}}^{3+}$ ions compared to that of $\text{Ce}_{\text{aq}}^{3+}$.

Yet another example of using conjugated SILD reactions is provided by the synthesis of nanolayers consisting of the double $\text{Fe}(\text{III})$ – $\text{Ni}(\text{II})$ hydroxide.¹⁰⁵ A freshly prepared solution of Mohr's salt $(\text{NH}_4)_2(\text{FeSO}_4)_2 \cdot 6\text{H}_2\text{O}$ and an ammoniacal solution of NiSO_4 (pH ≈ 8.0 – 8.5) with concentrations of $0.01 \text{ mol litre}^{-1}$ served as the reagents. The sequence of operations for the preparation of a $\text{Fe}(\text{III})$ hydroxide layer (this procedure has been reported⁶⁰) is as follows: Fe^{2+} ions are adsorbed from a solution of Mohr's salt, the excess of the solution is removed, the sorbed ions are oxidised in an H_2O_2 solution, and the excess of hydrogen peroxide is removed by washing with water. For the synthesis of the double hydroxide layer, it has been proposed¹⁰⁵ to combine the oxidation of sorbed $\text{Fe}(\text{II})$ ions with sorption of $\text{Ni}(\text{II})$ ions and to synthesise a double hydroxide layer over a minimum number of surface treatment cycles. In an ammoniacal $\text{Ni}(\text{II})$ solution, the $\text{Fe}(\text{II}) \rightarrow \text{Fe}(\text{III})$ catalytic oxidation with oxygen dissolved in water, the formation of a $\text{Fe}(\text{III})$ hydroxide layer on the surface and the adsorption of $\text{Ni}(\text{II})$ ions on this layer took place. The results of investigations of the layers showed that the $\text{Fe}:\text{Ni}$ concentration ratio in the layer is $1:0.4$, while the layer thickness increases by $\sim 0.7 \text{ nm}$ after every SILD cycle.

VI. Successive ionic layer deposition involving ions and molecules

The use of ionic reagents in one stage and molecular reagents (in the gas or liquid phase) in another stage of treatment allows one to markedly extend the range of obtained objects. This synthetic strategy can be referred to as ionic–molecular layer deposition. This method was first proposed by Tolstoy and Bogdanova¹⁰⁶ for the synthesis of a BaHPO_4 protective layer on the surface of carbon steel. The process was carried out in the following way: at a temperature of 280°C , the steel surface was treated with P_4O_{10} vapour, the excess of the vapour being removed by evacuation; then the specimen was cooled and placed into a solution of a Ba^{2+} salt. After removal of excess salt by washing with water and drying, the sequence of operations was repeated. This gave a dense BaHPO_4 layer on the surface, which efficiently protects steel from corrosion.

To carry out alternating treatment with a reagent solution and vapour, the specimen has to be dried in between, which restricts the scope of the procedure. The use of this procedure is justified only if the layer cannot be prepared by SILD using reagent solutions. It has been shown⁶⁹ that this situation arises if the layer to be synthesised is dissolved in the solution of either of the reagents. For example, synthesis of the $\text{ScF}_3 \cdot n\text{H}_2\text{O}$ layer is accompanied by layer dissolution during treatment with aqueous NaF to give the $[\text{ScF}_6]^{3-}$ complex ion. Therefore, a procedure including surface treatment with a solution of the Sc^{3+} salt and with gaseous HF was used for the synthesis.

Yet another example of this sort is the synthesis of Ag_2S layers.¹⁶ It was noted that with aqueous solutions of silver nitrate and sodium sulfid used as the reagents, no reproducible layer is produced, because of either the desorption of silver ions during washing of the specimen with water or the dissolution of the synthesised Ag_2S in excess Na_2S to give thio salts. Therefore, to attain the irreversibility of the surface reactions, a solution of ammoniacal silver with pH 8.8–9.2 and gaseous H_2S were used as

the reagents. After adsorption of $\text{Ag}(\text{NH}_3)_2^+$ cations, excess ammoniacal silver was removed from the substrate surface by washing with a solution of NH_4OH (pH 8.5). After that, the specimen was dried in an air flow at 70–80 °C. Apart from the removal of water, destruction of ammonia complexes took place during drying to give $\text{Ag}-\text{OH}$ and $\text{Ag}-\text{O}-\text{Ag}$ bonds on the surface. Treatment with gaseous H_2S followed by removal of its excess yielded a silver sulfide layer

The adsorbed hydrogen sulfide molecules and the S–H bonds on the surface served as the adsorption sites for the Ag^+ ions in the following SILD cycle and ensured a regular increase in the layer thickness.

VII. Successive ionic layer deposition involving ions and nanoparticles

The SILD reactions involving ions and nanoparticles were first accomplished by Iler,⁶ who studied the conditions for synthesis of multilayers of cations, for example, $\text{Al}_2(\text{OH})_5^+$, and nanoparticles from colloidal solutions of SiO_2 or boehmite on a silicate glass surface. Metal cations and negatively charged colloidal SiO_2 particles were successively adsorbed on the glass surface (Fig. 4).

The greatest number of publications is devoted to the synthesis of multilayers with participation of polyelectrolytes in the cationic or anionic form and nanoparticles in colloidal solutions (see Fig. 3). Pioneering studies in this field were published by Kotov *et al.*¹⁰⁷ and Fendler.¹⁰⁸ As an example, note the studies dealing with the syntheses of polyelectrolyte layers and nanoparticles of CdS ,¹⁰⁹ CdSe ,¹¹⁰ CdTe ,¹¹¹ ZnS ,¹¹² PbS ,¹¹³ TiO_2 ,¹¹⁴ ZrO_2 ,¹¹⁵ Ag ,¹¹⁶ Au ,¹¹⁷ SiO_2 ,¹¹⁸ MoO_2 ,¹¹⁹ and Fe_3O_4 ,¹²⁰ which have also been described in a monograph.¹¹

Among the most recent studies, noteworthy is the synthesis of mesoporous layers consisting of TiO_2 nanoparticles ~6 nm in diameter on the surface of a gold crystal.¹²¹ A specific feature of this study is that the researchers proposed to use, as the anion, the phytic acid multifunctional anion, which is adsorbed on the surface of TiO_2 nanoparticles through the PO_4^{3-} groups and simultaneously creates the adsorption sites for the next layer of nanoparticles.

VIII. Applications of nanolayers synthesised by successive ionic layer deposition

A highly important trend in the modern materials science is the design of devices with nanometre-range sizes of functional elements. The synthesis of ‘hybrid’ multilayers consisting of nanolayers of various classes of compounds is also topical, because in this case one can expect new practically valuable properties.

Among the methods used for the synthesis of nano- and multinano-layers, a special place is occupied by layer-by-layer methods, in particular, those using ion-containing solutions as precursors.

The scope of application of SILD reactions for the solution of practical problems is determined by features of the synthesis. In particular, the synthesis can be carried out under mild conditions at room temperature using automated devices with simple hardware; the layer can be applied on the surface of a series of articles of any complex shape, including disperse materials, rather than one article; dilute (10^{-1} – 10^{-3} M) solutions with a broad pH range can be used; the thickness of the resulting layer can be precisely controlled, *etc.* These features make this method promising for the synthesis of new protective passivating coatings on metal surfaces, sensors, optical coatings for the devices used for solar energy conversion, electrochromic, photochromic and magnetic materials, biocompatible coatings on the metal surface, polymeric pervaporation membranes, quantum-sized structures for optoelectronics and so on.

Now we will consider several examples of the use of these nanolayers.

1. Synthesis of biochemical and gas sensors

New opportunities for the design of structures comprising an inorganic substrate, a polyelectrolyte multilayer and a biologically active macromolecule were implemented in the existing biochemical sensors.¹²²

Several ways of immobilisation of biologically active molecules on the surface of a solid support can be distinguished: adsorption, adsorption in a matrix of a polymer layer fixed on the surface, positioning in space between the surface and a partially permeable membrane or in polymer capsules synthesised by SILD and fixed on a support surface. The last-mentioned version has been used to prepare glucose oxidase (GOx) encapsulated into the PSS/PAH layer and to study its sensory properties with respect to the glucose content in solutions. The sensor showed a linear response in the concentration range of 0–2 mmol litre⁻¹ and a non-linear response up to 5 mmol litre⁻¹. Encapsulation results in a pronounced increase in the time of sensor operation.

For deposition of cholesterol oxidase (COx) or cholesterol esterase (CE) layers on the ITO, platinum, mica, quartz or silicon surface, the PSS/PEI multilayers were used as the sublayers.¹²³ This gave the PSS/PEI/COx, PSS/PEI/COx/PEI/CE, and PSS/PEI/COx–CE/PEI structures. Study of the voltammetric characteristics of these structures has shown that they can find application in flow-type electrochemical cells for detecting cholesterol molecules.

A new approach to addressing the problem of glucose determination in physiological solutions has been proposed.¹²⁴

Figure 4. Schemes of SILD reactions involving SiO_2 colloidal particles and an $\text{Al}(\text{III})$ solution.

(1) Initial substrate, (2) after adsorption of $\text{Al}(\text{III})$ cations, (3) after treatment in a colloidal solution containing SiO_2 particles, (4) after adsorption of $\text{Al}(\text{III})$ cations, (5) after treatment in a colloidal solution containing SiO_2 particles.

According to this approach, the sensor is produced on the basis of the silicon cantilever of an atomic-force microscope coated with the pre-synthesised $(\text{PEI/PSS})_3(\text{PEI/GOx})_3$ layer. Study of the response of this sensor in various physiological solutions has shown that it is sensitive to the range of glucose concentrations of 1×10^{-2} – 1×10^{-3} mol litre $^{-1}$, which can be used for diabetes diagnosis.

If a PAH/PAA multilayer is synthesised on the surface of a quartz resonator (20 cycles),¹²⁵ this structure becomes sensitive to the adsorption of smoke particles from air. The adsorption of these particles in the multilayer is reversible: after heating in air or placing into hot water, the sensor restores its initial characteristics.

The ITO/PB/GOx – PAH structure (PB is the Prussian blue) was synthesised on the ITO surface on glass to design a sensor for determining the glucose concentration in solution.¹²⁶ The efficiency of this sensor is due to not only high level of enzyme immobilisation but also to the minimisation of the diffusion problem in nanolayers. The biosensor exhibited high selectivity with respect to glucose in the presence of acetoaminophene, ascorbic and uric acids and proved to be stable for 20 days.

To determine the concentration of oxygen dissolved in water, a sensor based on the $[\text{Ru}(\text{bipy})_3]^{2+}$ and PSS (or PDDA) multilayer has been proposed.¹²⁷ The layer shows a fluorescence maximum at 620 nm ($\lambda_{\text{excit}} = 450$ nm) whose intensity depends on the concentration of the dissolved oxygen (in the 0–12 mg litre $^{-1}$ range).

In addition to the use as biochemical sensors, the layers synthesised by SILD proved to be efficient as parts of conductometric gas sensors based on SnO_2 films. It is known that modification of SnO_2 with transition metal oxides or noble metal clusters results in the change in adsorption and catalytic properties of the surface with respect to oxygen, water and gas molecules to be detected. This is accompanied by the change in the electro-physical properties of the sensor, and, hence, its response to a change in the concentration of the mixture under analysis. A series of studies devoted to this topic were carried out by Korotchenkov *et al.*^{128–130} Both the SnO_2 layers synthesised by SILD on the quartz surface and SnO_2 films obtained on a glass-ceramic surface by spray pyrolysis and modified by oxide layers were used as investigation subjects. The SILD synthesis of SnO_2 layers was carried out by the procedure reported by Tolstoy⁵⁵ using solutions of SnF_2 and H_2O_2 . After 40 SILD cycles, a nanostructured amorphous SnO_2 layer appeared on the substrate surface; after heating at 200–400 °C, the layer consisted of 6–7-nm particles. Testing of this layer as the conductive layer in sensors for ozone, CO and H_2 demonstrated its high sensitivity with respect to ozone. The sensor shows a fast (about 2–3 s) response to the change in the concentration of this gas.

The effect of the layer synthesised on the surface of a SnO_2 film obtained by spray pyrolysis on the properties of the conductometric sensor has been studied.¹²⁹ The experiments were carried out for Cu, Co, Mn and Fe metal–oxygen layers and Ag and P metal layers. Prior to testing, all specimens were heated at 300 °C. At this temperature, the initial peroxide or hydroxide layer synthesised by SILD decomposed to give the layer of the metal oxide. It was found that the sensitivity with respect to CO and ozone increases most sharply for the sensor containing Fe–O layers. The synthesis of the Fe–O-containing layers on a SnO_2 film surface results in enhanced ‘gas response’ of the sensor, whereas the synthesis of Cu–O layers sharply decreases the response in an ozone atmosphere. The Mn–O layers are sensitive to CO.

The synthesis of Pd and Ag layers on the SnO_2 surface increases the ‘gas response’ of the sensor in a reducing gas atmosphere more than 5–10-fold and sharply suppresses the sensitivity towards ozone. For example, after two SILD cycles, the ‘gas response’ decreases more than 20–40-fold for SnO_2 –Pd samples and more than 100-fold for SnO_2 –Ag.

Thus, it follows from the foregoing that the sensitivity and the selectivity of SnO_2 -based sensors can be varied over a broad range by synthesising metal and metal oxide nanolayers on the surface.

2. Passivating protective coatings on the steel, zinc and silver surfaces

Nanolayers of inorganic compounds are widely used in the synthesis of passivating protective coatings on the metal surface. However, for some metals the corrosion resistance of this layer is limited due to its low thickness and porosity. Attempts to increase the corrosion stability by creating so-called ‘conversion’ passivating layers formed upon metal dissolution in a highly alkaline or acidic medium followed by deposition of a porous protective oxide layer on its surface have not provide the desired outcome.

Meanwhile, by using SILD, it is possible to synthesise protective layers under mild conditions using weakly alkaline or neutral solutions and to ‘after-grow’ the natural oxide layer on the metal. These experiments were carried out by Bogdanova and co-workers.^{131–134} The layers were synthesised using the SILD method by multiple treatment of the metal pre-passivated in a solution of an oxidant (as a rule, $\text{H}_2\text{Cr}_2\text{O}_7$) with salt solutions containing ions that react to form a poorly soluble compound. In particular, the following processes were conducted successively on a zinc surface. The specimen was placed into a solution of $\text{H}_2\text{Cr}_2\text{O}_7$; as a result, a polymolecular layer of hydrated chromic acid was adsorbed on the surface. Then the specimen was withdrawn and dried in air at 120–180 °C, and the excess reagent was removed by water. The specimen was placed into a solution of a metal salt [for example, $\text{Zn}(\text{OAc})_2$], dried and washed. This gave a surface layer of poorly soluble zinc chromate, which increased the corrosion resistance of zinc.

Apart from the above method, redox reactions have also been used to form a Cr(III) hydroxide layer.¹³³

The effect of nanolayers on the corrosion resistance of metals has also been demonstrated for silver.¹³¹ Corrosion tests were carried out by a drop method in a 0.18 M solution of Na_2S or by keeping the specimen in saturated vapour of a 0.1 M solution of Na_2S until a dark spot of Ag_2S appeared. The results of testing of Cr(III)–Cr(VI)-containing nanolayers showed that the corrosion resistance increases from 2–3 to 8–9 min as the number of SILD cycles increases from 1 to 6. Typically, the period of stability after six SILD cycles is 2–3 times longer than after other types of treatment.

3. Nanomaterials with magnetic properties

A nanomaterial synthesised using colloidal particles of Prussian blue, poly(ethyleneimine) and sodium poly(styrenesulfonate) can be a molecular ferromagnet.¹³⁵ The size of colloidal particles was 40 to 100 nm, the number of SILD cycles varied from 6 to 45. Fluorite, quartz, silicon and an ITO layer on glass were used as substrates. The synthesised layers were characterised by cyclic voltammetry, UV and IR spectroscopy, AFM and EPR. The researchers concluded that the concentration of, and the residence time in, the Prussian blue solution influence the content of colloidal particles in the synthesised layer; its magnetic properties at temperatures of 4–15 K were studied.

Multilayers of the PAH/PSS polyelectrolyte containing magnetite particles 20–30 nm in diameter were synthesised on the surface of melamine-formaldehyde (MF) grains 2.7 μm in diameter and human erythrocytes.¹³⁶ After dissolution of the MF matrix in an acidic medium, the polyelectrolyte capsule has nearly preserved its shape and still retained the magnetite particles. For capsules containing erythrocytes, the possibility of changing the orientation in space upon the change in the magnetic field was demonstrated. In view of these results, the researchers cited suggested that new nanomaterials with a unique set of physico-chemical properties could be designed on the basis of polyelectrolytes.

Kim *et al.*¹³⁷ designed a new material exhibiting magnetic and electrically conductive properties. On a silicon surface, the [(PSS/

PPy)₃PSS/ferrite]₂ structure was synthesised (PPy is polypyrrole). The ferrite Co_{0.67}Zn_{0.33}Fe₂O₄ with 9 nm particles was taken as the nanomaterial with magnetic properties. The layers had a conductivity of 18 S cm⁻¹ and exhibited a magnetic hysteresis.

Two procedures for the synthesis of Fe₃O₄ particles in PAH/PSS microcapsules 5.6 µm in diameter have been considered.¹³⁸ One is based on impregnation of the inner space of the microcapsule with a colloidal solution containing Fe₃O₄ particles 8 nm in diameter stabilised by citrate anions (pH 4.5). The other procedure involves the synthesis of nanoparticles inside the capsule. To this end, the capsules were kept in aqueous NaOH to create inside a solution with pH 10, which was treated with a solution containing 0.66 mol litre⁻¹ of FeSO₄ and 0.62 mol litre⁻¹ of Fe₂(SO₄)₃. This gave magnetite colloidal particles with an average size of 10 nm located inside the capsule.

A multilayer containing 10-nm Fe₃O₄ particles and PDDA macromolecules was prepared on the surface of SiO₂ nanoparticles.¹³⁹ It was shown by electron microscopy that one deposition cycle yields a 31 to 43-nm thick layer with a C : Fe ratio of ~ 2.3.

4. Luminophores, structures with a photochromic effect and photocatalysts

Europium-containing polyoxometallate layers exhibit photoluminescent properties. After UV excitation ($\lambda_{\text{excit}} = 276$ nm) of the PAH and [Eu(P₂W₁₇O₆₁)₂]¹⁷⁻ or [Eu(SiW₁₁O₃₉)₂]¹³⁻ layer, luminescence maxima are observed at 594 and 616–622 nm.^{88, 89} The intensity of the luminescence bands is directly proportional to the number of SILD cycles for layers synthesised in 1–12 cycles. The excitation of a PAH and [Eu(BW₁₁O₃₉)₂]¹⁵⁻ layer by the UV radiation of a xenon lamp gives rise to photoluminescence peaks at 591 and 613 nm,⁹⁰ while for [Eu(SiW₁₀VO₃₉)₂]¹⁵⁻ and PEI layers excited by the radiation with $\lambda = 310$ nm, the peaks are at 598 and 623 nm.⁹¹ The maximum of the photoluminescence band ($\lambda_{\text{excit}} = 276$ nm) from a [Eu(SiW₁₁O₃₉)₂]¹³⁻ and poly(4-vinylpyridine) layer containing Os(2,2'-bipy), which was obtained over 1–9 SILD cycles, was at 617 nm.⁹²

A layer containing PEI, [PMo₁₂O₄₀]³⁻ and the [Ru(bipy)₃]²⁺ complex has been synthesised.⁹³ Study of its photoluminescence showed that UV excitation with a xenon lamp results in an emission spectrum with a peak at 592 nm.

One of the polyanions can be represented by a molecule that gives a fluorescence spectrum. For example, it was shown¹⁴⁰ that a multilayer can be prepared from PVBC or PDDA polycations and fluorescein sodium salt anions. After nine SILD cycles, the PVBC/fluorescein layer exhibited an emission spectrum with peaks at 515 and 557 nm.

A luminescence spectrum was also observed for a multilayer consisting of CdTe_xS_{1-x} nanoparticles 4 nm in diameter and PAH formed after four SILD cycles on the surface of polystyrene (PS) particles with a diameter of 0.6 µm. The emission maximum in the spectrum of this specimen was at 600 nm.¹⁴¹ On the basis of these results, the researchers concluded that this method is suitable for preparing new coatings for photon crystals.

Layers of PAH and PSS polyelectrolytes with fluorescein isothiocyanate (FITC) on the surface of PS particles with a diameter of 640 nm have been proposed for the design of new class of particles with specified fluorescence and biofunctional properties.¹⁴² Fluorescein isothiocyanate has been used previously as a label in immunochemical and biomedical assays. For the PS/(PAH–FITC/PSS)_n specimen and $\lambda_{\text{excit}} = 492$ nm, the fluorescence peak was observed at 526 nm. It was shown that with allowance for the subsequent physical adsorption of proteins (immunoglobulin G), one can carry out biospecific recognition tests.

New multilayers of the hybrid compound [W₁₀O₃₂]⁴⁻ or [NaP₅W₃₀O₁₁₀]¹⁴⁻ and PEI exhibiting a photochromic effect have been reported.⁹⁴ Quartz and silicon served as substrates. The concentration of reagent solutions was 10⁻² mol litre⁻¹ and the residence time in each solution was 20 min. The number of bilayers applied varied from 1 to 12. After UV irradiation of the

layers from a mercury lamp, light-blue colour was noted to appear; this was due to the W⁵⁺ ions resulting from the redox reaction of W⁶⁺ with the NH₂ groups of PEI. The colour disappears after a 5-min exposure in air, apparently, due to the oxidation of W⁵⁺ with the atmospheric oxygen.

The colour of the [NaP₅W₃₀O₁₁₀]¹⁴⁻ and PEI layer can arise not only upon the UV irradiation but also on heating *in vacuo* to 120–180 °C.⁹⁵ In this case, a similar W⁶⁺ reduction takes place.

On the silica surface, a PEI/PSS layer and a multilayer composed of PDAC and colloidal particles Zn_{1-x}Cu_xSe stabilised by mercaptopropionic acid were obtained.¹⁴³ Excitation of the layer ($\lambda_{\text{excit}} = 322$ nm) induced an intensive blue luminescence with a peak at 450 nm, the highest intensity being observed for specimens with 2% Cu²⁺.

Photocatalysts for the oxidation of the iodide anion and decomposition of methyl orange based on TiO₂ nanoparticles and PAH with PAA have been developed.¹⁴⁴ Fused quartz, glass and silicon plates served as the substrates. The TiO₂ nanoparticles had a size of 4 nm and an anatase crystal structure. Photocatalytic reactions were induced by UV radiation of a xenon lamp (3 h). The specimens with different thickness of the TiO₂/PAH/PAA layer specified by the number of SILD cycles exhibited different activities. The final concentration of ions and molecules involved in the photocatalytic reaction in solution was lower for samples with thicker layers. Hence, no diffusion retardation for the reactants is present in the synthesised multilayer.

It has been shown¹⁴⁵ that polyelectrolyte multilayers on a glass surface may underlie the creation of a five-step photochemical structure having features of a natural photochemical structure analogous to plant leaves. The visible light is absorbed by so-called 'antennas', which represent PAH layers with coumarin (Coum) or fluorescein (Fl) additives and the porphyrin complex of divalent palladium (PdTSP⁴⁻) separated by inert Zr(HPO₄)₂ or HTiNbO₅ layers. Polyviologen molecules in poly(vinyltoluene) (PVT–MV) served as electron acceptors. The highest quantum yield was found for the Coum–PAH/PdTSP⁴⁻/Fl–PAH/HTiNbO₅/PVT–MV structure.

5. Electronic and optoelectronic devices and electrocatalysts

The synthesis of structures consisting of polyelectrolytes and semiconductor nanoparticles opens up the way for the development of a new class of electroluminescent devices, in particular, multicolour light-emitting diodes.^{146–152} These diodes can consist of a polymer with *p*-type of conduction, *viz.*, poly(*p*-phenylenevinylene) (PPV) and an *n*-type semiconductor (CdSe).

A brief review on the scope of the synthetic methods in question for the development of nanolayer-based diodes has been reported.¹⁵³ The following structures were considered: ITO/PPV/(HDT/CdSe)_n/Al layer (HDT is 1,6-hexanedithiol), ITO/PPV/(HDT/CdSe)₃/Al layer, ITO/(PDDA/TiO₂-nano)₁₀/PDDA/(GO)₃₀/PDDA/Au layer (GO is oxidised graphite), (*p*- or *n*-)Si–(Si-nano)PPy/Au layer. The CdSe nanoparticles in these structures had the size of 2–4 nm, TiO₂; 2.3 nm; Si, 5 nm.

Zener diodes have been produced.¹⁵⁴ To this end, a PPy layer and then (after several cycles), a PAH/CdSe layer were applied onto a gold substrate pre-treated with 2-mercaptoethylamine hydrochloride. The particle size of this compound was 2.0 nm. An aluminium layer sputtered onto the surface of a planar structure served as the second electrode. The synthesised nanolayers were studied by UV/Vis emission and absorption spectroscopy, AFM, X-Ray photoelectron spectroscopy and electrochemical methods.

Light-emitting diodes incorporating polyelectrolyte layers synthesised using SILD reactions have also been reported.^{84, 155, 156}

The possibilities of the design of materials for optoelectronics have been considered^{157–159} in relation to the layer-by-layer synthesis of a multilayer containing electron-conductive CdTe nanoparticles and hole-conductive polymers (for example, polyaniline and polypyrrole).

A new method for immobilisation of 5-nm CdS nanoparticles stabilised on the surface with 3-mercaptopropyltrimethoxysilane has been developed.¹⁶⁰ The method is based on nanoparticle adsorption on the substrate surface and hydrolysis of the Si—OMe groups of nanoparticles to give SiOH groups, which serve as the immobilisation sites in the next cycle of adsorption. The sequence of layer deposition cycles on the surface yields a multilayer of CdS nanoparticles non-uniformly coated by a SiO₂ layer. The photochemical reaction of CdS with atmospheric oxygen yields CdSO₄, which is water-soluble. The nanoparticle diameter decreases and they become enclosed in a SiO₂ nanocapsule.

In addition to semiconductor nanoparticles, an organic molecule giving an electroluminescence spectrum can be built-in into the multilayer of cationic and anionic polyelectrolytes. A light emitting diode was manufactured based on the PAH polycation, PAA polyanion and the Evans blue dye.¹⁶¹ The multilayer consisting of five bilayers was applied onto ITO-supported glass, heated *in vacuo* for 3 h at 120 °C, and coated with an aluminium layer by sputtering. Study of the electroluminescence intensity showed that the structure synthesised in this way has 2–3 times better parameters than the structure based on an Evans blue layer obtained by solvent evaporation on a rotating substrate.

Recent years have seen the enhanced interest in the synthesis of conductive polymer layers transparent in the visible region, in particular, PEDOT/PSS [PEDOT is poly(3,4-ethylenedioxythiophene)]. These layers are used in electroluminescent cells as buffers between the layer of a transparent conductive ITO and a layer of organic molecules with hole conduction. These polymers were obtained by SILD.¹⁶² To reduce the roughness on the layer surface, ultrasonic pre-treatment of the solution of PEDOT/PSS was carried out to destroy large colloidal particles. The resulting layers had a hole diffusion constant of $5 \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$, which is better than that for the layers synthesised by the mixing procedure.

The electrooptical properties of the layers obtained by SILD from high- and low-molecular-mass polyelectrolytes, PAH and PSS, have been studied.¹⁶³ It was found that stable layers are formed at pH 4.

A series of works on the synthesis and study of the nanowire exhibiting a diode effect was performed by Mallouk, Kovtyukhova, *et al.*^{164–166} First, a silver layer was applied by the electrochemical method as one of the contacts into the 70–200 nm pores of the Al₂O₃ film obtained by anodic treatment of Al or into a polycarbonate membrane. Then TiO₂/PSS, ZnO/PSS or ZnO/PAH layers were formed in nine SILD cycles, and the second contact, *viz.*, a gold or platinum layer, was synthesised on the surface by an electrochemical procedure. The oxide or polycarbonate matrix was dissolved. The ‘nanowire’ thus formed showed voltammetric characteristics corresponding to the rectifying effect.

The structure metal–insulator–gold nanoparticles–insulator–metal, functioning as a one-electron tunnelling device, has been produced.¹⁶⁷ The size of gold nanoparticles was 2.5 nm and the insulator was represented by a multilayer containing $\alpha\text{-Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ and PAH nanoparticles. The ‘upper’ conductive layer which ensured the contact consisted of polypyrrole applied by polymerisation.

The properties of the Ag₂S,¹⁷ (CdS)_{*x*}(Bi₂S₃)_{1–*x*},⁴⁹ Bi₂Se₃⁵⁰ and Bi₂Se₃–Sb₂Se₃⁵² nanolayers synthesised by SILD have been studied within the solar cells. The photoelectrochemical characteristics were obtained for the cells comprising an electrode that included a fluorinated tin oxide layer coated with a sulfide or selenide layer synthesised on its surface, a carbon electrode and a polysulfide electrolyte layer (Na₂S + NaOH + S). For these cells, electrophysical characteristics in the light and in the dark, spectral and temporal response and other parameters were studied.

Photoelectrochemical characteristics were also measured for a cell consisting of an electrode represented by a thin layer of fluorinated SnO₂ on a glass surface and a TiO₂ layer applied

thereon (from a TiF₄ solution).¹⁶⁸ To create internal porosity in this layer, prior to its deposition, a PAH/PAA layer was synthesised on the substrate in ten SILD cycles, and the resulting structure was heated in air at 650 °C to remove organic substances. A 0.3 M solution of LiI and a 0.03 M solution of I₂ in acetonitrile served as the electrolyte in this cell. Platinum was the counter electrode. The nanostructured TiO₂ layers showed a fourfold higher degree of light to electrical energy conversion than analogous continuous layers.

For the same purpose, SILD syntheses of polymer-based layers have been carried out.¹⁶⁹ Glass plates coated with an ITO layer were the substrates, and fullerene molecules positively or negatively charged by PPV and PSS polyelectrolytes and PAH served as the reagents. After 20–74 SILD cycles, the substrates were dried *in vacuo* at 270 °C and coated with a 200-nm thick Al layer. The voltammetric characteristics of the resulting structures were measured. A photoresponse whose magnitude depended on the ‘architecture’ of the resulting multilayer was found.

An important field of application of the SILD method is the development of new thin-layer structures exhibiting electrochromic effects. This was observed in relation to nanolayers of organic, inorganic and hybrid compounds. A polymer layer was obtained¹⁷⁰ on the ITO surface after successive treatments of the substrate in solutions of PANBUS, which is the anionic form of a polyelectrolyte, and VDAC, which is a polycation in solutions. The electrochemical cell contained ITO-coated glass with the PANBUS–VDAC bilayer applied by SILD as one electrode, an ITO layer on glass as the second electrode and the CF₃SO₃Li solid electrolyte in a photopolymerised polymer. Upon application of a potential from –3.0 to +3.0, the cell colour changed from yellow to dark-green. At 1–10 bilayers, the response time of the cell was ~10 s. If the number of bilayers exceeded 10, the response time sharply increased to be up to 24 s. Thus, the ‘depth’ of the colour of the active layer can be varied with high accuracy by specifying its thickness.

Electrochromic properties were found for layers of the hybrid compound consisting of tungstic acid and 4,4'-BPPOBP.¹⁷¹

A large number of publications report the synthesis of multilayers on the surface of electrodes and the study of their electrocatalytic activities. For example, it was found that the PDDA and cobalt tetrasulphophthalocyanine multilayer synthesised on a glass carbon surface¹⁷² functions as an electrocatalyst in the oxidation of hydrazine; the multilayer comprising [P₂W₁₇O₆₁]^{7–} and the complex obtained by the reaction of poly(4-vinylpyridine) with osmium bis(2,2'-bipy) chloride (*n*QPVP–Os)¹⁷³ reduces H₂O₂, NO₂[–] and BrO₃[–]; multilayers of PDDA and glucose oxidase involved in the redox reactions of enzymes were also studied. The properties of the layer of phosphomolybdic acid and PAMAM were studied on the surface of a gold electrode;¹⁷⁴ this layer was an efficient electrocatalyst in nitrite reduction and arsenite oxidation; an H₅SiMo₁₁VO₄₀ and *n*QPVP–Os layer¹⁷⁵ was studied in the electrocatalytic reduction of BrO₃[–] and HNO₂; and the layer of tris(2,2'-bipyridyl)ruthenium and sodium decatungstate on the ITO surface¹⁷⁶ was found to function as an electrocatalyst in the reduction of iodate ions and oxidation of oxalate ions. New electrodes exhibiting unique redox properties were produced on the basis of multilayers containing PSS polyelectrolyte and Co(II) ions with a supramolecular ligand [for example, 1,4-bis(2,2':6',2''-terpyridin-4'-yl)benzene¹⁷⁷].

6. Biomaterials and polymer membranes

Using the layer-by-layer procedure and polyelectrolytes, it is possible to incorporate biologically active molecules into the layer being synthesised, to carry out immobilisation on various surfaces and encapsulation. A multilayer of this type has been prepared¹⁷⁸ on the surface of quartz in aqueous solutions of TMPyP and DNA using 2–20 cycles. The DNA/hexadecylamine multilayers were prepared¹⁷⁹ on the fluorite, quartz and silicon surfaces; the DNA/PDDA layer was formed on the glassy carbon and quartz surfaces;¹⁸⁰ DNA/PLL, on the quartz, silicon and mica

surfaces.¹⁸¹ The PEI and DNA multilayer was produced on the surface of polylactic acid.¹⁸²

This method provides the possibility of partial solution of the biocompatibility problem of different materials by the synthesis of multilayers on their surfaces. For example, the hydrophobic surface of the major material of contact lenses permeable for oxygen molecules can be made hydrophilic and compatible with eye tissues by coating it with a polyelectrolyte multilayer (6–20 cycles).¹⁸³

For solving the biocompatibility problem for stainless steel and blood, it has been proposed¹⁸⁴ to use multilayers synthesised by multiple alternating treatment of steel surface in PEI and albumin solutions (in a citrate–phosphate buffer with pH 7.4). The morphology of these layers was studied by AFM. Investigations showed that 11 cycles of treatment of steel surface give a layer stable for 40 days which sharply increases the haemocompatibility. This synthesis was recommended for preparing biocompatible layers on the surfaces of other inorganic substrates.

Other researchers¹⁸⁵ increased the biocompatibility of stainless steel with blood by coating the steel surface with a PEI and heparin multilayer, which remained stable for 21 day after 13 cycles of SILD synthesis. The synthesis of such layers is possible on the surfaces of substrates having complicated shapes, in particular, on the inner surface of blood vessels.

The application of a polyelectrolyte layer on the surface with a complicated shape is used for encapsulation of various particles. The publications of Donat *et al.*,¹⁸⁶ Caruso *et al.*¹⁸⁷ and Radchenko *et al.*¹⁸⁸ should be considered among the first one along this line. First, a layer of macromolecules (in this case, a dextrin layer) is adsorbed on the surface of a matrix microparticle, for example, MF; subsequently, a PSS/PAH multilayer is deposited on its surface in four cycles. After dissolution of MF in 0.1 M HCl, dextrin becomes situated inside the PSS/PAH capsule (Fig. 5).

Figure 5. Scheme of SILD synthesis of a capsule on the surface of a solid particle.

(1) Initial particle; (2) after deposition of a multilayer consisting of cation- and anion-containing polyelectrolytes; (3) after dissolution of the initial particle.

The permeability of the PSS/PAH capsules for various compounds reversibly depends on pH.¹⁸⁹ When pH is low, defects and voids up to 100 nm in diameter appear on the walls due to the surface charge. This increases the permeability. In neutral and weakly alkaline media, the permeability disappears.

Apart from colloidal particles, biological blood cells or bacterial spores can be encapsulated into a polymer multilayer. In particular, the PDDA/PSS multilayers formed after two or four cycles¹⁹⁰ increased the adhesion of cells to the silicon surface (AFM study).

The multilayers of PEI/alginate or alginate/poly(L-lysine) polyelectrolytes on the surface of polylactic acid enhance its cytocompatibility with respect to chondrocyte cells, in particular, they are favourable for cell fastening on the surface, growth and activity.¹⁹¹

New systems for drug delivery in the form of microcapsules based on alginate/protamine multilayers have been proposed.¹⁹² The encapsulation procedure of a biologically active compound (α -chymotrypsin) was based on its electrostatic interaction with alginate molecules inside the capsule. A ~ 6.5 μm capsule accom-

modated up to 10^9 molecules, which is almost 1000 times larger than this value for the PSS/PHH capsule. For encapsulation of poorly soluble compounds, it has been proposed⁹⁷ to incorporate them into the multilayer of the capsule wall and then dissolve the matrix core; hence, the compound gets inside the capsule.

The possibility of increasing the time of action of drugs through encapsulation by polyelectrolyte layers has been considered.¹⁹³ Furosemide microcrystals with a size of 5 μm covered with 45- to 125-nm thick gelatin/PSS and gelatin/PDDA nanolayers served as the investigation subjects. The application of a layer formed in 2–6 SILD cycles on the single crystal surface increases the time of action of drugs 50–300-fold. The effect of multilayers on the solubility of biologically active compounds was elucidated taking dissolution of the initial and modified naproxen crystals as an example.¹⁹⁴ The alginate/gelatin, dextran/gelatin, PAA/chitosan and dextran/chitosan layers were used.

Polyelectrolyte multilayers can serve as efficient membranes for the separation of liquid and gas mixtures. The important characteristics of such membranes are the selectivity and high permeability with respect to one of the components. The SILD method provides a unique opportunity for the design of high performance membranes for pervaporation of low-molecular-mass compounds. On the one hand, it allows one to form continuous polyelectrolyte layers, and on the other hand, it is possible to specify precisely the layer thickness and modify the composition (by various additives) thus changing the permeability. The properties of membranes based on multilayers of chitosan, PEI and PDDA polycations and PAA, alginic acid and PSS polyanions have been studied.^{195,196} The density of ionogenic chemical groups was found to be an important parameter of a PEI membrane that increases the selectivity in the separation of a mixture of low-molecular-mass alcohols. Water removal from ethanol and isopropyl alcohol with a separation factor of 10 000 for a PEI/PAA membrane was observed for the multilayer obtained over six SILD cycles. The number of these groups is also important for increasing the membrane stability and enhancing the interaction at the substrate–membrane interface. Examples of separation of water and alcohols have been reported.^{197–199}

A membrane based on polyelectrolyte multilayers is also used for the separation of salt mixtures. The ion transport through ultrathin poly(vinylammonium)/poly(vinylsulfate) membranes, obtained by SILD using aqueous solutions of two polyelectrolytes, has been studied.²⁰⁰ The spectroscopic study of the permeability showed that the transport of CuCl_2 , LaCl_3 , BaCl_2 and $\text{K}_4[\text{Fe}(\text{CN})_6]$ is accompanied by simultaneous ‘intercalation’ of cations or anionic metal complexes into the membrane. In the case of Cu^{2+} , La^{3+} or $[\text{Fe}(\text{CN})_6]^{4-}$ ions, intermolecular bonds are formed inside the membrane, thus decreasing its permeability with respect to other salts, for example, NaCl and KCl. Conversely, the Ba^{2+} ions induce a decrease in the number of bonds; hence, the membrane permeability with respect to NaCl and KCl increases.

On the basis of poly(ethylene glycol methacrylate) and linear poly(2-hydroxyethyl methacrylate) layer on the porous Al_2O_3 substrate, membranes for the separation of O_2 – N_2 (with a selectivity of ~ 2) and CO_2 – CH_4 (with a selectivity of ~ 20) gas mixtures were developed.²⁰¹ The porous structure of the substrate was not changed and the layer thickness was ~ 50 nm.

Thus, different types of the SILD reactions are widely used to prepare nanostructures of inorganic and hybrid compounds on the substrate surfaces. Further development of studies along this line would apparently be related to variation of the layer composition by using diverse substrates and to the synthesis of new multilayers. This would extend the scope of practical application of nanolayers in nanotechnology.

This work was carried out with partial financial support of the Programme ‘Universities of Russia’, the Russian Foundation for Basic Research (Project No. 05-03-33207a) and the Civilian Research and Development Foundation (USA).

III. The influence of pressure and shear on the physicochemical properties of solids and chemical reactions with them	179
IV. Mechanical activation and mechanochemical reactions in mills	179
V. The use of mechanochemistry and mechanical activation for the solution of applied problems	184

Abstract. The effects of the hydrostatic and shear-inducing pressure on the physicochemical properties of solids are analysed. The mechanochemical reactions and mechanical activation are illustrated with various types of chemical transformations ranging from polymorph transitions to solid-state reactions. The prospects for the use of mechanochemistry for the solution of applied problems are discussed. The bibliography includes 299 references.

I. Introduction

The term ‘mechanochemistry’ was first introduced by W Ostwald in the ‘Textbook of General Chemistry’,[†] where he considered, in particular, various methods for the simulation of chemical processes. This term refers to chemical reactions involving reagents in any state of aggregation, although most frequently it is applied to solid-state processes and reactions either initiated by a mechanical means or involving reagents preactivated by a mechanochemical treatment.

The history of emergence and maturation of mechanochemical investigations has been reviewed elsewhere.^{1,2} M Carry-Lea, an American chemist, is commonly recognised³ as a pioneer of mechanochemistry owing to his works on the decomposition of silver halides,^{4,5} where he established specific features of the mechanochemical processes and clearly differentiated them from thermally activated ones. There are equally good reasons to consider M Faraday, who observed an acceleration of the dehydration of crystalline hydrates upon the mechanical treatment, as another father of mechanochemistry.

The first work in this field performed in Russia is likely the study of solid-state reactions with powders upon the mechanical activation by F M Flavitskii.⁶ Later, these investigations were continued in the Leningrad State University within the scope of development of a method for the qualitative analysis of ores and minerals,⁷ and further in the Tomsk State University.^{8–10} In the Soviet Union, in the 1940s, the nature of the shock sensitivity of explosives was systematically investigated.^{11,12} In approximately the same period, the importance of polymers in economics greatly

increased and thus mechanochemistry attracted specialists working in the field of macromolecular chemistry.^{13–16}

There were four major research centres actively involved into mechanochemical investigations.^{2,17}

1. The Institute of Physical Chemistry and the Institute of Chemical Physics of the Academy of Sciences in Moscow, where important theoretical studies on the nature and mechanisms of the mechanochemical processes in various systems have been accomplished.^{14,16,18–20}

2. The A F Ioffe Physico-Technical Institute in Leningrad, where the mechanisms of chemical reactions of polymers under the mechanical treatment have been elucidated by the research team of S N Zhurkov.^{21,22} More recently, a series of works on thermodynamics of the mechanochemical processes have been performed in St Petersburg by A I Rusanov and co-workers.^{23,24}

3. The Siberian scientific school of mechanochemistry of inorganic compounds. The first works in this field were performed in the mid 1950s in the Tomsk State University,^{8–10} but then the ‘centre’ of research activities moved to Novosibirsk, where studies on both the theory of the mechanochemical processes in inorganic systems and the use of mechanochemistry for the solution of applied problems related to the processing of minerals, inorganic synthesis, materials science, catalysis, *etc.* were deployed in the Institute of Chemical Kinetics and Combustion, the Institute of Geology and Geophysics, the Institute of Physico-Chemical Foundations of Mineral Processing, and the Institute of Inorganic Chemistry of the Siberian Branch of the Russian Academy of Sciences.^{25–37}

4. The Scientific Production Association ‘Dezintegrator’ and the Tallinn Polytechnic Institute in Estonia, where I A Hint and co-workers mainly elucidated the industrial applications of the rod disintegrator mills of their own design.^{38–40}

In addition, investigations in the field of mechanochemistry were conducted on a systematic basis in scientific and technological centres in Kiev,⁴¹ Ivanovo,^{42,43} Sverdlovsk,⁴⁴ Ufa,⁴⁵ Minsk,⁴⁶ and other cities of the former Soviet Union.

Nowadays, the interest of researchers to mechanochemistry does not subside but, in contrast, the community of scientists dealing with mechanochemistry and the mechanical activation expands and the number of publications in these fields rapidly increases.^{47,48} New dedicated mechanochemical centres appears in France, Italy, Germany, USA, China, South Korea, Japan, India, Canada, *etc.*

II. Studies on the influence of high pressure on the matter

A mechanical action on a solid can typically be represented as a combination of pressure and shear. Therefore, it is important to establish the role of each of the two factors in the modification of the physicochemical properties of substances subjected to a mechanical treatment. In this regard, studies on the effects of isostatic pressure, *i.e.*, the behaviour of a sample under equal loads from all directions, became important. This field was pioneered by works by G Tammann⁴⁹ and P V Bridgman,⁵⁰ which still retain their significance although they were done in the first half of the 20th century.

So far, the effects of pressure on solid-state reactions have been less explored than the temperature effects. The major reason for this is difficulties related to the experimental instrumentation and monitoring of processes taking place at elevated pressures. Nevertheless, three major aspects of the influence of high pressure on the course of chemical reactions in the solid state can be distinguished.⁵¹

The first aspect includes the influence on the intergrain interactions in mixtures of reacting solids. As has been pointed out by W Komatsu,⁵² it is important to correctly account for the total number and the overall area of the intergrain contacts, since it is they rather than the mere ratio of surface areas of reacting particles that govern the rate of a solid-state reaction, at least in its early steps.

This has been shown by W Poch⁵³ by the example of the synthesis of nickel ferrite and zinc and magnesium aluminates from the respective oxides at a pressure ranging from atmospheric to 60 kbar. The experimentally observed significant acceleration of the reactions under elevated pressures can be explained by an increase in the contact area between the reacting particles, which promotes the diffusion across the interface. The optimum pressure as regards the reaction rates is 40 kbar. A further increase in pressure decelerates the reactions, since under these conditions, the vacancy-mediated diffusion in the bulk of particles becomes the rate-limiting step and it is impeded by high pressures. In some cases, changes in the reaction rates and conversion levels are indicative of the involvement of an intermediate gas phase.⁵⁴

The second aspect of the pressure effects includes the changes within the particles of solid reagents themselves.⁵⁵ The changes can be subdivided into ones occurring with the real structure (primarily, concentrations of various defects), a modification of the interatomic distances and bond angles, and the changes inside the atoms or ions. The direction of the pressure-induced changes in the concentration of point defects is determined by whether the formation of a specific defect gives rise to a lattice dilation or shrinkage. Consequently, the concentration of the ion vacancies should always decrease and that of the interstitial ions increase with an increase in pressure, all other factors being the same. This explains the different possible net effects of pressure on the diffusion in solids and, consequently, on the solid-state chemical reactions, for which the diffusion through the layer of a solid product is the rate-limiting step.

An increase in pressure also modifies the properties dependent on the interatomic distances and bond angles.⁵⁶ In particular, this gives rise to a narrowing of the band gap so that a dielectric starts to behave as a semiconductor and even sometimes as a metal. Thus the effect predicted by K T Herzfeld⁵⁷ and N F Mott⁵⁸ in the beginning of the previous century has been successfully confirmed experimentally.

H G Drickamer and C Frank proposed⁵⁵ a classification of all transformations in solids under the isostatic compression into four groups. The first group includes the transformations accompanied by a rearrangement of atoms, molecules or ions in a crystal without substantial changes in the electronic subsystem. The conversion of the face-centred cubic lattices of alkali metal halides into primitive cubic lattices under the mechanical load can be taken as an example of this type of transformations. The second

group includes similar transitions that are accompanied by changes in the electronic subsystem. As a consequence, such transitions result in an alteration of the electrical or magnetic properties of the substance. The transition of ferromagnetic α -iron into paramagnetic γ -form can be mentioned as an example. The third group includes the structural and bulk transformations, which are characterised by the existence of a specific transition point and are accompanied by a change in the type of the electronic structure. The $\sigma \rightarrow d$ hybridisation of bonding in rubidium and potassium crystals and the transition from the f- to the d-character of bonding in crystals of cerium and other rare-earth metals upon compression fall into this group. Finally, the fourth group comprises the transformations accompanied by continuous changes in the bonding character, such as those observed in iron acetyl acetonate (the transition $\text{Fe}^{3+} \rightarrow \text{Fe}^{2+}$) as well as in some complex compounds with donor-acceptor bonds and molecular crystals upon compression.

Presently, this classification does not cover all the available experimental data and thus it cannot be considered comprehensive. Still, it can be taken as a basis for the analysis of the isostatic pressure effects on solids. Apparently, the consideration of the isostatic compression effects on molecular crystals as well as the analysis of pressure-induced changes in molecules and intermolecular interactions realised through the van der Waals and H-bonds may help to substantially extend this classification.⁵⁹

The range of studies devoted to the influence of high pressure on physicochemical properties of solids is constantly expanding. Over the recent years, the emphasis in such investigations has shifted exactly to molecular crystals.^{60–79} Probably, this relates to broad capabilities offered by this approach in the elucidation of the intermolecular interactions in biological systems and in the characterisation and modification of molecular crystals applied as functional materials (*e.g.*, a pressure-induced transition of an organic ferromagnet into an antiferromagnet).

The experimental results on the behaviour of molecular and ion-molecular crystals under the isostatic pressure have been reported. In particular, it has been established that the isostatic compression of a crystal of deuterated oxalic acid gives rise to a shortening of two hydrogen bonds and an elongation of the third one.⁵⁹ The pressure-induced structural changes in crystals with hydrogen bonds have been explored in detail by Katrusiak.^{60–64} It was demonstrated that the compressibility of an H-bond under the isostatic compression depends on its type, local environment and the type of molecular packing in the crystal.

The compressibility of hydrogen bonds in molecular crystals has been also investigated by other authors.^{65–71} In particular, it has been shown that the two $\text{NH}\cdots\text{O}$ hydrogen bonds present in the crystal structure of $\text{Co}(\text{NH}_3)_5\text{NO}_2\text{Cl}_2$ are characterised by different compressibilities: the longer bond proves more compressible. As a result of the compression, the nitro ligand is rotated, which results in a change in the bond lengths between the cobalt atom and the ligands. The $\text{NH}\cdots\text{Cl}$ bonds present in the structure behave differently: the *cis*- NH_3Cl bonds continuously shorten with an increase in pressure, whereas one of the two H-bonds in the *trans*-position elongates.^{76, 77}

The deformation of the H-bonds in crystals of the monoclinic paracetamol modification subjected to the isostatic compression is accompanied by a change in the molecular conformation: the angle between the planes of the acetamide group and the benzene ring is diminished. In contrast, similar compression of molecular layers in the orthorhombic paracetamol modification is isotropic. The results obtained made it possible to rationalise the mechanism of the polymorph transition of the monoclinic paracetamol modification to the orthorhombic one.^{65–68, 78, 79} Glycine polymorphs also produce different responses to pressure. The α -modification shows no phase transitions up to pressures of 4 GPa and the pattern of changes in the unit cell parameters is generally similar to that observed upon a temperature decrease.^{65, 66, 69–72} Meanwhile, the β -modification undergoes a phase transition already at 0.76 GPa,⁷⁹ whereas the γ -form converts in the pressure

range of 2.7–2.8 GPa into a new previously unknown modification referred by the authors to as δ -glycine.^{74, 75}

The investigations into the influence of pressure on biochemical objects is getting increasingly important. In particular, valuable information on the carbonyl–carbonyl interactions giving new insights into the nature of the β -folds and α -helices in proteins has been gained⁸⁰ and the structural changes in nucleic acids have been elucidated.⁸¹ Studies on the permeability of cell membranes as a function of pressure occupy a special place. Pressure can affect both the structure of the membrane itself and the conformations of its constituent molecules.⁸²

Changes in the intermolecular distances and mutual orientations of molecules at elevated pressures can result not only in the intermolecular changes but also in the intramolecular changes. This was evident already to Bridgman, who observed polymerisation of benzene at a pressure increased to 23–30 GPa.⁵⁰ Also, it has been found⁶¹ that the OH...O bonds joining molecules into chains, layers and helices in the crystal structures of cyclohexane-1,3-dione and dimedone are differently shortened upon compression. A more detailed review concerning the changes in molecular crystals subjected to the isostatic compression can be found elsewhere.⁸²

Studies on the influence of the isostatic pressure on reactions with inorganic compounds are rather numerous. Below, we consider only selected examples of systems, in which an increase in pressure either changes the chemical properties of components or initiates chemical reactions.

Semenenko *et al.*^{83, 84} investigated the formation of ternary intermetallics in pseudobinary systems Hf₂Fe–Hf₂Cu, Hf₂Ni–Hf₂Mn and Hf₂Ni–Hf₂Cu and their interactions with hydrogen. A model for the location of inserted hydrogen atoms within the cavities of the intermetallic matrices was proposed^{83, 84} as well as a dependence of the valence state of hydrogen atoms on their concentration therein.

An interesting inversion of the electronic levels with different symmetries has been observed, which can occur not only under the direct action of the external pressure but also in the course of a pressure-induced chemical reaction, as in the case of the alkali metal intercalation into graphite⁸³ or the formation of intermetallics containing an alkali metal as a component.

Goryainov *et al.*^{85–88} measured the Raman and IR spectra of natrolite at a pressure of 4 GPa. The experimental results were compared with the theoretical calculations of the crystal structure. According to the results obtained, natrolite behaves differently upon compression in water, which can penetrate into its cavities (in particular, the phase transitions occur at 0.75 GPa and 1.25 GPa), and glycerol, which cannot penetrate into the cavities (the compression in glycerol does not result in any phase transitions).

Therefore, the experimental data discussed above clearly indicate that studies of the behaviour of solids under pressure are necessary not only because they give important insights into the mechanisms of the mechanochemical processes but also because they represent a powerful method for the elucidation of structural and intermolecular interactions.

III. The influence of pressure and shear on the physicochemical properties of solids and chemical reactions with them

In addition to the studies of solids under the isostatic pressure discussed above, experiments providing conditions simultaneously for the compression and shear deformation yield valuable information. To the best of our knowledge, this type of studies were pioneered by Bridgman, who designed a dedicated apparatus, which provided control over the values of pressure and shear, deformation rate and sample temperature.^{89, 90}

Modified Bridgman anvil cells were utilised by R Roy *et al.*^{91–93} for the elucidation of various solid-state processes

ranging from polymorph transitions to decomposition reactions. They showed that the shear component strongly affects the process rates sometimes accelerating the reactions by a factor of a few hundred and thus increases the conversion levels, although it does not shift the equilibrium between the reactants and reaction products. For instance, the degree of decomposition of jadeite into nepheline and albite

does not exceed 10% under the action of the hydrostatic pressure at 350 °C, whereas it increases up to 60% under the simultaneous action of pressure and shear at the same temperature.

A similar apparatus was employed for the synthesis of alloys with anomalous concentrations of components and intermetallics.^{94, 95} A A Zharov *et al.*^{20, 96} demonstrated in a series of experiments that organic syntheses are possible under shear deformation and high pressure in a special reactor similar to the Bridgman anvil cells.

Studies of mechanochemical solid-state syntheses of organic compounds in anvil cells are worth a special discussion. However, the mechanisms of such processes as well as the mechanisms of solid-state reactions between organic compounds are significantly less explored as compared to inorganic synthesis.

More recently, studies of mechanochemically activated interactions between low-molecular-weight solid organic compounds appeared. As a result of these research efforts, new reactions of polymerisation of various classes of organic compounds and opening of benzene and pyridine rings were discovered and the dramatic acceleration of the polymerisation with respect to analogous reactions in the liquid phase was achieved.

Dadali *et al.*⁹⁷ demonstrated that the mechanically activated solid-state reactions between two reactants, one of which is an electron donor, while another is an electron acceptor, yield free radicals.

IV. Mechanical activation and mechanochemical reactions in mills

The mechanical activation in a mill is the most common operation in mechanochemistry. Probably, this is mainly due to two factors, *viz.*, the simplicity of the experiment and the interest of technologists, since mills are the most common devices realising the mechanical treatment of solids. Nevertheless, both mechanics and physics of the processes occurring in this type of devices remain a subject of numerous investigations.^{98–116} The vast majority of these studies are devoted to the optimisation of the grinding step for maximising the active surface area of the solid at the minimum energy consumption. The number of studies, in which mills are used exclusively for the mechanical activation, is significantly smaller.

Such studies are based on two main principles: the pulse time structure of the process (the regular alternation of two processes, *viz.*, the development of a stress field and its relaxation^{29, 98–100}) and the spatially local character of the mechanical treatment on solids (indeed, the stress field develops not in the whole volume of a solid particle but only in the areas of its contact with other particles or with the working medium).^{101–103} As a rule, this type of studies are aimed at the determination of the size of the area, where the stress field is developed under the mechanical treatment, as well as the lifetime and the actual form (*e.g.*, a pressure burst) of the field.^{104, 105} Additionally, possible relaxation channels of the stress field (*e.g.*, a temperature rise or formation of various metastable forms and new interfaces, *etc.*) and related secondary processes are explored.¹⁰⁶ Not pretending to the comprehensive survey of works in this filed, we shall just make mentions of several important contributions, *viz.*, by Maurice and Courtney,^{106–108} Gaffet *et al.*,¹⁰⁹ Tkačova *et al.*,¹¹⁰ Delogu *et al.*¹¹¹ performed abroad and by Urakaev *et al.*^{112–116} accomplished in Russia.

Studies in this field are far from being complete and probably they even should be intensified due to the potential applications of the mechanochemical processes in industry. As an example, we cite the results regarding temperatures developed in the contact areas estimated by different authors for the systems similar in terms of their chemical compositions and conditions of the mechanical treatment. The scatter in the reported values is as large as from 38 to 600–700 °C.¹⁰⁹

1. Mechanical activation of single-phase systems

If a compound subjected to the mechanical treatment is strictly single-phase, then the relaxation of the stress field can proceed by several independent pathways and be accompanied by various secondary processes, such as the heat liberation, emergence of new interfaces, accumulation of defects in crystals, formation of metastable polymorphs, amorphisation of solids and chemical transformations.

The exact share taken by each of the channels depends on the conditions of the mechanical load (*e.g.*, the energy input and the loading rate), physical properties of the solid, treatment temperature, *etc.* In some cases, the preferable relaxation channel can be altered at the course of the process. For instance, an increase in the propagation rate of a main crack during decomposition of oxy-acid salts switches the decomposition mechanism in its tip: the thermal decomposition is replaced with the mechanochemical one.^{117, 118} A gradual decrease in the size of particles subjected to the mechanical treatment results in a transition from grinding to plastic deformation.^{119, 120}

The factors affecting the formation of a stress field are depicted in Scheme 1, together with the main pathways of its relaxation.¹²¹ The left side of the Scheme relates to the grinding process, which is covered in detail in the literature, and thus it will not be considered here. The processes listed in the right half of the Scheme are typically classified as the mechanical activation.

Normally, grinding is used to create the maximum active surface of a powder at the minimum energy consumption, whereas the aim of the activation is to accumulate energy in the form of

defects or other structural modifications of a solid, which makes it possible to decrease the activation energy or improve steric conditions for its subsequent chemical transformations.

There are two distinct cases of the mechanical activation. In the first case, the duration of the mechanical treatment involving the formation of a stress field and its relaxation is longer than the chemical reaction time (these processes are commonly referred to as mechanochemical). In the second case, *vice versa*, the duration of the mechanical treatment involving the formation of a stress field is shorter than the chemical reaction time or these processes take place separately. The latter case is associated with the mechanical activation.

There are different forms of the energy storage upon the mechanical activation. Usually, they can be described as the formation of defects in crystals subjected to the activation.^{121, 122} Thermodynamics of the energy accumulation upon the mechanical load has been considered elsewhere.^{23, 24} Most frequently, the mechanical treatment gives rise to the plastic deformation and subsequently to the formation of linear defects, such as dislocations, ion and atom vacancies and interstitial ions. Recently, computer simulations of such processes have been surveyed by Gainutdinov *et al.*¹²³ In addition, this results in changes in the bond angles, emergence of broken bonds and further in the formation of free radicals (in covalent crystals) or amorphisation (in molecular crystals).

Since the defect formation in metal salts, oxides and carbides has been extensively discussed in numerous reviews and monographs (see Refs 122, 124–127), below we consider only those cases of the mechanical treatment, which are non-typical, in our opinion. These include, for instance, the activation of spinels, *i.e.*, ferrite-type complex oxides. Upon the mechanical treatment, the densely packed oxygen sublattice in spinels remains unchanged. The most important changes occur in the cation sublattice, which are manifested in the redistribution of bi- and trivalent cations over the tetrahedral and octahedral cavities.^{101–103, 128–131} This redistribution gives rise to a substantial change in the physical and chemical properties of spinels. An annealing of spinels at 500–600 °C results in the return of the cations to their typical positions so that the normal properties of spinels are restored. Similar results were obtained upon the activation of chalcogenides.¹³²

The mechanical activation enables relatively easy modification of both physical (*e.g.*, changes in the Neel temperature) and chemical (*e.g.*, changes in the leaching order of cations) properties of ferrosinels.^{133–137}

The discovery of the quasi-crystalline state, in which compounds manifest unusual physical and chemical properties, in 1984 (Ref. 138) gave a strong incentive to the search for the alternative methods for the production of quasi-crystals, in addition to the traditional method of quenching of alloys. Among other methods, the mechanochemical one was also evaluated. In 1989, Ivanov, Konstanchuk and Bokhonov^{139–141} obtained for the first time quasi-crystals by the mechanochemical treatment of intermetallics $Mg_{32}(Zn,Al)_{49}$, $Mg_{32}(Cu,Al)_{49}$ with the Frank–Casper structure.

They established that the formation of the icosahedral phase starts already in the early steps of the mechanical treatment. According to the high-resolution electron microscopy results, the nucleation and growth of the icosahedral phase are initiated by the production of rotational twinning defects, whereas the parent and the transformed phases are topotactically related to each other.¹⁴²

The same authors found^{143, 144} that the mechanochemically prepared icosahedral phase $Ti_{45}Zr_{38}Ni_{17}$ manifests a high hydrogenating activity. Similar studies were started abroad approximately at the same time.¹⁴⁵

In general, we note that the period of preliminary experimental information gathering in the field of mechanochemistry and mechanical activation of simple metal, oxide and salt systems comes to its conclusion. Likely, novel results may be anticipated in

Scheme 1

mechanochemistry of complex oxygen-containing (*e.g.*, spinels or silicic acid derivatives) and coordination compounds, where unusual (at least from the viewpoint of the compounds already elucidated) pathways of the energy accumulation due to the changes in the non-equilibrium concentrations of linear and point defects, emergence of shear structures or other pathways related, for example, to the isomerisation processes, changes in the bond angles or rotational defects can be realised.

Nevertheless, we believe that it would be more important for the moment to rationalise the whole array of the experimental information collected up to present. Very often, the results obtained are interpreted in the very standard way, something like: 'The mechanical activation gives rise to the accumulation of defects in reacting crystals thus increasing their reactivities', which is rather meaningless and worthless. Actually, no strict conclusions on the particular type of defects produced upon the activation can be derived based solely on the line broadening in powder diffraction patterns or the calorimetrically estimated enthalpies. Indeed, various defects differently affect chemical processes¹⁴⁶ and therefore a deeper analysis of the activation consequences is necessary, which is ignored by the majority of researchers.

As for the mechanical activation of molecular crystals, the number of studies devoted to the emergence and relaxation of stress fields in these systems is very limited. Although mechanochemistry of polymers is studied in sufficient detail, very little is known about the behaviour of molecular crystals under the conditions of the mechanical treatment.^{147–153} It is known^{149, 150} that structural disordering is frequently observed, which is manifested in the broadening of diffraction lines. In some cases, the H-bonds that join the molecules in the pristine crystal structure into dimers or more complex aggregates break down. Sometimes, zwitter-ionic groups are formed¹⁵⁰ or free radicals appear, if the mechanical treatment results in the scission of strong covalent bonds.^{97, 151–153}

2. Mechanical activation of multi-component mixtures

In addition to studies of the influence of the mechanical activation on single-component systems discussed above, similar studies of multi-component mixtures have been getting increasingly important over the recent years. Three major classes can be distinguished among such systems, *viz.*, solid–gas, solid–liquid and solid–solid mixtures.

a. Mechanical activation of solid–gas systems

As has been established already in the early studies (for instance, see Refs 126 and 154), the mechanical treatment affects both the sorption of gases upon their interaction with various solids and subsequent chemical reactions of adsorbed gases with solids.

The enhancement of adsorption of gases on solid surfaces upon the mechanical treatment is accompanied in some cases by the penetration of gas molecules into the mechanically deformed lattice. The sorption time *vs.* duration of the mechanical treatment function is characterised for many gases by the existence of an optimum value due to the competition of the mechanically activated adsorption and desorption processes as the active surface centres are getting gradually filled with gas molecules.

The adsorbed gas molecules can react with molecules of other compounds co-adsorbed on the same surface. As an example of such a reaction, the co-oxidation of hydrogen and carbon monoxide on quartz surfaces subjected to the mechanical activation can be mentioned. P Yu Butyagin was one of the first to start the elucidation of gas–solid reactions both under the conditions of mechanical preactivation and exactly during the activation.^{14, 18, 19} It was found^{155–157} that the mechanical treatment of metallic and oxide catalysts enhances their activity, which is traditionally associated with the accumulation of various defects in the catalysts, including point and extended defects (typically, dislocations) and changes in the ratio of areas of different crystal faces (*i.e.*, changes in the crystal habitus).

It is important to stress that not only the reaction rate but also the mechanism of the catalytic reaction changes due to the mechanical activation. This fact makes it possible to increase the selectivity of catalysts with the mechanical activation. Among recent works, studies by R A Buyanov *et al.*^{34, 35} devoted to the mechanocatalysis, *i.e.*, catalytic reactions under the simultaneous action of the mechanical treatment, deserve special attention. They accomplished a number of interesting and important catalytic transformations (*e.g.*, pyrolysis of butane over magnesium oxide or hydrogenation of butadiene over metal hydrides). Additionally, they elaborated a promising technique for the conduction of mechanochemical reactions under high pressures (10 MPa) of hydrogen, oxygen or ammonia.

The adsorbed gas molecules can not only react with the solid on its surface but also diffuse into the bulk of the solid in the course of the reaction. The influence of the mechanical activation on reactions in gas–solid systems was studied most thoroughly for oxidation, nitridation, hydrogenation and carboxylation of metals and various metal oxides. The influence of the mechanical activation on reactions of gases with polymers has been elucidated in substantially less detail, whereas the influence on molecular crystals remains virtually unexplored.

The influence of the mechanical activation on reactions of gases with metals yielding volatile products have been carefully investigated by the example of the formation of nickel carbonyl.^{126, 154} Owing to the mechanochemical treatment of nickel foil, the synthesis of nickel carbonyl can be realised under atmospheric pressure, although typically it is performed in an autoclave. During the activation process, the active centres are generated on the nickel surface, which are characterised by a weak (if any) dependence of the reaction rate on temperature. This suggestion explains the anomalies of the dependence of the reaction rate on temperature (*i.e.*, the negative temperature coefficient) and pressure.¹²⁶

The silicon chlorination is another example of the same type of processes. Both mechanical preactivation and the activation of silicon directly during the chlorination substantially accelerate the reaction and increase the yield of the product, methylchlorosilane.^{155, 156}

If the product of a mechanically activated reaction is solid, then the chemisorption of gaseous reactant on the active sites is followed by the generation and growth of the product nuclei and further by the formation of the product layer.

Since no thermal activation is involved, the occurrence of specific thermodynamically forbidden reactions under the conditions of mechanical activation was suggested, in particular, the oxidation of gold by carbon dioxide.¹⁵⁷

After the formation of a product layer, the process continues either in the kinetic or diffusion mode, depending on the ratio of molecular volumes of the solid reactant and product.

The mechanochemical hydrogenation of metals is one of the most common processes utilising the mechanical activation. The rapid attention of researchers to the hydrogenation of mechanically activated metals is likely caused by its potential in the technology of hydrogen storage. The first investigations in this direction were conducted in the Soviet Union in the mid-1980s.^{158–161} It was discovered that the mechanical activation of magnesium noticeably accelerates its hydrogenation. The conversion level can be dramatically increased by the addition of a catalytic amount of nickel, iron or chromium to the basic metal being activated.¹⁶⁰ Later, these studies were extended by foreign researchers^{162–172} to the influence of the mechanical activation on the rates and conversion levels of the hydrogenation of both traditional hydrogen absorbers (*e.g.*, FeTi, LaNi₅ or MgYNi₄) and the novel ones.^{158–161} As has been recently established,^{143, 144} the icosahedral structures produced mechanochemically or using the mechanochemical activation of some intermetallics act as highly efficient hydrogen absorbers.

More detailed information on the application of the mechanical activation for the metal hydrogenation can be found elsewhere.¹⁷³

In the case of the mechanochemically activated oxidation of metals with oxygen or halogens, the metal surface is constantly renewed due to the grinding with the product being fully or partly removed mechanically. The oxidation rate first increases until the minimum particle size is achieved and then starts to decrease.¹⁷⁴

The metal nitridation reaction proceeds through the intermediate formation of a solid solution of nitrogen in metal followed by the precipitation of the nitride phase above a specific critical nitrogen concentration in the solid solution. The further activation gives rise to the overstoichiometric accumulation of nitrogen.¹⁷⁵ The mechanically-assisted nitridation of titanium is only efficient if the nitridation is carried out directly during the activation, whereas the preactivation gives only insignificant gain in the reaction rate.¹⁷⁶

The nitridation of stainless steel in the atmosphere of ammonia is more efficient than in nitrogen. The activation however is accompanied by the conversion of γ -iron into α -modification.¹⁷⁷

The mechanical treatment of silicon in the atmosphere of ammonia at 100 °C yields α -Si₃N₄; the complete conversion requires 48 h. At room temperature, the complete conversion is reached only after ~168 h.¹⁷⁸

Kalinkin *et al.*¹⁷⁹ demonstrated that the mechanical activation of diopside CaMgSi₂O₆ is accompanied by the carbon dioxide adsorption on the surface of the sample.

b. Mechanochemistry of solid – liquid reactions

The investigations into the mechanical activation of solid – liquid reactions are dominantly stimulated by the progress in two industries broadly exploiting these processes. In hydrometallurgy, such processes offer a route to increase the efficiency and selectivity of leaching of valuable components from ores and minerals.^{26, 37} In pharmaceuticals, the mechanical activation is employed for the solubilisation of poorly soluble medicines.^{149, 152, 180}

As has been established already in the early works devoted to the mechanical activation, it is the accumulation of various defects in the reacting solid rather than mere increase in the specific surface area upon grinding that is responsible for the increase in reactivity. Extended defects, *i.e.*, dislocations, play a crucial role in the process of dissolution so that the dissolution rate correlates with the dislocation density.^{181, 182}

When a mixture of two components forming a galvanic pair rather than a single-component solid is dissolved, the mechanical activation of the components can change their electrode potentials and thus affect the dissolution rate.^{183 – 186}

It should be however taken into account that under specific values of viscosity of the slurry and the intensity of the mechanical load, the conditions suitable for hydrothermal processes can evolve in the system upon mechanically assisted dissolution.^{29, 187}

The dissolution of molecular crystals has certain distinctive features as regards the effects of the mechanical activation. Typically, the mechanical activation of such crystals induces either polymorph transitions or amorphisation. The exact mechanism of the process remains unclear: whether it proceeds through the intermediate step of the accumulation of extended defects or through the step of contact melting followed by the recrystallisation.

In some cases, the mechanical activation results in the decomposition of dimers initially present in the crystal structure. The amorphisation of molecular crystals or transition into metastable modifications increases the rates of dissolution and the solubilities (in the case of the micellar mechanism of the dissolution).

The influence of the mechanical activation on the processes of dissolution of solids has been elucidated not only for water but for other solvents as well. In particular, the mechanical activation increases the rate and the conversion level in the interaction of propyl iodide or bromide with aluminium,^{188, 189} initiates the

styrene polymerisation^{190, 191} and pyrazine oxoalkylation.¹⁹² However, very little information is available concerning the mechanisms of the activation for all these processes, despite their significance in chemistry.

c. Mechanochemistry of solid – solid reactions

Mechanochemically initiated solid-state processes have recently become a subject of intense investigations. Probably, this is due to the potential applications of such reactions in technology, in particular, for the development of the so-called dry processes, which are more environmentally friendly and cost efficient than the currently adopted technologies.¹⁹³

Any chemical interaction between solids proceeds neither in the entire volume of the reacting compounds nor on their entire surface but rather exclusively in the contact areas between the particles.¹⁹⁴ Thus the total number of such contacts between reacting particles plays the decisive role at the initial steps of a solid-state reaction. This means that it is always desirable to grind and mix components in such a way as to prevent the aggregation of particles of the same component (this dramatically decelerates the reaction). The mechanical alloying is often classified as a variant of the mechanochemical reactions. As a rule, the mechanical alloying is used for the preparation of solid solutions and metastable intermetallics provided that the traditional methods for their synthesis are either difficult or inconvenient for other reasons.^{195 – 208} Furthermore, a mechanochemical synthesis yields the respective product as a highly dispersed phase, which can be useful for the subsequent technological steps.¹⁹⁵

In order to illustrate such an approach, we mention the systems Mg – Ti or Al – Nb, in which the boiling point of the first component lies below the melting point of the second component.

By means of mechanochemistry, it proves sometimes possible to shift the boundaries of the formation of substitution solid solutions beyond the thermodynamical limits established for the equilibrium state. In particular, the ultimate solubility of aluminium in nickel, according to the respective equilibrium diagram, is 13.5 at.% at 1000 °C; it decreases by a factor of 3.5 at 500 °C and becomes fractions of a percent at room temperature. Notwithstanding, the mechanochemical method enabled preparation of solid solutions of aluminium in nickel with the aluminium content as high as 28 at.% (Ref. 198).

Solid solutions can be synthesised not only by the mechanical treatment of the respective mixtures but also by the mechanical activation of the intermetallic compounds that are characterised by low enthalpies of formation. In particular, solid solutions NiV and CoV manifesting anomalous magnetic properties have been prepared in this way.^{199, 200} Mechanochemical approach has been applied to prepare several solid solutions with positive enthalpies of mixing, such as solid solution of copper in iron.^{208, 209}

The similarity between the atomic sizes and general structures of the components are the main factors governing the possibility of the formation of solid solution under the mechanical alloying.^{197, 203 – 205} As has been established for the systems Ni – In, Cu – Sn and Cu – In, the formation of solid solutions proceeds as follows. First, after the complete intermixing of the alloy components, the respective intermetallics compounds, *viz.*, Ni₁₀In₂₇, Ni₂In₃, Cu₆Sn₅ and Cu₉In are produced. Then, their structures are distorted due to the second order microdeformations giving rise the deformational packing defects.^{204, 205}

Investigations into the mechanochemical transformations in the systems Fe – X (X = C, Si, Sn or Ge) can be illustrated by the results of E P Yelsukov *et al.*^{206 – 211} According to their model, the formation of binary compounds in these systems proceeds in several steps. First, nanostructures with a domain size of ~10 nm are generated due to the diffusion of X along the intergrain boundaries of iron. Then, the intermetallic compounds and the amorphous phase emerge. Further, the atoms X diffuse from the boundaries into the bulk of the iron grains thus giving rise to the intermixed solid solutions.

The sequence of transformations upon the mechanochemical iron carbonisation below 32 °C have been established by X-ray diffraction.²¹¹ If the carbon content $[C] < 20\%$, the product is amorphous; whereas for $[C] > 20\%$, crystalline iron carbides Fe_3C and Fe_7C_3 are formed. The initial steps of the process include grinding of the components, their intermixing and the generation of nanocomposites with a particle size of ~ 10 nm. In parallel, the atoms of the second component X diffuse into α -iron along the intergrain boundaries. In the case of metalloids with the atomic radius comparable to that of iron (*i.e.*, Si, Ge and Sn), the intermetallics (FeSi_2 , FeGe_2 and FeSn_2 , respectively) are directly nucleated in the areas of their local concentration, *i.e.*, along the intergrain boundaries. The further mechanical treatment affords solid solutions. In the case of metalloids with the atomic radius substantially smaller than that of Fe (*i.e.*, C), the emergence of the carbide phase is preceded by the formation of an amorphous phase.

A similar sequence of steps was observed in the solid-state synthesis of intermetallics Fe–Ti,²⁰⁹ Fe–Zr,²¹⁰ Ni–Ge²¹² and Ni–Bi.²¹³

P Yu Butyagin²¹⁴ proposed a classification of all mechanochemically activated solid-state reactions into two groups, depending on the rate-limiting step of the overall process: either the development of contacts (*e.g.*, as in the synthesis of lead niobate, where the reaction proceeds in the near-surface regions) or the mass-transfer into the bulk (as in the synthesis of nickel aluminide).

Very high diffusion coefficients of atoms or ions constituting a solid phase is a distinctive feature of mechanochemical solid-state syntheses. To be distinguished from the ordinary diffusion determined by the concentration gradients, this type of diffusion is denoted with a special term, ‘deformational atomic intermixing’, or ‘ballistic diffusion’. Several hypotheses regarding the mechanism of this process have been suggested. Butyagin proposed¹²² that the interstitial sites of the lattice are responsible for the diffusion, whereas Schwarz argued²¹⁵ that the diffusion proceeds through the dislocations, the number of which increases continuously upon the mechanical treatment. Therefore, the exact mechanism of the deformational atomic intermixing remains a subject of debate.

Sometimes, particular contact conditions are realised so that the direction of the mechanochemical process contradicts the thermodynamical calculations. For instance, the rate of the solid-state interaction of tungsten trioxide with alkali-earth metal carbonates is the maximum in the case of barium carbonate, although this should be opposite, assuming that the rate should correlate with the change in the free energy during the process.²¹⁶ A similar situation is observed for the interaction of potassium persulfate with methyl- and phenyl-substituted imidazoles.²¹⁷ According to both computer simulations^{218,219} and experiments,²²⁰ the mechanical treatment substantially accelerates the diffusion processes in solid phases. In particular, the coefficient of chromium diffusion into iron is $10^{-12} \text{ cm}^2 \text{ s}^{-1}$ and $2 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ at room temperature and at 1400–1600 K, respectively. Meanwhile, it can be increased up to 10^{-5} – $10^{-7} \text{ cm}^2 \text{ s}^{-1}$ with the mechanical activation.

Karagedov *et al.*²²¹ suggested that the accumulation of defects cannot be the only factor driving the marked acceleration of mechanically activated solid-state synthesis of complex oxides from simple oxides since the defects can be cured even before the initiation of the reaction. The most significant result is the adjustment of the size distribution of particles in the reaction mixture in such a way as to provide the densest packing and preventing aggregation.

The mechanochemical synthesis in multi-component systems represents yet another direction in the field of solid-state inorganic synthesis.²⁰⁰

The possibility of participation of fluidic (gaseous or liquid) phases in the processes at their intermediate steps has become increasingly important over the recent years. Indeed, a process,

which is formally considered as a solid-state reaction, can actually represent a certain combination of solid + gas or solid + liquid reactions. In this regard, the control over such processes requires alternative tools as compared to the case of truly solid-state reactions.²²²

The presence of water in solid-state systems either before or after a reaction is of particular interest. E G Avvakumov, E G Devyatkina and N V Kosova^{223,224} elaborated an original method referred to as the mild mechanochemical synthesis. Essentially, two hydroxides, one of which is acidic, while the other is basic, can be used as precursors in the synthesis of a complex oxide instead of simple oxides. The rate of the mechanically activated neutralisation reaction appears higher than the rate of the interaction of non-hydrated oxides.

Studies in the same directions were then continued by M Senna and co-workers²²⁵ The results of these joint research efforts were summarised in a monograph.²²⁶ The authors demonstrated that the mechanical activation converts the bridging metal–oxygen–metal bonds in the acidic component into the bridging bonds between the basic and acidic components, *i.e.*, in the case of the reaction of $\text{Ca}(\text{OH})_2$ with $\text{TiO}_2 \cdot 0.82 \text{ H}_2\text{O}$, the Ti–O–Ti bonds are converted into the Ca–O–Ti bonds.

Water released in the neutralisation process can act as an additional factor for the reaction acceleration. Conditions suitable for hydrothermal processes can evolve in the system. The first assumptions that hydrothermal reactions can be initiated under the mechanical activation of oxides containing water have been made already in the very early works devoted to the mechanochemical synthesis (see, for instance, Ref. 227). However, the comprehensive argumentation in favour of this hypothesis has been given later.^{29,228,229} There is serious experimental evidence of the attainability of hydrothermal synthesis in mechanochemical activators.^{230,231}

The heat delivered in a system as a result of a chemical reaction and the relaxation of a stress field upon the mechanical treatment can actuate the transition from the mechanochemical synthesis regime to the self-propagating high-temperature synthesis.^{232–234} Apart from the cognitive interest, this phenomenon holds some promise for applications. First of all, the self-propagating high-temperature synthesis can be realised in those systems, where the adiabatic temperature is not sufficient for sustaining the combustion. Second, this switch of the modes can eliminate the possible negative combustion impacts on the product, such as sintering and oxidation.^{235,236}

P G McCormick and co-workers²³⁷ discovered that if a system composed of two reactants that react to yield two solid products is diluted with one of the products, then the second target product can be produced in the form of nanoparticles. In particular, cadmium sulfide with the particle size of the order of a few nanometers can be produced by the solid-state reaction of cadmium chloride with sodium sulfide, if the reaction mixture is diluted with sodium chloride. The optical properties of such nanoparticles, the so-called quantum dots, differ substantially from those of crystalline cadmium sulfide.²³⁸ Similar syntheses have been realised for nanoparticles of metals,²³⁹ simple and complex oxides,^{240–245} nitrides²⁴⁶ and salts.^{247,248}

Balaž *et al.*²⁴⁹ reported on a mechanochemical method for the preparation of nanoparticles of cadmium, lead and zinc sulfides by the reaction of the respective metal acetates with sodium sulfide.

Gras *et al.*²⁵⁰ demonstrated that the mechanochemical synthesis of molybdenum silicide from elements yields particles with a size of ~ 90 nm, whereas only larger particles can be produced by the self-propagating high-temperature synthesis due to the sintering of particles in the combustion wave. Boron nitride nanotubes were successfully prepared by Chen *et al.*²⁵¹ by the mechanochemical reaction of boron with ammonia.

Investigations into the mechanochemical solid-state reactions of molecular crystals is a rather new but promising direction. The potential importance of this field relates not solely to the tradi-

tional fields of applications of molecular crystals, such as pharmaceuticals, but also to the newly discovered possibilities of their utilisation as functional materials for molecular electronics, molecular magnets and so on.

Within this field, mechanochemically assisted reactions of organic synthesis play the key role. Studies in this direction were started back in the 1950s.²⁵² Later, the possible implementation of a number of organic syntheses in reactors similar to the Bridgman anvil cells and extruders^{253, 254} was demonstrated by A A Zharov *et al.*^{20, 96} and by N S Enikolopov.¹⁶ More recently, various mills were tested as activators, especially ones providing the high energy input, such as vibrational planetary mills and attritors. It was established that many types of organic reactions (*e.g.*, halogenation, esterification, acetylation, *etc.*^{255–258}) can be realised with these devices. Furthermore, in some cases, the mechanochemical method has proven to be not only simpler and faster than the traditional syntheses but more selective as well.

The number of publications devoted to the use of mechanochemical approach in the synthesis of various organic compounds constantly increases. As selected examples, one can mention the solid-state synthesis of tris(4-imino-2-pentanonato)chromium by the mechanically activated reaction of chromium(III) chloride with (4-imino-2-pentanonato)sodium,²⁵⁹ the synthesis of oxazolidines by the mild mechanical treatment of mixtures of β -aminoalcohols with aldehydes and the synthesis of Schiff bases from mixtures of crystalline aldehydes and amines.^{260, 261} One of the traditional methods for the oxidation of organic compounds is the reaction with lead tetraacetate or manganese triacetate in a liquid phase. Nikishin *et al.*²⁶² implemented this process in the mechanochemical mode by the activation of the reaction mixtures in a vibrational mill.

The phosphorus atoms can be incorporated into the aluminosilicate framework of zeolites by the mechanically activated solid-state interaction of the respective sodium zeolites with aluminium phosphate. This gives rise to the variation in the lattice parameters, which makes it possible to design molecular sieves with improved thermal stability.^{263, 264} In a similar way, various organic molecules can be intercalated into the interlayer space of kaoline by the reaction between them in the presence of alkali metal halides.^{265–268} The mechanochemical method is also useful for other reactions. In particular, Hihara *et al.*²⁶⁹ utilised the mechanical activation for the synthesis of nickel and copper complexes with dimethylglyoxime. The use of solid-state mechanochemical synthesis for the preparation of various boron compounds, including diborane, borane adducts with nitrogen-containing organics, borazine and transition metal tetrahydroborates, have recently been reviewed by Volkov and Myakishev.²⁷⁰

As has already been mentioned, the mechanisms of the solid-state reactions of molecular crystals are less elucidated as compared to the reactions of ionic crystals. In some cases, even the actual solid-state character of the process cannot be proven, since the contact melting or sublimation of components in intermediate steps of the reaction cannot be decisively ruled out. In the case of macromolecular compounds (*e.g.*, cellulose), the interaction can be truly solid-state, whereas the involvement of fluidic phases is highly probable in the intermediate steps of reactions with crystals of low-molecular-weight organics.

Summarising all the experimental evidence discussed above, we note that the extensive experimental data have been gathered thanks to numerous investigations accomplished both in Russia and abroad. Nevertheless, the mechanisms of many processes realised in the mechanochemical reactors remain poorly understood. Partly, this is explained by the complexity of the processes under study. However the main problem, in our opinion, is that the elucidation of the mechanisms is rarely formulated as an aim of the investigation and researchers often limit themselves to the preparation of a material with desired properties or the realisation of a process with the target parameters. However, the deep

understanding of the mechanisms is a prerequisite for the fine control over the processes.

V. The use of mechanochemistry and mechanical activation for the solution of applied problems

Initially, such large-scale industries as hydrometallurgy,^{1, 26, 37, 271} production of construction materials and fertilisers^{39, 40, 272–274} were envisaged as potential fields of application of mechanochemistry. Nevertheless, despite very promising results obtained in laboratories, industrial implementations of the mechanochemical processes remain challenging owing to the lack of high-energy-input devices with sufficient performance. The available equipment (typically, mills) does not provide the energy input that is high enough for the large-scale mechanical activation.

Several attempts have been undertaken to perform industrial validation of the mechanochemical methods in these fields. In particular, mechanochemical processes were implemented in a plant for the hydrometallurgical processing of chalcopyrite into copper and sulfur in Wittenberg, in a facility for the acid-free production of fertilisers from natural phosphates in the Hubsugul deposit in Mongolia and in the production of silicalite in Estonia. Unfortunately, no anticipated benefits from the implementation of these processes were achieved.

On the other hand, mechanochemistry has proven its efficiency in smaller-scale factories aimed at the production of more expensive goods. In non-ferrous metallurgy, the mechanical activation is successfully applied to the opening of tungsten and gold ores.

Nowadays, the mechanochemical methods are in the wide use in the production of catalysts,^{34, 42} functional ceramics,^{275, 276} diverse special-purpose materials,^{277–283} materials for hydrogen storage,¹⁷³ ligatures for metallurgy, *etc.* In pharmaceuticals, the mechanochemical methods are commonly employed for the production of medicines and control of their stability with respect to grinding, mixing, pelletisation and preparation of dosage forms from substances.^{149–152, 284–286}

The mechanical activation is actively employed in the production of pigments and cosmetics.²⁸⁷ The use of this method opens new avenues in preparative chemistry, including both organic and inorganic synthesis.^{259–264}

The mechanical activation is used in processing of organic wastes, including poly(vinyl chloride), bromo- and chloro-containing aromatics.^{288–292} The mechanical treatment of hexachlorobenzene, 1,4-dichlorobenzene, octachloronaphthalene or *o*-nitrochlorobenzene in the presence of alkaline agents, such as calcium oxide or hydride, yields²⁸⁸ recyclable phenols and naphthols. The dechlorination can afford different products, depending on the intensity of the treatment. In particular, *o*-nitrochlorobenzene and 3-chloro-2-nitrophenol are obtained as the main products under mild and drastic conditions, respectively.

The mechanical treatment of clay minerals can be utilised for the extraction of phenol from aqueous solutions^{266, 267} and water purification from radionuclides.^{293, 294} It is of note that these efforts aimed at the application of the modern achievements of mechanochemistry to the intensification of small-scale expensive industrial processes are based on the specific results of dedicated fundamental investigations to the largest extent than ever before.^{295–299}

We believe that industrial implementations of mechanochemical processes should be expected in these directions. However, it would be a mistake to think that the process will be smooth and seamless, and this is due to several reasons.

The apparent simplicity of the method acts simultaneously as an advantage and a disadvantage of the method. Historically, experimentalists armed with ordinary mortars were commonly considered to be prepared for the conduction of mechanochemical investigations. Moreover, a team equipped with a mill instead of mortars was often recognised as one specialised in mechanochemistry.

As a result, the number of successful implementations of mechanochemistry in technology is relatively small despite the huge total number of related studies (as we have mentioned before, the number of publications and patents in this field has increased dramatically over the last decade). It is of no surprise taking into account the fact that the trial-and-error method remains the key methodological tool in the vast majority of the experimental works. In essence, all such studies fall into one simple scheme: a researcher takes a compound or a mixture of compounds, treats it mechanically and looks at the result. It is rather surprising that even this methodology sometimes yielded positive results at all.

Up to the present, mills are most commonly used for the mechanical activation, although these devices are not designed for this purpose, strictly speaking. The purpose of a mill is to treat the material in order to generate the maximum surface area at the minimum energy consumption for the grinding process. In contrast, the purpose of an ideal device for the mechanical activation is to insert the maximum amount of energy into the treated solid to enable the accumulation of the input energy as defects mostly affecting chemical reactivity. This requires high energy inputs to be transferred from the working medium to the treated solid during the mechanical activation, which cannot be achieved with ordinary disintegrators. The ordinary mills have to be redesigned (and sometimes quite significantly) to take this requirement into effect. This, however, can lead to another problem related to the possible contamination of the compound subjected to the mechanical activation with the materials composing the working medium and the reactor body. This problem becomes more and more prominent as the energy input increases.

In order to relieve this problem, hard materials, such as tungsten carbide or silicon nitride coated with teflon or other inert substances can be utilised. The most efficient way is to operate in the self-lining mode, *i.e.*, to use the treated compound itself as a material forming the protective coating of the working medium and the reactor body.

The mechanical activation of mixtures creates even more serious problems. As has already been mentioned above, in order to activate a solid-state process it is necessary, first, to grind the components of the mixture, second, to mix them in such a way as to generate the maximum number of contacts between the particles of reacting components and, third, to create conditions for the mutual diffusion of the atoms or ions involved into the reaction, formation of the intermediate solid solution and withdrawal of the reaction product. Naturally, the currently adopted simultaneous realisation of these three totally different physical operations in the same apparatus does not make much sense. It would be more advisable to separate these operations, which should be taken into account in the design of the activator (the use of three specialised machines could be an alternative). Another possibility is to combine the mechanical activation of a solid-state synthesis with other methods, *e.g.*, with the preliminary mixing of the components by co-precipitation or by the sol-gel technology.

We considered above only several main problems impeding the wide industrial utilisation of the recent advancements in the field of mechanochemistry. Although they are to be solved in different ways, all the ways include one common factor: fundamental investigations in the field of mechanochemistry should be stimulated and developed at the utmost in order to make progress towards applications. As for the character of the most topical investigations, the information gathering step should be already replaced with the systematisation of the available information and construction of models for the mechanical activation and mechanochemical reactions. So far, this has been accomplished only in a few particular cases. The accumulation of experimental facts is still underway but it should not last forever.

Chemistry of ureido carboxylic and ureylene dicarboxylic acids

A N Kravchenko, I E Chikunov

Contents

I. Introduction	191
II. Synthesis of ureido carboxylic and ureylene dicarboxylic acids	191
III. Chemical transformations of ureido carboxylic acids	197

Abstract. The review presents a comparative analysis of procedures for the synthesis of ureido carboxylic and ureylene dicarboxylic acids. Chemical transformations of these compounds are summarised. New fields of application of ureido carboxylic acids in the synthesis of chiral, diastereomeric and enantiomerically pure *N*-carboxyalkylglycolurils are considered. The bibliography includes 129 references.

I. Introduction

Procedures for the preparation of ureido carboxylic and ureylene dicarboxylic acids (hereinafter, ureido acids and ureido diacids, respectively) and their chemical transformations are being widely discussed in the literature. These compounds deserve attention because of diverse physiological activities.^{1–7} For example, the simplest representative of ureido acids, *viz.*, *N*-carbamoylglycine, exerts sedative, antihypoxic and anticonvulsant effects in mice.² *N*-Carbamoyl- β -alanine binds to the PEPT2 protein in *Pichia pastoris* yeast cells, serves as a peptide transporter in *Xenopus laevis* oocytes and has antidiabetic properties.³ *N*-Carbamoyl- γ -aminobutyric acid shows properties of a weak GABA antagonist (GABA is γ -aminobutyric acid).⁴ *N*⁶-Methyl-*N*⁶-nitroso-(*S*)-citrulline was shown⁵ to be an antitumor agent. *N,N'*-Carbonylbis(methionine) is used for the design of insulin analogues.^{6,7} Besides, ureido (di)acids are promising building blocks in the synthesis of various biologically active heterocyclic compounds.

The aim of the present review is to systematise procedures for the synthesis of ureido (di)acids and their chemical transformations. Reactions of achiral, racemic and optically pure ureido acids with α -dicarbonyl compounds and 4,5-dihydroxyimidazolidin-2-ones in the synthesis of potential biologically active glycoluril derivatives containing *N*-carboxyalkyl groups are considered.

II. Synthesis of ureido carboxylic and ureylene dicarboxylic acids

First syntheses of ureido acids were performed by Harries⁸ in the early twentieth century and were based on the reaction of glycine ethyl ester hydrochloride with potassium cyanate (by analogy with the first synthesis of urea from ammonium isocyanate⁹). The

reaction product, *viz.*, ethyl ester of ureidoacetic acid (*N*-carbamoylglycine), was not isolated in pure form but was subjected to cyclisation giving rise to hydantoin.

Various procedures have been developed for the synthesis of ureido acids. Let us mention the following three main methods:

- (1) reactions of amino acids with KOCN (the cyanate method);
- (2) reactions of amino acids with urea;
- (3) cleavage of 5-substituted imidazolidine-2,4-diones (hydantoins) and related compounds.

Selected representatives of this class were synthesised according to alternative procedures. Methods for the synthesis of ureylene dicarboxylic acids are reviewed in a special section.

1. Cyanate method for the synthesis of ureido carboxylic acids

Numerous ureido acids were synthesised by the cyanate method. *N*-Carbamoylation reactions were carried out with achiral, racemic and optically active *S*- and *R*-amino acids (Table 1). The reactions of KOCN with amino acids were carried out in aqueous solutions in the absence of catalysts or in the presence of an alkali or an acid at temperatures from 20 to 100 °C; the reaction time varied from 20 min to 48 h. The yields of ureido acids **1a–u** are 40%–67% (see Table 1).

R = H, X = (CH₂)_n; n = 0 (**a**), 1 (**b**), 2 (**c**), 3 (**d**); R = H, X = CH₂NHC(O) (**e**); X is absent: R = Me (**f**), Et (**g**), Prⁿ (**h**), Prⁱ (**i**), Buⁱ (**j**), Bu^s (**k**), CH₂SH (**l**), (CH₂)₂SMe (**m**), CH₂CO₂H (**n**), CH₂C(O)NH₂ (**o**), (CH₂)₂CO₂H (**p**), (CH₂)₂C(O)NH₂ (**q**), CH(OH)Me (**r**), Bn (**s**), CH₂C₆H₄OH-4 (**t**), (CH₂)₃NHC(O)NH₂ (**u**).

The reactions of amino acid esters with alkyl isocyanates also afford ureido acid derivatives. In both cases, the reactions proceed by the mechanism³³ analogous to the mechanism of the synthesis of urea from ammonium cyanate.^{9,28}

nor-Val	H ₂ O, 20 °C, 48 h, pH 2	h	19, 24
Val	H ₂ O, 50 °C, 15 h, pH 7.5	i	15
	H ₂ O, 60 °C, 4 h	i	11
	H ₂ O, 20 °C, 48 h, pH 2	i	19
Leu	H ₂ O, 20 °C, 72 h, pH 2	j	19
Leu·HCl	H ₂ O, 60 °C, 4 h or 50 °C, 18 h; pH 7.5	j	15
	H ₂ O	k	25
Ile	H ₂ O	k	25
Cys	KOH, H ₂ O ^a	l	26
Met	H ₂ O, Δ, 30 min	m	15
Asp	1 M KOH, H ₂ O ^b	n	27, 28
	H ₂ O, Δ	n	27, 28
Asn	H ₂ O, Δ ^c	o	29, 30
Glu	KOH, H ₂ O	p	12
Gln	H ₂ O, 20 °C, 40 h; HCl, pH 2, 5–7 h	q	31
Thr	H ₂ O, 50 °C, pH 8	r	15
Phe	H ₂ O, Δ, 4 h; pH 2	s	23
Phe·HCl	H ₂ O, 60 °C, 4 h	s	23
	H ₂ O, 50 °C, 15 h, pH 7	s	15
Tyr	H ₂ O, Δ	t	30
Cit	H ₂ O, Δ ^d	u	32

Note Hereinafter, δ-APA is δ-aminopentanoic acid and α-ABA is α-aminobutyric acid, Cit is citrulline; ^a the reaction was carried out also with the use of NaOCN and NaOH; ^b fulminic acid was used instead of KOCN; ^c partial racemisation of amino acid occurs; ^d the reaction was performed with the use of HNCO.

The mechanism and kinetics of the reaction of amino acids with cyanate anions have been considered in detail.¹⁵ In this study, a kinetic model of *N*-carbamoylation in the pH range of 2–13 at ~40–50 °C was suggested. In aqueous solutions, KOCN forms isocyanic acid, which undergoes to hydrolysis or nucleophilic addition of amines, *i.e.*, several competitive processes occur. It is assumed that the reactions of cyanate ions with water (reactions 1–3), ammonia (reaction 5) and alkylamines (reaction 6) involve the electrophilic (proton) or nucleophilic (OH[–]) attack on isocyanic acid to form carbamates or urea derivatives (in the case of *N*-nucleophiles). In addition, the CO₃^{2–} anion efficiently catalyses hydrolysis of HNCO (reaction 4). Each slow step (the rate constants of these steps are denoted by *k*₁–*k*₄) is followed by fast cleavage of carbamates (or carbaminic acid) to give NH₃ and CO₂. It should be noted that ureas are much more stable than

carbamates. Calculations and experimental data showed¹⁵ that all reactions are first order with respect to each reagent.

The following optimum conditions of the selective formation of ureido acids were found by studying the reactions of glycine, L-alanine, β-alanine, L-phenylalanine, L-valine, L-leucine, DL-methionine, *N*^ε-trifluoroacetyl-L-lysine and L-threonine: pH 7–8, 50 °C, a 1.5–2-fold excess of cyanate and the reaction time of 10–24 h. Under these conditions, the NH₃ and CO₂ concentrations are low, the formation of carbamates and urea is insignificant, and hydrolysis of ureido acids occurs so slowly that this process can be ignored. Consequently, ureido acids are formed as the major products. The results of kinetic studies were used to synthesise the corresponding ureido acids in preparative yields (40%–80%).

One of the authors of the present review has made an important contribution to the development of the cyanate method (see Refs 13 and 14). The conditions of the reaction of amino acids with KOCN were optimised taking into account the data¹⁵ on the kinetics of *N*-carbamoylation. A distinguishing feature of the procedure is that KOCN is added portionwise to an amino acid solution in water or aqueous isopropyl alcohol at 80–90 °C. Then the reaction mixture is heated to boiling followed by storage of the reaction mixture for 20–30 min, which afforded ureido acids **1a–u** in 60%–94% yields. In the procedures used earlier, KOCN was added in one portion, and, after 48 h, the reaction products were obtained in yields of only 43%–61%.²⁴ In addition, *N*-carbamoylation performed under the conditions used earlier²⁴ was accompanied by competitive hydrolysis of cyanate ions.

In many investigations,^{11–15, 17–27, 29, 31, 32} it was reported that the chiral carbon atom was not affected in transformations of optically active amino acids into ureido acids. However, partial racemisation of (*R*)- and (*S*)-aspartic acids was observed³⁰ in the reaction with potassium cyanate in the presence of an alkali. This fact remained unexplained.

2. Reactions of amino acids with urea

Some ureido acids were synthesised by the reactions of amino acids with urea (Table 2).

$n = 0$: $R = (CH_2)_4NH_2$ (**v**), CH_2Ind (Ind is indol-3-yl) (**w**).

Table 2. Synthesis of ureido acids by the reaction of amino acids with urea.

Ureido acid 1	Reaction conditions	Ref.
a	H ₂ O, NaOH, 110 °C, 2 h; 140 °C	34
	H ₂ O, Ba(OH) ₂	21, 35
c	110–112 °C, 1 h	36
	HCl, H ₂ O, Δ, 15 h	19
f	H ₂ O, Ba(OH) ₂	35
g	HCl, H ₂ O, Δ, 15 h	19
i	H ₂ O, Ba(OH) ₂	35
	H ₂ O, Na ₂ CO ₃	12
j	HCl, H ₂ O, Δ, 15 h	19, 35
n	H ₂ O, Ba(OH) ₂	37
p	H ₂ O, Ba(OH) ₂	35
s	HCl, H ₂ O, Δ, 15 h	19
	H ₂ O, Ba(OH) ₂	35
t	H ₂ O, Ba(OH) ₂	35
v ^a	H ₂ O, Na ₂ CO ₃	12
w ^b	H ₂ O, Ba(OH) ₂	38

^a Lys was used as the starting amino acid; ^b Trp was used as the starting amino acid.

The reactions can be carried out according to two procedures: either by prolonged (up to 15 h) refluxing of an acidified aqueous solution of the reagents or by heating in the presence of an alkali at 110–140 °C (see Table 2). In both cases, it is necessary to purify ureido acids by repeated recrystallisations. The yields of the

reaction products prepared according to both procedures are comparable with those attained by the cyanate method. However, the advantage of the latter is that the product precipitates from the reaction mixture, so that one recrystallisation from an appropriate solvent is sufficient to obtain pure products in individual form.

The synthesis of ureido acids **1a,j** by the reactions of Gly and Leu, respectively, with nitrourea was also documented.³⁹

On the whole, the procedure for the synthesis of ureido acids involving urea is less popular than the cyanate method.

3. Cleavage of hydantoins and related compounds

Virtually all ureido acids can be synthesised by the cleavage of the corresponding 5-substituted hydantoins or related compounds. Both chemical and biochemical processes are suitable for this purpose (Table 3).

Alkaline hydrolysis is the simplest method for the cleavage of heterocycles **2**. Under these conditions, ureido acids **1a–c** were prepared from the corresponding achiral compounds, viz., hydantoin (**2a**),⁴⁰ dihydrouracil (**2b**)⁴² and [1,3]diazepane-2,4-dione (**2c**),⁴⁴ and compounds **1f,m,n,s–u** were synthesised from chiral substrates, viz., 5-methylhydantoin (**2f**),⁴⁵ 5-[2-(methylthio)ethyl]-hydantoin (**2m**),⁵¹ 2,6-dioxohexahydropyrimidine-4-carboxylic acid (**2n**),²⁵ 5-benzylhydantoin (**2s**), 5-(4-hydroxybenzyl)hydantoin (**2t**)³⁰ and [3-(2,5-dioximidazolidin-4-yl)propyl]urea (**2u**).³² Generally, hydrolysis is performed with aqueous NaOH or Ba(OH)₂ on heating. This approach is suitable only for the synthesis of ureido acids in which the chiral carbon atom retains the configuration of the chiral centre of the starting hydantoin.

Biochemical cleavage of cyclic compounds **2** under the action of microorganisms or enzymes is the most common and preparative method.

Table 3. Synthesis of ureido acids by decomposition of hydantoins **2**.

Note. Tris is tris(hydroxymethyl)aminomethane; ATP is adenosine triphosphate. ^a Ureido acid **1n** was synthesised from (2,5-dioxoimidazolidin-

4-yl)acetic acid; ^b ureido acid **1y** was synthesised from  (**2y**); ^c ureido acid **1z** was synthesised from  (**2z**).

Biochemical methods for hydrolytic cleavage of hydantoin (**2a**), dihydrouracil (**2b**), 5-methylhydantoin (**2f**), 5-isopropylhydantoin (**2i**) and 5-isobutylhydantoin (**2j**) under the action of *Pseudomonas* sp. AJ-11220 in a Tris–HCl buffer were documented.⁴¹ Hydantoins **2f** and **2i**, 5-*sec*-butylhydantoin (**2k**), 5-[2-

(methylthio)ethyl]hydantoin (**2m**), 5-benzylhydantoin (**2s**) and 5-(4-hydroxybenzyl)hydantoin (**2t**) are transformed into the corresponding *N*-carbamoyl- α -amino acids **1** with different enantiomeric excesses under the action of hydantoin-hydrolysing enzymes in the presence of various inorganic salts (30 °C,

20 h).⁴⁶ Tetrahydropyrrolo[1,2-*c*]imidazole-1,3-dione (**2y**)⁵³ and 5-methylhydantoin (**2f**)¹⁸ are cleaved with immobilised cells of *Agromyces*, *Chromobacterium* or *Cellulomonas* in a yeast extract in 20 h. DL-Hydantoinase from bacterium *Bacillus stearothermophilus* NS_{1122A} in a phosphate buffer (pH 7.0) at 60 °C cleaves hydantoin **2f,j,k**.⁴⁸ Hydantoin **2f-m,s**, (5-mercapto-methyl)thiohydantoin (**2z**) and 5-(1-hydroxyethyl)hydantoin (**2r**) give ureido acids in high chemical and optical yields under the action of D-hydantoinase at 50 °C (pH 8.5).⁴⁹ Dihydrouracil **2b** is cleaved with dihydropyrimidinase (EC 3.5.2.2) from *P. putida* DSM 84;⁴³ 5-methylhydantoin (**2f**), with anaerobic bacterium *P. anaerobius* at 50 °C;⁴⁷ 5-isopropylhydantoin (**2i**), with bacterium *Hansenula sp.*;^{48, 50} 5-(4-hydroxybenzyl)hydantoin (**2t**), with bacteria *Flavobacterium sp.* AJ-3912;² and [3-(2,5-dioximidazolidin-4-yl)propyl]urea (**2u**), with bacterium *Agrobacterium radiobacter*.³²

The ring opening in (+)-2-amino-4,5-dihydrothiazole-4-carboxylic acid (**3**) occurs analogously to hydantoin. This transformation can be performed by either a biochemical method⁵⁴ or alkaline hydrolysis to give *N*-carbamoylcysteine.⁵⁵

Hydantoin derivatives **2** are precursors of substituted α -amino acids and pyruvic acid.^{56–59} Biochemical cleavage of optically active hydantoin occurs through ureido acids and is used for the synthesis of enantiomerically pure amino acids.^{60–65}

$R^1, R^2 = H, \text{Alk}, \text{Ar}$.

This method can be used for the synthesis of both natural and artificial amino acids having the desired absolute configuration.

4. Other methods for the synthesis of ureido carboxylic and ureido dicarboxylic acids

Examples of the synthesis of ureido acids by non-conventional methods are scarce. For instance, *N*-carbamoylglycine (**1a**) was synthesised⁶⁶ by heating of an aqueous solution of malonamide with bromine in an alkaline medium.

N-Carbamoylaspartic acid (**1n**) was prepared by the reaction of maleic acid with an aqueous urea solution at 60 °C or by the flame-induced radical reaction. In the latter case, compound **1n** is formed as a result of the thermal rearrangement of amidinoxy-succinic acid.⁶⁷

Ureido acid **1t** was synthesised from tyrosine by the reaction with guanidinium carbonate.³⁵ Under the reaction conditions, the guanidine moiety was transformed into the ureido fragment.

Currently, solid-phase syntheses are widely used in amino acid chemistry. In the study,⁶⁸ derivatives of ureido dicarboxylic acid monoallyl ester **4** were prepared. Protected amino acid **5** on a polystyrene support was used as the starting compound. The sequence of transformations is presented in Scheme 1.

Thus, the most convenient method for the synthesis of ureido acids is that developed in the studies.^{13, 14}

$R^1, R^2 = \text{Alk}, \text{Het}$; Fmoc is 9-fluorenylmethoxycarbonyl, $\bullet$ is a polymeric support, DIPEA is *N,N*-diisopropylethylamine.

Scheme 1

5. Synthesis of ureylene dicarboxylic acids

The simplest procedure for the synthesis of symmetric ureylene dicarboxylic acids involves thermal decomposition of ureido acid salts at 125–300 °C in a nitrogen atmosphere under elevated pressure. For example, this method was used for the synthesis of disodium 6,6'-ureylenedihehexanoate (**6a**).⁶⁹

Another procedure for the synthesis of symmetric ureido diacids is based on the reaction of a lactam with urea. For example, compounds **6a,b** were prepared by heating of an alkaline solution of the reagents in an autoclave followed by acidification of the reaction mixture.⁷⁰

$n = 2$ (**a**), 4 (**b**).

An analogous procedure for the synthesis of ureylene dicarboxylic acids $[\text{HO}_2\text{C(CH}_2)_m\text{NH}]_2\text{CO}$ ($m = 3–5$ or 11) with the use of an excess of ω -amino acid instead of lactam was covered by a patent.⁷¹ In this case, the products are purified by anion-exchange chromatography.

The reactions of β -aroylacrylic acids with urea produce different compounds depending on the reaction conditions.

$\text{Ar} = \text{Ph, } 4\text{-MeC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4, 2\text{-tetralyl.}$

For example, the reactions in boiling ethanol give ureido acids **7**, whereas the reactions in DMF yield ureido diacids **8**, which readily undergo decarboxylation.⁷²

Ureido diacids can also be synthesised by the reactions of amino acid derivatives with COCl_2 , CS_2 , 1,1'-carbonyldiimidazole, 1,1'-carbonyldi(benzotriazole), etc.

The reaction of COCl_2 with diethyl aminomalonate in the presence of pyridine gives urea derivative **9**, whose hydrolysis with an alkali or an acid affords ureido diacid **6c** or hydantoinoacetic acid **10**, respectively.⁷³

N,N' -Carbonyldi(phenylalanine) ester was synthesised⁷⁴ by the reaction of phenylalanine ethyl ester with carbon disulfide in benzene.

In the reactions of amino acids and their derivatives with CS_2 , the initially formed thioureas **11** are oxidised with hydrogen peroxide (or sodium hypochlorite) to form the corresponding ureido diacids **6**.⁷⁵ In an acidic medium, the former undergo cyclisation to give carboxyalkylthiohydantoin **12**, whereas the latter form oxygen-containing analogues **13**. In some cases ($n = 3$), the reactions afford N -substituted lactams **14** and **15** as by-products. These syntheses can be performed starting from lactams.⁷⁶ Substantial drawbacks of this method consists of the use of toxic flammable CS_2 and long reaction times (up to 12 h). The use of COS instead of carbon disulfide makes it possible to exclude oxidation of thiourea, the yields of diacids **6** being ~90%.⁷⁷

$n = 3–5$; $\text{X} = \text{S}$ (**12, 14**), O (**13, 15**).

The reaction of phenylalanine with 1,1'-carbonyldiimidazole proceeds smoothly to afford ureido diacid **6d**.⁷⁸

The solid-phase synthesis, which allows one to prepare both symmetric and non-symmetric derivatives, is most promising for the synthesis of ureido diacids. The majority of procedures were developed for the preparation of 1,3,3-trisubstituted ureas on a polystyrene support (see, for example, Refs 79 and 80).

Recently, 1,1'-carbonyldi(benzotriazole) has been successfully used⁸¹ in the solid-phase synthesis of non-symmetric ureido diacids **16a–g** containing two different amino acid residues (Table 4). The products can be purified from a benzotriazole impurity by extraction with a borate buffer (pH 9.2). This method

affords ureido diacids **16a–g** in good yields and with high optical purity (see Table 4).

$R^1 = \text{Bn}$, $R^2 = \text{CH}_2\text{OBu}^t$ (**a**); $R^1 = \text{Pr}^i$, $R^2 = \text{CH}_2\text{OBu}^t$ (**b**);
 $R^1 = (\text{CH}_2)_2\text{SMe}$, $R^2 = \text{Bu}^i$ (**c**); $R^1 = (\text{CH}_2)_2\text{C}(\text{O})\text{NH}_2$,
 $R^2 = (\text{CH}_2)_3\text{NHC}(=\text{NH})\text{NHNO}_2$ (**d**); $R^1 = \text{H}$, $R^2 = \text{CH}_2\text{Ind}$ (**e**);
 $R^1 = \text{CH}_2\text{Ind}$, $R^2 = \text{CH}_2\text{Im}$ (**f**); $R^1 = \text{CH}_2\text{Im}$, $R^2 = (\text{CH}_2)_2\text{CO}_2\text{Me}$ (**g**);
 Im = 3-tritylimidazol-5-yl.

III. Chemical transformations of ureido carboxylic acids

1. Mechanism of cyclisation of ureido carboxylic acids to hydantoins

In spite of low reactivity of ureido acids, many chemical transformations involving the amino group of these compounds were documented. Cyclisation of ureido acids **1** and their esters **17** to hydantoins **2** has been the subject of the most studies.^{11, 28, 60, 61, 82–91}

$R^1 = \text{Alk}$, Ar, Het, ArAlk; $R^2 = \text{H}$ (**1**), Alk (**17**).

These reactions are generally performed in an acidic medium; more rarely, in an alkaline medium. In most cases, the reactions are not accompanied by racemisation.

The kinetics and mechanism of cyclisation of ureido carboxylic acids giving rise to hydantoins were studied in-depth for *N*-substituted ureido acids **18**.^{11, 84}

$R^1 = \text{H}$, Me; $R^2 = \text{Me}$, Ph.

The reaction proceeds under conditions of general acid-base catalysis and involves the attack of the urea nitrogen atom on the carboxyl carbon atom.⁸⁴

Based on a detailed analysis of the mechanism of condensation under acidic conditions, it cannot be conclusively established whether general acid catalysis (pathway *a*) or kinetically equivalent specific catalysis (pathway *b*) occurs.⁸⁴

HA is acid; R = Me, Ph.

Since the cyclisation rate of ureido acids under conditions of general acid catalysis is too high to be determined precisely, the measurements were carried out for the corresponding esters, whose reactions are approximately 30 times slower due apparently to larger steric hindrance caused by the OEt group upon the formation of tetrahedral intermediates T^+ and T^0 . The substitution of the *N*-phenyl group in the ureido fragment for the *N*-methyl group would be expected to change the structure of the transition state in the ring closure reaction performed under conditions of general acid catalysis, which can be represented in the diagram using the More O'Ferrall–Jencks reaction coordinates.⁹² Blagoeva *et al.*⁸⁴ represented the alternative pathways *a* and *b* as a pair diagram, which shows that the formation of the tetrahedral intermediate T^+ is the rate-determining step in these reactions.

It is assumed that the initial formation of the imidazolidine ring by the reaction (7) is the rate-determining step under conditions of general base catalysis.

$\text{R} = \text{H}, \text{Et}.$

Therefore, the assumed mechanisms of cyclisation in the case of general base or acid catalysis involve the nucleophilic attack of the sp^2 -hybridised NH group giving rise to a C–N bond and deprotonation as either a concerted reaction [reaction (7)] or an individual step (pathway *a*). In the base-catalysed reaction, deprotonation of the urea cannot be an individual rate-determining step because this requires that reprotonation of the ureido anion be more slow than the nucleophilic addition of N^- to the CO_2R group. Although the latter reaction is very fast, reprotonation of the ureido anion should occur at a rate of at least 100 times higher. The mechanisms involving the formation of the iminol tautomer of urea [reaction (8)] can also be ruled out.

Cyclisation performed under conditions of both general base and acid catalysis is characterised by the strong influence of stereoelectronic factors. In the conformation **A** of the ground state, only the C(1) atom can deviate from the plane of the ureido group so that the formation of the bond between the C(1) and N(5) atoms is virtually impossible. For the bond between these atoms to be formed, rotation about the C(2)–N(3) bond and about one of the C–N bonds of the urea fragment must occur. Evidently, rotation about the C(4)–N(5) bond (transition $\text{A} \rightleftharpoons \text{B}$) is most efficient, because it is accompanied by violation of π -conjugation and makes accessible the partially localised lone pair of the nitrogen atom, which should act as a nucleophile.

Apparently, both mechanisms considered above give rise to the conformation **B**. General base catalysis partially restores the lost delocalisation in the transition state for the subsequent addition to the CO_2R group. In the acid-catalysed reactions, the partially protonated CO_2R group is electrophilic and can react without additional activation.

It was demonstrated¹¹ that the kinetics of the process is first order with respect to ureido acid, and the reaction is substantially accelerated as pH decreases. Cyclisation of ureido acids occurs more easily as the size of the substituent in the amino acid fragment and its hydrophobicity increase.

2. Reactions of ureido carboxylic acid derivatives

Cyclisation of ureido acids has attracted attention of researchers as a procedure for the preparation of various heterocyclic compounds containing the urea fragment. Hydantoins can also be used for the synthesis of acyclic ureido derivatives.

Intramolecular cyclisation of 3-carbamoyltetrahydro- β -carboline **19** in an acidic medium at high temperatures affords tetracyclic derivatives **20**, which are used as antihypoxic and psychotropic agents.⁸⁵

Heating of ureido acid amide **21** in methanol in the presence of triethylamine affords spirohydantoin **22**.⁸⁶

The cyclisation of diureidoacetic acid **23** gave allantoin (**24**),⁸⁷ which accelerates wound healing. Oxidation of compound **23** affords 1,4,5,6-tetrahydro-4,6-dioxo-1,3,5-triazine-2-carboxylic acid (**25**).⁸⁸

It should be noted that (*S*)-(2-thienyl)ureidoacetic acid (**26**) undergoes cyclisation under the action of thionyl chloride to form

(*S*)-2-amino-4-(2-thienyl)-4*H*-oxazol-5-one (**27**) rather than the corresponding hydantoin.⁸⁹

Acid-catalysed cyclisation of *N*-carbamoyl-2,2-diphenylaminoacetic acid in aqueous methanol gives 5,5-diphenylhydantoin.¹¹ The latter is known under the name difenin as an anticonvulsant and anti-arrhythmic drug.^{93–97}

The reaction of dimethyl 2,9-diureidodecanedioate (**28**) in the presence of HCl produced the corresponding 4,4'-hexamethylene-dihydantoin (**29**).⁹⁰

Intramolecular cyclisation of *N*-(2-chloroethylcarbamoyl) derivatives of glycine, valine and phenylalanine $\text{Cl}(\text{CH}_2)_2\text{NHC}(\text{O})\text{NHCHRC}(\text{O})\text{X}$ ($\text{R} = \text{H}$, Pr^i , Bn ; $\text{X} = \text{OH}$, Oalk , NH_2) affords imidazolidones **30**, oxazolines **31** or hydantoins **32** depending on the nature of the substituent R and the reaction conditions.⁹⁸

$\text{Y} = \text{OH}, \text{NH}_2$.

Like ureido acids, ureido lactone **33** was rearranged into hydantoin under the action of nitroso compounds.⁹¹

Ureido acids **1** can be used as the starting compounds in the synthesis of other heterocyclic compounds. For example, reduction of ureido acids to form ureido alcohols **34** followed by the reaction with a $\text{NO}-\text{O}_2$ mixture either in solution or in the solid phase affords oxazolidinones **35**.⁹⁹

$\text{R}^1, \text{R}^2 = \text{H}, \text{Alk}$.

Direct nitrosation of substituted ureido acids **1** (R^1 and $\text{R}^2 \neq \text{H}$) yields α -amino acid *N*-carboxyanhydrides (oxazolidine-2,5-diones) **36**, which can be used in the peptide synthesis.¹⁰⁰ The reaction is not accompanied by racemisation and gives products in quantitative yields both in solution and on a support.

Three-component one-pot condensation of ureido acids **1**, β -keto esters and aldehydes is a very promising synthetic procedure because it affords Biginelli dihydropyrimidinones **37**.¹⁰¹ Derivatives **37** have antiviral¹⁰² and antihypertensive¹⁰³ activities and block calcium channels in cell membranes.¹⁰⁴

$\text{R}^1, \text{R}^2, \text{R}^3, \text{R}^4 = \text{Alk}, \text{Ar}$.

The solid-phase reaction is a preferred modification, for example, in the case of GABA derivatives (Scheme 2). Products

Scheme 2

$\text{R}^1, \text{R}^2, \text{R}^3 = \text{Alk}, \text{Ar}$; DBU is diazabicyclo[4.5.0]undec-4-ene.

38 are formed in good yields and readily undergo benzylation at the peripheral carboxy group to give protected derivatives **39**.

The reaction of *N*-carbamoylglycine methyl ester **17a** with malonic acid derivatives in POCl₃ (or in Ac₂O) afforded 5-substituted derivatives of barbituric acid **40**,¹⁰⁵ which have a pronounced sedative effect.¹⁰⁶ On the whole, the reactions are similar to the conventional synthesis of barbituric acid¹⁰⁷ and its *N*- (see Ref. 108) and *C*(5)-substituted analogues (for example, of cyclobarbital¹⁰⁹).

R = Alk, Ar.

N-Carbamoylglycine esters **17**, like urea,¹¹⁰ react with oxalyl chloride to form the corresponding parabanic acids **41**.^{111, 112} In POCl₃, oxalourea also undergoes cyclisation to parabanic acid.¹¹³

R = H, CH₂CO₂Alk.

Ureido acids **1** are alkylated at the NH₂ group with certain alcohols. For example, *N*-carbamoylleucine (**1j**) reacts with xanthen-9-ol in acetic acid.¹¹⁴

In the study,¹¹⁵ *N*-carbamoylglycine ethyl ester **17b** (Ref. 116) was acylated with substituted carboxylic acid bromides (the synthesis of derivative **42** presented below is accompanied also by elimination of HBr).¹¹⁵

Compound **17b** gives *N,N*-difluoro derivative **43** under the action of fluorine.¹¹⁷

Oxidation of ureido acid **1aa** with sodium hypochlorite affords the corresponding hydrazine **44** in which the configuration of the chiral centre is retained.¹¹⁸

Like monomethylurea (see Ref. 107), ureido acids are nitrosated at the NH group with sodium nitrite in formic acid.¹³ The reactions of nitrosoarenes with ureido acids **1** make it possible to introduce aryl substituents into the primary amino group.¹¹⁹

Electrochemical oxidation of ureido diacids and their thio analogues [HO₂C(CH₂)_nNH]CX (X = O or S; *n* = 3 or 5) using a lead cathode and a PbO₂ anode in sulfuric acid affords urea and succinic (*n* = 3) or adipic (*n* = 5) acid.¹²⁰

3. Ureido carboxylic acids in the synthesis of *N*-carboxyalkylglycolurils

The first synthesis of 2-mono- and 2,6-dicarboxyalkylglycolurils was described in 1962.¹²¹ 2-(Carboxymethyl)glycoluril (**45a**) was synthesised by the reaction of *N*-carbamoylglycine (**1a**) with 4,5-dihydroxyimidazolidin-2-one (DHI) (**46a**). Condensation of *N*-carbamoylglycine (**1a**) with glyoxal afforded regioisomers, viz., 2,6-bis(carboxymethyl)glycoluril (**47**) and 2,8-bis(carboxymethyl)glycoluril (**48**). However, only the 2,8 isomer was isolated from the reaction mixture (14% yield).

Recently, we have demonstrated¹²² that the reaction of *N*-carbamoylglycine (**1a**) with glyoxal gave not only bis(carboxy-alkyl)glycolurils **47** and **48** but also bis-product **49**. Bis-product **49** (20% yield) and a mixture of regioisomers **47** and **48** in a ratio of 1:1 (12% yield) were successively isolated from the reaction mixture by fractional crystallisation.

The reactions of ureido acids **1** with 4,5-dihydroxyimidazolidin-2-one **46** and its alkyl derivatives were studied in detail with the aim of extending the range of *N*-carboxyalkylglycolurils **45** and searching for the optimal reaction conditions.¹²³ The influence of the reaction time, the presence of substituents at the

Table 5. Synthesis of *N*-carboxyglycolurils **45a–e**.¹²³

^a R¹ = NHCH₂CO₂H; for other compounds, R¹ = OH.

nitrogen atoms of DHI derivatives and the length of the alkyl fragment in ureido acids **1a–e** on the yields of the reaction products was examined (Table 5).¹²³

Glycolurils **45a–e** were synthesised in aqueous HCl (pH 1–2) at 80 °C (see Table 5).

Glycolurils **45a–e** were obtained in lower yields where the reactions were performed with dialkyl derivatives of DHI instead of unsubstituted DHI as well as where the length of the carboxyalkyl chain in starting ureido acids **1a–d** increased. Because of long reaction times, glycolurils **45d,e** were synthesised only from unsubstituted DHI. The optimum reaction times for the synthesis of glycolurils **45a–e** are given in Table 5.

The reactions under consideration are accompanied by the following two side processes: the rearrangement of compounds **46** and cyclisation of ureido acids **1a,b** giving rise to the corresponding hydantoins and their analogues.

m = 0: R = H, Me, Et; *m* = 1, R = H.

These processes are responsible for a decrease in the yields of the target glycolurils **45**. *N*-Carbamoyl-β-alanine (**1b**) appeared to be the least reactive in reactions with alkyl-substituted DHI **46** (R² = Me or Et). Under these conditions, compound **1b** undergoes virtually complete cyclisation to give dihydropyrimidine-2,4(1*H*,3*H*)-dione (**2b**).

The ability of glycolurils **45** to form conglomerates was investigated.^{123,124} For this purpose, glycolurils **45a–e**, which were prepared by crystallisation from H₂O, 30% aqueous MeOH and pure MeOH, were studied. Crystals suitable for X-ray diffraction study were obtained from H₂O. Compounds **45b** (R² = H, Me), **45c** (R² = H, Et) and **45d** (R² = H) crystallise as racemates in centrosymmetric space groups. 2-(Carboxypropyl)-6,8-dimethylglycoluril **45c** (R² = Me) exists as a mixture of homochiral crystals, which differ only in the optical rotation [*α*]_D = +21.92° (*c* = 1.31, H₂O) and [*α*]_D = −18.68° (*c* = 0.38, H₂O). Other physicochemical characteristics of the crystals are identical. The fact that crystallisation of glycoluril **45c** (R² = Me) gives rise to conglomerates was confirmed by X-ray diffraction (space group *P2₁*) (Fig. 1).¹²⁴

Figure 1. Molecular structure of compound **45c** (R² = Me) (a) and the scheme of formation of homochiral corrugated layers in the crystal through hydrogen bonds (b) (X-ray diffraction data, selected hydrogen atoms are shown).¹²⁴

Racemic *N*-carboxyalkylglycolurils **45** that do not form conglomerates were separated by chiral-phase HPLC. This method was used to resolve racemates of compounds **45a** (R² = H or Me) and **45b** (R² = H). It should be noted that the presence of the methyl substituents [compound **45a** (R² = Me)] results in an increase in the selectivity of enantiomer separation compared to **45a** (R² = H), whereas the presence of one more methylene unit between the carboxy group and the heterocycle [compound **45b** (R² = H)] decreases the selectivity of separation.¹²³

The synthesis of functionalised 1,5-diaryl-substituted glycolurils based on *N*-carbamoylglycine benzyl ester (**17c**) and diaryl-ethanediones was documented.¹²⁵ α-Diketones were subjected to condensation with ester **17c** in benzene with azeotropic distillation of water. Subsequent saponification of the ester groups in compounds **50** afforded substituted glycolurils **51**.

The above reactions give the 2,8-isomer of glycoluril **51** (for simplicity, the 2,6-isomer is ignored in the scheme) as the major product. If Ar = Ph, the 2,8 : 2,6 regioisomer ratio is 8 : 1. This fact can be accounted for by the following reaction mechanism:

The first step of the reaction affords 4,5-dihydroxyimidazolidin-2-one derivative **52**. After protonation, the latter can generate carbocations **53** or **54**. It was assumed¹²⁵ that it is the more electrophilic cation **53** that reacts with the more nucleophilic nitrogen atom of the urea fragment to form the 2,8-isomer of glycoluril **51a**.

In the latter study, compound **51a** (R = Ph) was subjected to esterification with pentafluorophenol to prepare bis(pentafluorophenyl) ester **55**. The reactions of the latter with amines (including amino acids and anilines) afforded derivatives **56**.

R = CH(CO₂H)Bu^s, CH(CO₂Bu^t)Bu^s;

(a) C₆F₅OH, EDC · MeI, DMAP; EDC is 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide; DMAP is 4-(dimethylamino)pyridine;

(b) (H-Leu-OBu^t) · HCl; Et₃N, CH₂Cl₂, DMF; (c) TFA.

Thus, *N*-carboxyalkylglycolurils can be prepared by condensation of *N*-carbamoyl amino acids and their esters with both DHI and α -dicarbonyl compounds.

4. Stereoselective syntheses of *N*-carboxyalkylglycolurils

The diastereoselectivity of the reaction of DHI with (*S*)-*N*-carbamoyl- α -alanine (**1f**) was described for the first time in 2001.¹³ The diastereomeric (1*R*,5*S*)- and (1*S*,5*R*)-2-(3,7-dioxo-2,4,6,8-tetraazabicyclo[3.3.0]oct-2-yl)propionic acids (**45f**) were obtained (¹H NMR spectroscopic data) in a ratio of 5 : 2.

More recently, the diastereoselective reactions of DHI with optically active *N*-carbamoyl derivatives of amino acids, viz., (*S*)-norvaline (**1h**), (*S*)- α -aminobutyric acid (**1g**), (*S*)- and (*R*)-methionines (**1m**) and (*S*)-glutamine (**1q**), and with racemic compounds **1f, h, m** were studied.¹²⁶ Cyclocondensation was carried out at pH 1–2 in water or aqueous isopropyl alcohol (depending on the solubility of the starting compounds) with heating (conditions *a*). In all cases, glycolurils **45** were obtained in 33%–40% yields (Table 6).

(a) H⁺, H₂O–PrⁱOH, 80–90 °C, 1–3 h; (b) H₃O⁺, 80 °C, 2 h.

The diastereomeric composition of the products was determined by ¹H NMR spectroscopy. It was found that glycolurils **45** were obtained as two diastereomers (major and minor), which is indicative of high diastereoselectivity of the reactions. This is evidenced by doubling of the signals for all protons, the signals for the CH protons of the major diastereomers being observed at lower field compared to the corresponding signals of the minor diastereomers. To determine the precise chemical shifts and coupling constants of the protons at the C(1) and C(5) atoms in compounds **45**, calculations were carried out by the NUMMRIT method implemented in the Xsim program (Linux OS).

Individual stereoisomers (1*R*,5*S*)-**45m** and (1*S*,5*R*)-**45m** prepared from (*S*)-*N*-carbamoylmethionine (**1m**) were separated by crystallisation from water.

The isolation of the major product obtained in the reaction of DHI with (*S*)-ureido acid **1q** (methanol, traces of HCl) was

Table 6. Diastereoselective and diastereospecific syntheses of diastereomeric and enantiomerically pure glycolurils **45**.^{126, 127}

^a Product **57** was formed in the course of isolation.

accompanied by hydrolysis of the amido group to form the carboxy group followed by esterification giving rise to glycoluril methyl ester **57**. The configurations of the chiral C(1) and C(5) atoms of the major diastereomers (1*R*,5*S*)-**45m** and (1*R*,5*S*)-**57q** and the minor diastereomer (1*S*,5*R*)-**45m** (Figs 2 and 3) were established by X-ray diffraction.

The reaction of DHI with (*R*)-*N*-carbamoylmethionine [(*R*)-**1m**] also proceeded with high diastereoselectivity (the diastereomer ratio was 15 : 1), but the reaction gave (1*S*,5*R*)-**45m** as the major diastereomer, which was also isolated by crystallisation from water.

Difficulties in the separation of stereoisomers is the major problems in the diastereoselective synthesis.

With the aim of searching for the conditions of the diastereospecific reaction of DHI with (*S*)- and (*R*)-*N*-carbamoylme-

**Figure 2.** Overall view of the molecule (1*R*,5*S*)-**45m** (a) and its stereoisomer (1*S*,5*R*)-**45m** (b) (X-ray diffraction data).¹²⁷**Figure 3.** Overall view of the molecule (1*R*,5*S*)-**45q** (a) and the formation of an N—H...O-bonded honeycomb-like structure in the crystals of this compound (b).¹²⁷

thionines (**1m**), the influence of pH (from 0 to 5), temperature (40–90 °C) and the reaction time (0.5–4 h) on the reaction pathway was examined. It was found¹²⁷ that the highest diastereospecificity can be achieved with the use of 2 equiv. of HCl at 80 °C for 2.5 h (conditions b). Under these conditions, individual isomers of glycoluril **45m** were obtained (see Table 6).

These conditions were used in the reactions of DHI **46a** with other (*S*)- or (*R*)-*N*-carbamoyl- α -amino acids, *viz.*, compounds **1i**, **k**, **s**. In all cases, individual isomers of the corresponding glycolurils were synthesised.

The diastereospecific reactions of compounds **46a** with (*S*)- and (*R*)-*N*-carbamoylmethionines (**1m**) and (*S*)- and (*R*)-*N*-carbamoylvalines (**1i**) afforded enantiomers characterised by identical physicochemical parameters, including the optical rotation, which is equal in magnitude but opposite in sign. Ureidoalkylation of (*S*)-*N*-carbamoylisoleucine (**1k**) and (*S*)-*N*-carbamoylphenylalanine (**1s**) also occurs diastereospecifically to give enantiomerically pure glycolurils (1*R*,5*S*)-**45k,s** (see Table 6).

The reactions of DHI with racemic (*R,S*)-*N*-carbamoyl- α -amino acids, *viz.*, (*R,S*)-*N*-carbamoylnorvaline (**1h**) and (*R,S*)-*N*-carbamoylmethionine (**1m**), under conditions of the diastereospecific synthesis affords racemates (*R,S*)-**45h,m**, respectively.

It should be noted that all known reactions yield the corresponding hydantoins as by-products.

With the aim of confirming the absolute configurations of the chiral C(1) and C(5) atoms in glycolurils derived from (*R*)-*N*-carbamoyl- α -amino acids, the coordination compound Ni(H₂O)₆L₂(H₂O)₄ (**58**), where L is deprotonated glycoluril, was synthesised by the reaction of glycoluril (1*S*,5*R*)-**45m** with nickel

Figure 4. Solvated nickel cation and two anions of deprotonated glycoluril (1*S*,5*R*)-**45m** in the crystals of coordinated compound **58** (X-ray diffraction data).¹²⁷

Figure 5. Projection of the molecular packing of **58** in the crystal structure illustrating alternation of the cationic layers and the anionic chains.¹²⁷

acetate in an aqueous solution. Single crystals of **58** grown from water were studied by X-ray diffraction (Figs 4 and 5). It should be noted that the metal atom in complex **58** is not involved in direct coordination to the functional groups of the ligand (see Fig. 4). In the crystal structure, the nickel cation lies on the C_2 axis

and is surrounded by six water molecules. In addition, the unit cell contains four water molecules of solvation. The presence of a large number of donors and acceptors in compound **58** results in a rather complicated supramolecular structure. The crystal structure consists of alternating inorganic (cation) and organic (anion) fragments (see Fig. 5).

5. Reactions of α,ω -diureido carboxylic acids with 4,5-dihydroxyimidazolidin-2-ones

Cyclocondensation of α,ω -diureido acids with DHI derivatives **46** was studied as an access to alkylendi(glycolurils). The starting compounds **1u** and **59** were prepared by the reaction of (*S*)-citrulline (**60**) and (*S*)-lysine (**61**), respectively, with KOCN.¹²⁸ To estimate the reactivities of the α - and ω -ureido fragments in α,ω -diureido acids, the charges on the nitrogen atoms in *N* $^{\alpha}$ -carbamoylcitrulline (**1u**) were calculated by the MNDO method. The calculations demonstrated that the charges on the α - and ω -nitrogen atoms of the ureido fragments in diureido acid **1u** are virtually identical, and a preference cannot be given to a particular reaction centre.

The reaction of compound **1u** was carried out with an equimolar amount of unsubstituted 4,5-dihydroxyimidazolidin-2-one **46a**, and the reaction of diureido acid **59** was performed with dimethyl-substituted DHI **46** ($R = \text{Me}$).¹²⁸ The structures of the resulting hydantoinoalkylenglycolurils **62** and **63** were established by the independent synthesis of compound **62**. Initially, the reaction of (*S*)-citrulline (**60**) with DHI **46a** under the conditions of the diastereospecific synthesis afforded glycoluril **64**, which was used in the reaction with KOCN to form the α -ureido fragment. However, this reaction gave compound **62** instead of the expected glycolurilureido acid (Scheme 3).

The chiral centre in the starting diureido acids is remote from the ureido fragments involved in cyclocondensation due to which the reactions give mixtures of diastereomers. The structures of the reaction products were established by ^1H and ^{13}C NMR spectroscopy with the use of the highly sensitive inversion HMQC (Heteronuclear Multiple-Quantum Correlation) and HMBC (Heteronuclear Multiple-Bond Correlation) methods.

It was demonstrated¹²⁸ that the α - and ω -ureido fragments of diureido acids differ substantially in reactivity with respect to DHI. Cyclisation of the α -ureido fragment to hydantoin is more favourable, whereas the ω -fragment is more reactive with respect to DHI, which gives rise to the glycoluril fragment of compounds **62** and **63**.

Scheme 3

(a) KOCN, H_2O , 100°C , 20 min; (b) HCl, 5°C ; $n = 1$ (**1u**, **60**, **62**), 2 (**59**, **61**, **63**); $R = \text{H}$ (**62**), Me (**63**).

The stereochemical aspects of diastereoselective and diastereospecific reactions of *N*- α -carbamoylamino acids open up new possibilities for the synthesis of enantiomerically pure glycolurils.

* * *

As is evident from the above-presented data, the chemistry of ureido acids and ureido diacids continues to be developed. Apparently, the use of modern solid-phase syntheses of both the starting *N*-carbamoylamino acids and various related heterocyclic compounds is most promising in this area of chemistry. The use of optically pure ureido acids provides approaches to the diastereoselective and diastereospecific syntheses of *N*-(*N*- α -carbamoyl)-substituted glycolurils, which are potential neurotropic compounds.¹²⁹

Abstract. The published data on the synthesis, structures and properties of triorganyltelluronium salts are generalised and systematised. Special attention is given to the applications of these compounds in preparative organic synthesis. The bibliography includes 163 references.

I. Introduction

Triorganyltelluronium salts comprise compounds of the general formula $R^1R^2R^3TeX$. Depending on the nature of the electro-negative group X, solvent and the structure of the crystal lattice, the degree of ionicity of the $Te-X$ bond varies from purely ionic to covalent. Whereas the first organotellurium compound, diethyl telluride, was synthesised in 1840,¹ the first representatives of telluronium salts, *viz.*, trimethyl- and triethyltelluronium iodides, were obtained only 25 years later.²

At present, triorganyltelluronium salts are widely used in preparative organic chemistry as starting materials for the synthesis of alkenes, alkylidene(or arylmethylidene)malonates, benzylic, propargylic and allylic alcohols. The trifluoromethyl derivatives are used as trifluoromethylating reagents, whereas triphenyltelluronium salts are used as catalysts in the liquid-phase oxidation of alkenes. It is recommended to use triphenyltelluronium salts as analytical reagents for Co^{2+} and Bi^{3+} ions (Refs 3 and 4); their trialkyl analogues are inhibitors of acid corrosion of iron and steel.^{5,6} Telluronium ylides generated *in situ* from telluronium salts are used in the synthesis of epoxides,⁷ cyclopropanes^{7,8} and alkenes containing electronegative substituents at the double bond.⁷

Separate chapters in the monographs^{9,10} of 1974 and 1983 are devoted to telluronium salts. However, a considerable number of papers on the synthesis and, particularly, on reactions and structures of telluronium salts have been published later. This review is intended to complement the published reviews and to

analyse the state of the art of the problem. The main attention is given to acyclic salts; the data on cyclic telluronium salts are reviewed in the monograph by Detty and O'Regan¹¹ devoted to heterocyclic tellurium derivatives, so they are mainly not included here.

II. Synthesis of telluronium salts

The reaction of tellurium tetrachloride with organoelement compounds is one of the main preparative methods for the synthesis of symmetrical triorganyltelluronium salts $R_3Te^+X^-$ (**1**). Diethylzinc was the first to be used for this purpose; however, it was organomagnesium ($RMgHal$) and organolithium (RLi) compounds that came in practice later.^{9,10,12,13} An attempt to obtain a triorganyltelluronium salt with the use of organocadmium compound is also reported.¹⁴ The reaction of tellurium tetrachloride with organoelement compounds is usually carried out under mild conditions and is followed by fast acid hydrolysis.

$M = MgHal, Li; X = Cl, Br, I; R = Alk, Ar.$

In the majority of cases, salts **1** were isolated as poorly soluble iodides upon treatment of the reaction mixture with an aqueous solution of potassium iodide. It should be noted that under these conditions the reaction of 2,4,6-tris(*tert*-butyl)phenyllithium with $TeCl_4$ affords the corresponding telluride $(2,4,6-Bu_3C_6H_2)_2Te$ instead of the expected telluronium salt.¹³

Recent studies have shown¹⁵ that depending on the procedure for quenching of the reaction mixture, the reaction of 2,6-dimethoxyphenyllithium with $TeCl_4$ in ether yields telluronium salts **2** or **3**. The former were isolated after hydrolysis with hot water, while the latter were isolated upon treatment of aqueous filtrates with 6 M HCl. In the latter case, bis(2,6-dimethoxyphenyl) telluride was formed as a side product (yield 15%).¹⁵

$Ar = 2,6-(MeO)_2C_6H_3; n = 2-2.5.$

Uspekhi Khimii 75 (3) 234–253 (2006); translated by R L Birnova

Reactions of diaryltellurium dihalides Ar_2TeY_2 ($\text{Y} = \text{Cl}^{9,10,13}$; Br , $\text{I}^{9,10}$) with arylmagnesium bromides or aryllithium compounds represent a general method for the synthesis of triaryltelluronium salts. This method was used for the preparation of both symmetrical telluronium salts ($\text{Ar}_3\text{Te}^+\text{X}^-$) (**1**) and their non-symmetrical analogues, $\text{Ar}_2^1\text{Ar}^2\text{Te}^+\text{X}^-$ (**4**).

$\text{M} = \text{MgBr}$, Li .

This reaction can obviously be used for the preparation of non-symmetrical telluronium salts of the type $\text{Ar}^1\text{Ar}^2\text{Ar}^3\text{Te}^+\text{X}^-$ from diaryltellurium dihalides $\text{Ar}^1\text{Ar}^2\text{TeY}_2$ and Ar^3M ($\text{M} = \text{MgHal}$, Li). However, no data on such a synthesis are available so far.

In the reactions of arenes with TeCl_4 , salts **1** or their mixtures with diaryltellurium dichlorides **5** are formed.^{10,16} Cresol derivatives of this type were obtained earlier with the use of TeOCl_2 ; however, these results seem doubtful now.⁹

(a) AlCl_3 , Δ (for **a**); (b) 110–130 °C (for **b, c**);

$\text{Ar} = \text{Ph}$ (**a**, 60%), 2-OH-5-MeC₆H₃ (**b**), 4-OH-2-MeC₆H₃ (**c**).

A new method for the synthesis of various types of telluronium salts has been developed recently.¹⁷ It is based on the reactions of electrophilic intermediates **6** (formed upon the reaction of diaryltellurium difluorides with $\text{BF}_3 \cdot \text{Et}_2\text{O}$) with silyl derivatives **7–9**. For example, these intermediates reacted with *O*-trimethylsilyl ethers **7** and **8** at room temperature to give **2-** (**10**) and 3-oxoalkyldiaryltelluronium salts **11** in 85%–100% yields. Similarly, allyldiphenyltelluronium tetrafluoroborate **12** was obtained from allyltrimethylsilane (**9**) in quantitative yield under very mild conditions.¹⁷

The use of tributyl(organyl)stannanes in a similar reaction enabled the synthesis of the telluronium salts $\text{Ar}_2\text{RTe}^+ \text{BF}_4^-$ containing $\text{Te}-\text{C}(\text{sp}^3)$, $\text{Te}-\text{C}(\text{sp}^2)$ and $\text{Te}-\text{C}(\text{sp})$ bonds, *viz.*, compounds **13** ($\text{R} = \text{Alk}$), **14** and **15**, respectively, as well as of non-symmetrical triaryltelluronium salts of the type **4** ($\text{Ar} = \text{Ph}$, $\text{R} = 4\text{-MeOC}_6\text{H}_4$).¹⁷

Compound	Ar	R	Yield (%)
4	Ph	4-MeOC ₆ H ₄	95
13	Ph, 4-MeOC ₆ H ₄	Bn	88–100
14	Ph	Me ₂ C=CH	87
15	Ph, 4-MeOC ₆ H ₄	PhC≡C	94–96

The method for the synthesis of telluronium salts described in Ref. 17 has a number of advantages. First, it enables preparation of diaryl(organyl)telluronium salts containing various substituents at the tellurium atom. Second, telluronium salts that are difficult to obtain by other methods are produced in high yields under mild conditions. And finally, nearly pure salts can be isolated upon evaporation of the solvent, since side reaction products, fluorotriorganylsilanes(stannanes), are volatile compounds.

Telluronium salts are synthesised from organic derivatives of boron¹⁸ and iodine.^{19,20} Thus treatment of diphenyltellurium difluoride with 4-methoxyphenylboronic acid in the presence of $\text{BF}_3 \cdot \text{Et}_2\text{O}$ and subsequent addition of an aqueous solution of NaBF_4 to the reaction mixture results in non-symmetrical triaryltelluronium salts **4** ($\text{Ar}^1 = \text{Ph}$, $\text{Ar}^2 = 4\text{-MeOC}_6\text{H}_4$) in a nearly quantitative yield.¹⁸ Hex-1-enyl(diphenyl)telluronium tetrafluoroborate **14** [$\text{Ar} = \text{Ph}$, $\text{R} = (E)\text{-hex-1-enyl}$] was prepared using a similar approach.¹⁸

Alkenyl(diphenyl)telluronium salts **14** [$\text{Ar} = \text{Ph}$; $\text{R} = \text{Me}_2\text{C}=\text{CH}$, $(\text{CH}_2)_5\text{C}=\text{CH}$] were also synthesised by the reaction of β,β -dialkylvinyl(phenyl)iodonium tetrafluoroborates with diphenyl telluride in the presence of diisopropylethylamine at room temperature.¹⁹ This reaction proceeds through intermediate alkylidene carbenes.

$\text{R} = \text{Me}$ (68%); $\text{R}-\text{R} = (\text{CH}_2)_5$ (89%).

The reaction of alkynyl(phenyl)iodonium tetrafluoroborates with diphenyl telluride was accompanied by transfer of the alkynyl group to the tellurium atom.²⁰ This reaction occurred under mild conditions (mixing of the reactants in CH_2Cl_2 at room temperature) and yielded alkynyldiphenyltelluronium tetrafluoroborates **15**.

$\text{R} = \text{H}$, Me , Pr^i , Bu^t , $n\text{-C}_8\text{H}_{17}$, Me_3Si , Ph .

Reactions of diorganyl tellurides (including those containing aromatic substituents) with alkyl halides represent the most general method for the synthesis of trialkyl-, dialkylaryl- and alkylaryltelluronium salts.

$\text{R}^1, \text{R}^2 = \text{Alk}$, Ar .

In the case of dialkyl tellurides, exothermic reactions occurred even upon mechanical mixing of the reactants.^{2,9,10,21–48} Alkyl aryl tellurides were found to be less reactive.^{9,10,49–57} Reactions of diaryl tellurides with alkyl halides usually required long-term refluxing of the reaction mixtures.^{9,10,58–60} It is noteworthy that reactions of diphenyl sulfide⁶¹ and diphenyl selenide,⁶² which are

less nucleophilic than diaryl tellurides, with alkyl halides yielded onium salts only in the presence of Ag(I) salts.

Divinyl telluride,^{63, 64} ethynyl phenyl, *tert*-butyl ethynyl, ethynyl vinyl, ethynyl propylthio and hexa-1,3-diynyl methyl tellurides¹⁰ as well as di(methyltellurio)acetylene⁶⁵ also yielded telluronium salts upon reactions with alkyl iodides.

Dimethyl sulfate, together with organic bromides and iodides of various structures, *viz.*, alkyl halides, allyl bromides, propargyl bromides, benzyl halides, α -bromo ketones, α -bromocarboxylic acids, esters and *N*-substituted amides, bromoacetonitrile, alkylmono- and dibromomalonates and 1,2-dibromoethane, are used as alkylating reagents. Among chloro derivatives, only chloroacetonitrile gives telluronium salts in reactions with dialkyl tellurides.^{27, 29, 36}

Because of their very unpleasant odour and easy oxidation by atmospheric oxygen, dialkyl tellurides are sometimes prepared *in situ*. Thus the reduction of readily available dialkyltellurium diiodides with sodium sulfite and subsequent reaction with alkyl iodides were used in the synthesis of triorganyltelluronium iodides.^{9, 10}

$R^1 = R^2 = Me, Pr^n$; $R^1 = Bu^n, R^2 = Me$; $R^1 = Me, R^2 = Ph$.

An alternative approach to the synthesis of these compounds is based on the treatment of lithium tellurolates with an excess of an alkylating reagent (methyl iodide) without preliminary isolation of the intermediate dialkyl(alkylaryl) tellurides.^{9, 10, 26}

Strong alkylating reagents, such as methyl fluorosulfonate and alkyl trifluoromethanesulfonate,^{66, 67} easily form dimethyl(organyl)telluronium salts **16** and **17** from dimethyl telluride in Freon solutions in the cold.

$X = F, R = Me$ (**16**); $X = CF_3, R = Me, Et$ (**17**).

5-Trifluoromethyldibenzotellurophenonium trifluoromethanesulfonate (**18**) was prepared by the reaction of trifluoromethanesulfonic anhydride (Tf_2O) with biphenyl-2-yl trifluoromethyl telluride in DMSO.^{68, 69} This reaction presumably occurs *via* intermediate **19** resulting from addition of sulfonium salt **20** to the tellurium atom.

Interesting results suggestive of high nucleophilicity of the tellurium atom in alkyl aryl tellurides were obtained while studying the alkylation, by methyl iodide^{50, 59, 70} or aryl iodides (PhI, *p*-MeOC₆H₄I or *p*-EtOC₆H₄I),⁵⁹ of aromatic compounds containing various nucleophilic substituents, *viz.*, dimethylamino-methyl-,⁵⁰ dimethylamino-,^{59, 70} 2-(4,4-dimethyloxazolino)-⁵⁰ or methylthio(seleno) groups⁷⁰ in the *ortho*-position relative to organyltellurium groups. These reactions yield telluronium salts **21–26**.

$R^1 = H, R^2 = Me$: $X = CH_2NMe_2$ (**21**), NMe_2 (**22**), SMe (**23**), $SeMe$ (**24**), 4,4-dimethyl-4,5-dihydrooxazol-2-yl (**25**); $X = NMe_2, R^1 = Me, R^2 = 4-YC_6H_4$ [$Y = H$ (**26a**), OMe (**26b**), OEt (**26c**)].

At the same time, dimethyl(2-methylselenobenzyl)amine is methylated at the nitrogen atom;⁵⁰ dimethyl(2-methyltellurophe-nyl)phosphine, -arsine and -stibine react with methyl iodide to give phosphonium, arsonium and stibonium salts, respectively.⁷⁰

$X = P, As, Sb$.

Bis(telluronium) salts were synthesised by the reaction of 1,2-dibromoethane with diphenyl telluride (product **27**)^{9, 10} or by alkylation of compounds containing two telluromethyl groups with methyl iodide [salts **28a** (see Ref. 70) and **28b** (see Ref. 57)].

It is of note that reactions of tellurides containing three tellurium atoms with MeI yield tris(telluronium) salts **29**.⁷¹

$R = Me, Ph$.

Tellurides containing electron-withdrawing perfluoroalkyl groups at the tellurium atom are alkylated only in the presence of silver tetrafluoroborate.¹⁰

Telluronium salt **30** was prepared from *N*-(2-butyltellurobenzylidene)aniline containing the intramolecular coordination bond $N \rightarrow Te$ in the presence of silver perchlorate.^{72, 73}

X = Cl, Br;

R¹ = Me, Et, Buⁿ, n-C₆H₁₃, Ph; R² = Me, Et, Buⁿ, Bn, CH₂CH=CH₂ (All).

A novel approach to the synthesis of trialkyl- and dialkyl-aryltelluronium salts containing a (1*S*)-2-*exo*-10-bornyl substituent has been developed (Scheme 1).^{74–76} Reactions of halooxa-telluranes **31** with organomagnesium or -lithium compounds and subsequent treatment of the reaction mixtures with aqueous NH₄Cl afforded optically pure triorganyltelluronium chlorides **32** in 60%–97% yields (for an alternative method for the preparation of chiral telluronium salts, see Section III). The structures of diastereomeric salts **32** (R¹ = Me, R² = Et; R¹ = Et, R² = Me) were confirmed by X-ray diffraction analysis.⁷⁵

The pyramidal inversion barrier of tricoordinated tellurium atoms in these compounds exceeds 30 kcal mol^{–1}. Thus 5-h refluxing of salts **32** in chloroform or methanol did not result in their epimerisation.⁷⁵

Organyldimethyltelluronium iodides **33** were formed, along with organylmethyltellurium diiodides **34** (molar ratio 1 : 1), upon treatment of diorganyl ditellurides with an excess of methyl iodide.^{9, 10, 77} The methylation of ditelluride, which obviously represents the first step in these reactions, gives intermediate organyltelluro(methyl)organyltelluronium iodides **35**. Spontaneous decomposition of these salts results in methylorganyl tellurides **36** and organyltellurenyl iodides **37**; their subsequent reactions with methyl iodide yield compounds **33** and **34**, respectively.

R = Me, Et, Prⁱ, Bu^t; 4-MeC₆H₄, 4-MeOC₆H₄, 4-EtOC₆H₄.

The reaction of diorganyl ditellurides with phenylacetylene in the presence of methyl iodide also seems to occur *via* salts of the type **35** and affords alkyl phenylethynyl tellurides.^{77, 78}

Tellurotelluronium salts with BF₄[–] and SbF₆[–] anions were isolated in the individual state, *e.g.*, compound **38**⁷⁹ and mesityl derivative **39**.^{80, 81}

The triaryltelluronium salts Ph₃Te⁺Br[–] and (C₆F₅)₃Te⁺X[–] (X = Cl, Br, OTf) were prepared in high yields by the reaction of tetraphenyltellurane Ph₄Te (see Refs 9 and 10) and tetrakis(pentafluorophenyl)tellurane (C₆F₅)₄Te (Ref. 82) with mineral acids^{9, 10, 82} or trimethylsilyl derivatives.⁸²

Reactions of a cyclic spirotetraaryltellurane, *viz.*, bis(2,2'-biphenylene)tellurane, with mineral^{9, 10} and organic acids⁸³ and phenols^{84, 85} were accompanied by the cleavage of one of the Te–C bonds. The corresponding reaction products (compounds **41** and **42**) were formed in 47%–95% yields.

X = Cl, I, BPh₄;

R¹ = MeCO, PhCO, 4-R²C₆H₄ (R² = H, Me, Cl, MeO₂C, Ac, NO₂), 2,4,6-Cl₃C₆H₂.

The preparative significance of these reactions is relatively low. Tetraaryltelluranes and bis(2,2'-biphenylene)tellurane are usually prepared by reactions of aryllithium derivatives with the corresponding tellurium dichlorides, which, as was shown above, can directly be converted into telluronium halides. Exchange reactions of the latter (see Section III) afford various triaryltelluronium salts including the derivatives of the type **41** and **42**.

The synthesis of triphenyltelluronium tetrakis(pentafluorophenyl)borate by thermal decomposition of a pentaphenyltelluronium-containing salt presents purely theoretical interest.⁸⁶

Refluxing of equimolar amounts of bis(4-methoxyphenyl) telluride and 3,5-dinitrobenzoyl chloride in neutral solvents (CH₂Cl₂ or benzene) yielded a compound with a tentative structure of telluronium salt **43a**.⁸⁷

Ar = 3,5-(O₂N)₂C₆H₃.

However, low melting point of this compound and low electric conductivity of its 10⁻³ M solution in acetonitrile are in favour of the covalent structure **43b** containing a tetracoordinated tellurium atom.

Triorganyltelluronium derivatives **44** containing two Te—C bonds and one Te—N bond are worthy of note. These salts are prepared by oxidation of diaryl tellurides by compounds that are sources of positively charged halogens (e.g., *N*-halosuccinimides^{88,89}). Derivatives **44** are high-melting crystalline compounds poorly soluble in common organic solvents.

Ar¹, Ar² = Ph, 4-MeOC₆H₄; R¹R²NX = PhCONHBr,

Diaryltellurium oxides manifest the highest basicity in the series of diarylchalcogen oxides Ar₂EO (E = S, Se, Te) and are therefore easily alkylated at the oxygen atom by dialkyl sulfates^{60,90} and benzyl bromide⁹¹ resulting in diaryl(alkoxy)telluronium salts **45**. The reaction of diaryltellurium oxides with perchloric acid yields diaryl(hydroxy)telluronium perchlorates **46**.^{60,92}

Compound	R	Ar	Ref.
45	Me	4-DC ₆ H ₄ , 4-Pr ⁱ C ₆ H ₄	90
	Me	2,6-(MeO) ₂ C ₆ H ₃	60
	Et	Ph, 4-DC ₆ H ₄ , 4-Pr ⁱ C ₆ H ₄	90

III. Reactions of telluronium salts

Anion-exchange reactions (see the monographs^{9,10} and references cited therein, as well as Refs 12, 25, 28, 93–106) are among the most important preparative methods for the synthesis of triorganyltelluronium salts. The direction of the exchange is determined by the relative solubilities of the original and final salts, which depend on the nature of the anion. By virtue of the large radius of the tellurium atom and its low electronegativity, the telluronium cation can be regarded as a mild acid. In accordance with the HSAB principle,⁹³ the salts containing hard anions (F⁻, Cl⁻, OH⁻, NO₃⁻, CrO₄²⁻, Cr₂O₇²⁻, BF₄⁻, BPh₄⁻, ClO₄⁻, etc.) should possess better solubilities in comparison with the salts containing soft anions (Br⁻, I⁻, N₃⁻, CN⁻, SCN⁻, etc.). In particular, the solubilities of telluronium halides R₃Te⁺Hal⁻ decrease in the order: F > Cl > Br > I; therefore, the exchange can be carried out in aqueous media under the action of alkali metal halides. Compounds with solubilities exceeding those of the starting

compounds are prepared using the corresponding silver salts. In this case, the direction of the exchange is determined by the relative solubilities of silver halides. The exchange reactions were used in the synthesis of many telluronium salts containing various anions.

M is an alkali metal or silver.

Anion-exchange reactions were also used in the synthesis of telluronium salts containing doubly charged anions.

Reactions of triphenyltelluronium chloride with silver nitro-solates afforded the corresponding triphenyltelluronium nitro-solates **47**.¹⁰⁷

R = Me (65%), Ph (25%).

Reactions of aqueous triphenyltelluronium chloride with an excess of sodium β-diketonates resulted in triphenyltelluronium β-diketonates **48** (yields 52%–90%).¹⁰⁸ The ¹H NMR spectra suggest that these compounds exist as mixtures of *E*- and *Z*-isomers.

R¹ = R² = Me, Ph; R¹ = Me, R² = Ph; R¹ = CF₃; R² = Ph, 2-thienyl.

Similarly,¹⁰⁹ enolates of heterocyclic β-diketones

R = Me, Ph.

gave triphenyltelluronium derivatives.

The exchange reactions of triphenyltelluronium chloride with sodium alkoxides gave triphenyltelluronium alkoxides **49** in high yields.¹¹⁰

R = Me, Et, Prⁱ.

Triphenyltelluronium organylchalcogenolates **50a–c** [X = S (**a**), Se (**b**), Te (**c**)] were synthesised from triphenyltelluronium chloride.^{111–113}

X = S: R = Et, Prⁱ, Bu^t, Bn, Ph, 4-MeOC₆H₄, 4-ClC₆H₄, 2-Py, 4-Py;
X = Se, R = 4-MeC₆H₄; X = Te: R = 4-MeC₆H₄, 4-MeOC₆H₄.

However, the reactions of Ph₃Te⁺Cl⁻ with sodium aryl-tellurolates in THF yielded diphenyl and aryl phenyl tellurides as the final products.¹¹³ Obviously, the latter were formed as a result of decomposition of intermediate compounds of the type **50c**.

Ar = 4-MeC₆H₄, 4-MeOC₆H₄.

Treatment of triphenyltelluronium alkoxides **49** with carboxylic acids resulted in the corresponding carboxylates **51**.⁹⁷ Similar compounds were synthesised by reactions of triorganyltelluronium hydroxides with carboxylic acids⁹⁷ and of triorganyltelluronium halides with silver salts of organic acids.^{58, 94, 97}

R¹ = Ph, R² = Me; R¹ = Me, R² = H; R³ = Me, CHCl₂, CCl₃, Ph.

R¹, R² = Me, Ph; R³ = Me, Ph, 2-MeOC₆H₄, 3-O₂NC₆H₄.

Triphenyltelluronium xanthates **52** were prepared by the insertion of carbon disulfide into the Te—O bond of triphenyltelluronium alkoxides **49**.¹¹⁰

R = Me, Et, Prⁱ.

However, the exchange reactions between triorganyltelluronium chlorides and the corresponding sodium (less frequently, ammonium) salts represent the most general method for the synthesis of xanthates **52**,^{95, 110, 114–116} thioxanthates **53**,^{95, 110} dithiocarbamates **54** (Refs 95, 114, 117–119) and dithiophosphates **55**.^{112, 114, 120}

X = O (**52**), S (**53**); R¹ = Me, Ph; R² = Me, Et, Prⁿ, Prⁱ, Buⁱ, Bu^t, cyclo-C₆H₁₁ (Cy).

R¹ = Me; R² = R³ = Me, Et, Ph; R¹ = Ph; R² = R³ = Me, Et, Prⁱ, Ph, (CH₂)₂OH; R¹–R² = (CH₂)₅, (CH₂)₂O(CH₂)₂.

R¹ = Me, Ph; R² = Me, Et, Prⁱ, Ph.

Compounds **55** were also synthesised by the reaction of methoxytriorganyltelluranes with dialkyl dithiophosphates.¹²⁰

R¹ = Me, Ph; R² = Me, Prⁱ, Ph.

Dithiophosphinates **56** were prepared using a similar approach, *i.e.*, by the reaction of methoxytriorganyltelluranes with diorganyldithiophosphinic acid HSP(S)R₂ (Ref. 120) or the corresponding chlorides with sodium (ammonium) dithiophosphinates MSP(S)R₂ (Refs 120 and 121) (M = Na, NH₄).

X = OMe, Cl; M = H, Na, NH₄; R¹ = Me, Ph; R² = Me, Prⁱ, Ph.

The phosphorus analogues of triorganyltelluronium dithiocarbamates **57** were formed in the reaction of triphenyl-

telluronium chloride with dialkylphosphines and carbon disulfide in the presence of triethylamine.¹²² Treatment of compounds **57** with equimolar amounts of sulfur was accompanied by the insertion of the sulfur atom into the Te—S bond resulting in derivatives **58**. At the same time, the reaction with excess sulfur in benzene at room temperature gave triphenyltelluronium diphenyldithiophosphinate **56**.¹²²

R = Prⁱ, Bn, Ph.

Triphenyltelluronium dichalcogenoimidodiphosphinates **59** were prepared by the exchange reaction of triphenyltelluronium chloride with tetraorganyl dichalcogenoimidodiphosphinates.^{121, 123}

M = Na, K; X = O, S; R¹, R² = Me, Ph.

The salts **59** containing diphenylphosphine residues (R¹ = R² = Ph) were isolated from the reaction mixture and characterised by X-ray diffraction analysis. The existence of other salts in solution was established only by ¹H, ¹³C and ³¹P NMR spectroscopy.¹²³

The exchange reaction of methyl(phenyl)(*p*-tolyl) telluronium iodide (*p*-TolPhMeTe⁺I[−]) with silver D-α-bromocamphorsulfonate (D-BCS) and subsequent crystallisation resulted in compound [*p*-TolPhMeTe]⁺[D-BCS][−] with molecular rotation [M]₅₄₆₁¹⁸ = +262° in ethyl acetate (*cf.* Lowry, cited in Refs 9 and 10). This salt undergoes fast mutarotation in various solvents.

Enantiomerically pure telluronium salts **60a** containing the camphorsulfonate anion were prepared by fractional crystallisation of a diastereomeric mixture.^{54–56, 124} The absolute configurations of both isomers were established by X-ray diffraction analysis. Anion-exchange reactions of (*R*)-camphorsulfonate were used for the synthesis of the enantiomerically pure (*R*)-telluronium salts **60b–g** with various anions.^{54–56, 124}

X = ClO₄ (**b**), BF₄ (**c**), BPh₄ (**d**), *p*-ClC₆H₄SO₃ (**e**), 2,4,6-(O₂N)₃C₆H₂SO₃ (**f**), bornane-10-sulfonate (**g**).

In contrast to the methyl(phenyl)(*p*-tolyl)telluronium salt with the D-BCS anion described above, perchlorate **60b** is resistant against pyramidal inversion; no racemisation occurred even upon refluxing in methanol for 3 days.

Some reactions of telluronium salts consist of conversions of the anionic fragments of the molecules. Thus reactions of triphenyltelluronium halides with halogens yield salts **61**, which contain the trihalide anion.¹⁰

X = Cl; Y = Br, I; X, Y = Br, I.

When xenon difluoride was used instead of halogens, it was the tellurium atom that underwent the attack. For example, the

reaction of XeF_2 with triphenyltelluronium fluoride yielded *mer*- Ph_3TeF_3 **62**, a hexacoordinate tellurium derivative; this reacted with PF_5 to give the pentacoordinate tellurium derivative **63**.^{125, 126}

Telluronium salts form 1:1 adducts with mercuric halides^{9, 10, 127} to which the structures of triorganyltelluronium trihalomercurates **64** were ascribed based on the data from elemental analysis and IR spectroscopy.¹²⁷ However, according to X-ray structural data, the reaction product of Ph_3TeCl with HgCl_2 has a dimeric structure, *viz.*, $(\text{Ph}_3\text{Te}^+)_2[\text{Hg}_2\text{Cl}_6^{2-}]$.¹²⁸

64

$\text{X} = \text{Cl}, \text{Br}, \text{I}; \text{R}^1 = \text{Ar}, \text{R}^2 = \text{Alk}, \text{Ar}.$

A new type of telluronium salts the tellurium atom in which is covalently bound to two organic radicals and one chlorine atom has been described.^{129–131} Reactions of aryltellurium trichlorides with arylmercury chlorides usually yield diaryltellurium dichlorides, Ar_2TeCl_2 .¹³² However, the reactions of *p*-ethoxyphenyltellurium trichloride with 2-[(2-pyridyl)phenyl]mercury chloride^{129, 130} and 2-dimethylaminobenzylmercury chloride¹³¹ unexpectedly gave telluronium salts **65** and **66**.

The molecules of salts **65** and **66** contain relatively short intramolecular coordination bonds $\text{N}-\text{Te}$. The length of this bond in salt **65** is equal to 2.31 Å,¹³⁰ whereas the sum of the van der Waals radii of tellurium and nitrogen is 3.65 Å.¹³³

Triorganyltelluronium halides form 1:1 adducts **67** with boron, aluminium, tin, arsenic and antimony halides and organytellurium trihalides, which have the structure of telluronium salts containing complex anions.^{9, 10, 24, 96}

$\text{X}, \text{Y} = \text{Hal}; \text{R} = \text{Me}, \text{Et}, \text{Ph}; \text{M} = \text{B}, \text{Al}, \text{As}, \text{Sb}, \text{Te}, \text{Sn}; n = 3, 4.$

As for the reactions of triorganyltelluronium halides with Lewis acids, for example SnBr_4 , SnCl_4 , TeBr_4 , TeCl_4 and TiBr_4 (molar ratio 2:1), they yield adducts **68**.^{24, 96}

$\text{R} = \text{Et}, \text{Ph}; \text{X}, \text{Y} = \text{Cl}, \text{Br}; \text{M} = \text{Sn}, \text{Te}, \text{Ti}.$

Complexes of telluronium salts with organic donors are poorly studied. It is known¹⁰ that the triphenyltelluronium halides $\text{Ph}_3\text{Te}^+\text{X}^-$ ($\text{X} = \text{Cl}, \text{Br}$) yield 1:1 adducts with dihexyl sulfoxide. Similar products were formed upon reaction of

$\text{Ph}_3\text{Te}^+\text{Cl}^-$ with 1-R-4,4,6-trimethyl-3,4-dihydro-1*H*-pyrimidine-2-thiones ($\text{R} = \text{Ph}, 4\text{-MeOC}_6\text{H}_4, 4\text{-O}_2\text{NC}_6\text{H}_4, \text{Bu}^n, \text{NH}_2$). It is noteworthy that it is the thionic form of the sulfur atom that is involved in the complexation.¹³⁴

Reaction of trimethyltelluronium iodide with phosphines occurs as demethylation of the original salt and results in high yield of dimethyl telluride.²⁶

$\text{R} = \text{Bu}^n, \text{Ph}.$

The dealkylation of telluronium salts is usually performed by heating in a solid state or in high-boiling solvents.^{9, 10, 49, 135}

$\text{X} = \text{Br}, \text{I}; \text{R}^1 = \text{Alk}; \text{R}^2, \text{R}^3 = \text{Alk}, \text{Ar}.$

In some cases, heating of salts was carried out in the presence of alkyl halide acceptors, *e.g.*, pyridine or dimethylaniline,^{9, 10} resulting in *N*-alkylpyridinium and alkyl dimethylphenylammonium salts, respectively. The thermal decomposition of telluronium salts has not been studied systematically so far. It was only noted¹⁰ that thermal stabilities of trimethyltelluronium salts depend on the anion and increase in the series $\text{F}^- < \text{Cl}^- < \text{SO}_4^{2-} < \text{Br}^- < \text{I}^-$; however, there are still no data on the effects of the leaving group, the anion and the solvent on the direction of dealkylation.

The thermal decomposition of triorganyltelluronium ethers¹¹⁰ and esters,⁹⁷ pseudohalides¹⁰ and xanthates¹¹⁰ as well as dithiocarbamates,¹¹⁷ -phosphates and -phosphinates¹²⁰ proceeds according to the same scheme as the decomposition of triorganyltelluronium halides. It is noteworthy that heating of $\text{Ph}_2\text{MeTeNCS}$ yielded Ph_2Te and MeSCN .¹⁰

$\text{R}^1 = \text{Me}; \text{X} = \text{OCOR}^2 (\text{R}^2 = \text{Me}, \text{CHCl}_2, \text{CCl}_3, \text{Ph}), \text{SP}(\text{S})\text{R}_2^2$
($\text{R}^2 = \text{Me}, \text{Pr}^i, \text{Ph}, \text{OMe}, \text{OEt}, \text{OPr}^i, \text{OPh}$);

$\text{R}^1 = \text{Ph}; \text{X} = \text{OR}^2 (\text{R}^2 = \text{Me}, \text{Et}, \text{Pr}^i), \text{OCOR}^2 (\text{R}^2 = \text{Me}, \text{CHCl}_2, \text{CCl}_3, \text{Ph}), \text{CN}, \text{NCO}, \text{NCS}, \text{NCSe}, \text{SC}(\text{S})\text{NR}_2^2 (\text{R}^2 = \text{Me}, \text{Pr}^i, \text{Ph}), \text{SP}(\text{S})\text{R}_2^2 (\text{R}^2 = \text{Me}, \text{Pr}^i, \text{Ph}, \text{OPh}).$

The decomposition of triphenyltelluronium thioxanthates upon heating is somewhat different.¹¹⁰

$\text{R} = \text{Et}, \text{Pr}^i.$

Heating of tris(2,6-dimethoxyphenyl)telluronium chloride in 0.1 M HCl at 80 °C gave bis(2,6-dimethoxyphenyl)tellurium dichloride in 60% yield.¹⁵ Presumably, the thermolysis proceeded as follows:

No such conversion is reported for other telluronium salts.

In contrast to aryltellurium trihalides and diaryltellurium dihalides, which are converted into diaryl ditellurides and diaryl tellurides, respectively, under the action of sodium sulfide, heating of telluronium salts with Na_2S affords mixtures of tellurides and aromatic derivatives. The compositions of the latter depend on the structures of the original salts.^{9, 10}

Other reactions of telluronium salts employed for the preparation of various classes of organic compounds are considered in the next Section.

IV. The use of telluronium salts in organic synthesis

Telluronium salts are widely used as precursors of non-stabilised and monostabilised telluronium ylides. The latter are prepared by treatment of the original salts with basic reagents and are introduced *in situ* into reactions with carbonyl compounds. Depending on the structure of the original salt, *i.e.*, the nature of the ylide generated, and the type of the carbonyl derivative, various classes of organic compounds are formed.^{7,8}

Diphenyltelluronium methylide **69** ($R^1 = \text{Ph}$, $X = \text{H}$) prepared from methyldiphenyltelluronium tetraphenylborate under the action of lithium 2,2,6,6-tetramethylpiperide (LiTMP) reacted with carbonyl compounds to give epoxides **70** ($R^1 = \text{Ph}$, $X = \text{H}$) in 55%–74% yields.¹⁰⁰ A similar reaction was used^{23,34} in the synthesis of α,β -unsaturated epoxides **70** ($X = \text{CH}=\text{CH}_2$). Dialkyltelluronium allylides **69** ($X = \text{CH}=\text{CH}_2$) were generated by treatment of triorganyltelluronium bromides with potassium *tert*-butoxide²³ or KOH.³⁴ The best results were achieved in reactions of the ylide prepared from allyl(diisobutyl)telluronium bromide with carbonyl compounds. The yields of vinyl epoxides did not depend on the nature of the dehydrobrominating reagent and amounted to 58%–98% for aromatic aldehydes; the yields are lower for aliphatic derivatives. Compounds **70** ($X = \text{CH}=\text{CH}_2$) are prepared as mixtures of *cis*- and *trans*-isomers, the former being slightly predominant.

Trimethylsilylvinyl (**70**, $X = \text{CH}=\text{CHSiMe}_3$, yields 83%–89%⁴⁰) and trimethylsilylethynyl epoxides (**70**, $X = \text{C}\equiv\text{CSiMe}_3$, 80%–96%^{38,39}) were obtained in reactions of ylides **69** ($R^1 = \text{Bu}^i$; $X = \text{CH}=\text{CHSiMe}_3$, $\text{C}\equiv\text{CSiMe}_3$) with aldehydes and ketones. Ylides **69** were prepared by dehydrobromination of the corresponding telluronium salts under the action of LiTMP and used *in situ*. Trimethylsilylvinyl(or ethynyl) epoxides **70** are predominantly represented by *cis*-isomers.

B (base) = LiTMP, BuⁱOK, KOH, *etc.*

Y = BPh₄, Br; X = H, CH=CH₂, CH=CHSiMe₃, C≡CSiMe₃; R¹ = Buⁱ, Ph; R² = H, Ph; R³ = Me, n-C₅H₁₁, n-C₆H₁₃, n-C₉H₁₉, Cy, R_n⁴C₆H_{5-n} [R_n⁴ = H, 4-F, 2-Cl, 3-Cl, 4-Cl, 4-Br, 4-O₂N, 2-Me, 4-Me, 2,4,6-Me₃, 4-Ph, 2-MeO, 4-MeO, 3,4-(MeO)₂, 3,4-(OCH₂O), 6-Br-3,4-(OCH₂O)], 2-Py, 3-Py, 1-naphthyl, 2-naphthyl; R²–R³ = (CH₂)₅.

Vinyl derivatives **70** ($X = \text{CH}=\text{CH}_2$) were synthesised by catalytic epoxidation without preliminary preparation of telluronium salts.³³ Allyl bromides reacted with aldehydes in the presence of catalytic amounts of diisobutyl telluride (20 mol.%) at 50 °C.

R = Cy, 4-XC₆H₄ (X = H, F, Cl, Br, NO₂, Ph), 2-naphthyl, 2-Py.

The sequence of steps resulting in epoxides **70** can be presented as a catalytic cycle. The reaction of telluride with allyl bromide yields a telluronium salt; treatment of the latter with Cs₂CO₃ leads to the generation of diisobutyl allylide, which reacts with the aldehyde to give the epoxide and Bu₂ⁱTe.

A more efficient (in comparison with diisobutyl telluride) catalyst has been proposed.¹³⁶ Vinyl epoxides **70** ($X = \text{CH}=\text{CH}_2$) were prepared by refluxing a mixture of an aldehyde, allyl bromide and catalytic amounts of a telluronium salt in the presence of solid Cs₂CO₃. Allyl(diisobutyl)telluronium bromide proved to be the catalyst of choice; the amount required was 10 times smaller (2 mol.%) than that of diisobutyl telluride (20 mol.%). However, this reaction is not stereoselective (the *cis,trans*-isomer ratio is ~1 : 1).

X = H: R = 4-ClC₆H₄; X = SiMe₃: R = n-C₉H₁₉, Cy, YC₆H₄ (Y = H, 4-Cl, 2-Cl, 4-O₂N, 4-Me), 2-naphthyl.

Telluronium ylides of the type **69** proved to be convenient synthons for the preparation of substituted cyclopropanes. Trimethylsilylvinylcyclopropanes **71** and **72** ($X = \text{SiMe}_3$, R¹ = OMe, OEt) were synthesised for the first time in >90% yields by the reaction of diisobutyltelluronium allylide **69** ($X = \text{SiMe}_3$), generated by deprotonation of the corresponding telluronium salt under the action of LiTMP, with α,β -unsaturated esters.⁴¹ The reactions of ylides **69** ($X = \text{SiMe}_3$) with β -aryl-substituted esters are characterised by high stereoselectivities and gave exclusively alkyl *trans*-2-trimethylsilylvinyl-*trans*-3-substituted cyclopropane carboxylates **71**. Reactions with methyl *trans*-but-2-enoate and methyl methacrylate are less stereoselective: mixtures of the isomers **71** and **72** were formed in 1.5 : 1 and 1 : 1 ratios, respectively.⁴¹ Later, this reaction was extended to other ylides of the type **69** ($X = \text{H}$,^{137,138} Me,¹³⁷ SiMe₃^{137–139}) and α,β -unsaturated esters^{137–139} and amides.^{137,138} Alkali metal bis(trimethylsilylamides), MN(SiMe₃)₂ (M = Na, K),¹³⁷ lithium diisopropylamide (LDA)¹³⁸ and LiTMP¹³⁹ were used as the bases.

B = MN(SiMe₃)₂ (M = Na, K), LDA, LiTMP;

X = H, Me, SiMe₃;

R¹ = Me, 2-furyl, R³C₆H₄ (R³ = H, 4-F, 4-Me, 2-MeO, 4-MeO);

R² = OMe, OEt, N(CH₂)₄, N(CH₂)₅.

All the reactions give high yields; the stereochemistry of the reaction product is determined primarily by the nature of the base. *trans,trans*-Isomers **71** are formed exclusively in the presence of lithium cations. In other cases, the stereoselectivity of the reaction changes towards the predominant formation of *trans,cis*-isomers **72**. By varying the nature of the base, the ratio of the isomers **71**:**72** can be changed from 1:99 to 99:1. Thus the **71**:**72** isomer ratio in the reaction of diisobutyltelluronium salt ($X = \text{SiMe}_3$) with methyl cinnamate under the action of $\text{KN}(\text{SiMe}_3)_2$ was <1:99, whereas that in the presence of the $\text{LiBr}-\text{NaN}(\text{SiMe}_3)_2$ system as a base was >99:1.¹³⁷ According to the reported data,^{137, 138} the effect of the lithium cation is determined by its chelation with the carbonyl oxygen atom and the ylide carbanion and formation of a stable six-membered ring. The addition to the reaction mixture of hexamethylphosphoramide (HMPA) able to coordinate the lithium cation and to inhibit the formation of lithium chelates resulted in the formation of *trans,cis*-isomers **72** in good yields and with high selectivity.¹³⁸

The reaction of ylide **69** ($X = \text{SiMe}_3$) with diethyl fumarate and dimethyl maleate also resulted in isomers **71** ($R^1 = \text{CO}_2\text{Et}$, $R^2 = \text{Et}$; $R^1 = \text{CO}_2\text{Me}$, $R^2 = \text{Me}$).⁴¹

Ylide **69** ($X = \text{SiMe}_3$) generated from the corresponding telluronium salt under the action of LiTMP ¹³⁹ was introduced into the reaction with (–)-8-phenylmenthyl esters of α,β -unsaturated acids. This resulted in the formation of *trans*-2-trimethylsilylvinyl-*trans*-3-substituted cyclopropyl carboxylates in high yields and with high diastereoselectivities.

Diisobutyltelluronium ylides **69** generated by deprotonation of telluronium salts with potassium (or sodium) bis(trimethylsilylamide) reacted smoothly with diethylalkylidene- and arylmethylidenemalonates to give vinylcyclopropane-1,1-dicarboxylates **73** and **74** in high yields (81%–93%) and with high *trans*-selectivities (the **73**:**74** ratio was in the range from 71:29 to 98:2).¹⁴⁰ The addition of lithium bromide to the reaction mixture increased slightly the percentage of *trans*-isomer **73**.

$X = \text{CH}=\text{CHSiMe}_3$; $R = n\text{-C}_6\text{H}_{13}$, $\text{CH}=\text{CHPh}$, Ph , 4-MeC₆H₄;
 $R = \text{Ph}$: $X = \text{CH}=\text{CH}_2$, $\text{CH}=\text{CHMe}$, Ph .

Cyclopropanes of yet another type are formed in the reaction of telluronium ylides **69** with α,β -unsaturated ketones. The ylides generated by treatment of the corresponding telluronium salts with solid NaOH in THF,⁴² $\text{KN}(\text{SiMe}_3)_2$ (for $X = \text{Ar}$)¹⁴¹ or Cs_2CO_3 in 1,2-dimethoxyethane (DME) containing traces of water,⁴⁵ $\text{KN}(\text{SiMe}_3)_2$,¹⁴¹ Bu^tOK ¹⁴¹ (for $X = \text{CH}=\text{CHR}$ where $R = \text{SiMe}_3$, H , Me , Ph) gave rise to cyclopropyl ketones **75** and **76** (yields 52%–95%). This reaction is highly stereoselective: ketones **75** are the main products (>90% in the mixture) where the keto group and the X fragment lie on the same side relative to the plane of the cyclopropane ring.

In contrast to α,β -unsaturated esters and amides, the stereochemistry of reactions of telluronium ylides with α,β -unsaturated ketones does not depend on the presence of lithium cation. Moreover, the presence of lithium salts in reaction mixtures decreases the yields of cyclopropanes and favours the formation of epoxides.^{45, 141} The use of α,β -unsaturated aldehydes in such reactions results in complex mixtures of reaction products.⁴⁵

$X = \text{CH}=\text{CH}_2$, $\text{CH}=\text{CHSiMe}_3$, $\text{CH}=\text{CHMe}$, $\text{CH}=\text{CHPh}$, Ph , 4-ClC₆H₄; $R^1 = \text{Bu}^n$, Bu^t ; $R^2 = \text{R}^4\text{C}_6\text{H}_4$ ($R^4 = \text{H}$, 4-Cl, 4-Br, 4-Me, 4-Me₂N, 3-O₂N, 4-O₂N); $R^3 = \text{Bu}^t$, Ph , $\text{CH}=\text{CHPh}$.

It is of note that triphenylarsonium allylides react with α,β -unsaturated ketones to give high yields of cyclopropyl ketones with an opposite configuration of substituents in comparison with the products generated from telluronium ylides.¹⁴¹

A one-pot synthesis of cyclopropanes without preliminary generation of telluronium ylides has been developed for reactions with chalcones.⁴⁵ This approach is based on the use of a biphasic system Cs_2CO_3 –THF (with traces of water) in the presence of catalytic amounts of diisobutyl telluride (20 mol.%).

Similar to sulfonium ylides, telluronium ylides react with *N*-sulfonylimines to give aziridines **77**.^{142, 143} Ylides **69** ($X = \text{CH}=\text{CHR}$,¹⁴² $\text{C}\equiv\text{CSiMe}_3$ ¹⁴³) generated from the corresponding telluronium salts under the action of potassium bis(trimethylsilylamide) in THF at low temperature react with *N*-tosylimines of aromatic aldehydes to give vinyl(or ethynyl)aziridines **77** with low stereoselectivity (the *trans*:*cis* ratio is 33:67–58:42).^{142, 143}

$\text{Ar} = 4\text{-ClC}_6\text{H}_4$; $X = \text{CH}=\text{CH}_2$, $\text{CH}=\text{CHSiMe}_3$,¹⁴²
 $\text{Ar} = \text{Ph}$; $X = \text{C}\equiv\text{CSiMe}_3$.¹⁴³

Sulfonium allylides afford aziridines only in reactions with arylimines activated by *N*-sulfonyl¹⁴² or *N*-diphenylphosphinoyl groups,¹⁴⁴ while more reactive telluronium allylides enter into aziridination reactions with less reactive imines. Thus treatment of telluronium allylides **69** ($X = \text{SiMe}_3$) prepared by deprotonation of the telluronium salt with $\text{LiN}(\text{SiMe}_3)_2$ in the presence of HMPA (toluene, –78 °C) with aryl imines gave aziridines **78**.¹⁴⁵ This reaction was highly stereoselective and yielded almost exclusively *trans*-isomers (>96%).

$X = \text{H}$, $\text{Ar} = \text{Ph}$; $X = \text{SiMe}_3$; $\text{Ar} = \text{Ph}$, 4-ClC₆H₄, 4-CF₃C₆H₄, 4-MeOC₆H₄, 2-MeOC₆H₄.

The reaction of diisobutylallylide **69** ($X = \text{H}$) with benzylidenedianiline results in aziridine **78** ($X = \text{H}$), however, in a lower yield (37%) and with lower stereoselectivity (the *trans*:*cis* ratio is 80:20) than in the case of the trimethylsilyl analogue **69** ($X = \text{SiMe}_3$).¹⁴⁵

In contrast to their sulfonium analogues, stabilised telluronium ylides containing electronegative substituents at the anionic carbon atom react with aldehydes and ketones to give alkenes.^{22, 29, 30} For the first time this was demonstrated in the example of dialkyltelluronium ethoxycarbonylmethylides **79** ($R^1 = \text{Me}$, Bu^n ; $Y = \text{CO}_2\text{Et}$).²² Ylides **79** were generated from (ethoxycarbonylmethyl)dialkyltelluronium bromides under the action of potassium *tert*-butoxide and coupled *in situ* with various carbonyl compounds. This resulted in α,β -unsaturated esters **80** ($Y = \text{CO}_2\text{Et}$, yields 52%–90%), predominantly in the *E*-form.²² Later, dibutyltelluronium methylide derivatives Bu_2TeCHY ($Y = \text{COPh}$,²⁹ CN ,²⁹ CONHBu^t , see Ref. 30) were employed in

a similar reaction. The ylides were generated by deprotonation of telluronium halides under the action of Bu^tOK ²⁹ or NaH ;³⁰ their *in situ* reactions with aldehydes and ketones gave good yields (36%–83% for $\text{Y} = \text{CN}$, 74%–81% for $\text{Y} = \text{COPh}$, and 40%–71% for $\text{Y} = \text{CONHBu}^i$) of alkenes **80** with *E*-configurations of the double bonds.

$\text{X} = \text{Br}, \text{Cl}; \text{Y} = \text{CN}, \text{CO}_2\text{Et}, \text{COPh}, \text{CONHBu}^i$;
 $\text{R}^1 = \text{Me}, \text{Bu}^n; \text{R}^2, \text{R}^3 = \text{Alk}, \text{Ar}$.

The reaction of dibutyltelluronium alkylcarbamoyl methylides **79** ($\text{Y} = \text{CONHR}$) prepared by treatment of (alkylcarbamoylmethyl)dibutyltelluronium halides with potassium carbonate in THF, with aldehydes gave α,β -unsaturated amides **80** ($\text{Y} = \text{CONHR}$) with high *E*-stereoselectivity and in good yields.¹⁴⁶

$\text{X} = \text{Cl}, \text{Br}$;
 $\text{R}^1 = \text{Pr}^i, \text{Bu}^i; \text{R}^2 = 4\text{-R}^3\text{C}_6\text{H}_4$ ($\text{R}^3 = \text{H}, \text{Cl}, \text{Me}, \text{MeO}$), $\text{CH}=\text{CHPh}$.

The synthesis of alkenes **80** from α -bromo esters or α -bromo ketones in the presence of dibutyl telluride can be carried out as a cyclic catalytic process using triphenyl phosphite as a reducing agent for the liberating Bu_2^+TeO .³¹ Catalytic amounts of dibutyl telluride react with α -bromo esters or ketones to give telluronium salts, which are converted into ylides under conditions of phase-transfer catalysis (solid K_2CO_3 , THF containing traces of water). The reaction of the ylide with aldehydes occurs in the presence of $(\text{PhO})_3\text{P}$ and yields alkenes and Bu_2^+TeO . The latter is reduced to the original dibutyl telluride, which again reacts with the bromo derivatives. Na_2SO_3 , NaHSO_3 and $\text{Na}_2\text{S}_2\text{O}_5$ can also be used as reducing agents for dibutyltellurium oxide.³¹

This catalytic reaction requires 20 mol.% of dibutyl telluride. The yields of alkenes decreased with a decrease in the amount of the catalyst even with the increase in the reaction time. Poly(ethylene glycol) (PEG) telluride, $\text{Bu}^n\text{Te}-\text{PEG}-\text{TeBu}^n$ (Refs 48 and 147), manifested higher catalytic activity in the olefination reaction. It was prepared by the reaction of *O*-tosyl-PEG with Bu^nTeLi (yield 83%).^{48, 147} Reactions of aromatic and aliphatic aldehydes with ethyl bromoacetate in THF or toluene in the presence of potassium carbonate as a base, $(\text{PhO})_3\text{P}$ or NaHSO_3 as a reducing agent and only 2 mol.% of $\text{Bu}^n\text{Te}-\text{PEG}-\text{TeBu}^n$,

give α,β -unsaturated esters **80**, mainly with the *E*-configured double bond (> 99% in the mixture).

$\text{R} = n\text{-C}_9\text{H}_{19}, \text{Cy}, \text{PhCH}=\text{CH}, 4\text{-XC}_6\text{H}_4$ ($\text{X} = \text{H}, \text{Cl}, \text{NO}_2, \text{CF}_3, \text{Me}, \text{MeO}$), 2-furyl.

Due to relatively low energy and high polarity of the $\text{Te}-\text{C}$ bonds, telluronium salts enter into the reactions that do not occur with their sulfur or selenium analogues. Thus coupling of telluronium salts with aromatic aldehydes to give alkenes without the intermediate formation of ylides occurs upon refluxing in THF.^{27, 29} In some cases, the yields of *E*-alkenes **80** are even higher than the yields attained in reactions with pre-formed ylides.

$\text{Y} = \text{Cl}, \text{Br}; \text{X} = \text{CN}, \text{CO}_2\text{Me}, \text{COPh}; \text{R} = 4\text{-Cl}, 4\text{-Br}, 3\text{-NO}_2, 4\text{-NO}_2$.

As telluronium salts are easily formed upon reactions of dibutyl telluride with α -bromo esters (or ketones) or chloroacetonitrile, the synthesis of alkenes **80** can be carried out by refluxing of equimolar amounts of dibutyl telluride, the halogen-containing substrate and the aldehyde in THF.²⁷ The yields of alkenes **80** are only slightly lower than with the use of the *in situ* prepared telluronium salts.

$\text{X} = \text{Cl}, \text{Br}; \text{Y} = \text{CN}, \text{COPh}, \text{CO}_2\text{Me}, \text{CO}_2\text{Et}$;
 $\text{R} = 4\text{-Cl}, 4\text{-Br}, 3\text{-NO}_2, 4\text{-NO}_2$.

The reaction of dibromomalonates with carbonyl compounds in the presence of dibutyl telluride (2 equiv.) is a convenient alternative to the Knoevenagel reaction.³⁷

$\text{R}^1 = \text{Me}, \text{R}^2 = \text{H}, \text{R}^3 = \text{Bu}^i; \text{R}^1 = \text{Me}, \text{R}^2 = \text{R}^3 = (\text{CH}_2)_5$;
 $\text{R}^1 = \text{Et}, \text{R}^2 = \text{H}; \text{R}^3 = n\text{-C}_9\text{H}_{19}, \text{R}^4\text{C}_6\text{H}_4$ ($\text{R}^4 = \text{H}, 2\text{-Cl}, 4\text{-Cl}, 4\text{-NO}_2, 4\text{-MeO}$), 2-Py, 2-(3-bromothieryl).

This reaction proceeds under mild conditions (heating of the reaction mixture in THF at 50 °C) and results in alkylidene- and arylmethylidene α,β -unsaturated malonates in 84%–98% yields. A tentative mechanism of the reaction is reported.³⁷

It was already mentioned that the deprotonation of methyl-diphenyltelluronium tetraphenylborate under the action of

LiTMP gave the ylide $[\text{Ph}_2\text{Te}^+\text{H}_2\text{C}^-]$ which reacted with carbonyl compounds to yield epoxides of the type **70**.¹⁰⁰ The reaction of the same salt with organolithium compounds and subsequent addition of aldehydes to the reaction mixture gave quite different results, *viz.*, secondary alcohols **81** (yields 55%–85%) were formed as the reaction products.⁹⁹ This can be attributed to the formation, from original telluronium salts and organolithium compounds, of unstable tetraorganyltelluranes **82** [similar to the formation of thermostable Ph_4Te from Ph_3TeCl and PhLi or thermally unstable tetrabutyltellurane Bu_4Te from Bu_3TeI and Bu^nLi (Refs 9, 10)]. The reactions of telluranes **82** with carbonyl compounds are accompanied by migration of one of the radicals bound to the tellurium atom to the carbonyl carbon atom resulting in intermediates **83**. In the case of methylphenyltelluronium tetraphenylborate, this reaction yields arylbenzyl alcohols **81** due to the preferential migration of the phenyl radical.⁹⁹

$\text{R}^1 = \text{Me}, \text{Bu}, \text{Bu}^i, \text{Ph}; \text{R}^2 = 4\text{-R}^3\text{C}_6\text{H}_4 \text{ (R}^3 = \text{H, Br, Cl, F, Me, MeO, 2-naphthyl, 2-Py.)}$

The Bn and $\text{CH}_2\text{C}\equiv\text{CSiMe}_3$ groups in tetraorganyltelluranes **82** ($\text{R}^1 = \text{Bn}$,³⁵ $\text{CH}_2\text{C}\equiv\text{CSiMe}_3$,³⁹) formed upon reaction of the corresponding telluronium salts with organolithium (or -magnesium) derivatives migrate to the carbonyl carbon atom. This yields alcohols **84** containing a benzyl³⁵ or a trimethylsilyl ethynyl-methyl³⁹ group at the α -carbon atom. A large series of β -hydroxy nitriles **84** ($\text{R}^2 = \text{CH}_2\text{CN}$) were synthesised from dibutyl(cyano-methyl)telluronium chloride using a similar approach.³⁶

$\text{X} = \text{Cl, Br}; \text{R}^1 = \text{Bu}^n, \text{Bu}^i; \text{R}^2 = \text{Bn}, \text{CH}_2\text{C}\equiv\text{CSiMe}_3, \text{CH}_2\text{CN};$
 $\text{R}^3\text{M} = \text{MeLi}, \text{Bu}^n\text{Li}, \text{Bu}^i\text{Li}, \text{PhLi}, 4\text{-MeC}_6\text{H}_4\text{Li}, \text{MeMgI};$
 $\text{R}^4 = \text{H, Me, Ph}; \text{R}^5 = \text{Alk, Ar, Het}; \text{R}^4-\text{R}^5 = (\text{CH}_2)_5, (\text{CH}_2)_3\text{CH}=\text{CH}.$

Yet another example of the use of telluronium salts in the synthesis of alcohols is the tellurium–zinc exchange reaction between telluronium salts and diethylzinc. This reaction proceeds under mild conditions (in CH_2Cl_2 at room temperature).¹⁴⁸ The diorganylzinc derivatives formed *in situ* reacted with carbonyl compounds (aldehydes, ketones, phenacyl chlorides) and afforded secondary and tertiary alcohols in high yields after hydrolysis.¹⁴⁸

$\text{X} = \text{Cl, Br, I, BPh}_4; \text{Y} = \text{CH}=\text{CH}_2, \text{C}\equiv\text{CSiMe}_3, \text{Ph};$
 $\text{R}^1 = \text{Bu}^n, \text{Bu}^i; \text{R}^2 = \text{H, Ph}; \text{R}^3 = n\text{-C}_{11}\text{H}_{23}, \text{CH}_2\text{Cl}, \text{CH}=\text{CHPh},$
 $\text{Ph}, 4\text{-ClC}_6\text{H}_4.$

Allyl(dialkyl)telluronium bromides are efficient reagents for the allylation of phenols. The reactions of these salts with phenols in the presence of solid NaOH in THF yielded allyl aryl ethers (yields 81%–95%).⁴³

$\text{R}^1 = \text{R}^2 = \text{H, Me}; \text{R}^1 = \text{H}, \text{R}^2 = 4\text{-ClC}_6\text{H}_4; \text{Ar} = \text{Ph}, \text{R}^3\text{C}_6\text{H}_4$
 $(\text{R}^3 = 4\text{-Cl, 2-Me, 4-Bu}^i), 1\text{-naphthyl, 2-naphthyl}.$

The reaction of telluronium salt **11** with sodium phenylsulfinate yielded the corresponding alkyl phenyl sulfone.¹⁷

However, in contrast to their iodonium [*e.g.*, $\text{PhI}^+\text{CH}=\text{CR}^1\text{R}^2\text{BF}_4^-$ (Ref. 149)] and bismuthonium [$\text{Ph}_3\text{Bi}^+\text{CH}_2\text{CORBF}_4^-$ (Ref. 150)] analogues, telluronium salts **10** and **14** do not enter into this reaction. It was thus concluded¹⁷ that the nucleofugicity of the diphenyltelluronium group is lower than those of the phenyliodonium and triphenylbismuthonium groups.

In the presence of a superacid (*e.g.*, the $\text{FSO}_3\text{H}-\text{SbF}_5-\text{SO}_2$ system), trimethyltelluronium trifluoromethanesulfonate alkylated toluene under very mild conditions (-78°C) resulting in the predominant formation of *o*-xylene (yield 25%); *m*- and *p*-isomers were formed as minor products (93 : 6 : 1).⁶⁷

Dibenzotellurophenonium trifluoromethanesulfonate **18**, like its selenium and sulfuric analogues, can serve as a trifluoromethylating reagent with respect to various enolates including trimethylsilyl enolates, anilines and sodium alkanethiolates. Their trifluoromethylating activities increase in the following order: $\text{Te} < \text{Se} < \text{S}$.⁶⁹ Trifluoromethyldibenzotellurophenonium-3-sulfonate¹⁵¹ is the most convenient trifluoromethylating reagent of this class as regards the ease of isolation of the reaction products, since dibenzotellurophene-3-sulfonic acid formed is readily soluble in water.

Among other important practical applications of telluronium salts, special mention should be made of the use of triphenyltelluronium tetrafluoroborate and phosphate as catalysts of liquid-phase oxidation of alkenes.¹⁵²

V. Crystal structures of telluronium salts

The molecular and crystal structures of over 60 telluronium salts were studied using X-ray diffraction analysis. The $\text{Te}-\text{C}$ and $\text{Te}-\text{heteroatom}$ bond lengths, $\text{C}-\text{Te}-\text{C}$ bond angles, coordination numbers (CN) of tellurium atoms and references are given in Table 1, the data being sorted in accordance with the type of the anion X .

Table 1. Bond lengths and bond angles in triorganyltelluronium salts $R^1R^2R^3Te^+X^-$.

^a The C—Te—Cl angles lie in the range 88.5–91.7° (Ref. 130); ^b the salt contains two independent ionic pairs; the C—Te—Br angles are equal to 91.6–101.8° (Ref. 81); ^c the salt was unexpectedly isolated in an attempt to obtain triethyltelluronium diethyl thiophosphate by the exchange reaction of triethyltelluronium iodide with silver diethyl thiophosphate;¹⁵⁸ ^d the data on secondary bonds are absent; ^e the solvate with benzene (1 : 1); ^f the bonds of the non-charged Te atom: Te—C(sp)³ and Te—C(sp) are 2.149 and 2.067 Å, respectively (Ref. 65); ^g the solvate with chloroform (1 : 0.5).

The nature of the Te—X bonds in the telluronium salts R_3TeX in the crystalline state varies from purely ionic to covalent and is largely determined by the nature of the electronegative group X and, to a lesser extent, by the nature of the organic radicals bound to the tellurium atom. Like other tellurium derivatives,^{157,158} telluronium salts form secondary bonds with various elements, which allows the CN of tellurium atoms to acquire values from 3 to 6. Besides, a significant role in the structures and reactivities of organotellurium compounds is played by intramolecular coordination bonds (ICB) $O \rightarrow Te$, $N \rightarrow Te$, *etc.*^{159,160} The nature of these bonds is mainly determined by the donation of the unshared electron pair (UEP) of a heteroatom in such group as CHO, COR, CO₂R, NO₂, $N=N$, $CH=N$, CH_2NR_2 , *etc.*, to the antibonding molecular orbital (σ^* -MO) of the Te—X bond. The intramolecular coordination bonds $O(or N) \rightarrow Te$ should always be taken into consideration in determining the CN for the tellurium atom, since these bond lengths are much smaller than the sum of the van der Waals radii of the elements involved in the interaction.

Salts **85a–c**, **86** containing tetraphenylborate anion and its perfluorinated analogue, as well as perchlorate **30** and trichloromercurate **64a** exist in the form of discrete cations and anions; in the majority of cases, they are not involved in significant secondary interactions with one another. The lengths of the $Te \cdots F$ bond in salt **86** (3.36 Å⁸⁶) and of the $Te \cdots O$ bond in salt **30** (average value of 3.45 Å^{72,73}) are close to the sum of the van der Waals radii for the Te, F (3.53 Å¹³³) and Te, O (3.60 Å¹³³) pairs and are not taken into consideration in the calculation of CN for the Te atom. The bonds at the Te atom in R_3Te^+ cations have a trigonal-pyramidal configuration; the CN of Te in compounds **85a,b** and **86** is 3. At the same time, the bonds at the Te atoms in salts **85c**, **30** and **64** acquire a trigonal-bipyramidal configuration as a result of which the CN increases to 4 due to the occurrence, in these salts, of ICB $O \rightarrow Te$, $N \rightarrow Te$. Their lengths are 0.7–1.3 Å smaller than the sum of the van der Waals radii of the corresponding elements. Tetrafluoroborate **10a** contains, together with ICB $O \rightarrow Te$ (2.892 Å¹⁷), an interionic secondary $Te \cdots F$ bond the length of which (3.06 Å¹⁷) is nearly 0.5 Å smaller than the sum of the van der Waals radii of Te and F (3.53 Å¹³³). With regard to this interaction, the CN of the tellurium atom increases to 5.

Secondary interionic $Te \cdots Hal$ bonds usually occur in salts containing complex halogen anions $MHal_n$ ($Hal = F, Cl$); it is noteworthy that these bonds are shorter than the sum of the van der Waals radii of the elements. Hexafluoroantimonate **87a** containing three bulky mesityl groups is an exception, it exists in the form of discrete non-interacting ions. The Te atom in this compound has the trigonal-pyramidal configuration, and its CN is 3. However, CN of the tellurium atom in bromodimesityltelluronium salt **87b** containing the shortest $Te \cdots F$ contacts is 4.⁸¹ It is of note that secondary bonds $Br \cdots F$ in this compound are relatively short (2.69–2.80 Å), *i.e.*, 0.5–0.6 Å shorter than the sum of their van der Waals radii (3.32 Å¹³³). In salt **88**, each Te atom forms secondary $Te \cdots Cl$ bonds with the chlorine atoms of three $AuCl_4^-$ anions¹⁰⁶ and, as a consequence, the CN of the tellurium atom is 6. Salts **89**, **90** containing the doubly charged anions MCl_6 ($M = Pt, Ir$) manifest three secondary interactions $Te \cdots Cl$.¹⁰⁶ However, only the shortest bonds are taken into consideration in determining the type of the coordination polyhedron of the tellurium atom (the trigonal bipyramid with allowance for the UEP of the Te atom¹⁰⁶) and its CN (equal to 4). Bis(triphenyltelluronium) di- μ -chlorobis(dichloromercurate) **91** contains symmetrical Cl-bridging dimeric $Hg_2Cl_6^{2-}$ anions.¹²⁸ Due to three secondary $Te \cdots Cl$ bonds, which are 0.24–0.47 Å shorter than the sum of the van der Waals radii, the CN of the Te atom is equal to 6.¹²⁸ The coordination number of the onium tellurium atom in bis(triphenyl)telluronium hexachlorotellurate **92** is also equal to 6.¹⁵³ In this salt, each of the two tellurium atoms in the triphenyltelluronium cations is linked to the $TeCl_6^{2-}$ anion by three secondary $Te \cdots Cl$ bonds, the average length of the bonds being 3.527 Å. The $TeCl_6^{2-}$ anion has an octahedral structure; the average length of the $Te \cdots Cl$ bonds is 3.545 Å.¹⁵³ Trimethyltel-

luronium methyltetraiodotellurate **93**¹⁰ and triethyltelluronium tetraargentatopenta iodide **94**¹⁵⁴ are made up of trigonal-pyramidal cations, Alk_3Te^+ and square-pyramidal anions $MeTeI_4^-$ or tetracoordinate Ag atoms constituting the $[Ag_4I_5]^-$ anions.¹⁵⁴ Considering that the shortest $Te \cdots I$ bonds in both salts are only 0.2 Å shorter than the sum of the van der Waals radii of Te and I (4.04 Å¹³³), the CN of the tellurium atom in these compounds can be taken equal to 3 and 4, respectively.

It is of note that the *R*- and *S*-diastereomers of ethyl(methyl)-phenyltelluronium camphor-10-sulfonate **60a** differ from one another not only in the lengths of their Te—C bonds and the C—Te—C bond angles, but also in the number of secondary interactions between the tellurium atom and the oxygen atoms of the sulfonate group. The *R*-isomer in the crystalline state was found to contain two secondary bonds $Te \cdots O$ (2.88 and 3.05 Å^{54–56,124}), which points to the square-pyramidal geometry of the Te atom (CN 5). At the same time, the *S*-isomer contains three $Te \cdots O$ bonds (3.00, 3.01 and 3.03 Å^{56,124}) with an octahedral configuration around Te (CN 6). Telluronium salt **95** containing a trifluoromethanesulfonate anion has only one $Te \cdots O$ bond (2.61–2.68 Å); the CN of the Te atom in this salt is equal to 4.⁸²

Presumably,⁵⁶ the difference in the type of secondary interactions between the optical isomers is determined by the peculiarities of the crystal packing of their molecules. It should be noted that the lengths of the $Se \cdots O$ bonds (3.03 and 3.32 Å) in (*R*)-ethyl(methyl)phenylselenonium camphor-10-sulfonate¹⁶¹ exceed those in its tellurium analogue (*R*)-**60a** despite the fact that the van der Waals and the covalent radii of selenium are smaller than those of tellurium. This suggests that the cation–anion interactions in telluronium salts are stronger than in selenonium salts.

The crystalline states of the salts containing nucleophilic halide anions are represented by several structural types. Each tellurium atom in triethyltelluronium bromide **1e** is involved in three secondary interactions with the bromine atoms (the average length of the $Te \cdots Br$ bonds is 3.56 Å;²⁴ the sum of the van der Waals radii of the elements is 3.91 Å¹³³). This favours the formation of cubane-like tetramers where the Te and Br atoms alternately occupy the vertices of the Te_4Br_4 backbone. The presence of three primary Te—C bonds and three secondary $Te \cdots Br$ bonds at tellurium atoms results in the distorted octahedral environment of Te (CN 6). Triethyltelluronium chloride **1b** has a similar structure: the average length of the $Te \cdots Cl$ bonds is 3.45 Å,²⁵ while the sum of the van der Waals radii of Te and Cl is 3.81 Å.¹³³ Trimethyltelluronium iodide **1h** was found to contain three secondary $Te \cdots I$ bonds with the average bond length of 3.75 Å²⁸ (the sum of the van der Waals radii being 4.04 Å¹³³); the CN of the Te atom is also equal to 6.

Triethyltelluronium iodide **1i** has a different structure.²⁵ Its cations form centrosymmetrical dimers linked together by bridging iodine atoms (the average length of the $Te \cdots I$ bonds is 3.84 Å). In contrast to the halides considered above, each tellurium atom is included into two secondary interactions, which is favourable for the square-pyramidal environment of the tellurium atom (CN 5). The same configurations of the bonds were found in trimethyl-(**1a**),²⁸ triphenyl- (**1c**)^{28,155} and tris(pentafluorophenyl)telluronium (**1d**) chlorides,¹⁵⁶ in tris(pentafluorophenyl)telluronium bromide (**1g**)⁸² and dimethylphenyltelluronium iodide (**1j**).⁵⁷ The CN (5) of the Te atom in the *S*-diastereomer of the optically active telluronium salt **32b** is determined by the presence of two secondary bonds: $Te \cdots Cl$ (3.153 Å) and $Te \cdots O$ (2.842 Å),⁷⁴ their lengths are much smaller than the sum of the van der Waals radii of the corresponding elements. All the three nitrogen atoms in tris(2-dimethylaminobenzyl)telluronium chloride (not included into the Table) are coordinated by the tellurium atom, which favours the formation of the octahedral environment of the latter¹⁴ (CN 6). The length of ICB $N \rightarrow Te$ in this compound slightly exceeds that in salts **30** and **64a**, which contain sp^2 -hybridised nitrogen atoms. Chlorine atoms are not involved in second-

dary interactions [the shortest distance $\text{Te}\cdots\text{Cl}$ is 4.72 Å, which exceeds the sum of the van der Waals radii of Te and Cl (3.81 Å)¹³³ by 0.9 Å]. Each iodine atom in (methyltelluroethynyl)dimethyltelluronium iodide (**1k**) forms secondary bonds with four tellurium atoms.⁶⁵ The $\text{Te}^+\cdots\text{I}$ bonds (3.45 and 3.70 Å) are shorter than the $\text{MeTe}\cdots\text{I}$ bonds (3.58 and 3.76 Å). The crystals of **1k** were found to contain relatively short $\text{Te}^+\cdots\text{Te}$ bond; their lengths (3.77 Å) are about 0.4 Å smaller than the sum of the van der Waals radii of the elements (4.12 Å).¹³³ The CN of the onium Te atom with consideration of these interactions is 6, that for the tellurium atom bound to $\text{C}(\text{sp}^3)$ - and $\text{C}(\text{sp})$ -atoms is 5.⁶⁵

The presence of bulky mesityl radicals in trimesityltelluronium iodide (**1l**) may account for the fact that this salt is not characterised by any significant secondary interactions involving the tellurium atom. The length of the $\text{Te}\cdots\text{I}$ bond is 4.13 Å,¹³ *i.e.*, exceeds the sum of the van der Waals radii of Te and I (4.04 Å)¹³³ by nearly 0.1 Å.

Biphenyl-2-yl(dibenzotellurophenium) benzoate (**42a**)⁸³ has a trigonal-bipyramidal structure characteristic of σ -telluranes R_2TeX_2 ($\text{X} = \text{Hal}, \text{OCOR}, \text{ONO}_2$, *etc.*)¹⁶² containing covalent bonds $\text{Te}-\text{X}$. The apical positions are occupied by the O atom and one of the $\text{Te}-\text{C}$ bonds of the dibenzotellurophene fragment (the angle between the apical substituents is 159.9°). The length of the $\text{Te}-\text{O}$ bond (2.469 Å) is 0.3 Å greater in comparison with diphenyl telluroacetate $\text{Ph}_2\text{Te}(\text{OCOCH}_3)_2$ (2.16 Å)¹⁶³. The secondary $\text{Te}\cdots\text{O}$ bond between the tellurium atoms and the carbonyl oxygen atom of this molecule (3.182 Å) is about 0.4 Å smaller than the sum of the van der Waals radii of the elements. With consideration of this bond, the CN of the Te atom is 5. Benzoate **42a** exists as a monomer in the crystalline state, while the acetate **42b** is a dimer due to the presence of secondary $\text{Te}\cdots\text{O}$ bonds with carbonyl oxygen atoms of not only its own molecule (2.491 Å), but also the adjacent molecule (3.181 Å).⁸³ If these bonds are taken into consideration, the CN of the Te atom becomes equal to 6. The difference between the structures of benzoate **42a** and acetate **42b** can be attributed to the effects of steric factors, *i.e.*, the different sizes of the OCOPh and OCOME groups.⁸³

2,2'-Biphenylene(biphenyl-2-yl)telluronium phenolates **42c**⁸⁴ and **42d**⁸⁵ have identical structures. The coordination polyhedra of the tellurium atom in these compounds are distorted trigonal bipyramids the apical positions in which are occupied by the oxygen atoms and by one of the $\text{Te}-\text{C}$ bonds of dibenzotellurophene (the angles between the apical substituents in both compounds are equal to 159.6°). The $\text{Te}-\text{O}$ bond in 4-nitrophenoxy derivative **42d** (2.461 Å) is nearly 0.2 Å longer than that in the unsubstituted derivative **42c** (2.294 Å). The lack of secondary interactions in the crystals of compounds **42c,d** makes the CN of the Te atom equal to 4. In contrast to the monomeric phenoxy derivatives **42c,d**, salt **42e** containing a 2,4,6-trichlorophenoxy substituent exists in the form of a dimer.⁸⁵ In the latter case, the lengths of the primary $\text{Te}-\text{O}$ bonds (2.762 Å) and secondary $\text{Te}\cdots\text{O}$ bonds between the tellurium atom and the oxygen atom of the adjacent molecule (2.787 Å) are virtually identical, the tellurium atom has a distorted square-pyramidal configuration of the bonds (CN = 5). Presumably,⁸⁵ the gradual increase in the lengths of the $\text{Te}-\text{O}$ bonds in phenolates **42c-e** reflects the gradual changes in the nature of the $\text{Te}-\text{X}$ bonds from predominantly covalent to ion-like.

Similarly to phenolate **42e**, triphenyltelluronium chalcogenolates **50b-c** exist as dimers with virtually planar cyclic fragments Ar_8Te_4 and $\text{Ar}_8\text{Te}_2\text{Se}_2$.¹¹³ The average lengths of four secondary interactions $\text{Te}\cdots\text{Te}$ are 3.451 (**50c**, $\text{X} = \text{TeC}_6\text{H}_4\text{Me-4}$) and 3.441 Å (**50c**, $\text{X} = \text{TeC}_6\text{H}_4\text{OMe-4}$), *i.e.*, much smaller than the sum of the van der Waals radii of the Te atoms (4.40 Å)¹³³. The lengths of the $\text{Te}\cdots\text{Se}$ bonds in selenolate **50b** (3.269 Å) are about 0.2 Å smaller than the $\text{Te}\cdots\text{Te}$ bonds and 0.7 Å smaller than the sum of the van der Waals radii of Te and Se (3.96 Å)¹³³. Thus, the CN of the Te atom in the above tellurolates and selenolates is equal to 5. At the same time, it is suggested¹¹² that triphenyltel-

luronium 4-chlorophenylthiolate **50a** exists in a solid state as a tetramer each tellurium atom in which forms two secondary bonds with sulfur atoms (the CN of Te is 5); the $\text{Te}\cdots\text{S}$ distances lie in the range 3.02–3.64 Å.

The structure of dimethyl(trifluoromethyl)telluronium 2,4,6-trinitrophenolate (**97**) differs from those of **42c-e** and **50a-c**.⁹⁸ The coordination polyhedron of the tellurium atom in **97** (with consideration of the UEP) represents a distorted pentagonal bipyramid. The apical positions are occupied by the trifluoromethyl group (the lengths of the $\text{Te}-\text{C}$ bonds reach 2.192 Å) and the phenol oxygen atom (the length of the $\text{Te}-\text{O}$ bonds is 2.496 Å), whereas two methyl groups (the average length of the $\text{Te}-\text{C}$ bonds is 2.113 Å), two oxygen atoms of the nitro groups of two neighbouring molecules (the lengths of secondary $\text{Te}\cdots\text{O}$ bonds are equal to 3.134 and 3.138 Å) and the UEP of the tellurium atom occupy the equatorial positions. Thus, the CN of the Te atom in phenolate **97** is 6.

With consideration of secondary interactions, salts **98a**, **99a**, **100a,b** containing the chalcogenocyanate anions XCN ($\text{X} = \text{O}, \text{S}, \text{Se}$) are characterised by the octahedral environment of the bonds around the Te atom (CN = 6).¹⁰⁴ As the XCN anions are ambident, both $\text{Te}\cdots\text{N}$ and $\text{Te}\cdots\text{X}$ interactions take place in the crystals of these compounds. In salts **99a** and **100a,b** containing soft S and Se atoms,⁹³ two bonds of these atoms with soft Te atom take place along with one secondary $\text{Te}\cdots\text{N}$ bond. Only one secondary $\text{Te}\cdots\text{O}$ bond (3.10 Å) and two secondary $\text{Te}\cdots\text{N}$ bonds (2.98 and 3.10 Å) are found in trimethyltelluronium cyanate (**98a**) containing a harder oxygen atom. Triphenyltelluronium cyanate (**98b**)¹⁰⁵ and thiocyanate (**99b**)¹⁰ were found to contain secondary $\text{Te}\cdots\text{X}$ bonds ($\text{X} = \text{O}, \text{S}$) and $\text{Te}\cdots\text{N}$ bonds of approximately the same lengths as in the corresponding trimethyltelluronium salts.¹⁰⁴ Cyanate **98b** contains discrete tetramers two Te atoms in which have distorted square-pyramidal environment (CN = 5), while the other two have distorted octahedral environment (CN = 6). Triphenyltelluronium thiocyanate **99b** is made up of dimers containing Te atoms with CN = 5, and tetramers the Te atoms in which are penta- and hexacoordinate.

In trimethyltelluronium (**101a**)¹⁰⁴ and triphenyltelluronium (**101b**)¹⁰⁴ azides, the tellurium atoms are linked to terminal nitrogen atoms of nearly linear azido groups, resulting in a distorted octahedral environment of the Te atom (CN = 6). The average length of secondary $\text{Te}\cdots\text{N}$ bonds is 3.0 Å, *i.e.*, 0.65 Å less than the sum of the van der Waals radii of Te and N. Such a coordination of tellurium atoms was observed in triorganyltelluronium dicyanoargentates **102a,b**.¹⁰⁴ The Te atoms form two shorter secondary $\text{Te}\cdots\text{N}$ bonds (3.15 and 3.27 Å in the trimethyltelluronium salt **102a** and 3.16 and 3.35 Å in its phenyl analogue **102b**) and one more extended $\text{Te}\cdots\text{N}$ bond (3.41, 3.50 Å, respectively). The latter are only 0.15–0.25 Å shorter than the sum of the van der Waals radii of Te and N.

Telluronium salts containing 1,1-dithio ligands $\text{SC}(\text{S})\text{X}$ ($\text{X} = \text{NR}_2$, OR) (**52a,b**, **54a**) are represented by two major structures. Triphenyltelluronium dithiocarbamate (**54a**)¹¹⁹ and triphenyltelluronium alkyl xanthate (**52a**)¹¹⁵ are dimeric in the crystalline state due to the formation of secondary $\text{Te}\cdots\text{S}$ bonds. This results in the distorted octahedral (with consideration of UEP) environment of the Te atom (CN = 5). The lengths of the $\text{Te}\cdots\text{S}$ bonds in salts **52a** and **54a** vary from 3.10 to 3.27 Å. In contrast to these salts, triphenyltelluronium isobutyl xanthate (**52b**) is monomeric.¹¹⁵ The xanthate fragment is chelated by only one tellurium atom. The length of one of the two secondary $\text{Te}\cdots\text{S}$ bonds (3.535 Å) exceeds that of the other bond (3.123 Å) by nearly 0.4 Å. The difference in the structures of methyl and isobutyl xanthates seems to be due to the steric hindrance created by the isobutyl groups in the dimer formation.

Salts **55a**, **56a** and **59a-c** with various phosphorus-containing ligands are always monomeric. The tellurium atom in compounds **55a** and **56a** containing dithiophosphoric substituents [$\text{SP}(\text{S})(\text{OEt})_2$ ¹¹² and $\text{SP}(\text{S})\text{Ph}_2$ ¹²¹], is pentacoordinate and has a distorted square-pyramidal environment. In addition to three

primary Te—C bonds, each tellurium atom forms two secondary Te...S bonds. It is noteworthy that the Te...S bonds (3.15 and 3.29 Å) in salt **55a** are somewhat shorter than those in salt **56a** (3.33 and 3.66 Å).

Six-membered chelate rings $\text{TeX}_2\text{P}_2\text{N}$ ($\text{X} = \text{O}, ^{123} \text{S}^{121}$) and $\text{TeOSP}_2\text{N}^{123}$ are formed in triphenyltelluronium dichalcogeno-imidodiphosphinates **59a–c**.¹²³ The distorted square-pyramidal geometry of the bonds at the tellurium atom ($\text{CN} = 5$) is determined by secondary bonds $\text{Te}\cdots\text{O}$ (2.65–2.93 Å) and $\text{Te}\cdots\text{S}$ (3.26–3.45 Å).

Hence, the structural diversity of telluronium salts suggests the existence of different types of interactions of tellurium atoms in crystalline states.

VI. Conclusion

The reviewed data suggest that the chemistry of telluronium salts has advanced considerably in the past two decades. This is manifested in the development of novel efficient methods for the synthesis of telluronium derivatives and preparation of hitherto unknown types of telluronium salts. Considerable progress has been achieved in the application of telluronium salts in preparative organic chemistry. Telluronium ylides prepared by deprotonation of telluronium salts and used *in situ* react with various carbonyl compounds and compounds with multiple bonds to give cyclopropanes, aziridines, oxiranes, alkenes, benzylic and propargylic alcohols and β -hydroxy nitriles. The majority of these reactions proceed in good yields and with high stereoselectivity. Of special interest is the synthesis of alkenes containing electron-withdrawing substituents (CO_2R , COR, CN) at the double bond by the reaction of dialkyl tellurides with the corresponding organobromine derivatives and aldehydes. Such reactions have no analogies in the chemistry of sulfonium and selenonium salts. X-ray diffraction analysis of more than 60 telluronium salts revealed that the coordination number of the tellurium atom varies from 3 to 6 due to its ability to form secondary bonds with various heteroatoms.

Further progress in the chemistry of telluronium salts seems to be associated with the development in three major areas, *viz.*, (i) development of novel preparative methods for telluronium salts from organoelement compounds, in the first place, from organomercury, organosilicon and organotin derivatives and highly electrophilic organotellurium intermediates; (ii) search for novel reactions aimed at the synthesis of various organic derivatives based on telluronium salts. This task is attainable due to the ease of cleavage of $\text{C}—\text{Te}^+$ bonds. Special attention should be given to further improvement of one-pot processes where catalytic amounts of telluronium salts or their precursors (diorganyl tellurides) can be used. And finally, (iii) the continuation of X-ray diffraction studies of telluronium salts containing various types of intramolecular coordination bonds ($\text{O} \rightarrow \text{Te}$, $\text{N} \rightarrow \text{Te}$) may result in the discovery of novel structural types of these compounds.

This review has been written with the financial support of the programme 'Leading Scientific Schools of the RF' (Grant NSh-945.2003.3).

Chiral hydroxy phosphonates: synthesis, configuration and biological properties

O I Kolodiaznyy

Contents

I. Introduction	227
II. Asymmetric synthesis of hydroxy phosphonates	227
III. Determination of the absolute configuration of hydroxy phosphonates	246
IV. Biological activities of hydroxy phosphonates	247
V. Conclusion	249

Abstract. Published data on the synthesis, absolute configurations and biological properties of chiral hydroxy phosphonates are generalised and described systematically. Examples of asymmetric synthesis of hydroxy phosphonates by the phospho-aldol reaction, reduction of keto phosphonates, chemo-enzymatic approach, and so on are discussed. Methods for determination of the optical purity and absolute configuration of hydroxy phosphonates using modification by chiral reagents, NMR, circular dichroism, GLC and HPLC on columns with chiral sorbents are considered. The significance of hydroxy phosphonates as promising compounds for the development of new drugs and bioregulators is demonstrated. The bibliography includes 263 references.

I. Introduction

Hydroxy phosphonic acids form an important class of compounds, some of which are encountered in nature. Organophosphorus compounds of natural origin with a C–P bond were unknown before 1959,^{1–3} when Horiguchi and Kandatsu³ first discovered them in living organisms. Soon after this, substantial amounts of amino and hydroxy phosphonates have been isolated from natural sources. The best known natural hydroxy phosphonic acids include 1-hydroxy-2-aminoethylphosphonic acid (HO-AEP), 3-(*N*-acetyl-*N*-hydroxyamino)-2-hydroxypropylphosphonic acid (FR-33289), 1,5-dihydroxy-2-oxopyrrolidin-3-ylphosphonic acid (SF-2312), phosphonothrixin, *etc.*^{1,2} Many of these compounds attract attention due to their interesting biological properties as antibacterial, antiviral and antitumour agents, antibiotics, enzyme inhibitors, amino acid mimetics and pesticides.^{4–8}

Received 25 February 2005

Uspekhi Khimii 75 (3) 254–282 (2006); translated by Z P Bobkova

The physiological activity of hydroxy phosphonates is due, on the one hand, to their structural similarity to biologically important phosphates with the P–O bond being replaced by P–C and, on the other hand, to the structural analogy between α -hydroxy-alkylphosphonic and α -hydroxy carboxylic acids. The replacement of the carboxy group in hydroxy carboxylic acids by a phosphonate group results in hydroxy phosphonic acids exhibiting an inhibitory effect with respect to enzymes and receptors to which natural hydroxy carboxylic acids usually bind. The biological activities of phosphonic acids are largely determined by the absolute configuration of the stereogenic α -carbon atom. For example, of the four possible diastereomers of the antibiotic alaphospholine, the *S,R*-diastereomer exhibits the highest activity with respect to the pathogenic microorganisms.⁹

At present, hydroxy phosphonates with various structures containing one or several hydroxy groups in the organic radical have been synthesised and studied in detail; these include derivatives of carbohydrates, purine bases, nucleotides, and so on. The most studied compounds are α - and β -hydroxy phosphonates, β -amino α -hydroxy phosphonates, polyhydroxy phosphonates and fluorine-containing hydroxy phosphonates, which are isosteric analogues of natural compounds exhibiting high biological activity.

The vast factual material accumulated to date on the synthesis, properties and practical application of hydroxy phosphonates still requires systematisation, some contradictory data calling for critical consideration. This stimulated us to write a review paper in which we generalise for the first time the published data on the methods of preparation and properties of chiral hydroxy phosphonates, as well as their applications as biologically active substances or pharmaceutical agents. Hopefully, information surveyed in this review will be useful for chemists engaged in various aspects of organic chemistry and stereochemistry.

II. Asymmetric synthesis of hydroxy phosphonates

The vigorous development of the chemistry and biology of hydroxy phosphonates in the last decade is due to the develop-

ment of highly efficient methods for their preparation.^{10, 11} Chiral hydroxy phosphonic acids can be prepared by a number of methods including kinetic resolution of racemic mixtures or enzymatic and asymmetric synthesis. The most important approach to the synthesis of hydroxy phosphonates is phosphorylation of carbonyl compounds leading to formation of a C–P bond (phosphorylation). Two methods for asymmetric phosphorylation of carbonyl compounds are known: phospho-aldol addition and the reaction of phosphonate carbanions with aldehydes or ketones. The phospho-aldol condensation (the Abramov reaction) occupies a leading position in this series, being a highly convenient method for the synthesis of chiral α -hydroxyalkylphosphonates.^{12, 13}

In recent years, the chemo-enzymatic method for the synthesis of optically active hydroxy phosphonates has been used more and more often.¹⁴ Other routes to these compounds are the enantioselective reduction of keto phosphonates,¹⁵ enantioselective hydroxylation of phosphonate-stabilised carbanions¹⁶ and [2,3]-sigmatropic Wittig rearrangements.¹⁷

1. Phospho-aldol condensation (the Abramov reaction)

Two types of phospho-aldol condensation are known, namely, the reaction of dialkyl phosphites with carbonyl reagents in the presence of a basic catalyst, which shifts the tautomeric equilibrium of dialkyl phosphites towards the P(III)-form, and the reaction of phosphorous triesters with carbonyl compounds in the presence of a proton-donor reagent (phenol, carboxylic acid, tertiary amine hydrochloride, aniline, and so on) or a Lewis acid. Phosphorous triesters react with carbonyl compounds in two steps: first, the reversible addition of a carbonyl reagent to the trivalent phosphorus atom gives a carbon–phosphorus bond and then the ester group at the phosphorus atom is hydrolysed to give α -hydroxy phosphonate.^{12, 18–20}

B is base.

In the presence of tertiary amines and some other bases, hydroxyalkylphosphonates decompose into the initial dialkyl phosphite and carbonyl components. This transformation is called the retro-Abramov reaction. Nuclear magnetic resonance^{21, 22} and kinetic studies^{19, 20} have shown that the retro-Abramov reaction has a substantial influence on the stereochemistry of the resulting hydroxy phosphonates. For example, the stereochemistry of the sodium methoxide-catalysed decomposition of the diastereomers of 3-hydroxy-2-methoxy-3,4-dimethyl-1,2-oxaphospholan-2-one (**1**) obtained by cyclisation of phosphite **2**, has been studied.²³ Under the action of sodium methoxide in methanol, diastereomerically pure hydroxy phosphonates **1** underwent racemisation. Presumably, the reaction mechanism includes cleavage of the P–C bond (retro-Abramov reaction) and epimerisation of the chiral P-anion **3**, which bring about the formation of a mixture of diastereomers **4** upon the subsequent

cyclisation. One more possible reason for racemisation is cleavage of the endocyclic P–O bond in compound **1**.

Chiral phosphonites and phosphinites, having a stereogenic phosphorus atom, and phosphites that contain residues of optically active alcohols, amino alcohols or amines at the phosphorus atom can serve as asymmetric inductors in the Abramov reaction. Phosphites based on chiral 1,2-diaminocyclohexane, ephedrine, binol, menthol, *etc.*, are used most often. The addition of chiral dialkyl phosphites and their anions to achiral aldehydes gives rise to α -hydroxy phosphonates with a moderate stereoselectivity.^{24–40} For example, the reaction of bicyclic chiral phosphorous diamides **5** with aldehydes yields α -hydroxyalkylphosphonamides **6** in good yields. The presence of bulky substituents in phosphoramidite and aldehyde molecules increases the reaction stereoselectivity.^{24–29}

LDA = LiNPr₂.

R ¹	R ²	dr	Ref.
2-MeC ₆ H ₄ CH ₂	PhCH = CH	1 : 1	24
Bn	CH ₂ = CH	1.4 : 1	24
1-NaphCH ₂	PhCH = CH	1.5 : 1	24
(S)-PhMeCH	Ph	1.8 : 1	29
Bn	PhCH = CH	4.0 : 1	24
Bu ^t CH ₂	PhCH = CH	7.9 : 1	24
Bu ^t CH ₂	Ph	25 : 1	24

dr is the diastereomer ratio.

The nature of the chiral alkoxy groups at the phosphorus atom has a pronounced effect on the stereoselectivity of the phospho-aldol condensation. For instance, the reaction of tris(glucosyl) phosphite **7** with benzaldehyde in the presence of chlorotrimethylsilane proceeds with good stereoselectivity to give hydroxy phosphonate **8** mainly as a single isomer with a diastereomeric excess (*de*) of 84%. Meanwhile, trimethyl and tribornyl phosphites react with aldehydes with low stereoselectivity, giving rise to mixtures of hydroxy phosphonate diastereomers **8**.^{30, 31} The reaction of dimethyl phosphite (**9**) with aromatic and aliphatic aldehydes in the presence of 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU) as the catalyst has a moderate stereoselectivity. The diastereomers **8** were separated and, after hydrolysis of ester groups, acids **10** were formed with enantiomeric purity (*ee*) 96%–98%.^{30–33}

R ¹	R ²	de (%)	Ref.
GF	Ph	84	31
Mnt	Pr ⁱ	60	31
Mnt	4-Me ₂ NC ₆ H ₄	40	31
Mnt	4-MeOC ₆ H ₄	35	30
Mnt	Ph	33	31
Brn	Ph	33	30

GF is (–)-1,2,5,6-di-*O*-isopropylidene-D-glucofuranos-3-yl, Mnt is (1*S*,2*R*,5*S*)-menthyl, Brn is *endo*-bornyl.

Gordon and Evans have established³⁴ that the reaction of 2-methoxy-1,3,2-oxazaphosphinane **11** with benzaldehyde in the presence of boron trifluoride etherate affords 2-(α -hydroxybenzyl)-2-oxo-1,3,2-oxazaphosphinane diastereomers **12** in 1 : 2 – 1 : 4 ratio. It was suggested that the reaction proceeds *via* a highly reactive complex of boron trifluoride etherate with benzaldehyde, which reacts with the phosphite to give complex **13**. The reaction stereoselectivity is determined first of all by the step affording complex **13**, which is converted into hydroxyalkylphosphonate **12** after treatment with lithium iodide and hydrolysis.

The phospho-aldol reaction of chiral silyl phosphites **14** with benzaldehyde at room temperature gives silyloxy phosphonates **15** with relatively low stereoselectivity.³⁵

The addition of chiral diazaphospholidines, which are ephedrine derivatives, to carbonyl compounds also proceeds with moderate stereoselectivity.^{36–39} An exception is the modified Mukayama reaction of silylated λ^3 -diazaphospholidines **16** with aldehydes, which furnishes only one diastereomer, the adduct **17** (*ee* > 98%).³⁶ Compound **17** is easily converted into α -hydroxy phosphonate, which possesses a pharmacological activity.^{37,38}

The stereoselectivity of condensation of achiral phosphites with chiral aldehydes is low. For example, the reaction of dialkyl phosphites with 2,3-*O*-protected D-glyceraldehyde **18** in the presence of catalysts such as triethylamine or lithium or cesium fluoride yields mixtures of hydroxy phosphonate diastereomers **19** and **20** in 45 : 55 – 35 : 65 ratio. The use of lithium diethyl phosphite somewhat increases the reaction stereoselectivity.⁴¹ Enantiomerically pure isopropylidene- and cyclohexylidene-protected 1,2,3-trihydroxypropylphosphonates (1*R*,2*R*)-**19** and (1*S*,2*R*)-**20** can be isolated from the diastereomer mixture by column chromatography.^{42–44}

R¹ = Me₂, (CH₂)₅; R² = Et, Prⁱ; Cat = DBU, Et₃N, CsF, LDA.

Phosphonylation of chiral α -amino aldehydes is the most convenient and versatile method for the preparation of optically pure stereomeric α -hydroxy- β -aminoalkylphosphonic acids.^{45–55} The reaction stereochemistry depends crucially on the number of substituents at the nitrogen atom. For example, the addition of dialkyl phosphites to *N*-*tert*-butoxycarbonyl-(*S*)-phenylglycinal (**21**, R¹ = Ph) yields (1*S*,2*S*)-2-amino 1-hydroxy phosphonate **22**,⁴⁸ the phosphonate analogue of the side chain of a natural antitumour agent, paclitaxel. The phosphonylation of *N*-benzoyl-(*S*)-phenylglycinal occurs in a similar way. Meanwhile, the reaction of dialkyl phosphites with *N,N*-dibenzylphenylglycinal (**23**) gives mainly (1*R*,2*S*)-diastereomer **24**.⁴⁹

Boc = Bu^tOC(O).

R = Me, Et.

The different stereochemistry of the reaction is due to the fact that in the molecule of (*S*)-*N*-Boc-derivative **21**, the intramolecular hydrogen bond stabilises conformation A; therefore, the *si*-stereofacial attack of the dialkyl phosphite on the carbonyl group gives rise to the *S*-adduct. In the case of (*S*)-*N,N*-dibenzyl derivative **23**, no intramolecular hydrogen bond is formed; therefore, phosphite attacks preferably the *re*-side of the carbonyl group (model B).

M = Ti, Sn.

The stereoselectivity of the reaction of phosphites with aldehydes depends on not only the structure of the initial reactants but also the catalyst.^{47–52} For example, titanium and tin tetrachlorides efficiently catalyse the reaction of silyl phosphites with chiral (*S*)-aldehydes **21** and **23** and promote the formation of (1*S*,2*S*)-diastereomers. In this case, the *si*-stereofacial attack is governed by the formation of chelate **C**.^{47, 50}

The reaction of chiral aldehyde **25a** with dimethyl and dibornyl phosphite followed by hydrolysis affords optically pure 2-amino-1-hydroxyalkylphosphonic acid (1*S*,2*S*)-**26**, whereas the addition of the same aldehyde to tris(trimethylsilyl) phosphite results in (1*R*,2*S*)-diastereomer **27**, which was isolated in the crystalline state.⁵⁵

R = Brn, Mnt.

The condensation of dialkyl phosphites with the Garner aldehyde **28** in the presence of triethylamine results in the formation of (1*R*,2*S*)-diastereomers of hydroxy phosphonates **29** (de 80%), which were purified by column chromatography. The reaction with titanium(IV) isopropoxide as the catalyst gives a mixture of (1*R*,2*S*)- and (1*S*,2*S*)-diastereomers **29** in ~1 : 1 ratio; pure (1*S*,2*S*)-diastereomer **29** was isolated by column chromatography on silica gel.⁵³

R = Me, Et; Cat = Et₃N, Ti(OPrⁱ)₄.

Patel *et al.*⁸ used the reaction of dialkyl phosphites with chiral aldehyde **30** for the preparation of enantiomerically pure phosphonate analogues of tripeptides, α -hydroxy phosphonates **31**, which are highly efficient renin inhibitors.

R = Me, Et; DCC = cyclo-C₆H₁₁–N=C=N–C₆H₁₁–cyclo.

Shibuya and co-workers⁵⁴ developed stereocontrolled methods for the synthesis of the hydroxy phosphonate analogue of tyrosine **32** based on the reaction of chiral pentane-2,4-diol acetal of protected 4-formyl-L-phenylalanine **33** with triethyl phosphite in the presence of titanium tetrachloride and by the reaction of diethyl phosphite with methyl ester of *N*-benzyloxy-carbonyl-4-formyl-L-phenylalanine (**34**) in the presence of a chiral heterobimetallic catalyst ALB.

The addition of dimethyl phosphite to 3-hydroxybutanal (**35**) results in a diastereomer mixture of 1,3-dihydroxybutylphosphonates **36** in 3 : 7 ratio. The absolute configurations of the C(1) and C(3) atoms in these diols were determined by ¹³C NMR spectroscopy of their *O*-benzylidene derivatives. The intramolecular cyclisation of phosphonates **36** in the presence of triethylamine gives a mixture of 3-hydroxy-2-methoxy-5-methyl-1,2-oxaphospholan-2-one diastereomers (**37**).⁵⁶

Chiral epoxy aldehydes **38** obtained by asymmetric Sharpless epoxidation of 2-trimethylsilylalk-2-enols reacted with dialkyl phosphites, yielding γ -hydroxy- β -oxo phosphonates **39** with *ee* 96%–97%.⁵⁷

The stereoselective hydrophosphonylation of α -benzyloxy aldehydes catalysed by titanium tetrachloride is used in the synthesis of the phosphonic analogues of amino hydroxy acids. Shibuya and co-workers^{65,66} used the phospho-aldol reaction to prepare β -benzyloxy α -hydroxy phosphonates **45**; their reactions with hydrazoic acid followed by reduction and protection gave substituted α -amino β -hydroxy phosphonates **46**.

$R = \text{Pr}^i, \text{Ph}$;
DEAD = $\text{EtO}_2\text{CN}=\text{NCO}_2\text{Et}$.

The reaction of triethyl phosphite with homochiral (2*S*,4*S*)-pentanediol acetals **47** in the presence of titanium tetrachloride results in diastereoselective formation of alcohols **48** (*dr* = 93 : 7). The Swern oxidation followed by treatment with *p*-toluenesulfonic acid yields hydroxy phosphonates (*ee* 95%).⁶⁷ Yamamoto and co-workers⁶⁸ used this strategy to prepare chiral (2*R*)-1-amino-1-deoxy-1-phosphinyglycerols.

R = Prⁱ, Buⁿ, Bu^t; Ts = 4-MeC₆H₄SO₂.

The Abramov reaction was used to prepare phosphorus-containing D-ribofuranose (compounds **49**) and D-glucopyranose (**50a**) analogues and 5-deoxy-5-C-phosphinyl-D-xylose (**50b**). These compounds were converted into pseudo-carbohydrate nucleoside derivatives that may possess biological activity.^{69–71}

The Abramov reaction is also utilised to prepare stereochemically pure δ -phostones **51** and **52**⁷² the structures of which were proved by X-ray diffraction analysis.⁷³

Polyhydroxyalkylphosphonates **53a,b** and **54** were synthesised⁷⁴ by the phospho-alcohol reaction of dimethyl phosphite with 2,4-*O*-benzylidene derivatives of D-erythrose and D-threose, while the addition of dimethyl phosphite to 2,3:4,5-di-*O*-isopropylidene-D-xylose afforded polyhydroxyalkylphosphonate **55** as a diastereomer mixture.⁷⁵

Wróblewski^{76–79} synthesised analogues of D-tetralose, D-ribose and some other carbohydrates containing phosphorus in the anomeric position. The addition of ethyl trimethylsilyl phosphite to 1,3-di-*O*-benzyl-4-*O*-(*tert*-butyldimethylsilyl)-D-tetralose results in the formation of hydroxy phosphonate diastereomers. The acid-catalysed cyclisation of (1*S*)- and (1*R*)-1-*C*-(dimethoxyphosphoryl)-D-erythritols produces methyl D-arabino- and D-ribofuranoside analogues containing phosphorus in the anomeric position.^{77–79}

R = Me, Ph.

A mixture of (1*S*)- and (1*R*)-2,4-*O*-benzylidene-1-(dimethoxyphosphoryl)-D-threitol diastereomers in 1:9 ratio was obtained by the addition of dimethyl phosphite to 2,4-*O*-benzylidene-D-threose in the presence of triethylamine.⁷⁹

Similarly, (1*S*)- and (1*R*)-diastereomeric 2,4-*O*-benzylidene-1-(dimethoxyphosphoryl)-D-erythritols were prepared in 1:1 ratio starting from 2,4-*O*-benzylidene-D-erythrose.

In recent years, asymmetric catalysis of the phospho-alcohol condensation gained strong impetus. Scheme 1 shows the tentative reaction mechanism involving an asymmetric catalyst.⁸⁰

Scheme 1

R¹ = Alk, R² = Alk, Ar, etc.

Several types of asymmetric catalysts have been proposed for the stereochemical control of the phospho-alcohol reaction. Shibasaki and co-workers⁸¹ reported that heterobimetallic complexes LLB and ALB containing chiral binaphthol ligands efficiently catalyse asymmetric hydrophosphonylation of aromatic aldehydes. The optical purity (*ee*) of the resulting α -hydroxy phosphonates reaches 95%. The reaction proceeds *via* an intermediate complex of the catalyst with the phosphite and aldehyde (for example, complex **56** in the case of LLB), the nucleophilic attack by the trivalent phosphorus on the aldehyde carbonyl carbon atom taking place within this complex.

R	Cat = LLB, –78 °C		Cat = ALB, –40 °C	
	yield (%)	ee (%)	yield (%)	ee (%)
Ph	88	79	95	90
4-MeC ₆ H ₄	93	78	82	86

4-MeOC ₆ H ₄	87	93	88	78
4-NO ₂ C ₆ H ₄	85	36	85	71
4-ClC ₆ H ₄	80	63	80	83
PhCH=CH	90	84	85	82
PhCH=C(Me)	94	92	47	56
n-C ₅ H ₁₁	88	61	95	16

Shibuya and co-workers,^{82,83} who carried out the same reaction, found that the enantioselectivity of hydrophosphonylation of arylaldehydes in the presence of LLB depends on the electronic nature of the substituent in the *para*-position of the aromatic ring.

Spilling and Rath²⁸ reported that the addition of dialkyl phosphites to cinnamaldehyde catalysed by (*R*)-LLB affords (*S*)-hydroxy phosphonates in good yields but the enantioselectivity (*ee*) is only ~30%. Subsequently, for increasing the reaction stereoselectivity, it has been proposed⁸⁰ to add the aldehyde to the reaction mixture very slowly, over a period of several hours.

The complexes obtained from titanium(IV) isopropoxide and some chiral diols efficiently catalyse the addition of diethyl phosphite to aromatic aldehydes. For example, the complex obtained from titanium(IV) isopropoxide and diisopropyl L-tartrate ensures the formation of (*R*)-hydroxy phosphonates with *ee* 36%–53%. The reaction enantioselectivity depends on the diol structure, the electronic nature of the substituent at the carbonyl group and the donor properties of the solvent.^{83,84}

The addition of methyl hypophosphite to achiral aldehydes in the presence of the ALB catalyst proceeds with a moderate diastereoselectivity, yielding diastereomer mixtures of (*S*)- α -hydroxy-H-phosphinates **57**, which cannot be isolated in a pure state. Compounds **57** react with methyl acrylate and benzaldehyde to give hydroxy phosphinates **58** and an (*S,S*)- and (*S,R*)-diastereomer mixture of α,α' -dihydroxy phosphinates **59**, from which pure (*S,S*)-stereoisomer was isolated after acylation.⁸⁵

The reaction of hypophosphorous acid with aldehydes initiated by microwave radiation giving rise to bis(α -hydroxyalkyl)-phosphinic acids has been reported.⁸⁶

The catalytic hydrophosphinylation of chiral α -amino aldehydes **25** in the presence of ALB results in β -amino α -hydroxy phosphinic acid derivatives with moderate stereoselectivity.^{87–89}

The formation of a complex diastereomer mixture in the reaction is due to the presence of three asymmetric centres in the product molecule, namely, the α - and β -carbon atoms and the phosphorus atom. Nevertheless, diastereomers (*1S,2S*)-**40** and (*1R,2S*)-**41** can be separated by column chromatography.^{54,87,88}

Chiral aluminium salcyan complexes catalyse the enantioselective route of the phospho-aldol reactions.⁹⁰ For example, the use of the chiral catalyst (*R,R*)-**60** in the reaction of dimethyl phosphite with substituted benzaldehydes results in *S*-isomers of the adducts with *ee* ~50%.

R = H, Bu^t.

R	H	Me	OMe	NO ₂	NMe ₂
ee (%)	52	57	47	18	22

Optically active quinine catalyses the reaction of *ortho*-nitro-benzaldehyde with dialkyl phosphites giving *S*-enantiomers of hydroxy phosphonates with *ee* 80%.^{91,92}

Multiple asymmetric induction, *i.e.*, a reaction proceeding under the stereochemical control of two or more chiral inductors, is an efficient method for increasing the stereoselectivity of the phospho-aldol condensation.^{93–98} Thus the reaction of the optically active di-(*1R,2S,5R*)-menthyl phosphite with 2,3-*O*-isopropylidene-D-glyceraldehyde (both reactants are chiral inductors) occurs with a higher stereoselectivity than the reaction involving one chiral inductor and gives a diastereomeric mixture of α -hydroxy phosphonates **61** and **62** with predominance of the *anti*-stereoisomer (*de* 60%).⁴³ The introduction of the third asymmetric inductor, the chiral catalyst ALB, increases the stereoselectivity to 90%.⁴² The ratio of isomers formed in the reaction depends on the natures of the solvent and the base and on the temperature. The resulting diastereomers (*R,R*)-**61** and (*S,R*)-**62** were separated by crystallisation and column chromatography on silica gel. The (*1S,2R*)-configuration of the adduct was confirmed by X-ray diffraction analysis.

The reaction of dimethyl phosphite with *galacto*-hexodialdose proceeds with high stereoselectivity, owing to double asymmetric induction, resulting in the formation of C(6)-phosphorylated galactose derivative **63** with *de* ~ 100%. The adducts was isolated as optically pure crystalline compound.⁹⁸

2. The reduction of keto phosphonates

The enantioselective reduction of keto phosphonates is a very convenient method for the synthesis of chiral hydroxy phosphonates. Keto phosphonates with optically active substituents, chiral reducing agents or catalysts can serve as asymmetric inductors in this reaction.

The reduction of diethyl α -keto phosphonates **64** with borane in the presence of chiral β -butyloxazaborolidines as catalysts yields diethyl (*S*)- and (*R*)-1-hydroxyalkylphosphonates **65** in good yields and satisfactory enantiomeric excesses (*ee* 53%–83%).⁹⁹

R = Et, Buⁿ, Buⁱ; Cat — β -butyloxazaborolidine.

The reduction of keto phosphonates **66** with the borane–ammonia complex affords hydroxyphosphonate diastereomers **67** and **68** in 25 : 1 ratio.¹⁰⁰

R¹ = Me, Et, Prⁿ, Buⁿ, n-C₅H₁₁; R² = Et, Prⁱ.

The reaction of γ -*N*-benzylamino β -keto phosphonates **69** with zinc borohydride gives *anti*- γ -amino β -hydroxy phosphonates **70** with good diastereoselectivity.¹⁰¹

R = Prⁱ, Ph.

This strategy has been used to prepare 1,5-dihydroxy-2-oxopyrrolidine-3-phosphonic acid (SF-2312), which is active against Gram-positive and Gram-negative bacteria.¹⁰²

Sodium borohydride reduces sodium acylphosphonates and bis(acylphosphonates) to the corresponding hydroxyalkylphosphonates and dihydroxyalkylenebis(phosphonates).¹⁰³

The reduction of dimethyl keto phosphonates **71** with sodium borohydride in THF has a low stereoselectivity, (*R*)-1-hydroxybenzylphosphonates **72** were obtained with *de* ~ 30%–35%.¹⁰⁴ The stereoselectivity can be increased through the formation of the chiral complex of sodium borohydride with natural D-tartaric acid. The enantioselective reduction of diethyl aroylphosphonates **73** with chiral NaBH₄–(*R,R*)-TA complex affords diethyl (*S*)-1-hydroxybenzylphosphonates **74** with *ee* ~ 60%, whereas the reduction of dimethyl aroylphosphonates **71** yields (*S*)-dimethyl 1-hydroxybenzylphosphonates **72** with the diastereomeric excess (*de*) 80%–93%.¹⁰⁵

R¹ = (1*R*,2*S*,5*R*)-Mnt (**71**, **72**), Et (**73**, **74**);

R² = Ph, C₆H₄F, C₆H₄OMe; TA is tartaric acid.

Higher stereoselectivity observed in the reduction of dimethyl aroylphosphonates is due to the double asymmetric induction effect, because in this case the inductions by the menthyl residues and tartaric acid are combined.

It has been proposed^{15, 106, 107} to prepare chiral α -, β - and γ -hydroxy phosphonates by the reduction of aroylphosphonates with catecholborane or a borane–dimethyl sulfide complex in the presence of 1,3,2-oxazaborolidine as the catalyst. The enantioselective reduction of diisopropyl α -keto phosphonates **75** with

Ar = 2-MeOC₆H₄, 2-MeC₆H₄, 2-ClC₆H₄, 3-ClC₆H₄, 4-ClC₆H₄, 2-FC₆H₄, 2-BrC₆H₄.

borane or catecholborane controlled by (*S*)-oxazaborolidines leads to (*S*)-1-hydroxybenzylphosphonates **76** with 53%–83% enantiomeric excess.

Conversely, the reduction of β - (**77**) and γ -keto phosphonates **78** under the same conditions affords β - and γ -hydroxyalkylphosphonates (**79** and **80**) with *R* absolute configuration.

Treatment of α -keto phosphonates **75** with (–)-chlorodiisopinocampheylborane affords diisopropyl (*S*)-1-hydroxybenzylphosphonates **76** with higher enantiomeric excesses than the reaction with catecholborane in the presence of oxazaborolidine.¹⁵

The reduction of α -keto β -phthalimido phosphonates with catecholborane in the presence of oxazaborolidine as the catalyst followed by deprotection of the amino group results in β -amino α -hydroxy phosphonates **81** with a high diastereoselectivity and in good yields.¹⁰⁸ The same procedure was used to convert γ -amino β -keto phosphonates into 3-amino 2-hydroxy phosphonates **82**, which are phosphate mimetics stable against hydrolysis.¹⁰⁹

R = Me, Prⁱ, Buⁱ, Bn, 4-BnOC₆H₄CH₂.

The diastereoselectivity of the reduction of γ -*N,N*-dibenzyl-amino β -keto phosphonates **83** does not depend on steric factors, which are determined by the size of the substituent at C(3). The configurations of hydroxy phosphonates **84** were confirmed by X-ray diffraction analysis and NMR spectroscopy.¹¹⁰

R	Reducing agent	Yield (%)	syn : anti
Pr ⁱ	AlHBu ₂ ⁱ (DIBAL-H)	50	82 : 18
Pr ⁱ	NaBH ₄	44	85 : 15

Me	catecholborane	85	> 98 : 2
Bn	catecholborane	89	> 98 : 2
Ph	catecholborane	82	90 : 10

The hydrogenation of (*R*)- α -acetamido β -keto phosphonates **85** in the presence of the chiral ruthenium binaphthyl complex gives hydroxy phosphonates (1*R*,2*R*)-**86** with good enantio- and diastereoselectivity.¹¹¹

binap is 2,2'-bis(diphenylphosphino)-1,1'-binaphthyl.

Tomioka *et al.*¹¹² carried out photoreduction of dialkyl keto phosphonates, which results in α -hydroxy phosphonates in ~60%–70% quantum yields.

3. Oxidation

The oxidation of alkyl- and alkenylphosphonates is widely used in the synthesis of hydroxy phosphonates. This method has found wide use since oxidation of double carbon–carbon bonds in the asymmetric epoxidation or the Sharpless dihydroxylation in the case of organophosphorus compounds gives products in high yields and with high optical purity.

The stereoselective oxidation of benzylphosphonates **87** with chiral oxaziridines gives α -hydroxy phosphonates **88** with a rather high optical purity, *ee* can reach 69%–98%. De-esterification of α -hydroxy phosphonates **88** with dimedone in the presence of the palladium catalyst occurs with almost no racemisation and affords α -hydroxy phosphonic acids **89** with *ee* 90%–96%.^{16, 113}

2-Furyl	AD-mix- α	17	88
n-C ₇ H ₁₃	AD-mix- β	63	84

The racemic mixture of (*S/R*)-1-acetoxy-2-(*E*)-alkenylphosphonates **93** can be resolved by kinetically controlled dihydroxylation with AD-mix- α or AD-mix- β .¹¹⁷ The stereochemistry of dihydroxylation depends on the configuration of the α -carbon atom and the nature of substituents at the double bond. For example, AD-mix- β oxidises mainly the (*R*)-enantiomer of compound **93**; hence, in addition to the optically active (1*R*,2*S*,3*R*)-1-acetoxy-2,3-dihydroxyphosphonate **94** formed, the reaction mixture contains non-consumed (*S*)-acyloxyphosphonate **93**, which can be isolated with a good optical purity.

R = H, Ph, 4-MeOC₆H₄.

Dihydroxyalkylphosphonates **95** and **96** are prepared by asymmetric dihydroxylation of vinyl- and allylphosphonates. Dihydroxy derivatives **95** and **96** are converted into 2-amino-1-hydroxy- and 3-amino-2-hydroxyalkylphosphonates through formation of azido derivatives and the catalytic reduction of the azide group.^{116–119} Chiral 3-amino-2-hydroxyalkylphosphonates are used in the synthesis of phosphocarnitine analogues.¹¹⁸

R = H, Ph, 4-BrC₆H₄, 4-O₂NC₆H₄, 4-MeOC₆H₄.

R¹ = H, Me, 4-MeOC₆H₄CO₂CH₂; R² = Et, Bn;
(a) AD-mix- α , K₂OsO₄; (b) SOCl₂, Py; (c) NaIO₄, RuCl₂;
(d) NaN₃, H₂SO₄; (e) PPh₃, H₂O.

The asymmetric aminohydroxylation of diethyl (*E*)-styrylphosphonates with potassium osmate(VI), tosylamine and AD-mix- α as the chiral inductor results in (1*R*,2*S*)-threo-2-amino-1-hydroxyphosphonic acids **97**.^{119, 120}

L* = AD-mix- α

R	Yield (%)	ee (%)
Ph	65	60
4-BrC ₆ H ₄	71	75
4-O ₂ NC ₆ H ₄	75	92
4-MeOC ₆ H ₄	72	45
H	55	15

The diastereomeric diethyl (1*R*,2*R*)- and (1*S*,2*R*)-1-benzoyloxy-2,3-epoxypropylphosphonates (**98**) were synthesised from 2,3-*O*-cyclohexylidene-1,2,3-trihydroxypropylphosphonate; its reaction with dibenzylamine yielded (1*R*,2*R*)- and (1*S*,2*R*)-3-dibenzylamino-1-benzoyloxy-2-hydroxypropylphosphonates.¹²¹

(a): (1) BnBr, Ag₂O; (2) HCl, dioxane; (3) MeC(OMe)₃, PPTS;
(4) AcBr, K₂CO₃, MeOH; (b) NHBn₂;
PPTS is pyridinium *p*-toluenesulfonate.

Cristau and co-workers^{122, 123} obtained 1,2-dihydroxyethylphosphonates **91** by hydrolysis of ethyl 1,2-epoxy alkylphosphonates **99**. Opening of the oxirane ring in compound **99** by amines resulted in 2-amino-1-hydroxyalkylphosphonates **100**, analogues of HO-AEP.

R = H, Bu^n , Ph, 2- MeC_6H_4 , 3- MeC_6H_4 , 4- MeC_6H_4 , 2- MeOC_6H_4 , 1-naphthyl.

Amino hydroxy phosphonates were also prepared by catalytic methanolysis of 2-phosphorylaziridine.¹²¹

Nakamura *et al.*¹²⁴ developed the synthesis of phosphonothrixin (**101**) starting from methyl bromomethacrylate, which was first converted into allylic phosphonate by the Michaelis–Becker reaction and then hydroxylated with osmium tetroxide. The dihydroxyalkylphosphonate thus formed was converted into (*R*)-phosphonothrixin (**101**), as shown in the scheme.

Another synthetic route to phosphonothrixin, which was also proposed by Nakamura *et al.*,^{124, 125} starts with the asymmetric Sharpless epoxidation of the dienic alcohol **102** to give chiral (*R*)-epoxy alcohol (*ee* 92%), which reacts with dibenzyl phosphite to give dihydroxyalkylphosphonate. The subsequent ozonolysis and debenzylation of the dihydroxyalkylphosphonate furnish (*S*)-phosphonothrixin (**101**) with *ee* 92%. The (*R*)-enantiomer of phosphonothrixin was also synthesised by this method.

The total six-step synthesis of phosphonothrixin (**101**) was developed on the basis of commercially available methyl 3-hydroxy-2-methylidenbutyrate, which reacts with diethyl phosphorochloridite in the presence of triethylamine; this is followed by reduction of the ester group and yields allylic phosphonate **103** in 60% yield.¹²⁶ Dihydroxylation of phosphonate **103** with osmium tetroxide and subsequent oxidation of the secondary alcohol group gives the protected phosphonothrixin **104** in 80% yield. After removal of the protecting groups, free phosphonothrixin (**101**) was obtained in an overall yield of 24%.^{126, 127}

TBDMS = $\text{Bu}^t\text{Me}_2\text{Si}$; TMS = Me_3Si ; PDC is pyridinium dichromate.

Natural 1-hydroxy-2-aminoethylphosphonic acid (HO-AEP), which was isolated from the membrane of the soil amoeba *Acanthamoeba castellanii*, is synthesised by the addition of sodium dimethyl phosphite to *N*-(2-oxoethyl)phthalimide followed by removal of the phthaloyl group with hydrazine and acid hydrolysis of the ester groups.¹²⁸

Phosphomycin, (1*R*,2*S*)-(Z)-1,2-epoxypropylphosphonic acid (**105**), was prepared by catalytic epoxidation of vinylphosphonate **106** with subsequent hydrolysis and resolution of racemic phosphomycin into enantiomers using (+)- α -phenylethylamine.¹²⁹

Kinetically controlled hydrolysis was proposed for the enantioselective resolution of racemic epoxyalkylphosphonates.^{117–130} The conventional acid hydrolysis of epoxide (*S*)-**107** gives diol (*S*)-**108** with *ee* of only 72%. However, partial kinetically controlled hydrolysis of racemic epoxide (*S*/*R*)-**107**, which occurs in the presence of cobalt (*R,R*)-salen complex, affords chiral diethyl (*R*)-2,3-dihydroxypropylphosphonate **108** with *ee* 98%.^{131, 132} Epoxide (*S*)-**107** with *ee* 82% remains in the reaction mixture.

Diethyl (*S*)-2,3-epoxypropylphosphonate **107** is converted into phosphocarnitine (*S*)-**109** according to the following scheme:¹³²

(a) MgBr₂, (b) Me₃N, (c) HCl, H₂O.

4. C-Modification

The addition of lithium derivative of (*S,S*)-2-(α -hydroxypropenyl)-2-oxo-1,3,2-oxazaphosphorinane **110** to benzaldehyde results in a diastereomer mixture of α -hydroxy-2-oxo-1,3,2-oxazaphosphorinanes **111** in 3 : 1 ratio.¹³³

The reaction of the lithium derivative of dimethyl ethylphosphonate **112** with aromatic aldehydes in THF provides β -hydroxyalkylphosphonates with 85% diastereoselectivity.¹³⁴

Diethyl isothiocyanomethylphosphonate **113** reacts with butyllithium to give a carbanion, which add to aldehydes yielding a diastereomer mixture of 2-thioxo-1,3-oxazolidin-4-ylphosphonates **114**.

R = Prⁱ, Bu^t, Ph, PhCH=CH, 1-furyl.

phosphonates **114**; these are converted into *N*-Boc-protected 1-amino-2-hydroxyalkylphosphonates in three steps.¹³⁵

N,O-Acetals **115** containing a chiral group react with triphenyl phosphite in the presence of TiCl₄ to give a mixture of (*R,R*)- and (*S,R*)-diastereomeric α -amino- β -hydroxypropylphosphonates **116** in 2 : 1 ratio. Pure diastereomers are obtained by fractional crystallisation.¹³⁶

5. Chromatographic separation

The resolution of racemic hydroxy phosphonates into enantiomers (in the form of diastereomers) by column chromatography is used rather often to obtain chiral hydroxy phosphonates.^{137–140} Good results can be attained by using silica gel Merck 60 (70–230 mesh); the course of separation is monitored by TLC. Iodine vapour or, whenever possible, an ultraviolet detector is used to visualise the plates.

Wróblewski and Piotrowska^{45,46} separated dimethyl 2-*tert*-butoxycarbonylamino- and dimethyl 2-benzoylamino-1-hydroxy-2-phenylethylphosphonate stereoisomers (**22**) upon esterification with (*S*)-*O*-methylmandelic acid followed by chromatography of the resulting diastereomer mixtures on silica gel. The yield of the less polar diastereomer was 43% and that of the more polar diastereomer, 36%, the latter being obtained in the crystalline state. Enantiomerically pure phosphonates (1*S*,2*S*)-**22** and (1*R*,2*S*)-**22** are formed in good yields upon ammonolysis of the ester.^{45,46}

R = Boc, PhC(O);

(a) (*S*)-PhCH(OMe)CO₂H, DCC, DMAP; (b) chromatography;

(c) 25% NH₃, H₂O.

By using a similar approach, Ordóñez *et al.*¹³⁸ resolved racemic (*S/R*)-2-hydroxy-3-(*N,N*-dibenzylamino)propylphosphonate **117** into optically pure enantiomers, which are analogues of γ -amino- β -hydroxybutyric acid.

Enantiomeric diethyl hydroxy(aryl)methylphosphonates containing *para*- or *ortho*-substituted benzene or other aromatic rings (naphthalene, thiophene) are separated by HPLC on a chiral stationary phase.¹³⁹ The resolution of enantiomers of diethyl

α -hydroxyfarnesylphosphonate, which is a precursor of a farnesyl protein transferase inhibitor, is attained by semipreparative HPLC on a chiral chromatographic column Chiralcel OD.¹⁴⁰

The separation of stereoisomeric 1-amino-2-hydroxy- and 2-amino-1-hydroxypropylphosphonic acid by capillary electrophoresis using chiral quinine carbamate has been described.¹⁴¹

6. Enzymatic synthesis

Enzymatic synthesis is an efficient alternative to the standard chemical synthesis of optically active hydroxy phosphonates. Bacteria, fungi and enzymes can be used as biocatalysts for the preparation of enantiomerically pure hydroxy phosphonates.^{142, 143} The following general approaches to the enzymatic synthesis of hydroxyalkylphosphonates are best developed: biocatalytic reduction of keto phosphonates; enantioselective acylation of racemic hydroxy phosphonates using microorganisms or enzymes for the separation of stereoisomers; enantioselective hydrolysis of acyloxyalkylphosphonates and epoxyethylphosphonates.

$n = 0, 1, 2$.

Ketophosphonates are reduced successfully using baker's yeast and some fungi. Baker's yeast is most convenient due to its ready availability, versatility and the ease of application.

Baker's yeast has been used^{144–146} for the enantioselective reduction of diethyl β -, γ - and δ -oxoalkylphosphonates, which yielded hydroxy phosphonates with a high optical purity ($ee > 95\%$). The reactions were carried out under aerobic conditions. In the case of low reactive compounds, anaerobic reduction was used.¹⁴⁵ This method has also been used to synthesise optically active β -keto γ - and δ -hydroxy phosphonates.¹⁴⁷

Maffei and co-workers¹⁴⁸ studied the enantioselective reduction of dialkyl 3-oxocycloalk-1-enylphosphonates **118** with baker's yeast and obtained dialkyl (*S*)-3-hydroxycycloalk-1-enylphosphonates **119**, which are important intermediates in the synthesis of a number of biologically active compounds. It was concluded that the reduction of six-membered cyclic keto phosphonates proceeds with a higher enantioselectivity (ee 76%) than that involving five- and seven-membered analogues. The highest stereoselectivity is achieved in the reduction of six-membered cyclic keto phosphonates in organic solvents (hexane, benzene, *tert*-butyl methyl ketone); in this case, hydroxy phosphonates **119** are formed with ee 65%–82%. An increase in the bulkiness of alkoxy groups at phosphorus (from methoxy to isopropoxy) increases the optical purity of dialkyl 3-hydroxycycloalk-1-enylphosphonates to ee 95% irrespective of the reduction conditions.

$R = \text{Me, Et, Pr}^i; n = 1–3$.

Solvent	The yield of 119 (%)	ee (%)
$n\text{-C}_6\text{H}_{14}$	84	65
$\text{MeC}(\text{O})\text{Bu}^t$	15	82
C_6H_6	7	69

Yuan *et al.*¹⁴⁹ performed the enantioselective reduction of 3-halo-2-ketopropylphosphonates **120** with baker's yeast; this gave optically active 3-halo-2-hydroxy propylphosphonates **121** in moderate yields and a satisfactory optical purity. Compounds **121** are used in the synthesis of 3-amino-2-hydroxypropylphosphonates **122**.

$X = \text{Br, Cl}$.

Enzyme-catalysed acylation or hydrolysis constitute convenient methods for the separation of racemic hydroxy phosphonates.^{150–161}

Optically pure *S*-enantiomers of the hydroxy phosphonate series have been obtained^{154, 157} in satisfactory yields with high enantiomeric excess by enzymatic hydrolysis of the acyl derivatives of racemic hydroxy phosphonates catalysed by lipases from *Aspergillus niger*, *Rhizopus oryzae* and *Candida rugosa*.

$R^1 = \text{Et, Pr}^i; R^2 = \text{Et, Pr}^n, \text{Pr}^i, \text{Bu}^n, \text{Bu}^i, \text{Bu}^t, n\text{-C}_5\text{H}_{11};$
 $R^3 = \text{ClCH}_2, \text{Me, Et}.$

Hydrolysis of racemic 1-butyryloxyalkylphosphonic acid **123** with lipolytic microorganisms (LM), namely, the bacteria *Pseudomonas fluorescens* or the fungi *Penicillium citrinum*, leads to optically pure (*S*)-hydroxy phosphoric acid.^{143, 152}

Racemic α -hydroxyalkylphosphonates **124** are subjected to acetylation catalysed by lipases from *Candida antarctica* B (CALB) and *Candida rugosa* (CRL); after that, the remaining *R*-isomer of hydroxy phosphonate **124** is separated from the *S*-isomer of acetyl derivative **125**.¹⁴⁷ Yuan and co-workers¹⁵³ used CALB in organic solvents for the enantioselective acetylation of racemic β -hydroxyalkylphosphonates **126**. The subsequent separation of the non-consumed alcohol (*S*)-**126** from ester (*R*)-**127** gives pure stereoisomers. In both cases, vinyl acetate was used as the acylation agent. This method for the preparation of chiral hydroxyalkylphosphonates is characterised by high enantioselectivity and experimental convenience.

phosphonates are converted into L-phosphoisoserine (**134**) and L-phosphoserine (**135**) using catalytic hydrogenation and the Staudinger reaction.

A similar method has been used to prepare chiral methyl sulfides (*ee* 93%–97%) from racemic α -hydroxy phosphonates, which are resolved using enzymatic hydrolysis of acyl derivatives.¹⁶⁶ The enzymatic acetylation of racemic diisopropyl α -hydroxy phosphonates with isopropenyl acetate in *tert*-butyl methyl ether allows one to obtain (*S*)-diisopropyl-1-hydroxy-(2-thienyl)methyl-, -1-hydroxyethyl-, -1-hydroxycyclohexylmethyl-phosphonate and (*R*)-2-hydroxypropylphosphonate acetates with enantiomeric excesses reaching 99%. Using enzymatic hydrolysis, (*S*)-2-hydroxy-2-phenylethyl- and (*S*)-2-hydroxy-3-methylbutyl-phosphonates can be converted into (1*R*,2*R*)-2-amino-1-hydroxy-phosphonic acids.^{167–169} Enzymatic hydrolysis was used in the synthesis of phosphomycin.^{169, 170}

Acetylation of racemic diethyl 3-hydroxybut-1-enylphosphonate (**136**) catalysed by various enzymes and subsequent separation of the components of the reaction mixture affords enantiomerically pure diethyl (*S*)-3-hydroxybut-1-enylphosphonate **136** and diethyl (*R*)-3-acetoxybut-1-enylphosphonate **137** with enantiomeric excesses reaching 99%.¹⁷¹

Enzyme	<i>ee</i> (%)	
	(<i>S</i>)- 136	(<i>R</i>)- 137

PPL	22	99
CRL	8	54

Lipases from *Geotrichum candidum*, *Rhizopus niveus*, *Penicillium* species, *Aspergillus usami*, *Mucor* species and *Pseudomonas cepacia* and porcine pancreatic lipase are used for stereoselective acetylation of racemic hydroxyphosphonates in toluene.^{172–181} Thus lipase from *Geotrichum candidum* catalyses the enantioselective acetylation of racemic hydroxy phosphonates to give the acetylated product in a 32%–34% yield and with optical an purity of 95%.¹⁷²

The optically pure monoacetate (*R*)-**138** is prepared from prochiral bis(hydroxymethyl)phenylphosphine oxide (**139**) by

Lipases Amano AK, PFK1 (from *Pseudomonas fluorescens*), Amano PS.

enzymatic acetylation with vinyl acetate in an organic solvent or enzymatic hydrolysis of bis(acetoxymethyl)phenylphosphine oxide.¹⁷³

Shibuya and co-workers¹⁷⁴ prepared optically active alcohols **140** by enantioselective acylation of prochiral 2-(ω -phosphonoalkyl)propane-1,3-diols **141** with vinyl acetate in an organic solvent catalysed by lipase from *Pseudomonas cepacia* (PSL). Chiral alcohols (+)-**140** are formed in good yields and high enantiomeric excesses. Alcohols (+)-**140** are then converted into optically active α -amino- ω -phosphono acids **142**, which possess various biological activities and are intermediates in the synthesis of aminopentylphosphonic acid analogues.

X = CH₂, (CH₂)₂, CH₂CF₂; DPPA is diphenoldiphenoxyposphoryl azide.

Solvent	The yield of 140 (%)	<i>ee</i> (%)
Pr ⁱ ₂ O	82	98
Pr ⁱ ₂ O (lipase AK)	98	70
THF	98	98
C ₆ H ₆	94	98
C ₆ H ₁₄	72	79

The same authors¹⁷⁵ carried out the kinetic resolution of racemic 1-diethoxyphosphorylmethyl-2-hydroxymethylcyclohexane (**143**) into enantiomers in good yields and high enantiomeric excesses by acetylation catalysed by lipases PSL or AK. Optically active alcohol (1*S*,2*R*)-**143** was converted into (*S*)- and (*R*)-hydantoin **144**.

PSL-catalysed hydrolysis of racemic or enantiomerically enriched acetates **145** gives enantiomerically pure α -hydroxy-alkylphosphinates (**146**) with *ee* 74%–99%.¹⁷⁶

This method has been used¹⁸⁶ to prepare monofluorodi-hydroxybutylphosphonic acid **158**, which is an analogue of glycerol 3-phosphate, the glycerol 3-phosphate dehydrogenase substrate.

The CuBr-activated reaction of (diethylphosphonyl)difluoromethylzinc bromide with aryl iodides results in aryldifluoromethylphosphonates. Treatment of these compounds with trimethylsilyl bromide gives free acids, some of which being low-molecular-mass inhibitors of phosphatase.¹⁸⁷

Berkowitz *et al.*¹⁸⁸ described a facile method for the synthesis of difluoroalkylphosphonates; this method was used to prepare difluoromethylphosphonic analogues of L-serine, L-allothreonine and L-threonine.

Shibuya and co-workers^{189,190} reported the synthesis of nucleotide analogues containing a phosphoryldifluoromethyl group. Titanium tetrachloride-catalysed glycosylation of the trimethylsilyl derivatives of heterocyclic bases with 2,3-dideoxy-ribofuranosides containing a thiophosphoryldifluoromethyl group at C(3) is a method for preparing pyrimidine β -nucleosides **159** with high stereoselectivity (*dr* 89 : 11). The oxidation of the thymine-containing nucleoside with *m*-chloroperbenzoic acid gives rise to the difluoromethylphosphonate analogue of thymidine 3'-phosphate.

A solid-state method for the synthesis of fluorinated α -hydroxy phosphonates has been proposed.¹⁹¹ Keen interest is aroused by the fluorophosphonates containing a cyclopropyldifluoromethyl group, which has a pronounced effect on the biological properties of compounds.^{192–195} For example, {(1*S*,2*S*)-2-[(1*S*)-1-(6-oxo-1,6-dihydropurin-9-yl)ethyl]cyclopropyl}difluoromethylphosphonate is an efficient inhibitor of purine nucleoside phosphorylase.¹⁹⁴

The reduction of [(1*S*,2*S*)-2-acetylcyclopropyl]difluoromethylphosphonates **160** with K-selectride occurs from the less hindered side of the carbonyl group (*si*-stereofacial) and gives cyclopropylethanols **161** with a high diastereoselectivity.

The synthesis of enantiomerically pure diethyl *trans*-4-hydroxy-1,1-difluoro-2,3-methanobutylphosphonate [(+)-**162**] by the reaction of diethyl 4-tetrahydropyranyloxy-1,1-difluorobut-2-enylphosphonate with diazomethane followed by enzymatic double resolution of the resulting racemic hydroxyphosphonates ($\pm$)-**162** has been reported.¹⁹⁵ By PPL-catalysed acetylation and hydrolysis of the enantiomerically enriched acetoxy phosphonate (+)-**163**, the optical purity of hydroxy phosphonate (+)-**162** was increased to *ee* 94%. Chiral hydroxy phosphonate (+)-**162**, the structure of which was confirmed by X-ray diffraction, was used for the synthesis of optically active 9-[(2*S*,3*S*)-4-phosphono-4,4-difluoro-2,3-methanobutyl]guanine (**164**), which is a purine nucleoside phosphorylase inhibitor.¹⁹⁵

Shibuya and co-workers¹⁹⁶ reported the synthesis of (hydroxycyclohexenyl)difluoromethylphosphonates **165** and **166** by the CuBr-catalysed reaction of (diethoxyphosphoryl)difluoromethylzinc bromide with hydroxycyclohex-2-en-1-yl phosphates. Compounds **165** and **166** are intermediates in the stereoselective synthesis of inositol phosphate analogues.

The reaction of dialkyl phosphites and thiophosphites with carbohydrate difluoromethylidene derivatives **167** yields anomeric mixtures of glycosyldifluoromethylphosphonates **168a** and -thiophosphonates **168b** with the isopropylidene protecting group.¹⁹⁷

$R^1 = \text{H}$, $\text{Bu}^t\text{Me}_2\text{Si}$; $R^2 = \text{Et}$, Bn ; $X = \text{O}$ (a), S (b).

The synthesis of nucleotides **169**, containing a difluoromethylphosphonate group, which are reverse transcriptase inhibitors, has been reported.²⁰¹ Compounds **169** were prepared by the reaction of the lithium derivative of difluoromethylphosphonate with the bromo-containing nucleoside analogue **170** and subsequent hydrolysis of the resulting diester.

$X = \text{CH}_2\text{CF}_2$, CHFCH_2 , $(E)\text{-CH}=\text{CH}$, $(E)\text{-CH}=\text{CH}$, $\text{O}(\text{CH}_2)_2\text{CF}_2$.

Fluorophosphonate derivatives of *N*⁹-benzylguanine **171** and **172**, functioning as purine nucleoside phosphorylase inhibitors, have been synthesised in a similar way.²⁰¹

8. Miscellaneous methods for the synthesis of hydroxy phosphonates

The asymmetric [2,3]-sigmatropic Wittig rearrangement of chiral phosphonate carbanions generated from allyloxymethyl and but-2-enyloxymethyl derivatives proceeds with high diastereo- and enantioselectivity.^{17,203} For example, deprotonation of allyl- and but-2-enyloxymethylphosphonamides under the action of butyllithium in THF at -70°C results in the formation of stable phosphonate carbanions **173**, which readily undergoes the

[2,3]-sigmatropic Wittig rearrangement to give hydroxy phosphonate **174** as the only diastereomer.¹⁷

$R^1 = R^2 = \text{H}$; $R^1 = \text{Me}$, $R^2 = \text{H}$; $R^1 = \text{H}$, $R^2 = \text{Me}$.

Hammerschmidt²⁰⁴ described the phosphate-phosphate rearrangement, which gives rise to hydroxy phosphonates and is the model reaction for the biosynthesis of compounds with the $\text{P}-\text{C}$ bond.

Hydroxy phosphonates are also obtained by the reaction of chiral epoxy chalcones with nucleophiles. In the presence of KF , diethyl phosphite adds preferentially to the *si*-face of the carbonyl group of epoxychalcones to give hydroxy phosphonates with *de* 50%.²⁰⁵

Shibuya and co-workers²⁰⁶ reported the synthesis of dihydroxy phosphonates **175** by the reaction of chiral isopropylidene-glyceraldehyde with bis(diethoxyphosphoryl)methane in the presence of butyllithium followed by deprotection of the hydroxy groups. The radical intramolecular cyclisation of the resulting dihydroxy phosphonates **175** yielded phosphonates **176**, which are analogues of 2-deoxyribose-3-phosphates, with the stereoselectivity (*de*) 76%–92%.

$R = \text{SiPh}_2\text{Bu}^t$, SiMe_2Bu^t ; NBS is *N*-bromosuccinimide.

The reaction of optically active lithium *N,N,N',N'*-tetraalkylphosphorodiamidites with 1,2-epoxybutane leads to hydroxybutylphosphonamides **177** with a diastereoselectivity (*ee*) not exceeding 33%. The reaction of chiral epoxides **178** with achiral lithium diethyl phosphite also proceeds with a low stereoselectivity.¹¹⁸

Considerable attention is paid to the synthesis of pharmacologically active hydroxyalkylphosphonates.²⁰⁷ For example, the Michaelis–Becker reaction of methanesulfonates with dialkyl phosphites furnished nucleoside analogues with a methylene-cyclopropylphosphonate fragment, some of which exhibited high antiviral activities.²⁰⁸ The reaction of [1-(diethoxyphosphoryl)-vinyl] *p*-tolyl sulfoxide with ethyl (dimethylsulfuranylidene)acetate yields (1*S*,2*S*)-1-diethoxyphosphoryl-2-ethoxycarbonylcyclopropyl *p*-tolyl sulfoxide, which is converted into optically pure 2-hydroxymethylcyclopropylphosphonate. This was coupled with adenin and chloropurine under conditions of the Mitsunobu reaction to give conformationally constrained analogues of the antiviral purine nucleotides.²⁰⁹

The hydroxy group in hydroxy phosphonates is replaced by the amino group using the Mitsunobu reaction.²¹⁰ Diisopropyl (*S*)-(+)- and (*R*)-(–)-hydroxy(cyclohexyl)methylphosphonates, prepared by the kinetic resolution of the racemic mixture using lipase AP 6, are converted by the Mitsunobu reaction, into optically active (*S*)-(+)- and (*R*)-(–)-amino(cyclohexyl)methylphosphonates with an optical purity of not less than 90%. The replacement of the hydroxy group by an amino group is accompanied by the inversion of configuration.

1-Amino-2-hydroxyalkylphosphonic acids **179**, which are isosteric analogues of biologically active and natural compounds, are synthesised by the asymmetric aldol condensation of aldehydes with isocyanomethylphosphonates **180**. The reaction is catalysed by the chiral complex of gold with the ferrocenylphosphine ligand **181**. The optical purity of the reaction products (*ee*) reaches 88%–96%.²¹¹

Rowe and Spilling²¹² described stereoselective arylation of hydroxyalkylphosphonates and used this reaction for the synthesis of (*S*)-(+)-aryl turmerone **182**.

The asymmetric synthesis of (1*S*,2*R*)-(1,2,3-trihydroxypropyl-diphenyl)phosphine oxides, which are structural analogues of the open form of D-erythrose, has been developed.²¹³

Silylphosphines react with chiral aldehydes with high stereoselectivity to give optically active protected α -hydroxyalkylphosphines **183**. In some cases, the formation of borane complexes is used to increase the optical purity. Bis(hydroxyalkyl)phosphines were also obtained using this reaction and isolated as borane complexes.^{213–215}

$R^1 = \text{Ph}, \text{Me}_3\text{Si};$

$R^2 = \text{H}_2\text{N}-\text{CH}(\text{CH}_2\text{Pr}^i)-, \text{H}_2\text{N}-\text{CH}(\text{CH}_2\text{Ph})-$

Cobalt complexes are used in the Reformatsky reaction of α -halo phosphonates with ketones or aldehydes to obtain diverse β -hydroxy phosphonates.²¹⁶

$R^1, R^2 = \text{H}, \text{Alk}, \text{Ar}; \text{X} = \text{Cl}, \text{Br}, \text{I}.$

III. Determination of the absolute configuration of hydroxy phosphonates

To determine the enantiomeric purity of dialkyl 1-hydroxyalkylphosphonates, modification by chiral reagents, resulting in the formation of diastereomeric derivatives, is used most often. In most studies, hydroxy phosphonates are modified by esterification with Mosher's acid **184**,^{217–219} camphoric acid²²⁰ and mandelic acid **185**,²²¹ amino acids^{222, 223} or with diazaphospholidine derivatives.²²⁴ (*S*)-Naproxen[®] (**186**) and (*S*)-Ibuprofen[®] (**187**) chlorides are convenient chiral reagents for determining the enantiomeric purity of 1-hydroxy- and 2-hydroxyalkylphosphonates by means of ³¹P NMR spectroscopy.²¹⁹ The ¹H NMR spectroscopy of chiral 1-(1-naphthyl)ethylammonium salts of hydroxy phosphonic acids,²²⁵ NMR in chiral media, GLC on capillary columns with chiral sorbents¹⁴⁶ and other methods^{226, 227} are also used.

Esterification of hydroxy phosphonates with optically active Mosher's acid **184** is a convenient method for determining their optical purity and absolute configuration.^{217–219} The diastereomeric esters formed can be analysed by ¹H, ¹⁹F and ³¹P NMR spectroscopy. The signals of the P atoms in the ³¹P NMR spectra of (*S*)-hydroxy phosphonate esters **188** are usually located in a lower field than those of (*R*)-hydroxy phosphonates **189** (Table 1). This is due to shielding of the phosphorus atom in ester (*R*)-**189** by the phenyl group. The substantial difference between the chemical shifts ($\Delta\delta_P = 0.40 - 1.09$ ppm) allows reliable determination of the absolute configurations of hydroxy phosphonates.

Table 1. Chemical shifts (δ_P) in the ³¹P NMR spectra of Mosher's esters.^{217–219}

Mosher's ester		δ_P , in the spectrum of		$\Delta\delta = \delta(S) - \delta(R)$
R^1	R^2	<i>S</i> -isomer	<i>R</i> -isomer	
Et	Me	22.21	21.77	0.44
Pr ⁱ	Et	19.33	18.93	0.40
n-C ₅ H ₁₁	Et	19.90	19.43	0.47
BnCH ₂	Pr ⁱ	17.42	17.01	0.41

Kozłowski *et al.*²²¹ determined the enantiomeric purity and the absolute configuration of α -hydroxy phosphonates using esterification with mandelic acid. The upfield or downfield shifts of the signals for the methyl-group protons in the ¹H NMR spectra of compounds **190** and **191** depend on the arrangement of the phenyl group in the molecule and its shielding effect. The absolute configurations of compounds **190** and **191** were additionally proved by X-ray diffraction analysis.

$R = \text{PhCH}=\text{CH}.$

Aryl(hydroxymethyl)phosphonates were separated by HPLC on chiral stationary phase.²²⁸ It was noted that (*R*)-(+)-hydroxyphosphonates are retained by the chiral stationary phase (3*R*,4*S*)-WHELK-01 more strongly than (*S*)-(–)-hydroxyphosphonates. This is due to the formation of a stronger hydrogen bond between the oxygen atom of the P=O group and the hydrogen atom of the amide NH group in the case of *R*-isomers than between the hydroxyl and NH groups in the case of (*S*)-hydroxyphosphonates.

The absolute configuration of hydroxy phosphonates is also determined by means of circular dichroism spectra.^{92, 114, 178} For example, Wynberg and co-workers⁹² used the CD spectra to

determine the absolute configuration of a number of chiral α -hydroxy phosphonates **192**. The enantiomers having *S*-configuration show a negative Cotton effect at 225 nm.

**192**

R = H, F, Cl, Br, NO₂, NH₂.

Yokomatsu *et al.*¹¹⁴ used the CD spectra to determine the absolute configuration of 1,2-dihydroxyphosphonates **91**. It was found that α,β -dihydroxy phosphonates having the (1*S*,2*S*)-configuration show a positive Cotton effect at 210–230 nm, whereas (1*R*,2*R*)-isomers show a negative Cotton effect at these wavelengths.

The enantiomeric composition of hydroxy phosphonates is determined using NMR spectroscopy in the presence of quinine, which is an efficient chiral solvating agent. The hydroxy phosphonate enantiomers are readily distinguished by ¹H and ³¹P NMR spectroscopy.^{227, 229, 230} No resolution of the enantiomer signals in the ³¹P NMR spectra of 1-hydroxy- and 2-hydroxy-alkylphosphonates was observed where quinine was replaced by brucine, cinchonine, ephedrine or 1-phenylethylamine.

Yet another method for determining the enantiomeric composition of chiral 1-hydroxyalkylphosphonic acids is the ³¹P NMR study of the diastereomeric derivatives obtained by the reaction of these acids with *N*-substituted L-amino acids.²²²

Dimethyl phosphorochloridite **193** is a convenient reagent for determination of the enantiomeric composition of hydroxy phosphonates (as well as amines, amino acids and alcohols).²³¹ The diastereomeric hydroxy phosphonate derivatives formed upon the reaction with this reagent differ appreciably in the chemical shifts δ_P ; therefore, the stereomer ratio can be easily determined by integrating the ³¹P NMR signal intensities.

**193**

IV. Biological activities of hydroxy phosphonates

Being structural analogues of hydroxy carboxylic acids, in which the carboxy group has been replaced by the phosphonate group,² hydroxy phosphonic acids function as their substrates, as they compete with the carboxy-containing analogues for the active sites of the enzymes and cell receptors.^{232–236} The structural differences between the CO₂H and P(O)(OH)₂ groups do not prevent hydroxy phosphonic acids from serving as substrates for the enzymes that usually interact with hydroxycarboxylic acids. Thus, hydroxy phosphonic acids inhibit the enzymes involved in

the metabolism of hydroxy carboxylic acids, thus affecting various biological processes in the cell.²³⁷ They behave as antibacterial agents, neuroactive compounds, antitumour agents, and so on.^{71, 72, 238} Therefore, study of the biological activities of hydroxy phosphonates appears promising for the development of new bioregulators and drugs.^{238–246}

Patel *et al.*⁸ found that phosphonopeptides **31a–g**, containing a hydroxy group at the α -carbon atom, inhibit the proteolytic enzyme renin, which possesses an angiotensinogenic action (Table 2). Angiotensin is a powerful octapeptide bioregulator possessing vasoconstrictive properties and increasing blood pressure. It was found that for attaining high activities of compounds **31a–g**, the presence of at least one alkoxyl group at phosphorus is required.

**31a–g**

Dellaria *et al.*²⁴² reported renin inhibitors **194a–f** (see Table 2), which are phosphonate analogues of the natural substrate renin **195**. Pseudo-peptides **194a–e** (R³ = Im) contain both a fragment of the natural structure Phe⁸-His⁹ and a new phosphostatine fragment whose presence induces a 130-fold boost in the activities of compounds **194** as compared with the natural substrate **195**.

**194a–f**

Table 2. Effect of the substituent structure in the molecules of phosphonopeptides **31** and **194** on the 50% inhibition concentration (IC₅₀) of renin.^{8, 242}

Compound ^a	R ¹	R ²	R ³	R ⁴	IC ₅₀ /nmol litre ^{−1}
31a	OEt	OEt	Pr ⁱ	Bu ^t O	28±3
31b	OEt	OEt	Pr ⁱ	cyclo-C ₅ H ₉	38±8
31c	OMe	OMe	Pr ⁱ	Bu ^t O	10±1
31d	OMe	OMe	Pr ⁱ	cyclo-C ₅ H ₉	16±1
31e	OMe	OMe	Pr ⁱ	H ₂ N(CH ₂) ₅	31±4
31f	OMe	OMe	Pr ⁱ		8.5±1.4
31g	OMe	OMe	Im ^b		41±14
194a (2 <i>R</i>)	OMe	OMe	Im	Bu ^t O	39
194a (2 <i>S</i>)	OMe	OMe	Im	Bu ^t O	90
194b	OEt	OEt	Im	Bu ^t O	72
194c	OMe	OMe	Im	Bu ^t CH ₂	47
194d	OMe	OMe	Im	EtO	50
194e	O(CH ₂) ₂ O		Im	Bu ^t O	80
194f	OMe	OMe	Pr ⁱ	Bu ^t O	20

^a Compounds **31a–g** have 2*S*-configuration; compounds **194b–f** have 2*R*-configuration; ^b Im is imidazolyl.

R^1 , R^2 are peptide residues.

N-Palmitoylsphingosine 1-phosphate analogue **196**, containing a hydrolytically stable difluoromethylphosphonic fragment, is a sphingomyelinase inhibitor ($IC_{50} = 3.3 \mu\text{mol litre}^{-1}$)²⁴⁰ with the same level of activity as schyphostatin, the most potent known low-molecular-mass inhibitor of this enzyme. Compound **197** inhibits non-competitively neutral sphingomyelinase in bovine brain microsomes, having $IC_{50} = 400 \mu\text{mol litre}^{-1}$ (Ref. 246). Phosphonic acid **197** prevents the action of the tumour necrosis factor TNF- α by inducing neuron PC 12 death at a concentration of $0.1 \mu\text{mol litre}^{-1}$.

Non-competitive sphingomyelinase inhibitors have also been described in another study.²²⁸

Phosphonic acids **198** and **199** inhibit human phosphoprotein tyrosine phosphatase (PTP-1B) with IC_{50} in the range 57.9–718.1 nmol litre^{-1} (Refs 238, 244–246). Phosphoprotein tyrosine phosphatase catalyses the abstraction of the phosphate group from the tyrosine residue in the molecules of phosphorylated proteins and enzymes, thus inactivating them. Compounds **198** and **199**, which inhibit dephosphorylation of the VEGFR (vein endothelium growth factor), induce fast division of endothelial cells of human umbilical cord vein.²⁴⁴ The introduction of the second difluoromethylphosphonic fragment into the phosphonic acid molecule increases the inhibitory activity.²⁴⁷ The protein tyrosine phosphatase inhibitors exhibit a pharmacological action in the therapy of some diseases.^{108, 247}

$X = \text{CF}_2, \text{CHF}, \text{CHOH}$.

Shibuya and co-workers¹⁹⁵ reported that purine-containing phosphonic acids **200**–**202** inhibit purine nucleoside phosphorylase (PNP). The PNP inhibitors are efficient in the therapy of proliferative diseases (T-cell leukemia, gout, some types of malaria). The introduction of a cyclopropane fragment, restricting the conformational mobility of the molecule, into the *N*-alkyl substituent enhances the inhibitory activity of compounds. For example, compound **202** has a 2400 times higher inhibitory activity with respect to PNP than compound **200**.¹⁹⁵ The replacement of the guanine residue by hypoxanthine also increases the inhibitory activity of hydroxy phosphonates.

Phosphonic acid derivatives **203**–**205** of the *N*⁹-benzylguanine series actively inhibit PNP isolated from calf spleen or human erythrocytes. Fluorine-containing compounds are more active than their non-fluorinated analogues.²⁰⁷

$X = \text{CH}_2\text{CF}_2, \text{CHFCH}_2, (E)\text{-CH}=\text{CF}, (E)\text{-CH}=\text{CH}, \text{O}(\text{CH}_2)_2\text{CF}_2, \text{O}(\text{CH}_2)_3$.

Difluoromethylphosphonates **158** behave as effective inhibitors of aspartate- β -semialdehyde dehydrogenase (ASA-DH) from *Escherichia coli*.²⁰²

Among the biologically active hydroxy phosphonates, interesting antibacterial and antiviral agents have been found;^{248–250} an example is (1*R*,2*S*)-(–)-1,2-epoxypropylphosphonic acid (phosphomycin, **42**), isolated from the culture medium of *Streptomyces fradiae* or *Pseudomonas syringae*.¹

Phosphonic acids **206** and **207** are structural analogues of the aldolase substrate,²⁴⁹ the enzyme catalysing cleavage of fructosyl 1-phosphate into D-glyceraldehyde and dihydroxyacetone phosphate (DHAP) occurring in the liver.

Hydroxy phosphonate derivatives containing residues of heterocyclic bases exhibit a high antiviral activity in the epithelial cells and organotypic cultures.²⁵⁰ The most active compounds of this type are 9-(*S*)-(3-hydroxy-2-phosphonomethoxypropyl)adenine [(*S*)-HPMPA, **208**], 9-(*S*)-(3-hydroxy-2-phosphonomethoxypropyl)-2,6-diaminopurine and 1-(*R*)-(3-hydroxy-2-phosphonomethoxypropyl)cytosine [(*R*)-HPMPC, **209**], known as cidofovir, efficient against human cytomegalovirus and the smallpox virus.

On the basis of hydroxy phosphonates, antitumour drugs have been developed.^{251–258} Nucleoside phosphate analogues **210** exhibit high antitumour activities in several lines of human malignant cells.²⁵³ Hydroxy phosphonic acids **211** have been proposed as inhibitors of phosphoprotein tyrosine phosphatase CD 45, which plays an important role in the inactivation of the protein growth factors and stabilisation of fast proliferation of the hematopoietic cells.²⁵⁴ The 5-methylenephosphonate analogue of D-*myo*-inositol-1,4,5-triphosphate **212** behaves as an intracellular messenger, favouring the opening of calcium channels and liberation of calcium ions.²⁵¹

$R^1 = \text{OH, OMe}; R^2 = \text{OH, NH}_2$.

Hydroxy-[4-(5,6,7,8-tetrahydronaphthyl-1-oxy)phenyl]methylphosphonate is an inhibitor of *myo*-inositol monophosphatase, the activity of which with respect to the recombinant bovine brain enzyme corresponds to the inhibition constant $K_i = 20 \mu\text{mol litre}^{-1}$ (Ref. 252).

Compounds **213** inhibit HIV protease and are promising for AIDS therapy.²⁵⁵ The IC_{50} values of these compounds with respect to HIV protease are in the nanomolar range.

Hydroxyalkylbis(phosphonates) are used as pharmacological agents for the therapy of some diseases such as osteoporosis, hypercalcaemia and some kinds of malignant tumours.^{257–260} The most important among them are Pamidronate (**214**) (also retards bone resorption), Alendronate (**215**), Risedronate (**216**) and zoledronic acid (**217**).²⁵⁹

The bis-phosphonate derivative of 3-azido-3-deoxythymidine exhibits an antiviral activity in the therapy of AIDS²⁶⁰ and is registered as Zidovudine.

Some hydroxyalkylphosphonates are plant growth regulators. A number of unsaturated cyclic hydroxy phosphonates synthesised by the reaction of 4-aryl-5,5-dimethyl-1,3,2-dioxaphosphinanes with 2-epoxy-5-aryl-(2*E*,4*E*)-pentadienecarboxaldehydes function as wheat stem growth inhibitors.²⁶¹

Aminohydroxy phosphonates are promising as bidentate ligands for the formation of complexes with transition metals.^{262, 263} For example, copper(II) and zinc(II) complexes of alkyl- and aryl-substituted 2-amino 1-hydroxy phosphonates were studied in an aqueous solution by potentiometry and spectroscopy. A comparison of the stability constants shows that these ligands coordinate Cu^{2+} and Zn^{2+} more efficiently than amino phosphonates containing no hydroxy group.²⁶²

V. Conclusion

The present review considers various methods of asymmetric synthesis, enzymatic, kinetic and chromatographic separation, and some other ways of preparing enantiomers of hydroxy phosphonates with high optical purity. It is noteworthy that, despite the impressive progress attained in the synthesis and study of the properties of hydroxy phosphonates, the problems existing in the chemistry of these compounds are far from being completely solved. The search for enantioselective methods opening an easy route to optically active hydroxy phosphonates still remains topical. Therefore, the development of efficient catalysts for asymmetric phospho-aldol Abramov reaction and for the reduction of keto phosphonates appears especially important. The scope of chemical modification of hydroxy phosphonates aimed at introducing new, more complex, in particular, chiral groups to the carbon, oxygen and especially phosphorus atom is far from being exhausted. The separation of enantiomers and purification of hydroxy phosphonates remain topical tasks. Exact determination of the structure and the absolute configuration of these compounds can be successfully carried out only in some cases.

One can expect that hydroxy phosphonates will remain the subject of intensive research, especially in the field of biological activities and use of these compounds as drugs and bioregulators. In addition, hydroxy phosphonates, their derivatives and analogues can find practical use as synthetic receptors and chiral ligands in metal complexes and selective highly efficient complexes, extractants and analytical reagents.

Pyrocatechol Violet in spectrophotometric and novel optical methods

V M Ivanov, G A Kochelayeva

Contents

I. Introduction	255
II. Chemical and analytical characteristics of Pyrocatechol Violet	256
III. Pyrocatechol Violet as a complexometric indicator	258
IV. Pyrocatechol Violet as a reagent in optical methods	258
V. Conclusion	264

Abstract. The published data on chemical and analytical characteristics and the use of binary and ternary Pyrocatechol Violet complexes in spectrophotometric and novel optical methods of analysis are generalised. New promising trends are considered including studies of chromaticity characteristics of complexes of this reagent with various metal ions formed in the presence of cationic surfactants on the surface of anion-exchange resins or neutral sorbents aimed at increasing the sensitivity of determinations and developing new, more efficient test scales and optical sensors. The bibliography includes 105 references.

I. Introduction

The development of methods and techniques that combine high sensitivity and high selectivity with rapidity of analysis, availability of instruments and low cost is a topical task in analytical chemistry. This is achieved, in particular, through combination of preconcentration of tested compounds with new sampling techniques and most advanced methods of analysis. Mixed-origin specimens including environmental subjects supplement traditional analytical (inorganic or organic) subjects. By virtue of rapidity of analysis and possibility of direct visualisation of the tested subjects, spectroscopic molecular absorption methods are in continuous development resulting in appearance of new versions of the determination, novel or modified reagents and combination of several approaches (*e.g.*, hybrid and combinatory methods of analysis). To relatively new procedures one can relate diffuse reflectance spectroscopy, solid-phase spectrophotometry, chromaticity measurement and diverse test methods. The latter are worthy of note in view of simplicity, availability and relatively low cost at reasonably high precision. These methods are especially suitable for express analysis of a broad range of organic and inorganic substances. Chemical test methods are usually based on well-known reagents and analytical reactions where colour change plays the role of an analytical signal. The reagents for test methods should possess high selectivities and high sensitivities in determination of metal ions or various compounds, the abilities to form stable complexes or analytical forms, possibilities to be immobi-

lised on solid supports and ensure sufficiently high contrast of reactions.

Basic and polyhydroxytriphenylmethane dyes are the two main classes that are widely employed as analytical reagents. The reagents of the former class contain alkyl- or arylamino groups in the phenyl substituents and are usually employed in extractive-photometric procedures. An ionic pair of a negatively charged tested component and the protonated form of the reagent can be extracted by weakly polar organic solvents; however, the reagent itself is also partially extracted. The contrast range in such reactions does not usually exceed 10–20 nm; the reactions are carried out in acidic media with very strict acidity control (the range of optimum pH is very narrow), however the sensitivity of the determination is rather high [the molar extinction coefficient (ϵ) is of the order of 10^5].

The reagents of the latter class contain hydroxy groups in the phenyl substituents. Two hydroxy groups in the *ortho*-position (pyrocatechol) form a functional-analytical group in the reagent, which can be involved in complexation with the formation of chelate complexes. The contrast range of such reactions, especially with involvement of additional approaches, can exceed 200 nm; the values of molar extinction coefficients are of the order of 10^5 , the optimum acidity range is of the order of several units of pH, while the selectivity of the reaction can be changed upon introduction of masking substances. The reagents of the second class include Pyrocatechol Violet (3,3',4'-trihydroxyfuchsin-2''-sulfonic acid, pyrocatecholsulfonephthalein, PCV), a popular reagent for photometric determination of some metal ions and an indicator for complexometric studies. Its applications in novel optical methods, solid-phase spectrophotometry and chromaticity present certain interest. Complexes with PCV usually have bright colours; their formation results in marked bathochromic shifts and is often highly selective. Thus, this reagent is suitable for different test methods, since the latter often include preconcentration in the form of a coloured complex.

This review generalises the published data on chemical and analytical characteristics of Pyrocatechol Violet and its applications in analytical chemistry. Special attention is given to the use of this reagent in modern optical methods, such as diffuse reflectance spectroscopy, solid-phase spectrophotometry, chromaticity measurement, as well as in test methods. This type of a review is missing, while the information sources are either dispersed or hardly accessible.

II. Chemical and analytical characteristics of Pyrocatechol Violet

1. Protolytic equilibria in solutions

The PCV molecule contains a pyrocatechol and an *o*-hydroxycarbonyl groups as well as a sulfo group in the third phenyl substituent and exists in different ionic forms depending on the acidity of the solution (Scheme 1).¹

The theoretical and experimental values of wavelengths of the absorption band maxima ($\lambda_{\max}$) of different forms of PCV are listed in Table 1. It is noteworthy that the band of the doubly ionised form could be identified only after the concentration of the reagent was increased to 8×10^{-4} mol litre⁻¹ (pH 13.0), while the analysis of alkaline solutions of PCV could be performed only after addition of 30 vol.% of acetone to suppress side reactions.¹

Table 1. Theoretical and experimental values of $\lambda_{\max}$ for different PCV forms.¹

Form of PCV	Existence conditions	$\lambda_{\max}$ /nm	
		theory	experiment
I (H_3R^-)	pH 1–6	450	450
II (H_2R^{2-})	pH > 7	591	600
III (HR^{3-})	pH > 9	646	650
IV (HR^{3-})	pH > 9	656	650
V (R^{4-})	0.5 mol litre ⁻¹ 40% NaOH	691	690
VI (H_5R^+)	0.5 mol litre ⁻¹ H_2SO_4 (conc.)	548	546

The hydroxy group of the Pyrocatechol fragment is ionised the first (ionisation of the SO_3H group is not taken into consideration), which results in a bathochromic shift of the long-wave absorption band. The appearance of the doubly ionised forms III and IV at pH > 9 with similar values of $\lambda_{\max}$ is equiprobable; however, with consideration of possible existence of an intramolecular hydrogen bond, the form IV is more likely. The triply ionised form V appears in strongly alkaline media.

Table 2. Dissociation constants of PCV ($c = 4 \times 10^{-5}$ mol litre⁻¹, $l = 1$ cm, $n = 5$, $P = 0.95$).¹

Dissociation step	$\lambda_{\max}$ /nm ^a	K	pK
$H_3R^- \rightleftharpoons H_2R^{2-}$	600	$(3.4 \pm 2.5) \times 10^{-10}$	9.48
$H_2R^{2-} \rightleftharpoons HR^{3-}$	650	$(3.7 \pm 2.2) \times 10^{-12}$	11.43
$HR^{3-} \rightleftharpoons R^{4-}$	690	$(2.9 \pm 2.1) \times 10^{-14}$	13.53

^a $\lambda_{\max}$ is related to more strongly ionised forms (right part of the equations).

The dissociation constants of the hydroxy groups are listed in Table 2. It has to be noted, however, that these data are not in full accord with those reported in Ref. 2 ($pK_{a1} = 7.82$, $pK_{a2} = 9.76$, $pK_{a3} = 11.73$).

Chelate-forming chromophoric organic reagents of the triphenylmethane series are Brønsted and Lewis bases. Therefore, studies of their complexation with metal ions should take into account the possible competition between the proton and the metal ion for the reagent. Partial protonation of analytically active groups of the polydentate ligand does not prevent its complexation with metal ions, but the protonation of the donor atom of the functional analytical group often makes this process impossible.

Hence, the reactivities of polydentate reagents of the triphenylmethane series with respect to metal ions in acidic media are largely determined by the formation of the protonated forms.

The attachment of the proton to the donor oxygen atom at pH 1 is a characteristic feature of PCV.

2. Effects of surfactants on acid-base properties of Pyrocatechol Violet

The acid-base properties of PCV are influenced by ionic strength, composition of the solution, the presence and the nature of organic co-solvents as well as the nature and concentration of surfactants. These factors determine also the optical characteristics of the reagents and complexes and stabilities of the latter.

Three types of effects were found to be responsible for enhanced sensitivities and selectivities of reactions in metal ion –

Scheme 1

reagent–surfactant systems and protolytic properties of the triphenylmethane reagents,^{3,4} such as Phenol Red, Cresol Red, *m*-Cresol Purple, Xylenol Blue, Thymol Blue, Bromophenol Red, Chlorophenol Red, Bromophenol Blue, Bromochlorophenol Blue, Bromocresol Purple, Bromothymol Blue, Bromocresol Green and Pyrocatechol Violet, containing different *ortho*-substituents relative to the phenolic OH group.

One of the effects is related to the increase in the number of coordinated ligands in the analytical forms. The second is associated with the activation by a cationic surfactant (CS), which enables complexation in more acidic media due to deprotonation of the heteroatom and formation of stable associates:

where LOH is the reagent and K_a is the association constant. In the presence of CS, determination of the dissociation constant (K_{dis}) is impossible due to competitive formation of the ionic associate. The absorption spectra of the reagents, in the presence of CS, contain additional bands of associates, therefore it is the association constant that is determined photometrically. It is usually shifted to a more acidic region as compared with pK for the dissociation of the corresponding acid group that is involved in the formation of the associate. Therefore, the complexation of such associates takes place in more acidic media in comparison with the corresponding ionic forms of the reagents. This effect, *i.e.*, the apparent pH shift of the dissociation of acid groups, should be distinguished from true changes in the properties of acid groups of the reagents induced, as a rule, by non-ionic surfactants. The reasons for this phenomenon are as yet little understood.

The third effect is connected with multisite interactions of polydentate ligands involving both chelating and auxochromic groups in the presence of CS. For example, the number of CS cations [*e.g.*, cetylpyridinium (CP)] that add to PCV is increased in the presence of metal ions, which is only possible where a proton of one of the auxochromic groups of PCV (most probably, the OH group at position 3, see Scheme 1) is replaced by a CP cation with formation of a chelate associate.

The pronounced effect of deprotonation of the auxochromic group at position 3 on the π -electron system of the reagent⁵ underlies the increase in the contrast of reactions in the presence of surfactants.

The higher the solution acidity the less pronounced the effect of deprotonation of the donor heteroatoms of the reagents and the greater the amount of CS required for the shift of the reaction equilibrium (1) to the left.⁴ It is possible to determine the acidity threshold below which no deprotonation takes place even at maximum possible concentration of CP that is much above the critical micelle concentration (CMC). For PCV, this value was equal to 4.5 mol litre⁻¹ of H₂SO₄; in 1% H₂SO₄, the deprotonation pK shift was 0.8. Analysis of this effect at CP concentrations from 10⁻⁵ to 10⁻² mol litre⁻¹ showed that the deprotonation at CP concentrations far below CMC was typical of all reagents containing sulfo groups.

If the reagent contains no sulfo groups, deprotonation occurs at [CP] $\geq$ CMC. At concentrations below CMC, the deprotonation is related with the formation of ionic associates involving sulfo groups. The formation of neutral associates of ionised forms of the reagents and CP cations was established by amperometry. Such associates are much more hydrophobic than the hydrated reagent ions. Therefore, the protonation of hydrophobic associates with CS under the action of H₃O⁺ species is hindered. The formation of ionic associates diminishes with a decrease in the solution acidity and an increase in CS concentration up to CMC, since dissociation of sulfo groups is suppressed and sorption begins to predominate.

In the presence of charged CS micelles, deprotonation of polydentate organic reagents obeys the Hartley rule⁴ and is reduced to primary sorption of negatively charged ions or neutral

species on the surface of positively charged CS micelles. In this case, the deprotonation is of sorption character and is described by the Langmuir saturation isotherm. Similar to formation of hydrophobic associates, this process is accompanied by a shift of the equilibrium (1) to the left, which is consistent with the viewpoint commonly accepted in colloid chemistry. Therefore, the deprotonation of reagents in the presence of CS takes place in both aqueous and micellar phases. The pK values for the deprotonation of PCV in the presence of different concentrations of cetylpyridinium chloride are given below:⁴

c_{CP} /mol litre ⁻¹	0	2×10^{-5}	4×10^{-5}	4×10^{-4}	1.2×10^{-3}
pK	0.86	0.78	0.54	0.03	0.02

The addition of CS with the length of the hydrocarbon chain C₁₂–C₁₆ to reagents of the triphenylmethane series at concentrations far below CMC (10⁻⁶–10⁻⁴ mol litre⁻¹) in a pH range corresponding to complete dissociation results in a pronounced (by 5–20 nm) bathochromic shift of the absorption band of H₂R²⁻. The effect of CS on the absorption spectra of the reagents in which only the sulfo groups dissociated was less apparent and was accompanied by a small hypsochromic shift of the absorption band.

Electronic and ¹H NMR spectroscopic studies of the effect of CP or cetyltrimethylammonium (CTMA) revealed⁶ that the appearance of a new band was due to the formation of reaction products of PCV with surfactants in a 1 : 2 ratio. In more acidic media, where the sulfo group dissociated, the ratio of the components was 1 : 1, as followed from the results of elemental analysis of solid products. As the length of the non-polar radical increases, the associates become more stable, since counterions are bound by both electrostatic and hydrophobic interactions.

From the practical viewpoint, the shifts or redistribution of absorption band intensities in the spectra of triphenylmethane dyes upon interactions of their anionic forms with polymeric cationic flocculants [*e.g.*, poly(diallyldimethylammonium) chloride] with formation of non-extractable ionic associates can be employed in spectrophotometric determination of microgram quantities of flocculants in aqueous solutions; the use of the addition method is recommended to minimise the effects of admixtures.⁷

The concentration of a surfactant strongly affects the solubility of ionic associates. Its 1.5–3-fold increase in comparison with the stoichiometric ratio of the associate components prevents formation of a solid phase consisting of aggregated species of the associate. This results from dispersion of the associates upon attachment of several additional surfactant cations owing to hydrophobic interactions. The charged ionic associates containing overstoichiometric surfactant ions are sometimes referred to as mixed micelles. The effects of added inorganic salts on the ionic associates of sulfophthaleins and CS have been studied.⁶ The nature of a strong electrolyte anion is important. If the electrolyte anion interacts with CS to form its own ion pair CS⁺–An⁻ (An⁻ = NO₃⁻, Br⁻, I⁻ or ClO₄⁻), the CS–reagent associate is destroyed under the competitive action of An⁻. The addition of salts with anions that weakly react with CS brings about abnormal effects of ionic strength: at a concentration of anions in a solution as high as 0.1–0.5 mol litre⁻¹, the associates are either not destroyed at all or the decrease in their concentration is much less than is expected for compounds with an ionic type of bonds.

Two approaches to modification of organic reagents by surfactants can be noted, *viz.*, preparation of ionic associates and solubilisation in micelles. This allows conversion of common organic reagents into new in principle, more efficient compounds possessing quite different analytical properties. The first route is typical of ionogenic surfactants and reagents that dissociate in aqueous solutions. The formation of the corresponding ionic associates can be predicted. The second route is largely known for non-ionic surfactants; it is still little studied and is virtually unpredictable.

Despite such a complex behaviour of PCV in solutions with different pH, this reagent easily modifies organic or inorganic supports, which makes rather promising the application of its kinetically labile complexes in test methods. The absorption bands of aqueous solutions of H_3R^- , H_2R^{2-} and HR^{3-} correspond to the bands in the diffuse reflectance spectra of the same forms.⁸ However, the absorption band of H_3R^- adsorbed on the anion-exchange resin AV-17 in the diffuse reflectance spectrum of the PCV sorbate was shifted towards longer wavelengths by 20 nm in comparison with the band characteristic of aqueous solutions of this form. The sorption of the H_3R^- form on AV-17 occurs at pH 1–4; at higher pH values, dissociation of the hydroxy groups takes place. The spectral characteristics of the dissociated form H_2R^{2-} are changed thereupon. The $F = (1 - R)^2/2R$ vs pH curve (R is the diffuse reflectance coefficient) displayed a minimum at pH 6.5 due to the superposition of the absorption spectra of H_3R^- and H_2R^{2-} .^{8,9} The sorption of the doubly charged form of PCV is weaker in comparison with the singly charged form, apparently due to delocalisation of the charge generated upon deprotonation of the OH group. It is of note that PCV sorption is irreversible: the reagent is only partly desorbed in strongly acidic solutions and is not desorbed at all in strongly alkaline solutions.

III. Pyrocatechol Violet as a complexometric indicator

The use of PCV as a complexometric indicator was studied in the presence and in the absence of the cetyltrimethylammonium ion.¹⁰ It is commonly known that the sensitivity and the contrast of the colour reaction are crucial in the choice of an indicator for complexometric titration. Besides, the complexes formed must be highly stable with respect to exogenous substances (*e.g.*, buffer components), but less stable than the metal complex with EDTA. Titration should be carried out at the lowest possible values of pH where the logarithm of the conditional stability constant of the complexate is ≥ 7 to increase selectivity. In fairly acidic media (pH 1–2), PCV forms coloured complexes with some metal ions; however, its reactions with many metals proceed effectively only in weakly acidic media (pH 5–6). Only metal ions that do not form stable complexes with fluoride ions can be used as titrants for reverse titration in the presence of fluorides; thus, Sc, Th, Zr, Ti(IV), Al and REE salts cannot be used. Chelates of many metals that form unstable fluoride complexes possess fairly high conditional stability constants in the presence of fluorides; however, coloured PCV complexes with these metals are stable in the presence of fluorides not at all pH values. At high pH values where the metal–PCV complexes possess high conditional stability constants they are stable in the presence of fluorides, but are destroyed at low pH values where the conditional stability constants are low. As is known, pH has little effect on the stabilities of fluoride complexes but strongly affects the stabilities of metal complexes with triphenylmethane dyes (including PCV). In many cases, the use of an NH_4F – H_3BO_3 mixture instead of NH_4F enables efficient titration even at low pH values, since the concentration of free fluoride ions in the solution decreases drastically due to formation of the complex ion BF_4^- . The metals that can be determined by complexometric titration with PCV in the absence and in the presence of cetyltrimethylammonium¹⁰ are listed in Table 3; the use of ternary complexes makes the titration more sensitive in a broader range of contrast of colour change than with PCV alone.

At present, further development of complexometric titration with PCV takes place. It was proposed to fix the titration endpoint automatically by monitoring the changes in chromaticity characteristics, such as L , A and B (tristimulus coordinates in the *CIELAB* system), ΔE , W and G (total colour difference, whiteness and yellowness indices, respectively) and ΔS (colour saturation difference):

$$\Delta S = S_o - S_{rs},$$

Table 3. Conditions for complexometric titration of metals with PCV in the absence and in the presence of cetyltrimethylammonium.

Metal	In the absence of CTMA			In the presence of CTMA	
	pH	buffer solution, supplementary conditions	colour change	pH	colour change
Bi(III)	2–3	HNO_3	blue–yellow	2	blue–red–yellow

where S_o and S_{rs} are the colour saturations of the tested and reference samples, respectively.¹¹ Methods have been developed for determination of Zr(IV) (Ref. 12) (where PCV is used together with other indicators), Cu(II) (Ref. 13) and Ni(II).¹⁴ A solution of the opposite problem, *i.e.*, determination of aminopolycarboxylic acids, such as nitrilotriacetic acid and EDTA, in natural waters, is also possible.¹⁵ These acids induce a bathochromic shift of the optical density maximum (580 nm) of a red coloured bismuth complex with PCV, which allows measurements of their concentrations in the range from 0.02 to 1.2 mmol litre^{−1}; other chelating reagents are masked with yttrium; the interference due to ions is suppressed by oxalic, citric and acetic acids.

IV. Pyrocatechol Violet as a reagent in optical methods

1. Binary Pyrocatechol Violet complexes with metal ions

PCV complexes with some metal ions have been investigated since the middle of the 20th century and described in numerous publications. However, in the majority of cases the complexation was studied in a narrow range of pH values. The spectrophotometric characteristics of these complexes are listed in Table 4.

As can be seen from Tables 1 and 4, the bathochromic shift of the absorption band in the complexation of PCV with the majority of metal ions listed exceeds 100 nm; the reason for the hypsochromic shift in a neutral medium for aluminium, gallium and indium remains obscure.²⁰ The molar extinction coefficients of copper, zinc, cadmium, scandium and vanadium complexes are small.

The complexation of PCV with aluminium was studied in most detail; this reagent was used for spectrophotometric determination of this metal in sea and underground waters as well as in industrial wastes (2–500 µg litre^{−1}, pH 6.1, urotropin buffer,

Table 4. Spectrophotometric characteristics of binary metal complexes with PCV.

Metal	$\lambda_{\max}$ /nm	pH _{opt} (see ^a)	$10^{-4} \epsilon$ (log β)	Ref.
Cu(II)	580	6	0.54	10
	630	5	— (8.42)	16

Pb(II)	570	6	1.0	10
	585	6	1.83	10

^a pH of the maximum complexation.

$\lambda_{\max}$ = 580 nm). It was shown²⁰ that PCV forms complexes with aluminium with the stoichiometry (*i.e.*, the metal : reagent ratio) from 3 : 1 to 1 : 5, gallium (from 2 : 1 to 1 : 5) and indium (from 3 : 1 to 1 : 1) as true solutions in several narrow intervals of pH values. In the case of indium, the formation of 2 : 3 complexes, which represent mixtures of 1 : 1 and 1 : 2 complexes, was possible with insufficiently pure PCV. The equilibrium in the reaction of Al(III) with PCV in aqueous solutions was studied.^{20, 22–24}

The coordination of PCV involves both quinonoid and *ortho*-dihydroxy fragments. At pH < 4.5, Al(III) ions, like Ga(OH)²⁺ ions,^{23, 24} displace one proton from each of two reagent molecules, since the metal : PCV ratio in the complexes is 1 : 2; higher pH values favour the formation of complexes with different ionic forms of PCV. In the intermediate range of pH, the coordination in the complexes involves both groups. The construction of the distribution diagram of complexes *vs* pH demonstrated that stoichiometric (1 : 2) complexes predominate at pH 5.6–6.5; this can be utilised in spectrophotometric determination of gallium and aluminium in natural waters. Computer simulation of conditions for the determination of aluminium ions revealed that in the given range of pH and in the presence of small excess of PCV the measurement error due to the formation of colloidal gibbsite species is minimum. A procedure for flow-injection spectrophotometric determination of total reactive aluminium in natural waters and other objects was developed.²⁵ It was found²⁶ that at pH 6.2 the rate of the reaction of aluminium with PCV strongly depended on the presence of competing ligands, such as oxalate, malonate, fluoride, salicylate, citrate and humic acids; the equilibration time was 10 min.

The mechanism and thermodynamic and kinetic characteristics of the reaction of indium with PCV were established by the temperature-jump method with the use of laser emitters.²⁷ Spectrophotometric measurements showed the predominant formation of (InH₃R)²⁺ and (InH₂R)⁺ species at [H⁺] > 0.015 mol litre^{−1} and of (In₂R)²⁺ species at [H⁺] < 0.015 mol litre^{−1}. Two relaxation effects were observed. Fast relaxation was associated with the reactions:

while slow relaxation was associated with the formation of (In₂R)²⁺. The electronic absorption spectra of gallium–PCV complexes in the absence and in the presence of electrolytes were studied.²⁸ It was found that the light absorption by a solution depends on the nature of the anion and the cation of the electrolyte.

On the whole, the utilisation of PCV–metal binary complex formation for analytical purposes is limited due to low reaction selectivity, narrow range of optimum pH values and, sometimes, by low molar extinction coefficients. Several approaches aimed at eliminating these drawbacks were proposed. One of them consists of a search for a third component of the complexes the introduction of which into the reaction system might significantly improve the spectrophotometric characteristics of the latter and increase the selectivity of the determination (see Section IV).

The second approach consists of preliminary separation of the tested element by extraction²⁹ or sorption^{30–32} on appropriate supports with subsequent re-extraction or desorption and determination in aqueous or organic phases using PCV. Alternatively, it is complexes with PCV that are extracted^{33, 34} or absorbed^{31, 32, 35–37} with subsequent determination of metals, as a rule, by spectrophotometric,^{29–31, 33, 34} atomic absorption^{32, 35–37} or atomic emission³² methods. Thus tin(IV) was extracted with tris(2-ethyl)hexyl phosphate in toluene;²⁹ the linearity range of the calibration curve (CC) was 10–100 $\mu\text{g ml}^{-1}$, the detection limit was 0.4 $\mu\text{g ml}^{-1}$. PCV complexes with Ga, Al, In³³ and Zr³⁴ were extracted with solutions of caproic (HL) and propionic (HA) acids in chloroform (Table 5). The linearity range of CC for gallium and aluminium determinations was 0.1–1.7 $\mu\text{g ml}^{-1}$; 100-fold concentrations of indium, 5-fold concentrations of bismuth and 10-fold concentrations of copper did not interfere with the determinations. It is noteworthy that PCV itself is extracted only by caproic acid, the extraction constant (K_{ex}) being equal to $(6.7 \pm 1.8) \times 10^3$.

The following schemes for the formation of extracted compounds were proposed [the subscripts (a) and (o) designate the aqueous and organic phases, respectively]: for PCV (H₃R[−])

**Table 5.** Extraction of PCV–metal complexes.

Metal	$\lambda_{\max}$ /nm	pH _{opt}	$10^{-4} \epsilon$	K_{ex}	Extractant (M : PCV ratio within the complex)
Al(III)	585	6.5–7.2	3.7	$(1.8 \pm 0.1) \times 10^{11}$	propionic acid (1 : 2)
Ga(III)	585	6.2–6.5	2.5	$(1.4 \pm 0.3) \times 10^4$	caproic–propionic acid mixture (1 : 1)
Zr(IV)	600	6.2–6.5	2.6	4.3 ± 0.5	caproic–propionic acid mixture (1 : 1)

for Ga(III)

for Al(III)

for Zr(IV)

Preconcentration of lead in its determination in atmospheric air and construction materials was performed using Polyorgs VII as the sorbent;³⁰ the sorption time was 10 min and desorption was performed with 0.1 M acetic acid. Tin was determined in zinc ingots using the anion-exchange resin Dowex 2 × 4;^{31,32} this was combusted and the ash was dissolved in nitric acid.

Direct sorption of metal–PCV complexes was carried out on the anion-exchange resins Dowex 2 × 4^{31,32} or XAD-2 (for determination of Zn, Cd, Pb and Ni).³⁵ A procedure for preconcentration in the determination of trace amounts of Cu, Mn, Cd, Pb, Ni and Cr in potable water was developed,³⁶ which consisted of sorption of complexes with PCV on a column with an anion-exchange resin at pH 4–8 and elution with 1 M nitric acid in acetone; the detection limits for Cd and Cr were < 0.1 and 1 µg litre⁻¹, respectively. A possibility of preconcentration of Cu, Ni and Zn on a PCV-modified cation-exchange resin with subsequent regeneration of the resin at pH 12 or with 3 M KCl was investigated.³⁷

2. Interactions of Pyrocatechol Violet with anions

Reactions of this type are documented.^{38–40} Procedures were developed for spectrophotometric determination of anions based on oxidation of PCV with halogens. The latter oxidise PCV whereupon its colour fades. Thus for BrO₃⁻ the conditional $\varepsilon = 3.7 \times 10^4$, $\lambda_{\text{max}} = 557$ nm, the linearity range of CC is 0.1–1.3 µg ml⁻¹ (Ref. 38); the anion:PCV stoichiometric ratios for I⁻ and Br⁻ are 1:5 and 1:3, respectively; the detection limit for iodide ions is 0.0006 µg ml⁻¹ (Ref. 38); for ClO₂⁻, the ClO₂⁻:PCV ratio is 1:2; chloride, nitrate, sulfate, phosphate, carbonate, perchlorate and arsenate ions are not interfering, but the bromide ion interferes with the reaction course;³⁹ a method for determination of oxalic acid in food substances, which is based on enhancement of PCV oxidation by dichromate, has been described.⁴⁰

3. Mixed-ligand complexes and ionic associates

As mentioned above, the use of two-component complexes of PCV with metal ions for analytical purposes often faces problems. Mixed-ligand complexes and ionic associates hold more promise for spectrophotometric determinations, since they are more stable, better extracted and demonstrate larger bathochromic shifts; in some cases, the selectivities are higher. Thus a ternary zirconium complex with PCV and EDTA with a component ratio Zr:PCV:EDTA = 3:2:3 was described⁴¹ as early as 1968 and a method for determination of zirconium was developed. Since 1962, yttrium has been determined in the presence of some rare-earth elements (Pr, Nd, Ce, La)⁴² using a red coloured boron–pyrocatechol complex (BPCC) with a component ratio Y:BPCC = 1:1; the linearity range of CC is 0.9–4.5 µg ml⁻¹ for yttrium; $\varepsilon = 1.85 \times 10^4$ (590 nm) and 1.90×10^4 (607 nm). Ce(IV) and La(III) ions also react with BPCC, but the complexes formed are less stable. The interfering effect of lanthanum was eliminated by addition of boric acid, that of cerium, of hydrogen peroxide. Of substantial interest for further investigations are synergistic effects in the formation of ion–metal associates with PCV and Rhodamine 6G or Rhodamine B (Table 6).^{43–45}

Table 6. Some characteristics of metal complexes with PCV in the presence of Rhodamine 6G.

Metal	λ_{max} /nm	pH _{opt}	10 ⁻⁴ ε	Linearity range of CC /µg ml ⁻¹	Subject of analysis	Ref.
Al(III)	580	6.5	6.8	0–0.28	gramineal plants	43
Ti(IV)	560	5.0	7.6	0.08–0.48	alloys	45
Sn(II) ^a	560	5.0	11.8	0–0.6	canned fruits, steel samples	44

^a In this case, as a complex with PCV and Rhodamine B.

The complexation of PCV with titanium(IV) was studied in the presence of diantipyrylmethane (DAM).⁴⁶ It is known¹⁰ that aluminium and copper ions interfere with determination of titanium with PCV (see Table 4). The addition of DAM to the reaction system enables determination of titanium in the presence of a 300-fold (with respect to titanium) excess of aluminium and a 150-fold excess of copper. The formation of the Ti–PCV–DAM complex was characterised by a high range of contrast ($\lambda_{\text{max}} = 610$ nm, pH_{opt} 1.4–2.4, $\varepsilon = 2.00 \times 10^4$); the Ti:PCV:DAM ratio was 1:2:2; the linearity range of CC was 0.2–1.9 µg ml⁻¹; the stability constant of the complex was $(4.00 \pm 0.09) \times 10^{19}$. Titanium reacted with PCV and DAM according to the following scheme:

It was demonstrated that the role of a coordinating ion is played by Ti(OH)_i³⁺, which displaces one proton from each PCV molecule (*i.e.*, $i = 1$, $n = 1$). DAM is bound to two OH groups of PCV through the carbonyl oxygen. A tentative structure of the complex formed was proposed.⁴⁶

Heterocyclic bases (HetB), *e.g.*, quinine,⁴⁷ 2,2'-bipyridine⁴⁸ and 1,10-phenanthroline, were used as third components in mixed-ligand complexes of PCV with metals.^{49–51} Compounds formed were insoluble or poorly soluble in water; the addition of gelatin brought about their stabilisation. A gallium complex with PCV and quinine was formed in a very broad pH range ($5 < \text{pH}_{\text{opt}} < 10$); the component ratio for the Ga:PCV:quinine complex was 1:2:1, $\lambda_{\text{max}} = 680$ nm, the linearity range of CC was $(0.2–2.0) \times 10^{-5}$ mol litre⁻¹; this could be used for the determination of both gallium and quinine.⁴⁷ 2,2'-Bipyridine⁴⁸ (pH_{opt} 3–3.5, Ge:PCV:2,2'-bipyridine = 1:2:3, $\lambda_{\text{max}} = 610$ nm) was used as a third component in the germanium complex with PCV; the solubility product was $(1.04 \pm 0.02) \times 10^{-32}$; $\varepsilon = (3.08 \pm 0.25) \times 10^4$. In this case, amine-type compounds $[\text{Ge}(\text{OH})_i(\text{H}_3-n\text{R})_2 \cdot (\text{HetB})_3]^{4-i-2-2n}$ are formed characteristic of reactions with amines as bases.

In the presence of 1,10-phenanthroline (Phen), the aluminium–PCV complex is formed at pH_{opt} 6.15; $\lambda_{\text{max}} = 590$ nm; the detection limit for aluminium is 20 µg litre⁻¹. A procedure for determination of total concentrations of monomeric aluminium in natural waters and soil extracts has been developed.⁴⁹

Vanadyl complexes with PCV and 1,10-phenanthroline⁵⁰ or cetylpyridinium bromide (CP-Br)⁵¹ were investigated and the possibility of their extraction was examined. The main characteristics of the complexes formed in aqueous and organic media are listed in Table 7. EPR studies revealed that the complex contained V(IV). The following complexation equation was proposed:⁵⁰

It was found that the character of formation of ionic associates in the presence of CP-Br strongly depends on pH. In acidic media,

as with PCV–Phen associates, cetylpyridinium binds to the SO_3^- group of PCV, as can be judged from the similarity of their absorption spectra. In aqueous (pH 6.4) and organic media, PCV reacts with CP-Br differently. Although under the given conditions the PCV molecule exists in a singly ionised form (H_3R^-), the hydroxy group of the pyrocatechol residue is in a pre-ionisation state. Loosening of the O–H bond occurs under the action of cetylpyridinium, which enables substitution of the cetylpyridinium cation for the hydrogen of the hydroxy group. This group favours additional delocalisation of π -electrons of PCV, resulting in a pronounced bathochromic shift of the absorption band of PCV. In the organic phase, the second CP-Br molecule is bound to the sulfo group of the reagent, owing to which the extraction of the ionic associate PCV-CP is possible.

The extractability of the complexes can also be enhanced by addition of guanidine (GU) ⁵² or diphenylguanidine (DPG) ^{17, 39, 53–56} to the metal–PCV reaction system (Table 8). Spectrophotometric and IR-spectroscopic studies as well as quantum-chemical calculations revealed that metal ions displace one proton from each PCV molecule in the formation of ternary complexes with GU or DPG; the coordination of the metal occurs with the *o*-hydroxyquinone group of PCV. The PCV polyassociates are destroyed under the action of GU and DPG, which, acting as bases, block the free sulfo and hydroxy groups. It is noteworthy that GU is a more efficient partner for ions with smaller ionic radii, while DPG is more suitable for extraction of ions with larger ionic radii in reactions with the same triphenylmethane dye; the differences between the properties of individual elements are eliminated upon addition of surfactants. The follow-

ing complexation reactions have been proposed for aluminium, ⁵³ tin ⁵⁵ and bismuth ⁵⁶ (Sol is a solvent):

Mixed-ligand complexes of metals with triphenylmethane dyes (including PCV) and quarternary ammonium salts (QAS) hold a special place. Their advantages include high molecular mass, pronounced basic properties and the fact that they do not form complexes directly with metals. This determines their more unambiguous reactions and rules out competitive effects of other cations. Mixed-ligand complexes of PCV with iron ⁵⁷ or molybdenum ⁵⁸ and dialkylbenzylmethylammonium chloride were obtained as long ago as 1968–1970. The methods for determination of metals (Groups 3–14 of the Periodic Table) based on the use of heteroligand complexes with triphenylmethane dyes and QAS are known (Tables 9 and 10). The formation of these

^a In these cases, as complexes with guanidine; in other cases, as complexes with diphenylguanidine.

complexes is accompanied by pronounced bathochromic shifts; however, the absorption maxima are usually shifted hypsochromically with an increase in triphenylmethane dyes concentration. This accounts for different $\lambda_{\max}$ values for a mixed-ligand complex of the same element reported by different authors. Contrary to the common opinion that the formation of mixed-ligand complexes is maximum at lower pH values than that of homoligand complexes, the complexation with triphenylmethane dyes and QAS occurs at nearly the same pH values, the number of coordinated triphenylmethane dye molecules in mixed-ligand complexes being larger.⁶⁷

The number of coordinated QAS ions is often not given, only the metal:PCV ratios are determined. But even if this number is indicated, it is most likely approximate. The determination of the metal:QAS ratio requires preparation of a panel of solutions containing different concentrations of QAS, while solutions with low concentrations of QAS are usually turbid; therefore, experimental determination of the component ratios cannot be exact. It is known that physicochemical properties of compounds (including solubility) change upon formation of complexes with various ligands. For the compounds under consideration, in the formation of mixed-ligand complexes their solubilities first decrease and then increase. This can be explained by the stepwise complexation, *viz.*, the formation of a less soluble mixed-ligand complex with a smaller number of coordinated ions of the second ligand is

followed by the formation of a more soluble complex with a larger number of coordinated ions. One can draw an analogy between mixed-ligand metal complexes with triphenylmethane dyes and QAS, on the one hand, and some metal complexes with inorganic ligands (hydroxide, halide, cyanide ions, *etc.*), on the other hand, where the formation of metal hydroxide, halide or cyanide residues is followed by their dissolution with a further increase in the ligand concentration. The effect of micelle formation of QAS on the state of PCV, in particular, on the degree of its dissociation, was discussed above. The properties of mixed-ligand complexes depend, to a certain extent, on the nature of QAS as can be evidenced from the differences in the $\lambda_{\max}$ values and molar extinction coefficients (see Tables 9 and 10); this can also be explained by different effects of QAS on the dissociation of triphenylmethane dyes. Physicochemical analysis showed⁶⁷ that mixed-ligand complexes have permanent compositions due to formation of ionic associates. A positively charged ion or a QAS micelle is bound to a negatively charged metal–PCV complex by electrostatic forces, which brings about changes in the conjugation chains and absorption spectra. Then the ammonium salt of the anionic complex is dispersed in the excess of the surfactant and, contrary to binary PCV–metal complexes, can be extracted by organic solvents. However, virtually no increase in the sensitivity occurs, although the selectivity of metal determination can some-

times be slightly increased through the adequate choice of a solvent.

4. The use of mixed-ligand Pyrocatechol Violet – metal complexes in the analysis of miscellaneous objects

Methods for determination of tungsten,^{65,81} chromium,⁷² titanium^{65,73,74} and molybdenum⁸⁰ in steels, of lanthanum in silver alloys,⁷¹ of gallium in GaAs–GaSb films,⁷⁰ of tin in bronzes⁶⁵ and aluminium ingots⁷⁹ as well as in metals and various biological objects⁸² are developed. The use of PCV complexes in the analysis of pharmaceutical substances is promising as well, *e.g.*, for determination of fluoxetine and fluvoxamine,⁸³ imipramine⁸⁴ and chlorpromazine hydrochloride.⁸⁵ Aminoglycoside antibiotics⁸⁶ react with PCV and aluminium at pH 3.0 to yield mixed-ligand complexes with the stoichiometry Al:PCV:antibiotic = 1:1:3 (monomycin and canamycin) and 1:1:4 (streptomycin and gentamycin); the linearity range of CC is 0.02–50 µg per ml of a biological fluid. These determinations can be carried out in the presence of 10⁴-fold excesses of tetracyclines, penicillins, amino acids, novocaine and nitrates. Of particular interest are methods for determination of proteins based on their interactions with PCV in the presence of Triton X-100 (pH 1.4–2.0)⁸⁷ (the linearity range of CC for bovine serum albumin or human blood serum content is up to 8.0 and 9.0 mg litre⁻¹, respectively) or in the presence of tin(IV);⁸⁸ the latter allows determination of down to 200 µg of albumin in 10 ml of biological fluids.

5. Novel optical methods

The concentration of a tested element or a compound in natural and biological objects is usually insufficient for its spectrophotometric measurement. As stated above, the introduction of a third component and preparation of a mixed-ligand complex is a way to enhance their chemical and analytical characteristics. An alternative approach to the increase in sensitivity of determinations is a search for novel methods of analysis and their optimisation. Rapid analyses performed under field conditions demand elaboration of easy-to-use novel versions of optical methods based on solid-phase spectrophotometry, which combines preconcentration of a complex on an appropriate sorbent with spectrophotometric determinations.

Sorption of PCV–gallium complexes in the presence of quinine on the cation-exchange resin KU-2 with subsequent solid-phase spectrophotometric analysis was studied as long ago as 1973;⁴⁷ sorption of 14 metals except for alkali metals and calcium complexes on silica gel impregnated with a PCV–Aliquat 336 mixture was demonstrated in 1994.⁸⁹ It is possible to determine metals by solid-phase spectrophotometry, which includes sorption of binary aluminium PCV complexes⁹⁰ on AV-17 or Amberlite IRA-458-Cl (pH 3–7) and of tungsten⁹¹ and molybdenum⁹² PCV complexes on Sephadex QAE-A-25 (the detection limit was 2–8 ng ml⁻¹).

Other promising methods for the solution of this problem include diffuse reflectance spectroscopy (DRS)⁹³ and chromaticity measurement.^{9,11,94} The latter can be regarded as a next stage in the development of DRS (particularly, with regard to colour characteristics). This opens up new opportunities for improvement of the sensitivity of determination and development of simple rapid test methods.^{95,96} Of special interest are procedures and techniques, which combine detection of an element owing to formation of coloured compounds, their preconcentration on various supports and determination in the sorbent phase without desorption, *e.g.*, by DRS, or semi-quantitative colorimetric determinations based on special scales built with the use of reference samples. Both methods are complementary: DRS allows investigation of chemical and analytical properties of sorbates, while colorimetry ensures rapid and inexpensive semi-quantitative production tests.

Thus a DRS procedure for determination of molybdenum(VI) (pH 1.5–3.5) and tungsten(VI) (pH 1–3) was developed, which includes sorption on a chemically modified silica S-80 containing

propionamidoxime and propionhydroxamic acid⁹⁷ or propylamine⁹⁸ residues with subsequent treatment with PCV.^{97,98} Complexation in aqueous solutions and on the surface of adsorbents occurred under identical conditions, but the spectral characteristics of the complexes differed considerably. As it was mentioned, the complexation mechanism and chemical and analytical characteristics of the complexes can change depending on the chemical nature of surfactants, whereas the properties of the ‘metal–chromophoric reagent–sorbent’ system were very similar to those of metal–chromophoric reagent–CS complexes. The complexation can thus be represented as follows. In the sorption step, MoO₄²⁻ and WO₄²⁻ form ionic associates with the protonated amino groups of the sorbent. Subsequent treatment of the latter with PCV yields PCV complexes with metal ions, which bind to the sorbent surface. The formation of ionic-associative bonds between the functional groups of PCV that are not involved in the coordination to the metal ion and the protonated amino groups of the sorbent results in more rigid structures of complexes. This brings about delocalisation of π -electrons and a shift of the absorption maximum towards the longer wavelength region [*e.g.*, $\lambda_{\max}$ for aqueous solutions of PCV at pH 1–5 is 480 nm, $\lambda_{\max}$ for aqueous solutions of molybdenum–PCV complexes at pH 2–5 is 560 nm, $\lambda_{\max}$ for the sorbent was 660 (Ref. 97) or 610 nm,⁹⁸ *i.e.* the bathochromic shift was 130–180 nm]. A similar effect was observed in the sorption of the molybdenum(VI)–PCV complex on the anion-exchange resin AV-17.⁸ Assuming that the effect of anion-exchange resins is similar to that of CS, it was expected⁹ that the sorptive effect would be enhanced after addition of a surfactant (CTMA). However, because of the competition⁹ between the anion-exchange resin and CTMA, the AV-17 resin had to be replaced by a neutral sorbent (Silochrome S-120). The bathochromic shift thereupon amounted to 230 nm, while the sensitivity of the determination increased owing to the use of chromaticity characteristics. These results were used for the development of novel test methods⁹ and fibre-optical sensors based on PCV. In a recently developed iron-specific fibre-optical sensor in which Sephadex DEAE is used as a sorbent and PCV, as an immobilised indicator,⁹⁹ the formation of a metal complex is accompanied by changes in the diffuse reflectance spectra at 460 nm.

V. Conclusion

As can be seen from the literature data, Pyrocatechol Violet is a valuable analytical tool and a popular reagent for classical (as a metal indicator in complexometry) and physicochemical (optical) methods of analysis. High reactivity of PCV is determined by its functional and analytical groups. The complexation of PCV involving these groups yields mixed-ligand compounds; this process can be controlled by introducing additional reagents or changing the solution acidity. The presence of a sulfo group favours the formation of ionic associates with cationogenic surfactants, whereas the non-compensated charge of binary complexes favours the formation of mixed-ligand complexes some of which are extracted by organic solvents.

Chromaticity offers new opportunities, especially in combination with sorption (sorption chromaticity) and diffuse reflectance spectroscopy. Being a representative of the triphenylmethane group and a close analogue of Pyrogallol Red (PGR), Pyrocatechol Violet is a conformationally active compound. Large molar extinction coefficients of ionic forms of both reagents and very high molar coefficients of chromaticity functions of PGR^{100,101} suggest high perspectiveness of PCV chromaticity, especially of its sorption chromaticity version. As regards specific characteristics, PCV complexes share many common features with PGR complexes with molybdenum,¹⁰² copper and titanium,¹⁰³ tungsten and vanadium(V),¹⁰⁴ tin(IV) and aluminium¹⁰⁵ as well as other metal ions. Determination of chromaticity characteristics of molecular and ionic forms of PCV will permit one to rationalise the choice of complexation conditions aimed at

the development of new optical methods for determination of various ions. Taking into account the discrepancy between literature data, it seems interesting to specify the values of dissociation constants of PCV using the chromaticity method. An objective confirmation of high practical utility of PCV as an analytical tool for advanced optical measurements can be derived from the values of molar coefficients of chromaticity functions of soluble complexes and sorbates.

Studies of chromaticity characteristics of PCV–metal complexes on the surface of anion-exchange resins and neutral sorbents in the presence of CS aimed at increasing the sensitivity of determinations and development of new, more efficient test scales and optical sensors is the most promising approach to their further application.

Analytical chemistry and chemical analysis

Analytical chemistry is often identified with chemical analysis. Nevertheless, the relationship between the analytical chemistry and chemical analysis is much the same as that between medical science and medical practice.

Modern analytical chemistry can be defined as a science concerned with the development of general approaches, methods and tools for the study of chemical compositions of substances and analysis of objects; chemical analysis is restricted to acquisition of information about chemical compositions of substances.

Chemical analysis is an essential tool for qualitative estimation of miscellaneous products and control over environmental objects and technological processes; besides, it is a valuable diagnostic tool in medicine. It is used in routine criminalistic studies and military practice. The conclusions in many sciences, such as molecular biology, geochemistry, chemical kinetics, *etc.*, are based, to a great extent, on the results of chemical analysis.

On the global scale, the number of analyses can be indirectly estimated, if one recalls at least some wide spread analyses, *e.g.*, measurements of carbon, phosphorus and sulfur in melted steels; of aromatic hydrocarbons and sulfur in natural oils and petroleum products; of carbon monoxide and hydrocarbons in motor car exhausts; of chlorine in swimming pool water; of pH levels in soils; of moisture content in grains and of fat content in milk, and, finally, analyses of blood and urine samples in clinical laboratories.

The range and complexity of problems facing chemical analysis and, as a consequence, analytical chemistry as a science, are steadily increasing with an increase in the number of subjects to be analysed. Who, in the middle of the 20th century, might surmise that the objects for investigation in molecular biology, biochemistry, biotechnology and, perhaps, contemporary medicine would occupy an important place among objects for analytical investigations; that the necessity of analysing complex oxides would emerge in connection with the discovery, in the 1980's, of high-temperature superconductivity; that rapid development of electronic engineering would place high-purity elements into the group of most important and most difficult objects of chemical analysis?

The number of problems facing chemical analysis and control over 'classical' objects and the new ones that constantly appear is also increasing. One of them, related to the increase in the number of components to be identified and characterised, demanded novel analytical methods for its solution. Thus inductively coupled plasma atomic emission spectroscopy (ICP-AES) made simultaneous measurement of 30–40 elements a routine practice, while the use of ICP-mass spectrometry made possible simultaneous determination of 60 elements at a sufficiently high level of sensitivity. Gas chromatography on capillary columns enables detection and, to some extent, quantitation of several hundred components of tested objects (*e.g.*, over 400 components were identified in coffee aroma). This list is far from being complete, and the problems continue to emerge over and over again.

In recent years, a demand arose for local (distribution) analysis as an alternative to bulk analysis, since in many objects the analysed components are characterised by non-homogeneous or non-uniform distribution over the thickness of the sample. The necessity to solve this task led to the development of complex and

expensive instrumental methods, such as electronic probe, X-ray electron and Auger spectroscopy, sophisticated versions of mass spectrometry, *etc.* It can be expected that the range of problems to be solved by distribution analysis will continue to expand in the future.

Problems demanding non-destructive analysis of specimens (*e.g.*, material exhibits, archeological finds, medieval paintings, *etc.*) arise regularly in some other fields, *e.g.*, technology, criminalistics, archeology, fine arts, science, *etc.*, aimed at prolongation of their functioning where required. Today, these problems are solved with either the help of X-ray fluorescence analysis, radioactivation method (in the case of short-lived radioisotopes) and IR spectroscopy or techniques producing minute destruction (electron probes, atomic emission analysis, *etc.*). There is no end to work here, and novel simple and inexpensive original procedures are required.

As time goes on, the need for continuous analysis (*e.g.*, on-line downstream analysis of sea water or express analysis of ore on a conveyor belt) as well as remote analysis (*e.g.*, control over technological processes involving radioactive or highly toxic substances or examination of extraterrestrial objects) is increasing. This is the scope of spectroscopic and electrochemical methods. However, challenging (or altogether intractable) problems of remote analysis still exist and tomorrow they will be even more numerous.

Throughout its history, analytical chemistry was trying to solve problems connected with increasing the sensitivity, accuracy, selectivity and rapidity of analysis and not without advantage. Today, there is seemingly no need in ultraprecise methods; the level of precision attained is usually very high. However, with consideration that practical requirements are changing continuously, the analysts must be ahead of time while developing ultraprecise methods for analysis.

On the other hand, it is not always necessary to perform multicomponent determinations. Sometimes, it is sufficient to establish a common parameter (the so-called integral index), which represents a cumulative effect of the whole gamut of the components. For instance, natural potable water can contain phenols, which are disagreeable by themselves, but especially hazardous are the toxic organochlorine compounds formed upon chlorination of water with participation of phenols. The detection of diverse phenolic species (nitrophenols, cresols, *etc.*) and, particularly, quantitation of each of them is a labour- and time-consuming process, at the least. However, their presence and total content can be established with the help of a single group reaction that is common for all phenols. This parameter is usually referred to as the 'phenol index' and provides a very simple example of the integral index. The degree of water pollution with oxidisable substances can be established with the help of an integral index called chemical oxygen demand (COD), which is determined from the consumption of an oxidant (as a rule, dichromate) and is proportional to the degree of contamination of water with organic compounds. Other determined parameters include total concentrations of heavy metals and polynuclear aromatic hydrocarbons. If such assays give positive results, individual analyses of compounds have to be performed where necessary.

Screening (two-step analysis) is usually employed in wide spread analyses in order to reduce labour, time and reagent consumption; in its first step, samples containing no components that are looked for are rejected. The negative result (*i.e.*, lack of the component) is considered to be final and the corresponding samples are excluded from subsequent analysis. The 'positive' samples are analysed more carefully. In this approach, the first step may include simplified and relatively inexpensive procedures, *e.g.*, test methods.

The mass character of analyses is provided by unification of experimental procedures. Carefully selected, repeatedly approved, well-developed techniques facilitate test operations. Standardisation is the highest grade of unification: while the use of unified protocols can only be recommended, the use of standardised protocols is often compulsory.

The productivity of analyses can be increased through automation and computerisation of analytical procedures. Thus the number of samples tested in agrochemical laboratories increased sharply after reorientation to analytical conveyors and the so-called continuous flow analysis.

The need for laboratory analyses is reduced with the advent of novel analytical methods and tools for their realisation: the instruments become more compact and portable and the methods are gradually becoming reagent-free as is the case with X-ray fluorescence analysis. Moreover, some analytical investigations, *e.g.*, remote analyses of extraterrestrial objects, cannot either be realisable in principle or impractical under laboratory conditions (*e.g.*, measurements of CO content in motor car exhausts or of methane content in coal mines).

The recently developed chemometric technique is yet another novel approach towards analysis. This area of research is intermediate between chemistry (analytical chemistry, in the first place), mathematics and information theory. For instance, the chemometric approach named image recognition has proved to be efficient in the analysis of complex mixtures. Here, the very paradigm of chemical analysis is changed and we renounce the idea of a 'one-after-another-component analysis'.

Since the middle of the 20th century, classical chemical methods of analysis have been continuously replaced by instrumental methods based on the use of physical phenomena, physicochemical regularities and most recent achievements in electronics, mathematics and informatics as well as in biochemistry, immunology and other biological sciences. Today, the absolute majority of practical analyses are carried out using these methods. Whereas in 1951 gravimetric, titrimetric and colorimetric methods were used as the major analytical procedures for certification of the most popular and universally employed standard geological samples, X-ray fluorescence and mass-spectrometric methods came to the foreground in 2004–2005.

The significance and abundance of one or another method change with time and space [*i.e.*, the place (country) where the analysis is carried out]. Its choice relies not only on its analytical potential and practicability for the solution of specific tasks, but also on extraneous (sometimes, critical) circumstances, such as financial situation, availability of experts, working areas, just traditions and even prejudices.

Hybrid methods became especially popular in the past decade; this refers primarily to a combination of separation and measuring techniques, *e.g.*, capillary electrophoresis and virtually all modern chromatographic techniques that combine chromatographic columns with detectors for continuous determinations. Flow-injection analysis is also related to hybrid methods, except that in this case the role of a column is played by a sampling unit, which includes an injector, chemical reactors and often a preconcentration device.

The recent trend is towards miniaturisation of analysis and analytical systems. Generally speaking, the transition from macroanalysis ('wet' chemical analysis) to semimicro- and microanalyses occurred very rapidly in due time; microscopic methods and techniques for ultramicrochemical inorganic analysis and

electrochemical analyses of biological objects including isolated cells were devised in the middle of the past century. An attempt to accommodate multifunctional devices on a microelectronic chip is the most promising recent trend; this concerns, in particular, capillary electrophoresis and, to some extent, flow-injection analysis. Many problems remain to be solved, especially in the design of mini-detectors, but the future is more than exciting. Pocket-size mini-analysers for determining a single substance (less frequently, several substances), *e.g.*, gas analysers, already appeared on the market. As a rule, the methodology for their operation is built-in, no calibration is also necessary. The instrument control is very simple: a single touch of a key and the result is displayed on the screen. The first devices of this type were, most probably, pH-metres.

However, an opposite trend, *i.e.*, the design and manufacture of sophisticated multifunctional instruments able to perform not one, but two or several related analytical procedures, also exists. The devices for surface analysis can serve as examples. These bulky and very expensive instruments combine X-ray emission microanalysis (electronic probe) with X-ray (photo)electronic and Auger spectroscopy and even secondary-ion mass spectrometry. It is noteworthy that the commercial production of analytical instruments is among the most dynamically developing branches of industry all over the world.

The formulation of adequate policy with regard to laboratory facilities still presents a problem. In case of difficult financial situations and high production cost of complex, often multifunctional instruments, their collective purchase and maintenance are of vital importance.

In conclusion, let us note once again the main trends in the development of modern analytical chemistry:

- miniaturisation of analysis including development of general-purpose analytical instruments and simple analysers based on microelectronic chips with microfluid and other systems;
- explosive development of methods and tools for extralaboratory ('field') chemical analyses including design of efficient easy-to-use tools for on-site detection of explosives and drugs;
- use of the most recent advances in mathematics and information theory (chemometrics) for effecting the transition from conventional ('one-after-another-component') analyses to estimation of integral indices and image recognition; design of expert systems; design of an 'electronic nose' and an 'electronic tongue'; development of approaches to multiparametric calibration;
- further improvement of methods and tools for distribution (local), continuous (flow-type), remote and non-destructive analyses;
- design of novel, in principle, tools for chemical analysis based on the use of nanotechnologies including development of continuously operating chemical sensors;
- expansion of studies aimed at perfection of analyses of biomedical objects;
- search for novel principles of generation of analytical signals, *e.g.*, the use of solid chemical (semiconductor, acoustic, *etc.*) sensors;
- further development and improvement of the existing spectroscopic, mass-spectrometric, chromatographic, electrochemical, *etc.* methods of analysis including surface analyses.

The past decade was marked by a departure from the conventional term 'analytical chemistry' to the term 'analytics'. This tendency is not random, of course. The matter of analytical chemistry underwent significant transformations. Today, it is far from being a mere chemistry, but rather an interdisciplinary science, which belongs partly to chemistry and partly to physics. To a considerable degree, the science of chemical analysis rests upon mathematics, information theory and biological sciences. Among analysts (especially those who are concerned with spectroscopic and nuclear-physical methods of analysis), physicists and engineers constitute rather a large group. They are analysts, but not chemists.

The present issue of the *Russian Chemical Reviews* is devoted to the state-of-the-art in individual methods of chemical analysis, since the description of all existing procedures cannot be published in one issue. Chemometric problems are considered in the review by O Ye Rodionova and A L Pomerantsev 'Chemometrics: achievements and prospects'. Spectrometric methods of analysis are described in the reviews by A A Bol'shakov *et al.* 'Prospects in analytical atomic spectrometry' and by A Kh Gilmutdinov *et al.* 'Spatially resolved atomic absorption spectrometry'. The prospects for Mössbauer spectroscopy in chemical analysis are discussed in the review by V G Semenov *et al.* The review by Ya I Yashin and A Ya Yashin 'Analytical chromatography. Methods, instrumentation and applications' is devoted to the state-of-the-art in chromatographic methods of analysis. And, finally, the review by S B Savvin *et al.* deals with the description of various methods for modification of organic reagents used in spectrophotometric assays.

Abstract. The key chemometric methods and models used to solve the problems of qualitative and quantitative analysis and for process analytical technology are considered. The achievements in the field of chemometrics made in the last 20 years are surveyed. The trends and prospects for its development are discussed. The bibliography includes 228 references.

I. Introduction

1. The history of chemometrics and its position in the system of knowledge

Twenty years have passed since the publication of the Russian translation of the only (until recently) book on chemometrics;¹ much has changed during this period. Currently, chemometric methods are used in various fields of science and engineering. This review is mainly devoted to analytical chemistry where three fields of application of chemometrics can be distinguished: qualitative and quantitative analysis, process analytical chemistry and design of experiments.² The attention is focused on the first application, the second one receives less attention and the third is barely considered. This choice of key points is due to the fact that the awareness of Russian chemists of the chemometric methods increases in exactly this order. Numerous papers dealing with design of experiments³ and metrology⁴ are published in Russian scientific journals.

The number of publications dealing with chemometrics rapidly grows: 15 years ago ~100 papers per year were published, while now their number is more than 5000 a year. Therefore, when preparing the review we reasonably restricted its scope. Analysis of chemical data is the most important direction in chemometrics. In recent years, it has been rapidly and fruitfully developing; analytical chemists have proposed not only new methods for data processing, but also new approaches to experiment setting.

Chemometrics is a synthetic discipline at the boundary of chemistry[†] and mathematics. As is often the case with boundary

disciplines, it still lacks a generally recognised definition. The most popular definition was proposed by Massart,⁶ namely, ‘Chemometrics is the chemical discipline that uses mathematical, statistical and other methods employing formal logic to design or select optimal measurement procedures and experiments, and to provide maximum relevant chemical information by analyzing chemical data’. Probably, many people would accept this definition. However, the scope of science should be determined by the objects and goals it pursues rather than by the methods and instruments used. Certainly, the problem of information retrieval from source data is very important for both practice and the development of the theory; however, the experiment setup that would give results containing the required information is equally important. These two equivalent aspects, *i.e.*, retrieval of information from the data and collection of data that contain the desired information, have been reflected in the modern definition of chemometrics proposed by Wold.⁷ Chemometrics solve the following problems in chemistry:

- how to get chemically relevant information out of measured chemical data;
- how to represent and display this information;
- how to get such information into data.

The vigorous development of chemometrics in the late 1970s is correlated with the advent, in the same period, of high-speed computer facilities, which have become universally available to scientists and engineers. This allowed implementation of many complicated algorithms, especially for analysis of data obtained in multiresponse and multivariate experiments. As a consequence, more complex equipment capable of performing a much higher number of measurements appeared. However, it turned out that a large amount of data does not necessarily mean that there is enough information. Therefore, analytical chemists have started to use chemometric methods to retrieve this information and to confirm that the conclusions drawn are reliable. This led to the first obvious success. It was found that traditional labour-consuming analytical methods that require unique equipment and expensive chemicals can be replaced by much faster and less expensive indirect methods. This trend is manifested most clearly in the use of IR spectroscopy, especially in the near region, which has previously considered to be of low utility due to high noise level difficult to eliminate, caused by intense absorption of water

[†] Chemometrics appeared as a separate subdiscipline within analytical chemistry in 1974.⁵ B Kowalski (USA) and S Wold (Sweden) can be considered its founders.

and by the scattering effect in reflectance spectra.⁸ Therefore, the first works in chemometrics were devoted to methods of analysis of spectroscopic data,^{9–11} construction of calibration models (calibrations) by the principal component analysis¹² and projections to latent structures.¹³

When speaking about the history of chemometrics, one cannot but mention the scientists who laid the grounds of the chemometric approach well before the 1970. Apparently, K Gauss, who proposed the least-squares method in 1795, is the first to be mentioned. Gosset (known under the name Student),¹⁴ who worked as the analyst at a brewer and used methods for analysis of chemical data back in the late 19th century, should also be regarded a first chemometrician. In the early 20th century, Pearson's study was published¹⁵ in which he proposed the principal component analysis; the works of Fisher,¹⁶ the author of numerous statistical methods such as the maximum likelihood method and factor analysis, and the pioneering studies on experiment planning¹⁷ were published somewhat later. Among Russian scientists, one should mention, first of all, Nalimov,¹⁸ who greatly contributed to the theory of design of chemical experiment.

The chemometrics appeared and has developed for a long period within the framework of analytical chemistry; specialists in this field still remain the main users of chemometric methods. However, a tendency appeared with time regarded by some researchers as the departure of chemometrics from 'under the wing' of analytical chemistry to become an independent discipline. Two circumstances provided grounds for this conclusion. The first one is complication of the mathematical tools used in chemometrics. Ten years ago analytical chemists could learn and accept the multivariate approach to data analysis, *i.e.*, methods such as the projection to latent structures¹⁹ or singular value decomposition.²⁰ However, subsequently, in the period of general enthusiasm of chemometricians about new methods of data analysis (multiway approach,²¹ wavelet analysis,²² support vector machines,²³ and so on), some gap between chemists and chemometricians started to form: chemists did not understand what and why chemometricians did, while the latter in turn did not realise why their new methods are not in demand in analytical chemistry. Second, numerous applications appeared in which the chemometric approach was successfully used in the fields far from analytical chemistry, for example in multivariate statistical process control,²⁴ image analysis²⁵ and in biology.²⁶ This lack of understanding is also obvious from the fact that at the last conference 'Chemometrics in Analytical Chemistry' (CAC-2004, Lisbon),²⁷ many participants argued whether chemometrics is still a part of analytical chemistry.

It can be seen from the foregoing that chemometrics is closely related to mathematics, especially mathematical statistics. Most analytical chemists understand the necessity of using statistical methods in chemical analysis and apply them to calculate average values, deviations or detection limits, to verify hypotheses and so on. They believe that these simple operations form the basis of chemometric approach in analytical chemistry. However, only some of researchers realise that this is not true and can use all diversity of chemometric methods for the analysis of chemical data.

It should be noted that for efficient application of chemometrics, it is not necessary to know, for example, the statistical theory of the principal component analysis; understanding of the fundamentals and basic ideas of this approach is sufficient. However, one should indeed know the methods of data preprocessing and variable selection principles, and, what is most important, know how to interpret correctly the data projections (loadings and scores) in the principal component space. As shown by long-term experience, this skill can be applied without in-depth mathematical knowledge. The idea of this review is to describe the main principles, methods and achievements of chemometrics using as little mathematics as possible and with geometric interpretation prevailing over the algebraic one.

Mathematicians²⁸ consider with every reason that many methods and algorithms used in chemometrics are poorly substantiated. Chemometric specialists regard their activity as a compromise between the possibility and necessity, believing that a practical result is more important than a theoretical substantiation of its impossibility. Being faced with practical problems of interpretation of very large and intricately organised data,²⁹ they create new methods of analysis so quickly that mathematicians, according to American statistician Friedman,[‡] have no time not only to criticise them, but even to merely understand what happens in chemometrics. This approach is in contrast with the situation existing in biometrics,³⁰ which can be figuratively called the 'elder sister' of chemometrics. Since Fisher's time, only approved classical methods of mathematical statistics such as factor analysis or linear discriminant analysis have been traditionally used in biometrics. Meanwhile, specialists engaged in another closely related field, psychometrics,³¹ are actively developing new approaches to data analysis. For example, the method of projection to latent structures, most popular in chemometrics, has been developed by Wold³² for application in this field.[§]

Owing to this vigorous approach to data analysis, chemometrics has found numerous applications in various fields of chemical science (for example, to study kinetics in physical chemistry,³⁴ to predict the activity of compounds from their structure (QSAR) in organic chemistry,³⁵ in polymer chemistry,³⁶ and in theoretical and quantum chemistry³⁷) and in related and other fields (for example, in brewing,³⁸ astronomy,³⁹ in forensic science⁴⁰ and quality control of the manufacture of superconductors⁴¹).

Some directions of chemometrics were developed in the USSR and later in Russia. Back in the 1950s, studies dealing with mathematical description of equilibria were carried out under Komar's⁴³ direction at the Kharkov State University. More recent relevant publications include the studies by Gribov⁴⁴ and Elyashberg⁴⁵ on spectroscopic methods, Mar'yanov⁴⁶ on titrimetric analysis, Derendyaev and Vershinin⁴⁷ on computer identification of organic compounds and Zenkevich⁴⁸ on chromatography. The active use of the chemometric approach is characteristic⁴⁹ of the scientific school of Academician Zolotov.² QSAR studies related to chemometrics headed by Academician Zefirov are underway.⁵⁰ The metrological aspects and control of the quality of chemical analysis are investigated in Dvorkin's works.⁵¹ A research group headed by Vlasov⁵² at the St Petersburg State University is working on sensor systems known as the 'electronic tongue', and analogous systems called 'electronic nose' are developed at the Voronezh Technological Academy.⁵³ All of these fields actively utilise chemometric methods. Razumov^{54,55} and his colleagues from the Institute of Chemical Physics of the RAS (Chernogolovka) employ multivariate methods of data analysis to solve problems of chemical kinetics. In recent years, new research groups that develop and utilise chemometric methods appeared in Russia, namely, the groups of Rodionova,⁵⁶ Pomerantsev,⁵⁷ Bogomolov^{58,59} (in Moscow); Kucheryavski,⁶⁰ Zhilin⁶¹ (in Barnaul); Romanenko⁶² (in Tomsk) and Shabanova and Vasil'ev⁶³ (in Irkutsk).

2. Information and software provision

We have already noted the monograph well-known in Russia,¹ which reflects the state-of-the-art in the chemometrics by the mid-

‡ J Friedman *Boosting and Bagging*. Available at <http://www.amstat.org/sections/spes/GRC2001.htm>

§ It is of interest that in the early 1970s the prevailing opinion was that 'the method seems to have few applications in the physical, engineering and biological sciences. It can sometimes be useful in the social sciences as a way of finding effective combination variables' (see Ref. 33).

¶ Detailed analysis of the use of chemometric methods in various fields is given in the monograph by Brereton,⁴² to which an interested reader can refer.

1980s. At present, the chemometric methods are described most comprehensively in a two-volume edition^{64,65} written by a group of authors headed by Massart. Apart from the detailed description of the key chemometric methods and techniques, this edition gives numerous examples of their practical application. In addition, there are lots of editions meant for different types of readers. The students and specialists in analytical chemistry who start to become familiar with chemometrics are advised to resort to the monograph by Brereton;⁴² other books^{66,67} would be useful for the researchers engaged in spectral analysis. A lot of useful information can be found in the publication by Beebe *et al.*⁶⁸ One cannot but mention the monograph by Malinowski,⁶⁹ which is still considered to be the best relevant handbook by many analytical chemists. The theoretical grounds of chemometrics can be found in other studies.^{70,71} Recently, a handbook⁷² containing a brief description of chemometric techniques has been translated into Russian. An interesting introduction to chemometrics was written by Maryanov.⁷³ An abridged translation of the handbook written by Esbensen⁷⁴ was published in Russia in a short run (for the participants of three scientific schools in chemometrics).

Two specialised journals, *Journal of Chemometrics* and *Chemometrics and Intelligent Laboratory Systems*, are devoted to the problems of chemometrics. Papers describing the results of application of chemometric methods for solving applied problems are routinely published by more than 50 scientific journals, for example, *Analytical Chemistry*, *Analytica Chimica Acta*, *Analyst*, *Talanta*, *Trends in Analytical Chemistry*, *Journal of Chromatography*, *Computers and Chemical Engineering*, *Vibrational Spectroscopy*, etc. The number of publications the authors of which use chemometric methods as the main tool for analysis and processing of experimental data increases every year (Fig. 1).

Problems of chemometrics are considered at both small regional conferences and seminars and at regular international conferences. The conference 'Chemometrics in Analytical Chemistry'²⁷ and 'The Scandinavian Symposium on Chemometrics' are most prestigious.[†] In Russia, international workshops symposia 'Modern Methods of Multivariate Data Analysis' are held annually starting from 2002.^{75–77} The theoretical and applied aspects of chemometrics are widely represented as Internet resources, mainly, English-language ones;[‡] however, some Russian resources are also available.

The software used in chemometrics includes specialised program packages,[¶] which allow fast and vivid data processing in the interactive mode. General-purpose statistical packages are also widely used.^{††} Often, researchers compose the procedures themselves, for example, in MATLAB codes,^{‡‡} and publish them for free access on the Internet or in books.⁷⁸

3. Designations and terms

The following designations are used in the review. The scalar variables are marked by italic, for example, *s*. The vectors

Figure 1. Diagram illustrating the growth of the number of papers in chemometrics among the publications in Elsevier periodicals.

(columns) are designated by Roman bold lower-case letters, for example, **x**, while matrices are shown by upper-case letters, for example, **W**; the multiway matrices are marked by italic, for example, *G*. The array elements are designated by the same but lower-case letter. For example, w_{ij} stands for an element of matrix **W**, the subscript *i* indicating the matrix row and varies from 1 to *I*; the subscript *j* corresponds to the column number and varies from 1 to *J*. Similar designations have been used for other subscripts, for example, $a = 1, \dots, A$. The transposition operation is denoted by superscript *t*, for example, **X**^{*t*}.

No generally accepted set of chemometric terms has been formed in the Russian literature as yet. Some concepts were translated incorrectly or inaccurately. In many cases, translators simply avoided giving Russian names to key concepts of chemometrics, such as scores and loadings and used complex euphemisms instead. In our opinion, chemometrics cannot do without such notions or their analogues.

As in any other field of knowledge, specialists in chemometrics, often use abbreviations, *i.e.*, abridged names of methods, algorithms and special terms. Below we present the list of the abbreviations used.

ALS, Alternating Least-Squares; ANN, Artificial Neural Network; DASCO, Discriminant Analysis with Shrunk COvariance matrices; EFA, Evolving Factor Analysis; GA, Genetic Algorithm; IA, Immune Algorithm; INLR, Implicit Non-linear Latent Variable Regression; ITTFA, Iterative Target Transformation Factor Analysis; KNN, *K*-Nearest Neighbours; LOO, Leave One Out; MIA, Multivariate Image Analysis; MSC, Multiplicative Signal Correction or Multiplicative Scatter Correction; MSPC, Multivariate Statistical Process Control; NAS, Net Analyte Signal; NIPALS, Non-linear Iterative Projections by Alternating Least-Squares; OSC, Orthogonal Signal Correction; PARAFAC, PARAllel FACtor Analysis; PAT, Process Analytical Technology; PC, Principal Component; PCA, Principal Component Analysis; PCR, Principal Component Regression; PLS, Projection on Latent Structures; PLS-DA, PLS Discriminant Analysis; PMN, Penalized Minimum Norm projection; QPLS, Quadratic PLS; QSAR, Quantitative Structure-Activity Relationship; RMSEC, Root-Mean Square Error of Calibration; RMSEP, Root-Mean Square Error of Prediction; SIMCA, Soft Independent Modeling of Class Analogy; SIMPLISMA, SIMPLEx-to-use Interactive Self-modeling Mixture Analysis; SIMPLS, SIMple Partial Least Squares regression; SMCR, Self-Modeling Curve Resolution; SPC, Statistical Process Control; SVD, Singular Value Decomposition; SVM, Support Vector Machine; WFA, Window Factor Analysis.

stances A and B was to be determined in the above experiment, then substance C would be an undesirable impurity and its contribution would be regarded as noise. What is to be attributed to noise and what should be considered information? This question is always solved with allowance for the goal and the methods used to attain the goal. This is the second principle of the chemometric approach to data analysis.

The noise and data redundancy are manifested through the correlation relationships between variables. Turning back to the idealised example, one can notice that in the matrix of 'pure' spectra $\mathbf{S}$ with the dimension 3×30 [3 rows (samples) by 30 columns (wavelengths)], only three columns would be linearly independent. Having fixed this triple, any fourth column can be represented as their linear combination. Naturally, the number equal to three is not occasional, as the system contains exactly three components. This number is called the rank of the matrix $\mathbf{S}$ and plays an important role in the chemometric analysis. When considering the same example in a more realistic version (with allowance for the errors), additional correlations between the data can be noted. This would be the case, for example, if the concentration of the third substance C is much lower than the error (noise). The data are now inadequate for reliable determination of all three concentrations and the effective rank of the matrix is equal to two. Thus, the errors in the data may give rise to random rather than systematic relationships between variables. Evidently, the former case deals with correlation relationship, while the latter case is a causal relationship.[¶]

The notion of effective (chemical) rank and hidden (latent) variables the number of which is equal to this rank underlies the third most important principle of chemometrics.⁶⁹ We shall illustrate this by the following example. Let there be several (I) mixtures of substances A, B and C, their pure spectra $s_A(\lambda)$, $s_B(\lambda)$, $s_C(\lambda)$ being unknown. One can obtain the spectra of these samples as two-way data and to construct matrix $\mathbf{X}$ with the dimension $I \times 30$. By usual mathematical analysis, one can determine the rank of this matrix. This number gives information of how many components are present in the system or, at least, how many components can be distinguished.

Thus, chemical data involve most often inner latent relationships between the variables, resulting in numerous correlations, *i.e.*, multicollinearity. This feature can be manifested as data redundancy, which increases the quality of estimates. However, in the case of a faulty method for data processing, the multicollinearity can have an adverse effect on the quality of analysis. For example, multiple linear regression cannot be used with multicollinearity.⁷⁴ For regression analysis of this sort of data, special methods are required, for example, ridge regression⁸⁶ or projection approaches.⁷¹

Sampling can be an essential source of noise. The sampling theory, a substantial contribution to which was made by Jy,⁸⁷ has become very popular in recent years.⁸⁸ Its numerous applications can be found in a publication⁸⁹ completely devoted to this subject. Yet another problem that may be faced by an analytical chemist is the gaps in the data,⁹⁰ caused by various reasons such as instrument failure, going beyond the detection limits, sample deficiency and so on. Most of chemometric methods do not work with missing data; therefore, special methods are used to fill the gaps, a method based on an iteration algorithm being used most often. Each iteration consists of two steps. In the first step, the model parameters are estimated as if the data were known completely. To this end, the gaps are filled by some *a priori* permissible values, for

example, average over the surrounding elements of the data array. In the second step, the model obtained is used to find the most probable values for the missing data, and the next iteration is carried out. An approach based on the likelihood maximum is also used to fill the gaps.⁹¹ Details of these algorithms largely depend on the data description model used.

2. General strategy of data analysis. Models and methods

The chemometric methods of data analysis can be divided into two groups corresponding to two principal tasks: (i) exploration of the data, for example, classification and discrimination; (ii) prediction of new values, for example for calibration. The first-group methods usually operate with one block of data, while the second one, with at least two blocks (predictors and responses). Depending on the goals, the methods can be directed to prediction either within the range of experimental conditions (interpolation) or beyond this range (extrapolation). The methods are classified into soft also called 'black' and hard or 'white'. When formal models are used,⁹² the data are described by an empirical dependence (most often, linear), which is valid in a limited range of conditions. In this case, one need not know the mechanism of the process under study. However, this method does not allow solving extrapolation problems. The parameters of soft models are devoid of a physical meaning and are to be interpreted using appropriate mathematical methods. The hard modelling⁹³ is based on physicochemical principles and permits extrapolating the system behaviour under new conditions. The parameters of a 'white' model have a physical meaning, and their values can help in interpretation of the elucidated dependence. However, this method is applicable only in the case where the model is known *a priori*. Each of the approaches has both advantages and drawbacks,³⁶ and both adherents and opponents. Historically, the hard method was intensively developed in Russia, while the soft method was developed more actively in other countries. The authors of many recent publications consider so-called 'grey' models,⁹⁴ which combine the advantages of both methods. Below we illustrate different approaches to modelling by examples from analytical chemistry.

Titrimetric processes, distinguished by a diversity of chemical reactions and signals registered, often serve as objects of mathematical modelling in analytical chemistry. The equations for titration curves are often fairly sophisticated and cannot be written in an explicit form with respect to the signal registered. This hampers the use of hard models for solving the inverse problem, namely, estimation of the parameters from the measured points of the curve. Nevertheless, by using modern computing systems, this problem can still be solved within the framework of the 'white' modelling.⁹⁵ It has been noted⁹⁶ that titration curves resemble in their shape the plots for reciprocal hyperbolic and trigonometric functions. Therefore, it has been proposed to use soft ('black') dependences composed of trigonometric functions $\arcsin$, $\arccos$, *etc.* According to the trade-off ('grey') approach proposed by Mar'yanov *et al.*,⁴⁶ a change in variables can transform a hard model into a piecewise-linear one. Subsequently, the parameters are estimated by the ALS method,⁹⁷ which implies progressive approximation of the model to the data: first, linear parameters are estimated by linear regression methods with non-linear parameters being fixed, and after that, non-linear parameters are estimated in a quickest descent procedure with the fixed linear parameters found previously. The procedures alternate until the results converge.

The interest in 'black' and 'grey' modelling methods is due to the difficulty of the selection and validation of a hard model. In many cases, this is reduced to mere enumeration of a small number of competing dependences, as a result of which a simple model with the smallest discrepancy is chosen. However, this does not validate the chosen method and may give rise to gross errors. Researchers often use models that have been reasonably called 'pink' [†] based on idealised dependences which poorly comply with artifacts present in real data such as baseline drifts, anomalous

[¶]The difference between the causality and correlation is amusingly illustrated in a book,⁸⁵ which cites an example of high positive correlation between the numbers of citizens and storks in Oldenburg (Germany) in the period from 1930 to 1936. Of course, these two variables are related by a correlation dependence caused by the fact that the system includes a third latent variable to which they are both related by a causal relationship.

errors, *etc.* The formal multivariate linear models and appropriate methods for their analysis are much better 'adapted' to handling artifacts. These models operate in those cases where the hard physicochemical approach is by no means applicable. The grounds for using linear models are provided by the fact that any, even a very complicated but continuous dependence in a rather narrow range can be represented as a linear function. In this case, a fundamental question is what range can be considered acceptable, in other words, the question of the scope of applicability of the constructed soft model. This question can be answered by using model validation techniques.

When the model has been properly constructed, the initial data consist of two rather representative sets obtained independently of each other. The first set, called training set, is used for model identification, *i.e.*, for estimation of its parameters. The second set, called test set, serves only for model validation. The constructed model is applied to the test set, and the results obtained are compared with the test data. The results of the comparison are considered to make decision about the model validity and accuracy. In some cases, the data array is too small for such validation. In this case, cross-validation is used.⁹⁸ According to this method, the test values are computed by the following procedure. Some invariable fraction (for example, the first 10%) of samples are excluded from the initial set of data. Then the model is constructed using only the remaining 90% of the data and then applied to the excluded set. In the next cycle, the excluded data are returned and another part of the data (the next 10%) are removed. A model is constructed once again and applied to the excluded data. This procedure is repeated until all data have functioned as excluded (in our cases, this requires 10 cycles). The leave-one-out (LOO) cross-validation procedure is used most often (without reason). Validation by the leverage correction algorithm is also employed in the regression analysis.⁷⁴ It is noteworthy that one or another validation procedure should be applied not only in quantitative, but also in qualitative analysis in solving discrimination and classification problems.

The results obtained in the analysis and modelling of experimental data always involve an uncertainty. The quantitative estimate or qualitative judgement may be changed after a repeated experiment as a result of diverse random or systematic errors either present in the initial data from the very beginning or introduced during the modelling.⁹⁹ The uncertainty in the quantitative analysis is described by either a value, *i.e.*, standard deviation,¹⁰⁰ or an interval, *i.e.*, a confidence¹⁰¹ or prediction interval.⁵⁶ In qualitative analysis, verification of statistical hypotheses is used¹⁰² in which the uncertainty is characterised by the probability of making a wrong decision.¹⁰³ The methods for estimation of the uncertainty during modelling of multivariate¹⁰⁴ and multiway¹⁰⁵ data arouse considerable interest in chemometricians. Various aspects of reliability of an analytical method are described using special characteristics: specificity, selectivity, detection limit, signal-to-noise ratio.⁷³ A topical method for their determination is the approach based on the NAS concept.¹⁰⁶ A multivariate NAS vector is defined as a part of the full signal (spectrum), which is used for modelling and prediction.¹⁰⁷ The remaining part of the signal, which includes errors and contributions from foreign components, is considered as noise. The NAS concept was applied to the problem of determining the detection limit in the analysis of two¹⁰⁸ and three-way¹⁰⁹ data. The obtained results have found numerous practical applications, one being considered below.

The reliability of an analytical method largely depends on the data that have been used to construct and validate the model. The presence of outliers¹¹⁰ or spurious data decreases the accuracy of the model and, conversely, the presence of representative (significant) samples in the experiment¹¹¹ substantially improves the model quality. The data significance can be estimated by classical regression methods¹¹² or by non-statistical procedures.⁵⁶ When the constructed model is used to determine desired parameters, similar problems arise. The method may prove inapplicable to some samples (an outlier in the prediction¹¹³) or give inaccurate results. Estimation of the method uncertainty for particular samples rather than on average¹¹⁴ is a complicated task, which is tackled by a number of research groups.¹¹⁵ Their effort determines the successful solution of practical problems such as calibration transfer,¹¹⁶ variable selection¹¹⁷ and the construction of robust models for data analysis.¹¹⁸

III. Qualitative analysis methods. Exploration, classification and discrimination

1. Principal component analysis

Modern instruments easily do a multitude of measurements per unit time. For example, if a spectroscopic sensor is used *in situ* to measure a spectrum at 300 wavelengths every 15 s, then after 1 h it will produce a 240×300 matrix of data, *i.e.*, 72 000 values. However, due to the multicollinearity, the fraction of useful information in this array may be relatively low. To isolate useful information, data compression methods are used in chemometrics (unlike the traditional approach in which only the results of some, especially significant measurements are selected from the data). For representing the initial data, new latent variables are used in these methods. Two conditions must be fulfilled. First, the number of new variables (chemical rank) should be much lower than the number of the initial variables, and, second, the loss caused by data compression should be commensurable with the noise. Data compression allows one to represent useful information in a more compact form convenient for visualisation and interpretation.

Data are compressed most often using the PCA technique,¹⁹ which underlies other similar chemometric methods including EFA,¹¹⁹ WFA,¹²⁰ ITTFA¹²¹ and numerous classification methods, for example, SIMCA.¹²² The principal component analysis implies decomposition of the original 2D matrix $\mathbf{X}$, *i.e.*, representing it as a product of two 2D matrices $\mathbf{T}$ and $\mathbf{P}$,⁷⁴

$$\mathbf{X} = \mathbf{TP}^t + \mathbf{E} = \sum_{a=1}^A \mathbf{t}_a \mathbf{p}_a^t + \mathbf{E} \quad (1)$$

In this equation, $\mathbf{T}$ is called the matrix of scores, $\mathbf{P}$ is the matrix of loadings and $\mathbf{E}$ is the matrix of residuals (Fig. 3). The numbers of columns, $\mathbf{t}_a$ in the matrix $\mathbf{T}$ and $\mathbf{p}_a$ in the matrix $\mathbf{P}$, are equal to the effective (chemical) rank of the matrix $\mathbf{X}$. This value is designated by A and is called the number of principal components; naturally, it is smaller than the number of columns in the matrix $\mathbf{X}$.

To illustrate the PCA method, let us turn back to the example considered in Section II.1. The matrix of the mixture spectra $\mathbf{X}$ can be represented as the product of the concentration matrix $\mathbf{C}$ and the spectrum matrix of pure components $\mathbf{S}$

Figure 3. Graphical view of the principal component analysis.

† See O N Karpukhin *Global (strategic) problems of the practical use of complex mathematical statistics methods (chemometrics)* Report at the fourth International Symposium 'Modern Methods of Analysis of Multivariate Data' (WSC-4). Chernoholovka, February 14–18, 2005. Available at <http://www.chemometrics.ru/articles/karpukhin>

$$\mathbf{X} = \mathbf{C}\mathbf{S}^t + \mathbf{E}. \quad (2)$$

The number of rows in matrix $\mathbf{X}$ is equal to the number of samples (I), each row corresponding to the spectrum of a single sample recorded for J wavelengths. The number of rows in matrix $\mathbf{C}$ is also equal to I and the number of columns corresponds to the number of components in the mixture ($A = 3$). The matrix of pure spectra is present in expansion (2) in the transposed form, as the number of its rows is equal to the number of wavelengths (J), while the number of columns is equal to A . As noted above, in the analysis of real data complicated by errors represented by matrix $\mathbf{E}$, the effective rank A does not necessarily coincide with the real number of components in the mixture. More often, it is greater due to the influence of non-concentration factors, for example, temperature.

The problem of resolution of the experimental matrix $\mathbf{X}$ into 'pure' components corresponding to the concentrations $\mathbf{C}$ and spectra $\mathbf{S}$ (understood in the generalised sense) is a special field in chemometrics called curve resolution.¹²³ Two directions can be distinguished in this field. The first one uses self-model curve resolution (SMCR)¹²⁴ and is mainly applied as a supplement to hyphenated chromatography.¹²⁵ The self-model approach is implemented using soft modelling method, for example, PCA or EFA, which do not utilise the conceptual knowledge about the system. Within the framework of this approach, the SIMPLISMA method can be distinguished,¹²⁶ which makes use of a simple but fairly effective procedure based on variable selection.¹²⁷ Conversely, the second direction employs *a priori* information about the processes and utilise 'grey' models.¹²⁸ This direction is applied in the studies of kinetics³⁴ and thermodynamics.¹²⁹ The key point in these problems is determining the chemical rank of the system, *i.e.*, the number of principal components A .¹³⁰ In the ideal case, the predicted spectra $\mathbf{S}$ and concentrations $\mathbf{C}$ should be close to the true values, although they cannot be exactly recovered. The reason is not only the experimental error, but also the fact that the spectra can partially overlap. When PCA is used to resolve the data into the chemically meaningful components, as in Eqn (2), it is also called factor analysis, unlike the formal principal component analysis.¹³¹

The principal component analysis is efficient not only in the problems of resolution. It is used to analyse any chemical data. In this case, the score $\mathbf{T}$ and loading $\mathbf{P}$ matrices can no longer be interpreted as the spectra and the concentrations, and the number of principal components A , as the number of chemical components present in the system. Nevertheless, even formal analysis of the scores and loadings is very useful for understanding the data structure. Below we present a simple two-dimensional illustration of PCA.

Data consisting only of two highly correlated variables x_1 and x_2 are presented in Fig. 4a. The same data in new coordinates are shown in Fig. 4b. Loading vector $\mathbf{p}_1$ of the first principal component (PC1) determines the direction of the new axis along which the data change more appreciably. The projections of all initial points on this axis form vector $\mathbf{t}_1$. The second principal component $\mathbf{p}_2$ is orthogonal to the first one, its direction (PC2) corresponding to the largest variation in the residuals (shown by segments perpendicular to the axis $\mathbf{p}_1$).

This trivial example shows that principal component analysis is executed successively, step by step. In each step, the residuals $\mathbf{E}_a$ are studied, the direction of the most pronounced change is chosen among them, the data are projected onto this axis, new residuals are calculated and so on (NIPALS algorithm).⁷⁴ According to another popular data compression algorithm, SVD,¹³² the same decomposition (1) is constructed without iterations. The number of principal components A is chosen (in other words, the iteration procedure is terminated) based on criteria that show the accuracy of the decomposition attained. Assume that matrix $\mathbf{X}$ has I rows

Figure 4. Graphical illustration of the principal component analysis. (a) data in the initial coordinates, (b) data in the principal component coordinates.

and J columns and A principal components participate in expansion (1). The values

$$\mu_a = 100 \sum_{i=1}^I t_{ia}^2 / \sum_{i=1}^I \sum_{j=1}^J x_{ij}^2, \quad (3)$$

$$E_a = 100 \left(1 - \sum_{i=1}^I \sum_{j=1}^J e_{ij}^2 / \sum_{i=1}^I \sum_{j=1}^J x_{ij}^2 \right), a = 1, \dots, A$$

are called the normalised eigenvalue and explained variance, respectively. They are usually plotted vs. value a . A sharp change in these values attests to the required number of principal components. For a correct choice of A , test-validation or cross-validation is required.

Equations (1) contain no absolute term; therefore, prior to data decomposition, data centring (*i.e.*, subtraction of the average over the column) is often required.

The principal component analysis can be interpreted as data projection onto a subspace with a lower dimensionality. The residuals $\mathbf{E}$ thus arising are regarded as noise containing no significant chemical information. In this subspace, one can introduce a sample dissimilarity measure called Mahalanobis distance,¹³³ which helps to solve many problems of qualitative analysis. Yet another potent method for data analysis in a projection subspace is the Procrustean rotation method.¹³⁴

When exploring the data by PCA, the attention is focused on score and loading plots. They bear information on the data structure. In the score plot, each sample is depicted in the $(\mathbf{t}_i, \mathbf{t}_j)$ coordinates, most often, $(\mathbf{t}_1, \mathbf{t}_2)$. The proximity of two points implies their similarity, *i.e.*, positive correlation. The points located at a right angle are uncorrelated, while those located in the opposite positions have a negative correlation. By using this approach in chromatographic analysis,⁴² one can find out, for example, that the linear section in the score plot corresponds to the

regions of pure components in the chromatogram, the curved sections are regions of peak overlap, and the number of such sections corresponds to the number of components in the system. Whereas the score plot is used for analysis of sample relationships, the loading plot is used to study the role of variables. In the loading plot, each variable is reflected by a point in the $(\mathbf{p}_i, \mathbf{p}_j)$ coordinates, for example, $(\mathbf{p}_1, \mathbf{p}_2)$. By analysing this plot similarly to the scope plot, one can understand which variables are interconnected and which are independent. A joint investigation of pair score and loading plots also helps to retrieve useful information from the data.⁷⁴

Consider an example of practical use of PCA in chemical analysis. The possibility of using near-IR spectroscopy for detection of counterfeit drugs has been considered.¹³⁵ Samples of true (N1, 10 items) and fake (N2, 10 items) tablets of a popular antispasmodic agent have been studied. Twenty diffuse reflectance spectra $R(\lambda)$ were recorded on a Bomem MB160 instrument with a Powder Sampler attachment in the 3800–10 000 cm^{-1} range (1069 wavelengths) without special sample preparation. The initial data were converted to $-\log R$, centred and prepared by the MSC procedure (Fig. 5).⁷⁴ The negative values of the signal are due to the use of different gain settings for the background and the sample spectra.

Figure 5. Spectra transformed by the MSC procedure.¹³⁵ Here and in Fig. 6 the following designations are used: N1 are true tablets, N2 are fake tablets.

In the PCA score plot (t_1, t_2) for these spectra (Fig. 6a), one can clearly see two groups of points corresponding to the true and counterfeit tablets. The scatter of points in group N2 (counterfeit) is much greater than in group N1 (original). This may be attributed to a better quality control in the legal production. In this example, it is sufficient to use only two principal components for which $\mu_1 = 94\%$, $\mu_2 = 4.9\%$, $E_2 = 99\%$.

2. Classification and discrimination

The example considered above refers to classification problems. This is a rather extensive class of problems of qualitative chemical analysis with the goal of attributing a sample to a particular class. Classification problems can be subdivided into two groups. One group includes so-called unsupervised problems that use no training set; they can be regarded as a sort of explorative analysis. This approach has been used in the above example with counterfeit tablets. The problems of the second group referred to as supervised classification are also called discrimination problems. They are solved using a training set of samples, which are known *a priori* to belong to particular classes. The methods for unsupervised classification are mainly based on PCA decomposition followed by analysis of distances between classes,¹³⁶ construction of dendrograms, the use of the fuzzy set,¹³⁷ etc. Procrustean rotation¹³⁸ and Mahalanobis distance^{139–141} have been used for

Figure 6. Determination of counterfeit drugs using PCA scores (a) and SIMCA (b).

these purposes. However, if discrimination is possible, these methods should be preferred.

A training set of samples is used to construct a classification, *i.e.*, a set of rules that can be used to assign a new sample to one or another class. When the model (or models) has been constructed, it has to be test- or cross-validated to determine the degree of its precision. If the validation is successful, the model is ready for practical use. In analytical chemistry, multicollinear data (spectra, chromatograms) are usually classified; therefore, the discrimination model is nearly always multivariate and is based on projection approaches, PCA and PLS. Note the use of linear discriminant analysis in the near-IR spectroscopy¹⁴² and canonical discriminant analysis.¹⁴³ The SIMCA method¹⁴⁴ developed by Wold¹²² is very popular.

The SIMCA method is underlain by the assumption that all objects that belong to the same class have both similar and distinctive features. When constructing a discrimination model, one should take into account only the similarity, while the distinctive features should be rejected as noise. To this end, every class from the training set is modelled independently using PCA with different numbers of principal components A . After that, distances between the classes and the distances between each class and the new object are calculated. Two values are used as distance functions. The distance from the object to a class (d) is found as the root-mean-square value of the residuals $\mathbf{e}$ arising upon projecting an object onto the class

$$d = \sqrt{\frac{1}{J-A} \sum_{j=1}^J e_j^2}.$$

This value is compared with the root-mean-square residue within the class

$$d_0 = \sqrt{\frac{1}{(I-A-1)(J-A)} \sum_{ij} e_{ij}^2}.$$

The second value, the distance from the object to the centre of the class (h), is found as the leverage (the squared Mahalanobis distance)

$$h = \frac{1}{I} + \sum_{a=1}^A \frac{\tau_a^2}{\mathbf{t}_a^T \mathbf{t}_a},$$

where τ_a is the projection of a new sample (score) on the principal component a , and $\mathbf{t}_a$ is the vector containing scores for all training samples in the class.

The use of the SIMCA method for tablet discrimination is illustrated in Fig. 6b. As the class, true tablets were used; the plot shows the distances d and h from counterfeit samples. The vertical and horizontal lines dictate the rules that can be applied to assign a new item to the class of true tablets. It can be seen that all samples of fake tablets are located far away from the true class; therefore, they can be readily discriminated. On the given scale, the points that correspond to true samples converge into one point, which almost coincides with the origin of coordinates.

Apart from SIMCA, a similar DASCO method,¹⁴⁵ as well as KNN,¹⁴⁶ SVM^{147,148} and many other methods are used for discrimination of chemical data. The PLS-DA method is a powerful tool.¹⁴⁹ The basic idea is that the discrimination rules for K classes are specified by linear regression of the form

$$\mathbf{X}\mathbf{B} = \mathbf{D},$$

where $\mathbf{X}$ is the full matrix of all initial data ($I \times J$), $\mathbf{B}$ is the matrix of unknown coefficients ($J \times K$), and $\mathbf{D}$ is a special matrix ($I \times K$) composed of zeros and ones. During the construction of matrix $\mathbf{D}$, ones should be placed only in those rows (samples) that belong to the class corresponding to the number of the column. The regression problem is solved by the PLS method (see below), which allows one to use subsequently the constructed regression to predict the assignment of new samples. For this purpose, the response of a new sample is predicted and the result is compared with zero or one.

3. Three-way methods

Principal component analysis has been developed for the analysis of data that can be represented as a two-way 2D matrix. However, in recent years analytical chemists deal more and more often with three (and higher) way data with a more complex structure. These data are gained, for example, by using hyphenated^{150,151} and evolution methods.¹⁵² The data are compressed using special approaches three of which (used most often) are briefly considered in this Section. The most comprehensive and systematic description of these methods with numerous examples of their application to chemical analysis can be found in a monograph.⁸⁰ A brief review of methods and algorithms used for analysis of three-way data has been reported.¹⁵³ The same algorithms are used to process the data obtained by hyperspectral measurements⁸³ and for image analysis.²¹

The unfolding method¹⁵⁴ is the simplest method of analysis of three-way data used to unfold 3D matrix $\mathbf{X}$ with dimension $I \times J \times K$ into a usual 2D matrix ${}^u\mathbf{X}$ with the dimension $I \times JK$ (Fig. 7). The value I is called the basic mode. After unfolding, the principal component analysis can be applied (see Section III.1). This approach is often efficient (see, for example, a study³⁶),

Figure 7. Graphical view of the unfolding method into a 2D matrix.

although it suffers from a number of drawbacks; first, any of three directions can be chosen as the basic mode, *i.e.*, unfolding involves uncertainty; second, the connection between neighbouring points is lost, since on passing from a 3D to a 2D matrix, it is no longer taken into account that the measurements x_{ikj} and $x_{ik+l,j}$ are neighbouring, which may be important.

The Tucker3 algorithm¹⁵⁵ allows processing three-way data, while maintaining their initial structure and, hence, the sequence of measurements, for example, the order of wavelengths in the spectrum or the time sequence of points in a chromatogram. The initial 3D data $\mathbf{X}$ are presented as three conventional 2D loading matrices ($\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$) and a three-way core array $\mathbf{G}$. The pattern of such data expansion is shown in Fig. 8. Each element of the initial 3D matrix $\mathbf{X}$ can be written as the sum

$$x_{ijk} = \sum_{p=1}^P \sum_{q=1}^Q \sum_{r=1}^R a_{ip} b_{jq} c_{kr} g_{pqr} + e_{ijk}, \quad (4)$$

where a , b and c are elements of the loading matrices, each of them corresponding to a particular way; g are elements of the core array $\mathbf{G}$. The number of principal components along each direction (P , Q , R) can be different.

Figure 8. Graphical view of the Tucker3 model.

The PARAFAC method¹⁵³ differs from the Tucker3 model in the fact that each way is represented by the same number of principal components R . The expansion is constructed to minimise the sum of squares of the residuals e_{ijk}

$$x_{ijk} = \sum_{r=1}^R a_{ir} b_{jr} c_{kr} + e_{ijk}. \quad (5)$$

The major advantage of this method is the uniqueness of expansion. If a mixture of several chemical substances was studied, then with a correct choice of the number of principal components, the loading matrices are pure spectra of the initial compounds. The graphical scheme of the PARAFAC method is shown in Fig. 9.

The MATLAB codes of the PARAFAC algorithm can be found in a publication.¹⁵⁰ Since the loading matrices in expansion (5) are determined by an iteration procedure, this method requires a very large amount of computation. Studies aimed at acceleration of computation procedures are now in progress. A critical analysis of the most recent achievements in this field has been reported.¹⁵⁵ The algorithms of all the considered methods for decomposition of three-way data are documented.¹⁵⁶

Figure 9. Graphical view of the PARAFAC model with R components.

IV. Quantitative analysis methods. Calibration

1. Linear calibration

Two blocks of data are used to solve problems of quantitative analysis.² The first block **X** is the matrix of analytical signals (for example, spectra, chromatograms and so on); the second block **Y** is the matrix of chemical parameters (for example, concentrations). The number of rows (*I*) in these matrices is equal to the number of samples, the number of columns (*J*) in the matrix **X** corresponds to the number of channels (wavelengths) in which the signal is recorded, and the number of columns (*K*) in matrix **Y** is equal to the number of chemical parameters, *i.e.*, responses. The purpose of calibration is to construct a mathematical model that would relate blocks **X** and **Y** and could be subsequently used to predict parameters **y** over a new row of analytical signals **x**.¹³

A simplest calibration model is one-dimensional regression ($J = 1, K = 1$)¹⁵⁷

$$y = a + bx,$$

which corresponds to a single channel of the analytical signal. Using classical regression analysis, it is possible to construct a more complex multiple regression ($I > J, K = 1$) involving several channels,³³

$$\mathbf{y} = \mathbf{Xb}.$$

Using these models normally implies that factors x_{ij} are known exactly, errors being present only in block **y**. Therefore, two approaches to the model construction can be distinguished: the first is called direct calibration and the other is inverse calibration.¹⁵⁸ In the first approach, chemical parameters (**X** = **C**) are used as independent parameters, while spectral measurements (**Y** = **S**) are used as responses. Previously, it has been believed that the direct model fits better to the assumption of the lack of errors in block **X** and, in addition, it is in agreement with the Bouguer–Lambert–Beer law.⁷² In the second approach, **Y** = **C**, **X** = **S**. This approach currently prevails in chemometrics, because it is more practically convenient, as it directly predicts the required analytical parameter (for example, the concentration **C**) from the measured signal (spectrum **S**). In addition, modern regression methods (PCR, PLS) make it possible to handle data with errors present in both blocks.

To illustrate various calibration methods, let us turn back to the example considered in Section II.1. Now we fill this with a particular content by simulating data **X** and **Y**. Let there be a mixture of two substances A and B ($K = 2$) and an instrument that measures an analytical signal *s* (spectrum) at 101 channels ($J = 101$). The spectra of ‘neat’ substances ($c_A = 1, c_B = 1$) are presented in Fig. 10*a* (curves *A* and *B*). The spectra significantly overlap; therefore, it is impossible to distinguish ‘selective’ channels for estimating the concentrations. Figure 10*b* shows nine simulated spectra ($I = 9$) of various mixtures of substances A and B in which a random error has been introduced with a standard deviation of 0.05. They will be used as the training set.

To construct a one-dimensional calibration, we took the intensities $s(\lambda_{50})$ of nine signals for channel 50 and plotted them in Fig. 10*c* as functions of concentrations c_A and c_B of A (points 1) and B (points 2). The calibration dependence $s = bc$ is shown by a straight line.

The calibration accuracy is usually characterised by the RMSEC value

$$\text{RMSEC} = \sqrt{\sum_{i=1}^I (y_i - \hat{y}_i)^2 / F}, \quad (6)$$

where y_i and $\hat{y}_i$ are the measured and predicted values of a chemical parameter (concentration) for the training samples $i = 1, \dots, I$; F is the number of degrees of freedom:⁴² $F = I - 1$ for one-dimensional regression without an absolute term. Evidently, the lower the RMSEC, the more accurate the description of the training data. In addition, the quality of calibration is

Figure 10. Examples of the construction of various calibrations.

(*a*) spectra of pure (curves *A*, *B*) and principal components (curves PC1, PC2); (*b*) model spectral data; (*c*) one-dimensional calibration, $R_A^2 = 0.50$, $\text{RMSEC} = 0.26$, $R_B^2 = 0.46$, $\text{RMSEC} = 0.219$; (*d*) PCR calibration, $R_A^2 = 0.999$, $\text{RMSEC} = 0.011$, $R_B^2 = 0.998$, $\text{RMSEC} = 0.012$.

characterised by correlation coefficient R^2 between values **y** and $\hat{\mathbf{y}}$: the closer this to unity, the higher the calibration quality. The corresponding values are given in the caption to Fig. 10*c*. The graphical dependences show that due to low instrument selectivity, the one-dimensional calibration is unsatisfactory. The calibration using multiple regression is considered below.

Consider the application of a multivariate model constructed by the PCR method.⁸⁶ The PCR method uses inverse calibration, so that **Y** = **C**, **X** = **S**. In terms of the PCA method, the matrix **X** can be expanded using formula (1); in our example, $A = 2$. Loading vectors **p**₁ and **p**₂ thus found are shown in Fig. 10*a* (curves PC1 and PC2). By comparing the plots presented in Fig. 10*a,b*, one can see that the first principal component describes a smooth trend in the data, whereas the second component shows the noised deviations from this trend. The obtained score matrix **T** is used as the block of independent variables (predictors) in the regression to the response block **Y**, *i.e.*, **Y** = **Tb**. The results of PCR calibration are presented in Fig. 10*d*, which shows the predicted concentrations $\hat{\mathbf{y}}$ as functions of the measured values **y** (points 1 for substance A and points 2 for substance B) and the regression lines, which coincide. The RMSEC and R^2 values demonstrate that PCR provides high ‘mathematical’ selectivity and gives estimates for the concentrations of A and B with much higher accuracy than the one-channel calibration. In the PCR method, the number of degrees of freedom appearing in Eqn (6) equals

$$F = I - A.$$

It has been noted above that each chemometric model requires a proper validation. In our example, the validation was carried out using a test set (test validation) comprising five samples (mixtures of A and B). The validation results for substance B are shown in Fig. 11*a*. The data for nine samples participating in calibration and five test samples are given in the ‘measured–predicted’ coordinates. The RMSEC and RMSEP values and the correlation coefficients for the training (R_C^2) and test (R_T^2) sets are also given.

Figure 11. Validation of the calibrations in the model example using the principal component regression (a) and multiple regression (b). (a) $R^2 = 0.999$, RMSEC = 0.008, $R^2_c = 0.998$, RMSEC = 0.12; (b) $R^2 = 0.86$, RMSEC = 0.14, $R^2_c = 1.0$, RMSEC = 0; (1) training set, (2) test set.

The RMSEP values are calculated similarly to RMSEC [see Eqn (6)] but only for test samples. The number of degrees of freedom F is equal to the number of these samples. It can be seen that the principal component analysis passed the validation: the calibration and validation lines coincide.

Let us consider in this context the calibration by means of multiple regression. The training set consists of nine samples; therefore, not more than eight channels can be used for model construction ($I > J$); for example, the first, fourteenth, twenty-seventh, etc. The calibration and validation results for multiple regression are presented in Fig. 11 b. Since the number of samples is greater than the number of the channels only by one, the calibration line passes exactly through all points of the training set (points 1); therefore, RMSEC = 0 and $R^2_c = 1$. However, validation showed an unsatisfactory quality of this calibration: the accuracy is ten times worse than the accuracy in the PCR method, and the validation straight line does not coincide with the calibration line. This is a typical example of model overfitting:⁷¹ the accuracy of calibration is much higher than the accuracy of prediction.

The problem of balancing of data calibration is considered in many publications by Höskuldsson,¹⁵⁹ which introduced a new modelling concept, the so-called H-principle. According to this principle, the accuracy of modelling evaluated by the RMSEC parameter and the prediction accuracy evaluated by RMSEP are interrelated. A better RMSEC entails a poorer RMSEP; hence, they must be considered together. For this reason, the multiple linear regression, which always involves a redundant number of parameters, yields unstable models unfit for practical use.

Currently, PLS is the most widely used method for multivariate calibration in chemometrics. It resembles the PCR method; however, an important distinction is that PLS implies simultaneous decomposition of matrices $\mathbf{X}$ and $\mathbf{Y}$

$$\begin{aligned}\mathbf{X} &= \mathbf{TP}^t + \mathbf{E}, \\ \mathbf{Y} &= \mathbf{UQ}^t + \mathbf{F}.\end{aligned}\quad (7)$$

The projections are constructed in coordination, in such a way as to maximise the correlation between the X-score ($\mathbf{t}_a$) and Y-score ($\mathbf{u}_a$) vectors. Therefore, the PLS regression describes much better the complex relationships using a smaller number of principal component. The PLS method has been considered in detail in a book.⁷⁴ This approach has served as the basis for numerous calibration methods used in chemometrics, for example, SIMPLS,¹⁶⁰ PMN,¹⁶¹ robust PLS,¹⁶² ridge-PLS¹⁶³ and other.¹⁶⁴

However, all these methods give predictions as point estimates, whereas in practice, an interval estimate including the prediction uncertainty is often required. The construction of

confidence intervals by traditional statistical methods is impossible due to the problem complexity,¹¹⁴ while the use of simulation methods⁹⁸ is hampered due to the long computation time.¹⁰¹ Kantorovich¹⁶⁵ proposed to replace minimisation of the sum of squared deviations by a set of inequalities, which is solved by linear programming. In this case, the prediction gives an interval; therefore, this method was called 'simple interval calculation'.^{36, 56} Several works in analytical chemistry have been performed using this method.¹⁶⁶

2. N-Way regression

The multivariate calibration methods are naturally extended to the case where blocks $\mathbf{X}$ and $\mathbf{Y}$ are represented by N -way matrices.⁸⁰ The regression can be constructed in different ways. Using PARAFAC and Tucker3, the predictor block $\mathbf{X}$ is represented as a product of 2D loading matrices, which are used to estimate the parameters. These methods can be regarded as extension of PCR to multiway data. An extension of PLS is the Tri-PLS decomposition of the 3D matrix $\mathbf{X}$, which can be represented as follows:¹⁶⁷

$${}^u\mathbf{X} \approx \mathbf{T} {}^u\mathbf{P}.$$

Here ${}^u\mathbf{X}$ is a 2D matrix (with the dimension $I \times KJ$) obtained by unfolding of the 3D matrix $\mathbf{X}$ (with the dimension $I \times K \times J$) (see Fig. 7); $\mathbf{T}$ is the 2D score matrix (with the dimension $I \times A$); ${}^u\mathbf{P}$ is the 2D weight matrix (with the dimension $A \times KJ$), which in turn represents the unfolding for the 3D matrix $\mathbf{P}$, represented as the tensor product of two 2D matrices

$$\mathbf{P} = {}^J\mathbf{P} \otimes {}^K\mathbf{P}.$$

The decomposition of block $\mathbf{Y}$ is carried out in a similar way

$${}^u\mathbf{Y} \approx \mathbf{U} {}^u\mathbf{Q}.$$

Here, as in the usual PLS method, the scores $\mathbf{T}$ are chosen in such a way as to maximise the correlation between vectors $\mathbf{t}_a$ and $\mathbf{u}_a$. The regression problem $\mathbf{U} = \mathbf{TB}$ is solved by the conventional procedure.

The mathematical tool used in the multiway calibration is rather complex. However, the currently existing software[‡] allows chemists to overcome mathematical difficulties. Numerous examples of using multiway calibration in chemical analysis have been documented. For example, this method is used in spectrophotometry to determine pesticides,¹⁶⁸ in high performance liquid chromatography with diode matrix detection for peak resolution,¹⁶⁹ to determine trace concentrations of metals,¹⁷⁰ etc.

The use of gas chromatography – mass spectrometry to determine traces of clenbuterol in biological samples has been described.¹⁷¹ In recent years, this method has been widely used to analyse traces of organic compounds. However, due to the complexity of biological products and low content of the analyte, the estimated detection limit depends appreciably on the method of mathematical processing of experimental data. In the study cited, seven standard samples with known clenbuterol concentrations were prepared. The mass-spectrometric detection was carried out both in the full-scanning mode (210 ions) and for eight particular ions. The obtained data are three-way, the first way being the samples, the second, the mass spectra and the third, chromatograms. The full-scanning mode gave a 3D predictor matrix $\mathbf{X}$ with the dimension $7 \times 210 \times 37$; the separate ion detection mode gave a $7 \times 8 \times 22$ matrix. The response block is a 1D vector $\mathbf{y}$, which includes seven concentrations.

The calibration was constructed using various three-way algorithms: PARAFAC, PARAFAC2, Tucker3 and Tri-PLS. The Tri-PLS method proved to be the method of choice as this gave the lowest detection limit. A comparison of the results obtained by this method and a standard univariate procedure

[‡] See R Bro, C A Andersson *The N-Way Toolbox for MATLAB*. Version 2.02 (2003). Available at <http://www.models.kvl.dk/source>

showed a pronounced decrease in the detection limit, in particular, from 283 to 20.91 mg kg⁻¹ in the full-scanning mode and from 73.95 to 26.32 mg kg⁻¹ for scanning of particular ions. The detection limits were calculated in terms of the NAS concept.¹²⁴

3. Non-linear calibration

In some cases, for example, in the titration problems considered above, it is impossible to build a linear calibration. In addition, the linear technique requires a large number of data, which are not always available. Two alternative approaches are possible. One implies multiple non-linear regression, while the other, multi-variate non-linear calibration. Both approaches are considered below.

The non-linear regression analysis¹⁷² can be successfully used to solve problems of quantitative analysis if the variables are few in number. In addition, a conceptual model relating the blocks **X** and **Y** is required. Apparently, the scope of such problems is not wide, including mainly kinetic (in particular, titration) problems.⁹⁵ This approach was employed, for example, in the analysis of the activity of antioxidants,³⁶ in solving the inverse kinetic problem^{34, 94} and for the above-mentioned titration.^{173, 174} A detailed analysis of the problems faced by a researcher who uses this approach has been reported.⁵⁷

An alternative to the classical regression is the soft approach, which does not require the knowledge of a hard model but implies the presence of a large number of data.⁷⁸ To take into account non-linear effects, the INLR,¹⁷⁵ GIF-PLS¹⁷⁶ and QPLS¹⁷⁷ methods representing the upgraded PLS method have been proposed.⁸¹ In addition to non-linear PLS, the ANN method^{178, 179} simulating signal propagation in the cerebral brain cortex is used in chemometrics. This method is used successfully for function interpolation. About 10 years ago the neural network method attracted attention of chemists, which started to use it for classification,¹⁸⁰ discrimination⁵³ and calibration.^{181, 182} However, more recently, the interest somewhat attenuated and the use of ANN in chemometrics became more seldom. The reason is the above-noted model overfitting. When using neural networks, it is very difficult to evaluate correctly the degree of complexity of the model, which results in an unstable and unreliable prediction. Yet another interesting version of non-linear modelling that simulates biological processes is the GA method.^{183, 184} This method and its modification, the IA method, are useful in those cases where the chemical analysis problem fails to be formalised in terms of the usual objection functions, for example, for resolution of overlapping multicomponent chromatograms.¹⁸⁵ Examples of practical application of non-linear approaches in chemiluminescent analysis have been reported.¹⁸⁶

V. Data preprocessing and signal processing

1. Data preprocessing

An important condition for correct modelling and, hence, successful chemical analysis is the preliminary data preprocessing, which includes various transformations of the initial ('raw') experimental values. The simplest transformations include centring and scaling.¹⁸⁷ Centring is subtraction of some matrix **M** from the initial matrix **X**

$$\tilde{\mathbf{X}} = \mathbf{X} - \mathbf{M}.$$

Usually, centring is carried out by columns: for each vector **x_j** the average values are calculated

$$m_j = \frac{x_{1j} + \dots + x_{Ij}}{I}.$$

Then

$$\mathbf{M} = (m_1 \mathbf{l}, \dots, m_J \mathbf{l}),$$

where **l** is a vector of ones with the length *I*. In some cases, centring by rows is also carried out: the average values for the rows are

calculated and these values are subtracted from the corresponding rows **x_i^t**. In the case of multiway data, centring can be carried out separately for each way. Centring is required if the model is uniform, *i.e.*, has no absolute term, as in Eqns (1) and (7). After this operation, the chemical rank of the model decreases by unity and the accuracy of description may increase. Centring may be considered as projecting onto a zero principal component,¹³ hence, it is always used in the PCA and PLS methods. However, centring should not be employed if there are gaps in the data.

The second simplest transformation of data is scaling. Unlike centring, this transformation does not change the structure of the data but only the weight of their parts on processing. Scaling can be carried out for each mode. Scaling by columns is multiplication of the initial matrix **X** by matrix **W** on the left

$$\tilde{\mathbf{X}} = \mathbf{W}\mathbf{X},$$

where **W** is a diagonal matrix with the dimension *J* × *J*. Usually, diagonal elements *w_{jj}* are equal to the reciprocal of the standard deviation

$$d_j = \sqrt{\sum_{i=1}^I (x_{ij} - m_j)^2 / I}$$

along column **x_j**. Normalisation by rows is multiplication of matrix **X** by diagonal matrix **W** on the right

$$\tilde{\mathbf{X}} = \mathbf{X}\mathbf{W}.$$

The dimension of **W** is *I* × *I*, while its elements *w_{ii}* are the reciprocal values of the standard deviations of the rows **x_i^t**. A combination of centring and scaling by columns

$$\tilde{x}_{ij} = \frac{x_{ij} - m_j}{d_j}$$

is called autoscaling.

Data scaling is often used in order to equalise the contribution of variables to the model (for example, in the liquid chromatography–mass spectrometry hyphenated method), to take into account the heteroscedastic errors, or for combined processing of different blocks of data. Scaling can also be considered as a method that allows one to stabilise the computation algorithms.⁷¹ However, this type of transformation should be used with caution, because it can distort the results of qualitative analysis.⁴²

Apart from linear transformations, non-linear transformations of experimental results are also used. For example, in analysis of the data of near-IR spectroscopy, the Kubelka–Munck transformation is often employed.¹⁸⁸ The purpose of this and other transformations, for example, the Box–Cox transformation,³³ is model linearisation. Simple operations with the data such as taking the logarithm⁵⁶ or extraction of the root³⁶ can often markedly improve the model.

Almost in all cases, the initial data contain errors both random and systematic. In order to reduce the influence of random noise, various methods of data smoothing are used, for example, moving average, the Savitzky–Golay method.^{42, 189} Reducing the effect of systematic errors, *i.e.*, removal of the systematic shift of the data, is more difficult. If this shift is invariable, it can be removed using centring. In the case of linear or square dependence on the variable (for example, wavelength), numerical differentiation may prove useful. In the case of more complex dependences, special methods are used; two of these are considered below.

The multiple signal correction method, called also multiplicative scattering correction (MSC),⁷⁰ was first developed¹⁹⁰ for near-IR spectroscopy and was based on ideas stated by Kubelka and Munck.¹⁸⁸ The MSC transformation procedure is simple. First, the 'basic spectrum' is determined as the average over all rows of matrix **X**.

$$\mathbf{m}^t = \frac{\mathbf{x}_1^t + \dots + \mathbf{x}_I^t}{I}$$

Then a regression is constructed for each row $\mathbf{x}_i^t$

$$\mathbf{x}_i^t = a_i + b_i \mathbf{m}^t + \mathbf{e}_i^t$$

and the coefficients a_i and b_i are determined. The transformed data are obtained from the equation

$$\tilde{\mathbf{x}}_i^t = \frac{\mathbf{x}_i^t - a_i}{b_i}.$$

The MSC parameters a_i and b_i can be found only for some (floating) window rather than for all variables.¹⁹¹

The second method (more precisely, a group of methods), OSC¹⁹² differs in the fact that the predictor matrix $\mathbf{X}$ is transformed using the response block $\mathbf{Y}$. This method is applied for data preprocessing in solving problems of quantitative analysis. The idea of OSC is to remove, from block $\mathbf{X}$, all the systematic dependences not related to the modelled response, *i.e.*, the part of matrix $\mathbf{X}$ that is orthogonal to matrix $\mathbf{Y}$. This should result in an increase in the correlation coefficient R^2 and decrease the number of PLS components A needed for data modelling. There are many versions of this method, which was first proposed by Wold *et al.*¹⁹³ and developed by other researchers.^{194,195} The OSC procedure, like the PLS procedure, is accomplished successively by steps. In each step, a part of matrix $\mathbf{X}$ related to one OSC component is removed. The part of the matrix

$$\mathbf{X} = \mathbf{X}_1 + \mathbf{X}_2,$$

orthogonal to $\mathbf{Y}$, *i.e.*, such that

$$\mathbf{Z} = \mathbf{Y}^t \mathbf{X}_2 = 0,$$

is determined using an algorithm similar to PLS. The OSC method and MATLAB codes have been described in detail in a publication.¹⁹⁵

An approach that improves the model quality by selection of variables is an alternative to the MSC and OSC methods. The utility of selection, *i.e.*, elimination of some columns $\mathbf{x}_j$ from the initial data $\mathbf{X}$, was confirmed by both theoretical investigations and experimental results. This approach is used in both qualitative¹⁹⁶ and quantitative analysis.¹⁹⁷ The variable selection is performed using a number of methods, in particular,¹⁹⁸ Pareto optimisation¹⁹⁹ and 'jack knife'.¹¹⁷ Of special importance is variable selection in those cases where the analytical signal continuously depends on the channel, for example, in the analysis of spectrometric data.²⁰⁰ In this case, variables are selected by blocks, as in methods considered in Refs 195, 201. Apart from variable selection, the selection of samples, *i.e.*, rows $\mathbf{x}_i^t$ in matrix $\mathbf{X}$ (together with the corresponding values in the response matrix $\mathbf{Y}$), is also used. The sample selection may also improve the model quality, but it is especially important for detection of outliers,¹¹³ for calibration transfer from one instrument to another.^{116,202,203} The new approach to sample classification and selection has been reported.⁵⁶

2. Signal processing

The processing of analytical signals using various transformations and filters plays an important role in chemical analysis.^{204,205} The Fourier transform has actually revolutionised NMR, IR and X-ray spectroscopy during the last 20 years. The initial data are not recorded as primary spectra but as temporal series in which all the spectroscopic information is mixed, and recovery of the spectra requires a mathematical processing. A main reason for using Fourier spectrometry is increasing the signal-to-noise ratio; in addition, the experiment can be carried out about 100 times faster than with a conventional spectrometer. For example, this allowed ¹³C NMR spectroscopy to become a routine analytical method, despite the low sensitivity of the ¹³C nuclei to an external magnetic field. Using pulse NMR spectroscopy, one can accumulate and sum up signals for a large number of pulses. Simultaneously with Fourier transform spectroscopy, numerous methods appeared for improving the quality of data. These methods

include the so-called Fourier deconvolution (signal separation), some operations with the initial data in the temporal domain and the subsequent use of the Fourier transform.

Yet another modern method for signal processing is wavelet analysis.²⁰⁶ This allows encoding, compression and modelling of large data containing thousands of variables. This analysis is a natural development and continuation of the Fourier method. A drawback of the Fourier method is that its basis functions depend continuously on time; therefore, they cannot be used to present time-dependent data. Wavelet analysis employs basis functions with a limited range of variation of the argument, which satisfy special requirements of a scaled range. These functions shift along the signal axis and the spectra obtained upon verification provide a time-and-frequency representation with different resolutions depending on the range width. If wavelet analysis precedes the PCA or PLS method, these methods can be applied to analyse very large data without loss of information.²⁰⁷ Wavelet analysis is also used for compression and smoothing of mono- and two-way IR spectra and NMR spectra.²⁰⁸

In some cases, it is necessary to perform a fast signal smoothing in real-time. The Kalman filter is a method developed for this purpose. It can be used, for example, to model the variation of the kinetics during a process. The general idea of the Kalman filter is correction of the model following the process development. As soon as new data become available, the model is supplemented and improved. With the advent of fast and powerful computers, the Kalman filter has become of virtually no use, although some works performed with this tool still appear (see, for example, Ref. 209).

VI. Conclusion

1. Process analytical technology

We have considered the key achievements of chemometrics during the last 15–20 years and their applications in analytical chemistry. Many topical issues and applications both related to and far from analytical chemistry remained beyond the scope of the review. One issue deserves special attention, as it reflects most vividly the trends and prospects of the development of chemometrics and analytical chemistry, in particular, we are speaking about methods for the process analytical technology.

In the 1930s, the American statistician Shewhart²¹⁰ proposed to use statistical methods for the control of industrial processes. His idea is very simple: if data on a normally operating industrial process over a long period are collected and statistically processed, then for a controlled operating parameter x , a range can be established, $[x_{\min}, x_{\max}]$, in which the process operates normally. The departure of the parameter x beyond these limits gives warning about some emergency that requires immediate intervention. This method was called statistical process control. It has been successfully used in practice (Shewhart charts). However, subsequently, as the process technology became more complicated, it turned out that each parameter x_i cannot be monitored separately independently of other parameters. This often resulted in faulty decisions such as false alarms, off-spec products, *etc.* The point is that the measured operating parameters $x_1, x_2, \dots$, are usually interrelated (correlated) with each other and they should be considered together. The situation largely resembles analysis of multichannel chemical data (*e.g.*, spectra). Taking into account this analogy, MacGregor²¹¹ developed a new approach to the solution of this problem, MSPC.²¹² He proposed to use the PCA method for the analysis of multivariate data and to construct control limits in the score space by means of the Mahalanobis distance. The idea proved highly fruitful and found numerous supporters. Chemometric specialists developed methods for the multivariate control of batch (for example, biochemical) processes based on the three-way calibration;²⁴ hierarchical,²¹³ block²¹⁴ and path⁸² methods have been developed for the analysis of complex processes. The authors of some studies proposed not only to monitor but also to optimise the processes.²¹⁵ These theoretical

results have been used in practice, first of all, in the food²¹⁶ and pharmaceutical²¹⁷ industries. Systems for the quality control in the production of polymers,²¹⁸ non-ferrous metals²¹⁹ and semi-conductors⁴¹ have been developed.

Thus, a new trend appeared in chemometrics²²⁰ dealing with problems far from the problems of analytical chemistry. However, it was found that sensors and transducers used traditionally in various branches of industry do not provide information necessary for the control of complex (first of all, pharmaceutical) processes. There appeared urgent need for methods of real-time or even *in situ* monitoring of chemical reactions.²²¹ Traditional analytical methods, first of all, UV⁹⁴ and IR²²² spectrometry proved suitable for this purpose. The chemometric methods for the resolution of curves and estimation of kinetic constants from spectroscopic²²³ and chromatographic²²⁴ data were found to be useful for monitoring of chemical reactions and processes. A combination of MSPC with analytical monitoring and with process analytical chemistry²²⁵ gave an impetus to the development of a new line of research in analytical chemistry, process analytical technology (PAT).²²⁶ PAT is a system for designing, analysing and controlling the manufacture through timely measurements (*i.e.*, during processing) of critical quality and performance attributes of raw and in-process materials and processes, with the goal of ensuring final product quality.

The major problem faced by modern industry is to ensure high quality of the final product. In view of the increasing global competition and fluctuating market demands, the necessity of effective control of industrial processes in real-time becomes obvious, and chemometrics plays a crucial role in solving this problem. The USA Food and Drug Administration²²⁷ confirmed this role legislatively in September, 2004.

Within the framework of chemometrics, remarkable methods and algorithms have been created; however, they were approved very slowly and reluctantly by the regulating authorities of all developed countries. This is attributable to the fact that ideas of the multivariate approach are more difficult to perceive and visualise than the traditional univariate methods, which are not always able to reflect the full situation. For example, it is much easier to state that the product quality is described by the height of some peak at a particular wavelength than to explain that this quality is determined by whether or not the projection of the whole spectrum falls into a definite area in the PLS-score space found using the Mahalanobis distance, *etc.*

Throughout the whole history of the development of chemometrics, only one regulatory document has been adopted in this field.²²⁸ After the PAT document is approved, chemometrics will necessarily become a legitimate tool for any company willing to follow the FDA guideline principles. In our opinion, approval of this regulatory document would mark a crucial turn in technology and a new industry paradigm, the mission of which is to build quality into products. A fundamental distinction of this paradigm from the existing one is replacement of the standardisation and unification principles by flexible on-line control of the future product quality at every stage of the manufacture starting from raw material analysis. Consider a simple example: the products of catering facilities that work with the 'standardisation' paradigm have an obviously poorer quality than home-made food, which is produced with flexible on-line control. However, with the introduction of the PAT system, large-scale producers would be able to ensure the same high quality while maintaining large output.

2. Prospects of development

What is the role of analytical chemistry in the formation of this new technological paradigm? What can be chemists' answer to this question? In our opinion, the following trends would prevail in the development of analytics. First, the objects of analysis would become more complex and complicated. The industry requirements would not put peripheral questions such as how much of substance X is present in a sample but general questions of whether a product with the required quality will be obtained

from the given raw material or whether the chemical reaction in the given column develops in a right way. Second, methods of analysis will be changed to gain the required data directly in the plant in real-time (*in line*) rather than in the laboratory (*at line*). Third, the amount of multiway and multivariate data will sharply increase. The role of hyphenated and composite methods of analysis will grow. Fourth, the desired chemical information will be deeply hidden in these data; moreover, it will be less formalised, which will call for the use of fine methods for its retrieval. Fifth, the organisation of the analytical experiment will change: instead of analysis of a single sample in one experiment, it will be necessary to use a system approach according to which numerous samples are analysed simultaneously by different methods in an automated mode under different conditions. This large-scale computer-assisted experiment (which already exists, for example, in the microarray approach) will become a routine analytical practice. Sixth, the analytical investigation will be focused on biological objects and biochemical processes and on industrial processes as a whole.

All these trends are already visible in analytical chemistry. The role of analytical chemist will change: he will inevitably become more an analyst than a chemist. The problems tackled by the researcher will be reduced to two key problems. The first is to set up an experiment that could give data suitable for retrieving the required information. The desired information may be a prognosis for the final state of the system rather than a quantitative (concentration) or qualitative (yes/no) result. The second problem is how to retrieve the desired information from the data and interpret it from the utility and quality standpoints. To solve these problems, a researcher must use the experience and tooling of chemometrics. Thus, chemometrics as an inherent part of analytical chemistry will largely determine the trends of its development.[§]

It should be emphasised that the pronounced extension of the scope of analytical methods should be based on close cooperation of chemometric specialists not only with chemists but also with other scientists, first of all, mathematicians, physicians and biologists.

The authors are grateful to O N Karpukhin (Institute of Chemical Physics, Moscow) and A Yu Bogomolov (EMBL, Hamburg) for valuable advice during preparation of the review and to K Esbensen (Aalborg University Esbjerg, Denmark) for his effort aimed at popularisation of chemometrics in Russia.

Abstract. The trends in the development of five main branches of atomic spectrometry, *viz.*, absorption, emission, mass, fluorescence and ionisation spectrometry, are analysed. The advantages and drawbacks of various techniques in atomic spectrometry are considered. Emphasised are the applications of analytical plasma- and laser-based methods. The problems and prospects in the development in respective fields of analytical instrumentation are discussed. The bibliography includes 279 references.

I. Introduction

Analytical atomic spectrometry embraces a multitude of techniques of elemental analysis that are based on the decomposition of samples into the state of free atoms followed by spectroscopic determination of their concentrations. One can distinguish five major branches of atomic spectrometry, *viz.*, absorption, emission, mass, fluorescence and ionisation spectrometry. The first three are most popular and versatile; atomic mass spectrometry is the most sensitive. Other methods used in elemental analysis (X-ray fluorescence, nuclear magnetic resonance, Auger electron spectrometry, neutron activation analysis, *etc.*), which are not based on the analyte atomisation and unrelated to the spectroscopy of atomic vapour, are not considered in this review.

The main goals of analytical atomic spectrometry are to attain the lowest limits of detection (down to single atoms) and the broadest dynamic range (ideally, from single atoms to 100% content), suppress the matrix effect, eliminate spectral interferences, minimise the time and cost required for sample preparation, and pass from multistage to direct methods. Fundamental studies on the development of methods for absolute and standardless analyses, aimed at avoiding calibration by standards, are in progress. Ever increasing is the role of the software development, which in certain cases facilitates substantially the deconvolution of complex background components, allows digital

processing (averaging) of noise and enhances the analysis accuracy due to the use of correlation models and neural network algorithms.

The development of analytical spectrometry and detection techniques is stimulated by the diverse and increasing demands in industry, medicine, science, environmental control, forensic analysis, *etc.* The development of portable analysers for the determination of elements in different media at the immediate point of sampling, which eliminates the stages of collecting, transportation and storage of samples, is one of the most important directions.

It should be noted that the development of atomic spectrometry slowed down in recent years; particularly, a trend towards a decreasing number of scientific publications occurred. Such a deceleration could be due to the fact that the overwhelming majority of issues in elemental analysis can successfully be solved using the available techniques and instrumentation.

The above statements may be supplemented by several general remarks.

1. According to the amount of scientific publications and conference presentations, the inductively coupled plasma emission and mass spectrometers (ICP-AES and ICP-MS) are the most popular. This is because of the fact that the inductively coupled plasma in argon heated to 6000–9000 K at the electron density of $\sim 10^{15} \text{ cm}^{-3}$ represents a virtually ideally linear atomiser and ioniser (*i.e.*, virtually independent of the sample matrix and providing the linear relationship between the analyte concentration and the analytical signal).

2. In practice, any sensitivity required for the majority of applications can be provided using commercial instruments, in particular, ICP-MS (high resolution double-focusing ICP-mass spectrometers are used in especially difficult cases).

3. Atomic absorption, arc and spark emission spectrometers remain a less expensive alternative to ICP-MS and ICP-AES instruments. Moreover, in practical applications, atomic absorption spectrometers have held the leading position for many decades. Current proliferation of ICP-AES spectrometers approaches that of the former.

4. The throughput of analysers has reached a sufficiently high level, which allows thousands of routine analyses to be performed daily. The main current tendency is to provide faster and more efficient performance using modern analytical instruments, thus spending less time and efforts.

5. Further development is aimed at improving sample introduction and simplifying the sample preparation, reducing the total

Table 1. Main abbreviations used for particular techniques of analytical atomic spectrometry.

Atomic Absorption Spectrometry (AAS)	Atomic Emission Spectrometry (AES)	Atomic Mass Spectrometry (MS)	Atomic Fluorescence Spectrometry (AFS)	Atomic Ionisation Spectrometry (AIS)
Electrothermal Atomisation AAS (ETA-AAS)	Inductively Coupled Plasma AES (ICP-AES)	Inductively Coupled Plasma MS (ICP-MS)	Inductively Coupled Plasma AFS (ICP-AFS)	Laser-Enhanced Ionisation Spectrometry (LEIS)
Cavity Ring-Down Spectroscopy (CRDS)	Laser Ablation ICP-AES (LA-ICP-AES)	Laser Ablation ICP-MS (LA-ICP-MS)	Laser-Excited Atomic Fluorescence Spectrometry (LEAFS)	Laser Optogalvanic Spectrometry (LOGS)
Intracavity Laser Spectroscopy (ICLS)	Laser-Induced Breakdown Spectrometry (LIBS)	Laser Ablation Mass Spectrometry (LA-MS) Resonance Ionisation Mass Spectrometry (RIMS)		

cost, using new software for the automation of the analysis and data processing, making faster analysis and reducing the size of the instruments (while the earlier ICP-AES analysers could have the size of a wardrobe, the modern ICP-MS instruments measuring $110 \times 60 \times 58$ cm can be installed on a desk). An active progress is observed in the development of specialised equipment for the analysis of specific samples and determination of particular elements.

Annual reviews^{1–6} on the analytical atomic spectrometry published by the *Journal of Analytical Atomic Spectrometry* (London) represent the most convenient literature source to follow the trends in this field. They summarise new information on the progress along several directions, including optical and mass spectral methods, as well as use of spectrometric analysis in environmental monitoring, industry, biology and medicine. The total number of citations in these reviews and their distribution over different analytical methods reflect the trends of modern studies in atomic spectrometry. The publications cited in these reviews may be classified (on the average, over the last 5 years) as follows: modernisation of optical methods — 83%, improvement in ICP-MS — 17%, laser-based methods (including laser ablation in ICP-MS) — 16%. The latter figure illustrates an increased interest in the development of laser-based methods of analysis (publications on routine applications were not considered here).

The American journal *Analytical Chemistry* also publishes summarising overviews^{7,8} on the atomic spectrometry every two years. A particularly interesting comparison of different spectrometric methods was carried out on a five-grade scale.⁹ Several techniques at a glance were also compared.^{10,11} Moreover, several books were recently published and analytical series were supplemented with new volumes.^{12–21} The information contained in these sources allows us to consider the state-of-the-art in the field of analytical atomic spectrometry.

In this paper, we present the best detection limits achieved to date in the analytical techniques under discussion. However, these lowest detection limits can hardly be realised for each element; and thus, in many real analytical situations the detection limits may exceed those cited by several orders of magnitude. Most often we cite only the latest publications, in which the reader can find references to earlier articles. The list of references by no means reflects the chronological priorities. Table 1 lists the abbreviations used for individual spectrometric techniques; however, it does not exhaust all methods discussed in this review.

II. Atomic absorption spectrometry

While the pace of the development in modern atomic spectrometry continues to slow down (a reducing number of scientific publications, reports and presentations at exhibitions), the atomic absorption analysis continues to hold its position among the most dynamic themes, even though the history of commercial instrumentation in this field can be traced back to more than 40 years ago. Several new modifications of this method were discussed in reviews;^{22,23} first of all, it is atomic absorption spectrometry based on diode lasers (with the aim of size and cost reduction) and use of continuum spectrum sources that allow simultaneous multi-

element analysis. Studies on the improvement of graphite furnaces, automated introduction of powder and solid samples, flow-injection method and the use of echelle polychromators and charge-coupled detectors (CCD) for the rapid determination are in progress.

The advantages of continuum spectrum sources (e.g., a powerful xenon short-arc lamp), starting with the possibility of combining simultaneous multielement analysis with simultaneous background correction, were described.^{24–26} It was shown²⁷ that the use of the linear photodiode arrays or two-dimensional CCD arrays as detectors facilitated reduction of the inaccuracies caused by spatial absorption inhomogeneities in electrothermal atomisers (ETA). Some of the latest developments, in particular, use of continuum spectrum sources and cross-dispersed echelle spectrometers, as well as devices for automatic introduction of powder samples, have already found their application in commercial analysers.

Several summarising papers^{28,29} were devoted to the possibilities of the use of diode lasers in AAS. The advantages of broadly tuneable vertical-cavity surface-emitting laser diodes were illustrated in Ref. 30 that also cites the original publications on different experimental applications of diode lasers as the sources of tuneable radiation for determination of absorption by Al, Ba, Ca, Cr, Cs, Cu, Gd, Hg, I, In, K, La, Li, Mn, Pb, Rb, Sm, U, Y and Zr atoms. However, a much greater number of studies on the use of diode lasers were devoted to the determination of simple molecules such as H₂O, CO₂, CO, NH₃, HF, HCl and *etc.* (see reviews^{31–33}).[†] Simultaneous determination of several elements has been realised in multiplexing schemes with several diode lasers. It is also possible to use light emitting diodes in absorption spectroscopy.^{34,35}

The very narrow spectral width of the output emission of diode lasers (usually, $\sim 10^{-5}$ nm in a single-mode operation) is of primary importance for spectrometric purposes. The laser output radiation can be scanned over the wavelength throughout the absorption line from one wing to another. This allows one to assess the non-selective background absorption at both wings of the absorption line, thus eliminating the need for calibration with a reference beam. The signal can be detected by a photodiode without using dispersion optical devices (monochromators, spectrometers); in this case, high resolution achieved is due to the spectral narrowness of the laser output. Diode lasers can be modulated at frequencies up to 100 MHz; in combination with lock-in detection (on the fundamental or higher harmonics) of the absorption signal, this facilitates cutting off the low-frequency noise and drift effects. Moreover, the spectral resolution of diode lasers is sufficient for direct discrimination of isotopes of light (Li) and heavy (U) elements. The discrimination of intermediate isotopes is possible with the sub-Doppler saturation absorption spectroscopy.

Recently, an interest in cavity-based absorption techniques used for the many-fold increase in an effective optical path

[†] This subject was also thoroughly surveyed by T Imasaka *Talanta* **48** 305 (1999).

through the absorbing medium was renewed. It is known^{21, 36} that in the family of such techniques the method of intracavity laser spectroscopy (ICLS) in which the sample is placed inside an active laser cavity is characterised by the lowest detection limits. However, numerous non-linear effects that arise in an active cavity complicate severely the practical application of this method. Both a linear response and relative simplicity are achieved with laser-pumped passive cavities. Moreover, here the diode lasers can be used for pumping. These reasons along with the need for compactness and affordability of analytical instruments have defined the rapid development of the absorption methods based on passive optical cavities.

Here, in contrast to the ICLS technique, the sample is placed in an external (with respect to the laser) cavity with high-reflectivity mirrors. The higher the mirror quality the longer the photon lifetime in the cavity, *i.e.*, the longer is its path through the sample. Thus one can achieve pathlengths of several tens kilometres for a cavity 30–50 cm long, which makes it possible to obtain very low detection limits. One can use, as an analytical signal, either the intensity of the radiation leaking out of the cavity or the rate of signal decay upon the abrupt interruption of laser pumping, while a laser wavelength can be scanned through the absorption line. The first version corresponds to traditional extracavity absorption spectroscopy and is now often called the cavity-enhanced absorption spectroscopy (CEAS). In the second version called cavity ring-down spectroscopy (CRDS), the characteristic time of the energy loss in a passive cavity is measured.

In both versions utilising passive cavities, the analytical responses are directly related to the absolute concentration of absorbing impurities in the cavity. Both techniques exhibit approximately equal high sensitivities. The use of the CRDS method requires more complicated equipment, however it facilitates the absolute calibration. The output insusceptibility to fluctuations of the excitation laser radiation is one of the major merits of CRDS. Note that in both versions one has to match the cavity spectral modes to the pumping laser mode (or modes), the piezoelectric modulation of the cavity length being often used for this purpose. This technique, although being relatively new, has been the topic of a monograph²¹ and several reviews.^{37–40}

The use of cavities allows one to measure absorption signals that are several orders of magnitude weaker than those in conventional absorption spectroscopy. To date, only preliminary experiments have been carried out on the combination of the plasma atomisers with the CRDS detection.^{41–46} The optimum conditions for igniting the plasma used as the AAS atomiser substantially differ from those conventionally employed in the emission analysis (in the same way as the requirements imposed on plasma in ICP-AES and ICP-fluorescence spectrometry differ). At the same time, insofar as CRDS is a pulsed technique, it is reasonable to couple it with the synchronised pulsed plasma, which allows substantial reduction of the plasma background emission (this is implemented, for instance, in the plasma/laser-excited fluorescence spectrometry of gases⁴⁷).

So far, we are aware of only one paper devoted to the electrothermal atomisation combined with CRDS detection.⁴⁸ Despite experimental difficulties associated with thermal stabilisation of the cavity while an electrothermal furnace is placed inside, it was concluded that this method holds a great promise, especially related to the possibility of using diode lasers. Detection of trace amounts of mercury vapour was an example^{49, 50} showing that the sensitivity of the CRDS technique can far exceed that of the conventional atomic absorption.[‡] A relatively narrow spectral range in which the dielectric mirrors retain their high efficiency is a disadvantage of cavity-based methods. This limits the possibilities of these techniques regarding the number of elements that can be determined simultaneously.

‡ This is also evident from the results of determination of gallium in flame. See M Emig, R I Billmers, K G Owens, N P Cernansky, D L Miller, F A Narducci *Appl. Spectrosc.* **56** 863 (2002).

Diode laser-based atomic absorption spectrometry has not yet left the walls of research laboratories. However, progress in the development of absorption enhancement techniques in passive cavities and the gradual increase in the number of elements detectable with diode lasers give us the grounds to hope that such commercial analysers will be available in the future. In principle, diode lasers allow determination of up to 54 elements.²⁹ The scope of this method can be further extended to include the elements, resonance lines of which are beyond the wavelength range accessible with diode lasers, while their lower excited states may be highly populated in the high-temperature or plasma atomisers.

Studies on the use of the hollow-cathode glow discharge plasma as a 'cold' atomiser in absorption spectrometry are in progress.^{51, 52} Direct sputtering of the cathode material or the material of films coated on the cathode makes it possible in certain cases to simplify substantially the atomisation procedure and reduce the matrix effects on the results of determination of impurities owing to efficient dissociation of all sample components in the plasma. In principle, by using plasma atomisers, it is possible to simultaneously acquire the absorption and emission spectra. A miniature low-frequency (5–20 kHz) discharge in combination with a semiconductor laser source was proposed⁵³ as a prototype of absorption sensors.

Modernisation of conventional atomic absorption instrumentation leads to both the realisation of multielement analysis (by using continuum sources or sets of multielement lamps) and the increase in data acquisition rates, *i.e.*, rapid sequential determination of several elements in one sample. The latest improvements can boost the characteristics of the atomic absorption analysers with electrothermal atomisers (ETA-AAS) to approach those of the ICP-AES instruments, without compromising their simplicity and low cost. Although the dynamic range of AAS spectrometers usually does not exceed three orders of magnitude, their detection limits are low, *viz.*, down to $\sim 10^{-10}\%$ for electrothermal atomisation and $\sim 10^{-7}\%$ in flames. Using ETA-AAS, one can perform sequential determination of about 50 elements with high sensitivity.

Physico-chemical processes that occur in a graphite furnace with coatings and chemical modifiers used for the sample stabilisation, reduction of the graphite corrosion and decrease in the effect of thermochemical reactions on the graphite tube were considered.^{54–56} A kinetic model of the absorption signal was developed.⁵⁷ Studies on further corrections for the non-selective background absorption^{58, 59} and use of the principal component analysis⁶⁰ are in progress.

The application of AAS with gaseous sample introduction (in the case of volatile hydrides, halides, organometallic and other compounds) is being gradually expanded. The atomisation is provided by decomposition of the molecular vapours, *e.g.*, in a heated quartz tube. The merits of this method include nearly 100% efficiency of the gas-phase transport and low detection limits ($\sim 10^{-8}\%$). Determination of quite a number of elements (Ag, As, Au, Bi, Cd, Co, Cu, Ge, Ni, Pb, Sb, Se, Sn, Te, Zn, *etc.*) is possible by this method, however most often volatile hydrides are used for the determination of arsenic and selenium.^{61–64} Some of commercial instruments for atomic absorption are equipped with exchangeable atomiser modules, which include flame, ETA, and also a quartz tube for the introduction of volatile compounds and mercury vapour.

The concept of absolute absorption analysis is subject to continuous development. Thus, L'vov believes^{65, 66} that the possibility of the analysis without using standards for calibration might be realised in the future. For this purpose, one would need spectrally narrow and bright radiation sources, thermally stabilised atomisers that can provide complete atomisation in a defined volume, and matrix array detectors that would take into account all spatial inhomogeneities in the analysed vapour distribution. In our viewpoint, the former and latter conditions can be best met with diode lasers and two-dimensional CCD detectors.

III. Atomic emission spectrometry

In the field of atomic emission spectrometry, the leading role is played by ICP-AES. Such instruments have been commercially available for more than 30 years. Besides using conventional inductively coupled argon plasma in atmospheric-pressure torches, the emission spectra are also excited in other kinds of plasma, including direct-current plasma, glow discharge, radio-frequency discharge, microwave-induced plasma, as well as inductively coupled discharges at reduced pressure and other plasma sources. Several fresh reviews on this subject can be found in the literature^{67–71} (see also the monograph¹⁷). Such conventional sources as sparks and arcs are still used in practice.^{72,73} The plasma of laser-induced breakdown at the focus of the laser beam in the bulk of gas (air) or on the sample surface represents a special case.

Further progress is observed in advanced light-collection schemes in ICP-AES. An increase in the optical throughput of the instruments is achieved by using both aspherical optics and high-efficiency holographic gratings. Echelle gratings incorporated into the cross-dispersed schemes are utilised^{74–76} with the aim of collecting the whole spectrum on a single CCD array detector, thus providing virtually simultaneous recording of the whole data envelope, including information required for the automatic background correction. However, due to the high density of information per pixel, the spectral resolution is compromised in such schemes; hence, in the latest versions of ICP-AES instruments the plasma emission spectrum is dispersed along the Rowland sphere segment, with 10 to 20 CCD cameras installed along the spectrum span. This results in excellent resolution and very rapid recording. Most of the ICP-AES instruments allow simultaneous determination of 75 elements with a linear dynamic range of 5–6 orders of magnitude.

Simultaneous recording of a whole cluster of spectral lines opens up the possibility of more advanced processing of analytical information, particularly, when several lines for each element are considered.⁷⁷ Thus, one can reduce or correct the matrix effects on the results of analysis, avoid systematic errors due to self-absorption of strong lines, take into account the temporal instability of the electronic gain factor and the baseline drift, utilise multicomponent calibration and the regression relationships. Sometimes spectrometers filled or purged with inert gases are used, which enables recording of the vacuum UV spectrum where the most sensitive lines of many elements are located and fewer spectral interferences are found.

Microwave plasma with a relatively low gas temperature and high energy of free electrons is often used for the elemental analysis of compounds separated by chromatography or capillary electrophoresis. The advantages of this kind of plasma include the high excitation capability combined with the low power and compact equipment. However, due to the low temperature of plasma, its parameters strongly depend on the amount and composition of the introduced sample eluents. The analytical applications of the microwave plasma were surveyed.^{78,79}

Interesting publications^{80–82} were devoted to the combination of the graphite furnace atomisation with microwave plasma excitation of emission from the analysed vapour, which provided high atomisation temperature within a compact instrument and made it possible to determine all elements at once in micro-samples. Such plasma in a graphite furnace can also be used for the elemental analysis of compounds separated by gas chromatography.⁸¹ The dependence of the plasma parameters on the sample matrix composition (especially those rich in easily ionised elements) cannot be totally avoided; however, this dependence is weaker than that in conventional schemes where both atomisation and excitation take place in a microwave plasma.

Aimed at miniaturisation of spectrochemical analysers, keen attention is paid currently to the development of microplasma sources and analytical techniques based on their application. Echelle⁷⁵ and other microspectrometers (with a satisfactory

spectral resolution and the cigarette-pack dimensions) can be used to detect the emission. The evident advantages of such miniature analysers are the possibility of using them in field and constraint environments, the very small consumption of samples and reagents, the low cost and the possibility of forming wide sensor networks with a large number of remote detectors. Several reviews^{83–85} were devoted to the recent advances in the development and application of microplasma (sources of plasma volume ranging from 10^{-6} to 10^{-2} cm³ were discussed).

Rapid progress is observed in the development of methods and instrumentation in the field of laser-induced breakdown plasma (laser spark) used for the analysis of solids, liquids, gases, suspended dust and aerosols. The interest arises due to the possibility of developing universal emission analysers suitable for any kind of samples, including microscopic samples, for all elements simultaneously, with excellent spatial resolution along the surface and in depth, with no contact to the samples (remotely) and no sample preparation, that are designed for the real-time operation in a compact portable fashion. In practice, the greatest difficulties are associated with calibration ambiguities and modest detection limits ($\sim 10^{-3}\%$ with a relative error of 5%–10%). In many cases, only approximate calibration could be achieved. In the last 5 years, more than 1500 publications were devoted to the development of this method. The theory and diverse analytical applications of laser-induced breakdown spectrometry (LIBS), including laser-induced breakdown in gases and on ablated surfaces, were the subject of a book¹⁸ and several reviews.^{9,40,86–91}

To date, the major mechanisms of the formation and development of laser-induced plasma are well understood and can be predicted based on models. For the purposes of the analysis, it is desirable that the extracted mass is independent of possible heterogeneities in the sample; hence, very short pulses should be used (to eliminate the effect of thermalisation and heat transfer across the sample). For pulses of ~ 1 ps and shorter, the duration of the laser field is sufficient to heat up only the electrons in the vicinity of the laser-illuminated spot on the sample surface. An explosion-type ejection of these electrons causes simultaneous destruction and ejection of the 'cold' lattice material due to the Coulomb forces. Thus, in the femtosecond mode (≤ 1 ps), the process of instantaneous vaporisation and ionisation of the sample can be greatly simplified, without inducing any transfer of heat across the sample and any shielding of the laser irradiation by the plasma plume that forms only after the end of the laser pulse. These factors improve significantly the reproducibility of the analysis.

The use of short-wavelength (ultraviolet) lasers provides more efficient and reproducible ablation and hence higher accuracy of the analysis as compared to that attainable with less intricate infrared lasers. Advantages of the ultraviolet irradiation are associated with more efficient absorption in the sample bulk (*i.e.*, smaller losses due to reflection from the surface and less absorption in the plume above the sample surface), as well as due to the lower degree of the multiphoton ionisation as compared to the laser-induced breakdown in the infrared range. Because of the higher photon energy, the ultraviolet radiation can break lattice bonds even in a single-quantum absorption event.

Thus, the ablation by short-pulse UV lasers is a direct and the most efficient method of microextraction with the lowest probability of fractionation effects, which may cause the ratios of elements in a plume to differ from the stoichiometry of the sample. This occurs if the radiation power density is sufficient for a robust laser-induced breakdown; and this condition explicitly distinguishes the laser spark from the laser desorption mode. Although the fractionation cannot be entirely avoided in any case, it is the ablation with short-pulse UV lasers that allows one to reduce the difficulties associated with calibration, reproducibility and accuracy of the analysis.

The elimination of heat transfer and meltdown effects in the femtosecond mode becomes of particular significance for local

lateral and layer-by-layer analyses where one must avoid thermal 'mixing' of neighbouring areas in the sample. Moreover, the UV focus spot can be reduced to a smaller size compared to the infrared. At the same time, use of short-wavelength lasers results in deterioration of resolution in layer-by-layer analysis (due to deeper penetration of the UV laser field into the sample).

In a laser spark, very hot plasma is formed (up to 40 000 K at the electron density up to $\sim 10^{18} \text{ cm}^{-3}$). Moreover, plasma in plumes extracted from entirely different samples often exhibit similar characteristics. However, despite the efforts to minimise any differences, the amount of vaporised material and the plasma parameters depend on numerous factors. Therefore, laser-induced plasma as an atomiser is inferior to analytical ICP in linearity, completeness of atomisation and versatility (*i.e.*, the degree of insusceptibility to the matrix effects). As in a conventional ICP, argon is the ideal atmosphere for the formation of a plasma plume during laser spark. However, ambient air mixed with the vaporised sample material appears to be the most common medium.

The LIBS enables analysis of substances in any state, while recording the spectra on CCD arrays makes it possible to determine all emitting elements in each pulse. Numerous examples of using laser-induced plasma in emission spectrometers range from the detection of gases and aerosols in air^{92–94} to the analysis of melted minerals and steels in industry^{95,96} and even rocks on other planets.^{97,98} The recent development of miniature emitter modules of the laser-amplifier type⁹⁹ brings a hope that in future the LIBS analysers will fit into a flashlight-size module connected to the control-panel notebook by a fiberoptic cable. The examples of compact laser-induced plasma spectrometers are documented.^{88, 89, 95, 100–103}

Sometimes double-pulse lasers are used for reducing the detection limits in LIBS. Ideally, the first short-duration UV laser pulse induces extraction (generates a plume), while the second longer pulse in the infrared provides additional heating of the plasma in a plume, because the IR radiation is more efficiently absorbed by the plasma (*i.e.*, heats up the free electrons to a greater extent) as compared to the UV radiation. Due to this heating, more complete atomisation in a plume is achieved.^{92,96,104,105} In the other similar scheme, the second heating pulse uses the laser wavelength tuned in resonance with the absorption line of the main component of the sample.¹⁰⁶ Thus, one can reduce the detection limits by more than an order of magnitude.

The most direct way of achieving complete atomisation of the laser extraction products is their transport with a flow of argon into a conventional ICP torch. In this fashion, laser ablation is merely used for converting the sample into the aerosol state, *i.e.*, as a sampling method, followed by the analysis using ICP-AES or ICP-MS (see reviews^{40, 87, 90, 91}). This reduces the detection limits down to $\sim 10^{-7}\%$ at the expense of merits of compactness and viable remoteness of the analysis. The main application area of laser-ablation ICP-AES (LA-ICP-AES) is the analysis of heterogeneous samples with a micron resolution.¹⁰⁷

Note that the unique nature of laser ablation with direct recording of emission spectra, *i.e.*, LIBS, is fully revealed only if a remote or local microanalysis is required, since a classical electric spark (as opposite to a laser spark) can be easily made more powerful with a multi-fold superiority in the analytical volume and, correspondingly, in sensitivity. The cost of equipment for the electric spark is also much less than that for laser ablation. Moreover, the analysis of electrically non-conducting samples with no pretreatment, as well as the analysis of aerosols, dust and ash in gases can well be performed using compact electric spark sources.^{108,109} Nonetheless, the laser sparks provide more flexible control over the discharge parameters relative to the electric sparks. The laser-induced breakdown is free of a drawback typical for the electric sparks, *viz.*, the fast uncontrollable movement (twisting) of the contracted discharge body. The higher temperature in the laser-induced plasma determines both the higher

degree of atomisation and the linearity of calibration, and reduces spectral interferences.

Yet another relatively simple, rapid and inexpensive method for the analysis of surfaces and near-surface layers employs 'cool' glow discharges (usually at reduced pressure and room temperature) used for simultaneous atomisation, excitation and ionisation of samples. Both direct-current and capacitively coupled radiofrequency (RF) discharges using both hollow and planar cathodes are utilised (see reviews^{69,70}). The detection limits of hollow cathode-based analysers are usually somewhat better as compared to the planar-cathode instruments (order of $\sim 10^{-4}\%$). The advantage of radiofrequency discharges is the possibility of direct sputtering (*i.e.*, plasma-induced atomisation) of electrically non-conducting samples and coatings.

Gradual sputtering of the sample surface in a 'mild' discharge and the continuous recording of the emission spectra allow one to carry out the layer-by-layer analysis with unprecedented high resolution ($\sim 1 \text{ nm}$ of depth). A sputtering rate can be further decreased using a pulsed discharge. It is also advantageous to use pulsed discharges for the analysis of samples especially sensitive to high temperature (*e.g.*, films and polymers). Moreover, with the use of pulsed discharges, one can sometimes obtain two-dimensional spectral images of the surface, *i.e.*, perform an instantaneous analysis of heterogeneous surfaces. Using glow discharges, it is possible to analyse both very wide surface areas and very small samples. Application of different gas mixtures in glow discharges was reviewed;¹¹⁰ while analytical applications in the layer-by-layer analysis of thin films and for environmental purposes were also surveyed.^{111–113}

Standardless emission analysis is possible if one has an adequate theoretical model that relates the intensities of spectral lines to the concentrations of elements in a plasma.¹¹⁴ Dense plasmas such as an arc, ICP and a laser-induced breakdown can sometimes be considered within the framework of the local thermodynamic equilibrium (LTE). In the LTE model, the populations of all emitting states of atoms and ions are unambiguously related to the plasma temperature and the concentrations of elements, according to the Saha–Boltzmann law. By means of deriving the temperature from relative line intensities, one can then determine the concentrations of elements with normalisation at the sum of all concentrations set equal to unity. Such a procedure of the standardless analysis (including the effect of self-absorption of lines) was developed for the case of the laser-induced breakdown spectroscopy (see Ref. 115).[§] A similar idea was used for indirect calibration of ICP-AES in the analysis of gases.¹¹⁶ Generally, the models more complicated than LTE are often used for simulating plasmas (such as microwave, glow discharge, and *etc.*).

IV. Atomic mass spectrometry

In the mass spectrometric analysis, there is a number of different methods for ionisation of the analyte atoms. They include ionisation in plasma sources (electron impact, collisional charge exchange, plasma-chemical reactions or sputtering of secondary ions from the surface), electrothermal ionisation (heated filaments and graphite cups), ionisation of vapour in the resonance laser field, radioactive source ionisation, *etc.* The most comprehensive reviews on analytical atomic mass spectrometry can be found in books^{17,19,20} and papers.^{3,117–120} Each issue of the *Journal of Mass Spectrometry* (UK) contains a list of recent publications in the field of mass spectrometry.

Analytical mass spectrometry based on ionisation in plasma plays the leading role in the elemental analysis due to its capability of highly sensitive, multicomponent, versatile and rapid analysis.

[§] For recent publications on this topic, see I B Gornushkin, A I Kazakov, N Omenetto, B W Smith, J D Winefordner *Spectrochim. Acta, Part B* **60** 215 (2005).

To date, the potential of contemporary ICP-mass spectrometers (the first commercial instruments appeared more than 20 years ago) represents virtually the reference point for all other methods and instruments. Indeed, ICP-MS enables the simultaneous determination of several dozens of elements at trace concentrations down to $\sim 10^{-9}\%$ in solid samples and $\sim 10^{-13}\%$ in ideal aqueous solutions, within a dynamic range of up to 9 orders of magnitude.

This technique is applied most often to the analysis of environmental and geological samples, and high-purity substances. However, not only the ICP but also other kinds of plasma are widely used for ionising atoms, particularly, in glow and corona discharges, and also in laser-induced plasma (laser ablation and laser desorption from the surface). Inductively coupled and corona discharges are usually ignited at atmospheric pressure, whereas glow discharge is ignited at low and reduced pressures. Corona discharge is utilised in the mass-spectrometric analysis of gases.^{121, 122} Electric spark in vacuum is also successfully used as the atomiser/ioniser of conducting and non-conducting samples (the latter are pre-ground and pressed into graphite electrodes).¹²³

In the majority of cases, the IPC-MS instruments incorporate quadrupole mass spectrometers (they are usually more expensive than the AAS and ICP-AES analysers, but less expensive than other kinds of mass spectrometers). One of the main problems related to quadrupole-based ICP-mass spectrometers concerns the isobaric interferences, *i.e.*, overlaps of isotopes of different elements with equal charge-to-mass ratios. Moreover, in the argon plasma, in addition to the proper atomic ions, some parasitic molecular ions are also formed such as Ar_2^+ , ArO^+ , ArH^+ , ArOH^+ , ArN^+ and other, as well as multicharge ions, which introduce additional interferences. This can be alleviated if the high-resolution magnetic sector mass spectrometers in a double-focusing mode (with crossed electrostatic and magnetic fields) are used.^{124–127} High-resolution instruments are very expensive but highly sensitive and facilitate recording of extremely small differences in the isobaric masses of elements.

An attractive innovation for minimising the isobaric interferences is related to the development of the RF multipole reaction cells that can be installed in conventional quadrupole mass spectrometers.^{128–131} The cell is filled with a reactive gas (*e.g.*, ammonia, oxygen, or methane) under reduced pressure, and the field-driven analyte ions drift towards the main mass analyser (quadrupole) and the detector. In the simplest case, the buffer gas molecules collide with the parasitic molecular ions produced in an ICP and break them apart into the atomic form. However, transforming particular parasitic ions into the molecular ions with a different mass in ion–molecule charge exchange reactions is a much more efficient way of eliminating specific interferences. Quadrupole, hexapole and octopole systems are used as RF multipole cells.¹³¹ Sometimes RF ion traps are used for this purpose. The best performance was observed for quadrupole dynamic reaction cells, which can be tuned synchronously with the main mass analyser (*i.e.*, in resonance with the analyte mass), thus cutting off possible secondary interferences in the upper and lower mass ranges. As a result, the common quadrupole mass spectrometers equipped with RF multipole reaction cells are presently a sound alternative to the very expensive high-resolution magnetic sector mass spectrometers.

Since the quadrupole mass spectrometers are the scanning devices in their principle of operation, the speed (throughput) of detection is low in the multielement analysis, because the acquisition time required for determining each element in the vicinity of its detection limit is about ~ 10 s. As a result, further efforts take place in the development of magnetic sector mass spectrometers with multichannel/multicollector detectors for simultaneous detection of all ions arriving to the focal surface.^{125, 132–134} For the similar purposes, the time-of-flight mass spectrometers that can simultaneously record the whole spectrum of elements in each ion extraction pulse, are being used.^{135–138} There are commercial models of the ICP-time-of-flight mass spectrometers.

In contrast to magnetic sector multichannel (multicollector) mass spectrometers, the time-of-flight mass spectrometers have long been used in analytical studies and are available in various models. However, potential advantages of magnetic sector mass spectrometers are related to the fact that they are continuous, and consequently, superior in the integration time, accuracy, stability and noise averaging possibilities. Time-of-flight mass spectrometers can determine ions in a broad range of masses simultaneously; moreover, they are less bulky and less expensive. A certain method of simultaneous recording is specifically required in those cases where fast or transient processes are studied, *e.g.*, in chromatographic or electrophoretic separation, in flow-injection analysis, electrothermal vaporisation, laser ablation or laser desorption.

A combination of ICP-MS with the direct sampling based on laser ablation (LA-ICP-MS) facilitates circumventing the complex and lengthy sample preparation and atomisation procedures. The reviews on this subject have been mentioned above.^{87, 90, 91, 120} For the accurate trace determination by ICP-MS at very low detection limits, the sterile direct laser sampling plays an important role because omitting the sample preparation stage reduces sharply the probability of accidental contamination during sample preparation to the analysis. At the same time, undesirable fractionation of elements during the aerosol transport along the analyser ducts does sometimes occur in LA-ICP-MS.¹³⁹ The calibration reproducibility and accuracy may also become difficult to assure. In those cases where the acquisition of spectra from each laser pulse is essential, the ICP-sector mass spectrometers with detector arrays¹⁴⁰ or ICP-time-of-flight mass spectrometers¹⁴¹ are used.

The overall dimensions of the instrument can be substantially reduced by using the laser-induced plasma directly as an atomiser/ioniser in mass spectrometry.¹⁴² Usually, the time-of-flight mass spectrometers are employed in laser ablation mass spectrometry (LA-MS). In this case, the pulsed nature of the laser ablation almost perfectly matches the pulsed extraction of ions.^{143–146} Such instruments surpass the laser-induced breakdown emission analysers in sensitivity and could have been quite competitive in regard of compactness¹⁴⁷ if continuous evacuation was not necessary. Using ablation at the resonance wavelength, one can further reduce the detection limits.^{148, 149} Laser irradiation at lower power does not cause any crater-like destruction of the analysed surface, thus atomic and molecular ions can be detached from it in a desorption mode. Measurement of these ions with time-of-flight mass spectrometers enables very careful analysis of the art, jewelry and documents for forensic examination.¹⁵⁰

Thin films, coatings and other surfaces can be sputtered layer-by-layer in glow discharges with excellent depth-profiling resolution (but measurements are in emission most often). Using a mass spectrometer as the detector,^{69, 117} one can reduce the detection limits by several orders of magnitude (down to $\sim 10^{-7}\%$ for single element detection). The uncertainties of quantitative calibration are lower^{151, 152} in this case than in LA-ICP-MS. This method was successfully used for analysing the environmental samples and nuclear waste.¹¹³ In the ICP-MS spectrometers manufactured by Finnigan MAT, the ICP module was exchangeable with a direct-current glow discharge module. Recently, high-resolution mass spectrometers with ionisation in the direct-current glow discharge and the radiofrequency discharge have been introduced by VG Elemental. Despite their high cost, they have already found various applications ranging from analysis of high-purity metals to analysis of powders and dielectrics. The analysers that include both a pulsed glow discharge and a time-of-flight mass spectrometer have recently started to be produced in Russia.¹⁵³

Mass spectrometry can also be integrated with other plasma sources, such as microwave plasma^{154, 155} and capacitively coupled RF plasma in a graphite furnace.¹⁵⁶ However, these sources are used much more often in emission spectrometry. Their advantage is the possibility of small sample volume intro-

duction, including a continuous (flow-injection) mode. Microwave plasma enables the analysis at the temperature near ambient, whereas the discharge in a graphite furnace makes it possible to maintain high atomisation temperature with the independently regulated efficiency of ionisation in plasma. A mass-spectrometric detector facilitates the reduction of the detection limits relative to the corresponding emission detection; however, some setbacks in the design still remain unsolved. Application of such instruments is justified in those infrequent cases where the analytical problem cannot be solved using common ICP-MS analysers (*e.g.*, due to the specific spectral interferences).

The capability of determining different isotopes and their ratios is also among the advantages of mass spectrometry. To date, the thermal ionisation mass spectrometry continues to be the most precise technique for measuring isotope ratios (for a comparison with other techniques, see Refs 157 and 158). However, this technique requires complicated sample preparation and is almost inapplicable to both refractory substances and elements with high ionisation potentials. The precise data on the isotopic composition are necessary for studying the synthesis, evolution or the absolute age of samples (geological, organic, biological, *etc.*). Conventional methods of determination of stable isotopes in gaseous samples (and any other samples that can be converted into the gaseous phase) using magnetic sector mass spectrometers were surveyed¹⁵⁹ with a focus in climatology.

A unique possibility of minimising the isobaric interferences in mass spectrometry is offered by selective ionisation in the resonant laser radiation (resonance ionisation mass spectrometry, RIMS). A laser (or several lasers) is used for the optical excitation and selective stepwise transfer of the analyte atoms into the ionised or auto-ionised states. Sometimes the atomiser is placed in the electric field to reduce the effective ionisation potential of the atom. Examples of the atomisers include a graphite furnace,¹⁶⁰ or low-power laser ablation^{149, 161} or laser desorption¹⁶² at low power to minimise the non-selective ionisation. Use of tuneable solid-state lasers and particularly diode lasers holds a promise for this technique.¹⁶³ The main application field is the determination of stable and long-lived isotopes as well as radioactive contamination. The detection limits can be below a femtogram at a $\sim 10^{-11}\%$ relative content of the rare compared to the abundant isotopes. This method has already been used for determination of more than 40 elements; in some cases multielemental isotope analysis was performed.¹⁶⁴ Laser ionisation schemes for many elements were described.¹⁶⁵ Recent information on RIMS has been reported.^{166, 167}

High-energy accelerator mass spectrometry, which utilises tandem linear particle accelerators, is aimed at the determination of cosmogenic and other very rare isotopes (^3H , ^{10}Be , ^{14}C , ^{26}Al , ^{32}Si , ^{36}Cl , ^{39}Ar , ^{41}Ca , ^{55}Fe , ^{59}Ni , ^{81}Kr , ^{99}Tc , ^{129}I , ^{182}Hf , ^{244}Pu).^{168, 169} This method can be used for the determination of very low amounts of particular isotopes (at isotope ratios down to $\sim 10^{-14}\%$). Such a high sensitivity is determined by both several selection stages discriminating the ion mass and charge and selection in the kinetic energy loss per track unit in the gaseous or semiconductor detector. The specific energy loss depends on the nucleus charge (not the ion charge) that facilitates effective elimination of the isobaric interferences, however such detectors can determine only particles with high velocities. Sputtering of samples is usually performed using a beam of Cs^+ ions in vacuum. This method is applied in archaeology, dendro- and geochronology, climatology, medicine and forensic examination.^{168–172} The equipment usually occupies an area of several tens square metres; however new instruments with dimensions of only $2.25 \times 1.25 \text{ m}^2$ are already under development.

The theory, instrumentation, and applications of ion mobility spectrometry are being actively developed (see a review¹⁷³). This technique differs from the classical mass spectrometry in a way that the ions are separated by their charge-to-mass ratio while drifting in the gas medium driven by the electric field, rather than in vacuum. The main advantage is that there is no need for

evacuation and, correspondingly, the cost is lower and miniaturisation of such high-sensitivity instruments is possible. The ion mobility analysers have been applied so far only for the gas analysis (detection of contaminations and toxic compounds in air or trace impurities in technological gases).^{174–177} They will possibly find broader applications with the progress in this field because of the obvious advantages of combining such detectors with non-vacuum ionisation sources (*e.g.*, laser ablation and desorption, discharges at atmospheric and slightly reduced pressures, including microplasma discharges). An increasing body of information on applications of RF multipole reaction cells (based on drift and ion reactions in the gas medium) in mass spectrometry will also favour development in ion mobility spectrometry.

For quantitative calibration, especially in ultra-trace mass spectrometric analysis where the standards cannot be prepared, the method of isotope dilution is often used, *e.g.*, in ICP-MS.^{178, 179} An increase in accuracy of the semiquantitative analysis in ICP-MS can be achieved by simulation of the plasma-chemical processes.¹⁸⁰ Worth to note are the studies devoted to the calculation of the relative sensitivity¹⁸¹ and the standardless analysis¹⁸² in ICP-MS and LA-MS.¹⁸³ The possibility of simultaneous acquisition of spectra from atoms, molecules and fragments represents another advantage of mass-spectrometry. Moreover, this technique can be hyphenated to chromatography or other methods of preliminary separation of chemical compounds (see a review¹⁸⁴).

V. Atomic fluorescence spectrometry

At present, the atomic fluorescence spectrometry (AFS) plays a relatively minor role in elemental analysis. An attractive feature of the fluorescence techniques is the fundamental possibility of combining the advantages of absorption and emission spectrometry. Theoretically, the analytical signal is proportional to the concentration of atoms in the (most populated) ground state as in the case of absorption; but it is being measured on a 'zero' or weak background as in emission spectrometry. The selectivity of atomic fluorescence is very high because both mechanisms of absorbing and emitting of photons are discrete quantum processes. Excitation of the selected atoms only on their characteristic spectral lines and shielding the detector from direct rays of the light source enable measurement of fluorescence without recourse to any optical dispersion devices. Moreover, one can modulate the excitation source for better subtraction of the stray light background.

These advantages determine the application area of AFS. The development occurs in two major directions. Where high selectivity and high sensitivity are required that cannot be reached by other methods, one can use the laser-excited fluorescence (pulsed most often) with detection by means of optical and electronic schemes that are optimised for subtracting the non-selective background, reducing the spectral interferences and minimising the noises. In the other cases where moderate sensitivity is sufficient, while a simple and rapid analysis procedure and inexpensive equipment are desirable, then simple optical filters (in place of dispersion spectrometers) and traditional light sources, *e.g.*, hollow cathode lamps or RF electrodeless lamps, are used. Naturally, weak sources and thus unsaturated fluorescence bring about a number of drawbacks including the non-selective absorption of radiation in the atomiser.

In line with the development in chemistry of stable and unstable volatile compounds, there is an increasing interest in the simplest version of AFS that involves continuous sample introduction in the form of vapour (*e.g.*, mercury^{185–187}) or volatile hydrides^{188–193} with their low-temperature atomisation. High selectivity of this technique facilitates analysis of samples of a very complex chemical composition with high sensitivity. Modern commercial atomic fluorescence analysers¹⁹⁴ employ hollow-cathode lamps, graphite atomisers, and continuous flow-injection introduction of samples in the form of volatile hydride

compounds. The detection limits are often below $10^{-7}\%$. Note that it is the detection by fluorescence or absorption techniques rather than by emission that is more suitable for these compounds, because introduction of large amounts of volatile compounds into a plasma almost always causes instabilities in the discharge.

Commercial ICP-AFS instruments made earlier in USA were equipped with hollow cathode lamps and conventional nebulisers for sample introduction. These instruments were used for the determination of certain metals with weak emission spectra but easily excitable fluorescence spectra. The plasma was ignited in a relatively 'cool' regime in order to merely atomise the sample without generating too high emission background. Further development of this method is associated¹⁹⁵ with the use of new light sources of high spectral brightness, namely, diode lasers or narrow-band light-emitting diodes. These sources can also improve the characteristics of the simplest fluorescence analysers that involve introduction of samples in the form of vapour or volatile compounds.

One of the main advantages of the laser-excited fluorescence is that it makes possible the saturation (bleaching) of optical transitions. Thus, it is possible to obtain maximum analytical signals and simultaneously reduce both the effects of fluorescence quenching and its dependence on fluctuations of the excitation radiation. Unfortunately, during the past 25 years, laser-excited atomic fluorescence was developing very slowly (see a review¹⁹⁶) owing to the slow progress in the development of tuneable laser technologies. The real-time switching of dye lasers from one element to another is virtually impossible. It is the single-element nature of this technique that presents the main obstacle for its analytical application, although more than 40 elements were determined one by one using AFS with dye lasers.

The dynamic range of laser-excited atomic fluorescence spectrometry (LEAFS) can reach 7 orders of magnitude (much broader than in AAS). Moreover, LEAFS is characterised by better linearity compared to AAS. The lowest detection limits in LEAFS are of the order of $\sim 10^{-11}\%$ (~ 0.1 fg) in the analysis of ideal aqueous solutions using an electrothermal atomiser.¹⁹⁶ The best results for low-volatility elements (Eu, Y, Tl) were obtained using atomisation in a glow discharge. Use of flame, ICP, laser spark and other plasma atomisers has been studied. In the analysis of gases, the plasma was used for the pre-population of the metastable states, from which further excitation of laser-induced fluorescence was performed.⁴⁷

About ten years ago, new solid-state laser sources appeared;^{197–200} they are the optical parametric oscillators (OPO) with tuneable output radiation, which can be scanned over the whole spectrum from 220 to 2000 nm in ~ 20 min (previously, such sources were called parametric light generators). Using the modern software, it is possible to scan discretely the OPO output radiation, *viz.*, by jumping from one characteristic line to another, thus facilitating reduction in the scanning time (similarly to the newest analytical mass spectrometers). Obviously, OPO open up the prospects for the development of multi-element LEAFS. However, so far only few studies devoted to simultaneous detection of several elements using the OPO-excited fluorescence technique have been accomplished.^{201, 202}

In our viewpoint, the commercial LEAFS instruments based on OPO can be developed in the future, despite their high cost at present. An ICP-AFS spectrometer based on OPO would be comparable in cost with a high-resolution ICP-mass spectrometer. However, despite the virtually equally high sensitivity of mass spectrometry and laser-excited AFS, the selectivity of the latter technique is higher relative to high-resolution mass spectrometry and much higher relative to either quadrupole or time-of-flight mass spectrometry. Furthermore, theoretically, the sensitivity of AFS should be higher than that of mass spectrometry, because each atom can produce only one ion but can emit up to $\sim 10^8$ photons per second. The throughput of mass spectrometers is usually $\sim 10^{-6}$ of the ion flux, whereas the typical efficiency of collection and registration of photons is of the order of $\sim 10^{-4}$.

Perhaps, the commercialisation of LEAFS analysers will be aided by the development of multifunctional laser spectrometers with modular architecture aimed at enabling application of several analytical techniques within a single instrument.

New potentials in LEAFS are opening up with the development of magneto-optical traps (laser traps) for neutral atoms.²⁰³ Single atoms including their particular isotopes can be captured in a laser trap, and the resonance fluorescence of each individual atom can be reliably detected. Using this method, rare isotopes ^{81}Kr and ^{85}Kr with the natural abundance of the order of $10^{-11}\%$ and $10^{-9}\%$, respectively, were determined.²⁰⁴ The detection limit of the ^{41}Ca isotope in biological samples atomised in a furnace was below $10^{-7}\%$ with respect to the abundant ^{40}Ca isotope.²⁰⁵ So far, such low amounts of rare isotopes could only be detected using high-energy accelerator mass spectrometry. Certainly, the LEAFS instrumentation based on magneto-optical traps is less expensive and less massive. Laser traps have already been successfully used for confinement of alkali and alkali-earth atoms, as well as noble gas atoms (pre-excited in plasma into the metastable states for laser manipulation).

It is hoped that further development of atomic absorption techniques based on diode lasers will also be beneficial for their application in AFS. The high spectral brightness of the diode lasers (due to the very spectrally narrow output emission) at their typical optical power of ~ 1 mW with a beam focused into a zone of a diameter of ~ 1 mm allows one to achieve complete saturation of fluorescence on strong transitions, if the quenching is not considerable. Multielement analysis can be achieved (as in AAS) by using diode laser arrays incorporated into multiplexing schemes. However, so far AFS with excitation by diode lasers has been used only in a single-element fashion.^{206–212}

Similar to the absorption spectrometry, the saturated (laser-excited) AFS provides a theoretical possibility of the absolute analysis. This possibility arises from both the simple theoretical dependence of the saturated fluorescence intensity on the analyte atom concentration and the reliable knowledge of the photon detection efficiency achievable in practice. In the case of AFS, the conditions originally formulated by L'vov^{65, 66} as necessary for the absolute absorption analysis, are supplemented here by an additional requirement for the sufficient power of the output radiation of the excitation laser. The measurement of the non-selective background is made by detuning the laser from the absorption line. If the power of the excitation source is far from saturating, the fluorescence intensity usually depends on many unaccountable factors, which necessitates the use of standards to implement the calibration for the quantitative analysis.

Note that at this stage the practical applications of LEAFS are largely limited by the tasks that require the highly sensitive and selective analysis. The preparation, storage and use of standard solutions for calibrating the instruments in the range of extremely low concentrations of elements pose serious problems and require certain measures to be undertaken due to the high probability of accidental contamination at any step of calibration. Hence, the development of methods for the absolute (even if semi-quantitative) analysis has gained crucial importance. The idea of the absolute AFS analysis appears even more attractive, since this method usually demonstrates a precisely linear dependence of the analytical signal on the analyte concentration.

VI. Atomic ionisation spectrometry

The atomic ionisation analysis is based on selective stepwise ionisation (laser-induced in most cases) of atoms. It resembles in essence the RIMS technique. However, the intensity of the current formed by the electron–ion pairs upon ionisation is measured in this method rather than the ion masses. One such technique called resonance ionisation spectrometry implies usually two- or three-step laser-induced photoionisation of atoms, most often in vacuum as in RIMS. The other more popular version of the method is the laser-enhanced ionisation (LEI) spectrometry in flames at

atmospheric pressure, where the analyte atoms are selectively excited by the laser irradiation into the highly excited states, thus enhancing (by up to 8 orders of magnitude) the collisional thermal ionisation. Optogalvanic spectrometry is also based on a similar scheme, which employs the plasma discharge at reduced pressures for cathodic sputtering of the samples followed by laser-induced excitation of atoms and registration of the change in the current owing to the change in the ionisation rate, that is largely of the non-thermal origin in this case.

The main advantage of all forms of the atomic ionisation spectrometry is the high sensitivity achievable with relatively simple instrumentation, especially if the diode lasers are used. The efficiency of collection and registration of single electrons in both vacuum and weakly ionised flames (the electron density in flames is usually $< 10^9 \text{ cm}^{-3}$) can, in principle, be brought close to 100%. High-stability hollow-cathode lamps characterised by fluctuations of plasma current only at the shot-noise level, facilitate reliable measurements of the very weak optogalvanic signals ($\sim 1 \text{ nA}$). The selectivity in this method with simple recording of current is lower than in more sophisticated mass spectrometric or laser-excited fluorescence detection. The main disadvantage of the method is a strong matrix dependence (especially in the presence of easily ionised elements that not only increase the background noise but can also change the electric field between the electrodes owing to the space charge formation). The interferences due to the parasitic multiphoton ionisation of the flame-generated molecules and radicals such as NO , CO , O_2 , *etc.* are also encountered in laser-enhanced ionisation in flames.

Laser-enhanced ionisation spectrometry (LEIS) is the leading technique among other techniques of the atomic ionisation analysis, although its development is also impeded because the suitable tuneable lasers are still unavailable. LEIS provides low detection limits of $\sim 10^{-10}\%$ ($\sim 1 \text{ fg}$) at very small sample amounts (less than 1 pg) and with a fairly simple design. Further increase in sensitivity can be achieved with avalanche ionisation, *i.e.*, with the 10^3 – 10^5 -fold multiplied current of the primary electron–ion pairs.^{213, 214} Application of nanosecond lasers and nanosecond-resolution registration electronics in some cases enables separating the fast response due to the parasitic molecular ionisation from the slower collisional ionisation response in LEIS at reduced pressures.²¹⁵ The parasitic ionisation can also be minimised by shielding the flame from air with an outer concentric argon flow.^{216, 217}

For the purpose of sample introduction into the flame and more complete atomisation in LEIS, one can use either electrothermal vapourisation²¹⁸ or transformation of samples into volatile compounds,²¹⁷ or flow-injection introduction with a possibility of sorption pre-concentration.²¹⁹ The advantage of the microsample analysis in LEIS is most evident when it follows either chromatographic separation²²⁰ or laser ablation sampling into the flame.^{216, 221–223} As the laser-induced plasma creates high temperature and high densities of charged particles, one may opt to separate the sampling from the signal registration either temporally^{221, 222} or spatially.^{216, 223} In the latter case, the product of laser ablation (aerosol) is carried by the argon flow into the miniature flame where the LEIS signal is generated. This concept is similar to LA-ICP-MS and LA-ICP-AES. Use of a miniburner reduces the effect of aerosol dilution during the analysis. Such schemes open up the possibilities of detecting trace impurities in each laser ablation pulse (15 atoms per pulse²¹⁴). Moreover, it is possible to simultaneously determine several elements (Pb, In) in samples.²²³

Electrothermal atomisation in an inert atmosphere of a graphite furnace can become an alternative to the use of flames in LEIS. This method provides very low detection limits for noble metals.²²⁴ A direct comparison of the detection limits in LEIS and LEAFS under the same conditions indicates the latter to be more sensitive,^{217, 225} if the optical pumping power of the laser is sufficient for the fluorescence saturation. However, under the

conditions most favourable for LEIS (collision frequency $> 10^9 \text{ s}^{-1}$), the fluorescence quantum yield is small due to the quenching processes. In the case of unsaturated transitions, LEAFS is inferior to LEIS.²²⁰ It is fundamentally difficult to achieve complete saturation of all optical steps in LEIS, because transition probabilities to reach highly excited states are usually low.

It is interesting to compare the detection limits of LEIS and purely optical laser-induced resonance photoionisation in metal vapour at atmospheric pressure.²²⁴ Thus for silver atoms, the two-step resonance photoionisation through the auto-ionising state provides a better detection limit ($2 \times 10^{-11}\%$) compared to the two-laser LEIS ($2 \times 10^{-10}\%$). Generally, a success of any of these schemes depends on the relationship between the efficiency of collisional ionisation and the rate of optical pumping into auto-ionising states. However, an increase in the ionisation rate provided by two- and three-step schemes, is usually several orders of magnitude greater than in a single laser excitation step. A complex laser spectrometer for the laser-enhanced ionisation in both vacuum and flame was developed for the analytical research purposes.^{226, 227} Recent developments associated with the LEIS technique were discussed in a review;²²⁸ the earlier records were systematised in monographs^{36, 229} and a review.⁴⁰

Laser optogalvanic spectrometry (LOGS) may be appealing due to its simple electric gas-discharge assembly used simultaneously for both sample atomisation and photoelectron detection. The literature records on optogalvanic detection of overall 40 elements were summarised^{230, 231} (data on indium are also documented²³²). Uncomplicated design can apparently be achieved only with diode lasers,^{233–235} the advantage of which is not only their miniature size but also their capability to resolve the isotopic spectra. A narrow single-mode spectrum generated by a diode laser enhances the selectivity of analysis. To our knowledge, the methods for determination of mercury²³⁶ and uranium isotopes^{233, 234} are the only real analytical applications that have been developed so far.

A prototype of the portable analyser for uranium isotopes (most important element in the nuclear power industry) based on LOGS with a modulated diode laser and lock-in detection was described.²³³ This device enabled determination of isotopes ^{235}U , ^{236}U and ^{238}U in the enriched and depleted samples of uranium oxides and fluorides. Such a method under laboratory conditions²³⁴ enables measurements of the isotope ratio $^{235}\text{U}/^{238}\text{U}$ down to 0.02% with the detection limit in atomic number density $\sim 10^7 \text{ cm}^{-3}$ in the analytical zone. This sensitivity is comparable to that provided by AAS with the same modulation of the diode laser wavelength.²³⁴ A similar technique may be used for the determination of many other isotopes of actinides and lanthanides.

The LOGS technique propped with the RF electrodeless discharges²³¹ may eliminate introduction of the impurities by electrodes and, in principle, makes it possible to analyse non-conducting samples directly. In this case, the laser-induced changes in the plasma impedance are measured using a separate resonant induction coil. The optogalvanic spectrometry usually utilises ‘cold’ plasmas with the temperature of about 300 K. This is convenient, *e.g.*, for the analysis of gases,^{231, 235} but problematic for atomising aerosols. A comparison of the analytical merits of LOGS and LEIS for the detection of metals in smoke particles²³⁷ revealed the undeniable advantages of LEIS regarding the completeness of atomisation at the flame temperature of $\sim 2500 \text{ K}$.

At the same time, the characteristic noise in LEIS is determined by fluctuations of thermal (and turbulent) velocities of charged particles in flame. Thus, in principle, the noise can be reduced by decreasing the temperature. On the contrary, in LOGS, a number of atoms in the analytical zone can be increased by increasing the pressure. For this purpose, it was proposed²³⁵ to use a non-sustained discharge at atmospheric pressure and room temperature with the electron density $\sim 10^{12} \text{ cm}^{-3}$ below a threshold of the self-sustained gas discharge. The electric current

noise in this arrangement is reduced to ~ 0.1 pA ($\Delta I/I \approx 10^{-8}$). The detection limit for the excited hydrogen atoms H^* in neon was estimated from an optogalvanic response to the modulated irradiation by a diode laser to be $\sim 10^{-12}$ g (at the 656-nm line). For other elements, the sensitivity may be even higher if the laser excitation scheme provides a chance to climb closer to the ionisation potential.

A problem of the space charge formation is also largely curbed, because only a weak electric field (~ 100 V cm $^{-1}$) preserving the plasma parameters unperturbed, is used for the proper electron collection, whereas in LEIS the fields of ~ 1000 V cm $^{-1}$ are commonly used. Note that the conditions necessary for this concept may be realised in a late afterglow of the laser-induced plasma.

Generally, the atomic ionisation spectrometry is yet of little use in practice but continues to be developed and has its potentials. As with other laser-based techniques, a hindering factor relates to a slow progress in the development of tuneable lasers that cannot yet support in practice the multielement analysis. High susceptibility of the ionisation degree to the matrix composition presents another serious drawback of this technique. A fundamental possibility of the absolute analysis is one of the potentially important merits of the atomic ionisation technique. An absolute number of the collected electrons (charge) is equal to the absolute number of the analyte atoms, the 100% ionisation of which can be easily achieved in the analytical volume limited by the intersection area of the laser beams, while a correction for the non-selective background is obtained by tuning the laser over the full profile of the analytical absorption line. It is necessary to know either the atomised mass or the degree of sample vaporisation, as well as the dynamics of vapour transport. These parameters can be estimated using mathematical models.

VII. Sample preparation and introduction, atomisation and data processing

Here we cite only a small part of the latest reviews among the vast number of publications on the modernisation, automation and miniaturisation of the instrumentation for sample preparation,^{238–241} including those dealing with the programmed microwave reaction systems,^{240, 241} as well as with further integration of the sample preparation and introduction stages. In particular, there are many different methods of the physicochemical separation, pre-concentration and extraction (e.g., see a review²⁴² on the pre-concentration of microcomponents). Many studies were devoted to coupling of the chromatographic separation with continuous atomic spectrometric analysis of the eluates.^{184, 243–247} Recently, the method of continuous flow-injection sample introduction became very popular.^{248–251} The methods of sample introduction in the form of vapour of volatile compounds find an increasing number of application.^{252–256}

The methods of electrothermal vaporisation^{257–259} and their combinations with chemical transformations of the samples into volatile compounds for flow-injection introduction^{260, 261} are also subject to further development. The possibilities²⁶¹ of complete automation of the whole process of pre-concentration, separation, vaporisation, introduction and atomisation of samples including microwave-assisted decomposition of samples, and a possibility of the direct introduction of large amounts of undiluted organic solvents, viscous liquids as emulsions and solid insoluble samples as slurries are considered. The reviews^{262, 263} devoted to the simple tungsten and molybdenum electrothermal atomisers were also published. Great attention is being paid to further research on improvement of nebulisers for introduction of the analysed solutions into inductively coupled and microwave-induced plasmas.^{264, 265} Many studies in elemental analysis were devoted to introduction and vaporisation of the dissolved samples using high-voltage electrohydrodynamic micronebulisers^{266–269} (originally this method was named the 'Extraction of Dissolved Ions at

Atmospheric Pressure' but now it is most often called electro-spray).

Many studies ponder about the software issues on automation of analytical instrumentation and about new mathematical methods for data processing. The journal *Analytical Chemistry* publishes detailed reviews on this subject every two years (for the latest review, see Ref. 270). Most popular approaches used in the modern spectroscopy were systematised.^{271, 272} A substantial improvement in both reproducibility and correctness of the analytical results could be achieved using the multidimensional matrix and cluster methods of statistical data treatment. Such methods allow one to recognise and take into account unknown active factors (e.g., the presence of hidden impurities, drift, etc.) without carrying out frequent calibrations of the equipment or to restrict oneself to only one 'permanent' calibration. In some cases, it is possible to transfer the calibration from one spectrometer to the whole family of this kind of spectrometers.²⁷³ As mentioned above, the mathematical simulation also opens up possibilities for the absolute (standardless) analysis.

A progress in the computer-assisted methods of operation, self-diagnosis and self-control in analytical instrumentation, as well as the comprehensive processing of analytical data, is largely due to the impressive development in the neighbouring fields. In future, one can expect application of the methods of digital image recognition, machine self-learning, digital filtration of noises and processing of the hyperspectral spatial images. The computational methods using genetic algorithms and artificial neural networks will certainly find their application for spectrometric purposes.²⁷⁴ There is a wealth of prospects for further development in these directions but even today the software and continuous automatic self-diagnosis enable the analytical instruments to 'advise' the operator the ways for resolving problems or identifying the possible errors.

VIII. Conclusion

At present, AAS, ICP-AES and ICP-MS are the undeniable leaders among a multitude of the techniques in the analytical atomic spectrometry. During several past decades, the inductively coupled plasma displaced other sources of excitation and ionisation of atoms in the emission analysis and mass-spectrometry. Among these universal multielement techniques, the ICP-MS exhibits the best overall sensitivity. Electrothermal atomisers continue to play the key role in the absorption analysis. Currently, the laser-induced plasma is becoming the leading technique for the direct analysis of solids, while the further development evolves in the three main directions: direct laser-induced breakdown emission spectrometry, direct laser ablation mass spectrometry, and laser ablation with aerosol transport into ICP-MS.

In the atomic absorption spectrometry, one should expect the increasing use of both diode lasers and light-emitting diodes as the sources of radiation, as well as the use of optical cavities to expand the effective path of absorption. Application of the atomic fluorescence and ionisation will still be limited to unique special tasks, while further progress will depend primarily on the development of the tuneable solid-state lasers. Nonetheless, in those cases where the extreme sensitivity is required for detecting single atoms and their individual isotopes, the laser-excited fluorescence and resonance ionisation techniques have already begun to compete with the accelerator mass spectrometry.

In the development of analytical instrumentation, the following most general trends may be outlined:

- combine all stages of the analysis in a single device including sample preparation (the latter remains being intricate and the least reproducible procedure);
- provide high sensitivity and low detection limits, while decreasing the sample amount and increasing the throughput of the analysis;
- develop more advanced software, maximum degree of automation, on-line capabilities of the instrument diagnostics,

switching on and off, and remote acquisition of the results through the Internet;

– design miniature (using diode lasers, microplasma, *etc.*), compact or portable analysers;

– make steps towards a modular architecture of the multi-functional spectrometers combining the capabilities of several analytical techniques in a single instrument.

The importance of the issues discussed in this paper is further supported in the most recent reviews on the subject.^{275–279} There is no doubt that the analytical atomic spectrometry will continue to play an indispensable role in science, research, laboratory practice, industry and other diverse fields of human activity.

Abstract. The review provides an overview of the main steps of development of spatially resolved atomic absorption spectrometry. The results of research on the dynamics of spatial distributions of atoms, molecules, condensed nanoparticles, temperature fields in atomisers and the transmitted radiation intensity are generalised. The influence of spatial inhomogeneities on the formation of absorption signals is considered. The advantages of spatially resolved atomic absorption spectrometry are illustrated with examples. The bibliography includes 82 references.

I. Introduction

Due to high sensitivity and selectivity, atomic absorption spectrometry (AAS) has found wide application in physics (in measurements of oscillator strengths, diffusion coefficients, gas temperatures, *etc.*), astrophysics (in studies of the chemical composition of stars) and physical chemistry (for the determination of the saturated vapour pressure, heats of vaporisation, rate constants, *etc.*). However, this method is most widely used in analytical chemistry. This technique provides the basis of atomic absorption analysis as a method of quantitative chemical analysis based on atomic absorption spectra. Nowadays, analytical atomic absorption spectrometry is one of the most commonly used methods for elemental analysis.¹ Initially, flame atomic absorption spectrometry has been developed.² However, AAS with electrothermal atomisation has received most attention in more recent years.³ The use of semiclosed graphite tube atomisers made it possible to reduce the method detection limit by a factor of $\sim 10^3$. As a result, it becomes possible to perform microanalysis and direct analysis of solid substances and suspensions. Presently, more than 60 chemical elements can be determined by AAS at ppb (or lower) levels in virtually all substances and materials.⁴

Atomic absorption spectrometry is based on interaction of transmitted radiation (generally, at the resonance wavelength λ) with a cloud of free analyte atoms produced in an atomiser. The larger the amount of absorbing atoms in the gas phase in an atomiser, the stronger the absorption of transmitted radiation. Two aspects of this interaction can be distinguished. First, the absorption depends on the overlap of the spectral profile of the analytical line of the radiation source $J(\lambda)$ with the absorption line profile of the analyte atoms $k(\lambda, T)$ (Fig. 1 *a*). The mechanism of this interaction, which can be referred to as the spectral interaction, has been studied and described in detail.^{5, 6}

The absorbance (A), which is determined as the logarithm of the ratio of the luminous flux (Φ_0) incident on the absorbing layer to the flux passed through the atomiser (Φ_t), serves as the quantitative measure of absorption. The absorbance in AAS plays the same role as the analytical line intensity in atomic emission spectrometry. If the spectral linewidth of transmitted radiation is substantially smaller than the absorption linewidth, the absorbance of a spatially homogeneous absorbing layer is directly proportional to the number of absorbing atoms (N) as follows from the Bouguer–Lambert–Beer law

$$A = \log \frac{\Phi_0}{\Phi_t} = C(\lambda, T) N, \quad (1)$$

where the coefficient $C(\lambda, T)$ depends on the atomiser temperature and accounts for the spectral features of the analytical line. Taking

Received 3 October 2005

Uspekhi Khimii 75 (4) 339–353 (2006); translated by T N Safonova

into account broadening and shifts of the spectral lines and the hyperfine structure of the spectral transition, linear dependence (1) is violated: each factor leads to a decrease in the slope of the plot and its curving in the high-absorption region.⁴

Another aspect of interaction is associated with spatial inhomogeneity of the absorbing layer and the transmitted radiation intensity. The transmitted beam characterised by the intensity distribution $J(x, y, z)$ is absorbed by atoms and molecules non-uniformly distributed in an atomiser $n(x, y, z)$. This aspect can be referred to as the spatial interaction (Fig. 1 *b*).

Evidently, the atomic absorption depends not only on the spectral characteristics of the analytical line but also on the characteristic features of the spatial distribution of the analyte atoms and the probe beam. In addition, it should be taken into account that absorption of transmitted radiation occurs in the volume of an atomiser characterised by spatially inhomogeneous temperature fields. However, in spite of this fact, AAS has been developed over many years with consideration only for spectral interaction,[†] because it has been implicitly assumed that the absorbing layer in the cross-section of an atomiser is spatially homogeneous. In this case, $n(y) = \text{const}$ (see Fig. 1 *b*), and the detected absorption is independent of the transmitted radiation intensity distribution. This assumption was not in doubt because atomisation temperatures are thousands of degrees centigrade and it seemed reasonable that all spatial inhomogeneities would be smoothed in the transmitted beam with a height of only 2–5 mm due to fast gas-phase diffusion. However, more recently it has been demonstrated that all key parameters of AAS, *viz.*, the temperature of the absorption zone and the distributions of atoms, molecules and condensed species, are characterised by substantial non-uniformity. In this connection, the need arose to take into account the spatial factor.

The present review briefly summarises the results and the state of the art in the field of spatially resolved AAS, which equally takes into account both the spectral and spatial aspects of interactions between the resonance radiation and absorbing atoms. Initially, the spatial distributions of the transmitted radiation intensity, absorbing atoms, molecules and condensed species and the temperature fields in the volume of an atomiser are considered. Then analysis of the influence of the non-uniformity of the distributions of these parameters on the atomic absorption is presented and the ways of eliminating this influence are described. Finally, examples of the analytical use of spatially resolved AAS are given and this method is compared with conventional AAS (where spatial inhomogeneities are ignored).

II. Spatial distribution of transmitted radiation intensity

1. Hollow cathode lamps

Hollow cathode lamps are the most common transmitted radiation source for AAS. Narrow (with a width of about 1 pm) spectral lines $J(\lambda)$ of analyte atoms are generated in the glow discharge plasma in a hollow cylindrical cathode. The cathode material includes the analyte element, the line spectrum of which is necessary to record. This chemical element is introduced into the plasma by vaporisation of the cathode by fill gas ions (generally, neon or argon) at a pressure of a few Torr. Results of studies of physical processes occurring in the glow discharge plasma and the spectral characteristics of the generated radiation are summarised in reviews.^{5–9} The spatial characteristics of the radiation beam from hollow cathode lamps at resonance and non-resonance lines of different elements and the atomic and ionic lines of a fill gas were studied in-depth.^{10–12} The character of the spatial distribution of the spectral intensity in hollow cathode lamps was demonstrated to depend primarily on the cathode radius. A typical distribution of the spectral intensity in the cross-section

Figure 2. Spatial distributions of the normalised radiation intensity of a hollow cathode lamp (*a*), an electrodeless lamp (*b*) and a deuterium lamp (*c*) measured at the resonance wavelength of lead (283.3 nm).

of a hollow cathode lamp is illustrated in Fig. 2 *a*. The radiation was detected at the resonance wavelength of lead (283.3 nm). The distribution is dome-shaped, has an intensity maximum at the cathode axis and decreases monotonically to zero at the ends of the cathode. These distributions are characteristic of not only the metal lines but also the fill gas lines and are well described by parabolic functions. This is indicative of charge localisation in the cathode hollow and direct electron impact excitation of metal and

[†] This technique is called classical or conventional AAS.

fill-gas atoms. The distribution presented in Fig. 2a is typical of most hollow cathode lamps. However, lamps designed for analysis of non-volatile elements include hollow cathodes with larger radii. In such hollow cathode lamps, electron impact excitation/ionisation can be accompanied by other processes. In particular, this is evidenced by the fact that the spatial intensity distribution for barium ion has a dip in the near-axis region due to Penning ionisation.¹⁰

2. Electrodeless discharge lamps

Hollow cathode lamps used in AAS for most analyte elements give rather intense and narrow spectral lines. However, electrodeless discharge lamps (EDL) offer better metrological characteristics for some volatile elements, such as As, Hg, Se, Cd, Pb, *etc.* The service time of these lamps is much longer and they give more intense (5–100-fold more intense) radiation at the resonance wavelengths than the corresponding hollow cathode lamps. Line spectra in EDL are excited by inductively coupled plasma generated in a sealed valve at a frequency of tens of megahertz (and higher). Argon or krypton is used as a fill gas at a pressure of ~ 1 mm Hg. Analyte atoms are introduced into the high-frequency plasma by thermal vaporisation from the base of the valve as the latter is heated. Therefore, the valve must be preheated for 30–40 min to provide a steady-state mode.

The results of investigations of the spectral characteristics of EDL were summarised in a review.¹³ The intensity distributions of electromagnetic fields were reported.^{14–16} As in hollow cathode lamps, the widths of the spectral profiles are about 1 pm and are determined primarily by the hyperfine splitting and Doppler broadening. Spatial distributions of the radiation intensity in EDL for different elements with the use of different fill gases were examined.^{17,18} It was found that the excited argon atoms and ions are characterised by a dome-shaped distribution with the maximum radiation intensity in the near-axis region of plasma.¹⁷ This distribution is due to direct (or stepwise) electron impact excitation.

The introduction of metal atoms substantially complicates the situation. In this case, the plasma in EDL becomes strongly structured. Clouds of metal and argon atoms are spatially separated. A typical radiation intensity distribution for metal atoms in the cross-section of EDL is exemplified by the radiation intensity distribution for lead at the resonance wavelength of 283.3 nm¹⁷ presented in Fig. 2b. It can be seen that this distribution is strongly non-uniform. A pronounced minimum is observed on the axis of the plasma and the radiation beam is located primarily in the narrow region along the walls of the valve (optical skin effect). Detailed studies demonstrated¹⁷ that neither the electromagnetic skin effect nor self-absorption can account for such anomalous distributions. It was found¹⁷ that the observed distributions are determined by the radial cataphoresis effect resulting in a strongly non-uniform distribution of neutral metal atoms with a maximum near the walls of the valve. Together with the dome-shaped distribution of the electron concentration, this leads to the spatial distribution of the excited atoms presented in Fig. 2b.

3. Continuous spectrum radiation sources

In addition to line radiation sources, continuous spectrum radiation sources are also widely used in AAS. These are deuterium, hydrogen, xenon, tungsten and halogen lamps. Generally, xenon arc lamps are used as transmitted radiation sources for the detection of selective absorption,¹⁹ whereas deuterium lamps are widely used for non-selective absorption correction.

In deuterium lamps, radiation is generated in a low-pressure non-self-sustained arc discharge. This discharge provides a high-intensity continuous spectrum in the 190–360 nm spectral range, which contains the majority of analytical lines used in AAS. Since electron impact is the main excitation channel in these sources,²⁰ the radiation intensity distribution is evidently determined by the electron concentration distribution in the positive column of an

arc discharge. It was shown²⁰ that the maximum electron density occurs on the discharge axis and monotonically decreases toward its ends. Measurements of the spectral intensity distribution in the cross-section of a deuterium lamp confirmed the above suggestion. The spatial distribution of the spectral intensity of a deuterium lamp is presented in Fig. 2c.¹² The distribution is dome-shaped with a maximum on the axis of the cathode hollow and minima at the cathode ends. A plateau present at the base of the distribution is associated with the presence of a circular screen near the arc cathode.

Analysis of the data presented in Fig. 2 showed that spatial distributions of radiation generated by sources used in AAS are strongly non-uniform (in the case of EDL, they are additionally non-monotonic), and the character of non-uniformity strongly depends on the type of the source.

4. Spatial structure of transmitted radiation in an atomiser

Special optics is used to convert the radiation from the source into a transmitted beam, which is directed to an atomiser. An optical system of an atomic absorption spectrometer focuses a source image onto the centre of the atomiser and then it is directed to the entrance slit of the monochromator with the use of another optical system. Then a probe beam, which is passed through an absorbing layer in the atomiser and through a narrow vertical slit of the monochromator is recorded by a detector at the outlet of the spectrometer. The spatial structure of the transmitted beam in an atomiser was examined.²¹ A typical radiation intensity distribution in the transmitted beam produced by a lead hollow cathode lamp is shown in Fig. 3. Since a source image is formed in the

Figure 3. Radiation intensity distribution in the vertical cross-section of the transmitted beam at the inlet (1), at the output (2) and in the centre (3) of an atomiser (a) and the shape of the transmitted beam inside the atomiser (b);²¹ (b): horizontal lines indicate the walls of the tube atomiser and arrows show the cross-sections of the beam, in which curves 1–3 presented in (a) were measured.

centre of an atomiser, curve 3 coincides with the central cross-section of the distribution presented in Fig. 2*a*. These results reveal an interesting fact. As can be seen from Fig. 3*a*, the areas under the distribution curves differ from each other. The radiation intensity in the vertical cross-section at the inlet of the atomiser is much lower than that at the output. This accounts for the change in the shape of the cross-section of the beam as it passes through the atomiser. At the inlet and outlet of the atomiser, the beam is elongated in the horizontal and vertical directions, respectively.²¹ Radial radiation intensity distributions analogous to those presented in Fig. 3*a* were constructed with a step of 1 mm along the axis of beam propagation. As a result, the structure of the beam in the atomiser was quantitatively characterised. The beam thus constructed is shown in Fig. 3*b*. It can be seen that the beam becomes narrower in the centre of the atomiser and again becomes broader at the outlet.

The spatial structure of the transmitted beam produced by electrodeless lamps is different in principle.²¹ It should be noted that this beam is also characterised by a strongly non-uniform radiation intensity distribution.

III. Dynamics of spatial temperature distributions in atomisers

The overwhelming majority of substances analysed by atomic absorption methods exist in the condensed state. However, only free atoms in the gas phase can be detected by AAS. Consequently, it is necessary to convert the analyte into the gas phase before atomic absorption analysis. Atomisation is performed in atomisers with the use of different flames, plasma, laser radiation and electrothermal vaporisation (graphite atomisers). The main parameters governing the kinetics of vaporisation and atomisation, diffusion, absorption coefficients and distribution coefficients of atoms and molecules in an atomiser depend on the temperature.^{22–24} Therefore, it is necessary to know the temperature field dynamics for the interpretation of all effects in AAS. Nowadays, only plasma and electrothermal atomisers are commercially produced, the latter being characterised by substantially more complicated temperature distributions and gradients. Below, we focus on the temperature fields in graphite electrothermal atomisers. The temperature fields in spectroscopic flames used for atomisation were examined.^{25–28}

Graphite tube atomisers are used for converting an analyte from the condensed state into an atomic vapour by thermal vaporisation using fast ($> 2000 \text{ K s}^{-1}$) heating to ~ 2000 – 3000 K . Presently, two types of electrothermal atomisers (with longitudinal and transverse heating) are commercially produced. In the former type of atomisers, a graphite tube is heated by passing the electric current along the tube [Heated Graphite Atomiser (HGA)]. In another type of atomisers, the electric current is passed transversely [Transversely Heated Graphite Atomiser (THGA)].

The temperature of the walls of tube atomisers is measured by optical pyrometry.^{29–31} The temperature distributions on the surface of end-heated HGA-type atomisers are strongly non-uniform both in the longitudinal and radial directions. The dynamics of the longitudinal temperature distribution in a graphite tube during its heating to 2273 K is characterised by the plots presented in Fig. 4*a*.³⁰ It can be seen that at the initial instant of time (within the first second), the temperature distribution along the atomiser is virtually uniform because thermal exchange is a sluggish process. Then the longitudinal temperature drops progressively increase as a result of heat transfer to cold contacts and, in a steady-state mode, the temperature drops are larger than 900 K .

The changes in the gas-phase temperature in electrothermal atomisers were studied by different methods.^{31–33} Coherent anti-Stokes Raman scattering (CASR)^{32,34} proved to be the most informative for this purpose. This method allows one to record the gas temperature with a high space-time resolution. The gas-phase

Figure 4. Plots characterising the space-time dynamics of the longitudinal temperature distributions in HGA- (*a*) and THGA-type (*b*) atomisers.

Time /s: (1) 0.8, (2) 1.0, (3) 10, (4) 1.2, (5) 1.5, (6) 3.0, (7) 2.0.

temperature depends substantially on protecting gas flows. In HGA-type atomisers, the gas-phase temperature drops in the longitudinal direction can be as large as 1500 K , and the drops in the radial direction can reach 800 K (with the use of a platform).^{32,35}

The temperature distributions in THGA-type atomisers were also studied by CASR. The changes in the gas-phase temperature along the axis of such atomisers are evident from the plots presented in Fig. 4*b*.³⁴ It can be seen that THGA-type atomisers (unlike HGA-type atomisers) are virtually isothermal throughout the tube length. As a result, the memory effects in measurements are reduced and the determination of non-volatile elements becomes much easier. However, the available THGA-type atomisers are not completely isothermal because substantial temperature gradients occur in the radial section, which is associated with the design parameters of these atomisers (see below).

IV. Three-dimensional structures of absorbing layers

1. Structure of absorbing layers in longitudinally heated atomisers

The dynamics of the formation and dissipation of absorbing layers in electrothermal atomisers was examined in numerous studies. The results of these investigations were summarised in monographs.^{4,31} However, only a few methods provide both the

time resolution and the spatial resolution in measurements. The spatial structures of absorbing layers are studied by Schlieren spectroscopy,³⁶ spatial separation³⁷ and different laser imaging techniques.^{38–43} These methods were used in a series of studies aimed at atomising various elements. Shadow spectral filming⁴⁴ has gained wide acceptance. According to this method, monochromatic radiation at the wavelength of analyte atoms or molecules is passed through an atomiser. When this radiation is transmitted through the absorbing layer, a shadow image of a cloud of atoms (molecules or condensed nanoparticles) that absorb light at this wavelength appears on the detector surface. The higher the concentration of absorbing particles, the larger the absorbance of the shadow. The advantage of shadow spectral filming is that it allows one to visualise the structures of layers consisting of different atoms (molecules or particles) that absorb in the 190–900 nm range with a space-time resolution in the cross-section of an atomiser.

a. Spatial distributions of free atoms

The dynamics of the formation and dissipation of absorbing layers of atoms of elements, which differ substantially in the physicochemical properties under different experimental conditions (atomisation from the walls and the platform in the gas-stop mode or purging with an inert gas), were studied by shadow spectral filming.^{44–62} It was demonstrated that the structure of the absorbing layer is determined by physical (vaporisation, diffusion and convection mass transfer, condensation and reevaporation) and chemical (chemisorption, gas-phase and heterogeneous reactions) processes. The distributions of noble metal atoms in the cross-section of an atomiser appeared to be virtually uniform upon atomisation from both the platform and the walls of an atomiser.^{40–42, 44–46, 63–65} A typical pattern giving an insight into the dynamics of the formation and dissipation of the absorbing layer of silver atoms is shown in Fig. 5*a*. Each photograph in the figure is a monochromatic image of the inner surface of an atomiser with a platform. The measurements were carried out at the resonance wavelength of silver (328.1 nm). Silver atoms are vaporised from the platform, absorb light and are observed as a shadow image. The virtually uniform atom distribution in the cross-section of the atomiser is indicative of high efficiency of diffusion mass transfer (due to which the spatial non-uniformity of the distribution is smoothed) and the absence of chemical reactions involving silver atoms.

A completely different atomic distribution is observed in atomisers with internal inert gas purging. The absorbing layer

Figure 5. Images of the inner cavity of an HGA-type atomiser equipped with a platform, which were obtained by shadow spectral filming at the resonance wavelengths of silver (*a*, *b*) and gallium (*c*);^{44, 47} (*a*) 50 ng Ag, the gas stop mode; (*b*) 50 ng Ag, internal purging at a rate of 300 ml min^{−1}; (*c*) 50 ng Ga in the gas stop mode. Hereinafter, the time intervals from the onset of the atomisation cycle are given in seconds below the shots.

becomes strongly inhomogeneous with a sharp decrease in the atomic concentration from the bottom to the top of the atomiser (Fig. 5*b*). This distribution is associated with the character of the inert gas flow. The gas enters from the ends of the atomiser and leaves the latter through a small dosing hole in the centre, which results in a substantial acceleration of the gas flow.

Anomalous effects were observed when performing atomisation of Group III elements (Al, In, Ga and Tl).^{47–51} The dynamics of formation of an absorbing layer of gallium atoms is illustrated in Fig. 5*c*. These results are indicative of a pronounced anomaly; that is, the atoms are introduced into the gas phase from the upper part of the atomiser rather than from the platform onto which a sample was dosed, *i.e.*, inverse atomisation occurs. This effect is attributed to initial vaporisation of a substance in the form of gallium suboxide molecules, which do not absorb at the atomic wavelength, and their reduction on the walls of the graphite atomiser followed by introduction of gallium into the gas phase, now, as free atoms.^{44, 48}

The anisotropy of the propagation velocity of metal vapour in the longitudinal and cross-sections of the atomiser was revealed. Vapour diffusion along the atomiser tube occurs in a medium, in which the temperature sharply decreases (see Fig. 4*a*), and the diffusion rate is limited by the velocity of thermal front propagation in this direction. In addition, some shots in Fig. 5*c* show a sharp decrease in the concentration of atoms near the platform due to their condensation on the substantially colder platform. Then the condensed atoms again pass to the gas phase as the platform is heated. Therefore, the dynamics of formation and dissipation of an absorbing layer consisting of gallium atoms is complicated by the simultaneous occurrence of numerous physicochemical processes. Analogous features of the dynamics of formation of absorbing layers were revealed in studies of Tl, In, Ge and Bi atomisation.

An even more complicated dynamics was observed in studies of aluminium atomisation.^{48, 52–54} The analytical signal recorded on a conventional Perkin-Elmer Zeeman 5000 atomic absorption spectrometer (Fig. 6*a*) appears as a regular peak without anomalies. However, investigation of this process by shadow spectral filming revealed a series of effects, which were not manifested in the conventional absorption signal. Images obtained by digital shadow spectral filming (Fig. 6*b*) show that the atomic distribution in the cross-section of the atomiser is strongly non-uniform. The maximum concentration is observed near the graphite walls, and the minimum is observed near the dosing hole. This is indicative of oxygen diffusion into the atomiser through the dosing hole and a high rate of gas-phase oxidation of aluminium. The near-axis region of the atomiser also contains a large amount of aluminium, but it is involved in oxides, which do not absorb at the atomic wavelength. A region selected by the entrance slit of the monochromator is indicated by a rectangle in shot 1 (see Fig. 6*b*). The radiation from only this region is focused onto the detector and is recorded by a conventional atomic absorption spectrometer. In the plot $A(t)$ (see Fig. 6*a*), the instant of time corresponding to this shot is indicated by point 1. The absorbance detected by a spectrometer at this instant of time is virtually equal to zero. However, the atomiser contains a substantial amount of aluminium atoms, which are located along the walls (see Fig. 6*b*, shot 2) and are beyond the detection limit of conventional spectrometers.

The above results also suggest that free atoms are redistributed inside the atomiser. In the early steps of atomisation, the concentration of aluminium atoms is higher above the platform. In the final step, the concentration maximum is shifted to the region under the platform (see Fig. 6*b*, shots 3 and 4). This additionally confirms a substantial role of oxygen in the distribution of aluminium. Evidently, the conditions under the platform are more reductive than those in the upper part of the atomiser. In addition to the above-mentioned anomalies of the atomic spatial distribution, atomisation of aluminium (as well as of ytterbium

(b): contours of the absorbance are given, the arrow in shot 1 indicates the position of the dosing hole.

and some other elements) is accompanied by explosive atomisation.^{53, 54, 66, 67}

The results obtained in the study⁵⁵ of boron atomisation also provide evidence that oxygen diffusion through the dosing hole has a strong effect on the atomic distribution of this element.

b. Spatial distributions of non-selectively absorbing particles

In electrothermal AAS, molecules play a very important role in the formation of free atoms.^{68, 69} In addition, molecules are responsible for non-selective absorption.^{70, 71} Studies of the dynamics of formation of molecular layers by shadow spectral filming also revealed a number of anomalies.^{46, 48–51, 54, 56, 57} The structure evolution of an absorbing layer composed of gallium molecules in graphite tube atomisers is illustrated in Fig. 7a. The images were obtained at the wavelength of 254 nm, where one of the molecular absorption maxima of gallium is located.

Figure 7. Images of the inner cavity of a graphite tube atomiser obtained by shadow spectral filming at a wavelength of 254 nm for vaporisation of 1 µg of Ga (a) and Al (b) salts.⁴⁸

Contrary to the commonly accepted opinion that molecules are located at the colder ends of atomisers, their true distribution is quite opposite. Vaporisation leads to a strongly non-uniform distribution of molecules inside an atomiser. The concentration maximum is located near the platform, and the concentration minimum is near the graphite walls. No molecules are observed under the platform, whereas molecules are observable in the central regions of the atomiser. Taking into account this distribution, it was concluded that these are metal suboxide molecules. A comparison of the atomic (see Fig. 5c) and molecular (see Fig. 7a) distributions of gallium revealed the following fact. Molecules disappear in the regions where atoms appear. The same situation was observed in studies of the structures of absorbing layers composed of indium- and aluminium-containing molecules. This led to the conclusion that reduction of gaseous metal oxide on the graphite surface is a heterogeneous process, which can be described in the general form by the equation

This is one of the most important processes in electrothermal AAS.

Studies of absorbing layers of aluminium suboxide molecules showed yet another anomaly.^{48, 54, 56} The dynamics of formation of such layers is typical of two-step processes. Initial vaporisation of molecules from the platform (the characteristic features of this process are virtually identical to those described above for gallium vaporisation) is followed by the formation of an absorbing cloud having a complicated toroidal structure inside the atomiser (Fig. 7b). A detailed analysis demonstrated that the cloud consists of aluminium oxide nanoparticles condensed in the gas phase. Vaporisation of microgram amounts of various elements affords analogous structures consisting of nanoparticles. Therefore, not only atoms and molecules but also nanoparticles are present inside electrothermal atomisers at extremely high temperatures, and all these species are characterised by a strongly non-uniform spatial distribution.

2. Structures of absorbing layers in transversely heated atomisers

In the previous section, we noted that temperature fields in transversely heated atomisers differ radically from those in longitudinally heated atomisers.⁵⁸ Transversely heated graphite atomisers are almost longitudinally isothermal but are characterised by considerable temperature inhomogeneities in the cross-section.⁵⁹ This is responsible for the formation of new three-dimensional atomic, molecular and nanoparticulate structures in THGA.

a. Atomic distribution

The dynamics of formation and dissipation of an adsorbing layer of silver atoms in THGA⁵⁹ is evident from an analysis of the results of shadow spectral filming presented in Fig. 8a. It can be seen that atoms appear directly above the bottom of the atomiser

Figure 8. Images of the inner cavity of THGA obtained by shadow spectral filming for atomisation from the walls of 25 ng of Ag (a) and 200 ng of In (b).⁵⁹

onto which a sample was dosed, and their spatial distribution in the initial step of atomisation is normal, *i.e.*, the atom concentration monotonically decreases from the bottom to the top. However, the absorbance maximum is gradually shifted to the side walls of the atomiser. This redistribution can be accounted for only by vapour adsorption (condensation) on colder regions followed by revaporisation during further heating of the atomiser. In the study,⁴⁷ a cascade mechanism of the substance transfer in the longitudinal direction of HGA-type atomisers was proposed. The same mechanism (but in the radial section) is observed in THGA-type atomiser. An analogous substance transfer in transversely heated atomisers was documented.^{41, 42} Interestingly, the vapour concentration is somewhat higher near the left side surface. This is due to the fact that the temperature in the left part of the tube in the atomiser used in experiments was somewhat lower than that in the right part because the cooling liquid is introduced from the left to the right contact.

The dynamics of formation and dissipation of an indium absorbing layer is presented in Fig. 8 b. A sample was dosed from the bottom of the tube.⁵⁹ It can be seen that the spatial atomic distribution is opposite to that observed in the case of silver atomisation. Indium atoms appear simultaneously in the upper and lower parts of the atomiser (shots obtained within 0.20 and 0.52 s after the onset of atomisation), and a pronounced absorbance minimum is observed on the side surfaces during the whole cycle. Analogous distributions are also typical of Ga, Tl and Bi atoms. It is known that, when vaporisation of aqueous samples of In, Tl, Bi and Ga is performed in graphite furnaces, oxides of these elements are the first to go into the vapour phase, and these oxides do not absorb at the resonance wavelengths of the corresponding atoms.⁴⁸ The effect presented in Fig. 8 b is indicative of decomposition of indium suboxide molecules. Evidently, the gas-phase temperature along the vertical diameter is higher than the decomposition temperature of oxides. This accounts for the minimum concentration of atoms near the side walls of the tube characterised by the lowest atomiser temperature.

Small inhomogeneities of the absorbing layer are observed during silver atomisation in THGA-type atomisers (Fig. 9 a). The atoms appear directly above the platform onto which a sample was dosed and gradually fill the whole volume of the atomiser (shots obtained within 1.32 and 1.40 s after the onset of the atomisation cycle). In this case, as in above-considered experiments (see Fig. 8 a), the vapour redistribution to the left side of the atomiser is observed (shots obtained within 2.32 and 2.84 s after the onset of the atomisation cycle). In the presence of a platform, this effect is less pronounced because atoms appear in the gas phase at a higher atomiser temperature. Analogous spatial structures of absorbing layers were observed also in manganese and copper atomisation. The observed atomic redistributions in the cross-section of atomisers also substantially influence the temperature gradients in atomisers.

The effect of inverse atomisation, which has been observed for the first time in HGA-type atomisers,^{44, 48} is clearly pronounced in

Figure 9. Images of the inner cavity of THGA with a platform obtained by shadow spectral filming for atomisation of 5 ng of Ag (a) and 675 ng of Ga (b).⁵⁹

the case of gallium atomisation in THGA-type atomisers equipped with a platform. The dynamics of the formation and dissipation of absorbing layers of gallium atoms is presented in Fig. 9 b.⁶⁰ An excess of gallium was used to improve visualisation of the process. As in the earlier study,⁴⁴ the characteristic features of the atomic distribution are attributed to the fact that gallium is initially vaporised as suboxides, which do not absorb at the atomic wavelength of 417.2 nm and, consequently, remain invisible in these measurements. Then suboxide molecules are reduced on the opposite surface of the atomiser (shots obtained within 0.24–0.40 s after the onset of the atomisation cycle) according to reaction (2).

An analogous dynamics of atomic spatial distributions was observed also for In, Tl and Bi atomisation. Therefore, inverse atomisation of Group III elements occurs also in THGA-types atomisers.

b. Molecules and condensed particles

The above-considered structures of absorbing layers were determined at wavelengths that did not overlap with the wavelengths of molecular absorption bands. Vaporisation of a salt containing 10 µg of indium was studied by shadow spectral filming and the results of this study are presented in Fig. 10 a. Shadow shots were measured at a wavelength of 294.4 nm⁶⁰ corresponding to the absorption maximum of indium suboxide.⁴⁸ It can be seen that a vapour cloud was initially formed at the bottom of the atomiser directly above the sample and had a normal three-dimensional structure (the vapour density monotonically decreases from the bottom to the top of the atomiser; see the shots obtained within 0.46 and 0.50 s after the onset of the atomisation cycle). However, the cloud is then transformed into a diffuse horizontal band between the side walls of the atomiser (shots obtained within 0.54–0.70 s after the onset of the atomisation cycle). In the final step of vaporisation, the band is broken and the vapour is accumulated near the side surfaces of the tube. The distributions

Figure 10. Images of the inner cavity of THGA obtained by shadow spectral filming for vaporisation from the wall of salts containing 10 µg of In (a) and 50 µg of CaCl_2 (b).^{60, 61}

of indium-containing molecules differ from those of indium atoms (see Fig. 8 *b*; the atoms were distributed along the vertical diameter of the atomiser, the density being higher at the ends). The observed three-dimensional structures of the absorbing layers are due to the characteristic features of the temperature gradients in the radial section of the atomiser.^{59, 60} The lower-temperature region inside THGA-type atomisers is located along their horizontal diameter. Evidently, the lowest degree of dissociation of molecules occurs in this region. A higher-temperature region of the gas phase inside atomisers is located along the vertical diameter far from the cooled side contacts. It is this region where indium atoms are predominantly located.

Vaporisation of an excess of a substance in an atomiser gives rise to a cloud of condensed nanoparticles. Their distribution in the cloud is strongly non-uniform and complicated. The results of study of vaporisation of CaCl_2 (50 μg) in a THGA-type atomiser by shadow spectral filming are given as an example in Fig. 10 *b*. Visualisation was performed at a wavelength of 352 nm, which differs from the wavelengths of both molecular and atomic absorption bands. Therefore, it is evident that the above-considered structures of the absorbing layers are formed by particles condensed in the gas phase. Further studies demonstrated⁶⁰ that the absorbing cloud consists of nanoparticles the sizes of which are smaller than the wavelength of the light beam used. Interestingly, the absorbing cloud has a well-defined shape and is located along the horizontal diameter of the atomiser. This is consistent with the character of the temperature field distribution inside the atomiser. Evidently, vapour condensation should occur in lowest-temperature regions. However, shots obtained within 0.52–1.08 s after the onset of the atomisation cycle show an anomaly, *e.g.*, two small symmetrically arranged absorption regions appear in the lower part of the atomiser. This anomaly was reproduced in all experiments and its nature remains unclear. These regions can be due to the complex gas dynamics in atomisers as a result of the simultaneous occurrence of convective heat transfer from the ends of the tube and gas expansion caused by fast heating. The internal gas flow is also complicated by fast vaporisation of a considerable amount of the substance, which can cause a substantial change in the pressure distribution inside the atomiser. Under these conditions, the appearance of local vortex flows is probable, and the vapour can be partially trapped (and retained) by these flows. It should be noted that the cloud of condensed particles oscillates about the horizontal diameter of the atomiser (see Fig. 10 *b*), which is manifested as insignificant oscillations of absorption signals as the pulse is gradually changed.⁶²

V. Influence of spatial inhomogeneities of absorbing layers on absorption

The above-considered data show that the distributions of all key parameters in AAS are characterised by spatial non-uniformity. This brings up the question of how these parameters influence the atomic absorption.

The spectrophotometric absorbance A serves as the analytical signal in AAS. In the ideal case of an infinitesimally narrow spectral line of the source and on the assumption that the absorbing layer is spatially homogeneous, the absorbance is proportional to the number of absorbing atoms [see Eqn (1)]. However, real measurements are performed with the use of sources the spectral lines of which are of finite width, for inhomogeneous absorbing layers. This substantially complicates the basic dependence of AAS, which has the following general form⁷²

$$A = \log \left\{ \left[\int_0^H \int_{-b/2}^{b/2} \int_{-\lambda^*}^{\lambda^*} J(x, y, -L/2) J(\lambda) dx dy d\lambda \right] \times \right. \quad (3)$$

$$\times \left[\int_0^H \int_{-b/2}^{b/2} \int_{-\lambda^*}^{\lambda^*} J(x, y, -L/2) J(\lambda) \times \right.$$

$$\left. \times \exp \left(- \int_{-L/2}^{L/2} K(x, y, z; \lambda) dz \right) dx dy d\lambda \right]^{-1} \left. \right\}.$$

In this equation, H and b are respectively the height and width of the transmitted radiation beam selected by the entrance slit of the monochromator, $\{-\lambda^*, \lambda^*\}$ is the spectral region selected by the monochromator (Fig. 11), $J(x, y, -L/2)$ is the intensity distribution of the transmitted beam at the entrance of the atomiser, L is the atomiser length, $J(\lambda)$ is a function describing the spectral profile of the incident beam, and $K(x, y, z, \lambda)$ is the absorption coefficient

$$K(x, y, z, \lambda) = C(\lambda, T) n(x, y, z),$$

where $C(\lambda, T)$ is the coefficient dependent on the temperature and spectral characteristics of the analytical line (the direct expression for this coefficient was reported in the study²⁴) and $n(x, y, z)$ is the local concentration of absorbing particles.

From Eqn (3) it follows that the absorbance in conventional AAS depends on three factors: (1) spectral characteristics of the analytical line (the dependence of J , T and K on λ); (2) spatial distributions of absorbing particles and the atomiser temperature (the dependence of K on x , y and z); (3) spatial intensity distribution of the transmitted radiation beam. In the limiting case of the uniform distributions of absorbing particles, temperature and transmitted radiation intensity and on the assumption that the analytical line is single and infinitesimally narrow, the absorbance is directly proportional to the number of absorbing particles inside the atomiser at each instant of time. Equation (3) is substantially simplified and reduces to Eqn (1). The most comprehensive analysis of the influence of the spectral factors on the atomic absorption was performed in the study.²⁴ In the general case, the spectral profiles of emission lines $J(\lambda)$ and absorption lines $K(\lambda)$ are determined by Doppler and impact broadening, the absorp-

Figure 11. Cross- (*a*) and longitudinal sections (*b*) of a tube electrothermal atomiser and the transmitted beam as well as the spectral line $J(\lambda)$ selected within the transmitted band $\{-\lambda^*, \lambda^*\}$ of the monochromator (*c*).²⁴

Figure 12. Spectral profiles of absorption (1) and emission (2) for the resonance line of Pb at 283.3 nm (a) and the dependence of the absorbance on the number of absorbing atoms for this line, which takes into account all spectral characteristics of the line (1) and inhomogeneity of the absorbing layer (2) (b).²⁴

tion line shift and the hyperfine structure of the spectral transition. Figure 12 a gives the emission and absorption line contours for the resonance line of lead at 283.3 nm, which were calculated for the typical conditions of AAS taking into account the above-mentioned mechanisms of broadening.²⁴ The plot of the absorbance vs. the number of absorbing atoms corresponding to this spectral transition is shown in Fig. 12 b (curve 1). In calculations of this dependence, the spatial distribution of absorbing atoms was assumed to be uniform. It can be seen that broadening of the spectral line leads to curving and a decrease in the slope of the plot $A = f(N)$, which are particularly substantial for the spectral lines consisting of far-separated hyperfine components.

In addition to the above-described spectral factors, the shapes of the concentration curves strongly depend on the spatial distributions of the temperature gradients in the atomiser and the concentration of absorbing atoms. This influence is manifested in two directions. The longitudinal temperature and concentration gradients lead to a decrease in the slope of the plot given by Eqn (3), whereas the transverse gradients lead to further curving (see Fig. 12 b, curve 2).

The spectral transitions for some other elements were studied analogously. It was demonstrated²⁴ that the inhomogeneity of absorbing layers in the cross-section is one of the major factors responsible for curving of the calibration plots in AAS.

Therefore, the absorbance in conventional AAS depends not only on the number of absorbing atoms but also on their distribution inside the atomiser, as well as on the spatial structure of the probing beam, and is described by the following equation⁷²

$$A = A_t(N) - \Delta A(N', J'),$$

in which the first term can be referred to as the true absorbance (which depends only on the number of absorbing atoms N) and the second term depends on the gradients of spatial distribution of atoms (N') and the transmitted radiation intensity (J') and is

essentially the photometric error of the atomic absorption detection associated with inhomogeneity of the absorbing layer.

This error in conventional atomic absorption spectrometry is explained as follows. The luminous flux Φ_0 incident on the atomiser can be represented as consisting of n beams with intensity J_{i0} each. Then

$$\Phi_0 \sim \sum_{i=1}^n J_{i0}.$$

Analogously, the luminous flux Φ_t passed through the absorbing layer can be represented as

$$\Phi_t \sim \sum_{i=1}^n J_i,$$

where J_i is the local intensity of the probing beam passed through the corresponding region of the atomiser.

Therefore, the absorbance measured by conventional spatially integrated detection (SID) systems is described by the following equation:

$$A_{\text{SID}} = \log \frac{\Phi_0}{\Phi_t} = \log \frac{\sum J_{i0}}{\sum J_i}. \quad (4)$$

As demonstrated above, the absorbance depends on all types of inhomogeneities and is not proportional to the number of absorbing atoms N . At the same time, the number of these atoms can be represented by the sum

$$N = \sum_{i=1}^n N_i \Delta S_i,$$

where N_i (in cm^{-2}) is the atom density in the i th beam and ΔS_i is the cross-section area of the i th beam. If the elemental beams have equal cross-sections,

$$\Delta S_i = \frac{S}{n},$$

where S is the cross-section area of the total beam. Evidently, the local absorbance A_i becomes proportional to N_i as the transverse size of the beam decreases

$$A_i = \log \frac{J_{i0}}{J_i} \sim N_i.$$

Therefore, if the absorbance is represented as

$$A = \frac{1}{n} \sum_{i=1}^n A_i = \frac{1}{n} \sum_{i=1}^n \log \frac{J_{i0}}{J_i},$$

this parameter is proportional to the number of absorbing atoms regardless of their spatial distribution and the distribution of transmitted radiation intensity. Consequently, the spatially resolved detection (SRD) is required for correct photometric measurements of the absorbance of spatially inhomogeneous layers. The analytical signal A_{SRD} determined by the sum

$$A_{\text{SRD}} = \frac{1}{n} \sum_{i=1}^n \log \frac{J_{i0}}{J_i}, \quad (5)$$

is the true absorbance, which depends on spatial inhomogeneities, i.e.,

$$A_{\text{SRD}} = A_t(N).$$

VI. Spatially resolved atomic absorption analysis

The above-formulated idea of the spatially resolved detection was realised in practice in the studies.^{73,74} Below we describe an original experimental apparatus for the space-time resolved light absorption detection. The new detection system includes a linear position-sensitive detector (a photodiode bar or a charge-

coupled device) vertically located along the exit slit of the monochromator in the plane optically coupled with the centre of the atomiser. In this method, in contrast to conventional AAS, the distribution of transmitted radiation intensity along the vertical diameter of the atomiser, rather than the spatially integrated luminous flux passed through the absorbing layer, is measured at each instant of time.

Let us consider an example of the detection for atomisation of 0.1 ng of cadmium from a platform. The spatial intensity distributions of the radiation beam from cadmium EDL passed through the atomiser under different conditions are shown in Fig. 13. The spectral intensity distribution at the resonance wavelength of 228.8 nm is qualitatively analogous to that presented in Fig. 2*b*. The maximum is located at the periphery of the source. Since the diameter of EDL is approximately twice as large as the inner diameter of the atomiser (6 mm), the radiation beam from only one-half of the distribution shown in Fig. 2*b* enters the system. The tube of the atomiser substantially shields the incident beam. Curve 1 in Fig. 13 shows the intensity distribution of the radiation beam, which is passed through the cylindrical tube of the atomiser, along the exit slit of the spectrometer.

In atomisers equipped with a platform, the lower part of this distribution is substantially transformed (curve 2). The intensity near the platform ($y = 1$ mm) is equal to zero and has a small peak of the radiation beam passed under the platform ($y = 0.5$ mm). In conventional electrothermal AAS, a short slit (with a height of 2 mm) of the monochromator of the spectrometer is used to shield intrinsic emission of the atomiser. This slit selects a small region above the platform along the vertical diameter of the atomiser. This region is dashed in the inset to Fig. 13 and the spatial profile of EDL radiation passed through this short slit is shown by curve 3. In conventional AAS, the total luminous flux passed through the short slit, *i.e.*, the surface area under curve 3, rather than the intensity distribution is measured. In spatially resolved AAS, the profile of the radiation beam passed through the total cross-section of the tube, $J(y)$, (curve 2) is measured at each instant of time. This is the main difference between the methods under consideration. Spatially resolved AAS is substantially more informative than conventional AAS.

The evolution of the distribution of transmitted radiation intensity $J(y, t)$ in the course of platform atomisation of 0.1 ng of cadmium is shown in Fig. 14. The intensity dip starting from 0.25 s is determined by resonance radiation absorption at a wavelength of 228.8 nm by cadmium atoms vapourised from the platform. After completion of the atomisation cycle ($t > 1.5$ s), the spatial profile of the incident beam is completely restored.

Figure 13. Intensity distribution of radiation from cadmium EDL passed through an atomiser without a platform (1), with a platform (2) and through a short monochromator slit (3).⁷⁹

The cross-section of a tube atomiser equipped with a platform and regions inside the atomiser selected by tall and short slits is shown in the inset.

Figure 14. Changes with time in the spatial profile of the transmitted radiation intensity in the case of platform atomisation of 0.1 ng of Cd.⁷⁹ The detection was carried out at the resonance wavelength of cadmium (228.8 nm).

With a knowledge of the changes with time in local intensities, it is easy to obtain spatially resolved absorbances $A_i(t)$ corresponding to the absorption in different regions of the atomiser along its vertical diameter. Therefore, the spatially resolved detection gives a family of pulses recorded in different regions of the absorbing layer (Fig. 15*b*) instead of one atomic absorption

Figure 15. Absorption pulse obtained with the use of a conventional detection technique (a) and a family of 149 pulses obtained with the use of the spatially resolved detection (b) of atomisation in an HGA-type atomiser.⁷³

The absorption pulse detected for a region under the platform is indicated by a dashed curve. The absorption pulses obtained when moving from the platform to the upper part of the atomiser are indicated by an arrow.

pulse integrated over the cross-section of the atomiser, which is obtained in conventional AAS (Fig. 15a). Evidently, such a high spatial resolution is excessive. Consequently, the signals from the adjacent pixels of the detector can be combined to obtain the desired degree of spatial resolution. For HGA-type atomisers, depending on the degree of spatial inhomogeneity of particular distributions, 10–20 pulses along the diameter (6 mm) of an atomiser are sufficient.

The atomic absorption peaks monotonically decrease from the platform to the upper region of the atomiser (an arrow in Fig. 15b). The integrated absorption

$$\int_0^{\infty} A_i(t) dt,$$

which was measured directly above the platform onto which a sample was placed, is almost twice as large as the integrated absorption in the upper region of the atomiser. Interestingly, the radiation beam passes under the platform (see the small peak at $y = 0.5$ mm in Fig. 13), which makes it possible to obtain an atomic absorption pulse even from this region (the latter is indicated by a dashed curve in Fig. 15b). It can be seen that cadmium atoms appear in the region under the platform with a substantial delay.

Atomic absorption spectrometry is widely used in fundamental physicochemical studies,³¹ in particular, for the determination of the activation energies of vaporisation or atomisation. Evidently, the signal detected directly above the vaporisation source (the upmost curve in Fig. 15b) most adequately describes the kinetics of sample vaporisation in the above-considered example. It can be seen that this signal is not an absorption monopulse, which is evidence that cadmium vaporisation occurs by a complex mechanism. In measurements with the use of conventional spatially integrated detection systems, these features become less pronounced (see Fig. 15a), with the result that the activation energies of vaporisation are incorrect. In measurements with the use of spatially resolved detection systems, each measurement becomes much more informative due to which the conditions of atomisation and the formation of an absorbing layer of atoms can be better controlled.

A photometric error in the detection of atomic absorption of spatially inhomogeneous layers does not necessarily lead to an error in the determination of the number of absorbing atoms. If the character of spatial distribution of atoms in the analyte is identical to that in a reference sample, conventional atomic absorption analysis provides correct results. However, the spatial distribution of an analyte often depends substantially on the influence of the matrix of the analyte. In this case, the photometric error necessarily leads to an analytical error. This is clearly demonstrated by the following example.⁷⁴ Figure 16a shows the dynamics of changes in non-selective absorption detected at the resonance wavelength of cadmium (228.8 nm) for atomisation of the certified reference sample SRM 1572 (Citrus Leaves). The distributions are clearly non-uniform, the absorbance being changed by a factor of 10–20 from the platform ($y = 0$) to the upper wall of the atomiser ($y = 3$ mm). The pulses of space-time resolved selective absorption of cadmium atoms shown in Fig. 16b are characterised by substantially larger spatial gradients than those observed for atomisation from aqueous solutions (see Fig. 15b). In this case, the difference (relative change) between the analytical signals

$$\int_0^{\infty} A_{\text{SID}}(t) dt \text{ and } \int_0^{\infty} A_{\text{SRD}}(t) dt$$

is 86%. In atomic absorption spectrometry with the use of the conventional (spatially integrated) detection, this leads to an analytical error of 67%. The possibility of appearing a considerable analytical error associated with the photometric error

Figure 16. Space–time distribution of non-selective (a) and selective (b) absorption measured at the resonance wavelength of cadmium (228.8 nm) in the detection of cadmium in a certified sample SRM 1572 (Citrus Leaves).⁷⁴

in measurements with the use of the conventional detection of inhomogeneous layers was also demonstrated.⁷⁵

It is necessary to use matrix modifiers in electrothermal atomic absorption analysis of most substances. Taking into account the above-considered data, it is evident that the matrix modification of a sample leads not only to the known effect of separation of vaporisation of the analyte and the matrix but also to a unified spatial distribution of the analyte when it is atomised from an aqueous reference sample and from a real sample.

In conventional atomic absorption spectrometers, short monochromator slits are used with the aim of shielding intrinsic emission of the atomiser (see the rectangular region in the first shot in Fig. 6b and the inset to Fig. 13). Tall slits used in spatially resolved spectrometers provide the space-time resolved detection of radiation beams from both a source and the walls and platform of the atomiser. The results of these studies can be used for the on-line monitoring of temperature changes. An example is illustrated in Fig. 17. Thermal emission from the platform and walls sharply increases as their temperature raises and the detection wavelength increases. In this example, the measurements were performed at the resonance wavelength of calcium (422.7 nm) in the visible spectral region. The peaks corresponding to glow of the

Figure 17. Changes in the intensity (I) of the radiation from the source, the walls and the platform of a tube atomiser measured with the use of the space-time resolved detection for calcium atomisation (a) and the radiation intensity distribution along the vertical diameter of the atomiser before atomisation (1) and at the instant when the maximum absorption was achieved (2) (b).⁷³

Calcium atomisation from the platform, $\lambda = 422.7$ nm, $T = 2500$ °C.

walls of the atomiser and the platform are seen in Fig. 17 *a*. Before heating of the atomiser, when its walls are cold, only the intensity profile of the source is detected (curve 1, Fig. 17 *b*). At the instant the atomisation temperature is achieved, the intensity profile of the transmitting source virtually disappears (vaporisation of a large amount of absorbing calcium atoms occurs), but three other peaks corresponding to emission from the upper and lower walls and the platform of the atomiser appear (curve 2, Fig. 17 *b*). Changes with time in emission from the walls of the atomiser and the platform follow directly after a rise of the atomiser temperature (see Fig. 17 *a*). This fact can be used to estimate quantitatively the degree of heating of the system. The relative peak intensities of emission from the upper and lower walls strongly depend on the alignment of the atomiser.⁷⁶ The difference in the peaks of emission from the walls (see curve 2, Fig. 17 *b*) indicates that the measurements were performed so that the atomiser tube was inclined to the optical axis of the spectrometer. This information can be used for the quantitative control of the alignment of the atomiser. The spatially resolved detection provides the possibility of seeing the exact position of the transmitted beam relative to the axis of the atomiser (see curve 1 in Fig. 17 *b*), which also substantially simplifies the alignment of the radiation source.

With a knowledge of the transmitted radiation intensities measured with the use of space-time resolved detection systems (see Fig. 14), it is always possible to obtain the absorption signal, which can be detected by a conventional spectrometer. For this purpose, it is sufficient to process the measured data according to Eqn (4). Therefore, AAS with the spatially resolved detection has all advantages of conventional AAS and includes them as a special case.

An idea of absolute atomic absorption analysis has been proposed back in 1955,² which marked the beginning of the development of analytical AAS. Over the history of AAS, this idea was extensively developed.^{77–79} Taking into account the above-considered results of investigation of spatial distributions and their influence on the formation of analytical signals, it is evident that reference-free atomic absorption analysis cannot be performed without the space–time resolved detection.^{80, 81}

Consequently, AAS with the spatially resolved detection appeared as the development of conventional AAS. The inclusion of additional measurements, *i.e.*, the measurements of the dependence of the key parameters on the spatial coordinate, provides substantially more informative data and higher accuracy of atomic absorption analysis.

VII. Conclusion

The development of methods and apparatuses, which could give higher-quality analytical signals, is one of the main fields of instrumental analytical chemistry. Atomic absorption signals detected in conventional AAS depend not only on the atomic concentration of the analyte element (the informative component of the signal), but also on their spatial distribution and the distribution of transmitted radiation intensity (the interference component of the signal). In AAS with the use of the spatially resolved detection, atomic absorption signals are independent of the spatial effects, due to which the resulting analytical signals are of higher quality. The present review shows that the key parameters of AAS (the atomiser temperature, distributions of atoms, molecules and condensed particles and transmitted radiation intensities) are characterised by a high degree of spatial inhomogeneities. The atomic absorption signal depends on these inhomogeneities, which are responsible for the photometric error in measurements with the use of conventional AAS. The absorption in spatially inhomogeneous media can be correctly measured only with the use of the spatially resolved detection. The above-considered examples of atomic absorption analysis of real substances confirm the practical importance of spatially resolved AAS.

According to the general classification of analytical chemistry methods,⁸² AAS with the spatially resolved detection is a second-order method, because it provides two-dimensional data sets, *viz.*, the absorbance as a function of the time and the spatial coordinate. Conventional AAS belongs to first-order methods. A higher order of a method always provides higher-quality analytical signals.⁸²

Abstract. Basic knowledge about Mössbauer spectroscopy, necessary for gaining qualitative and quantitative information on the substance composition from Mössbauer spectra, is considered. Methods of Mössbauer spectra processing are discussed and databases ensuring the search for information on objects under study are described. Applications of Mössbauer spectroscopy in various fields of chemistry, mineralogy, biology and materials science are considered. The bibliography includes 135 references.

I. Introduction

More than 45 years ago Rudolf Mössbauer discovered the phenomenon of resonant nuclear fluorescence of γ -radiation in ^{191}Ir .¹ A spectral method based on the phenomenon was named Mössbauer spectroscopy (more rarely, it is also called nuclear gamma-resonance spectroscopy). The technique immediately became a powerful tool for studying the structural and chemical state of solids and found wide application in various areas of science and technology,² such as materials science, chemistry, biology, geology, mineralogy, etc. At present, a number of monographs devoted to Mössbauer spectroscopy are available (see, e.g., monographs^{3–9}). In these books, the emphasis is placed on consideration of the physical principles and theoretical aspects of the method and on the most interesting objects of investigation. The number of such objects continuously increases, especially in connection with increasing interest in the materials science. Now we can say with certainty that Mössbauer spectroscopy is no longer an exotic physical method of investigation. At present, this is a routine analytical method with its specific methodology and objects of analysis.

Comprehensive information on Mössbauer spectroscopy studies and their results can be found on the Website of the Mössbauer Effect Data Centre (MEDC) at the University of North Carolina (USA) at URL <http://www.unca.edu/medc>. The MEDC database includes about 40 000 records, including a reference to the discovery of the Mössbauer effect. New references are published on a regular basis in *Mössbauer Effect Reference and Data Journal* (MERDJ, ten issues per year).¹⁰ MEDC publications also include collections of works aimed at summarising information concerning various avenues and objects of Mössbauer spectroscopy studies (mineralogy, materials science, analytical chemistry, catalysis, etc.).¹¹

Until recently, Mössbauer spectroscopy took a back seat among other analytical chemistry methods. Often, analyst chemists simply had no information on the analytical potential of Mössbauer spectroscopy. Recently, the situation has become better. In particular, two Mars exploration rovers, 'Spirit' and 'Opportunity', were equipped with Mössbauer spectrometers, which is evidence of increasing interest in the analytical potential of Mössbauer spectroscopy. This made it possible to obtain reliable information on water-driven chemical processes on Mars. The aim of this review is to attract the attention of analytical chemists to the title method. We will consider the key methodological issues of Mössbauer spectroscopy, methods of processing of Mössbauer spectra in order to obtain qualitative and quantitative information and the most typical objects of analysis in chemistry, geology, mineralogy, biology and materials science. In considering the results of analysis of particular objects, the emphasis will be placed on the experimental design depending on the nature of the object under study.

II. Physical principles of Mössbauer spectroscopy and its modifications

Mössbauer spectroscopy is based on recoilless resonant absorption of γ -quanta with energy E_0 , emitted by nuclei of Mössbauer isotopes in an excited state (source of radiation), by corresponding nuclei in an object under study (absorber) that are in the ground state. After absorption of γ -quanta, the latter nuclei undergo transition to the excited state of energy E'_0 . Resonant absorption is only possible at $E_0 = E'_0$. Mössbauer's merit consisted in that he found the conditions suitable for observation of resonant absorption of γ -quanta by atomic nuclei. He found that if the

emitting nuclei are incorporated into a solid,[†] it becomes highly probable that emission will occur in a recoilless fashion (without energy loss), because energy is transferred to the entire crystal rather than a particular atom, thus converting into energy of crystal lattice vibrations. In this case the emission and absorption lines have the same natural width (Γ) that is determined by the quantum-mechanical Heisenberg uncertainty relation:

$$\Gamma = \frac{\hbar}{\tau},$$

where $\hbar = h/2\pi$ and τ is the excited-state lifetime of the Mössbauer nucleus. Typical lifetimes of excited nuclear states lie between 10^{-10} and 10^{-6} s, which corresponds to linewidths $\Gamma = 10^{-5}$ – 10^{-9} eV. The relative linewidths of nuclear transitions with energies in the range 10^4 – 10^5 eV are 10^{-10} to 10^{-15} eV, being responsible for extremely high resolution of Mössbauer spectroscopy with respect to energy, which much exceeds the resolution of all other physical methods.

In real situations one should allow for a change in the γ -quantum energy due to thermal motion of atoms. Therefore, measurements of Mössbauer absorption (scattering) spectra require a controllable variation of the γ -quanta energy of the source of radiation in the range from a few neV to tens of neV. Most often, this is achieved by mounting the source of radiation on a Doppler modulator that provides continuous motion of the source relative to absorber (sample under study). The Doppler energy change, ΔE_D , due to the motion of the source of radiation with controllable speed v , is calculated as follows:

$$\Delta E_D = \frac{E_0 v}{c},$$

where c is the speed of light. In this case the energy of γ -quanta emitted towards the absorber is given by

$$E(v) = E_0 \left(1 + \frac{v}{c} \right) = E_0 + \Delta E_D, \quad (1)$$

where $E(v)$ is the energy of the γ -quantum emitted by the source moving at velocity v and E_0 is the energy of the γ -quantum emitted by the immobile source.

The Mössbauer absorption spectrum is usually represented as the dependence of the relative intensity of radiation passed through or scattered by the sample on the velocity of the source of radiation relative to the sample (Fig. 1). In fact this means that the Mössbauer spectrum represents the dependence of the γ -quanta absorption section on the Doppler energy (ΔE_D) added to the energy E_0 of these quanta. In order to obtain a convenient quantitative estimate of the signal, the effect (relative difference between the signal and background) is used instead of the relative

Figure 1. Mössbauer spectrum of Fe_3O_4 .

intensity. Additional information on the object under study can usually be obtained by varying external parameters that affect the resonant absorption effect (e.g., temperature, pressure and external magnetic field and electric field).

Measuring Mössbauer spectra includes registration of either γ -radiation that has passed through the absorber (absorption geometry) or radiation associated with resonance processes and scattered by the absorber (scattering geometry). Since the Mössbauer transitions are to some extent converted, experiments with the scattering geometry allow not only the resonance γ -radiation but also X-ray radiation or conversion electrons accompanying resonant scattering of γ -rays to be detected. X-Ray radiation contains information on the state of a thin (several tens of micrometres) surface layer of the sample and conversion electrons contain information only on the state of the surface layer 200–300 nm thick, which is determined by the short distance they travel within the sample material. The corresponding modification of Mössbauer spectroscopy is called conversion electron Mössbauer spectroscopy.⁷ Since recently, ultrathin surface layers (2–200 nm thick) have been studied using a new modification of conversion electron Mössbauer spectroscopy, namely, small-angle conversion electron Mössbauer spectroscopy.^{14–16} By varying the angle of incidence of γ -quanta it is possible to vary the depth to which γ -rays penetrate the surface layers of the sample under study.

Conventional sources of radiation represent long-lived parent radionuclides that are necessary for creating an intense flux of monochromatic resonant γ -radiation, which is then used for studying the state of corresponding Mössbauer nuclei in the absorber or in the scatterer. However, yet another experimental geometry is possible. Here, the sample to be analysed contains an incorporated Mössbauer isotope and acts as the source of γ -quanta and a known compound containing the same isotope characterised by a single monochromatic line for corresponding Mössbauer radiation acts as absorber or scatterer. This modification is called emission Mössbauer spectroscopy.¹⁷ This type of Mössbauer spectra is sensitive to specific features of the chemical environment of the resonance atom and of the structure that contains the resonance atom. The sensitivity of emission Mössbauer spectroscopy is as high as 10^{12} atoms per cm^2 of the surface area of the sample, which is much higher than the sensitivity of the scattering and absorption Mössbauer spectroscopies. An important feature and limitation of emission Mössbauer spectroscopy is the need of non-protected manipulation of radioactive substances. Therefore, this modification of Mössbauer spectroscopy is of limited practical use.

The possibility of studying certain objects by Mössbauer spectroscopy is determined by their elemental composition. At present, the Mössbauer effect is documented for more than 40 elements whose isotopes can be used in Mössbauer spectroscopy studies. However, physical and technological limitations reduce the number of isotopes suitable for being used for analytical purposes to at most seven (^{57}Fe , ^{119}Sn , ^{121}Sb , ^{125}Te , ^{129}I , ^{151}Eu and ^{197}Au). The ^{57}Fe and ^{119}Sn isotopes are of the greatest practical value. In spite of a relatively small number of 'Mössbauer' isotopes, numerous objects can be studied by Mössbauer spectroscopy, because the 'Mössbauer' elements are constituents of many objects to be analysed. For instance, iron belongs to the most abundant elements on Earth; therefore, ^{57}Fe Mössbauer spectroscopy has been intensively employed in geochemical and materials science studies of iron-containing solid samples.

^{119}Sn Mössbauer spectroscopy is of lesser use, because tin is 1000 times less abundant than iron. Nevertheless, numerous studies of tin-containing materials and minerals were carried out and tailor-made instruments for geological exploration for tin were designed in the early stage of development of Mössbauer spectroscopy.

[†] More recently, it was shown that Mössbauer effect can be observed not only in solids (regular crystals), but also in amorphous solids or solutions.^{12, 13}

III. Mössbauer spectra as a source of analytical information

The nucleus of a Mössbauer atom is a highly sensitive probe, namely, the energies of nuclear sublevels vary depending on the electronic environment of the nucleus and on the internal and external electric and magnetic fields.

The Mössbauer spectra bear information on various interactions, many of which are indirectly related to the chemical nature

of the Mössbauer atom and its nearest environment. The relation is indirect because the chemical properties of an atom are determined by its outer electrons, which are shielded from the Mössbauer nucleus by inner electrons. Table 1 lists the most important parameters that can be extracted from Mössbauer spectra and used for qualitative analysis. We also present here the energy diagrams that demonstrate the influence of the parameters in question and the corresponding patterns of Mössbauer spectra. As resonance nuclei we consider those of the most widely

Table 1. Most important parameters of ^{57}Fe and ^{119}Sn Mössbauer spectra.

Characteristics of Mössbauer spectra	Schemes of energy levels and transitions for ^{57}Fe (or ^{119}Sn) isotopes in		Mössbauer spectral pattern
	source of radiation (s)	absorber (a)	
Resonance linewidth (Γ)			
Isomer (chemical) shift (δ_c)			
Second-order temperature (Doppler) shift (δ_T)			
Quadrupole energy splitting (ΔE_Q)			
Magnetic splitting			

used Mössbauer isotopes, ^{57}Fe and ^{119}Sn , having the ground- and excited-state nuclear spins of $I_g = 1/2$ and $I_e = 3/2$, respectively.

Each parameter of the Mössbauer spectra listed in Table 1 has its own physical nature and bears analytical information. Detailed consideration of these parameters is available in the literature.^{4–9} The set of parameters listed in Table 1 should be augmented with the probability of Mössbauer effect (f_M), which plays an important role in quantitative analysis using Mössbauer spectroscopy.

Quantitative analysis is based on the assumption that the area, S , under a line in the spectrum of a thin absorber is proportional to the number, n , of the atoms containing Mössbauer nuclei:

$$S = kf_M n,$$

where k is the factor including the resonant absorption cross section, emission intensity, time taken to collect the spectral data, energies of γ -quanta, effect of background emission and the angle between the direction of the γ -quanta flux and the normal to the absorber surface; and f_M is the Mössbauer effect probability (*i.e.*, probability of recoilless elastic processes). The f_M value depends on the root-mean-square displacement of the absorber nuclei from their equilibrium positions ($\langle x^2 \rangle$) at temperature T

$$f_M = \exp\left(\frac{-p^2 \langle x^2 \rangle}{\hbar}\right),$$

where $p = E_\gamma/c$ is the momentum of the γ -quantum ($E_\gamma = \hbar\nu$ is the photon energy).

The stronger the coupling between atoms in the crystal lattice, the higher the characteristic (Debye) temperature of the substance Θ_D and the smaller the root-mean-square nuclear displacement at a given temperature and, hence, the higher the probability of the Mössbauer effect. This dependence of the area under the spectral curve on the number of resonance nuclei is valid in the thin absorber approximation where $n\sigma \ll 1$ (σ is the resonant absorption cross section), *i.e.*, when the shape of the resonance line is undistorted by saturation effect.

Resonance linewidth. In the thin absorber approximation an experimental Mössbauer spectral line has a Lorentzian shape¹ (see Table 1) and the minimum linewidth is given by the doubled natural width of the absorption line, Γ . It was theoretically shown and experimentally proved that there exists line broadening due to diffusion of atoms. The linewidth is influenced by crystal lattice defects that cause changes in the local environment of resonance atoms. Line broadening is most pronounced in the spectra of amorphous and glassy materials.

Isomer (chemical) shift (δ_c) arises in the case where Mössbauer nuclei in the source and in the absorber are in different chemical environments. The isomer shift manifests itself as a shift of the resonant absorption line relative to the absorption line at $\nu = 0$. The δ_c value is given by:

$$\delta_c = \frac{4\pi}{5} e^2 Z R^2 \frac{\Delta R}{R} \{ |\Psi(0)|_a^2 - |\Psi(0)|_s^2 \}, \quad (2)$$

where e is the charge of electron, Z is the charge of the nucleus, R is the average radius of the nucleus, ΔR is the change in the nuclear radius on going from excited state to the ground state and $|\Psi(0)|_a^2$ and $|\Psi(0)|_s^2$ are the electron densities at the nuclei of the resonance atoms in the absorber (a) and source (s), respectively. For a particular nucleus, the $\Delta R/R$ ratio is a constant and the chemical shift is determined only by the difference between the electron densities at the resonance nuclei in the source and in the absorber, which in turn mainly depends on the s-state populations. Electrons from other shells (p, d, f) can indirectly affect the δ_c value through partial shielding of s-electrons or formation of hybrid states with the s-orbitals (generally, this should be allowed for when interpreting the chemical shift values). The δ_c values obtained by Mössbauer spectroscopy make it possible to draw conclusions about the character of a chemical bond, its degree of covalence, coordination, degree of electron delocalisation, *etc.*

Second-order temperature (Doppler) shift (δ_T) is due to the energy difference between emitted and absorbed γ -quanta (owing to temperature difference between the source and absorber) and manifests itself as a shift of the resonant absorption line. The shift value is calculated as follows

$$\delta_T = -\frac{\langle v^2 \rangle}{2c^2} E_0, \quad (3)$$

where $\langle v^2 \rangle$ is the temperature-dependent root-mean-square velocity that characterises atomic motions in solids.

Thus, the energy shift δ observed in Mössbauer spectra is the sum of two contributions

$$\delta = \delta_c + \delta_T.$$

Quadrupole splitting (ΔE_Q) is a result of the interaction between the quadrupole moment of non-spherical resonance nucleus with the gradient of the electric field created at the nucleus by the electron shell and ligands. This interaction leads to splitting of a nuclear energy level into sublevels. For ^{57}Fe nuclei the separation, ΔE_Q , is calculated as follows:

$$\Delta E_Q = \frac{eQ}{2} V_{zz} \sqrt{1 + \frac{\eta^2}{3}}, \quad (4)$$

where eQ is the quadrupole moment of the nucleus, V_{zz} is the principal component of the electric field gradient at the nucleus along the z axis and $\eta = (V_{zz} - V_{yy})/V_{xx}$ is the asymmetry parameter (V_{xx} and V_{yy} are the electric field gradients along the x and y axes). The coordinate axes are chosen in such a way that $0 \leq \eta \leq 1$. The electric field gradient at the nucleus is determined by the environment geometry, by the effective charges of ions surrounding the resonance nucleus in the object under study and by the presence of partially filled non-spherical electron shells (p, d, f) in the resonance atom. Thus, in the general case the quadrupole interaction of a Mössbauer nucleus bears information on the structure of the atomic environment of the nucleus in the crystal lattice and on the state of its valence shells.

If the Mössbauer spectrum simultaneously exhibits the chemical shift and quadrupole splitting (these parameters are affected by s- and p-electrons in different fashion), it is possible to obtain more diverse information on the state of the electron shell of the resonance atom and on the local structure of the crystal lattice.

Magnetic (Zeeman) splitting (ΔE_m) arises due to the interaction between the magnetic moment of the nucleus (in both ground and excited states) with the effective magnetic field (B) created by the electron shell at the nucleus. The Zeeman splitting is given by

$$E_m = -g_I \mu_N B \Delta m_I, \quad (5)$$

where g_I is the nuclear gyromagnetic ratio for a given nuclear level (I is the nuclear spin), μ_N is the nuclear magneton, m_I is the magnetic quantum number and Δm_I is the change in the magnetic quantum number corresponding to transition of a ^{57}Fe , ^{119}Sn or ^{125}Te nucleus from excited state (spin $I_e = 3/2$) to the ground state ($I_g = 1/2$). Emission of a γ -quantum from each of the four excited-state sublevels ($+3/2$, $+1/2$, $-1/2$, $-3/2$) causes a transition of the nucleus to one out of two ground-state sublevels ($+1/2$, $-1/2$). The transition occurs in accordance with the selection rule for dipole transitions ($\Delta m = 0, \pm 1$) and results in the appearance of magnetic hyperfine structure (magnetic sextet) in the Mössbauer spectrum (see Table 1). If the nucleus in question is simultaneously involved in the magnetic and quadrupole interactions, energy level calculations are complicated. The magnetic field strength B is a function of structural and electronic parameters, namely, the number of unpaired d-electrons, the type of the chemical bond formed by the resonance atom, the environment geometry, *etc.* Therefore, the appearance of hyperfine magnetic splitting makes the Mössbauer spectra much more informative and allows one to reveal peculiar features of the electronic, crystal and magnetic structures of compounds analysed.

The informativity of the key parameters of Mössbauer spectra (see above) shows that this relatively simple (from experimental standpoint) method not only has a great potential for studies of the structure and electronic properties of solids but is also an efficient method of analysis of solid samples in spite of a limited number of Mössbauer isotopes. A proof of this statement is provided by numerous examples of solution of complex analytical problems using Mössbauer spectroscopy.

The possibility of obtaining unique information on the local chemical state of a resonance atom and on the electric and magnetic fields at the atomic nucleus led to setting up emission Mössbauer spectroscopy experiments in which the resonance atoms were introduced into the sample as specific probes (see, e.g., Ref. 18). This approach was employed, in particular, in a study of high-temperature superconductors. For instance, the copper atoms in the crystal lattices of $\text{Ti}_2\text{Ba}_2\text{CuO}_6$ and $\text{Ti}_2\text{Ba}_2\text{CaCu}_2\text{O}_8$ superconductors were replaced by ^{67}Cu isotopes by diffusion doping and then the ^{67}Cu (^{67}Zn) Mössbauer spectra were measured at 4.2 K with ^{67}ZnS as absorber.¹⁸ In this case the main problem is to confirm the fact that the resonance (dopant) atoms occupy the substitution sites in the crystal lattice.

IV. Methods of processing of Mössbauer spectra and databases

An important moment in Mössbauer spectroscopy is processing of experimental spectra using special programs that permit theoretical description of an experimental spectrum using a set of resonance lines. The aim of the spectral data processing is to determine the physical parameters considered in the previous Section.

The Mössbauer spectra are usually processed by the least squares method.^{19–21} The functional to be minimised has the form

$$\chi^2 = \sum_{i=1}^n \frac{1}{N_i} [N_i - S_i(p_0, p_1, \dots, p_k)]^2 \quad (6)$$

where $p_0, p_1, \dots, p_k$ are parameters, N_i is the number of counts in the i th channel[‡] of the experimental spectrum, $S_i(p_0, p_1, \dots, p_k)$ is the model spectral amplitude for the i th channel and n is the total number of channels. Processing of an experimental spectrum is preceded by the choice of the model spectral shape. The choice is based on *a priori* information on the object analysed. A model spectrum is assumed to be a spectrum comprising a set of resonance lines corresponding to a particular type of the hyperfine structure of resonance nuclei.[§] The model spectrum of a thin absorber can be represented by superposition of Lorentzian lines with negative (absorption spectra) or positive (scattering spectra) amplitudes with respect to the baseline.

The model spectrum of a thick absorber is represented by either convolution of a Lorentzian and a Gaussian function²² or the transmission integral,²³ which describes the motion of the resonance γ -quantum through an absorber containing resonance nuclei. This approach is best for quantitative analysis.

In a large class of substances, such as amorphous solids, alloys, ultradisperse media, *etc.* the nearest spatial and elemental environment of the atoms containing resonance nuclei continuously changes. The spectra of such substances represent superpositions of continuous series of subspectra and cannot be processed using the algorithms considered above, because the problem becomes ill-posed (no unique solution exists). The approach employed in this case is based on representation of the model spectrum by convolution of k elementary subspectra $L_i^k(p_0, p_1, \dots, p_k)$ with one or two continuously varying hyperfine

interaction parameters and the weight function $P^k(p_0, p_1, \dots, p_k)$ of these subspectra, which is often called the hyperfine field distribution function.^{24,25} This function provides information on the distribution of chemical bonds and electric or magnetic fields at nuclei of the resonance atoms in the substance under study.

An alternative approach to solution of ill-posed problems is based on the principle of limited density of spectral lines depending on the statistical significance of the spectrum.²⁶ The efficiency of this approach was demonstrated taking analysis of complicated Mössbauer spectra of high-temperature superconductors as examples.

Informativity of Mössbauer spectra for qualitative and quantitative analysis can be exemplified by the processing of a γ -ray scattering spectrum of oxidised surface of metallic iron (conversion electrons were detected). Figure 2 presents the experimental Mössbauer spectrum (points) and its decomposition into subspectra corresponding to iron atoms in different phases. Using the Mössbauer parameters of the subspectra, it is possible to identify iron-containing phases (qualitative analysis), while measuring the areas under individual lines provides a quantitative estimate of the relative content of these phases. To obtain a more correct estimate, the surface areas should be corrected for the f_M factor (probability of resonant absorption in each phase). However, determination of the f_M factor faces practical and theoretical difficulties and therefore the relative content of phases is estimated to an accuracy of the f_M factor.

Figure 2. Decomposition of experimental Mössbauer spectrum into subspectra corresponding to iron atoms belonging to a particular phase.

V. Geochemical and cosmochemical analyses

Applications of Mössbauer spectroscopy in chemical analysis mainly concern solution of topical problems of geochemistry and cosmochemistry. They include determination of the oxidation states and coordination numbers of iron and tin atoms in minerals,^{27–35} phase analysis of rocks,^{36–39} meteorites^{40–42} and lunar soil⁴³ and determination of the age and genesis of minerals.^{44,45}

Among the last-named group of research avenues, of special interest are the Mars surface studies,^{46–48} in particular, investigations of the mineralogical composition of Martian soil using tailor-made Mössbauer spectrometers MIMDS II. These studies are aimed at understanding the evolution of the planet and answering the question on the existence of water on Mars. Iron-based minerals were studied. Analysis was carried out using the conversion resonant radiation backscatter geometry. The results of analysis of Martian soil near the Gusev crater and on the plain were different. The detection of olivine and pyroxene (silicate

‡ The intensity of γ -quanta flux is fixed using a multichannel analyser. The channel number is proportional to the velocity of the source of radiation.

§ If resonance nuclei are in inequivalent positions, the shape of the model spectrum corresponds to superposition of hyperfine structures.

Figure 3. First Mössbauer spectrum taken on the Mars surface near the Gusev crater (points) and its decomposition into subspectra corresponding to iron atoms in different environments.

minerals that are usually contained in volcanic rocks, Fig. 3) near the Gusev crater appeared to be unexpected. The greatest portion (~95%) of the Mössbauer spectra of Martian soil taken on the plain falls on the component corresponding to such a highly abundant Earth mineral as hematite, Fe_2O_3 (Fig. 4). The formation of hematite is usually preceded by hydrolytic transformations of water-soluble forms of Fe(III) , which provides indirect evidence for the existence of water on Mars. Confirmation of conclusions about the genesis of Martian minerals requires continuous research involving drilling in order to obtain soil from greater depth.

Mössbauer spectroscopy belongs to the main methods of investigation of the genesis of minerals in the Earth crust. In the last decade there has been a rapidly increasing interest in studies of microbiological pathways of formation of iron-containing minerals *via* anaerobic dissimilatory iron-reducing bacteria involved in reduction of iron oxides. It was assumed that these bacteria could participate in formation of pre-Cambrian iron–silicon formations. Being a highly sensitive method of analysis of

Figure 4. Mössbauer spectrum of Martian soil taken on the plain and its decomposition into subspectra corresponding to iron atoms of hematite Fe_2O_3 (sextet) and olivine Fe^{2+} (doublet).

iron-containing objects, Mössbauer spectroscopy allowed not only the kinetics of the phase transformations induced by iron-reducing bacteria to be studied but also factors affecting this process to be determined.^{49–54} The results obtained suggested the existence of various pathways of biosynthesis of iron-containing minerals by micro-organisms that favour the reduction of Fe(III) to Fe(II) . At present, the biosynthesis mechanisms are still to be clarified and there has been intensive accumulation of experimental information.

VI. Mössbauer spectroscopy in the analysis and investigations of biological objects

Iron atoms play an important role of active centres in such vitally important proteins as hemoglobin, myoglobin, cytochromes, *etc.* These proteins are responsible for reversible binding and transfer of oxygen and participate in photosynthetic redox chains owing to electron transport. The possibility of application of Mössbauer spectroscopy in studies of biomolecules (mainly proteins) has been best considered in Refs 55–57. An important avenue of biological research is comparison of the Mössbauer parameters obtained in studies of healthy (normal) organisms and the organisms with various diseases or affected by external factors.^{58–61}

Methods of measuring the Mössbauer spectra of biological objects are generally identical to those employed in the studies of inorganic objects. However, the concentration of iron in the samples under study (except for ferredoxin) is so low that obtaining statistically significant results requires enrichment with ^{57}Fe isotope. Therefore, an important aspect of the studies and analysis of biological objects is establishing sample preparation conditions suitable for directed exchange of iron atoms in the sample by the ^{57}Fe isotope without destruction of the initial protein structure. This can be attained using incubation of microorganisms in ^{57}Fe -containing media or by injecting a ^{57}Fe salt solution into living organisms.

Using Mössbauer spectroscopy, heme and non-heme proteins (*e.g.*, constituents of photosynthetic centres), iron–sulfur, iron-transport and iron-accumulating proteins were studied. Fine details of the electronic and spin transformations of iron in heme and in sulfur-containing proteins were investigated. In particular, the Fe(II) atom in heme is responsible for reversible binding of oxygen in hemoglobin (Hb) and the operation of hemoglobin. Mössbauer spectroscopy studies showed that violation of normal heme functions is accompanied by oxidation of Fe(II) to Fe(III) . Iron(II) in heme is in two spin states, a high-spin ($I = 2$) and a low-spin state ($I = 0$). The high-spin state is observed only for the Fe(II) atom of the deoxy form of Hb in a pentaligand environment. The low-spin state is characteristic of the Fe(II) compound with six ligands, with an O_2 or CO molecule as the sixth ligand. The spectra of Hb, HbO_2 and HbCO are significantly different. The addition of O_2 to Hb is accompanied by dramatic change in the chemical shift value, which is due to transition of Fe^{2+} from the high-spin state in Hb to the low-spin state in HbO_2 . The addition of CO to hemoglobin causes the formation of a symmetrical structure HbCO (as indicated by a decrease in the quadrupole splitting) with the $\text{Fe(II)}-\text{CO}$ bond being stronger than the $\text{Fe(II)}-\text{O}_2$ bond. Since CO adds to Hb irreversibly and thus prevents Hb from doing oxygen exchange, poisoning with carbon monoxide leads to fatal case.⁵⁵

Iron-sulfur proteins were among the first biological objects studied by Mössbauer spectroscopy, because they contain a relatively large number of iron atoms in the molecule. The active centre of sulfur-containing proteins comprises the iron and sulfur atoms.^{62–66}

Figure 5. Mössbauer spectra of plant ferredoxin measured at 195 K. Oxidised Fd (a) and reduced Fd (b). Vertical lines denote positions of the doublet lines.

Usually, the Fe(II) and Fe(III) atoms in sulfur-containing proteins are in the high-spin state. Figure 5 presents the classical Mössbauer spectra of plant ferredoxin (Fd)[¶] in the oxidised [Fe(III)] and reduced [Fe(II)] states.

The Mössbauer spectrum of oxidised Fd containing two tetrahedrally coordinated Fe(III) atoms exhibits two doublets with nearly identical parameters ($\delta = 0.22\text{--}0.25\text{ mm s}^{-1}$ and $E_Q = 0.6\text{--}0.7\text{ mm s}^{-1}$) at a measurement temperature of 195 K. The low δ value indicates a high degree of covalence of Fe–S bonds. In spite of the same ligand composition, it is clear that positions of the iron(III) atoms in the active centre of Fd are inequivalent. This is probably due to the effect of polypeptide chains, resulting in changes in the bond lengths and bond angles in the active centre. This inequivalence is well pronounced in the reduction of Fd. Transfer of an electron to Fd leads to its localisation on a Fe(III) ion and to reduction of this ion to Fe(II) ($\delta \approx 0.7\text{ mm s}^{-1}$ and $E_Q = 3.0\text{ mm s}^{-1}$), the electronic state of the other Fe(III) ion being changed insignificantly.

In pharmacology, Mössbauer spectroscopy is used in studies of the state of iron atoms in iron-containing pharmaceuticals used in medical practice. Most of the preparations contain divalent iron, because in this case [in contrast to Fe(III)] the side effects characteristic of iron compounds are less pronounced. Besides, specific biological activity of the Fe(II)-containing preparations is higher than that of the preparations containing Fe(III) ions. Therefore, for pharmaceutical analysis it is important to determine the oxidation state of iron in iron-containing drugs. Mössbauer spectroscopy is also used for the determination of the oxidation state of iron on storage of drugs. The results of Mössbauer spectroscopy tests of iron-containing vitamins produced by the leading pharmaceutical companies were reported.^{67,68} It was shown that all vitamins contain small amounts of trivalent iron; however, in some samples the content of Fe(III) exceeded the permissible rates. This suggests that Mössbauer spectroscopy should be included in the group of methods for control of iron-containing pharmaceuticals.⁶⁸

[¶] Ferredoxin is an iron-containing protein acting as electron carrier in many biological redox processes.

In addition to conventional absorption Mössbauer spectroscopy, biological objects are also analysed by emission Mössbauer spectroscopy^{12,69–72} (here, a radioactive isotope ⁵⁷Co is introduced into the object to be analysed). Despite the fact that this technique allows the sensitivity of Mössbauer spectroscopy to be improved by several orders of magnitude, it is rarely used due to the need of unprotected operation with radioactive preparations (see above).

Mössbauer spectroscopy studies of the molecular mobility of proteins, biopolymers and their fragments occupy a special position. These experiments are carried out using the Rayleigh scattering of Mössbauer radiation. The technique made it possible to reveal various groups of motions and to determine corresponding frequency ranges and vibrational amplitudes.^{55,73–77}

VII. Mössbauer spectroscopy in structural studies

Mössbauer spectroscopy has been an efficient tool for structural analysis in studies of structural and magnetic phase transitions in organic and inorganic compounds^{78–87} containing such Mössbauer isotopes as ⁵⁷Fe, ¹¹⁹Sn, ¹²¹Sb, ¹⁵¹Eu, ¹⁵⁵Gd or ¹⁹⁷Au. In this case Mössbauer spectroscopy makes it possible to significantly complement the results obtained from IR and NMR spectroscopies. High structural sensitivity of Mössbauer spectroscopy is due to the fact that parameters of the hyperfine structure of the Mössbauer spectrum (chemical shift, quadrupole splitting and magnetic hyperfine splitting) depend on the population of the valence states of the Mössbauer atom in the compound under study and on the spatial structure of this compound. Changes in the parameters of Mössbauer spectra depending on the external factors, affecting the samples under study (temperature, pressure, magnetic fields, *etc.*), provide additional information on the structural and phase transitions in such compounds. The application of Mössbauer spectroscopy to structural studies of Fe(II) complexes can be exemplified by the investigation of the spin-transition state (so-called spin-crossover^{88–90}), *i.e.*, an equilibrium state between the high-spin (HS) and low-spin (LS) states. Spin-crossover can occur in d⁴-, d⁵-, d⁶-, d⁷- and d⁸-transition metal complexes. Depending on the ratio of the splitting energy of the transition metal atom in the ligand field (Δ) to the spin pairing energy (P) the ground state of the transition metal complex can be high-spin (for weak ligand field $\Delta < P$) or low-spin (for strong ligand field $\Delta > P$). If the difference $|\Delta - P|$ becomes comparable in magnitude with the thermal energy $k_B T$, the equilibrium coexistence of the high-spin and low-spin states becomes possible. Figure 6 presents the energy diagram of Fe(II) 3d-AO energy levels (3d⁶-electron configuration) in octahedral complex for the high- and low-spin states and for the spin equilibrium state.

The Mössbauer spectra of [Fe(phen)₂(NCS)₂] measured at different temperatures are shown in Fig. 7. The spectrum obtained at 300 K (see Fig. 7f) exhibits a single doublet with

Figure 6. Fe(II) 3d-orbital levels in octahedral complex at weak (a), intermediate (b) and strong (c) ligand field. $\text{Fe}^{2+} : \text{Fe}_{\text{tot}} \approx 0.6$.

Figure 7. Mössbauer spectra of $[\text{Fe}(\text{phen})_2(\text{NCS})_2]$ measured at different temperatures. The subspectra corresponding to iron atoms in the low-spin and high-spin states are bright and dark shaded, respectively. Temperature /K: 77 (a), 180 (b), 184 (c), 186 (d), 188 (e), 300 (f).

the parameters corresponding to a pure HS state of $\text{Fe}(\text{II})$ ($\delta \approx 1 \text{ mm s}^{-1}$ and $E_Q = 2.6 \text{ mm s}^{-1}$) while the spectrum at 77 K (Fig. 7a) exhibits a single doublet with the parameters corresponding to pure LS state ($\delta \approx 0.35 \text{ mm s}^{-1}$ and $E_Q = 0.25 \text{ mm s}^{-1}$). The spectra obtained in the temperature range 180–188 K exhibit two quadrupole doublets corresponding to two spin states (HS and LS). As the temperature decreases, the proportion of $\text{Fe}(\text{II})$ atoms in the HS state decreases and in the LS state increases. Transition from one state to the other occurs jumpwise in a narrow temperature range (180–188 K).

Spin transitions in $\text{Fe}(\text{III})$ complexes were studied by measuring the magnetic susceptibility using Mössbauer spectroscopy.^{91–93} At present, Mössbauer spectroscopy is employed in studies of spin transitions under the action of electromagnetic radiation, in magnetic field and under pressure.^{94–96}

Recently, the emphasis in structural studies of tin compounds has been placed on determination of the charge states and possible crystallographic positions of tin atoms.^{97–99} The possibility of

simultaneous determination of the chemical shift and quadrupole splitting allows Mössbauer spectroscopy to be used in studying the structure, reactivity and mechanisms of transformations of organotin compounds (see Refs 100–103).

VIII. Mössbauer spectroscopy and the studies and monitoring of corrosion and catalytic processes

The first chemical application of Mössbauer spectroscopy was the study of iron oxides as corresponding corrosion products. Qualitatively, the phase composition of corrosion products can be established by comparing the parameters of Mössbauer spectra with the parameters of the reference spectra of artificially synthesised oxides and hydroxides. Comprehensive information on the structure, magnetic properties and Mössbauer parameters of iron oxides, hydroxides and ferrihydrides was reported by Murad and Johnston.¹⁰⁴ The advantages of Mössbauer spectroscopy as a method of investigation of corrosion processes are as follows:

- uniqueness of information on the chemical and structural transformations during corrosion (in many cases different phases can be identified based on the spectral pattern);
- minimum requirements for sample preparation for analysis and studies;
- possibility of *in situ* studies in aggressive atmosphere and in aggressive liquids;
- possibility of layer-by-layer and phase analyses under coating (thickness of the layers under study can vary over a very wide range);
- the same types of contributions of X-ray amorphous and ultradisperse substances to the Mössbauer spectrum (similar to the contributions of well-crystallised compounds).

Owing to the advantages listed above, Mössbauer spectroscopy has found wide application in studies of corrosion processes, such as corrosion in gases,^{105–109} in water and aqueous solutions,^{110–112} in aggressive media,¹¹³ in studies of inhibition and passivation,^{114–116} internal oxidation and electrode reactions. The availability of Mössbauer spectroscopy also allows it to be employed in solving problems of analytical control, such as monitoring of corrosion of bridges^{117,118} and ship hulls,¹¹⁸ thermal and nuclear power plant circuits,^{117,119,120} etc. Here, the use of Mössbauer spectroscopy made it possible not only to determine the phase composition of oxide films that grow on the surface of pearlitic steels contacting the aqueous phase but also establish the interrelation between different forms of iron existing in the aqueous phase and the compositions of the films grown on the steel surfaces.^{119,120} Using Mössbauer spectroscopy, it was shown that the quality of protective corrosion films on the steel surfaces can be improved by targeted choice of the composition and structure of the dissolved iron compounds involved in film formation.^{119,120}

Mössbauer spectroscopy is a highly informative method of research on such surface phenomena as the catalytic activity, dynamics and chemical state of atoms in highly disperse particles, resins, zeolites, on the surface of sorbents and on surface-modified materials.^{17,121} The possibilities of using Mössbauer spectroscopy in studies of nanoclusters and nanocluster systems have been considered.¹²²

Mössbauer spectroscopy is employed in production of heterogeneous catalysts and in their characterisation, in analysis of the chemical state of the catalyst surface, in analysis of chemisorption products and in the course of catalyst operation. The use of X-ray diffraction methods in studies of real catalysts is complicated by the fact that catalysts are ultradisperse particles. Mössbauer spectroscopy is free from this limitation, which makes it possible to obtain information on the size and distribution of catalytic particles over the catalytically active phase.

Most often, solid catalysts comprise an active component coated on a support. The latter operate various functions, namely, provide the largest surface area to be coated with the active component, stabilise an unstable structure and interact, through

electron exchange, with the active component, thus forming a unique catalytic system. If the active component of a catalyst includes atoms with Mössbauer nuclei, information on the oxidation state of these atoms can be obtained from the chemical shift in the Mössbauer spectra. For instance, Mössbauer spectroscopy data show that iron supported by zeolite LTL is more catalytically active than iron supported by SiO_2 , Al_2O_3 , C and MgO .¹²³ The effect of the annealing temperature on the state of ^{191}Au atoms for two types of catalysts, Au/TiO_2 and $\text{Au/TiO}_2/\text{SiO}_2$, was studied,¹²⁴ as well as the mechanism of low-temperature oxidation of CO using $\text{Au/Fe}_2\text{O}_3$ as catalyst.¹²⁵ Recently, there has been new interest in studies of tin-containing catalysts. For instance, ^{119}Sn Mössbauer spectroscopy was employed to study the catalytic properties of the $\text{Pd-SnO/Al}_2\text{O}_3$ and Pd-SnO/SiO_2 systems designed for water denitration.^{126–128}

IX. Conclusion

Summing up, it should be noted that the examples given above do not exhaust the list of analytical applications of Mössbauer spectroscopy that can be found in special publications on the subject (see above). But it is almost impossible to draw a line between applications of Mössbauer spectroscopy in scientific research and in chemical analysis, because distinctions between these fields are rather conditional. Here, the method remains the same, the main goals being different. The results of basic research into outworld can appear to be in demand for chemical analysis after a very short time they have been obtained. For instance, information on the mechanisms of corrosion processes is necessary for control of technological processes. Therefore, in this review we deliberately do not draw this line. The examples given above illustrate the main avenues of applications of Mössbauer spectroscopy in chemistry, mineralogy, biology and materials science. Undoubtedly the list of examples will be appreciably extended in the future. Here, objects in which the Mössbauer effect was observed for the ^{57}Fe isotope were chosen to be the main part of illustrative material. This can be explained by not only high abundance of iron-containing objects (see above) but also the fact that in the last decade the vast majority of studies ($\sim 90\%$) were carried out with this isotope and therefore they are best to exemplify the range of analytical applications of Mössbauer spectroscopy. The next place is occupied by ^{119}Sn Mössbauer spectroscopy studies with $\sim 6\%–7\%$ of the total number of publications. A total of $3\%–4\%$ of the overall number of communications falls on the studies with other isotopes.

In connection with advances made in the field of excitation of nuclear resonance levels using synchrotron radiation one can hope that this will open new prospects for applications of nuclear γ -resonance for analytical purposes.^{129,130} First, the use of nuclear resonant scattering of synchrotron radiation eliminates problems associated with preparation of Mössbauer sources, especially short-lived ones. Second, auxiliary equipment on facilities for nuclear resonant scattering of synchrotron radiation makes it possible to carry out measurements in a wide range of temperatures, pressures, magnetic fields, in high vacuum, etc., and thus obtain a greater body of information on the object analysed. Particular information on great potential of nuclear resonant scattering of synchrotron radiation for obtaining analytical information can be found in recent literature.^{131–135}

VI. Major application fields of analytical chromatography	335
VII. Conclusion	338

Abstract. The state-of-the-art and the prospects in the development of main methods of analytical chromatography, viz., gas, high performance liquid and ion chromatographic techniques, are characterised. Achievements of the past 10–15 years in the theory and general methodology of chromatography and also in the development of new sorbents, columns and chromatographic instruments are outlined. The use of chromatography in the environmental control, biology, medicine, pharmaceuticals, and also for monitoring the quality of foodstuffs and products of chemical, petrochemical and gas industries, etc. is considered. The bibliography includes 153 references.

I. Introduction

In the end of the 20th–beginning of the 21st century, analytical chemistry constantly faced the problems of the on-line environmental control, the monitoring of the quality and safety of foodstuffs and beverages and the quality and identity of drugs, as well as the problems of global safety associated with the destruction of chemical weapons, the prevention of terrorists' threats by the timely control over toxic agents and explosives in airports, railway stations and other crowded places and the detection of strong drugs. Chromatographic techniques played the key role in the solution of these problems.

Chromatography was discovered by the Russian botanist M S Tsvet in 1903.¹ In addition to being the pioneer of this method, he also developed in detail the methodological fundamentals of chromatography. Suffice it to say that Tsvet examined more than 100 different adsorbents. The procedure of chromatographic analysis he proposed was used for 50–60 years virtually without changes. His chromatographic columns were highly efficient. He also was the first to demonstrate the high effectiveness of multicolumn versions of chromatography. In 1931, R Kuhn, A Winterstein and E Lederer² repeated, in effect, the Tsvet's experiments and convinced in their great potential. Since

that, the rapid spread of the chromatographic techniques in European countries has begun.

In the first 50 years, chromatography was used either for the separation and isolation of pure substances or as a research method. Its wide use as an analytical technique started only in the second part of the 20th century.

In the period from 1937 to 1972, fourteen Nobel Prizes were awarded for the studies in chemistry, biology, physiology and medicine with chromatography as the key method. Undoubtedly, chromatography has contributed to the progress in many fields of science, technology and industry; this is why it is ranked among 20 outstanding discoveries of the twentieth century that had the greatest impact on the mankind life.

A combination of chromatographic techniques allows one to solve most analytical problems. Gases and volatile substances are well determined by gas chromatography; high-molecular compounds can be determined by high-performance liquid chromatography (HPLC); mixtures of ions (both cations and anions) are separated by ion chromatography and ion-pair chromatographic techniques and also by capillary electrophoresis; the separation of macromolecules (polymers, biopolymers) is carried out by the gel-permeation and exclusion chromatography; for the separation of optical isomers, the methods of chiral chromatography were developed, while the analysis of microparticles uses the methods of force-field fractionation.

The progress in the major chromatographic techniques (gas, liquid, ion chromatography) was very rapid. The literature contains numerous publications that describe the state-of-the-art and the prospects in the development of chromatographic techniques,^{3–5} the reviews devoted to the 20th anniversary of HPLC,⁶ the 25th anniversary of ion-exchange chromatography,⁷ the 30th anniversary of affinity chromatography,⁸ 40 years of gas-chromatographic instrumentation industry,⁹ 90 years of chromatography,¹⁰ 100 years of chromatography.^{11–13} The constant evolution of chromatographic methods was also surveyed.^{14–16} The place of chromatography among other analytical methods was discussed.¹⁷

The present review briefly analyses the most remarkable advances achieved over the past 10–15 years in the theory and general methodology of chromatography as well as in the development of new sorbents and instruments for chromatographic studies.

II. Advances in the theory and general methodology

At present, the main efforts in the field of chromatographic theory are directed towards the problems associated with the selectivity of separation. First of all, the relationship between the structure of molecules and their retention on sorbents of different chemical nature is studied. Attempts are undertaken to develop a retention theory that would be general for the gas, liquid and supercritical fluid chromatographic techniques and also to advance the methods of theoretical modelling. Recently, the geometric factor was invoked for the enhancement of the selectivity of chromatographic separation, which involves the use of cyclodextrins, crown ethers, liquid crystals, molecular sieves, *etc.*

The degree of resolution R in chromatography is determined by the relationship

$$R \simeq \frac{1}{4} \left(\frac{\alpha - 1}{\alpha} \right) \left(\frac{K_e}{1 + K_e} \right) \sqrt{N},$$

where α is the separation factor equal to the ratio of the adjusted retention times for the separated substances, K_e is the retention factor equal to the ratio of the net retention volume to the free column volume, N is the number of theoretical plates. The comprehensive theory of elution made it possible to design columns with the efficiency close to the theoretical one (for both gas and liquid chromatography). Especially high efficiency is characteristic of the capillary versions of chromatography. Taking the average efficiencies (the number of theoretical plates per metre, t.p. m⁻¹) of packed columns to be 1.5×10^3 (for GC) and 5×10^4 (for HPLC) and the efficiency of capillary columns to be 4×10^3 (GC), 3×10^5 (HPLC) and $> 1 \times 10^6$ (capillary electrophoresis and capillary electrochromatography), it is possible to assess the maximum separation potential of columns in chromatography. The packed columns in GC allow only mixtures with $\alpha > 1.05$ to be separated, while capillary columns are capable of separating mixtures with $\alpha > 1.005$ in GC and $\alpha > 1.003$ in capillary electrophoresis.

The studies of the retention mechanism in the reversed-phase chromatography on bonded phases are carried on. For this purpose, spectral methods are invoked. A very promising direction is the optimisation of separation by using expert systems, which includes the optimisation of gradient elution. Considerable progress was achieved in the theory of separation of optical isomers (in both gas and liquid chromatography).^{18, 19}

The development of the theory of chromatography under critical conditions for the gel-filtration method is a considerable step forward.²⁰ Advances have been made in the establishment of a link between the retention parameters and the biological and chemical activity of molecules.²¹ This offers much promise in the field of pharmaceuticals at the quest for new drugs.

In recent years, the effect of the temperature on the retention in HPLC was studied, which led to the development of the high-temperature HPLC characterised by high resolution and fast performance. The elaboration of heat- and hydrolysis-resistant polymeric sorbents for this chromatographic version is in progress. At present, instruments are being developed that would allow the programmed control over the temperature in this method.[†] Of great importance is the optimisation of separation with simultaneous variations in the temperature and the eluent rate.²⁵

Databases containing retention indices in HPLC in which nitroalkanes and alkylbenzenes are used as standard substances are compiled.²⁶

The effect of the electric field on the retention and elution of compounds in the columns packed with carbonaceous sorbents was studied,²⁷ as well as the effect of the magnetic field on the retention in columns packed with magnetic particles.²⁸

[†] For the first application of high-temperature chromatography (at 200 °C) for analytical purposes, see Refs 22–24.

III. Development of new sorbents and instruments for chromatographic studies

1. Gas chromatography

The major achievements in GC include the synthesis of stable sorbents with chemically bonded (immobilised) phases for packed and capillary columns and the development and application of capillary columns of relatively large diameters (0.32 and 0.53 mm) and high capacities that contain bonded liquid-phase films with a thickness of up to 5 μ m (and even up to 16 μ m)²⁹ and also of porous layer open tubular columns PoraPLOT with a fixed adsorption layer of silica or alumina, zeolyte, carbonaceous sorbents and porous polymers.³⁰

For such stable columns, the databases (libraries) of the retention parameters can be created to help the identification of unknown components in a mixture. A combination of these databases with those of mass spectra allows valuable information to be retrieved.³¹ By and large, the development of stable chromatographic columns resulted in the higher reliability and accuracy of the chromatographic analyses. Determination of microimpurities on capillary columns can be made using the methods that allow introducing large samples into the columns (on-column injection, cryofocusing, sampling with the solvent blow-out, *etc.*).³² The electronic control over the carrier-gas rate and the pressure was beneficial for the stable operation of chromatographs. This allowed an automated programme for maintenance of the retention time upon changeover of columns to be developed.³³

Recently, the analytical practice was supplemented with poly-capillary columns,[‡] which allow quick separation of mixtures to be carried out without programming the column temperature.³⁴ The use of adsorption polycapillary columns was documented.³⁵

2. Liquid chromatography

The recent progress in analytical liquid chromatography was associated with the development and the use of methods of high-performance capillary chromatography that combines the chromatographic and electrophoretic separation methods.³⁶ It is due to the coupling of various methods of liquid chromatography and capillary electrophoresis that the nucleotide sequence in DNA was decoded and the programme 'Human genome' was completed.³⁷

The potentials of liquid chromatography are substantially extended with the introduction of chiral,³⁸ immunoaffinity,³⁹ high-temperature⁴⁰ and perfusion⁴¹ chromatographic techniques. The quick chromatographic analysis of proteins on non-porous particles deserves attention.⁴²

The active development of new highly stable and selective sorbents based on dioxides of zirconium and titanium, porous polymers and carbonaceous adsorbents, which are stable over the whole pH range, is in progress.⁴³ For HPLC, a wide spectrum of sorbents are developed and manufactured. Dozens of companies all over the world produce more than 300 sorbent types. Most often (in 70% of cases), HPLC columns are packed with silica gels both pure and grafted with non-polar and polar groups (their fraction is 70%). Styrene–divinylbenzene copolymers, polymethacrylates, celluloses, *etc.* are used less often (20%), as well as porous carbonaceous sorbents and porous oxides of titanium and zirconium (4%) and alumina (1%).

The reversed-phase HPLC version, which employs silica gel sorbents with immobilised alkyl groups (the alkyl chain length varies from C₁ to C₃₄, C₁₈ and C₈ being the most common), finds wide application in the analytical practice (more than 70% of chromatographic analyses are carried out using this LC version).

Depending on the synthetic method, the C₁₈ sorbents can be either monomeric or polymeric. Polymeric C₁₈ sorbents are synthesised from trifunctional silanes in the presence of water, while monomeric sorbents are prepared from monofunctional

[‡] The discovery by Novosibirsk scientists [USSR P. 2986181 (1980)].

silanes. In certain cases, particularly, in the separation of complex mixtures of isomers, polynuclear aromatic hydrocarbons, the polymeric C_{18} sorbents are preferred. The retention capacity and the selectivity of monomeric C_{18} with respect to non-polar and weakly polar compounds depend on the number of immobilised alkyl chains (or on the total content of carbon per the sorbent mass unit, which varies from 8% to 20%). Small percentage of carbon leads to the small sorption capacity, fast separation and the rapid establishment of the equilibrium during the gradient elution.

However, silica-gel-based sorbents with immobilised alkyl groups have many drawbacks. They are unstable in acidic and alkaline media, *viz.*, their Si—O—Si bonds are hydrolysed at pH < 3 and silica gel is dissolved at pH > 10 (especially at high temperatures). These sorbents are non-selective with respect to the separation of polar compounds and isomers, while the characteristics of basic compounds determined on these sorbents substantially depend on the purity, geometry and chemical nature of silica gels as well as on the method used for the immobilisation of alkyl groups, *etc.*

In recent years, great efforts are made to overcome these drawbacks. First of all, the manufacturing of original silica gels is modernised. The production of special grade silica gels (containing minute amounts of heavy metals) with spherical particles, the composition of which remains invariant from batch to batch, is organised. Unfortunately, not all hydroxyl groups in silica gels are completely substituted. The residual hydroxyl groups can take part in parasitic interactions with small polar molecules, giving rise to asymmetric peaks. It was proposed to block the OH groups with bulky isopropyl or isobutyl groups (the sorbent Zorbax Stable Bond). It is also possible to block hydroxyl groups by bonding the silica gel with bidentate reagents where two neighbouring alkyl groups are linked by a bridge of 3–4 methylene groups. These bridges shield the OH groups, making silica gels much more stable and capable of operating even at high pH (Zorbax Extend- C_{18}). For the sorbents based on silica gels that contain immobilised alkyl groups, the selectivity with respect to polar compounds can be enhanced by modifying their alkyl chains with polar groups, particularly, carbamide groups.

Silica gels with the average pore size of 80, 100 and 120 Å are used in the separation of low-molecular compounds, those with pores of ≥ 300 Å are applied for the separation of high-molecular compounds and biopolymers. Thus, a silica gel modified with C_{30} -alkyl groups was used for the separation of polynuclear aromatic compounds, oligonucleotides, fullerenes and alkylbenzenes.

Among other sorbents applied in the reversed-phase chromatography, the polyethylene glycol-based sorbents, which are used in the separation of phenolic compounds, deserve attention, as well as the perfluorinated sorbents for the analysis of halogen-containing compounds.

Polymeric sorbents based of poly(divinylbenzene) with 500-Å and 1000-Å pores were proposed (Jordi).

Today, hundreds of sorbent types are manufactured. To choose a sorbent for reversed-phase chromatography, different estimation procedures were developed.

The development of columns for turbulent chromatography should be assigned to the achievements of recent years. In columns 1-mm in diameter packed with 50- μ m particles, high-velocity flows are employed; large molecules of proteins are not retained, while small molecules have time enough to diffuse into pores and are retained.

In the recent decade, considerable progress was achieved in the synthesis of new types of sorbents and the construction of columns for HPLC. Particularly, sorbents for perfusion chromatography and monolithic columns with a unified porous block based on polymeric materials or silica gels were developed.

The first application of perfusion chromatography dates back to 1990; its theory was developed later. Perfusion chromatography is conventionally used in the preparative isolation of substances (specifically, proteins) in their pure state and, to a

lesser extent, for analytical purposes (particularly, for the analysis of food proteins). Perfusion columns are considered as intermediate between the conventional packed columns and monolithic ones. In perfusion columns, the eluent flows through the sorbent grains rather than around them as in conventional packed columns. In perfusion chromatography, styrene–divinylbenzene copolymers are used as the sorbents. Such sorbents have the shape of beads ~ 20 μ m in diameter with two kinds of pores, namely, large pores (6000–8000 Å), along which the eluent percolates through the sorbent, and diffusion pores (800–1500 Å), through which the substances easily penetrate into the sorbent. Due to the enhanced mass transfer in perfusion columns, high eluent rates can be used, which reduces the separation time. This is especially important for large molecules. At present, perfusion sorbents are produced for various types of chromatography, namely, for reversed-phase, normal-phase, ion, hydrophobic and affinity versions.

In monolithic columns, the sorption layer represents a continuous rigid porous rod. Polystyrene, styrene–divinylbenzene copolymers, polyacrylates, polymethacrylates (PMA), poly(glycidyl methacrylate), poly(ethylene dimethacrylate), *etc.* are used as the materials (Table 1). Monolithic columns of large diameters (> 5 cm) are manufactured for preparative purposes. Special monolithic columns are developed for the separation of enantiomers as well as for polypeptides and polynucleotides. A new generation of monolithic columns based on silica gels of the Chromolith type were developed. In 2001, a series of analytical monolithic columns (Chromolith Performance RP-18e, Chromolith Flash RP-18e, *etc.*, Merk, column size 100 $\times$ 4.6 mm, 50 $\times$ 4.6 mm, 25 $\times$ 4.6 mm) was rewarded with a gold medal at the Pittsburg Conference as the best product. These columns can operate at high eluent flow rates without sacrifice in separation, moreover, the input pressure is substantially lower as compared with packed columns. Chromolith RP-18e columns are suitable for the separation of acidic, basic and non-polar compounds.

Table 1. Monolithic chromatographic columns used in reversed-phase chromatography.

Name	Shape	Manufacturing company	Material
CIM-Disk	disk	BIA Separations	PMA and PS
CB Silica Plate	"	ConChrom	silica gel
Onyx	cylinder	Phenomenex	silica gel
SWIFT	"	ISCO	PMA and PS
Chromolith	"	Merck	silica gel
Monoliths	"	LC Packing	PS

For the sorption of only one type of molecules or a group of related molecules, the sorbents with molecular-size pores (SMSP) were developed. The major method of SMSP preparation is polymerisation of methacrylic acid or ethylene dimethacrylate. These selective sorbents are applied for the separation and preconcentration (such separation relies on the principle of molecular recognition). They selectively bind non-polar super-toxic agents, particularly, 2,3,7,8-tetrachlorodibenzodioxine, and are well suited for the selective concentration of noxious substances (*e.g.*, pesticides), as well as for the concentration and separation of medicinal drugs. Special SMSPs allowed successful separation of phenylalanine and tryptophane.

A template technology for the production of macroporous carbon sorbents with the surfaces resembling that of graphitised thermal carbon black was developed. Macroporous 5- μ m silica gel beads were used as the templates. The pores in such particles were filled with a phenol–formaldehyde polymer, after which the polymer was carbonised by heating to 1000 °C in an inert medium so that the pores turned out to be filled with carbon. Then, silica gel was dissolved in 5 M NaOH to produce a macroporous carbon sorbent, a mirror replica of the porous silica gel. Unfortunately, in

this stage, the carbon sorbent contained too small pores (measuring 30 Å), which were hardly suitable for HPLC, and also had the amorphous surface (specific surface area of $\sim 400 \text{ m}^2 \text{ g}^{-1}$). Graphitisation at temperatures above 2000 °C led to the total restructurisation of the carbon sorbent, particularly, to the disappearance of micropores and the formation of a uniform crystalline surface. Upon the graphitisation, only those pores retained that were present in the original silica gel. Fractionation was the final technological step.

The commercially produced sorbents called 'Hypercarb' (Shendon) have the specific surface of $\sim 120 \text{ m}^2 \text{ g}^{-1}$, the average pore diameter is $\sim 250 \text{ Å}$, the volume of pores amounts to 75% and the particle size is 5 or 7 μm . This sorbent is stable throughout the pH range (0–14), it is neither dissolved, nor hydrolysed, nor swelled in the solvent and withstands pressures up to 400 atm. Columns packed with Hypercarb are highly efficient, *viz.*, up to 60 000 theoretical plates.

At present, the Hypercarb sorbent is widely used for the separation and the analysis of different mixtures, namely, aromatic compounds, various pharmaceuticals, cations and anions, as well as structural isomers. Hypercarb has no drawbacks typical of the C_{18} sorbent in reversed-phase chromatography; particularly, polar compounds are well retained in Hypercarb-packed columns. For example, the retention factor is 1.8 for phenol, 2.35 for resorcinol and 2.7 for 1,3,5-trihydroxybenzene. The latter two compounds could not be separated on the C_{18} column. In addition, Hypercarb can be used for the separation of carbohydrates and compounds containing carboxyl and amino groups.

In recent years, size-exclusion chromatography was actively developed, which was favoured by the introduction into the chromatographic analysis practice of Sephadexes, *i.e.*, dextran gels cross-linked with epichlorohydrin. Sephadexes are extensively used in medicine.

To date, the HPLC techniques are actively used in proteomics,⁴⁴ in the metabolism studies,⁴⁵ as well as for the determination of the components of a single cell.⁴⁶

3. Ion chromatography^{47,48}

The main achievements of ion chromatography include the development of fast monolithic columns for superfast separation of substances, particularly, inorganic anions (H_2PO_4^- , Cl^- , NO_2^- , Br^- , NO_3^- , ClO_3^- , I^- , SO_4^{2-}) and columns for the simultaneous separation and detection of anions and cations; synthesis of sorbents for micropacked and capillary columns; the extension of the array of detection systems used in ion chromatographs (up to 10 types), particularly, the development of pulsed amperometric detectors for the determination of carbohydrates, amino acids, biogenic amines and alcohols; the development of the eluent generator (the add-only-water system) and a 10-port valve for the analysis of samples with widely different concentrations; the use of non-metallic materials (ceramics, PEEK plastics, sapphire, PTFE, *etc.*) in pumps and liquid tracts in ion chromatographs; the introduction into practice of a 'heart-cut' system for the partial disposal of the sample to prevent its entering into the column; the increase in the sensitivity and stability of detection systems in the determination of ions down to the ppt level (1 ppt = $1 \times 10^{-10}\%$).

4. Thin-layer chromatography

Conventional thin-layer chromatography (TLC) represents a popular, simple and cheap chromatographic technique used for the detection and determination of different classes of substances.^{49–51} In TLC, the separation is usually carried out on glass, metal or plastic plates measuring 100 × 100 mm and covered with an adsorbent layer 50–300 μm thick and containing 3–15 μm grains. At present, the following four types of plates are used most often: classical, high-performance, microplates and preparative.

Silica gels as such and containing immobilised alkyl groups, alumina, cellulose, cyclodextrins, Florisil (magnesium silicate), inorganic ion-exchangers, *etc.* are used most often as the adsorbents. The main advantages of TLC include the simultaneous

parallel separation of several samples (up to 10 and more), high efficiency, the possibility of two-dimensional separation and the fast and cheap determination. Yet another positive feature is the possibility to observe the separation process, in particular, see the remainders of a non-soluble sample at the application point. The drawbacks of TLC include the exposedness of the separation plates to atmosphere, which may result in the decomposition of easily oxidisable and hydrolysable compounds.

The detection of spots on a plate involves the use of different methods including mass spectrometry, Raman spectrometry, spectrophotometry with diode matrices, plasma-ionisation detectors, fluorescence indicators. Electrochemical detection is also used.

In recent years, the TLC techniques were constantly developed and improved. New TLC versions were proposed, namely, polyamide, thin-film, high-performance, rotation, two-dimensional, micellar, flow-through, *etc.*^{52,53} Densitometers were developed for the quantitative TLC determination of substances. Chiral plates are used for the separation of optical isomers.

The standardisation of TLC procedures, namely, pretreatment of adsorbents, preparation of plates, the processing of the results of separation favoured the introduction of TLC into the wide practice of analytical laboratories in many industrial fields.

IV. The main advantages of analytical chromatography

According to Zolotov,⁵⁴ chromatography pertains to the hybrid analytical methods. In chromatographs, the analysed mixture is preliminarily separated on a column due to the different sorption ability of the mixture components, then, at the column outlet, a sensitive element, *viz.*, a detector, registers each of the separated components.

Insofar as the separation capacity of modern chromatographic columns is extremely high (tens and even hundreds of components of a mixture can be separated), the modern chromatography has no rivals in the analysis of complex natural and industrial multicomponent mixtures. In principle, it allows the separation of any mixtures of molecules including all kinds of isomers, particularly, enantiomers, to be performed. However, chromatography has to pay a price for this advantage, namely, this analytical method is indirect rather than direct. The point is that the initial concentration of a substance in the original mixture by no means remains unchanged. Following the injection to the chromatograph, a component is diluted with the eluent and then is spread over the column due to diffusion and kinetic factors. At the outlet, the detector measures a concentration different from the initial one. This situation calls for the calibration in order to establish the relationship between the initial concentration of a substance and that at the outlet from the column.

Yet another peculiarity of analytical chromatographic techniques is their periodicity.

Let us consider the advantages of chromatography over other analytical methods.

1. Versatility and high separation capacity

Chromatographic methods allow virtually all kinds of mixtures to be separated and analysed.[§] Modern chromatographic techniques exhibit high separation capacities. They make it possible to separate multicomponent mixtures including complex mixtures formed by all kinds of isomers and also certain isotopes and isotopically substituted compounds.

Gas chromatography allows more than a thousand of components in gasoline fractions to be separated from a single injection; two-dimensional high-performance TLC makes it possible to separate hundreds and even thousands of components; capillary

§ It is evident that in this case only those mixtures can be analysed that can be separated in principle.

electrochromatography allows the separation of more than a thousand of proteins (the majority of scientists working in the proteomics field are confident that coupling of HPLC with tandem mass spectrometry would provide a rapid breakthrough in proteomics).

2. Low detection limits (high sensitivity)

Among the advantages of chromatography is its compatibility with almost all analytical methods known. However, this cannot be the grounds for the comparison of chromatography with other modern analytical methods, because chromatography employs all the achievement of these methods. At the same time, it is within the latter methods that the sensitive flow-through cells were developed specially designed for the chromatographic applications and the procedures were modernised to fit chromatographic techniques.

For chromatographic techniques, various detection systems, both versatile and selective (specific) were developed. Table 2 shows the detectors used most often in gas chromatographs. In addition to those listed in the table, the Hall electrolytic, chemiluminescence, infrared, fluorescence, helium ionisation, radioactive and ultrasonic detectors are used, as well as densitometers. In total, more than 50 types of detectors are known. The most sensitive of them make it possible to determine impurities at a level of $10^{-5}\%$ – $10^{-7}\%$ without preconcentration.

Selective detectors have a great advantage in the determination of impurities in complex mixtures. It is possible to provide the conditions where the impurities would be determined, while the basic substances in the mixture would not, for instance, in the determination of chlorine-containing organic pesticides in the environment by means of an electron-capture detector.

In HPLC, the detection schemes based on almost all determination methods are used. Table 3 shows the detectors used in high-performance liquid chromatographs. Under favourable conditions, the electrochemical and fluorescence detectors allow determining impurities at a level of pico- or femtograms (10^{-12} – 10^{-15} g) without preconcentration.

Unfortunately, even most sensitive detection systems fail to determine microamounts of certain environmental pollutants, for example, supertoxicants. In this case, the methods of preliminary concentration of samples are used, which makes it possible to reduce the detection limits by two–four orders of magnitude and determine certain contaminants, *e.g.*, dioxins, at the ppt level.

In the past decade, the interest in the concentration methods increased [they were the subject of a monograph⁵⁵ and several reviews (*e.g.*, see Refs 56–59)]. The conventional methods of concentration are modernised, new methods are proposed and new instruments are developed.

Earlier, the liquid–liquid extraction has been used for the preconcentration; however, since this method required very expensive special-grade solvents and sometimes did not provide the complete extraction, which necessitated the regeneration or utilisation of great amounts of solvent wastes, its current application in the classical version progressively decreases. Today, the following new methods of liquid extraction are used: the extraction with small amounts of solvents (merely several millilitres) in a special vessel; the extraction with small amounts of solvents at elevated pressures and temperatures under dynamic conditions (the instrumentation resembles that used in liquid chromatographs); the extraction with a single drop of an organic solvent in water; the extraction with superhot water[¶] under elevated pressure (the dynamic version is possible). In the latter case, the utilisation presents no special problems, because water is 'friendly' to the environment.

At present, the solid-phase extraction occupies the first place in the popularity, because this provides more efficient (nearly 100%) extraction of microcomponents, makes the automation of the preconcentration procedure possible and allows direct coupling with chromatographs in the on-line mode. Various polymeric, carbonaceous and inorganic sorbents (polar, non-polar and ion-exchange) were developed for the solid-phase extraction.⁶⁰ Many companies manufacture filters of large diameters and 96-cartridge kits for performing concentration from large volumes.

The determination of impurities in aqueous media effectively employs the solid-phase microextraction, *i.e.*, the preconcentration on a sorption-layer-coated rod, which is drawn out from the tip of a special syringe. In those cases where selective solid-phase extraction is required solely for the determination of a certain class of compounds or even a single compound, the methods of ion-pair⁶¹ and immunoaffinity⁶² solid-phase extraction are used. In recent years, technologies for the synthesis of porous polymers with molecular-scale pores of fixed sizes have been actively

¶ High temperatures increase the solubility of non-polar compounds in water.

Table 2. Technological characteristics of detectors used most frequently in GC.

Detector	Detection limit /g s ⁻¹	LDR ^a	Detector type	Determined compounds
Flame-ionisation (FID)	2×10^{-12}	10^7	selective	organic compounds ionisable in the hydrogen flame
Heat conductivity (DHC, katharometer)	4×10^{-10} (see ^b)	10^6	universal	all compounds differing in heat conductivity from that of the carrier gas

Atomic-emission (AED)	2×10^{-11} – 1×10^{-13}	10^4	universal	all compounds containing 12 basic elements (H, C, O, S, N, P, <i>etc.</i>)
Mass spectrometric (MSD) ^d	1×10^{-9} – 1×10^{-11}	10^5	"	all compounds

^a LDR is linear dynamic range; ^b in g ml⁻¹; ^c UV radiation; ^d identifies a compound from its mass spectrum.

Table 3. Technological characteristics of detectors applied in HPLC.

Detector	Detection limit /mol litre ⁻¹	Selectivity	Advantages and drawbacks
Coulometric	10 ⁻¹¹ –10 ⁻¹²	high	three-dimensional signals can be recorded; complete oxidation or reduction of the determined substance
Amperometric	10 ⁻¹⁰ –10 ⁻¹¹	"	low cost; selectivity with respect to electroactive compounds
Mass spectrometric	10 ⁻¹⁰	very high	allows identification of unknown compounds; high cost
Fluorescence	10 ⁻⁷ –10 ⁻¹⁰	high	many mixtures should be derivatised; high cost
Chemiluminescence	10 ⁻⁷ –10 ⁻¹⁰	very high	high cost; limited application (only for N- and S-containing compounds)
Spectrophotometric with diode arrays	10 ⁻⁶ –10 ⁻⁷	high	possibility of recording three-dimensional signals; high cost
Spectrophotometric	10 ⁻⁵ –10 ⁻⁷	low	low cost, versatility
Light-scattering-based	10 ⁻⁴ –10 ⁻⁵	"	versatility
Refractometric	10 ⁻⁵	"	versatile detector very sensitive with respect to the temperature and eluent rate variations

developed, aimed at the extraction of the molecules with dimensions corresponding to the pore sizes.

The supercritical fluid extraction is a very promising method;⁶³ however, its instrumentation is very expensive. The supercritical fluid extraction utilises substances at the temperatures and pressures above the critical points. Carbon dioxide is used most often. The potential prospects of the application of the extraction with supercritical CO₂ in the recycling of nuclear fuel wastes were demonstrated.

The preconcentration of light admixtures from solutions is carried out most often by gas (head-space) extraction, which is adequately automated. The method itself and its instrumentation are constantly improved. In particular, the procedure of gas extraction at high temperatures and coupling of gas extraction with solid-phase microextraction were developed as well as other procedures.⁶⁴ Among the dynamic versions of extraction, mention should be made of the purge-and-trap methods⁶⁵ and also the membrane extraction,⁶⁶ which allows the continuous isolation of microcomponents from the flows.

3. Reproducibility of determination and express separation

Modern chromatographs make possible achieving good reproducibility of measured quantities. For the best instruments, the relative standard deviation of the retention parameters on capillary columns can reach record-breaking values, *viz.*, 0.1% and even 0.01%.

For ordinary chromatographs, the root-mean-square deviation of retention parameters and peak heights and areas lies normally within 1%–3%. For the determination of microimpurities, these values are, naturally, larger.

Chromatographic techniques are used most often for the determination of microcomponents (10⁻¹%–10⁻¹⁰%). For the impurity contents within 10⁻¹%–10⁻⁵%, the relative standard deviations of commercial chromatographs are quite comparable with those provided by other methods.

Most often, the duration of separation and determination is within 5–30 min. In this period, tens and even hundreds of substances are separated and determined. Recalculated per a single substance, the analysis is in the range of minutes. At present, the methods for rapid separation, which allow several dozen of components to be separated in two minutes, are developed for GC, HPLC, TLC and capillary electrochromatography.^{67–70}

V. Chromatographic instrumentation

The advances of analytical chromatography are largely associated with the modernisation of the chromatographic instrumentation. The wide distribution of one or another chromatographic technique in the analytical practice was closely related with the commercial production of the corresponding chromatographs. Thus the development by Moore and Stein in 1956 of an amino acid analyser based on ion-exchange chromatography, post-column derivation and photometric detection gave impetus to its wide application in the analysis of amino acid mixtures. The commercial production of gas chromatographs in many countries in 1955–1960 determined the boom in the application of gas chromatography in numerous fields of science and technology. The development in 1965–1970 of high-pressure pumps, flow-through liquid detectors, columns packed with stable fine-grain sorbents and other parts of modern liquid chromatographs made it possible to convert the classical liquid chromatography into a rapid high-performance technique that meets the analytical goals.

In the end of the 20th century, the chromatographic instrumentation represented an individual, sufficiently large industrial branch. Hundreds of companies all over the world produced different types of chromatographs and accessories for the total sum of above USD 10 billions.

The chromatographic instrumentation has reached a very high level; the control over the analysis and the processing of its results are carried out on the basis of microprocessors, most procedures are automated. These instruments employ the latest achievements of electronics, fine mechanics, pneumatics, planar technology and optics.

The commercial production of gas chromatograph–mass spectrometers (GC-MS) is the major achievement in chromatographic instrumentation. Recently, mass spectrometers have occupied a prominent place among detectors for gas chromatographs, they are constantly modernised and their cost decreases. Annually, 3000–3500 such detectors are sold, 80% of which are quadrupole and the other are equipped with ion traps. Their considerable part (above 25%) are used in the environmental control.⁷¹ Table 4 shows the major types of gas chromatographs, which include analytical laboratory instruments, industrial, portable, preparative and multidimensional chromatographs, chromatographs as the gas analysers, GC-MS, GC-IRS and radiochromatographs.^{1, 72}

Table 4. Basic types of gas chromatographs.

Basic types of chromatographs	Functions	Advantages, specific features
Laboratory	for stationary laboratories	wide set of accessories and options
Industrial, automatic	for monitoring industrial processes	in most cases, explosion-proof construction
Two-dimensional, multi-dimensional	for complete separation of complex multicomponent mixtures	separation on twin columns of different selectivity
Chromatographs mass spectrometers	for identification of already separated compounds	quantitative and qualitative analysis of unknown mixtures
Compact	for mobile and stationary laboratories	economy without reducing analytical characteristics, low weight (10–25 kg)
Portable, mobile, field	for on-the-site analysis	high rate analysis with autonomous power and gas supply, low weight (5–15 kg)
Chip-based microchromatographs (silicon-based technology) personal, pocket-size	the same	rapid analysis, complete autonomy, small weight (0.2–3 kg); used only for simple tasks
Special microchromatographs	for space studies	automated analysis, shock- and shake-resistant

To extend their analytical potential, the gas chromatographs are also equipped with sets of additional options, namely, instruments for the sample preconcentration (units for solid-phase, solid-phase micro-, supercritical and gas extraction, systems for purge-and-trap, *etc.*), supplemental sampling systems (autosamplers, cryofocusing systems, gas valves), facilities for the pyrolysis, pre- and postcolumn derivatisation (*e.g.*, methanators, *etc.*).

The main achievements involve the development of portable field chromatographs,⁷³ portable industrial devices in the explosion-proof versions, thermostats with new methods of heating (microwave, IR-radiation), instruments with the temperature programming facilities for the direct heating of columns, new methods and instruments for feeding large samples into capillary columns (cryofocusing, solvent blow-out, programmed heating, on-column introduction), and also the development and introduction into analytical practice of large-diameter (0.53 mm) capillary columns with thick bonded layers of stationary phases (up to 5 μm) and capillary adsorption columns with layer thickness of up to 10–20 μm of the PoraPlot type,^{74,75} the use of electronic control over the gas flow rate and pressure, *etc.*

The development of instruments for the analytical liquid chromatography started 15 years later than that for gas chromatography; nonetheless, its current production and market exceed those of gas chromatographs. Among liquid chromatographs, mention should be made of high-pressure liquid chromatographs (closed systems), gradient, isocratic, ion, exclusion, microcolumn, counter-current, multidimensional and high-temperature chromatographs, instruments for HPLC-MS, *etc.* (nearly 20 types of instruments). Commercial liquid chromatographs can be equipped simultaneously with several detection systems, *viz.*, optical, electrochemical, fluorescence, mass spectrometric, elemental, gas-chromatographic, immune, *etc.* The lowest detection limits (below several femtomoles or attomoles) are typical of electrochemical (coulometric and amperometric) liquid chromatographs.
