Special mention should be made of the development of chromatographs for HPLC-MS. This method is actively developed since 1990. At present, sufficiently reliable and sensitive systems based on the electrospray ionisation at ambient pressure are developed, which are suitable for wide analytical application. The 2001 Nobel Prize was awarded for the development of these systems and their use in biochemical studies. The HPLC-MS technique has found the wide application in pharmaceuticals, medicine, in the analysis of herbs, in biology and biotechnology (particularly, in proteomics). As the mass analysers in HPLC-MS,

the quadrupole, ion, time-of-flight, magnetic (sector), and other traps are used.^{71,72}

VI. Major application fields of analytical chromatography

Undeniably, the chromatographic methods occupied the leading position among other analytical methods in the past decade.⁷⁶

According to publications of the last 20 years, gas chromatography was largely applied for the analysis of environmental objects (12.5%), foodstuffs and beverages (10%), medicinal drugs (10%), for clinical studies (4%), in forensic medicine (3.5%) and for the determination of enantiomers (2.5%). Moreover, it was widely used in the gas, chemical and petrochemical industries, although only few publications were devoted to these issues.

The detection and identification of biological compounds (in particular, amino acids, proteins, lipids, carbohydrates, vitamins, steroids, *etc.*) is the main application field of HPLC (> 50% publications). Among the other application fields, mention should be made of the analysis of medicinal drugs (16%) and the products of chemical and petrochemical industries (more than 10%), the separation and determination of enantiomers (5.5%), the analysis of inorganic compounds (mainly the determination of anions and cations by the ion technique), the analysis of foodstuffs and beverages (4.5%), in the environmental control (3%), clinical analyses (2.8%) and in toxicology (1.3%).

At present, there are virtually no fields in industry, science and technology that do not apply chromatographic techniques. Here, we list the most important advances achieved with the use of chromatographic methods:

- decoding of the human genome;
- separation of multicomponent protein mixtures for the proteomics purposes;
- analysis of the components of a single cell;
- studies in the field of pharmacokinetics (studies of the effect of drugs on the human organism);
- early recognition of diseases (detection and identification of biochemical markers);
- separation of optical isomers, analysis of the enantiomeric purity of medicinal drugs;
- doping-control of sportsmen;
- forensic and medical tests, detection of drugs;
- environmental control, which includes the monitoring of supertoxicants (dioxins, polychlorinated biphenyls, polynuclear aromatic compounds at the ppt level);

— purity control of foodstuffs and beverages, including the detection of most dangerous mycotoxins, nitrosamines, pesticides, *etc.*;

— studies of the components in smells and aromas of foodstuffs and beverages;

— analysis of natural gas, gas condensate, gasoline, kerosene, mineral oils and crude oil; simulation of oil distillation;

— separation and determination of metal ions, including transuranic ions;

— complete analysis of the polluted urban atmosphere;

— determination of Freons in the stratosphere;

— detection and identification of insect pheromones;

— analysis of atmospheres and soils of other planets (Venus, Mars and Moon);

— studies of isotopically substituted compounds.

Below, some of these achievements are discussed in detail.

1. Environmental analysis^{77–81}

Gas chromatography coupled with mass spectrometry is used for the detection and quantitation of organic impurities in the atmosphere of large industrial cities. The impurities are first concentrated on non-polar sorbents that do not retain moisture, then, desorbed and collected at the top of a capillary column (cryofocusing), separated with temperature programming and, finally, detected and identified using a mass spectrometric detector.

Harmful gases in the atmosphere (NO_2 , SO_2 , SO_3 , HCl , HF , Cl_2 , NH_3 , *etc.*) are determined using gas and ion chromatographs. Petrochemicals, being the abundant contaminants of water and soil, are determined most often using certified HPLC methods. Residual pesticides in the environment are determined in most cases by GC, HPLC and TLC techniques. Thousands of analyses are carried out at plant protection stations, veterinary laboratories and various environmental centres.

Carcinogens, namely, certain chlorine-containing organic compounds[†] and aromatic compounds, phthalates, polyamines, *etc.*, are the most hazardous environmental pollutants. Their detection and quantitation in water, air and soil involves most often the use of GC and HPLC techniques. For example, polynuclear organic compounds (*e.g.*, 3,4-benzopyrene) are determined in water and soil by HPLC, while benzene, toluene, ethylbenzene and xylenes in the urban atmosphere are determined by means of GC equipped with photoionisation detectors. Phenol and its derivatives can be determined at the MPC level with a liquid chromatograph 'TsvetYauza' equipped with an amperometric detector. This instrument was also used for the determination of cyanide ions in drinking water.⁸¹

All major anions in drinking water are determined using ion chromatography (in 10–15 min at a level of $1 \times 10^{-4}\%$ – $1 \times 10^{-5}\%$), while volatile chlorine-containing organic compounds are determined by the GC method combined with head space analysis. Ion chromatography is also used in the determination of nitrates and heavy metals in water and soil.

2. Quality control of foodstuffs and beverages

The quality and safety control of foodstuffs is at present among the topical problems of analytical chemistry. In certain sense, it is even more important that the problem of environmental control, because, according to scientists, more than 70% of toxic impurities get into a human organism with food, 20%, with water and 10%, with inspired air.⁸² In addition to technological contaminants that get into foodstuffs through soil, water and air, the foodstuffs can also contain natural contaminants that either are formed during their improper storage, due to failures in the food

processing technology or get into them through the wrapping, *etc.*^{83, 84}

Currently, the safety of people (especially in Russia[‡] largely depends on the cleanness and quality of foodstuffs, spirits and non-alcoholic beverages, because many contaminants possess carcinogenic, mutagenic, teratogenic and immunosuppressive properties. In addition to direct poisoning, the contaminated foodstuffs can reduce the immunity and cause hereditary changes. In some cases, they can directly cause diseases (allergic, oncological, cardiovascular, *etc.*) as a result of the changes in the biochemical reactions in the organism.

The monitoring of the foodstuff quality often involves using chromatographic techniques.^{85, 86} The latter are used to control the quality and freshness of foodstuffs, determine the technological and natural contaminants, reveal counterfeit foodstuffs and determine synthetic dietary supplements and residual veterinary drugs in meat (Table. 5).

Table 5. Main applications of chromatographic techniques in the food-stuff monitoring.

Analysis goal	Determined compounds	Ref.
Determination of nutrition validity of products	food proteins	87
	amino acids	88
	lipids	89
	organic acids	90
	carbohydrates	91
	vitamins	92
Determination of impurities in foodstuffs	carotenoids	93
	pesticides	94
	mycotoxins including:	95
	aflatoxins	96
	patulin	97
	ochratoxins	98
	fumonizins	99
	zearalinon	100
	nitrosoamines	101
	polynuclear aromatic hydrocarbons	102
	dioxins	103
Determination of dietary supplements	biogenic amines	104
	antioxidants	105
	synthetic dyes	106
	sweeteners	107
	aromatisers	108
Determination of residual veterinary drugs in foodstuffs	bitter substances	109
	antibiotics (tetracycline, <i>etc.</i>)	110
	sulfamide drugs	111
	hormones	112
	anabolic steroids	113
	cytostatin	82

A new direction, the enantioselective analysis of food components, has appeared, which, based on the ratio of optical isomers of amino acids, hydroxy acids, *etc.*, makes it possible to infer whether a given foodstuff is natural or contains synthetic substitutes and additives. For instance, the development of a procedure of gas chromatographic separation and analysis for all fatty acid isomers has forced the manufactures to reduce several-fold the content of *trans*-isomers of unsaturated acids in margarine.

[†] Chlorine-containing organic compounds (polychlorobiphenyls, dioxins, *etc.*) are among twelve most dangerous contaminants.

[‡] In recent years, the counterfeit foodstuffs and beverages (butter and vegetable oil, mineral water, juices, wine, brandy, vodka, *etc.*) became more frequent. The spread of retail trade has resulted in the improper storage of foodstuffs (without refrigeration) and their delivery at long distances in poorly equipped vehicles.

3. Early recognition of diseases by determination of biological markers

The successful curing of various dangerous diseases depends on their early recognition. Many diseases can be recognised by their markers, *i.e.*, substances contained in biological fluids and expired air.

Most often, the markers represent low-molecular biologically active compounds, namely, nucleosides, nucleotides, catecholamines, hydrocarbons, amino acid derivatives (*e.g.*, homocysteine, *etc.*), steroids, carbohydrates, indoles, porphyrins, organic acids, vitamins, *etc.*¹¹⁴ Large molecules, for example, proteins and lipids, can also be the markers.

Chromatographic techniques allow many biochemical markers to be determined at the level of 10^{-9} – 10^{-15} g (depending of the preconcentration and detection techniques used).^{115, 116} The large volume of available information (due to the possibility of the separation and determination of tens–hundreds compounds per cycle), the low detection limits,[§] the reliable instrumentation, the automated analysis that provides the complete test report, the data storage in the PC memory, the versatility (a single chromatograph can be used for carrying out numerous tasks), the preferential use of non-invasive samples (urine, saliva, tears, sweat, hair, expired air, *etc.*) make the chromatographic techniques irreplaceable in the analysis of markers.

GC and HPLC are the techniques used most often for the analysis of markers.

Naturally, the markers of dangerous, particularly, oncological diseases attract the keenest attention (Table 6).

Here, we consider the diagnostics of oncological diseases, namely, breast and lung cancer.

Table 6. Biochemical markers of oncological diseases.

Disease to be recognised	Disease markers	Ref.
Breast cancer	(1) modified nucleosides (1-methyl-guanosine, 2-methylguanosine, pseudouridine, 5,6-dihydrouridine) in urine (2) polyamines (spermine, spemidine, putrescine, cadaverine) in urine	117–119
Lung cancer	hydrocarbons(n-butane, n-pentane, n-heptane, 2-methylhexane, 3-methylhexane, 4-methyloctane, 5-methyldecane, 3-methyltridecane, 7-methyltridecane) in expired air	120
Malignant melanoma	cysteine and indole derivatives in urine	121
Ovarian carcinoma	polyamines in urine	119, 122
Oestrogen-initiated tumours	4-hydroxyoestradiol in urine	123
Carcinogenic diseases	5-hydroxyindoleacetic acid in urine	124
Cancerous growth (children)	fucose in urine	125
Neuroblastoma (children)	homovanillic acid and vanillyl mandelic acid in urine	126
Pheochromocytoma	catecholamines (adrenaline, nor-adrenaline and dopamine) in blood plasma or urine	127

§ Due to the low detection limit, only small amounts of biological samples are required for the analysis (often, several microlitres).

The specialists at the American Oncological Centre who studied the possibility of early recognition of cancer based on biological markers have found that high concentrations of modified nucleosides in the blood of oncological patients points to the presence of a tumour. Such an analysis allows the disease to be recognised at the earliest stage. The determination of nucleosides in urine can be performed with the use of HPLC. The results of the analysis of urine samples of 62 women suffering breast cancer (reliably confirmed) and 100 healthy women were described.¹¹⁹ Their statistical processing confirmed the higher diagnostic value as compared with the analyses that used conventional markers of breast cancer, *viz.*, CEA and CA 15-3. The sensitivity and selectivity of the diagnostics from the analysis of modified nucleosides exceed 80%. The examination of the transformed nucleosides allows certain types of leukaemia, lung and brain cancer to be recognised.^{117–119}

The prospects of the early recognition of lung cancer are associated with the analysis of expired air.¹²⁰ The air expired by the patients suffering lung cancer was found to contain higher concentrations of alkanes and methylalkanes such as n-butane, n-pentane, 3-methyltridecane, 7-methyltridecane, 4-methyloctane, 3-methylhexane, heptane, 2-methylhexane and 5-methyldecane. These hydrocarbons were present at the level of nano-(pico)moles; hence, their determination should involve their preconcentration on special adsorbents that do not absorb moisture. The chromatographic method of the diagnostics based on the analysis of the expired air has advantages over other methods due to its safety, low cost and high selectivity. Therefore, it was proposed for the early initial screening of oncological patients.

4. Pharmaceutical and pharmacological applications

The major application fields of chromatography in the analyses and examination of medicinal drugs (pharmaceutics) and also in the determination of drugs in biological fluids (pharmacology) are as follows:

- pharmacopeia control over the quality of drugs;¹²⁸
- monitoring of impurities in drugs;¹²⁹
- studies of the stability of drugs;¹³⁰
- analysis of medicinal herb extracts;¹³¹
- analysis of drugs based on the herbs used in traditional Chinese medicine;¹³²
- application of the LC-MS technique in the development of new drugs;¹³³
- application of supercritical fluid chromatography for the separation of drug enantiomers;¹³⁴
- the use of HPLC for the separation of drug enantiomers;¹³⁵
- the use of HPLC in pharmaceutical industry;¹³⁶
- determination of natural phenolic compounds in plants (flavonoids, hydroxy acids, natural dyes, *etc.*);^{137–140}
- analysis of drugs in the doping control;¹⁴¹
- clinical pharmacy;¹⁴²
- chromatography in pharmacokinetics;¹⁴³
- toxicologic analysis;¹⁴⁴
- binding of drugs in the organism.¹⁴⁵

The use of chromatography in pharmaceutics was also the subject of monographs.^{146, 147}

High-performance liquid chromatography is the main method used in the analysis of medicinal drugs at pharmaceutical factories. Ion chromatography is widely used for the determination of ions in drugs, of anions and cations in special-grade water and water used for injections. Ion chromatography coupled with a pulsed amperometric detector allows mono-, di-, tri- and polysaccharides, alcohols and free acids to be determined (without preliminary derivatisation). Gas chromatography is used in the analysis of solvent residues that can be present in pharmaceutical products.

5. Chromatographic methods for the analysis of natural gases, gas condensates, mineral oils and crude oil

Chromatography is widely used in the gas, oil and oil-refining industries.^{148–151} Analyses are carried out at all stages, *viz.*, during the geological survey of gas and oil areas, gas and oil production, piping, at different stages of technological processing and, ultimately, for monitoring the finished products. Moreover, the chromatographic techniques are used for the monitoring of pollution of the environment (soil, water, air, bottom sediments, *etc.*) with mineral oils.

Modern high-performance capillary columns make it possible to completely separate the gasoline fractions into components (200–1000 components in a single sample). These analyses cannot be accomplished by other methods.

Chromatographic techniques (GC, HPLC, ion, gel-filtration chromatography) are used for the monitoring of natural and accompanying petroleum gases, gas condensates, gasoline and kerosene fractions, diesel fuel, lubricating oils, oil heavy fractions, pyrobitumen and even crude oil. The methods of the analysis of natural gases and different fractions of mineral oils are specified by the Russian State Standards (GOSTs).

Chromatography makes it possible to determine both individual (component-after-component) and group compositions; to simulate the distillation of petroleum and its derivatives according to their boiling points; to assess the environmental characteristics of petroleum derivatives, in particular, determine the benzene content, the total sulfur and nitrogen contents and the concentrations of heavy metals and polynuclear aromatic compounds.

High-performance liquid chromatography allows one to easily perform the 30-min separation of petroleum into the following four fractions: asphaltenes, saturated hydrocarbons, aromatic hydrocarbons and polar compounds. After such a grouping, the separation of saturated, aromatic and polar compounds into individual components is possible. The group type separation (to paraffins, naphthens and aromatic compounds) of gasoline is carried out on 13X-zeolite-packed columns, whereas their separation into individual components is accomplished on capillary columns. The chromatographic separation of oxygenates in gasoline is performed using a flame ionisation detector, which is selective with respect to oxygen-containing compounds. The operation of the detector is based on the conversion of oxygen-containing compounds into methane, which allows one to avoid the effect of the hydrocarbon background and determine oxygenates at the trace level.

Multidimensional gas chromatography[¶] is used for the separation of complex multicomponent mixtures in petrochemistry and also for the determination of the hydrocarbon content of natural and accompanying gases. The increase in the gas cost places more stringent requirements upon the reliability of the natural gas analysis, which is necessitated by the interpayments between the oil-production, oil-delivery and oil-consumption companies.

Chromatography plays the exceptionally important role in the chemical, pulp and paper and many other industrial fields. It is used, first of all, to exercise technological control (analyses at all technological stages) and maintain the optimum conditions and, secondly, to analyse rough materials, finished products and wastes. The technological control at hundreds of Russian plants involves the use of more than 50 thousand gas chromatographs. Thousands of gas, liquid and ion chromatographs are constantly operated at the laboratories and centres of Gosepidnadzor (State Sanitary and Epidemiological Control), environmental control committees and centres, toxicological laboratories, organisations such as Vodokanal, laboratories of Goskomgidrometeotsentr (State Hydrometeorology Centre), veterinary laboratories, plant

protection stations and the laboratories of forensic and medical examination, *etc.*

In recent years, the role the chromatography plays in power engineering increased, namely, it is used for the determination and evaluation of the calorific power of gases and in the analysis of pollutant emissions. Ultimately, chromatography finds application in archaeology and art (for studying old paints, varnishes, coatings, *etc.*).

Chromatography surpasses other analytical methods in the number of publications. More than 300 thousand books, reviews and papers were published (including 110 thousand on the liquid column chromatography, 65 thousand on the gas chromatography, 65 thousand on the planar chromatography and about 50 thousand on the capillary and planar electrophoresis.).

VII. Conclusion

In summary, we outline the main directions in the development of chromatography.

Upgrading the selectivity of separation due to the development of new sorbents. In GC, this is the synthesis of new liquid phases with bi- or trifunctional groups, the development of adsorption capillary columns of the PoraPlot type of different chemical nature, the use of the geometric factor for the increase in the selectivity. In HPLC, this is the synthesis of reversed-phase sorbents that contain immobilised polar groups in alkyl chains and also sorbents with molecular-size pores for the retention of molecules of both single and related types, the use of Hypercarb carbonaceous sorbents based on porous graphitised carbon black to enhance the selectivity of the separation of isomers.

Enhancement of the column efficiency due to the changeover to capillary columns. At present, more than 60% of studies are carried out with the use of capillary columns. The share of micropacked, capillary, and nanocolumns in HPLC has substantially increased. In capillary electrochromatography, the separation is carried out exclusively on capillary columns. In GC, HPLC and capillary electrochromatography, the efficiency of columns exceeds one million of theoretical plates.

The development of new rapid separation methods. In GC, the high separation rate is achieved due to the decrease in the column volume and also due to the high-gradient temperature changes (up to 1800 deg min⁻¹). Dozens of components can be separated in a minute. In HPLC, the high separation rates are achieved by using columns packed with fine non-porous particles (measuring 1.0–1.5 µm), monolithic columns and columns with perfusion sorbents and turbulent flows.

Miniaturisation of instruments is the common trend of all chromatographic techniques. The most significant progress is observed in GC, HPLC and ion chromatography. Portable field chromatographs, hand-held devices, and also chip-based instruments are developed.

Improvement of microprocessor programmes for the analysis-data processing and the control over the chromatograph parameters. Attention is drawn to the computer-assisted processing of the results of chromatographic analysis. The systems for recording, processing and storage of chromatographic information are constantly renewed and refined. The number of publications on the simulation of chromatographic processes increases, particularly, the publications devoted to the use of neural networks and the linear and non-linear regression analysis for the simulation and optimisation of these processes. The chromatographic databases are constantly replenished.

Organic reagents in spectrophotometric methods of analysis

S B Savvin, S N Shtykov, A V Mikhailova

Contents

I. Introduction	341
II. Individual organic reagents	341
III. Modified organic reagents	342
IV. Immobilised organic reagents	344
V. New classes of organic reagents	345
VI. Conclusion	346

Abstract. The role of organic, in particular, complex-forming, reagents in the formation and development of spectrophotometric analysis is discussed. The prospects for the use of organic reagents in modern analytical methods are considered; the attention is focused on modified and immobilised reagents, receptor molecules and on the use of nonaqueous and organised media. The bibliography includes 170 references.

I. Introduction

For many years, organic reagents play an important role in the chemical and physicochemical methods of analysis. They are employed for qualitative or quantitative determination of chemical elements and compounds (both organic and inorganic), as well as for separation, concentration, masking and other auxiliary operations that precede or accompany the analysis.

Theoretically, the possibilities of design of new organic compounds for analytic purposes are boundless; however, in practice only several dozens of classes of chemical compounds are effective as organic reagents.¹ The requirements for the organic reagent are dictated by the analytical method used.

The reagent for the determination of metals should, first of all, contain a proper functional analytical group that enables its interaction with the determined element and subsequent observation of the respective analytical signal. Currently, several tens of such functional analytical groups are known and documented.^{2,3}

The determination of organic compounds requires that the reagent molecule contained specific groups able to react with functional groups of determined compounds (hydroxyl-, carbonyl-, halogen-, sulfur-, nitrogen-containing) with the formation of intensely coloured or luminescent products. Reactions used for the determination of functional groups differ considerably from those used for inorganic ions. In particular, the nature of the

molecular core (aliphatic or aromatic) is important. Besides that, the course of many reactions depends substantially on the media and the reactions are not often sufficiently selective.

New problems that the chemical methods of analysis encounter with have stimulated wider studies of organic reagents. Novel directions have appeared, that are associated with the modification and immobilisation of the conventional organic reagents, as well as with the use of non-aqueous, water – organic and organised media. The variation of conditions of the analytical reactions, *viz.*, the control over the reaction rates and solvation processes, changes in the solubilities or hydrophobicity of the reactants, utilisation of solid matrices, is becoming more and more popular.

There are also completely new directions dealing with the use of receptor molecules and reagents based on the principles of supramolecular chemistry, host – guest interaction mechanisms, as well as immune reactions with organic and bioorganic compounds. Some organic compounds act as reagents in excited states; reagents that form π -complexes with analytes, bacteria and micelles (vesicles), *etc.* are also known.

At present, organic reagents are widely used not only in spectrophotometry^{2–10} and luminescence analysis,^{11,12} but also in atomic absorption^{13–16} and atomic emission spectrometry,¹⁷ inverse voltammetry,^{18–21} in the methods based on the use of ion-selective electrodes²² and different chemical sensors,²³ in the kinetic,^{24,25} flow-injection²⁶ and tracer analysis,²⁷ in capillary electrophoresis,²⁸ and in liquid²⁹ and gas chromatography.³⁰ As usual, organic reagents play a crucial role in titrimetry,^{31,32} extraction^{33,34} and many other methods of determination, separation and preconcentration.^{35–37} Comprehensive textbooks^{38,39} on the use of organic reagents in the inorganic analysis have been published.

In the present review, we discuss the role of organic reagents (mostly, complex-forming) in the spectrophotometric analysis and consider the perspectives of their use in modern analytical methods.

II. Individual organic reagents

In the first third of the 20th century, a new scientific direction based on the application of chelating reagents, mostly organic, in chemical analysis emerged at the joint of organic, inorganic, coordination and analytical chemistry. The concept of functional analytical groups was formulated, the effects of substituents (called later the analytical active groups) in the reagent molecules were studied, and the general conditions of formation of stable complex compounds were revealed.

Uspekhi Khimii 75 (4) 380–389 (2006); translated by I S Neretin

In the next years, organic reagents have acquired wider applications in different analytical methods. New more efficient reagents were synthesised and exploited, *viz.* oxine (8-hydroxyquinoline), dithizone (1,5-diphenylthiocarbazone), cupferron (*N*-nitroso-*N*-phenylhydroxylamine ammonium salt), dialkyldithiocarbamates, arsenazo I [sodium 2-(2-arsenophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonate], 1,3-diketones. Theoretical concepts on the mechanisms of their action were developed. It can be said for sure that Russian science has made a major contribution to the development of theory and practice of the use of organic reagents in the analytical chemistry.⁴⁰

In the 1950–1980's, complexones,³¹ the reagents of the triphenylmethane^{4–7,41} and fluorone⁴² series, antipyrin derivatives,⁴³ mono- and bis-azo compounds, for example, arsenazo III,⁴⁴ acquired a broad use in the photometric analysis. Hydroxyflavones, hydrazones and Schiff bases were often used in the fluorimetric analysis, whereas rhodamines, in the version with extraction.

In the last two decades, heterocyclic mono-azo compounds,^{45,46} including both the well-known 1-(2-pyridylazo)-2-naphthol (PAN), 4-(2-pyridylazo)resorcinol (PAR) and 4-(thiazol-2-ylazo)resorcinol (TAR), and especially halogenated heterocyclic compounds began to play an important role in the photometric analysis. Extremely high molar extinction coefficients of the latter [often reaching $(1.0–1.5) \times 10^5$], contrast ranges and higher selectivity as compared to PAN and PAR are their main advantages. Complexes of water-soluble analogues of natural porphyrins also possess high molar extinction coefficients.⁴⁷ Besides, new principles of the reagent design were developed, using the concept of functional analytical group duplication. In particular, the series of bis-azo compounds of the arsenazo III group has been considerably broadened.

The unusually high apparent molar extinction coefficients [$\epsilon_{\text{mol}} = (1–10) \times 10^5$] were obtained in the flotation of ionic pairs of organic reagents (Rhodamine 6G, Crystal Violet, Methylene Blue, *etc.*) with analytes.⁴⁸ The highly sensitive kinetic and catalytic methods for the determination of metal ions, anions and organic compounds in photometric and fluorimetric versions, are very promising.^{49–51} A number of works on the determination of different anions with the use of organic reagents that have been analysed in detail in a fundamental review,⁵² should be specially noted. Many of the above-mentioned applications of organic reagents for the analytical purposes have been discussed.⁵³

Quantum-chemical methods for the calculation of the characteristics of the coloured compounds gained further development. An attempt was made of quantum-chemical design of photometric reagents with optimal characteristics.⁵⁴

However, it is obvious that the synthesis of many novel organic reagents for the determination of metal ions will not give considerable benefits. At present, diverse modifications of the known organic reagents by complication of their chemical structures or changes in the media properties where the analytical reaction is carried out, are becoming popular. In particular, non-aqueous and water–organic media, as well as organised media, are used more and more widely.

III. Modified organic reagents

1. Types of modifications of organic reagents

There is still no clear definition of a modified reagent. One can consider the modification as the purposeful change in the properties not related to the formation of new in principle chemical compounds. According to this definition, a chemical compound with an additional substituent is a new organic reagent. It can be similar to the prototype reagent in its chemical and analytical properties (*e.g.*, in the selectivity, provided that the functional groups were not affected), but cannot be considered as the modified reagent.

On the other hand, different salts, ionic and other associates of organic reagent with other organic and inorganic compounds

formed due to electrostatic or hydrogen bonds or hydrophobic interactions, can be regarded as modified organic reagents. Solvates (adducts) involving the organic solvent molecules also fall in this category. In our view, the solubilisation of organic reagents in various types of nanosized organised systems, which serve as the nanoreactors in analytical reactions, is also a kind of modification.

One of the main features of the modified reagent, according to our definition, is the reversibility of the modification, so that upon changes in the conditions, *e.g.* upon acidification or dilution of the solution or change in the solvent, *etc.*, the reagent dissociates into the starting components.¹ It is noteworthy that the modification of organic reagents has long been employed, especially for their hydrophobisation upon formation of neutral ion associates. However at present, diversification of the modification pathways and the use of this approach in the routine analysis is in progress. Several examples of analytical systems where, in our view, the authors deal with the modified organic reagent, are discussed below.

2. Modification upon association of organic reagents

This type of modified organic reagents comprises different associates, *viz.* associates of the initial organic reagent with its counterion (ion associates or pairs), associates of an acidic organic reagent with a base (amine or amide) or of a basic organic reagent with a proton donor (see, for example, Ref. 55). In 1954, it was proposed⁵⁶ to use organic co-precipitants to concentrate elements from very dilute ($1:10^{10}$ and more) solutions. The use of large molecules as organic co-precipitants and for the determination of trace amounts of elements proved beneficial. Different types of co-precipitants were found. The mechanism of their effect is described in the original works, reviews and monograph (see, for example, Refs 56–58).

Let us limit ourselves to the consideration of the mechanism of co-precipitation of ionic associates, poorly water-soluble and containing an extended hydrophobic organic fragment. It is known that the majority of organic reagents that form complexes with precipitated metal ions contain sulfo, carboxy, and other negatively charged groups. Their effect on the solubility can be levelled by formation of a salt or an ion associate with a 'heavy' hydrophobic organic cation. In this case, it is pertinent to consider this as a modification of the respective organic reagent by organic cations, since it is the salt or ion associate that serves as the ligand for the metal ion. Other versions are also possible, for example, precipitation of actinides by the arsenazo-type reagents and the precipitate of diphenylguanidinium anthracene- α -sulfonate,^{57,58} precipitation of thorium by SPANDS [sodium 2-(*p*-sulphophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonate] and Methylene Blue, and precipitation of rare-earth elements by stilbazo[4,4'-bis(3,4-dihydroxyphenylazo)stilbene-2,2'-disulfonic acid] and so on.⁵⁵

In the 1960–1980's, ion associates were most often employed in extraction systems. The role of reagent modification for the extraction of charged complexes is similar in many aspects to that of counterions in the precipitation reactions, since in both cases charge neutralisation is required for the passage of a complex to another phase (solid or liquid). In the extraction of anionic chelates it is necessary to block sulfo, hydroxy, and other hydrophilic groups by 'heavy' hydrophobic organic (or sometimes inorganic) cations, which thus serve as the modifiers of the original organic reagent. Large hydrophobic organic cations include, *inter alia*, tetrabutylammonium, tetraphenylarsonium, trioctylammonium, and potassium is used as the inorganic cation.³³ The use of diphenyl- and triphenylguanidinium salts as a source of cations and extraction with higher alcohols allowed one to expand this approach onto a large group of complex organic reagents belonging to the family of azo-dyes.⁴⁴

Chelates with multiply charged metal cations can have a positive charge. To compensate it, a sufficiently hydrophobic anion (*e.g.*, tetraphenylborate, naphthalenesulfonate, or acid dye

anions) should be added to the solution.^{34, 55} In any case, it can be said that the anionic or cationic chelates are modified by hydrophobic cations or anions, respectively.

3. Modification upon formation of multicomponent complexes and outer-sphere chelates

The passage from binary to ternary and multicomponent systems is a well known (since the 1950's) approach aimed at improving the analytical characteristics of photometric organic reagents. Hundreds of papers on the so-called mixed-ligand complexes were published in the 1970–1980's; a monograph devoted to this topic appeared, in which the authors propose the term 'hetero-ligand' for such complexes. The interactions between ligands can differ in nature, namely, hydrophobic interactions, stacking interactions, π -bonding, hydrogen bond. On the whole, they lead to the change in the character of complex formation by the original organic reagent.^{55, 59–61} It is believed that the interaction between two ligands gives a new 'compound' reagent, which is more efficient than the original reagents.

Yet another route to the modification characteristic of multicomponent systems is the outer-sphere complexation, which also changes the analytical parameters of the reaction products.^{55, 62} A specific effect of the outer-sphere reagents enhances the differentiating action of organic reagents in respect of metals. Outer-sphere complexes occupy an intermediate position between the inner-sphere complexes and ion associates.⁵⁵

4. Modification of organic reagents caused by changes in the media properties

a. Non-aqueous media

Extensive investigations into non-aqueous solutions, especially in the mid-20th century, has led to their use not only in research studies, but also in the routine chemical analysis. It was found that the properties of organic reagents (protolytic, redox, donor-acceptor, complex forming, tautomeric, solubility, *etc.*) vary dramatically in different solvents, therefore changing the sensitivity, selectivity, contrast and rate of a reaction, and even the end products. Thus, a solvent is not only a medium, but is rather a kind of an active reactant. Its effect on the chemical process is determined primarily by the two principal characteristics, *viz.*, donor-acceptor properties and dielectric permeability. As a result, one can control the process by changing the character of solvation of both the reagent and the element under study.⁶³

However, the change in solvent results in simultaneous changes in both the dielectric permeability and donor–acceptor properties. Therefore analytical chemists have begun to use mixed (non-aqueous and water–organic) solvents. New ways of increasing the selectivity and contrast of metal ion reactions with organic reagents were revealed also in the use of strongly acidic media.⁶⁴

Despite a sufficient progress in the control over chemical processes with the use of such solvents, many problems still remain unsolved. In addition, these media are sometimes unsuitable due to toxicity, strong odour or volatility. Non-aqueous media have certain advantage only in the extraction version of photometric, fluorimetric and atomic absorption methods, because they allow one to unite separation, preconcentration and determination, thus increasing both selectivity and sensitivity of the analysis.

b. Surfactants

A broad class of ionic surfactants can serve as versatile modifiers of physico-chemical properties of chromophore polydentate multifunctional organic reagents of different chemical nature.⁶⁵ It is for this reason that the analytical determination of elements with the use of surfactant-modified reagents considerably exceeds the best known conventional methods in sensitivity, selectivity and contrast. A vast literature on the theoretical aspects and analytical applications of surfactants includes two books^{65, 66} and a number of reviews.^{67–72}

Formation of ion associates is one of the main routes of modifying electronegative or electropositive organic reagents by surfactant ions of the opposite charge. The surfactant ions interact with the analytical active group of the organic reagent, so that no competition with the complexation of the metal ion occurs. This allows creation of many new and more efficient modified organic reagents from the known ones. It is applicable to ionogenic surfactants and chromophore polydentate chelating or, more generally, complex forming reagents.

The best known and the most analytically efficient reagents belong to the following classes: sulfophthalein indicators (Pyrocatechol Violet, Xylenol Orange, Phthalexones), phenolcarboxylic acids of the triphenylmethane series (chromazurol C, eriochromcyanin R, eriochromazurol B, sulfochrom), trihydroxyfluorones (disulfophenylfluorone, salicyl fluorone) and other reagents of the xanthene series (Pyrogallol Red, Bromopyrogallol Red), as well as from some other classes of organic reagents.^{65, 70, 72–78} For the modification of organic reagents with the negatively charged analytically active groups, one should use a long-chain cationic surfactant with no less than twelve carbon atoms in the alkyl chain, *i.e.*, salts of quaternary ammonium bases (for example, cetyltrimethylammonium bromide), alkylpyridinium salts (*N*-cetylpyridinium chloride) and salts of other heterocyclic amines, primary, secondary and tertiary amines that can be protonated in water with the formation of cations.^{65, 70–78}

The basic idea of modification of this type of organic reagents is the concept of formation of ion pairs or ion associates.^{65, 75} The scheme of a reaction of a reagent $R(OH)_2$ containing one functional analytical group and one analytical active group (CO_2H , OH , SO_3H) with a cationic surfactant (Sur) can be written as follows:

Due to the addition of the biphilic surfactant cation with a large non-polar chain to the organic reagent molecule, the associate becomes significantly more hydrophobic than the original more hydrophilic reagent, *i.e.*, the character of the species hydration changes.^{65, 78, 79} As a result, a local decrease in the polarity of the medium occurs in the microenvironment of the organic reagent molecule.⁷² This leads to a decrease in the hydration of the functional analytical group and the bound metal ion, which, in turn, causes the change in protolytic properties of the groups involved in the functional analytical group,^{65, 72} and the increase in the number of adjoining chelating ligands.^{65, 78}

There are at least four features of the complexation with surfactant-modified ligands:^{65, 78} the increase in the number of coordinated ligands in the analytical forms; the multisite interaction of polydentate reagents; activation of complex formation in strongly acidic media; and the increase in the stability of the chelates. A widening of the pH plateau of complex formation to acidic or basic region is sometimes considered as the fifth effect.⁶⁵ These factors ensure the increased sensitivity and selectivity of the reactions in the presence of surfactants. Cationic surfactants in such systems bring into interaction both analytical functional and analytical active groups, *i.e.*, induce multicentre interaction involving the chromophore π -electron system. Thus, the potential of the given reagents can be used to their full extent in order to enhance the contrast of the photometric reaction. In the case of multiply charged metal cations, the number of coordinated ligands increases, which also leads to an increase in the sensitivity of the determination. For instance, in the case of titanium complexation with Pyrocatechol Violet, the molar extinction coefficient of the complex reaches 1.5×10^5 and the contrast of the reaction $\Delta\lambda$ is 250 nm upon modification of the reagent by cationic surfactants.

It should be noted that in the case of a stoichiometric component ratio in the reagent–surfactant system, as a rule, neutral ion associates precipitate. Their solubilisation can be effected by addition of a 2–5-fold excess of the surfactant, which

causes surfactant adsorption on the precipitate particles, their charging and dispersion to the virtually molecular level. Such charged particles of ion or chelate associates containing small excess of the surfactant ions, are sometimes called mixed micelles.⁶⁶

c. Water-soluble polymers

Water-soluble polymers are commonly used in chemical technology, for example, in water purification. However, their use in the analytical chemistry has long been limited to the concentration by membrane filtration.^{80, 81} Later it was found⁸² that the modification by water-soluble polymers is an almost versatile way to transform water-insoluble (hydrophobic) organic analytical reagents or dyes into the water-soluble form. The molecular mass of these organic polymeric compounds is usually in the range of 10^4 – 10^5 ; they contain both the hydrophobic chain and the hydrophilic groups incorporating tertiary or quaternary nitrogen atoms.

The mechanism of the interaction of water-soluble polymers with the organic reagents is as follows. Hydrophobic (water-insoluble) organic reagents are solubilised as a result of their hydrophobic interaction with the non-polar carbon skeleton of the polymer molecules.^{65, 83} Since the solubilisation of the neutral organic reagent molecules does not block the cationic centres of the water-soluble polymer, its interaction product with the reagent retains the properties inherent in the original polymer and is also water-soluble. Moreover, if the analytical functional groups of the reagent responsible for the complexation of metal ions are neither blocked by the water-soluble polymer, the modified organic reagent does not lose its chemical analytical properties with retention of the coloration reaction, which determines the analytical value of the organic reagent. In addition, due to the solubilisation and related structuring of water in the close vicinity of the chelate, the stability constant of the complex of the polymer-modified reagent with the metal ion increases, which favours virtually complete binding of the element.

The use of the organic reagent–water-soluble polymer systems, as well as the organic reagent–surfactant systems, broadens the potential of the spectrophotometric analytical methods. For example, the use of organic reagents in the flow-injection analytical methods is limited due to the reagent sorption on the capillary walls and on the other parts of the flow system. Due to higher affinity of the hydrophobic organic reagent to the water-soluble polymer than to the material of the instrument parts, the introduction of water-soluble polymer solves this problem and prevents the organic reagents and their metal complexes from sorption on the working parts of the instrument. The use of water-soluble polymers also broadens the potential of the classical titrimetric analysis due to the use of metal indicators of different nature. For example, a scheme of a reaction of poly[N-(4-vinylbenzyl)trimethylammonium] chloride, (VBMA)⁺Cl[−], with the two-basic reagent H₂RSO₃[−] containing one dissociated sulfo group and doubly-charged metal cation M²⁺ can be written as follows (for one unit of the polymer chain):

The water-soluble polymer–organic reagent–M systems are successfully used for retention and preconcentration (for example, by the membrane filtration method) with the subsequent determination of elements.^{84, 85} Ionenes represent yet another example of charged water-soluble polyelectrolytes used in analysis.⁸⁶

d. Organised micellar media

Organised media differ in principle from the classical homogeneous media described above since they are microheterogeneous. They consist of a solvent and a huge number of ensembles of tens or hundreds of distributed biphilic surfactant molecules or ions. The species in such an ensemble form a nano-sized micellar pseudo-phase (dispersed phase), the properties of which differ sharply from those of the bulk solvent (a dispersion medium),

which produces a reaction medium of a new type, combining the properties of both polar and non-polar media.^{70, 71, 87, 88}

More complex micellar systems can contain two or three components in addition to the surfactant molecules. The examples of surfactant-based micellar systems are represented by direct and inverse micelles, microemulsions ('oil-in-water' and 'water-in-oil'), vesicles, liposomes, lipid membranes, Langmuir–Blodgett films (LBF), liquid crystals and other systems.⁷¹ Micellar systems can also appear on the solid surface being in a contact with the solution in a form of hemimicelles (half-micelles) or adsorption bilayers.⁶⁶

A peculiarity of the nano-sized phase created by an ensemble of surfactant species is that it has virtually no macroscopic analogue.⁸⁹ It is worth noting also that the formation of micellar systems as a result of self-organisation (self-assembly) of surfactant molecules or ions does not include a formation of intermolecular chemical bonds, and is therefore related to supramolecular chemistry, a new section of chemistry that emerged in the last decade of the 20th century.⁹⁰

The microheterogeneous organised media differ in principle from the common homogeneous solutions in that the main feature of the former is the local effect based on the solubilisation of hydrophilic and hydrophobic reagent molecules in the nanoscale volume of the micellar system.^{70, 71, 87, 88} In this case, the change in properties and the reactivities of organic reagents is determined by the change in the state of the medium in their microenvironment (rather than in the entire volume). If the analytical reaction occurs in the nano-sized microphase rather than in the bulk, the former is called a micro- or nano-reactor.^{71, 87, 88}

It was shown that the solubilisation of organic reagents in micelles, microemulsions, LBF or cyclodextrins changes their protolytic,^{91–94} redox⁹⁵ and complexation^{65, 66, 96} properties, as well as the tautomeric transformations.^{94, 97–99} These changes in turn result from changes in the properties of the reaction media (polarity, acidity, dielectric permeability) in the microenvironment of the solubilised reagents and changes in their hydration type.^{72, 100–102} Numerous applications of the organised media for the modification of the organic reagent's properties are summarised in books^{65, 66} and reviews.^{67–71}

IV. Immobilised organic reagents

The term 'immobilisation' of organic reagents on the surface layers or in the bulk of a solid phase (matrix) has come to analytical chemistry from biochemistry. If, as a result, some properties of the compound change (which is the goal of immobilisation in the analytical chemistry), this compound can be considered modified. Thus, it is possible to consider that the immobilisation is a particular case of the modification.

1. Complex-forming sorbents

Complex-forming sorbents are organic or inorganic polymeric compounds with groups or reagents attached in one or another way, which can interact with metal ions or other compounds in the solution.

The mode of attachment can be based on both the sorption of the reagent molecules on the matrix and their covalent binding with the formation of a new polymer containing reactive fragments of the original reagent. It can be said that it is immobilisation of an organic reagent on the solid matrix that occurs in the former case, while in the latter case one deals with the formation of a new polymeric compound.

There are numerous examples of immobilisation of organic reagents on polymeric matrices.^{103, 104} One of the first developed methods was preparation of ion-exchange resins with absorbed reagents.¹⁰⁵ This consisted of common organic reagents containing sulfo or other acidic groups on an appropriate ion-exchange resin. The analytical functional groups in the sorbed reagent molecules do not lose their ability to bind metal ions. A wide range of different materials, e.g., linear and network polymers

(ion-exchange resins based on styrene and divinylbenzene), polyurethane foams, activated charcoal, other organic and inorganic materials serve as solid matrices. The possibility of using ion-exchange resins in photometry was established¹⁰⁶ and reviewed.¹⁰⁷ A linear coloristic method was proposed for the determination of iron(III) and copper(II) with the use of hydrophobic silica gels with non-covalently immobilised Xylenol Orange or PAN as indicator powders.¹⁰⁸ Luminescent reagents can be immobilised as well, for example, luminol (3-aminophthalohydrazide), Rhodamine B {[9-(2-carboxyphenyl)-6-diethylamino-3*H*-xanthen-3-ylidene]diethylammonium chloride}, while glass, silica gel or organic polymers serve as the inert support.¹⁰⁹ For instance, it was proposed to use immobilised morine for the sorption-fluorimetric determination of zirconium and tin.¹¹⁰ Polyurethane foams also present a considerable interest as sorbents due to their high efficiency in combination with versatility and high chemical and mechanical stability. Methods of concentration and determination were developed for more than 50 chemical elements.^{111–116}

The detection of an analytical signal can be based on direct measurement of light absorption by the organic reagent modified by an ion-exchange resin, as well as on the application of reflectance spectroscopy. The former method called solid-phase spectrophotometry was proposed by Japanese researchers,¹¹⁷ who were the first to establish a linear dependence of the light absorption by the solid phase on the concentration of the element in the initial solution. Different versions of this procedure were developed, including sorption of the metal–reagent complex by the ion-exchange resin and, *vice versa*, preliminary sorption of the reagent and its reaction with the metal in the sorbent phase.¹¹⁸ Since the reagent is the active principle in both cases, it is possible to say that the organic reagent is immobilised on, and modified by, the ion-exchange resin.

2. Ion-exchange membranes

Yet another modern material that is used as a solid matrix is the ion-exchange membrane in a form of a thin film, plate or filter. It was established that the analytical efficiency of organic reagents increases upon immobilisation on such membranes. There are different versions of the practical implementation of this method of preconcentration and determination. Optically transparent membranes [for example, based on poly(vinyl chloride)], impregnated with trioctylamine in order to make them work as ion-exchange resins, are treated with a solution of a complex of a metal with an organic reagent (for example, Nb with PAR). The complex is adsorbed on the membrane and then the optical density is measured in a usual manner (in transmission mode).

As the interaction between the complex and the membrane active groups is mainly electrostatic in essence (formation of a salt or an ion associate), one can say that in such systems, *e.g.*, with polycapraamide membranes, the complex or the reagent incorporated in the matrix is modified (and immobilised). The equation of a reaction for a single unit can be written as follows:

where $\rightleftharpoons \text{N}^+ \text{Cl}^-$ is a membrane polymer chain unit, $-\text{O}_3\text{SRM}$ is an anion of metal complex with the reagent and $\rightleftharpoons \text{NO}_3\text{SRM}$ is a polymer chain unit with an attached complex.

Other applications of membranes are also known.^{119, 120} For instance, a cobalt complex with PAN was concentrated on thin ion-exchange films with subsequent determination of the metal directly in the sorbent phase. A number of reviews is devoted to the use of organic reagents in the sorption spectral methods.^{121–124} Dynamic sorption preconcentration of elements with subsequent spectroscopic study has been surveyed.¹²⁵

V. New classes of organic reagents

1. Receptor molecules

Macrocyclic ethers, the so-called crown ethers, are of considerable interest in many fields of chemistry, in particular, in analytical chemistry.¹²⁶ The molecules of crown ethers represent rings of nine or more atoms, at least three of them being oxygen atoms. 18-Crown-6 with six oxygen atoms in the ring is the most famous. A number of macrocyclic compounds containing secondary, tertiary, pyridinium-type, pyrrolium-type, azomethine, *etc.* nitrogen atoms (azacrown compounds), oxygen and nitrogen (oxazacrown compounds, cryptands), sulfur (thiacrown compounds), oxygen and sulfur (oxathiacrown compounds), nitrogen and sulfur (azathiacrowns) and so on were synthesised. Porphyrins belong to natural macrocycles.

The area of the use of macrocycles in the chemical analysis is extremely wide. They serve as reagents in photometry, in luminescence analysis (in conventional and extraction versions for ion pairs with the dye anion) and flow-injection analysis. They are also used as components of membranes for ion-selective electrodes, in sorption methods (following immobilisation on a surface), liquid and gas chromatography, extractive separation of alkali and alkaline-earth metals as well as radionuclides, *etc.*^{126, 127}

The ability of macrocycles to form more stable complexes with metals with higher selectivity as compared to the acyclic ligands was called the macrocyclic effect.⁹⁰ This effect is caused by the fit of the macrocycle cavity to the size of the metal ion, as well as by the properties of the donor heteroatoms. In addition, a multi-centre and multifunctional ion-to-ligand binding occurs, which forms the basis of the molecular recognition effect, or the host–guest correspondence principle. The multifunctional nature of the interaction is caused by the involvement of electrostatic (ion–ion, ion–dipole, dipole–dipole), donor–acceptor, π – π -stacking, van der Waals and hydrophobic interactions and hydrogen bonding. With account of the enthalpy factor, such systems have much in common with biosystems.

3D Receptor molecules with cavities of definite size, such as cryptands, spherands, cryptospherands, cavitands in a form of a bowl, and also carcerands which have a form of coupled cups are the most efficient as regards both selectivity and the strength of binding to the analyte.^{90, 126}

These receptor molecules exhibit quite unique properties.^{128, 129} One of the spherands forms a stable complex with sodium ions ($\log K_{\text{stab}} = 14.1$) with the $\text{Na}^+ : \text{K}^+$ selectivity of 10^{10} ! A photometric reagent for lithium ions of the torand family changes its colour upon replacement of the protons at the secondary nitrogen atom inside the ring. Molar extinction coefficients of such compounds (*e.g.*, metal porphyrins) are in the range of $n \times 10^5$.

The receptor molecules most widely used in different methods of analysis, separation and preconcentration are cyclodextrins (having the shape of a truncated cone) and calixarenes (having the shape of a basket).⁷¹ The use of cyclodextrins in chemical analysis is reviewed.^{130–135}

An important feature of the receptor molecules is the ability to bind not only metal cations, but also anions^{90, 126, 128} or neutral organic molecules. In the case of organic compounds, the selectivity of receptors is manifested not only with respect to molecules of different sizes and nature, but also with respect to structural, geometrical and optical isomers. The separation and determination of enantiomers of pharmaceutical preparations, amino acids and other biologically active compounds by means of gas-liquid^{130, 131, 134, 135} and liquid^{136–138} chromatography, capillary electrophoresis,¹³⁸ extraction¹³¹ and other methods^{131, 136, 139} with the use of cyclodextrins as a mobile or stationary phase have become a common tool in the analytical practice. Cyclodextrins and calixarenes are widely employed in the luminescence analysis^{130, 133} and in chemical sensors.^{133, 140, 141} A series of receptor molecules for the anion determination were synthesised.¹⁴² Aptamers belonging to the class of oligonucleotides¹⁴³

represent a new type of analytical reagents the action of which is also based on molecular recognition.

2. Miscellaneous new classes of organic reagents

In recent years, the methods of determination of organic compounds both in the common objects (*e.g.*, in liquid media) and in biomaterials, were successfully developed. Enzymes used for the determination of metal ions,^{144, 145} organometallic¹⁴⁶ and organic compounds^{147, 148} both in solution and in the immobilised state are a new type of organic reagents. These reagents exhibit not only high sensitivity allowing the determination of many compounds on the nano- and picomolar levels, but also an extremely high selectivity that is characteristic of all enzymatic reactions. Fluoroimmunoassay based on the use of antigen–antibody interaction in different variants of registration of fluorescence as an analytical signal^{149, 150} is closely related to this group of methods.

Many other organic reagents for determination of organic compounds are known, for example, widely used *o*-phthalaldehyde for primary and secondary amines and thiols,^{151, 152} lophine derivatives (for a review, see Ref. 153) and other reagents (see reviews^{154, 155}). Organic reagents are used for the determination of biological macromolecules,¹⁰ the action of some reagents is based on the formation of charge-transfer complexes,^{156, 157} metal diketonates can be used for the recognition of organic molecules.¹⁵⁸ Carbon tetrachloride can be determined by photochemical reactions.¹⁵⁹ New types of acyclic reagents for metals exhibit surprisingly high selectivity.¹⁶⁰

Yet another method, the potential of which is not highly appreciated, is the determination of some metals and especially organic compounds by organic reagents in excited states. These analytical reactions are based on intra- and intermolecular transfer of excitation energy of molecules solubilised in different organised systems, which favours the concentration and close contact of the reactants. For example, in the widely known multicomponent system Eu(III)–thenoyltrifluoroacetone (TTA)–phenanthroline (or trioctylphosphine oxide)–surfactant, three TTA molecules excite to the singlet state as a result of light absorption, and then pass to the triplet state by intersystem crossing. Due to the relatively long lifetime and high energy of the excited state, the excitation energy is transferred intramolecularly from the TTA to the excited levels of Eu³⁺ (the antenna effect). As a result, the intensity of Eu³⁺ radiation increases virtually by an order of magnitude, and its detection limit drops to 10^{−9}–10^{−12} mol litre^{−1} (Refs 161 and 162).

An additional decrease in the europium detection limit by 1–2 orders of magnitude can be acquired on addition of a second rare-earth ion (for instance, gadolinium, terbium, yttrium), which serves as the intermediate unit in the energy transfer from ligand to the europium ion.^{162, 163} In addition to TTA, a number of other types of reagents, including macrocycles, can be used as antenna ligands.¹⁶⁴ This method also allows determination of samarium, terbium, gadolinium, dysprosium, and curium.¹⁶⁵ The advantage of these multicomponent systems is that they provide a possibility of determination of not only metal, but also an organic ligand from quenching¹⁶⁶ as well as from enhancement of the sensitised fluorescence.¹⁶⁷

Yet another implementation of organic reagents in the excited state is the determination of polycyclic aromatic hydrocarbons with the use of acridine dyes by means of sensibilised phosphorescence at room temperature in micelles.^{168, 169} The method is selective, because the excitation of a dye takes place in the visible range. The dye molecule excites from the singlet to the triplet excited state under the influence of a heavy atom, and then a triplet-to-triplet energy transfer to the hydrocarbon molecule occurs (the triplet excitation energy for polycyclic aromatic hydrocarbon is lower than that for dye), and the hydrocarbon phosphorescence is detected. With the use of micelles, one can avoid liquid-nitrogen techniques and study the phosphorescence in solution at room temperature. Reagents based on self-organ-

ised supramolecular ensembles are also promising (for a review, see Ref. 170).

VI. Conclusion

The analysis of more than hundred years history of applications of the organic reagents in the analytical chemistry shows that they have played a significant role in both the development of the theoretical concepts in this area of science and the practical chemical analysis of many organic and inorganic subjects. Virtually each element of the Periodic Table in various concentrations, amounts and forms can be determined with the help of different classes of organic reagents. According to a rough estimate, more than 6000 organic compounds were proposed as analytical reagents. About 100 of them can be considered 'basic', *i.e.*, original as regards their chemical structures and analytical properties (sensitivity, selectivity, *etc.*), while others are in fact their derivatives exceeding them in the major analytical parameters. Usually, this excess is not higher than 2–3 times, so the replacement of the 'basic' reagents by their analogues (which often are much more expensive) is not always reasonable, taking into account the necessity of modifying the established protocols.

An intense development of physical methods of analysis, especially since the mid-20th century together with their obvious advantages (sensitivity, possibility of express analysis and automation, in many cases multielement analysis, *etc.*) was seemingly condemning the chemical methods (in particular, those with the use of organic reagents) to the gradual deprecation. However, new approaches and potentials emerged in the 1970–1980's and are actively implemented since then.

1. Automation of almost all stages of chemical analysis (from sampling, decomposition, component separation, concentration, *etc.* to the determination of compounds and elements) became possible. This allows quick analysis of a large number of samples, which is especially important in environmental monitoring, sanitary analysis and in many other cases.

2. Low cost of chemical methods of analysis as compared to physical ones plays an important role since the necessary equipment and reagents in the former are by orders of magnitude cheaper. A set of test methods have been developed (much of them with the use of organic reagents), which use quite a compact equipment and are low energy-consuming, and hence can be used in field analysis and are indispensable for environmental control, in extraordinary situations, *etc.*

3. In the last 20–30 years, the approach to the synthesis of new organic reagents has changed dramatically. Chemists engaged in analysis (as well as in synthesis) came to a conclusion that the infinite broadening of the assortment of related organic reagents containing the same analytical functional group and giving only a slight enhancement of the analytical properties as compared to the parent reagent is unreasonable. The use of modified and immobilised organic analytical reagents (or systems) appeared to be more promising. It is important that the reagents in use are basically the same, but their analytical characteristics are enhanced multiply due to their modification with auxiliary reagents. The efficiency of their analytical use grows in the same proportion. The same statement holds to even greater extent for the organised media and the receptor molecules that operate on the principle of molecular recognition.

4. Modern electronic techniques and small-sized measurement devices (pocket-type of third and fourth generations) open up broad perspectives of the use of chemical methods of analysis (including those using organic reagents) for extensive quick analyses in the environmental monitoring, medicine and other fields of science and technology. Further progress in this direction can provide us with the new measurable parameters for such systems and ways of their measurement, as well as with the new instrumental and computing methods, taking into account the intense development of the computing techniques and high technologies.

The review was prepared with the financial support of the Russian Foundation for Basic Research (Project Nos 04-03-32526 and 04-03-32946). Authors are grateful to L S Shtykova for the cooperation in the preparation of this review.

Principal trends in the chemistry of amidinate complexes of main-group and transition elements

D A Kissounko, M V Zabalov, G P Brusova, D A Lemenovskii

Contents

I. Introduction	351
II. Structures of amidinate complexes	351
III. Synthesis and chemical properties of amidinate complexes	354
IV. Conclusion	372

Abstract. Principal trends in modern organometallic chemistry of transition and main group elements containing amidinate ligands are analysed. The nature of element–amidinate ligand bonding inferred from the X-ray structural data and computational studies is discussed. Synthesis and reactivity of Group 1–15 metal amidinate complexes are reviewed. Particular emphasis is drawn to the use of amidinate complexes as catalysts for olefin polymerisation and organic synthesis. Prospects in the development in this area of chemistry are suggested. The bibliography includes 151 references.

I. Introduction

Over the past decade there has been a growing interest in non-metallocene main group and transition metals complexes as catalysts for olefin polymerisation and organic synthesis.¹ The rational for a closer attention to such systems is often explained as the lack of new groundbreaking chemical transformations for analogous metallocene complexes, which have been extensively studied since the mid-1950s. Hence, there is an essential need for other ancillary ligands, which would provide new types of organometallic complexes exhibiting unusual electronic and structural properties.

Complexes with allylic ligands and their heteroanalogues, *viz.*, NNN- (triazene) and PNP- (phosphazene) ligands are typically referred as non-metallocene derivatives. These compounds are widely used in such important area as asymmetric catalysis.^{2–4} Over the past decade the considerable attention has also been paid to NCN-analogues of allylic group, *viz.*, to amidinate ligands:

Received 27 June 2005

Uspekhi Khimii 75 (5) 395–421 (2006); translated by D A Yufit

The particular interest to amidinate is caused primarily by the commercial availability of a wide range of synthetic precursors — carbodiimides. Also of significant importance is the simplicity of preparation of amidinate complexes. Moreover, amidinate ancillary ligand is known to enhance the thermodynamic stability of a corresponding complex; thus, many cationic intermediates, which are unstable for related metallocene analogues, were isolated for amidinate derivatives. The ability to study such intermediates has greatly improved the knowledge of reaction mechanisms in such vital area as cationic olefin polymerisation.⁵

Synthesis and properties of amidinate complexes published prior to 1994 were comprehensively discussed in earlier reviews.^{6–9} However, despite the growing number of publications in this field over the past decade, there has been only a single review article dealing with ruthenium amidinate complexes.¹⁰ Hence, this justifies the need for an updated review on organometallic amidinate complexes. The present review is divided into two parts. The first part is devoted to a discussion of metal–amidinate ligand bonding inferred from X-ray diffraction data and computational studies. The other one deals with the chemical behaviour of amidinate complexes. The latter also contains detailed discussion of applications of amidinate derivatives in organic synthesis and catalysis. Future developments in the research of amidinate complexes are analysed in Conclusion.

Due to the limited space available, the metal complexes with neutral analogues of amidinate systems, *i.e.*, amidine ligands, are out of scope of the present review. Information about these compounds can be found in earlier reviews.^{11–13}

II. Structures of amidinate complexes

To date, the structures of amidinate complexes of different elements are reasonably well studied. Amidinate ligands behave as two- or (more often) four-electron donors depending on the nature of the central atom.⁷ Therefore, this system might be referred to as a hetero-analogue of the well known allylic ligand. However, the presence of molecular orbitals n^+ and n^- (Fig. 1) where the electrons of the nitrogen lone pairs are mostly localised results in significant difference in coordination modes of the amidinate and allylic fragments to metals.

Analysis of bonding of amidinate ligands with Group 14 elements (Si, Ge, Sn, Pb) as well as of the structure of a non-coordinated amidinate anion has been performed by detailed quantum-chemical calculations (by the extended Hückel method and by MP2/ECP-31G*).¹⁴ It was found that the N–C bond in a coordinated ligand is significantly longer (by ~ 0.1 Å) and the NCN bond angle is smaller in comparison with those in the non-coordinated anion. The decrease in the NCN bond angle occurs in

Figure 1. Molecular orbital diagram for the amidinate anion.

parallel to the decrease in the atomic radius of the corresponding element ($\text{Pb} < \text{Sn} < \text{Ge} < \text{Si}$). The calculated bond lengths and bond angles in amidinate complexes of Group 14 elements are listed below.

	E	The C≡N bond length/Å	The NCN angle/deg
—	—	1.252	125.7
Si	—	1.349	106.2
Ge	—	1.348	108.6
Sn	—	1.347	111.6
Pb	—	1.347	113.9

It should be noted that no calculations of this type have been documented for transition metal complexes. The only publication¹⁵ reports DFT calculations of ethylene molecule coordination parameters in titanium and zirconium bis(amidinate) complexes. However, no data on the geometrical parameters of the amidinate ligand itself are given and only bond angles NTiN and NZrN (128.3° and 127.8° , respectively) are presented.

Eight types of coordination of the amidinate ligand to metals can theoretically be predicted based on its electronic and spatial structures (structures **A–H**).

It should be noted that no η^3 -coordinated amidinate ligands (structure **A**, an analogue of the π -allylic system) and structures **E** have been reported so far. The other structural types have been discussed.^{8,9}

M is metal, An is anion.

The main sources of information about the structures of amidinate complexes are single crystal X-ray structural studies and the spectroscopic data (IR, NMR, *etc.*). Typically, the $\text{MN}(1)\text{CN}(2)$ metallacycle in amidinate complexes of transition and main-group elements is non-planar. In the **C**- and **D**-type structures, this ring usually adopts the 'folded envelope' conformation with dihedral angles between the $\text{MN}(1)\text{C}$ and $\text{MN}(2)\text{C}$ planes varying over a wide range (from 5° to 45°) (see Refs 8 and 9). The degree of pyramidalisation (ΣQ_N) of the nitrogen atoms in the amidinate ligand is yet another important criterion of non-planarity of the $\text{MN}(1)\text{CN}(2)$ metallacycle. This parameter is the sum of all bond angles of a nitrogen atom and is opposite to planarity. A decrease in ΣQ_N value, for example, due to a decrease in the bulk of substituents corresponds to higher degree of nitrogen pyramidalisation and, therefore, to greater deviation of the $\text{MN}(1)\text{CN}(2)$ metallacycle geometry from planarity. The mean values of the degree of pyramidalisation of nitrogen atoms in amidinate complexes are in the range of 335 – 360° (see Refs 8 and 9).

A short description of complexes of each known structural type is given below. The selection of examples of the structures **B–D** and **F–H** is entirely random. We just tried to emphasise the features of each coordination type as clearly as possible. Further in the text (see Section III), schematic depiction of complexes **B–G** implies a real structure determined objectively.

Very few examples of the structural type **B** with monodentate σ -amidinate ligands are known to date. Thus the $\text{Pt}–\text{N}$ distance in platinum complex **1** is equal to $2.132(6)$ Å and the NCN bond angle is $113.4(5)^\circ$ (see Ref. 16).

$p\text{-Tol} = 4\text{-MeC}_6\text{H}_4$.

Yet another stable compound of this type is σ -organomercury complex **2** with unusual dynamic properties in solution.¹⁷ Also, type **B** compounds were postulated (based on the IR spectra) to serve as intermediates in the insertion of CO into the $\text{M}–\text{N}$ bond of rhodium amidinate complexes to yield the corresponding carbamide complexes.¹⁸ Unusual zwitter-ionic thallium amidinate complexes of the general formula **3** with formally positively charged amidinate groups have recently been obtained by Minkin and co-workers.¹⁹

E = CO_2Me ; Ar = 1-naphthyl, 2- ClC_6H_4 , 2- $\text{Cl-6-MeC}_6\text{H}_3$.

According to X-ray diffraction data, the thallium atom in these complexes is σ -coordinated to the nitrogen atom and therefore these complexes may be regarded as type **B** compounds. The Tl–N distance is equal to 2.833(6) Å (for Ar = 2-Cl-6-MeC₆H₃). The distinctive features of complexes **3** include also η^5 -coordination of thallium with the π -system of the cyclopentadienyl ring and Z-configuration of the amidinate ligand. The C–N bond lengths are equal to 1.374(10) and 1.283(10) Å, the NCN bond angle is 119.8(7)°.

Most of known amidinate complexes belong to the structural type **C**. Dimers **4** (see Ref. 20) and **5** (see Ref. 21) are the most typical examples of such complexes of the main-group and transition elements, respectively.

The Na–N distances in compound **4** are equal to 2.617(5), 2.482(5), 2.426(5) and 2.725(5) Å; all NCN bond angles are 121.0(5)°. The Cr–N distances in complex **5a** amount to 2.100(4), 2.096(3), 2.092(4) and 2.095(3) Å; both NCN bond angles are equal to each other [116.4(4)°] as in the case of compound **4**. The derivatives of other alkali and alkaline-earth metals often form stable dimeric associates in crystals.^{8,9} The ‘ladder’-type aggregates are also known, in which dimerisation of amidinate salt is inhibited by co-crystallisation with inorganic salts MX (M is an alkali metal, X is an inorganic acid anion, for example Cl, I, Br) or with alkalis. Thus associate **6** was obtained by co-crystallisation of Li[BuⁿNC(Buⁿ)NBu^t] with LiI from a solution in THF.²²

Monomeric amidinate complexes with ‘constrained’ geometry can also be mentioned. In 2000, Lappert and co-workers²³ synthesised lithium complex **7**, which was transformed into aluminium (**8**) and gallium (**9**) amidinate derivatives.

Complexes **8** and **9** are monomeric due to additional coordination of the nitrogen atom of the CH₂CH₂NMe₂ fragment by the central atom of the main-group metal. Usually, in the case of such additional coordination, the M–NMe₂ bond lengths became effectively equal to the M–N bond lengths in normal amidinate complexes. The structural parameters of compounds **7–9** are listed below.

Parameter	Compound		
	7 (M = Li)	8	9
Bond lengths / Å			
M–N(1)	2.050(3)	2.0929(16)	2.1407(18)
M–N(2)	2.015(3)	1.9053(15)	1.9592(15)
M–N(3)	1.989(3)	2.0182(16)	2.1130(17)
Bond angle N(2)CN(3) / deg	119.0(2)	111.20(15)	112.27(16)

The NCN bond lengths in these complexes are within a standard range of the values for all amidinate ligands,^{8,9} which is common for all coordination types (**C**, **D**, **F** and **G**). A detailed structural analysis of a series of tris(amidinate) complexes of transition metals (Cr, Fe, Co, Ru) of type **C** is given by Cotton *et al.*²⁴

Non-symmetrically coordinated amidinate ligand represents the structural type **D**. In this case both nitrogen atoms are bonded to metal, but one forms formally a M–N σ -bond while another is coordinated by its lone electron pair. Quite a few complexes of this coordination type are known. Complex **10** can be taken as an example.²⁵

According to the X-ray data, the pairs of Ta–N distances are equal to 2.098(14), 2.196(16) and 2.058(15), 2.180(20) Å. The NCN bond angles are within expected values and are equal to 109.4(16)° and 105.4(20)°. Dihedral angles between TaN(1)C and TaN(2)C, where C is the central carbon atom in the NCN fragment of the amidinate ligand, are equal to 10.7° and 15.5°. The mean value of $\Sigma Q_N = 346.9^\circ$ indicates significant pyramidalisation of nitrogen atoms.

Structures **F** are relatively common for amidinate complexes possessing metal–metal bond. For instance, the platinum atom in bimetallic complex **11** (see Ref. 26) has a square-planar coordination with distances Pt–N equal to 2.155(9), 2.097(9) and 2.080(1) Å for nitrogen atoms N(1), N(3) and N(4) respectively.

HgBrCl occupies an apical position relative to the plane of the platinum atom and two nitrogen atoms of the bis(dimethylamino)methylphenyl substituent with the Pt–Hg distance equal to 2.8331(7) Å. The amidinate ligand itself is bonded to mercury atom through the nitrogen atom of the NPrⁱ fragment, the Hg–N(2) bond length is 2.16(1) Å. The five-membered NCNHgPt ring is non-planar and the HgClBrN fragment is rotated such as to avoid staggered conformation of M–N bonds. In this case, the dihedral angle N(2)–Hg–Pt–N(1) is equal to 16.5(4)° and the NCN bond angle [125.0(1)°], in contrast to those found in most amidinate complexes, is larger than the theoretical value (120°). The ΣQ_N parameter for both nitrogen atoms is 360° indicating virtually planar trigonal configuration of nitrogen atoms in the amidinate ligand.

The structural type **G** is rather rare and has only been found in cluster complexes. For example, the amidinate ligand in the osmium cluster $[\text{Os}_3(\mu\text{-H})(\text{CO})_9]\{\text{NPhC(Ph)NH}\}$ **12** (see Ref. 27) is formally a five-electron donor. According to data from ^1H NMR spectroscopy, a bridging hydrogen atom is present in complex **12**; however, its position could not be located from X-ray diffraction analysis.

The Os–N bond lengths in metal complex **12** are equal to 2.198(23), 2.193(23) Å for osmium atoms linked to the nitrogen atom by a coordinated bond and to 2.141(22) Å for the σ -bond Os–N. Remarkably, the NCN bond angle [121.7(25)°] is slightly larger than the theoretical value, as it was also observed in complex **11**. Over the last decade, no new complexes of type **G** have been synthesised and therefore they are not discussed in the present review.

Structures **H** are of the most uncommon type of metal amidinate derivatives. In this case the protonated amidinate cation is a counter-ion of an organometallic anion, *i.e.*, there is no bonding between the amidinate moiety and the metal atom. Ionic complex **13** (see Ref. 28) is an example of such compound. Nitrogen atoms in salt **13** are virtually planar, the ΣQ_N parameter is 358°.

In closing this Section, it can be noted that the use of sterically hindered amidinate ligands often imparts unusual structural features to the molecules. For instance, the metal–metal distances in complexes **5b** (see Ref. 29) and **14** (see Ref. 30) are very short [$r_{\text{Cr-Cr}} = 1.913(3)$, $r_{\text{V-V}} = 1.698(2)$ Å] due to the presence of bulky cyclohexyl substituents at the nitrogen atoms.

Cy = cyclo- C_6H_{11} .

Presumably,³⁰ strong repulsion between the axial hydrogen atoms of the cyclohexane rings forces the two metal atoms to approach each other (a fragment of complex **14** is shown below). As a result, the equilibrium van der Waals radii of hydrogen atoms are equal to ~ 1.89 Å.

III. Synthesis and chemical properties of amidinate complexes

A large number of amidinate complexes of transition and main-group metals are currently known. In this Section synthesis and chemical properties of these compounds as well as their industrial applications are discussed. For the sake of convenience, the data are divided in two parts dealing separately with main-group and transition metals. The derivatives of the elements of Groups 1 to 15 of the Periodic Table are discussed.[†]

Four main approaches to the synthesis of amidinate complexes are known. The first one is the insertion of a σ -alkyl group (usually, the methyl group) of an organometallic fragment of the $\text{M}-\text{R}$ type into the $\text{C}=\text{N}$ double bond of carbodiimides. This method is fairly popular, since these reactions usually proceed under mild conditions and produce the corresponding amidinate derivatives in high yields.

The second approach involves deprotonation of amidine ligands by organometallic compounds containing σ -alkyl ($\text{M}-\text{R}$) or σ -amide ($\text{M}-\text{NR}_2$) groups. This method is mainly used for the synthesis of alkali and alkaline-earth metal amidinates and derivatives of transition metals of Groups 3–5.

X = Alk, NMe_2 .

The most widespread method of synthesis of amidinate complexes of transition and main-group elements is the reaction of anionic amidinate salts of alkali and alkaline-earth metals with halides of Group 3–15 elements.

Finally, the reaction of metal bis(trimethylsilyl)amides with alkyl or aryl cyanides has to be mentioned as a general method of synthesis of 1,3-bis(trimethylsilyl)amidinate complexes.

[†] The 'long-period' version of the Mendeleev Periodic Table, in which the Groups of elements are indicated by Arabic numerals from 1 to 18, is used.

R = Alk, Ar.

Below we discuss the general methods of synthesis of amidinate complexes as well as specific reactions for each group of elements. The structures of all compounds mentioned in this Section are established by physicochemical analytical methods (IR- and UV-spectroscopy, NMR spectroscopy, mass spectrometry and in some cases by X-ray crystallography).

1. Amidinate complexes of main-group elements

a. Group 1 elements (Li, Na and K)

Alkali metal (mainly, lithium and sodium) amidinate derivatives attract attention as starting compounds in the synthesis of other amidinate complexes. Two major methods of synthesis of such compounds are known. The first one is the addition of an organometallic compound R–M (M = Li, Na) to the N=C double bond of carbodiimides.^{31–33}

R¹, R², R³ = Alk, Ar; M = Li, Na, K; X = Buⁿ, N(SiMe₃)₂.

An alternative way is the deprotonation of amidines by an organometallic base, for example, by BuⁿLi, NaN(SiMe₃)₂ or KN(SiMe₃)₂.^{34–36} Usually such reactions proceed in quantitative yields.

The reaction of carbonitriles with alkali metal bis(trimethylsilyl)amides is a convenient method of synthesis of 1,3-bis(trimethylsilyl)amidinate complexes.^{9, 37–40}

R = Alk, Ar; M = Li, Na, K.

Particular synthetic aspects for these compounds and their applications for the preparation of a series of 1,3-bis(trimethylsilyl)amidinate complexes of transition and main-group elements are described in detail in a review.⁹

Amidinate complexes of Group 1 metals react with organic electrophiles yielding substituted amidines, and their reactions with metal halides afford the corresponding amidinate complexes. Preparation of complexes **15** and **16** is an example of the use of alkali metal amidinate complexes in the synthesis of the corresponding derivatives of transition and main-group elements.^{41, 42}

R = H, C₆H₄Ph-*p*.

These reactions will be discussed in detail in appropriate Sections. Studies on the synthesis of different amidinate complexes of Group 1 metal derivatives are summarised in reviews.^{6–9} This method is still widely used. A new development of this method is the synthesis of sterically hindered and/or chiral amidinate derivatives of alkali metals. These compounds can further be transformed into the corresponding transition metal complexes with a potential practical application in asymmetric catalysis.⁴³

In 2002 chiral bis(amidinate) complexes **17a–c** were obtained by direct metallation of amidines by lithium, sodium and potassium bis(trimethylsilyl)amides.⁴⁴

Ar¹ = Ar² = C₆H₄Me-*p*; M = Li (**a**), K (**c**);

Ar¹ = C₆H₄Bu^t-*p*, Ar² = C₆H₄OMe-*p*, M = Na (**b**).

Similar trimethylsilyl derivatives **18** were obtained³⁵ by the addition of N-anions formed on treatment of bis(trimethylsilyl)amines) with 2 equiv. of butyllithium to the benzonitrile C≡N bond. Lithium monoamidinate complex **19** is formed in this reaction if equimolar amounts of the base and nitrile are used (Scheme 1).

Sterically hindered amidinate complexes **20a–c** were synthesised recently by the reaction of the corresponding aryllithium derivatives with diisopropylcarbodiimide.³⁴

Ar = Ph (**a**), C₆H₄Bu^t-*p* (**b**), 2,4,6-Me₃C₆H₂ (**c**).

Scheme 1

b. Group 2 elements (Mg, Ca, Sr and Ba)

Amidinate complexes of Group 2 elements are less studied than their alkali metal analogues. Data on the synthesis of these complexes published before 1994 were summarised in a review.⁹ No papers on the preparation of calcium, strontium and barium amidinate complexes have been published since 1994 and very few articles on the synthesis of the corresponding magnesium derivatives appeared. It has to be noted that no beryllium amidinate complexes are known so far.

As for amidinate complexes of Group 1 metals, three general methods are used for the synthesis of organomagnesium derivatives. The first two methods afford the products in high yields (>80%). Thus complex **21** was synthesised³⁴ by addition of sterically hindered arylmagnesium iodide to the N=C double bond of diisopropylcarbodiimide. This complex was isolated and characterised as a THF solvate.

Mono- (**22**)⁴⁵ and bis(amidinate) (**23**)³⁴ complexes were obtained by deprotonation of amidines with organomagnesium compounds.

Cp = $\eta^5\text{-C}_5\text{H}_5$.

Mes = 2,4,6-Me₃C₆H₂.

Similar method was used in the synthesis⁴⁶ of dinuclear magnesium complexes **25a,b** from bisamidines **24a,b**.

X = OMe (a), NMe₂ (b).

The addition of magnesium hexamethyldisylazide to the multiple C≡N bond of benzonitrile results in the formation of magnesium 1,3-bis(trimethylsilyl)amidinate complex **26**.⁴⁷

Magnesium amidinate complexes can also be obtained by amidinate ligand exchange between lithium amidinate and magnesium halide.⁴⁸ These reactions are usually carried out in ether and the driving force of the process is the formation of insoluble salt LiX (X = Cl, Br). Depending on the character of the substituents at the nitrogen atoms of the amidinate ligand, either mononuclear (**27a,b**) or dinuclear (**28, 29**) magnesium complexes are formed.

27a,b: R = Me (a), Ph (b)

Currently synthesis of sterically hindered ligands (for example, as in type **21** and **23** complexes) is the most intensively developing area in the chemistry of amidinate complexes of Group 2 metals. These derivatives were successfully used for the preparation of transition metal-based asymmetric catalysts.⁴³ For the same reason, the complexes with 'constrained' geometry (**25a,b**) are also of interest. In addition, magnesium amidinate derivatives **22** and **25a,b** are used as volatile organomagnesium compounds in CVD (Chemical Vapour Deposition) technology.^{45, 46}

c. Group 12 elements (Zn, Cd and Hg)

Unusual structural properties are the main reasons for the interest in zinc, cadmium and mercury amidinate derivatives. For example, the most unusual coordination types **B**,¹⁷ **F**²⁶ and **G**⁸ of the amidinate ligand are common for these compounds. A detailed discussion of the data on the synthesis, structure and properties of amidinate complexes of Group 12 elements is reviewed.⁸

Due to the high toxicity of such elements as cadmium and mercury, no chemical studies on the amidinate complexes of Group 12 elements have been carried out since 1994. Therefore, this group of compounds is not discussed in the present review.

d. Group 13 elements (B, Al, Ga, In and Tl)

Among the amidinate complexes of Group 13 metals, aluminium derivatives, which are used as olefin polymerisation catalysts, are of prime importance.^{49–52} At present, gallium, indium and thallium amidinate complexes are of limited theoretical and practical interest; very few papers^{23, 53–57} have been published on this subject since 1994. Only one paper⁶⁰ dealing with the synthesis of new boron amidinate derivatives has been published since the discovery of organoboron amidinate complexes by Lappert and co-workers^{58, 59} in the early seventies. Difficulties encountered with the isolation of these boron compounds due to large amounts of by-products have been noted in all the three papers.

There are four major methods of synthesis of amidinate complexes of Group 13 elements.

The first one is the deprotonation of amidines by organoaluminium compounds, in most cases by trimethylaluminium. Complexes **30a,b** with 'constrained' geometry were obtained from bis(amidines) **24a,b** by this method.⁴⁵

X = OMe (**a**), NMe₂ (**b**).

Bis(amidinate) complexes **31a,b** were synthesised similarly in moderate yields (35%–60%).⁶¹ If the amidine nitrogen atoms of compound **31** carry different substituents, this complex exists in solution as two structural isomers **31b** and **32b**. Depending on the mutual orientation of the amidinate ligands, these isomers are of either C_s- (**31b**) or C₂-symmetry (**32b**). According to data from

NMR spectroscopy (EXCHSY-experiment),⁶¹ the rotational barrier is very low and equal to 0.00(4) kcal mol^{−1}.

R¹ = R² = Prⁱ (**a**); R¹ = Et, R² = Bu^t (**b**).

This method was successfully used for the synthesis (in satisfactory yields) of dialkylgallium amidinate derivatives⁵⁶ and organoaluminium complexes **33a,b** with bulky amidinate ligands.⁶²

R = Prⁱ (**a**), Cy (**b**).

The second method is the addition of trialkylaluminium derivatives to the N=C double bond in carbodiimides.^{63, 64} These reactions proceed under mild conditions (ambient temperature) and in high yields.

R = Prⁱ, Cy, 2,6-Pr₂C₆H₃, 1-adamantyl.

The addition of a B–Cl fragment to the carbodiimide double bond is a modification of this method. This reaction has been used by Lappert and co-workers^{58, 59} for the synthesis of boron amidinate complexes **35** and **36**.

R¹, R² = Ar; X = Cl, OAlk.

Unfortunately, the absence of X-ray diffraction data precludes unambiguous determination of the coordination mode of amidinate ligands in complexes **35** and **36**.

The third most widely used method of synthesis of amidinate complexes of Group 13 elements is the reaction of lithium amidinates with the corresponding metal halides. Dialkyl derivatives ($X = \text{Alk}$) of aluminium (**34**),^{63–65} gallium (**37**), indium (**38**) and thallium (**39**) were obtained by this method from the corresponding dialkylmetal chlorides used as halides.⁶⁵ Aluminium and gallium trichlorides were used as the starting compounds in the synthesis of the corresponding dichloroamidinate complexes **40**,^{63, 64} and **41**.⁵⁴

M = Al (**34**, **40**), Ga (**37**, **41**), In (**38**), Tl (**39**);

X = Alk (**34**, **37–39**), Cl (**40**, **41**); $\text{R}^1 = \text{Alk}$, SiMe_3 ; $\text{R}^2 = \text{Alk}$.

Aluminium, gallium and indium bis(amidinate) complexes, viz., compounds **42–44**, respectively, are formed in the reaction with a double excess of the starting amidinate salt.^{53, 54, 63}

42: M = Al; $\text{R}^1 = \text{Me}$, Bu^t ; $\text{R}^2 = \text{Pr}^i$, Cy;

43: M = Ga; $\text{R}^1 = \text{H}$, Me; $\text{R}^2 = \text{Me}$, Bu^t , Ph;

44: M = In, $\text{R}^1 = \text{Bu}^t$, $\text{R}^2 = \text{Cy}$.

Aluminium and gallium amidinate complexes with 'constrained' geometry (**8** and **9**) were synthesised similarly.²³

M = Al (**8**, 85%), Ga (**9**, 78%).

The yields of the complexes obtained by three above-mentioned methods vary from moderate to high (40%–90%).

Finally, the fourth method is metathesis of N–Si bonds in trimethylsilyl-substituted amidines and M–X bonds in Group 13 metal halides. This method was successfully used for the synthesis of corresponding dichloroamidinate derivatives of boron (compound **45**), aluminium (**46**), gallium (**47**), indium (**48**) and thallium (**49**).⁶⁰ All reactions proceeded under mild conditions and resulted in high yields of the target products.

M = B (**45**), Al (**46**), Ga (**47**), In (**48**), Tl (**49**).

Complexes of monoalkyl and dialkyl derivatives of the elements of this Group can also be obtained by the reaction of the corresponding mono- and dichlorides with alkylmagnesium compounds. For instance, treatment of indium chloride amidinate complex **44** with methylmagnesium chloride results in the substitution of the methyl group for the chlorine.⁵³

A series of dialkylaluminium⁶³ and -gallium⁵⁴ amidinate complexes were synthesised by this method.

34: M = Al; $\text{R}^1 = \text{Pr}^i$, Cy; $\text{R}^2 = \text{Bn}$, CH_2Bu^t ;

37: M = Ga; $\text{R}^1 = \text{Pr}^i$, Bu^t , Cy; $\text{R}^2 = \text{Me}$, Et, Bn.

It should be noted that amidinate complexes of Group 13 elements are not Lewis acids. Thus treatment of aluminium derivative **50** with *tert*-butyllithium in toluene resulted in displacement of the amidinate ligand out of the coordination sphere of aluminium and the formation of compound **51**,⁶⁶ i.e., a complete destruction of the original complex occurred. The cationic fragment $(\text{Li}_4\text{Am}_3)^+$ of the product **51** is a lithium–nitrogen cluster. Another unusual product was obtained in the reaction of *tert*-butyllithium with compound **50** in a mixture of toluene–THF.¹⁰ Alongside with unidentified compounds, an aluminium tris(amidinate) complex was formed.

The reaction of bis(amidinate) derivatives with the corresponding lithium amidinate is yet another method of synthesis of tris(amidinate) complexes. Indium tris(amidinate) complex was obtained by this way from chloride **44**.⁵³

Dinuclear gallium and indium complexes with bridging amidinate ligand are known. Thus compounds **52** and **53** were obtained in the reaction of amidines with trimethylgallium⁵⁶ and -indium.⁵⁷

52: M = Ga; R¹ = R² = Me; R¹ = H, R² = Ph;

53: M = In, R¹ = Cy, R² = H.

Catalysis of olefin polymerisation is the main application of amidinate complexes of Group 13 elements. Cationic monoalkyl complexes with central aluminium atom are the most active in these processes.^{49, 50, 55} Their gallium analogues were also studied.⁵⁵ Such cationic complexes were obtained in quantitative yields by dealkylation of aluminium (**34**) and gallium (**37**) derivatives with arylboron reagents — [Ph₃C][B(C₆F₅)₄], [PhNHMe₂], [B(C₆F₅)₄] or B(C₆F₅)₃.

Either bi- (**54**) or mononuclear (**55**, **56**) aluminium and gallium complexes are formed in these reactions depending on the amount of the reagent used (0.5 or 1 equiv.). If the equimolar amount of [PhNHMe₂][B(C₆F₅)₄] is used as a cationic activator, the products contain the group X = NMe₂Ph in the organometallic cation.

M = Al (**34**, **54**, **55**), Ga (**37**, **56**); R¹ = Prⁱ, Cy, R² = Me, Bu^t;

[B] = [Ph₃C][B(C₆F₅)₄], X is absent, An = [B(C₆F₅)₄];

[B] = B(C₆F₅)₃, X is absent, An = [MeB(C₆F₅)₃];

[B] = [PhNHMe₂][B(C₆F₅)₄], X = NMe₂Ph, An = [B(C₆F₅)₄].

Two amidinate ligands in dinuclear complexes **54** coordinate aluminium atoms differently.⁴⁹ One of them is bound to two aluminium atoms in the $\mu\text{-}\eta^1, \eta^1$ -mode (structure **F**, Section II). Another ligand coordinates one aluminium atom in the mixed $\mu\text{-}\eta^2, \eta^1$ -mode (structure **D**) and forms a donor-acceptor bond with the second one, *i.e.*, coordinates metal atom in the η^1 -mode. The Al–N distances in amidinate complex **54** (R¹ = Prⁱ, An = [B(C₆F₅)₄]) are 1.979 [Al(2)–N(1)], 1.927 [Al(2)–N(2)] and 2.027 Å [Al(1)–N(1)].⁵⁵ Complexes **54** are dynamically

active in solution, which was confirmed by ¹H NMR spectroscopy.⁵⁵ The dynamic equilibrium observed can be expressed as follows:

Cationic complexes **55** (R¹ = Prⁱ, R² = Bu^t) were used as catalysts of ethylene polymerisation.⁴⁹ Their efficiency appeared to be dependent on the character of the anion An[−] and temperature.

Thus the catalytic activity of compound **55** {An = [MeB(C₆F₅)₃]} at 23 °C in CD₂Cl₂ is low. Raising the temperature to 60 °C (polymerisation in toluene) results in a significant enhancement of the activity (up to 700 g mol^{−1} h^{−1} atm^{−1});[‡] the polyethylene (PE) produced had the following properties: the number average molecular mass (*M*_n) was equal to 176 100, the ratio *M*_w/*M*_n = 2.84 (*M*_w is the weight-average molecular mass). A more active catalyst was formed from amidinate complex **34** (R¹ = Prⁱ, R² = Bu^t) using [Ph₃C][B(C₆F₅)₄] as the demethylation reagent. Complex **55** {An = [B(C₆F₅)₄]} is more active in the reaction of ethylene polymerisation: its activity in toluene at 60 °C is 2480 (*M*_n = 272 200, *M*_w/*M*_n = 3.30) and at 85 °C, 3050 g mol^{−1} h^{−1} atm^{−1} (*M*_n = 184 700, *M*_w/*M*_n = 2.23).

Polymerisation of ethylene in the presence of aluminium amidinate complexes **54** and **55** became the subject of detailed theoretical studies.^{67–70} This process was simulated by different quantum-chemical methods: *ab initio*,^{67, 70} semi-empirical (AM1)⁶⁹ and DFT.^{67, 68, 70} According to these calculations, the transfer of the polymeric chain occurs by a β -hydride shift mechanism. Low catalytic activity of dinuclear complexes of type **54** is due to a high activation barrier for the rate-determining stage of ethylene insertion. Mononuclear complexes **55** are more active polymerisation catalysts. The activity depends on their concentration in the solution. It was shown that the presence of bulky substituents (for example, Bu^t and Prⁱ) in the amidinate ligand favours the formation of mononuclear complexes and decreases the energy barrier to ethylene insertion during polymerisation. An increase in temperature has a similar effect.

Gallium amidinate complexes **56** are also used as catalysts of olefin polymerisation. Besides, they are used for the preparation of gallium nitride-based materials.^{71–73}

e. Group 14 elements (Si, Ge, Sn and Pb)

The recently increased interest in amidinate complexes of Group 14 elements is due to their potential application as starting materials in the manufacture of semiconductors based on germanium and tin nitrides.⁷⁴ The major method of the synthesis of amidinate derivatives of divalent (**57**, **58**) and tetravalent (**59–61**) elements is the reaction of element chlorides with 2 equiv. of lithium amidinate.^{75–80}

[‡] The activity of a catalyst is defined as the mass of a polymer per mol of the catalyst per hour at 1 atm.

57, 60: $M = Ge$, $R^1 = Me$, $R^2 = Pr^i$;
58: $M = Sn$; $R^1 = Me, Bu^t, Ph$; $R^2 = Cy, SiMe_3, SiMe_2Ph$;
59: $M = Si$, $R^1 = Me$, $R^2 = Pr^i$;
61: $M = Sn$; $R^1 = H, Me, Bu^t$; $R^2 = Cy, SiMe_3$.

These reactions proceed under mild conditions and for the tetravalent elements result in the corresponding bis(amidinate) complexes **57–61** in satisfactory yields (> 50%).

The process can be selectively stopped at the stage of mono-derivative **62** if one equivalent of the lithium salt is used in the reaction.⁷⁸ Further addition of $NaN(SiMe_3)_2$ results in the corresponding silylamidoamidinate derivative **63**. If the divalent germanium derivative **62** contains bulky substituents (*e.g.*, cyclohexyl), the second amidinate ligand coordinates the central atom in a σ -mode to form complex **64**.

$R = Me, Bu^t$.

Divalent germanium (**63, 64**) and tin (**65**) amidinate derivatives undergo oxidative addition of chalcogens (sulfur and selenium).^{78, 79, 81} Elementary sulfur and selenium,⁷⁸ 2-phenylthiirane(selenerane) as well as organic disulfides(diselenides) were used as reagents in these processes.^{79, 81}

The reaction products are formed in high yields (> 80%). The structures of complexes **66–75** were determined by X-ray diffraction analysis. The $Ge-N$ bond lengths in η^1 -coordinated amidinate ligands are in the range of 1.8–2.0 Å, *i.e.*, they are shorter than the corresponding $Ge-N$ bonds in chelated amidinate ligands (2.0–2.05 Å). Interestingly, the coordination of the second amidinate ligand is changed upon formation of germanium bisulfide (or biselenide) amidinate complexes **74** and **75**. Such transformations are not observed in Sn-analogues due to the smaller atomic radius of germanium in comparison with that of tin.

$R = Me, Bu^t$; $M = Ge$ (**63, 68, 69**), Sn (**65, 70, 71**);
 $E = S$ (**66, 68, 70, 72, 74**), Se (**67, 69, 71, 73, 75**).

One of the amidinate ligands in complexes **72** and **73** (as well as in the starting compound **64**) is linked to the metal atom through only one nitrogen atom.

The steric strain in amidinate ligands also affects the structures of the complexes obtained in the oxidative addition reactions. Thus the structure of the reaction product of compound **58** with phenylthiirane depends on the bulk of the substituent at the amidinate carbon atom.⁷⁹ If this substituent is a methyl group, then bridged bisulfide dimer **76** is formed. In the case of a bulky *tert*-butyl substituent in the amidinate ligand, the tin atom is sterically overcrowded and only monomeric complex **77** containing a double bond $Sn=S$ is formed in this reaction.

The reaction of germanium biselenide complex **69** with elementary selenium yields compound **67** and diphenyl diselenide is eliminated.⁸¹

Tin(II) mixed amidinate-alkoxide complexes **78** were obtained in the reaction of the corresponding silylamide derivatives **58** with triphenylmethanol.⁸⁰ The coordination number 3 relatively rare for tin compounds is found for the tin atoms of both complexes by X-ray diffraction analysis.

R = SiMe₃, SiMe₂Ph.

Compounds **78** turned out to be active catalysts of lactide polymerisation in toluene at 80 °C. The activity of complex **78** with a trimethylsilyl substituent is 63.5 kg mol⁻¹ (polydispersity of the polymer obtained was 1.48), which is more than twice that of the compound with dimethylphenylsilyl group (28.9 kg mol⁻¹). However, the polydispersity of the polymer obtained using the latter catalyst was 1.18.

It can be noted at the end of this Section that not a single paper was published on lead amidinate derivatives during the last decade. Earlier papers dealing with lead amidinate complexes are cited in the review.⁹

f. Group 15 elements (Sb and Bi)

So far no practical application has been found for antimony and bismuth amidinate complexes due to their lability and difficulties of preparation. Data on the chemistry of these derivatives published before 1994 has been summarised in reviews.^{6,9} Phosphorus and arsenic amidinate derivatives, being purely organic compounds, are beyond the scope of the present review on organometallic complexes.

2. Amidinate complexes of transition metals

a. Group 3 elements (Sc, Y, lanthanides and actinides)

The chemistry of lanthanide amidinate complexes has been significantly developed over the last decade. Most of the data are documented in the review⁸² published in 2002. Here we discuss only those papers that have not been surveyed previously.

The reaction of the corresponding alkali metal (usually, lithium) amidinates with commercially available lanthanide chlorides is the major method of synthesis of tris(amidinate) derivatives of lanthanum group metals **79–83** as well as of the most similar complexes of transition metals.^{23, 82–85} These reactions proceed under mild conditions and result in high yields of the target products.

In some cases (like for yttrium), stable adducts **84** and **85** containing one or two lithium atoms coordinated to chloride ligands are obtained.

(a) MCl₃ (1/3 equiv.), Et₂O; (b) YCl₃ (1/2 equiv.), *N,N,N',N'*-tetramethylethylenediamine (TMEDA) or THF; (c) YCl₃ (1 equiv.), TMEDA, THF;

79: M = La; R¹ = Prⁱ; R² = Me, Bu^t;

80: M = Nd; R¹ = Cy; R² = Me, Ph;

81: M = Gd, R¹ = Cy, R² = Me;

82: M = Yb; R¹ = Cy; R² = Me, Ph;

83: M = Y, R¹ = Cy, R² = Ph;

84: R¹ = SiMe₃, 2,6-Et₂C₆H₃; R² = Ph, *p*-Tol; L = TMEDA, THF;

85: R¹ = Prⁱ, R² = 2,6-Me₂C₆H₃.

It should be noticed, that, due to their larger atomic radii, the lanthanum group metals are more prone to form bis- and tris(amidinate) complexes, than the Group 13 elements (B, Al, Ga, In). Thus the reaction of lithium derivative **7** with lanthanum and cerium trichlorides yields bis(amidinate) dinuclear complexes **86** containing pentacoordinated dimethylamino groups. At the same time, aluminium and gallium trichlorides form monoamidinate complexes **8** and **9** with 'constrained' geometry under similar conditions.²³ The yields of complexes **86** are ~70%.

M = La (67%), Ce (78%).

Uranium bis- (**87**) and tris(benzamidinate) (**88**) complexes are formed in the reaction of uranium tetrachloride with two or three equivalents of lithium amidinate, respectively (yields are 60%–70%).⁸⁶ No corresponding mono- or tetrasubstituted amidinate derivatives were obtained.

An alternative method of synthesis of lanthanide amidinate complexes is the addition of carbodiimide to the metal–carbon bond of alkylmetal derivatives. This method was applied for the synthesis of europium, ytterbium and gadolinium compounds.⁸⁷ For instance, amidinate complexes **89–91** were obtained by reaction of di(*tert*-butyl)carbodiimide with *n*-butyllanthanide dicyclopentadienyl complexes.

M = Er (**89**), Y (**90**), Gd (**91**).

Deprotonation of arylamidines by silylated lanthanide tris(amides) results in the corresponding amidinates. Thus a mixture of yttrium mono- (**92**) and bis(amidinate) (**93**) complexes was obtained by this method.⁸⁸

Ar = 2,6-Et₂C₆H₃.

A lanthanum bis(amidinate) complex with tridentate ligands was synthesised similarly from amidine **94**.⁸⁸

X = (CH₂)₃Py-4.

Little is known about the properties of amidinate complexes of lanthanides. Dynamic behaviour of some of them in solution and reactions with alkenes and terminal alkynes have been discussed.⁸² Practical interest in these compounds is caused by

their high catalytic activities in polymerisation reactions of ethylene (compound **86**),⁸⁹ ε-caprolactone (complexes **79–83**),⁸⁴ D,L-lactide (compounds **84** and their phenoxide analogues obtained by substitution of the OC₆H₃R₂-2,6 group, where R = Me, Bu^t, for the chlorine)⁸⁵ as well as in the reaction of cyclotrimerisation of phenyl isocyanide (complex **90**).⁸⁷ The polymers formed have high molecular mass (> 10⁴) and low polydispersity (< 2). Moreover, volatile lanthanum amidinate derivatives were used in membrane manufacturing by CVD.⁸³

b. Group 4 elements (Ti, Zr and Hf)

Most of the papers on amidinate derivatives published over the last decade deal with the Group 4 metal complexes. This is due to several reasons: cheap and commercially available starting materials, simplicity of the synthesis of complexes, their thermal stabilities and, first of all, potential application in such an important area as catalytic polymerisation of olefins.

As for most known amidinate derivatives, the main method of synthesis of amidinate complexes of the Group 4 metals is the reaction of lithium amidinate with the corresponding metal halide (usually, chloride). Reactions with these commercially available reagents proceed under mild conditions and result in acceptable yields of the target products (> 60%). Lithium salts of different amidinate ligands are usually synthesised *in situ* from carbodiimides and alkyl lithium derivatives. Below, there are examples of three types of reaction of lithium amidinate with the Group 4 metal derivatives:

— reactions with chlorides [either bis- (**95–97**) or tris(amidinate) (**98, 99**) derivatives are formed depending on the ligand type];^{83, 90–93}

M = Ti (**95, 98**), Zr (**96, 99**), Hf (**97**); myrtanyl is 6,6-dimethylbicyclo[3.1.1]hept-2-ylmethyl.

— reactions with monocyclopentadienyl derivatives to give monoamidinate monocyclopentadienyl compounds **100–102**;^{94–97}

Cp* = η⁵-C₅Me₅;

100: M = Ti, R¹ = Me, R² = R³ = SiMe₃;

101: M = Zr; R¹ = H, Me, Bu^t, Ph; R² = R³ = Prⁱ, SiMe₃;
R² = Et, R³ = Bu^t;

102: M = Hf; R¹ = Me; R² = R³ = SiMe₃; R² = Et, R³ = Bu^t.

— reactions with monoimide complexes to give monoamidinate monoimide complexes **103** or their dimers **104**.^{98, 99}

$\text{R}^2 = \text{Bu}^t, \text{Ar}$.

Another relatively common method of synthesis of amidinate complexes of the Group 4 metals is an insertion of free carbodiimide into a metal–carbon σ -bond. This approach was successfully used for the synthesis of titanium (**105**), zirconium (**106**) and hafnium (**107**) monocyclopentadienyl monoamidinate complexes.^{100–105} An alkyl (mostly, methyl) group is the most common substituent. The insertion reactions proceed under mild conditions and afford target products in good yields.

105: $\text{M} = \text{Ti}$; $\text{R}^1 = \text{Bu}^t, \text{Cy}$; $\text{R}^2 = \text{Et}, \text{Pr}^i, 2,6\text{-Me}_2\text{C}_6\text{H}_3$; $\text{Cp}^R = \text{Cp}, \text{Cp}^*$; $\text{X} = \text{Me}$;

106: $\text{M} = \text{Zr}$; $\text{R}^1 = \text{Et}, \text{Pr}^i, \text{Bu}^t, \text{Cy}, o\text{-Tol}$; $\text{R}^2 = \text{Et}, \text{Pr}^i, \text{Bu}^t, \text{Bu}^t, \text{neo-C}_5\text{H}_{11}, \text{Bn}, 3\text{-ClC}_6\text{H}_4, \text{Mes}$; $\text{Cp}^R = \text{Cp}, \text{Cp}^*$; $\text{X} = \text{Me}, \text{Cl}$;

107: $\text{M} = \text{Hf}$; $\text{R}^1 = \text{Et}, \text{R}^2 = \text{Bu}^t, \text{Cp}^R = \text{Cp}^*, \text{X} = \text{Me}$.

The third method of synthesis of titanium and zirconium complexes is the deprotonation of amidines, which has already been discussed earlier. Tetrabenzyl and tetrakis(dimethylamide) metal derivatives can be used as the deprotonating agents. Zirconium complexes **108** and **109** containing sterically hindered amidinate ligands were synthesised by this method.^{95, 106} Titanium bis(amidinate) complex **110** was also obtained by similar way.¹⁰⁷ However, this method is used less often than the two mentioned above mainly due to longer reaction times. In some cases, it also requires higher temperature, which usually results in lower yields of the target products.

$\text{R}^1 = \text{R}^2 = \text{Pr}^i, \text{X} = \text{Bn}$; $\text{R}^1 = \text{Et}, \text{R}^2 = \text{Bu}^t, \text{X} = \text{NMe}_2$.

Yet another method of synthesis of amidinate complexes of the Group 4 metals is metathesis of metal tetrachlorides and silylated amidine derivatives.^{9, 108}

$\text{M} = \text{Ti}, \text{Zr}$.

At present, this method is almost out of use due to its synthetic limitations and the existence of other more convenient synthetic procedures.

The properties of amidinate complexes of the Group 4 metals are fairly well studied. Thus the reaction of monocyclopentadienyl monoamidinate dichloride complexes **101**, **102** with the Grignard reagents and organolithium compounds (1 or 2 equiv.) has been investigated. In these reactions, mono- (**111**, **112**) and dialkylamidinate (**113**, **114**) derivatives are formed, respectively, in 40%–80% yields.^{109–113}

$\text{M} = \text{Zr}$ (**101**, **111**, **113**); Hf (**102**, **112**, **114**);

$\text{R}^1 = \text{Et}, \text{R}^2 = \text{Bu}^t$; $\text{R}^1 = \text{R}^2 = \text{Pr}^i$; $\text{R}^3 = \text{Me}, \text{Bu}^t$; $\text{R}^4 = \text{Bu}^n, \text{Bu}^i$.

The reaction of zirconium bis(amidinate) dichloride complex **96** with 2 equiv. of methyllithium proceeds similarly furnishing compound **115**.⁹²

Unlike metallocene dialkyl complexes, their amidinate analogues are less prone to β -hydride elimination reactions. Some amidinate derivatives undergo thermal conversions resulting in metallacycles. Thus the intermediate dialkyl complex **116**, obtained from dichloride **101** ($\text{R}^1 = \text{R}^2 = \text{Pr}^i$) and dialkyl lithium, converts into phenylzirconacyclop propane derivative **117** on heating in ether.¹¹⁰

Thermolysis of *n*-butyl and isobutyl derivatives **116** results in the formation of complexes **118** and **119** as the main products in moderate yields and in elimination of butane and isobutane, respectively (according to data from NMR spectroscopy) and hydrogen.^{109, 111} The mechanisms of these thermal conversions are not established yet.

$\text{R}^1 = \text{R}^2 = \text{Pr}^i$; $\text{R}^1 = \text{Et}$, $\text{R}^2 = \text{Bu}^t$; $\text{R}^3 = \text{Bu}^n, \text{Bu}^i$.

Trimethylenemetane (TMM) derivatives **119a,b** were obtained by another method, *viz.*, by the reaction of corresponding dichlorides **101a,b** with dipotassium isobutylenediide.¹¹⁴

$\text{R}^1 = \text{R}^2 = \text{Pr}^i$ (**a**); $\text{R}^1 = \text{Et}$, $\text{R}^2 = \text{Bu}^t$ (**b**).

The chemical properties of zirconacyclop propane complex **117** and TMM derivatives **119** were studied in detail.^{111, 114, 115} A remarkable feature of these compounds is their high reactivities with respect to weak electrophilic reagents, such as Me_3SiCl , Me_3SnCl , *etc.*,^{111, 115} which does not occur for simple σ -alkyl zirconium complexes. Most of the reactions for compounds **117** and **119** proceed with quantitative yields. DFT quantum-chemical calculations of the complex **119a** reveal high polarisation of the molecule in the ground state,¹¹³ which was confirmed by relatively high experimental value of the dipole moment of this compound (3.5 D). Hence, the organic ligand (TMM) in such complexes carries significant negative charge and can react even with weak organic electrophiles.

Reactions of the phenylzirconacyclop propane derivative **117** with chlorotrimethylsilane and -stannane accompanied by three-

Scheme 2

membered ring opening have been described.¹¹¹ Chiral organo-metallic complexes **120** and **121** thus formed epimerise in benzene at room temperature (Scheme 2).

Compound **117** reacts with hydrogen at room temperature yielding an unusual zirconanorbornadiene complex **122** (see Ref. 111). The latter is of particular interest as a thermodynamically stable homoaromatic structure. In complex **122**, the lengths of two Zr–C σ -bonds are 2.313(2) and 2.3501(19) Å. Relatively short contacts between the metal atom and carbon atoms of the alkene (~ 2.51 Å) suggest the presence of non-valent interactions between the electron-deficient zirconium atom and C=C double bonds of the norbornadiene moiety. These interactions provide additional stability to the structure.

Metathesis of σ -alkyl bond in compound **117** in the presence of an excess of *tert*-butylamine results in the formation of corresponding bis(amidinate) derivative **123**. It should be noted that dimethyl derivative **105** ($R^1 = \text{Et}$, $R^2 = \text{Bu}^t$, $\text{Cp}^R = \text{Cp}^*$) is completely inactive in similar reaction even at elevated temperatures.¹¹¹ Bis(amidinate) complex **123** undergoes unique deamination in the presence of $[\text{Ph}_3\text{C}][\text{B}(\text{C}_6\text{F}_5)_4]$ yielding a cationic complex **124**.

Protolysis of compound **117** with phenylacetylene results in σ -alkynyl derivative **125**. Thermolysis of the latter furnishes zirconacyclopentenyl complex **126**.

Trimethylmethane complex **119a** also reacts with weak organic electrophiles. On treatment of trimethylsilyl derivatives **127** ($R^3 = \text{SiMe}_3$; $X = \text{Cl}$, OTf) with strong electrophiles (*e.g.*, B-catecholchloroborane or chlorotrimethylstannane) non-symmetrically substituted isobutylenes **128** are formed.¹¹⁵

The reaction of TMM complex **119** with carbonyl compounds yields C=O insertion derivatives **129**.

$R^1 = R^2 = \text{Pr}^i$ (a); $R^1 = \text{Et}$, $R^2 = \text{Bu}^t$ (b); $R^3 = \text{Me}$, Et, Bn, SiMe_3 ;

$R^4 = \text{phenylene-O-B}$; SnMe_3 ; $R^5 = \text{H}$, Ph; $X = \text{OTf}$, Cl, Br.

Complexes **119a,b** also react with Brønsted (*e.g.*, $[\text{PhNHMe}_2]$, $[\text{B}(\text{C}_6\text{F}_5)_4]$) and Lewis [*e.g.*, $\text{B}(\text{C}_6\text{F}_5)_3$] acids to give the corresponding allylic cationic (**130a,b**) and zwitter-ionic (**131a,b**) derivatives as the reaction products.¹¹⁵ The transition from neutral covalent complex **119b** to the metallyl derivative **130b** is accompanied by a significant shortening of the Zr–N bonds from 2.2306(12) to 2.149(3) Å. Such shortening of the metal–nitrogen bonds compared with those in neutral complexes is also typical of the majority of cationic amidinate derivatives of other elements, for example, aluminium,⁵⁶ and ruthenium.¹⁰

In spite of diverse reactivity of Group 4 metal amidinate complexes, the primary attention is paid to their application as olefin polymerisation catalysts.¹¹⁰ Monoalkyl cationic complexes of zirconium **132** (see Refs 102–104 and 116–120) and hafnium **133** (see Ref. 121) were obtained from dialkyl complexes **106**, **107** in the reaction with $[\text{Me}_2\text{NHPh}][\text{B}(\text{C}_6\text{F}_5)_4]$ as a protonating reagent in quantitative yields.

106, **132**: $M = \text{Zr}$; $R^1 = \text{Et}$, Pr^i , Bu^t , Bu^i , *neo*- C_5H_{11} , Cy, Bn, *o*-Tol, 3- ClC_6H_4 , Mes; $R^2 = \text{H}$, Me, Bu^t , Ph; $R^3 = \text{Et}$, Pr^i , Bu^t , Cy; $R^4 = \text{Me}$, Et, Bu^i ;
107, **133**: $M = \text{Hf}$; $R^1 = \text{Et}$; $R^2 = \text{Me}$; $R^3 = \text{Bu}^t$; $R^4 = \text{Me}$, Bu^i .

Really unique was the discovery of a high catalytic activity of such monoalkyl complexes in stereoregular living polymerisation of a number of α -alkenes (ethylene, propylene, but-1-ene, hex-1-ene, oct-1-ene, dec-1-ene, dodec-1-ene) as well as hexa-1,5-diene. Polymerisation of these olefins in chlorobenzene at -10°C results in isotactic polymers in almost quantitative yields and low (< 1.1) polydispersity, which is characteristic of living polymerisation. β -Hydride abstraction under these conditions is negligible. Cationic complex **132** ($R^1 = \text{Et}$, $R^2 = R^4 = \text{Me}$, $R^3 = \text{Bu}^t$)¹⁰² is the most efficient catalyst, but other complexes, for example, compounds **132** with $R^1 = \text{Bn}$, *neo*- C_5H_{11} , also show similar activity.¹⁰⁴ Such catalysts can be used for the preparation of different block co-polymers¹⁰³ and isotactic–atactic block co-polymers by degenerated alkyl group transfer mechanism (for details, see Ref. 120). The structure of catalytically active species has been studied.¹²⁰

A series of titanium and zirconium monoamidinate complexes (**105** and **106**) were tested as catalysts for ethylene polymerisation in the presence of methylalumoxane (MAO).^{92, 101, 121–123} Quantum-chemical calculations were performed for this reaction.¹⁵ A detailed analysis of the polymerisation results is published in a recent review.⁵

A study of the reactions of zirconium and hafnium dichloride derivatives (**101** and **102**)¹²⁴ has to be noted among the latest papers on the properties of Group 4 metal amidinate complexes. Thus these compounds react with strong non-nucleophilic bases producing dimeric derivatives **134** and **135**, respectively.

The deprotonated carbon atom of the amidinate ligand in dimers **134** and **135** is nucleophilic. For instance, hafnium complex **135** ($R^1 = \text{Et}$, $R^2 = \text{Bu}^t$) reacts with such organic electrophiles as CH_2Cl_2 , BnCl and SiMe_2Cl_2 to give CH_2 -substituted amidinate derivatives **136**.¹²⁴

Similar reaction has been used for the synthesis of a polymer-bound amidinate catalyst **137**. The commercially available polystyrene polymer Bio-Beadstm S-X1 has been used as a support; the transformations involved immobilised zirconium complexes **138** and **139**.¹²⁵

(P) is a polymer.

Cationic complex **137** is quite resistant toward oxidation and at the same time is highly active as a polymerisation catalyst.

A possibility of synthesis of a hydride chloride monoamidinate analogue of Schwarz catalyst, Cp_2ZrHCl , starting from zirconium monocyclopentadienyl amidinate complexes was

studied. Hydride chloride intermediate **111b** was obtained by hydrogenation of the corresponding silyl chloride complex **111a**.¹²⁶

Intermediate **111b** is unstable and rapidly decomposes. However, it may be quenched as α -alkene hydrozirconation products, for example, as complex **111c** upon hydrozirconation of isobutylene.

Recently a stable zirconium hydride amidinate complex **140** has been obtained.

$R^1 = \text{Pr}^i$, $R^2 = \text{CH}_2\text{SiMe}_3$.

It was formed upon hydrogenation of the corresponding zirconium tetrakis(trimethylsilylmethyl) dinuclear derivative **109**.⁹⁵ Complex **140** exhibit dynamic behaviour, which results in exchange between bridged and terminal hydrogen atoms.

At the end of this Section, two recent publications^{127, 128} have to be noted. They describe the reactivities of titanium amidinate complexes **141** and **142**. The chloride ligand in monochloro derivatives **141** may be nucleophilically substituted by such groups as Cp , OAr , $\text{N}(\text{SiMe}_3)_2$, CHRSiMe_3 or by second amidinate ligand (Scheme 3).¹²⁷

Titanium pentamethylcyclopentadienyl amidinate complex **142** rapidly reacts with CO_2 giving rise to the insertion product **143**.¹²⁸ Depending on the duration of the reaction with carbon dioxide, different products, *viz.*, complexes **144** or **145**, are formed.

$R = \text{Bu}^t$, 2,6- $\text{Me}_2\text{C}_6\text{H}_3$.

c. Group 5 elements (V, Nb and Ta)

Very few papers were published on Group 5 metal amidinate complexes over the last decade. The primary attention was given to vanadium and tantalum derivatives, while no niobium amidinate complexes have been synthesised during this period. Earlier work in this area has been summarised in reviews.^{8, 9}

Scheme 3

At present, the only method of synthesis of such derivatives is the reaction of lithium amidinates with Group 5 metal chlorides or organometallic chlorine-containing complexes.^{129–132} These reactions proceed under mild conditions in yields not less than 50%. For example, vanadium mono- (**146a,b**) and bis(amidinate) (**147a–c**) derivatives were synthesised by this method.

146: $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{SiMe}_3$ (**a**); $\text{R}^1 = \text{Bu}^t$, $\text{R}^2 = \text{Pr}^i$ (**b**);
147: $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{SiMe}_3$ (**a**); $\text{R}^2 = \text{Cy}$; $\text{R}^1 = \text{H}$ (**b**), Me (**c**);
 $\text{L}_n = \text{Cl}$, $\text{X} = \text{THF}$, L_m is absent;
 $\text{L}_n = \text{TMEDA}$, THF : $\text{X} = \text{Cl}$, $\text{L}_m = \text{L}_n$.

Vanadium complex **148** with a tridentate amidinate ligand was obtained similarly.¹²⁹

When bulky substituents, such as cyclohexyl ring, were present at the nitrogen atoms of the amidinate fragment, the bridged dinuclear complexes **14** were obtained in the reaction of vanadium chloride with 2 equiv. of lithium amidinate.¹³⁰

Tantalum mono- (**149**)¹³³ and bis(amidinate) (**150**)¹³² complexes were synthesised from lithium amidinates using the organo-tantalum chlorides as the reagents.

A characteristic feature of vanadium amidinate complexes is the formation of adducts with donor molecules, for example, with THF, which is a common solvent.¹³¹ Thus, either a solvent molecule or a ligand from the reagent (organometallic complex) can be inserted into the coordination sphere of the metal. It becomes possible, because the coordination of vanadium atom in such complexes is incomplete. Sometimes, especially in the cases of sterically hindered complexes like **147a**, such insertion is reversible: heating of the product results in formation of penta-coordinated vanadium compound **151a**.

R = SiMe₃.

The mechanism of formation of amidinate derivatives of Group 5 metals discussed above may be regarded as nucleophilic substitution of the amidinate group for the chloride ligand. Chloride ligands in complexes **147b** and **147a,d** undergo further substitution in reactions with alkyl and allyl (All) Grignard reagents resulting in acceptable yields of the corresponding derivatives **152** and **153a,d** (see Refs 131 and 134).

R¹ = Ph, R² = SiMe₃ (**a**); R¹ = Bu^t, R² = Prⁱ (**d**); R³ = Et, All.

Different types of coordination of allylic ligands in vanadium mono- (**153**) and bis(allyl)- (**152**) complexes are worth mentioning. In the former, the allyl group is η¹-bound to the metal, while in the latter, both allyl ligands are η³-coordinated.

An unusual reaction has been found in the reduction of compound **151b** with sodium triethylborohydride in THF.¹³⁰ The reaction product is a dimeric complex **154** containing a diazo-bridge, which is formed upon insertion of a molecule of the atmospheric nitrogen.

Cationic compound **155** is formed in reaction of silver hexafluoroantimonate with tantalum monocyclopentadienyl amidinate complex **149**.¹³³ The reaction of the latter with 3 equiv.

methylmagnesium chloride yields compound **156** in which all three chloride ligands are substituted by alkyl groups.

Chemical properties of tantalum trialkyl bis(amidinate) derivatives **150** are described in detail.¹³² The structure of the protonation product of complex **150** depends on the protonating reagent. Ionic derivative **157** is formed when [PhNHMe₂][B(C₆F₅)₄] is used. The reaction of compound **157** with phosphorus ylide yields the carbene complex **158**. If the trifluoromethanesulfonic acid (TfOH) is used as a protonating reagent, the dialkyl monotrifluoromethanesulfonate derivative **159** is obtained. In the presence of an excess of CO, the starting complex **150** undergoes double insertion of carbon dioxide into the Ta–C bond furnishing compound **160**.

And finally, it has to be noted that vanadium and tantalum amidinate complexes were studied as catalysts of olefin polymerisation. Thus compounds **147** (X = THF), **148** and **149** are highly reactive as catalysts of ethylene polymerisation in the presence of MAO.^{133, 134} The activity of tantalum complex **149** containing three chloride ligands is equal to 470 g mol^{−1} h^{−1} (see Ref. 133),

while its trimethyl analogue is inactive under similar conditions. Vanadium complexes **147** ($X = \text{THF}$) are significantly less reactive, $\sim 10 \text{ g mol}^{-1} \text{ h}^{-1}$ (see Ref. 134), the molecular mass of the obtained polyethylene is 80 kDa. At the same time, the activity of vanadium complex **148** with tridentate amidinate ligand is nearly the same ($447 \text{ g mol}^{-1} \text{ h}^{-1}$) as the activity of tantalum derivative **149**.

d. Group 6 elements (Cr, Mo and W)

Seven papers on the amidinate complexes of Group 6 metals have been published since 1994. The unusual structures of chromium derivatives with very short Cr–Cr distances ($1.84\text{--}1.96 \text{ \AA}$)^{135, 136} are of special interest.

Most of the described chromium and molybdenum amidinate complexes were obtained by standard method, *viz.*, by the reaction of lithium amidinate salts with the corresponding metal halides or with organometallic halogen-containing complexes.^{24, 135, 137–139}

Mononuclear bis(amidinate) derivatives **161** are obtained by the reaction of chromium(II) compounds with amidinates containing bulky substituents (Pr^i , Bu^t) at the both nitrogen atoms. In the case of less sterically hindered amidinate salts, dinuclear complexes **5c** with multiple $\text{Cr}\equiv\text{Cr}$ bonds are obtained.¹³⁵ The yields of compounds **161** and **5c** are 50%–60%.

The same method was used for the synthesis of chromium mono- (**162**) and tris(amidinate) (**163**) complexes¹³⁷

as well as molybdenum derivatives **164**.¹³⁸

$R = \text{Me, Ph}$; $\text{Ar} = 2,6\text{-Pr}_2^i\text{C}_6\text{H}_3$; DME is dimethoxyethane.

Refluxing of molybdenum tetrakis(phosphine chloride) derivative in toluene with 4 equiv. of amidine yields molybdenum dinuclear tris(amidinate) complexes **165**.¹³⁹ According to the X-ray diffraction data, the Mo–Mo bond in the complex **165** is single.

The chemical properties of the amidinate complexes of Group 6 metals are scarcely studied. Only the reactions of chromium complexes **162** and molybdenum complexes **164** with the Grignard reagents or alkyllithium resulting in substitution of the chloride ligands have been described.^{137, 138}

Allylmagnesium bromide reduces compound **162** into Cr(II) derivative **166**, while benzylmagnesium chloride replaces the chloride ligand yielding complex **167** (see Ref. 137).

Methyl-substituted amidinate complex **168** was obtained in the reaction of molybdenum complexes **164** with methyllithium.

$R = \text{Me, Ph}$; $\text{Ar} = 2,6\text{-Pr}_2^i\text{C}_6\text{H}_3$.

No new tungsten amidinate derivatives have been synthesised during the last decade. Earlier results are summarised in the reviews.^{8,9}

e. Group 7 elements (Mn, Re and Tc)

There are very few studies of amidinate complexes of Group 7 metals. Earlier papers mainly discussed the results of X-ray structural studies (see, for example, a review⁸). However, the

application of manganese bis(amidinate) complexes as starting compounds for CVD has been mentioned recently.⁸³

All known Mn(II) bis(amidinate) complexes were synthesised by reaction of lithium amidinates with MnCl_2 .^{83, 140} Mononuclear bis(amidinate) derivative **169a** was obtained in the reaction where the amidinate ligand carried bulky *tert*-butyl substituent at the nitrogen atom. In the case of less bulky isopropyl group, the dinuclear compound **170** was formed.

However, if the starting salt contains sterically hindered substituent at the carbon atom of the amidinate fragment (for example, 2,6-dimesitylphenyl in complex **20c**), the bis-derivative **169b** is also formed. The yields of compounds **169a,b** and **170** vary from low to moderate.

Techetium dinuclear tris- (**171**) and tetrakis(amidinate) (**172**) derivatives were obtained by heating ditechetium tetrakis(phosphine chloride) with 4 equiv. of amidine.¹³⁹

f. Group 8 elements (Fe, Ru and Os)

The chemistry of the amidinate complexes of Group 8 metals was successfully developed during the last decade. First of all, it concerns ruthenium amidinate derivatives, which are widely used as the catalysts of the Harash and Tsuji–Trost reactions.¹⁰ The

methods of synthesis and chemical properties of these compounds are summarised in a recent review¹⁰ and therefore will not be discussed here.

The studies of iron amidinate complexes were focused mainly on the synthesis of Fe(II) bis(amidinate) derivatives containing bulky chiral amidinate ligands and ferrocenyl substituents.^{43, 83, 140–142} Complexes **173** were obtained in satisfactory yields from lithium amidinates and iron dichloride as the starting compounds.

$\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{Bu}^t$; $\text{R}^1 = (\eta^5\text{-C}_5\text{H}_5)\text{Fe}(\eta^5\text{-C}_5\text{H}_5)$ (Fc), $\text{R}^2 = \text{Cy}$;
 $\text{R}^1 = 2,6\text{-Mes}_2\text{C}_6\text{H}_3$, $\text{R}^2 = \text{Pr}^i$.

However, in the reaction with $\text{CpFe}(\text{CO})_2\text{Cl}$, ferrocenyl-substituted lithium amidinate forms compound **174**, which is an insertion product of one of the carbonyl groups into the Fe–N bond.¹⁴² UV irradiation of derivative **174** yields the amidinate complex **175**, which is converted to the starting complex **174** on heating in a CO atmosphere.

The synthesis of iron chiral dinuclear complex **176** is described.⁴³ It appeared that this complex can also add the CO ligands reversibly.

$\text{R}^1 - \text{R}^2 = (\text{CH}_2)_4$.

However, in this case the carbonyl group coordinates the iron atom rather than inserts into the Fe–N bond.

No new osmium amidinate derivatives have been synthesised during the last decade. Data on the chemistry of iron and osmium amidinate complexes can be found in reviews.^{8,9}

g. Group 9 elements (Co, Rh and Ir)

Only one systematic study¹⁴⁴ on the chemistry of amidinate complexes of Group 9 metals has emerged since the publication of a series of papers^{8,9,18,143} on the synthesis and reactivity of rhodium amidinate complexes. The authors synthesised iridium derivatives **177** starting from lithium acetamidinates and a chlorine-containing iridium complex and studied their properties.

$\text{R}^1 = \text{Pr}^i, \text{Cy}$; $\text{R}^2 = \text{Me, Et, Bn}$; $\text{L} = \text{Py, CO}$.

The corresponding monoalkyl derivatives **178** were obtained from compounds **177** in good yields ($>70\%$) by reaction with equimolar amounts of the Grignard reagents. In the presence of compounds that easily coordinate to metals, such as pyridine or CO, compound **177** reacts with AgSbF_6 yielding cationic complexes **179**. In the absence of such ligands, the iridium intermediate decomposes. The reaction of compound **177** with sodium isopropoxide proceeds in an unusual way: hydride complexes **180** are formed instead of the expected isopropoxide derivatives. Apparently, the β -hydride shift accompanied by elimination of acetone occurs in the isopropoxide intermediate.

Both conventional cobalt bis(amidinate) derivatives **181a,b** and their analogue **181c** with sterically hindered 2,6-dimesitylphenyl substituent in the amidinate ligand have been synthesised recently.^{83,140,142}

$\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{Pr}^i$ (**a**); Bu^t (**b**); $\text{R}^1 = 2,6\text{-Mes}_2\text{C}_6\text{H}_3$, $\text{R}^2 = \text{Pr}^i$ (**c**).

Compound **182**¹⁴² is the only ruthenium amidinate complex described so far.

Complexes **181a,b** and **182** are used as starting compounds in the manufacture of metal oxide thin films.⁸³

h. Group 10 elements (Ni, Pd and Pt)

There was no new significant breakthrough in the chemistry of amidinate complexes of Group 10 metals during the last decade. A small number of new complexes have been synthesised from the corresponding lithium amidinates.^{83,140,145} Thus nickel bis(amidinate) derivative **183** was obtained by the reaction of lithium salt with nickel chloride. Similar reaction with nickel bis(acetylacetonate) furnishes monoamidinate complex **184**. The yields of the products in these cases are moderate (40%–60%).

acac is acetylacetonate.

A series of dinuclear palladium (**185**) and platinum (**186**) complexes containing two bridging amidinate ligands were synthesised by similar method.¹⁴⁵ Chlorine-containing phosphine complexes of these metals were used as the reagents.

185: $\text{M} = \text{Pd}$; $\text{X}_3 = \text{Et}_3, \text{Bu}_3^i, \text{Me}_2\text{Ph}$; $\text{R}^1 = \text{H, Me}$; $\text{R}^2 = \text{Ph, } p\text{-Tol, } 4\text{-MeOC}_6\text{H}_4$;

186: $\text{M} = \text{Pt}$; $\text{X}_3 = \text{Bu}_3^i, \text{Me}_2\text{Ph}$; $\text{R}^1 = \text{H}$; $\text{R}^2 = \text{Ph}$.

Chemical properties of amidinate derivatives **183–186** are almost unknown. The use of compounds **183** and **184** as the starting components in the manufacture of oxide thin films is an example of practical application of amidinate complexes of Group 10 elements.⁸³

i. Group 11 elements (Cu, Ag and Au)

Homoleptic complexes with the composition $[\text{M}(\text{R}^2\text{NC}(\text{R}^1)\text{NR}^2)]_n$ ($n = 1\text{--}4$) are at present the best known amidinate derivatives of Group 11 metals. The metathesis reaction of trimethylsilyl derivatives of amidinates with inorganic metal salts is the main method of synthesis of such complexes.^{146,147}

Typically, silver complexes **187** obtained by this method have tetranuclear structures.^{8, 147}

$R^1 = \text{Me, Pr}^n, \text{Bu}^n, n\text{-C}_5\text{H}_{11}, n\text{-C}_8\text{H}_{17}$;
 $R^2 = \text{Ph, 4-Bu}^n\text{C}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$.

Silver dinuclear (**188**) and trinuclear (**189**) complexes are also known.⁸³ They were synthesised by the reaction of AgCl with lithium amidinate salts.

Dinuclear structure is also typical of copper amidinate complexes. The synthesis of bis(amidinate) derivatives **190** containing bridging ligands is described.¹⁴⁶ An exception from this structural type is the mononuclear complex **191** obtained by the reaction of lithium amidinate salt with copper dichloride.¹⁴⁶ Wet acetonitrile has to be used as a solvent in the synthesis of this compound.

$R^1 = \text{H, } R^2 = 4\text{-Bu}^n\text{C}_6\text{H}_4$; $R^1 = \text{Me, } R^2 = \text{Pr}^i$; $R^1 = \text{Ph, } R^2 = \text{SiMe}_3$.

Copper amidinate complexes **190** and **191** were tested as catalysts in polymerisation of carbodiimides¹⁴⁶ and methyl methacrylate.¹⁴⁸ In the presence of these complexes, the polymerisation of carbodiimides proceeds without chain transfer, *i.e.*, living polymerisation occurs, and the activity of the catalysts in an inert atmosphere is almost the same as that in the presence of oxygen. The yields of polymers are 70%–90%.

Unusual gold amidinate complexes with chiral cyclopentadienyl ligands with *N*-donor side chain have recently been

obtained by Minkin and co-workers.^{149–151} Treatment of zwitter-ionic cyclopentadienyl ligands with alkaline solution followed by addition of Ph_3PAuCl results in the formation of complexes **192** in high yields.

$\text{Ar}^1 = \text{Ph, Ar}^2 = p\text{-Tol}$; $\text{Ar}^1 = 1\text{-naphthyl}$; $\text{Ar}^2 = m\text{-Tol, } o\text{-Tol}$.

According to X-ray diffraction analysis, the metal in these compounds is σ -coordinated by a nitrogen atom of the amidinate ligand and, therefore, complexes **192** belong to the structural type **B** (see Section II). Moreover, the η^2 -type coordination of metal by the π -system of cyclopentadienyl ligand is observed, which is highly unusual for gold cyclopentadienyl derivatives.

Copper and silver amidinate complexes are used as starting components in the production of oxide thin films.⁸³

The earlier references to the chemistry of amidinate complexes of Group 11 metals can be found in the review.⁸

IV. Conclusion

In conclusion to the review, the large number of publications into the chemistry of main Group and transition metal amidinate complexes unambiguously suggests that this field of research is still under rapid development and growth. It is evident that this trend will continue for at least a near future. Furthermore, despite the fact that there has been no single unique method for the synthesis of amidinate complexes developed since 1994, the existing synthetic methods allow for almost any amidinate derivatives. Most of the metal amidinate complexes known to date are mononuclear. However, di- and polynuclear structures are more common for the late transition metal amidinates (nickel and copper groups) as well as for cationic aluminium amidinate complexes. Metal amidinate complexes have found significant application as catalysis for olefin polymerisation (including stereocontrolled synthesis of block-copolymers) and for a number of organic transformations, as demonstrated for ruthenium amidinate derivatives.

Several potential areas of further studies may be outlined. Thus amidinate complexes of Group 4 and 5 metals may find use as catalysts for nitrogen fixation. Amongst all, Group 4, 8 and 13 metal amidinate complexes are most promising for further studies. Dinuclear amidinate complexes and organometallic clusters with amidinate ligands, which are barely studied yet, may demonstrate unusual reactivity as chemical reagents as well as catalysts of various chemical transformations. Moreover, amidinate ligands are promising precursors for synthesis of volatile organometallic compounds used for the production of metal coatings and membranes. Successful development in this area is related to several factors, namely, availability of starting materials, existence of convenient methods for the synthesis of amidinate complexes, and also thermal stability of amidinate derivatives even when similar metallocene compounds are labile.

Thus, this paper has demonstrated a significant potential of main Group and transition metal amidinate complexes for both fundamental and applied research studies.

VI. Biochemical role of peroxynitrite	391
VII. Conclusion	392

Abstract. Methods for the preparation of peroxynitrite and its physical and chemical properties are considered. The pathways, mechanisms and kinetics of the decomposition and best-studied reactions with hydrocarbons, dimethyl sulfoxide and other substrates are analysed. The emphasis is placed on the nature of reactive species in peroxynitrite reactions and on the reasons for its high and polyfunctional reactivity. The biochemical role of this important inorganic oxidant formed *in vivo* is outlined. The bibliography includes 268 references.

I. Introduction

Peroxynitrous acid ONOOH and peroxynitrite anion ONOO[−] have the same conventional name ‘peroxynitrite’. [According to IUPAC recommendations,¹ they should be called hydrogen oxoperoxonitrate and oxoperoxonitrate(1 −), respectively.]

Peroxynitrite was first detected more than 100 years ago as unstable product of the interaction of nitrites with hydrogen peroxide in acid media, which possesses unusually high oxidative ability. Its formula, ONOOH, which is commonly accepted at present, was proposed in 1929.²

About 40 studies concerning peroxynitrite were reported before 1990. They were followed by rapidly increasing interest in this research avenue due to the discovery³ of *in vivo* formation of ONOO[−] and to establishment of its important role in physiological processes,^{4–11} in atmosphere chemistry¹² and in chemistry of natural water.¹³ The total number of reports on the subject vigorously increases, being more than 7300 at the moment.

The main avenues of research in chemistry of peroxynitrite include (1) pathways and mechanisms of ONOOH decay over a wide range of pH values, (2) reasons for high reactivity and the mechanisms of reactions with organic compounds and biomolecules and (3) pathways of synthesis and transport of peroxynitrite in biological systems.

Uspekhi Khimii 75 (5) 422–444 (2006); translated by A M Raevskiy

High reactivity of peroxynitrite is usually explained by generation of ‘hydroxyl-like’ radicals in the homolysis of ONOOH. However, in spite of numerous studies in this field, the nature of the reactive species is still highly debatable. This is due to instability of peroxynitrite in neutral and acid media, large number of possible transformation paths and to the fact that many reactions involving the compound are catalysed by metal complexes, carbon dioxide and carbonyl compounds.

The first systematic review¹⁴ on the chemistry of peroxynitrite appeared in 1994; biochemical aspects were first considered in detail in a monograph.¹⁵ A number of more recent interesting reviews are also available.^{4, 7, 9, 11, 16–18} In this review we will dwell on the reactions of peroxynitrite formation (including *in vivo* formation), preparative synthesis, pathways and mechanisms of peroxynitrite decay and other reactions involving the compound. We will also briefly outline its role in biochemical processes. In addition to the results of studies on the interaction of peroxynitrite with sulfides, carbon dioxide, carbonyl compounds, phenols and ascorbic acid, we will present a detailed consideration of recent data on the kinetics and mechanisms of model reactions with hydrocarbons (alkanes, alkenes, alkylbenzenes) and DMSO obtained in the authors’ laboratory.

II. Formation of peroxynitrite

Chemical reactions resulting in peroxynitrite are shown in Scheme 1.

1. Reaction of H₂O₂ with HNO₂ (route *a*). It was established^{14, 19–23} that peroxynitrous acid is rapidly formed (as

intermediate) in acidic media, but the compound is unstable (half-life is a few seconds at 0 °C).^{14, 21, 24, 25} In practice, relatively stable ONOO[−] anions can be generated using instantaneous 'quenching'^{25, 26} of the reaction mixture with an excess of alkali. Solutions thus obtained contain nitrite, hydrogen peroxide and nitrate impurities. The yield of peroxynitrite can be significantly increased using simple flow reactors (Fig. 1).^{22, 23, 27} The nitrite and acidified hydrogen peroxide solutions are introduced, by means of compressed gas²⁷ or vacuum,²² into a mixing cell and then, through a short pipe, into the second mixing cell where the reaction is 'quenched' with a sodium hydroxide solution. Optimisation of the reagent feed rates and the tube length allows peroxynitrite to be synthesised in high yield (> 91%) and with low impurity content.

Figure 1. Scheme of peroxynitrite formation in a quenched flow reactor.²²

Reaction *a* is reversible:²⁸

K (25 °C) = $(1.33 \pm 0.05) \times 10^3$ litre mol^{−1}.

Formation of ONOOH in the H⁺–HNO₂–H₂O₂ system involves intermediate generation of nitrosyl cation²⁰

The corresponding kinetic equation has the form

$$\frac{d[\text{ONOOH}]}{dt} = \frac{k_2 k_3 [\text{H}^+]^2 [\text{NO}_2^-] [\text{H}_2\text{O}_2]}{k_{-2} [\text{H}_2\text{O}] + k_3 [\text{H}_2\text{O}_2]},$$

where $k_2 = 5.8 \times 10^6$ litre² mol^{−2} s^{−1} and $k_3/k_{-2}[\text{H}_2\text{O}] = 2.4$ litre mol^{−1} (pH 4–6, 25 °C).²⁰

It is believed^{23, 29} that protonated nitrous acid H₂NO₂⁺ is a more probable nitrosating agent in this system:

where $k_4 = 600$ litre mol^{−1} s^{−1} and $k_5/k_{-4} = 2.31$ litre mol^{−1}.

Nitrosyl chloride NOCl formed in the presence of chloride ions also reacts with hydrogen peroxide:²³

2. Reaction of H₂O₂ with NO in alkaline media (route *b*).^{19, 30, 31} This reaction cast some doubt until it was found³¹ that it proceeded only in the presence of oxygen involving formation of N₂O₃ as intermediate, which is then attacked by the hydroperoxide anion [$k = (1.0 \pm 0.6) \times 10^9$ litre mol^{−1} s^{−1}] (see Refs 19, 30, 31). The rate constant for the reaction of N₂O₃ with H₂O₂ is three orders of magnitude lower.

3. Reaction of NO with O₂^{•−} (route *c*). Both being of radical nature, the superoxide ion and nitrogen(II) oxide recombine at a diffusion rate [$k = (3.8–19) \times 10^9$ litre mol^{−1} s^{−1}, Refs 32–38]

to give −OONO.[†] The reaction plays a key role *in vivo*^{3, 9, 11, 16, 39} (see Section VI). It is reversible, but the equilibrium is almost completely shifted towards ONOO[−]. Indeed, $K = (3.1–3.6) \times 10^{-12}$ ($k = 0.017–0.0023$ s^{−1} for the reverse reaction) in aqueous solutions at 25 °C.^{40–42} Based on this reaction, new efficient methods of synthesis of peroxynitrite were developed, namely, the interaction of trimethylammonium superoxide with nitrogen(II) oxide in liquid ammonia⁴³ and a heterogeneous reaction of crystalline potassium superoxide with NO.⁴⁴ Both methods result in high yield of peroxynitrite and minimum content of nitrates and nitrites.

4. Reaction of alkyl nitrites with hydrogen peroxide (route *d*)^{45, 46} proceeds in alkaline media involving hydroperoxide anion HOO[−] as reagent. The reaction is of preparative value, but peroxynitrite thus obtained contains an equimolar amount of alcohol as impurity (alcohol can be oxidised with peroxynitrite). The advantage of this procedure consists in low content of nitrite, nitrate and hydrogen peroxide impurities.

5. Autooxidation of hydroxylamines and chloramines (route *e*). Alkaline oxidation of the compounds containing nitrogen in the oxidation states below +3 results in peroxynitrite in 20%–25% yield with respect to the starting substrate.^{47, 48} The reaction involves formation of a triplet NO[−] anion as intermediate.

The interaction of oxygen with triplet NO[−] produced in the photolysis of trioxodinitrates also leads to peroxynitrite.⁴⁹

6. Ozonation of azides (route *f*) makes it possible to prepare peroxynitrite solutions that are of low ionic strength and free from H₂O₂ impurities.^{50, 51}

7. Radiolysis and photolysis of nitrates in solutions or in the crystalline state (route *g*).^{14, 52–55} These processes occur in atmosphere, natural water and on the Earth surface. Photolysis of nitrates is associated with the formation of peroxynitrite on Martian surface, which was detected by the 'Viking' Mars landers.¹⁴ Various photolysis techniques are used for fast generation of peroxynitrite in studies of its reactivity. For instance, pulse radiolysis was used for measuring the rate constants for formation, breakdown and other reactions of peroxynitrous acid; its UV spectrum was also recorded.⁵⁵ Solid solutions of ONOOK in KNO₃ were prepared by photolysis of crystalline KNO₃ ($\lambda = 250–450$ nm, 2 h).^{55, 56}

Preparative syntheses of peroxynitrite are mainly based on the reactions *a*, *e*, *f* and *c*. The last-named method makes it possible to obtain pure tetramethylammonium peroxynitrite that is free from nitrites, nitrates, hydrogen peroxide, hydroxylamine and azide.

III. Physical and chemical properties

The physicochemical properties of peroxynitrite are summarised in Tables 1–4. The experimental standard enthalpy of formation, $\Delta_f H^\circ$, of ONOO[−] anion in aqueous solutions is -42 ± 4 kJ mol^{−1}. Different values were reported for the absolute entropy ($\Delta_f S^\circ$) of ONOO[−] anion in solution, ranging from 63 (see Ref. 59) to 130 J K^{−1} mol^{−1} (see Refs 13 and 61). The standard free energy of formation ($\Delta_f G^\circ$) of ONOO[−] lies between ~ 70 and 42 kJ mol^{−1}. A recently reported⁴² $\Delta_f G^\circ$ value of 68.5 ± 1.4 kJ mol^{−1} was derived from the experimental rate constants for the direct and reverse reactions in equilibrium

[†] The most reliable value of the rate constant, $(16 \pm 3) \times 10^9$ litre mol^{−1} s^{−1}, was obtained in the studies^{37, 38} carried out using three different flash photolysis techniques.

^a pK_a = 6.5.

The free energy of peroxynitrite is 150 kJ mol^{-1} higher than that of isomeric nitrate;^{24,57} nevertheless, ONOO⁻ anion is relatively stable, that is, it lives in alkali solutions for a few weeks. The reason is the conformation of this species. According to quantum chemical calculations,¹⁴ the order of the bond between the nitrogen atom and the peroxide oxygen atom, O(2), in peroxynitrite approaches a value of 1.5, thus providing an explanation for the existence of *cis*- and *trans*-isomers.

The *cis*-isomer is $8\text{--}17 \text{ kJ mol}^{-1}$ more stable than the *trans*-isomer^{70–73} due to (i) partial delocalisation of negative charge over the entire molecule and (ii) partial bonding between the O(1) and O(3) atoms (the bonding energy is comparable with the energy of a hydrogen bond). Delocalisation stabilises peroxynitrite in the *cis*-conformation and precludes either rotation of the O(3) atom about the N–O(2) bond axis or a change in the N–O–O bond angle in order to adopt the *trans*-configuration. In *cis*-ONOO⁻, the terminal atom O(3) cannot attack the nitrogen atom to give a nitrate, in spite of high driving force of the reaction

Table 2. Activation parameters of peroxynitrite isomerisation (ONOOH $\rightarrow$ HNO₃).

Parameter, units of measurement	Value	Ref.
$\Delta_{\text{iso}}H^\circ / \text{kJ mol}^{-1}$	75 ± 4	24
	82	21
	86 ± 4	16
	88.7	40, 62
$\Delta_{\text{iso}}S^\circ / \text{J K}^{-1} \text{mol}^{-1}$	13 ± 8	24
	31	21
	54	40, 62
$\Delta_{\text{iso}}V^\ddagger / \text{cm}^3 \text{mol}^{-1}$	1.7 ± 1.0	16, 36
	4.8 ± 0.2	63
	6.7 ± 0.9	63
	9.7 ± 1.4	64
	10.2 ± 1.1	65
	10.7 ± 1.9	66

($\Delta G = -150 \text{ kJ mol}^{-1}$). Such an attack becomes possible in the *trans*-configuration owing to a decrease in the N–O–O bond angle ($\sim 117^\circ$ for the *cis*- and $\sim 112^\circ$ for the *trans*-isomer) and to elongation of the O–O bond (from $\sim 1.37 \text{ \AA}$ for the *cis*- to $\sim 1.40 \text{ \AA}$ for the *trans*-isomer) (results of *ab initio* calculations).

According to calculations,^{70–73} the energy barrier to isomerisation of the *cis*-anion to the *trans*-isomer lies between 88 and 113 kJ mol^{-1} and the process is impossible at physiological temperatures. For peroxynitrous acid, this barrier reduces to $40\text{--}50 \text{ kJ mol}^{-1}$, *cis*-ONOOH being only $2\text{--}8 \text{ kJ mol}^{-1}$ more stable than *trans*-isomer.^{70,71,73–76}

Spectral studies confirmed that peroxynitrite in alkali solutions exists only as *cis*-isomer. In particular, the ¹⁵N NMR spectra of peroxynitrite in 0.3 M NaOH exhibit^{15,71} a single peak (would both *cis*- and *trans*-isomers be present in solution, two peaks should be recorded). Small frequency shifts in the Raman spectra of ¹⁵N-peroxynitrite are consistent with the presence of only *cis*-isomer.⁷⁰

Table 3. Gibbs free energies of peroxynitrite homolysis reactions.

Infrared spectra in Ar matrix obtained at -260 and -266 °C showed^{77,78} that under these conditions the *cis*- and *trans*-isomers of peroxyxynitrous acid are in equilibrium, with the higher content of *cis*-isomer. Exposure of ONOOH to UV irradiation leads to an increase in the content of the *trans*-isomer, whereas the action of IR radiation causes the equilibrium to completely shift towards the *cis*-isomer.⁷⁸

The UV spectrum of peroxyxynitrite anion in aqueous solutions exhibits²⁵ a broad absorption band with a maximum at 302 nm and an extinction coefficient, ϵ , of 1670 ± 50 litre mol⁻¹ cm⁻¹. The UV spectrum of unstable peroxyxynitrous acid was obtained⁵⁵ by pulse radiolysis: $\lambda_{\text{max}} = 240$ nm and $\epsilon = 770 \pm 50$ litre mol⁻¹ cm⁻¹. The IR and Raman spectra of these species and other relevant information are also available.^{70,79,80}

The values of the ionisation constant ($\text{p}K_a$) of this acid, ONOOH, measured by different methods range from 5.3 to 8.3 (Refs 3, 25, 26, 47, 54, 81–83) as a consequence of instability of the compound. More reliable values, namely, $\text{p}K_a = 6.8$ – 6.5 at 25 °C were obtained^{4,36} by the stopped-flow technique from the plot of the rate of ONOOH isomerisation to nitrates *vs.* pH values.

The reaction is described by the following kinetic equation

$$-\frac{d[\text{PN}]}{dt} = k_{\text{eff}}[\text{PN}] = \frac{k_6[\text{PN}][\text{H}^+]}{K_a + [\text{H}^+]}, \quad (7)$$

where $[\text{PN}] = [\text{ONOO}^-] + [\text{ONOOH}]$ and $k_6 = 1.2$ – 1.3 s⁻¹ at 25 °C.^{4,24,36,84} The ionisation constants determined from Eqn (7) depend on the compositions and concentrations of buffer solutions, which can be illustrated using the following data for 25 °C:³⁶

Buffer	Buffer concentration / mol litre ⁻¹	$\text{p}K_a (\pm 0.10)$
Phosphate	0.65	7.33
	0.25	7.12
	0.05	6.71
	0.001	6.55
Ammonium	0.05	7.11
Borate	0.1	8.59

This dependence of $\text{p}K_a$ was explained³⁶ by an increase in the apparent rate of isomerisation of peroxyxynitrous acid owing to either general acid catalysis (phosphate buffer) or the reaction of peroxyxynitrite with ammonium and borate components of the solutions.

The ionisation constant of ONOOD in phosphate buffer (concentration 0.1 mol litre⁻¹) at 25 °C is 3.3 times lower ($\text{p}K_a^D = 7.3$) than that of ONOOH.⁸⁵ The thermodynamic parameters of the ionisation reaction are listed in Table 1.

Peroxyxynitrite is a strong one- and especially two-electron oxidant. The E° potential of the two-electron reaction of the acid, ONOOH (see Table 4) is similar to the E° values for alkyl peroxides and peroxy acids,^{59,86} whereas the potential of one-electron reaction of ONOOH is 0.95 and ~ 0.8 V higher compared to alkyl peroxides and peroxy acids, respectively.⁵⁹

IV. Decomposition and isomerisation

1. Decay pathways

Decay[‡] of peroxyxynitrite can occur as isomerisation to nitrate or as decomposition into nitrite and oxygen.

The former reaction is the major pathway at $\text{pH} < \text{p}K_a$, while the latter becomes significant at $\text{pH} > 7$ and peroxyxynitrite concentrations above 10^{-4} mol litre⁻¹ (see Refs 38, 88–91). Quantitative yield of nitrate in acid solutions ($\text{pH} \sim 4$) was reported.²⁰ At $\text{pH} < 7$, the yield of nitrate is at least 90%, being slightly dependent on the initial concentration of peroxyxynitrite, pH value and temperature.⁹¹ As the acidity of the medium decreases, the yield of nitrate also decreases, while the yield of nitrite increases and reaches a limiting value at $\text{pH} \sim 10$, being strongly dependent on the initial concentration of peroxyxynitrite.^{90,91} For instance, the yields of nitrite are 30% and 80% at pH 10 for the 5×10^{-5} and 2.5×10^{-3} M peroxyxynitrite solutions, respectively.⁹¹ The formation of nitrite is accompanied by production of oxygen ($[\text{NO}_2^-]:[\text{O}_2] \approx 2$, see Refs 88–91).

In phosphate buffer, the yields of NO_3^- and NO_2^- depend on acidity ($\text{pH} = 1$ – 14) in a complex manner; the curves exhibit inflection points at pH values of about 3.1, 5.8, 6.8, 8.0 and 11.9 (Fig. 2).⁹⁰ At $\text{pH} > 7$, the yield of nitrite appreciably increases while the yield of nitrate correspondingly decreases, namely, $65 \pm 5\%$ for NO_2^- and $35 \pm 5\%$ for NO_3^- at pH 9–10. Contrary to earlier data,^{40,62} it was found recently⁹⁰ that at $\text{pH} > 11$ the yield of nitrate again increases and the nitrate becomes the major product in strong alkaline media (80% at pH 14). At all pH values, the sum of the yields of nitrite and nitrate is a constant equal to the initial concentration of peroxyxynitrite. The dependences of the yields of NO_2^- , NO_3^- and O_2 on the initial concentration of peroxyxynitrite, measured at pH 5.8, 7.4 and 8.5, were linear only at pH 5.8 (see Ref. 90).

A study⁹² of the reactions of peroxyxynitrite with methaemoglobin and 9,10-diphenylanthracene (specific probes for the presence of singlet dioxygen, $^1\text{O}_2$) revealed the formation of nitrosylhaemoglobin and intracyclic 9,10-diphenylanthracene peroxide in high yields. Based on this, it was assumed that a possible pathway of decay of peroxyxynitrous acid involves its transformation to $^1\text{O}_2$ and $^1\text{NO}^-$ *via* a four-membered cyclic intermediate.

Figure 2. Yields (Q) of nitrate (1) and nitrite (2) plotted *vs.* pH value for the decay of peroxyxynitrite $[(1.02 \pm 0.03) \times 10^{-3}$ mol litre⁻¹] in phosphate buffer (0.05 mol litre⁻¹) at 30 °C.⁹⁰

[‡] According to the IUPAC recommendations⁸⁷ for the names of various processes, the decay of peroxyxynitrite is any process accompanied by disappearance of the compound; isomerisation is a process resulting in nitrate; and decomposition is the breakdown into nitrite and oxygen.

However, no nitrosylhaemoglobin was revealed in a more thorough study of the interaction of methaemoglobin with peroxynitrite containing no H_2O_2 and NO_2^- impurities;^{93,94} nor was observed emission at 1270 nm characteristic of $^1\text{O}_2$.⁹⁴ Besides, according to quantum chemical calculations,⁹⁴ the energy barrier to formation of cyclic intermediate in reaction (8) is about five times higher than the experimental activation enthalpy of decay of peroxynitrite (415 vs. 86.5 kJ mol⁻¹, respectively).⁸⁵ Probably, the reason for difference between the results reported in Ref. 92 and in studies^{93,94} consists in that peroxynitrite contained⁹² hydrogen peroxide impurity.

The formation of $^1\text{O}_2$ in the oxidation of H_2O_2 by peroxynitrite was detected in another study.⁹⁵ Two mechanisms were proposed, namely, a concerted reaction of *cis*- ONOO^- with H_2O_2 (see Ref. 95)

and one-electron of oxidation hydrogen peroxide by peroxynitrous acid followed by heterolysis of peroxy nitrate that formed in the reaction^{96,97}

The formation of singlet oxygen in reaction (9) was reported to be thermodynamically unlikely.⁹⁴ Direct oxidation of superoxide by nitrogen dioxide

is thermodynamically favourable and seems to be more probable.

2. Decay kinetics

Earlier studies^{14,21,24–26,98} were carried out assuming that Eqn (7) is valid for the whole range of pH values at which ONOOH breaks down. However, recent data³⁶ showed that this holds only at low peroxynitrite concentrations and at $\text{pH} < \text{p}K_a$ (e.g., at a pH value of 7.9 and $[\text{PN}] = 4.8 \times 10^{-5} \text{ mol litre}^{-1}$; see Fig. 3, curve 1). If the initial concentration of peroxynitrite is ten times higher, the decomposition of this compound is described by a simple exponent only in the initial portion and then dramatically decreases (Fig. 3, curve 2). It was assumed³⁶ that at $\text{pH} > 6.8$ and high concentrations of peroxynitrite it decomposes involving the for-

Figure 3. Kinetic curves for peroxynitrite decomposition in phosphate buffer ($\text{pH } 7.9$, 25°C).³⁶ $[\text{PN}] = 4.8 \times 10^{-5}$ (1) and $4.8 \times 10^{-4} \text{ mol litre}^{-1}$ (2).

mation of $[\text{ONOOH} \cdots \text{ONOO}^-]$ adduct as intermediate. The decomposition rate and the character of kinetics are strongly affected by the buffer composition,^{15,36} impurities (H_2O_2 ²⁹ and NO_2^- ^{29,36,38,99}) and trace amounts of transition metals.^{14,25,100} Recently,¹⁰¹ it was established that the decomposition rate of peroxynitrous acid in phosphate buffer at $\text{pH } 5.8\text{--}8.0$ decreases upon addition of ethanol or mannitol. This effect was explained by the mechanism involving stabilisation of peroxynitrite owing to fast equilibrium formation of a complex with the alcohol.

The stability constants K'' are $(9.6 \pm 1.5) \times 10^{-3}$ and $(6.7 \pm 0.9) \times 10^{-3}$ and the rate constants for decomposition of the complexes k_{ROH} are 0.95 ± 0.01 and $0.83 \pm 0.01 \text{ s}^{-1}$ for ethanol and mannitol, respectively.

The plots of the apparent rate constants for decomposition (k_{eff}) on the acidity of the medium exhibit three portions (Fig. 4).^{14,24} In the pH region from 10 to 7 the constant k_{eff} increases as the acidity increases and reaches a plateau at $\text{pH} \approx 6$. Here, Eqn (7) obeys at $k_6 = 1.2 \text{ s}^{-1}$ and $\text{p}K_a = 6.8$.^{24,26,36,83,85} The activation parameters for this portion are listed in Table 2. The secondary kinetic isotope effect for the decomposition of ONOOH (ONOOD), $k_6^{\text{H}}/k_6^{\text{D}}$, weakly depends on temperature in the range $5\text{--}55^\circ\text{C}$ and is equal to 1.6 ± 0.2 and the ionisation isotope effect, $K_a^{\text{H}}/K_a^{\text{D}}$, of peroxynitrous acid is 3.3.⁸⁵ At $\text{pH} < 2$, the decomposition rate increases with an increase in acidity. This was treated^{14,21} as indication of an acid catalysed route:

$$-\frac{d[\text{ONOOH}]}{dt} = k_{\text{H}^+} [\text{ONOOH}][\text{H}^+]. \quad (10)$$

The k_{H^+} values are listed in Table 5. The activation enthalpy and activation entropy corresponding to this route are $\Delta H^\ddagger = 61.2 \pm 0.8 \text{ kJ mol}^{-1}$ and $\Delta S^\ddagger = 22.2 \pm 2.9 \text{ J K}^{-1} \text{ mol}^{-1}$, respectively (see Refs 14 and 21).

At $\text{pH} > 10$, the decomposition kinetics are less understandable. Experimental k_{eff} values are much higher than those calculated from Eqn (7) for $[\text{H}^+] \ll K_a$, $k_6 = 1.2 \text{ s}^{-1}$ and $\text{p}K_a = 6.8$ and show a rather large scatter (see Fig. 4).¹⁴ These deviations

Figure 4. Rate constants for peroxynitrite decay plotted vs. pH values: at 1.5°C (1),²¹ at 25°C (2),²⁴ (3),¹² (4),²⁵ (5)¹⁰² and in the presence of Cu^{2+} (6).¹⁷ Line 7 corresponds to data calculated from Eqn (7) with $k_6 = 1.2 \text{ s}^{-1}$ and $\text{p}K_a = 6.8$.²⁴

Table 5. Rate constants for the acid catalysed route (10) of peroxyxynitrite isomerisation.

T/K	k_{H^+} /litre mol ⁻¹ s ⁻¹	Ref.
281.5	1.295 ± 0.196	14
286.0	2.450 ± 0.112	14
297.0	5.414 ± 0.312	14
308.5	15.790 ± 1.547	14
273.7	0.596 ± 0.008	14, 21
310.0	14.30 ± 0.49	14, 21

were associated¹⁴ with a catalytic route in this range of pH values owing to the presence of transition metal (M) ions, especially copper:

$$k_{\text{eff}} = \frac{k_6[H^+]}{K_a} + k_M[M][H^+].$$

Indications of metal complex catalysis of this reaction were also reported in other studies.^{25, 26, 100, 102}

3. Isomerisation mechanisms

Four routes of isomerisation of peroxyxynitrous acid to nitrate are assumed.^{16, 24}

1. Heterolysis and interaction of nitroyl cation with water:^{16, 24}

Although the change in the Gibbs free energy of reaction (11) is nearly zero,^{16, 24} high activation energy (188 kJ mol⁻¹) (see Ref. 24) makes this route unlikely under normal conditions. However, it can occur in the case of acid catalysed decomposition of peroxyxynitrous acid at pH < 2.^{16, 24} Yet another possible mechanism of acid catalysed isomerisation involves equilibrium protonation of ONOOH followed by O–O bond homolysis with the formation of two radical species, H₂O^{•+} and NO₂[•], that recombine to give a nitrate:¹⁴

2. Homolysis followed by recombination of HO[•] and NO₂[•] radicals:^{19, 60, 62, 65, 88, 100, 103, 104}

The mechanism of homolysis belongs to the most debatable issues in chemistry of peroxyxynitrous acid. In 1952, Halfpenny and Robinson¹⁰⁵ observed the formation of biaryls in the oxidation of arenes by peroxyxynitrous acid and assumed that ONOOH undergoes homolysis. In 1990, Beckman *et al.*³ reported that decomposition of peroxyxynitrite generates a strong oxidant capable of initiating many reactions typical of OH radical. The maximum yields of [•]OH in the decomposition of peroxyxynitrite (pH 6.0), determined using deoxyribose and DMSO as scavengers of OH radicals, are $5.1 \pm 0.1\%$ and $24 \pm 1.0\%$, respectively.³ Different methods give for the yield of OH radicals a range of values from 0% to 40%.^{40, 62, 98, 100, 103, 104, 106}

Koppenol *et al.*^{16, 36, 38, 61} reported kinetic and thermodynamic arguments against the sequence of reactions (12) in aqueous solutions. Using the estimate of the free energy of homolysis of ONOOH, $(\Delta G_{\text{hom}}^{\circ})_{\text{aq}} = 67 \pm 10$ kJ mol⁻¹ and the experimental rate constant for the reverse reaction

($k_{-13} = 4.5 \times 10^9$ litre mol⁻¹ s⁻¹), they found⁶¹ $k_{13} = 0.6 \times 10^{-4}$ s⁻¹ and, taking into account the rate constant for

isomerisation (k_6), concluded that homolysis of ONOOH in aqueous solutions is unlikely. In the gas phase, the free energy of homolysis of peroxyxynitrous acid is much lower [$(\Delta G_{\text{hom}}^{\circ})_{\text{gas}} = 30$ kJ mol⁻¹] and production of OH radicals is more probable.^{61, 104} Besides, it was shown^{16, 54} that in aqueous solutions (in contrast to the gas phase¹⁰⁷) the interaction of hydroxyl radicals with nitrogen dioxide results in quantitative formation of peroxyxynitrous acid following reaction (–13) rather than formation of nitrate following reactions (12).

Homolysis of the O–O bond is inconsistent with two other data sets. Namely, (i) the yield of ¹⁵N-nitrate in the oxidation of ¹⁵N-nitrite by peroxyxynitrous acid is much lower than it follows from the homolytic model^{38, 99} and (ii) no ascorbyl radicals were detected in the oxidation of hydroascorbate anion.^{38, 108}

Sometimes, the activation volume for isomerisation ($\Delta_{\text{iso}}V^{\ddagger}$) (see Table 2) is used as argument *pro* (or *contra*) the homolytic mechanism. However, data obtained by different methods are significantly different (from 1.7 to 10 cm³ mol⁻¹; see Refs 36, 63–65) and can therefore not serve as indicators of a particular mechanism.^{38, 63}

3. Intramolecular rearrangement. An alternative to the homolytic mechanism of isomerisation of ONOOH involves a *cis*–*trans* conversion of peroxyxynitrite accompanied by migration of the terminal oxygen atom to the nitrogen atom and formation of nitrate.^{16, 24, 70, 74, 85}

Oxygen shift in the course of *cis*–*trans*-isomerisation is only possible if the O–O bond is directed normal to the O=N–O plane.^{16, 74} The reactive species in the oxidation reactions is thought^{16, 24, 70, 74} to be the excited peroxyxynitrous acid. Its molecule has a *trans*-configuration with elongated O–O bond and the terminal oxygen atom located near the nitrogen atom; this is structurally similar to the transition state of the isomerisation of ONOOH to HONO₂. The radical-like reactivity of ONOOH is associated with the presence of two unpaired electrons in the triplet excited state.^{16, 74} Quantum chemical calculations confirmed the existence of such a low-lying state.⁷⁴

4. Homolysis in the solvent cage. A mechanism was also proposed,^{4, 59, 62, 103, 104} which involves intermediate formation of a radical pair in a ‘cage’. Diffusion of the radical pair out of the cage produces what is called free radicals [•]OH and NO₂[•] while their recombination results in nitrate.

Quantum chemical calculations⁶⁸ showed that in the gas phase the radical pair [ONO[•]...OH] is 8 kJ mol⁻¹ more stable than free radicals NO₂[•] + [•]OH owing to the formation of the OH...O hydrogen bond but ~63 kJ mol⁻¹ less stable than *cis*-HOONO.

The sequence of reactions (14) is similar to the homolytic mechanism if we assume that hydroxyl radicals can escape the cage and react with substrate or to the ‘triplet’ mechanism of intramolecular rearrangement under assumption that the radicals remain within the cage. The ratio of the rate constants for these routes, $k_{\text{iso}}/k_{\text{dif}}$, is about 2 (Ref. 62) and 2.6,¹⁰³ which corresponds to 30%–40% yields of the OH radicals.

Earlier,²⁰ it was reported that nitrate formed in the reaction retains both peroxide oxygen atoms. However, a recent study¹⁰⁹

revealed that 17% of the oxygen atoms of peroxynitrite are involved in oxygen exchange with water in the course of isomerisation. These data were treated as substantiation of the intramolecular mechanism. The kinetic isotope effect of solvent (1.4–1.5) is also consistent with intramolecular rearrangement of ONOOH to nitrate.^{16,85} Besides, oxygen exchange between the $\cdot\text{OH}$ radical in the radical pair and H_2O should be fast,¹⁰⁹ which excludes this structure from being considered as intermediate. Calculations of the models including a molecule water showed that homolysis (12) is the most energetically favourable mechanism and, therefore, the radicals $\cdot\text{OH}$ and $\text{NO}_2\cdot$ should collapse to nitrate without oxygen exchange;¹¹⁰ however, this contradicts experimental data. At the same time, chemically induced nuclear polarisation (enhanced absorption of $^{15}\text{NO}_3^-$ signal) observed during the decomposition of peroxynitrous acid indicates that nitrate is formed as a result of recombination of the radical pair $[\cdot\text{OH}\cdots^{15}\text{NO}_2\cdot]$.¹¹¹

4. Peroxynitrite decomposition mechanisms

In weak alkaline media, isomerisation of peroxynitrite is accompanied by its decomposition following the stoichiometric equation^{88–91} given below

The mechanisms of decomposition and isomerisation have been highly debatable issues. A radical mechanism^{40,42,62,64,88,89} and a bimolecular one^{36,38,60,91} are possible.

The radical mechanisms imply either homolysis of the $\text{ONO}-\text{OH}$ bond at the rate-limiting step,^{64,89} resulting in the $\cdot\text{OH}$ and $\text{NO}_2\cdot$ radicals,

or homolysis of the $\text{ON}-\text{OO}^-$ bond, resulting in nitrogen oxide and superoxide.^{40,42,62,64,88}

The radical pathway is substantiated by the absence of the dependence of the relative yields of nitrite and oxygen on the initial concentration of peroxynitrite^{88,89} and by coincidence of experimental yields of NO_2^- as function of the pH value with the results of the calculations based on reactions (15).^{64,90} Production of superoxide in reactions (16) was proved using the $\text{O}_2^{\cdot-}$ scavengers, namely, tetranitromethane^{41,64,112,113}

and methyl viologen ($\text{MV}^{\cdot+}$) radical⁴²

The rate constant for ONOO^- homolysis was found to be the same for both cases ($k_h = 0.017 \text{ s}^{-1}$). The homolytic mechanism (16) is also substantiated by a decrease in the yield of $\text{C(NO}_2)_3^-$ anion in the presence of excess nitrogen oxide,^{41,113} which shifts the equilibrium in reactions (17) towards peroxynitrite.

In contrast to the results^{41,64,113} presented above, Koppenol *et al.*⁶⁰ reported that NO^* radicals do not inhibit the formation of $\text{C(NO}_2)_3^-$ and that the decomposition of peroxynitrite ($>10^{-4} \text{ mol litre}^{-1}$) at $\text{pH} > 7$ does not obey the first-order kinetics in the general case.³⁶ They also found that the relative yields of nitrite and oxygen^{38,91} and the apparent rate constants for decomposition^{16,36} increase as the initial peroxynitrite concentration increases. Quantum chemical estimates¹¹⁴ showed that homolysis of the anion by the mechanism (16) is possible, but this is a thermodynamic 'dead end' because the $[\text{NO}^*\cdots\text{O}_2^{\cdot-}]$ radical pair formed mostly reverts to the starting peroxynitrite. All these results are inconsistent with the homolytic mechanisms. It is believed¹¹⁴ that strong solvation effects make the decomposition of ONOO^- anion a more complicated process (compared to isomerisation of the acid, ONOOH) which involves the formation of an acid–anion adduct.^{16,36,38,91}

The $[\text{ONOOH}\cdots\text{ONOO}^-]$ dimer undergoes a concerted rearrangement involving a cyclic transition state.

The sequence of reactions (18) is analogous to a commonly accepted mechanism of the decomposition of peroxy acids¹¹⁵ and correctly describes the dependences of the yields of nitrate and nitrite and the apparent rate constants for decomposition on the initial concentration of peroxynitrite and on the pH values at $k_{\text{iso}} = 1.15 \text{ s}^{-1}$, $\text{p}K_a = 6.8$, $k_{\text{ad}} = 1.7 \cdot 10^4 \text{ litre mol}^{-1} \text{ s}^{-1}$, $k_{\text{-ad}} = 0.025 \text{ s}^{-1}$ and $k_d = 0.05 \text{ s}^{-1}$ (see Ref. 38). The effective rate constant ($k_{\text{eff}} = 1.8 \times 10^4 \text{ litre mol}^{-1} \text{ s}^{-1}$) for peroxynitrite decomposition at pH 4.7 was obtained¹¹⁶ from the slope of the initial portion of the curve of O_2 accumulation. This is similar to $k_{\text{eff}} = k_{\text{ad}}k_d/(k_{\text{-ad}} + k_d) = 1.1 \times 10^4 \text{ litre mol}^{-1} \text{ s}^{-1}$ calculated from the results of study³⁸ and substantiates¹¹⁶ the mechanism (18).

Thus, in spite of intensive research the mechanisms of isomerisation and decomposition of peroxynitrite are still to be clarified. This requires detailed studies on the kinetics of peroxynitrite decomposition and on the reactions of peroxynitrite with various model substrates.

V. Reactions with hydrocarbons and other compounds

1. Typical mechanisms

Peroxynitrite is a strong one- and two-electron oxidant (see Table 4). The interaction of peroxynitrite with the substrates (S) possessing the properties of strong reducing agents can follow four routes (Scheme 2).

Scheme 2

Routes *a* and *b* are first-order reactions with respect to substrate and peroxynitrite. They are characteristic of the reac-

tions involving sulfides,^{117,118} thiols,⁸³ Ni(II)-cyclam complex (cyclam is 1,4,8,11-tetraazacyclotetradecane),¹¹⁹ Br[−] and I[−] anions (see Refs 105 and 119, respectively) and of nucleophilic addition of ONOO[−] to CO₂.^{120–123} Reactions with [Fe(CN)₆]^{4−} (see Ref. 119) and typical scavengers of free radicals, namely, DMSO^{3,98,104} and 2,2'-azinobis(3-ethylbenzothiazole-6-sulfonate) (ABTS)⁹⁸ follow routes *c* and *d*, which are first-order reactions with respect to peroxynitrite and zero-order reactions with respect to substrate; they involve the formation of a hydroxyl-like reactive intermediate.^{3,68,106,119} In addition to free OH radical and [HO[•]...NO₂][•] pair,⁶⁸ a possible candidate is the excited *trans*-ONOOH, which is similar to the radical pair.^{16,24,70,74,98,124} The oxidation of methionine, 2-keto-4-thio-methylbutanoic acid and ascorbate anion follows route *b* (or routes *b* and *d*) at high (or low) substrate concentrations.^{125,126}

Production of OH radicals in the homolysis of ONOOH was first proposed by Halfpenny and Robinson¹⁰⁵ who observed not only nitration and hydroxylation products, but also conversion of arenes to biaryls (Scheme 3).

Scheme 3

The rate constants for the oxidation of hydrogen peroxide and nitrite by peroxynitrous acid and hydroxyl radicals are similar.¹⁰⁰

Using the stopped-flow technique, it was found^{98,119,127,128} that the oxidation of many compounds by peroxynitrous acid has no effect on the decomposition kinetics of ONOOH. It was assumed that the rate-limiting step of decomposition of peroxynitrous acid (but not peroxynitrite anion!) involves the formation of a reactive intermediate which then rapidly reacts with substrates in a fashion typical of OH radicals. For instance, peroxynitrous acid can initiate polymerisation of methyl acrylate,¹⁹ hydroxylation and nitration of alkanes, alkenes¹²⁹ and arenes,¹⁰⁵ oxidise DMSO and deoxyribose to formaldehyde and malonic dialdehyde, respectively,³ damage DNA and cause degradation of proteins.⁵⁶ Many of these reactions are inhibited by scavengers of OH radicals (alcohols, benzoic acid and their derivatives, uric acid) and are not catalysed by metal ions.

Hydroxylation at the aromatic ring of phenylalanine results in approximately equal yields of *ortho*-, *meta*- and *para*-derivatives. This feature is used as highly sensitive and specific method for detection of OH radicals.¹³⁰ Similar products and an identical distribution of isomers was reported for the reaction with ONOOH.¹²⁴ The yield of tyrosine and its *ortho*- and *meta*-isomers increases with the acidity of the medium (at pH 6–9) and the concentration of ONOOH, being independent of the substrate concentration. Not only hydroxylation products but also 3-nitro-tyrosine and 4-nitrophenylalanine (and fluorescing bityrosine, in the reaction with tyrosine) were detected among reaction products. These facts and a decrease in the yields of reaction products in the presence of mannitol (specific scavenger of OH radicals) are consistent with route *d* (see Scheme 2).

Production of reactive radical species is accompanied by isomerisation of peroxynitrite following reaction (14). The yield of free radicals was estimated at about 32% based on the O₂ evolution in the oxidation of hydrogen peroxide or nitrite by peroxynitrous acid,¹⁰⁰ at about 24% based on the yield of formaldehyde in the oxidation of DMSO³ and at 40% based on the yield of ABTS^{•+} radical cations in the oxidation of ABTS.^{98,106}

Both peroxynitrous acid and its anion can immediately react with various substrates (routes *a* and *b* in Scheme 2). Since many studies were carried out at neutral pH values, it is often difficult to conclude which of the two forms, ONOOH or ONOO[−], is more reactive. Table 6 lists the rate constants for some second-order reactions of organic and inorganic substrates with peroxynitrite. Under particular conditions, these reactions can proceed much faster than homolysis of ONOOH and be of physiological value.

A mechanism was proposed,^{84,143} which involves a direct oxidation of substrate by the acid, ONOOH, and an indirect oxidation by the activated form of the acid (ONOOH*).

In the direct oxidation (first-order reaction with respect to substrate and reagent) the yield of products with respect to peroxynitrite can be as high as 100%. In the indirect oxidation (first-order reaction with respect to peroxynitrous acid and zero-order reaction with respect to substrate) about 50%–60% of ONOOH isomerise into nitric acid (*k*_{iso}) and only 40%–50% is

Table 6. Rate constants for second-order reactions involving peroxynitrite in aqueous solutions.

^a Reaction with peroxynitrite anion; ^b 5,10,15,20-tetrakis(*N*-methylpyridinium-4-yl)porphyrin; ^c at pH 7.4; ^d At pH 4.6; ^e at pH ~ 13; ^f for protein tetramer.

converted to the activated form ONOOH^* (k_{act}), which then rapidly interacts with the substrate (k^*) or produces nitrate (k_{N}). Therefore, even at very high concentration of substrate ($k^*[\text{S}] \gg k_{\text{N}}$), the yield of oxidation products in the indirect process is less than 50%. The nature of the reagent ONOOH^* is unknown. Competitive inhibition studies showed that in some cases the addition of free radical scavengers has no effect on the yields of products of indirect oxidation^{144, 145} or only partial inhibition is observed,¹¹⁹ which is weaker than that predicted from the known rate constants for the reactions of the scavengers with hydroxyl radicals. In those cases^{3, 100, 146} where the degree of inhibition correlated to the rate constants for hydroxyl radicals, the involvement of these species in indirect oxidation of substrates was excluded⁸⁴ based on the kinetic data and product yields.

The contributions of different oxidation routes strongly depends on the pH value (Fig. 5).^{3, 15, 22, 83, 127} In particular, the yields of products of DMSO oxidation following routes *c* and *d* decrease while the rate of oxidation of thiol group following route *a* increases with an increase in pH value.

Figure 5. Oxidative reactivity of peroxynitrite plotted vs. pH values.^{15, 22} The results are presented in per cent of the maximum yield under optimum conditions.

(1) Oxidation of thiol group (100% yield), (2) $\text{HO}^{\cdot} \cdots \text{NO}_2^{\cdot}$ (yield 25%–35%), (3) nitration by NO_2^+ (8% with superoxide dismutase, 100% with Fe^{3+}).

A great diversity of types of the chemical reactions of peroxynitrite is due to involvement (depending on reaction conditions) of various reactive species that are formed as a result of decomposition or activation of peroxynitrite and to unique properties of the peroxynitrite molecule that can simultaneously act as a strong one- and two-electron oxidant, an electrophile and a nucleophile.^{22, 38, 69, 147}

Now we will consider specific features of the mechanisms of the best studied peroxynitrite reactions in more detail.

2. Reactions with hydrocarbons; role of $\cdot\text{OH}$ -like species

The authors of the present review have found^{148–150} that the oxidation of alkanes and alkylbenzenes involves an intermediate step called ‘pre-activation’ of the reagent. At this step, reactive radical species, biradicals or metal complexes with a coordination vacancy are produced. The kinetics of reactions of hydrocarbons with various oxidants and radicals have been studied^{148, 150–152} so thoroughly that hydrocarbons are the best substrates for establishing the nature of the reactive species. Besides, investigations on the reactions of alkanes, alkenes and arenes with peroxynitrite are important for elucidating the mechanisms of oxidation of C–H bonds of alkanes and alkenes in cell membranes and arene- and sulfur-containing fragments of proteins. Prior to our publications, only the reactions of peroxynitrite with strong reducing agents (see Scheme 2) were studied. Only two experimental investigations concerning products of the oxidation of cyclohexane and cyclo-

hexene¹²⁹ and arenes¹⁰⁵ in the H_2O_2 – HNO_2 system were available. According to quantum chemical calculations, the interaction of alkanes with peroxynitrous acid involves most probably production of OH radicals as intermediates¹⁵³ and the oxidation of alkenes involves *cis*- ONOOH and formation of a cyclic transition state^{68, 114, 154} similarly to epoxidation of olefins by organic peroxy acids.

We pioneered in systematic studies on the kinetics of peroxynitrite reactions with hydrocarbons as reducing agents and found¹⁵⁵ that alkanes, alkenes and alkylbenzenes are oxidised by aqueous solutions of peroxynitrous acid at $\text{pH} < 7.5$. In the case of cyclohexane, a number of products are formed simultaneously; these are cyclohexanone, cyclohexanol, bicyclohexyl and trace amounts ($< 1\%$) of nitrocyclohexane.^{155–157} Oxidation of alkylbenzenes under these conditions results in a mixture of phenols, nitrophenols and nitroarenes (see Scheme 3).¹⁰⁵ The oxidation of cyclohexene by peroxynitrous acid in phosphate buffer ($\text{pH} \sim 7$) and in the H_2O_2 – HNO_2 system ($\text{pH} 4.3$) gives a broad spectrum of products including cyclopentanecarbaldehyde, epoxycyclohexane, cyclohexanone, cyclohex-2-enol, cyclohex-2-enone, 2-hydroxycyclohexanone, 1-nitrocyclohexene and cyclopent-2-enecarboxylic acid that were identified by GC/MS.¹⁵⁸

The oxidation of cyclohexane by peroxynitrite in a three-phase system ‘aqueous solution–cyclohexane–gas phase’ (O_2 or He) proceeds in the aqueous phase and results in cyclohexanol, cyclohexanone and bicyclohexyl.¹⁵⁹ In both helium and oxygen atmospheres the alcohol is formed at a constant initial rate, whereas production of ketone is preceded by a rather long induction period due to the formation of O_2 in the decomposition of ONOOH . At $\text{pH} 4.7$ and $[\text{RH}]_{\text{aq}} = 7 \times 10^{-3} \text{ mol litre}^{-1}$, only 1% of ONOOH is consumed for the oxidation of hydrocarbon.¹¹⁶ This is due to fast decomposition of peroxynitrous acid. A decrease in the yield of cyclohexanol and an increase in the yield of cyclohexanone on going from the helium to oxygen atmosphere was explained by competition between the routes involving and not involving O_2 (Scheme 4).

Scheme 4

Thus, only a fraction of alcohol formed in the reaction is a product of primary oxidation of cycloalkane by peroxynitrite, whereas the remaining part of alcohol and the whole amount of ketone are products of the secondary radical reactions involving oxygen.

Extremely low solubility of hydrocarbons in water and rapid decomposition of ONOOH at $\text{pH} \sim 7$ make the use of conventional kinetic methods impossible. The problem was solved using the kinetic distribution method (KDM)¹⁴⁸ and a H_2O_2 – HNO_2 /acetate buffer model system ($\text{pH} 4.27$) where peroxynitrous acid is generated *in situ*. Of particular value is the fact that the method allows one to obtain not only the rate constants but also valuable thermodynamic data on the distribution of volatile reactants between the gas phase and solution.

When studying the oxidation of hydrocarbons in aqueous solutions,^{148, 149} the apparent rate constants, k_{λ}^{RH} , for the loss of volatile substrate in the gas phase of a closed reactor are usually related to the liquid-phase rate constants k_1^{RH} as follows:

$$-\frac{1}{[\text{RH}]_{\text{g}}} \frac{d[\text{RH}]_{\text{g}}}{dt} = k_{\lambda}^{\text{RH}} = \frac{k_1^{\text{RH}}}{(1 + \alpha^{\text{RH}}\lambda)}, \quad (19)$$

where $\lambda = V_{\text{g}}/V_{\text{l}}$ is the ratio of the volume of the gas phase to the volume of the liquid phase in the reactor and $\alpha^{\text{RH}} = [\text{RH}]_{\text{g}}/[\text{RH}]_{\text{l}}$ is the distribution coefficient of the hydrocarbon between these phases. The relative liquid-phase rate constants for substrates A and B are related to the measured quantities $k_{\lambda}^{\text{A}}/k_{\lambda}^{\text{B}}$ as follows:

$$\frac{k_1^{\text{A}}}{k_1^{\text{B}}} = \frac{k_{\lambda}^{\text{A}}(1 + \alpha^{\text{A}}\lambda)}{k_{\lambda}^{\text{B}}(1 + \alpha^{\text{B}}\lambda)}. \quad (20)$$

However, the oxidation of hydrocarbons in the H_2O_2 – HNO_2 system cannot be described by Eqn (19) in a wide range of changes in λ . The apparent rate constants are unusual bell-shaped functions of λ and the relative liquid-phase rate constants $k_1^{\text{A}}/k_1^{\text{B}}$ for different pairs of substrates A and B change by 1.2 to 8 times for λ values ranging from 0.65 to 21.^{160, 161} Calculations using Eqn (20) gave an inverted order of selectivity (alkanes > alkenes > alkylbenzenes) and inversely proportional dependence of the relative rate constants on the solubility of hydrocarbons ($1/\alpha^{\text{RH}}$). These facts have no analogies with other hydrocarbon oxidation reactions;^{148, 150} they were explained^{160, 161} by the following mechanism (Scheme 5):

This includes the formation of peroxyxynitrous acid in solution at the rate $W_f = d[\text{ONOOH}]/dt$, the equilibrium distribution of the hydrocarbon (α^{RH}) and acid ($\alpha^{\text{PN}} = [\text{ONOOH}]_{\text{g}}/[\text{ONOOH}]_{\text{l}}$) between the gas and liquid phases, the decomposition of ONOOH (k_{g}^{PN} , k_1^{PN}), pre-activation of reagent (K_{g} , K_1) with production of a reactive species X (radical pair $[\text{HO}\cdots\text{NO}_2]$ or OH radical) and the interaction of X with the substrate RH (k_{g} , k_1) in both phases.

Kinetic studies of the H_2O_2 – HNO_2 system are complicated by simultaneous occurrence of reactions in solution and in the gas phase and by rapid decomposition of ONOOH. Therefore, even at large excess of reagent the loss of hydrocarbons does not obey the first-order kinetics with respect to substrate (Fig. 6). Calculations of Scheme 5 are simplified^{160, 161} at $[\text{H}^+] = \text{const}$ (buffer solutions) in two cases, namely, if $[\text{H}_2\text{O}_2]_0 \gg [\text{NO}_2^-]_0 \gg [\text{RH}]$ (system I) or $[\text{H}_2\text{O}_2]_0 = [\text{NO}_2^-]_0 \gg [\text{RH}]$ (system II).

In the case of system I the loss of substrate obeys¹⁶⁰ the following equation

$$\ln \frac{[\text{RH}]_{\text{g}}^0}{[\text{RH}]_{\text{g}}} = \frac{k_{\lambda}^{\text{RH}}}{k_{\lambda}^{\text{PN}}} [\text{NO}_2^-]_0 \left[1 - \exp(-k_{\text{f}}^{\text{I}}\tau) \right], \quad (21)$$

where $[\text{RH}]_{\text{g}}^0$ and $[\text{RH}]_{\text{g}}$ are the initial and current concentration of RH in the gas phase, respectively; k_{λ}^{RH} and k_{λ}^{PN} are the effective rate constants for the loss of substrate and decomposition of ONOOH, respectively,

Figure 6. Kinetic curves of cyclohexane decay.¹⁶⁰

Open and solid circles denote experimental data obtained at pH 4.27, 25 °C, $\lambda = 2.31$: $[\text{H}_2\text{O}_2] = 0.1$, $[\text{NaNO}_2] = 0.01 \text{ mol litre}^{-1}$ (1) and $[\text{H}_2\text{O}_2] = [\text{NaNO}_2] = 0.042 \text{ mol litre}^{-1}$ (2); lines 3 and 4 correspond to data calculated from Eqns (21) and (24), respectively. Methane was used as internal reference that is stable under the reaction conditions.

$$k_{\lambda}^{\text{RH}} = \frac{k_1^{\text{RH}} + k_{\text{g}}^{\text{RH}}\alpha^{\text{RH}}\alpha^{\text{PN}}\lambda}{(1 + \alpha^{\text{RH}}\lambda)(1 + \alpha^{\text{PN}}\lambda)} \quad (22)$$

($k_1^{\text{RH}} = K_1k_1$, $k_{\text{g}}^{\text{RH}} = K_{\text{g}}k_{\text{g}}$ are the effective rate constants for the reaction of peroxyxynitrite with the hydrocarbon in the liquid and gas phases, respectively),

$$k_{\lambda}^{\text{PN}} = \frac{k_1^{\text{PN}} + k_{\text{g}}^{\text{PN}}\alpha^{\text{PN}}\lambda}{1 + \alpha^{\text{PN}}\lambda}. \quad (23)$$

The effective pseudo-first-order rate constant for production of ONOOH (k_{f}^{I}) is given by²⁰

$$k_{\text{f}}^{\text{I}} = \frac{W_{\text{f}}}{[\text{NO}_2^-]} = \frac{k_2k_3[\text{H}^+]^2[\text{H}_2\text{O}_2]}{k_{-2}[\text{H}_2\text{O}] + k_3[\text{H}_2\text{O}_2]}.$$

Taking the oxidation of cyclohexane as an example, it was shown that Eqn (21) is valid in the whole range of substrate decay (see Fig. 6, curve 3). The ratio $k_{\lambda}^{\text{RH}}/k_{\lambda}^{\text{PN}}$ is independent of the initial concentrations of H_2O_2 and NaNO_2 and the k_{f}^{I} values at a specified pH value depend only on $[\text{H}_2\text{O}_2]$ (Table 7). The k_2 and $k_3/k_{-2}[\text{H}_2\text{O}]$ values calculated from these data are similar to the estimates²⁰ obtained in basically different manner, from the kinetics of formation of ONOOH (see below).

	$(k_{\text{f}}^{\text{II}})_{\text{aver}} = (2.5 \pm 0.1) \times 10^{-2}$ /litre mol ⁻¹ s ⁻¹		$(k_{\text{f}}^{\text{II}})_{\text{aver}} = (2.3 \pm 0.1) \times 10^{-2}$ /litre mol ⁻¹ s ⁻¹		$(k_{\text{f}}^{\text{II}})_{\text{aver}} = (2.6 \pm 0.1) \times 10^{-2}$ /litre mol ⁻¹ s ⁻¹		$(k_{\text{f}}^{\text{II}})_{\text{aver}} = (2.6 \pm 0.1) \times 10^{-2}$ /litre mol ⁻¹ s ⁻¹	

For system II, the loss of substrate in the gas phase obeys the following equation

$$\ln \frac{[\text{RH}]_0}{[\text{RH}]_t} = \frac{k_{\text{f}}^{\text{II}} k_{\lambda}^{\text{RH}} [\text{NO}_2^-]_0^2 t}{k_{\lambda}^{\text{PN}} (1 + [\text{NO}_2^-]_0 k_{\text{f}}^{\text{II}} t)}, \quad (24)$$

where k_{f}^{II} is the effective second-order rate constant for production of ONOOH at a specified pH value.

In system I the loss of hydrocarbons in the course of reaction is at most 30%.^{160, 161} On going to system II, it reaches 60% to 80%^{160, 161} (see Fig. 6, curve 4), which makes the determination of k_{f} and $k_{\lambda}^{\text{RH}}/k_{\lambda}^{\text{PN}}$ (Table 8) much more accurate.

The bell-shaped dependences of $k_{\lambda}^{\text{RH}}/k_{\lambda}^{\text{PN}}$ on λ (Fig. 7) were quantitatively explained in the framework of the extended KDM model (see Scheme 5).^{155–157, 160, 161} From Eqns (22) and (23) it follows that the dependence of the ratio $k_{\lambda}^{\text{RH}}/k_{\lambda}^{\text{PN}}$ on λ

$$\frac{k_{\lambda}^{\text{RH}}}{k_{\lambda}^{\text{PN}}} = \frac{(k_{\text{g}}^{\text{RH}} \alpha^{\text{RH}} \alpha^{\text{PN}} \lambda + k_{\text{f}}^{\text{RH}})}{(k_{\text{g}}^{\text{PN}} \alpha^{\text{PN}} \lambda + k_{\text{f}}^{\text{PN}}) (1 + \alpha^{\text{RH}} \lambda)} \quad (25)$$

includes terms proportional to λ in the numerator and terms proportional to λ and λ^2 in the denominator. At particular values of the parameters k_{f}^{RH} , k_{g}^{RH} , k_{f}^{PN} , k_{g}^{PN} , α^{RH} and α^{PN} , the plot of $k_{\lambda}^{\text{RH}}/k_{\lambda}^{\text{PN}}$ vs. λ passes through an extremum.

**Figure 7.** $k_{\lambda}^{\text{RH}}/k_{\lambda}^{\text{PN}}$ Ratios plotted vs. λ for the oxidation of cyclohexane (1), n-hexane (2) and propene (3) in the H_2O_2 – NaNO_2 /acetate buffer system (pH 4.27; 25 °C).¹⁶⁰

The lines correspond to data obtained from Eqn (25) for the $k_{\text{g}}^{\text{PN}}/k_{\text{g}}^{\text{RH}}$, $k_{\text{f}}^{\text{PN}}/k_{\text{f}}^{\text{RH}}$ calculated using the data from Table 9, at $(k_{\text{g}}^{\text{RH}} \alpha^{\text{RH}}/k_{\text{g}}^{\text{PN}}) \gg (k_{\text{f}}^{\text{RH}}/k_{\text{f}}^{\text{PN}} \alpha^{\text{PN}} \lambda)$.

The ratio (25) provides quite a correct description of the experimental data for alkanes, alkenes and alkylbenzenes in the whole range of changes in λ studied so far (see Fig. 7) and makes it possible to calculate^{160, 161} the ratios of the rate constants $k_{\text{g}}^{\text{PN}}/k_{\text{g}}^{\text{RH}}$ and $k_{\text{f}}^{\text{PN}}/k_{\text{f}}^{\text{RH}} \alpha^{\text{PN}}$:

$k_{\text{g}}^{\text{PN}}/k_{\text{g}}^{\text{RH}}$ /mol litre ⁻¹	$k_{\text{f}}^{\text{PN}}/k_{\text{f}}^{\text{RH}} \alpha^{\text{PN}}$
n-Hexane (1.4 ± 0.2) $\times 10^{-3}$	27 ± 4
Cyclopentane (1.7 ± 0.2) $\times 10^{-3}$	27 ± 3
Cyclohexane (1.2 ± 0.2) $\times 10^{-3}$	26 ± 2
Propene (3.3 ± 0.5) $\times 10^{-4}$	26 ± 5

Using a version of the KDM method for competitive processes, we calculated^{155–157} the relative rate constants for the oxidation of a large number of hydrocarbons in solution and in the gas phase (Table 9). Because of high α values in aqueous solutions (8–110), alkanes and alkenes at $\lambda > 1$ are mainly in the gas phase where they interact with ONOOH. For arenes, the reaction rates in two phases are comparable.

The reactive species in the reactions studied are hydroxyl radicals ($\text{X} = \cdot\text{OH}$ in Scheme 5), the contribution of the radical pair being insignificant.^{160, 161} The radical pair $[\cdot\text{OH} \cdots \text{ONO}]$ is 8 kJ mol^{-1} more stable than free radicals $\cdot\text{OH} + \text{NO}_2$ owing to formation of a hydrogen bond.⁶⁸ Therefore the rate constant for the reaction

cannot be higher than the rate constant for the following reaction

with free hydroxyl radicals (10^9 – $10^{10} \text{ litre mol}^{-1}$).^{148, 151, 152} For kinetic measurements, one has $[\text{RH}] < 10^{-4} \text{ mol litre}^{-1}$ and $k_{26}[\text{RH}] \leq 10^5$ – 10^6 s^{-1} . At the same time the estimate of the rate constant for decomposition of the radical pair to $\cdot\text{OH} + \text{NO}_2$ is $k_{\text{dif}} = 10^{10}$ – 10^{12} s^{-1} (assuming an activation energy of 8 kJ mol^{-1} and the pre-exponent $A = 10^{12}$ – 10^{14}). Since $k_{26}[\text{RH}]$ is 4–7 orders of magnitude lower than k_{dif} , it was concluded that the major route of transformation of the radical pair involves its decomposition and production of free hydroxyl radicals that are the reactive species in the oxidation of hydrocarbons.

The mechanism (27) is also substantiated by (1) general correlation

$$\Delta \log k_{\text{g}}(\text{ONOOH}) = (0.98 \pm 0.01) \Delta \log k_{\text{g}}(\text{OH})$$

Table 9. Distribution coefficients, α , and relative gas-phase rate constants, $(k_g^{\text{RH}}/k_g^{\text{n-C}_5\text{H}_{12}})$, for oxidation of hydrocarbons by H_2O_2 – HNO_2 /acetate buffer system (pH 4.27) ^{155–158} and by OH radicals ^{148, 151, 152} at 25 °C.

Hydrocarbon	α	$k_g^{\text{RH}}/k_g^{\text{n-C}_5\text{H}_{12}}$		Hydrocarbon	α	$k_g^{\text{RH}}/k_g^{\text{n-C}_5\text{H}_{12}}$

that is valid for gas-phase oxidation of all the substrates studied (alkanes, alkenes and alkylbenzenes) (Fig. 8); ^{155–158} (2) similar products of the two reactions; ^{155, 158, 162, 163} (3) yield ratio ([cyclohexanol]:[cyclohexanone] $\approx$ 2) determined ^{155–157} for the reaction of cyclohexane with peroxyntous acid and characteristic of the reactions with $\cdot\text{OH}$ radicals (see Ref. 162); and (4) experimental proofs of high yield of OH radicals in the decomposition of ONOOH. ^{40, 62, 88, 98, 103, 104}

**Figure 8.** Generalised correlation between the relative rate constants for gas-phase oxidation of alkanes (1), alkenes (2) and alkylbenzenes (3) by the H_2O_2 – HNO_2 system (see Refs 155–158) and OH radicals (see Refs 148, 151, 152).

The calculated ratios $k_g^{\text{RH}}/k_g^{\text{PN}}$, $k_1^{\text{RH}}/k_g^{\text{PN}}\alpha^{\text{PN}}$ and $k_1^{\text{PN}}/k_g^{\text{PN}}\alpha^{\text{PN}}$ were used for estimating the rate constant for gas-phase decomposition of peroxyntous acid and the distribution coefficient α^{PN} . According to Scheme 5, the following reactions proceed in the two phases:

and also reaction (27). Based on the values of the free energy of homolysis of ONOOH, $\Delta G_{\text{hom}}^\circ = -RT \ln K_{28}$ (see Table 1), the equilibrium (28) in solution [$K_{28(\text{l})} = (0.01–1) \times 10^{-12}$ mol litre^{−1}] and in the gas phase [$K_{28(\text{g})} = (0.3–6) \times 10^{-6}$ mol litre^{−1}] is almost completely shifted to the left. With allowance for this fact the overall rate constant for the decomposition of ONOOH according to Eqns (28) and (29) in the gas phase or in solution is given by

$$k^{\text{PN}} = k_{28} + k_{29}. \quad (30)$$

Using the method of quasi-steady-state concentrations, for the effective second-order rate constant for the oxidation of RH according to Eqn (27) one gets

$$k^{\text{RH}} = \frac{k_{27}k_{28}}{k_{28} + k_{29}}. \quad (31)$$

From Eqns (30) and (31) it follows that

$$\begin{aligned} \frac{k_g^{\text{PN}}}{k_g^{\text{RH}}} &= \frac{(k_{28} + k_{29})^2}{k_{27}k_{28}}, \\ \frac{k_1^{\text{PN}}}{k_g^{\text{PN}}\alpha^{\text{PN}}} &= \frac{k_1^{\text{PN}}}{(k_{28} + k_{29})\alpha^{\text{PN}}}. \end{aligned} \quad (32)$$

From the known rate constants $k_1^{\text{PN}} = (k_{28} + k_{29})_0 = 1.2 \text{ s}^{-1}$ (Ref. 24) and $k_{28(\text{l})} = (0.34 \pm 0.08) \text{ s}^{-1}$ (Ref. 29) it is possible to determine the yield of OH radicals [$k_{28(\text{l})}/k_1^{\text{PN}}$] in the decomposition of peroxyntous acid in aqueous solutions at 25 °C, which is equal to 28%.

Taking into account the equilibrium constant $K_{28(\text{g})} = (0.3–6.0) \times 10^{-6}$ mol litre^{−1} and the rate constant for the reverse reaction $k_{-28(\text{g})} = 4 \times 10^8$ litre mol^{−1} s^{−1} (Ref. 164), the rate constant for homolysis, $k_{28(\text{g})} = K_{28(\text{g})}k_{-28(\text{g})}$, was estimated ^{160, 161} at $(0.1–2.4) \times 10^3 \text{ s}^{-1}$, which is much higher than for aqueous solutions.

If $\text{X} = \cdot\text{OH}$, one has $k = k_{27} = k_{\text{OH}}$ (see Scheme 5). Using the published data for n-hexane, cyclopentane, cyclohexane and propene ($k_{\text{OH}(\text{g})} = 3.6 \times 10^9, 2.8 \times 10^9, 4.0 \times 10^9$ and 16×10^9 litre mol^{−1} s^{−1}, respectively), ^{148, 151} experimental ratios $k_g^{\text{PN}}/k_g^{\text{RH}}$ and the value $k_{28(\text{g})} = (0.1–2.4) \times 10^3 \text{ s}^{-1}$, the constant k_g^{PN} was estimated ^{160, 161} from Eqn (31) at $(0.2–1) \times 10^5 \text{ s}^{-1}$. From comparison of the k_g^{PN} and $k_{28(\text{g})}$ values it follows that the yield of OH radicals in the gas-phase decomposition of ONOOH can range from 0.1% to 10%.

The ‘gas–solution’ distribution coefficient of peroxyntous acid estimated ¹⁶⁰ using Eqn (32) lies between the α values of H_2O_2 and O_2NOOH (calculated using the Henry law constants ^{165, 166} in aqueous solutions at 25 °C, $\alpha = 0.041/K_{\text{h}}$):

Compound	ONOOH	H_2O_2	O_2NOOH	MeCOOOH	MeOOH
$10^6 \alpha$	0.4–2	0.5	3	50	130

The α^{PN} value corresponds to the energy of solvation of peroxyntous acid in water $\Delta G_{\text{sol}}^\circ = -RT \ln \alpha^{\text{PN}} = 32.6–36.4 \text{ kJ mol}^{-1}$, which is in rough agreement with the estimate $\Delta G_{\text{sol}}^\circ = 25 \pm 12 \text{ kJ mol}^{-1}$ obtained from the free energies of formation of peroxyntous acid in the gas phase and in aqueous solution (see Table 1).

3. Oxidation of dimethyl sulfoxide

Dimethyl sulfoxide is an efficient scavenger of hydroxyl radicals, being converted to methanesulfinic acid MeS(O)OH (in 91% yield) and methyl radicals that can produce formaldehyde.¹⁶⁷ The oxidation of DMSO by peroxyxynitrite in neutral media results in the same products while the reaction in alkaline solutions yields dimethyl sulfone Me_2SO_2 .^{98, 104} The major reaction pathways are a radical route involving $\cdot\text{OH}$ at $\text{pH} < 7$ and bimolecular oxygen transfer from peroxyxynitrite to the substrate molecule in alkaline media.¹⁶⁸

In addition to formaldehyde, Me_2SO_2 and methanesulfinic acid the products of DMSO oxidation by peroxyxynitrite include methane, methyl nitrite and methyl nitrate, which are accumulated in the gas phase of a closed reactor.¹⁶⁹

Detection of these volatile products indicates a complex mechanism of the interaction of DMSO with peroxyxynitrite.

The dependence of yields of CH_4 , CH_2O and MeONO on acidity of the medium passes through maxima in the range of pH values 6.4–6.9 (Table 10). The major product formed under neutral conditions is methyl nitrite ($\sim 17\%$ with respect to initial peroxyxynitrite). The yield of methyl nitrate rapidly increases from 1% ($\text{pH} < 7$) to 17% ($\text{pH} \sim 10$) and then abruptly decreases. The yield of Me_2SO_2 monotonically increases from 2% to 45% as the pH value increases from 6.0 to 11.5. The dependences on the pH value show that methane, formaldehyde and methyl nitrite are produced in the reaction of DMSO with the same reactive species, whereas the formation of MeONO_2 and Me_2SO_2 involves other reaction routes.

Under neutral conditions, the yield of CH_2O reaches a maximum value (1.8% at 0.01 M DMSO) as the substrate concentration increases (see Table 10) and then slowly decreases. The yields of CH_4 , MeONO and Me_2SO_2 reach their maximum values at $[\text{DMSO}] \approx 1 \text{ mol litre}^{-1}$ while the yield of methyl nitrate depends only slightly on the DMSO concentration. The $[\text{CH}_4]:[\text{MeONO}]$ ratio is proportional to $[\text{DMSO}]$, thus indicating the involvement of two DMSO molecules in production of

methane. At pH 6.8, the yields of CH_4 and MeONO are linearly (that of MeONO_2 , quadratically) related to the peroxyxynitrite concentration (see Table 10). Under the same conditions the nitrite anions inhibit the formation of methane and methyl nitrite but have no effect on the yield of methyl nitrate. However, the introduction of NaNO_2 ($0.15 \text{ mol litre}^{-1}$) at pH 10.1 reduces the yield of MeONO_2 from 17% to 1%. In contrast to many other reactions involving peroxyxynitrite,^{120–122} the formation of methane and methyl nitrite (under neutral conditions) and methyl nitrate (at pH 10.4) is inhibited by adding NaHCO_3 . In the presence of a large excess of DMSO, the overall yield of the products ($\text{CH}_4 + \text{CH}_2\text{O} + \text{MeONO}$) with respect to peroxyxynitrite is $55 \pm 10\%$, being higher than the upper limit ($\sim 40\%$)¹⁰⁶ for the formation of OH radicals from ONOOH . It is impossible to explain all these results by considering the reaction route involving OH radicals.

It was assumed¹⁶⁹ that the reaction proceeds *via* a cyclic intermediate which can decompose into MeONO and MeS(O)OH and produce methane in the reaction with the second DMSO molecule (Scheme 6). Here, the role of the reactive species is played by *cis*- ONOO^- and the conversion of the intermediate to product is catalysed by the acid.

Scheme 6

trans-Peroxyxynitrite, which cannot form a cyclic intermediate, reacts with DMSO to give Me_2SO_2 . In the presence of CO_2 and NO_2^- , competing reactions of *cis*- ONOO^- with carbon dioxide proceed.^{120–122} Taking into account the quadratic dependence of the yield of methyl nitrate on the peroxyxynitrite concentration, it

was concluded¹⁶⁹ that MeONO_2 is formed in the interaction of DMSO with a complex between ONOO^- and ONOOH .^{16, 36, 38, 91}

4. Oxidation of sulfides

Sulfides are oxidised by both peroxynitrous acid and its anion to give sulfoxides and NO_2^- (Refs 117, 118, 125, 170). The yield of DMSO and nitrite in the reaction of dimethyl sulfide with ONOO^- is 100% (with respect to peroxynitrite) and 80% in the interaction with ONOOH .¹¹⁸ The reaction of methionine (Met) with both forms of peroxynitrite is also stoichiometric but the reaction equation takes another form:¹¹⁷

The reactivity of peroxynitrous acid in the reactions with sulfides is more than two orders of magnitude higher than that of its anion (see Table 6). The activation enthalpy and activation entropy of the reaction of Me_2S with ONOOH are respectively $24.7 \pm 2.1 \text{ kJ mol}^{-1}$ and $-(96 \pm 13) \text{ J K}^{-1} \text{ mol}^{-1}$ [cf. $40.6 \pm 2.5 \text{ kJ mol}^{-1}$ and $-(121 \pm 13) \text{ J K}^{-1} \text{ mol}^{-1}$, respectively, for the reaction with ONOO^-].¹¹⁸ The reaction of Me_2S with ONOO^- is characterised by strong solvation effects.¹¹⁸ Namely, with an increase in the concentration of the organic component (EtOH, BuOH, MeCN, tetrahydrofuran, tetramethylenesulfone) in aqueous-organic media, the reaction rates decrease while the rate of the reaction of Me_2S with ONOOH remains unchanged.

According to quantum chemical calculations,⁷³ the reaction of Me_2S with *cis*- ONOO^- involves transfer of an oxygen atom (two-electron oxidation) *via* an equilibrium formation of a complex $\{\text{Me}_2\text{S} \cdots \text{OONO}\}$ followed by O—O bond cleavage at the rate-limiting step:

Gas-phase interaction between the negatively charged terminal oxygen atom of peroxynitrite and the sulfur atom bearing a partial positive charge is characterised by $\Delta H^\circ = -27$ and $\Delta G^\circ = -5.0 \text{ kJ mol}^{-1}$. The activation parameters, $\Delta H^\ddagger$ and $\Delta G^\ddagger$, of O—O bond homolysis in the transition state $[\text{Me}_2\text{S} \cdots \text{O} \cdots \text{ONO}]^\ddagger$ are 64 and 110 kJ mol^{-1} , respectively. The energy ΔH (ΔG) of the intermediate $[\text{Me}_2\text{SO}(\text{NO}_2^-)]$ is 215 (177) kJ mol^{-1} lower than those of the initial reagents. Dissociation of the intermediate to Me_2SO and NO_2^- is an endothermic process ($\Delta H^\circ = 72$, $\Delta G^\circ = 36 \text{ kJ mol}^{-1}$) with a low activation barrier. On the whole, the reaction of Me_2S with ONOO^- is exothermic, namely, $\Delta H^\circ = -143$ and

$\Delta G^\circ = -141 \text{ kJ mol}^{-1}$. Estimates⁷³ showed that solvation of ONOO^- increases the reaction rate, which is consistent with the experiment.¹¹⁸ The equilibrium complex between Me_2S and $(\text{H}_2\text{O})_n(\text{ONOO}^-)$ is destabilised with respect to the reagents at $n = 1, 2$; namely, $\Delta H^\circ(\Delta G^\circ) = -19$ (13) and 0.4 (26) kJ mol^{-1} , respectively. The activation enthalpy of O—O bond homolysis decreases from 64 ($n = 0$) to 62 ($n = 1$) and 56 kJ mol^{-1} ($n = 2$).

The reaction of Me_2S with *cis*- ONOOH can proceed⁷³ either as a stepwise or a concerted process that is much faster than the reaction with ONOO^- . The stepwise route involves homolysis of the ONO—OH bond and generation of free radicals ($\cdot\text{OH}$ and $\cdot\text{ONO}$), formation of the intermediate $[\text{Me}_2\text{S}(\text{OH})(\text{NO}_2)]$, which then can undergo either a barrierless endothermic transformation to radicals $[\text{Me}_2\text{S}(\cdot\text{OH})$ and $\text{NO}_2^\cdot$ or an exothermic proton transfer [$\Delta H^\ddagger = 48$, $\Delta G^\ddagger = 55 \text{ kJ mol}^{-1}$] to give DMSO and HONO. Parameters of the energy barrier to the concerted route involving O—O bond cleavage in the transition state $[\text{Me}_2\text{S} \cdots \text{HOONO}]^\ddagger$ were estimated as follows; $\Delta H^\ddagger = 25.5$ and $\Delta G^\ddagger = 26.4 \text{ kJ mol}^{-1}$. The stepwise reaction of Me_2S with ONOOH is more probable in the gas phase, whereas both routes are efficient in solution. Since H_2O interacts with ONOOH much weaker than with ONOO^- , solvation effects for the reaction of Me_2S with peroxynitrous acid are less pronounced.^{73, 118}

Methionine plays a key role in transfer of the unpaired electrons in peptides and proteins.¹⁷¹ The oxidation of this compound can proceed as reaction (33) resulting in methionine sulfoxide and as a one-electron oxidation by activated peroxynitrous acid ONOOH^* to give ethylene.¹²⁵ The second route is substantiated by nonlinear dependences of the rate constants on the concentration of methionine.^{84, 125}

However, more recently¹¹⁷ this dependence was shown to be linear and the formation of nitrate (in addition to sulfoxide and nitrite) in accordance with Eqn (33) was established; *i.e.*, methionine catalyses the isomerisation of peroxynitrite to nitrate. The relative yields of products are independent of the pH value and substrate concentration. It was concluded that the reaction obeys Scheme 7 and that nitrite (either an impurity or the species formed in the reaction) is not chemically inert. Namely, it oxidises methionine in the one-electron process to ethylene and methional ($\text{MeSCH}_2\text{CH}_2\text{CHO}$).

Using the formation of acetaldehyde as a test for one-electron oxidation, it was found¹⁷⁰ that only 1.5% and 1.85% of threonylmethionine are oxidised in the one-electron process under anaerobic and aerobic conditions (pH 7.4), respectively, whereas the contribution of this route estimated from the yield of ethylene is at least 8%.¹²⁵

5. Interaction with carbon dioxide and carbonyl compounds

The reaction of peroxynitrite with bicarbonate buffer has long been known,²⁶ but attracted considerable attention of researchers only in 1993 when its biological importance was reported.¹⁴⁵ More

Scheme 7

recently, it was shown¹⁴¹ that ONOO^- rapidly forms an unstable nitrosoperoxy carbonate with CO_2 :

The activation enthalpy and activation entropy are $45 \pm 3 \text{ kJ mol}^{-1}$ and $27 \pm 2 \text{ J K}^{-1} \text{ mol}^{-1}$, respectively. Using the stopped-flow technique, it was found^{172, 173} that ONOOCO_2^- is characterised by an absorption band at $\lambda_{\text{max}} = 650 \text{ nm}$. At present, reaction (34) is considered as the major route of peroxynitrite decomposition in biosystems because the physiological concentration of bicarbonate $(1-3) \times 10^{-2} \text{ mol litre}^{-1}$ (see Refs 96, 122, 141, 174–176) is sufficient for the process to proceed. Carbon dioxide affects many reactions involving peroxynitrite. Namely, it considerably accelerates nitration of arenes,^{142, 174, 175} DNA¹⁷⁷ and ethyl acetoacetate,¹⁷⁸ catalyses one-electron oxidation of metal complexes $\text{Fe}(\text{CN})_6^{4-}$, $\text{Mo}(\text{CN})_8^{4-}$, $\text{Os}(\text{bipy})_3^{2+}$, $\text{Fe}(\text{bipy})_3^{2+}$, $\text{Ru}(\text{bipy})_2^{2+}$ and I^- anion (see Ref. 121); partially inhibits the oxidation of thiols,¹⁴² DMSO,¹⁴² oxyhaemoglobin,¹⁴² DNA¹⁷⁷ and cytochrome c ;¹⁴² and completely inhibits the hydroxylation of benzoate anion.¹⁴²

In the absence of other reagents the reaction of CO_2 with peroxynitrite results in nitrate as the major product.^{120, 121} It is assumed^{120, 122, 123, 141, 142, 174, 176} that nitrosoperoxy carbonate formed in the reaction homolytically decomposes into a radical pair, which then transforms to nitrocarbonate ($\text{O}_2\text{NOCO}_2^-$)^{18, 120, 178–182} or decomposes into radical species, $\text{CO}_3^{\cdot-}$ and $\text{NO}_2^{\cdot}$.

The standard Gibbs energy diagram for the sequence of reactions (35)¹⁸² is shown in Fig. 9 and the rate constants for particular steps are listed in Table 11.

The rate of decomposition of $\text{O}_2\text{NOCO}_2^-$ to nitrate and CO_2 is 28 orders of magnitude higher than the rate of decomposition to

Figure 9. Standard Gibbs energy diagram of the reaction of peroxynitrite with CO_2 .¹⁸²

$\text{O}_2\text{NOCO}_2^- (e)$		
	$k_{-d} = 5.6 \times 10^{-15} \text{ s}^{-1}$	182
$\text{O}_2\text{NOCO}_2^- \rightleftharpoons$	$k_f = 4 \times 10^{13} \text{ s}^{-1}$	182
$\text{NO}_3^- + \text{CO}_2 (f)$	$k_{-f} = 8 \times 10^3 \text{ litre mol}^{-1} \text{ s}^{-1}$	182

$\text{NO}_2^{\cdot}$ and $\text{CO}_3^{\cdot-}$ (Table 11, steps f and $-d$, respectively). In a number of studies^{18, 59, 96, 111, 176, 185} nitrocarbonate is excluded from the sequence of reactions (35) assuming that the radical pair $[\text{NO}_2^{\cdot} \cdots \text{CO}_3^{\cdot-}]$ can either decompose into free radicals (30%–35%) or undergo intracage conversion to nitrate and CO_2 (65%–70%). The yield of radicals $\text{NO}_2^{\cdot}$ and $\text{CO}_3^{\cdot-}$ in the decomposition of nitrosoperoxy carbonate is $3 \pm 1\%$ (cf. $96 \pm 1\%$ for the yield of nitrate).¹⁷³

The catalytic effect of CO_2 in the nitration of arenes by peroxynitrite was explained^{120, 142, 175, 178–181} by heterolytic decomposition of nitrosoperoxy carbonate.

Although the formation of NO_2^+ cation in reaction (36) is thermodynamically allowed ($\Delta G^\circ = 16 \pm 29 \text{ kJ mol}^{-1}$), the very short lifetime in aqueous solutions (1.4 ns) (see Ref. 186) makes it a poor candidate for playing the role of the reactive species.^{96, 122} Nitrosoperoxy carbonate is a strong one-electron oxidant.¹⁸

Other possible reagents in the bicarbonate-catalysed processes included^{96, 120–122, 178–181} nitrocarbonate and $\text{NO}_2^{\cdot}$ and $\text{CO}_3^{\cdot-}$ radicals. However, instability of the ONOOCO_2^- and $\text{O}_2\text{NOCO}_2^-$ species (see the rate constants listed in Table 11) causes them to decompose much faster than to interact with the substrate.^{18, 121, 174, 185, 187, 188}

The most plausible reactive species are the $\text{NO}_2^{\cdot}$ and $\text{CO}_3^{\cdot-}$ radicals (Refs 18, 120, 123, 141, 142, 174, 175, 178–182). The carbonate radical anion is a strong oxidant [$E_{\text{CO}_3^{\cdot-}/\text{CO}_3^-}^\circ = 1.58 \pm 0.02 \text{ V}$ at pH 12.5 (Refs 188, 189) and $E_{\text{CO}_3^{\cdot-}/\text{HCO}_3^-}^\circ = 1.78 \pm 0.02 \text{ V}$ at pH 7.0 (Ref. 190)] capable of abstracting an electron from various substrates. The $\text{NO}_2^{\cdot}$ radical is a weaker one-electron oxidant ($E_{\text{NO}_2^{\cdot}/\text{NO}_2^-}^\circ = 1.04 \pm 0.02 \text{ V}$).¹⁹¹ A two-step mechanism was proposed for nitration of arenes (in particular, tyrosine, a compound of great biochemical value).^{111, 142, 174, 192}

The rate of the reaction of tyrosine with $\text{CO}_3^{\cdot-}$ is more than 300 times higher than that of the reaction with $\text{NO}_2^{\cdot}$.^{193, 194} In agreement with the redox potentials, direct interaction of the substrate

^a HA refers to NH₄⁺.

with NO₂⁻ (and in other cases) proceeds much slower than with CO₃²⁻ (Ref. 18).

Nucleophilic addition of ONOO⁻ anion to carbonyl compounds^{97, 185, 195–198} proceeds similarly to reaction (34). It involves rapid equilibrium between the starting reagents and tetrahedral anionic adduct, which is strongly shifted towards the former (Table 12).^{185, 198}

R = H, Me.

The anionic intermediate in reactions (37) is rapidly protonated under the action of water or buffer components. The rate of the bimolecular reaction of ONOO⁻ with RMeCO strongly depends on the pH value and buffer concentration. Rapid homolysis of weak O—O bonds in the anionic and neutral adducts is followed by production of radical pairs in the solvent cage and subsequent formation of free alkoxy radicals and nitrogen dioxide (Scheme 8).

The yield of free radicals in the reactions of acetone and acetaldehyde with ONOO⁻ is ~15% at high and low pH values.¹⁹⁸

Like CO₂, aldehydes catalyse the oxidation of ABTS by peroxynitrite but, in contrast to carbon dioxide, have no effect on the rate of nitration of 4-hydroxyphenylacetate.¹⁹⁵ High rate constants for homolysis of peroxynitrite adducts with carbonyl compounds¹⁹⁸ indicate that they cannot act as reactive species, as was proposed earlier.¹⁹⁵

6. Reactions with other substrates, catalysis by metal ions

Ascorbic acid has two acidic protons characterised by pK_a values of 4.04 and 11.34 (see Ref. 199). This compound is an *in vitro* and *in vivo* antioxidant of paramount importance.²⁰⁰ Early studies^{123, 201} on the oxidation of hydroascorbate anion (HAsc⁻)

revealed that the reaction is first-order with respect to substrate and peroxynitrous acid ($k = 235$ litre mol⁻¹ s⁻¹). Based on the EPR spectra of ascorbyl radicals, it was concluded²⁰¹ that the reaction involves consecutive one-electron transfer.

According to recent data,^{38, 108} the rate constants are nearly 5000 times higher than those reported earlier (see Table 6). Kinetic, UV and EPR spectral studies and product analysis led to a mechanism that involves a rapid equilibrium formation ($k_+ = 1 \times 10^6$ litre mol⁻¹ s⁻¹, $k_- = 500$ s⁻¹ at 25 °C and pH 5.8; $k_+ = 1.5 \times 10^6$ litre mol⁻¹ s⁻¹, $k_- = 1 \times 10^3$ s⁻¹ at 37 °C) of a first intermediate (Int₁), which undergoes conversion to a second intermediate (Int₂) characterised by absorption maximum at 345 nm. At low concentration of HAsc⁻, the second intermediate decomposes into hydroascorbate and nitrate while at [HAsc⁻] > 4 mmol litre⁻¹ it reacts with the other substrate molecule to give hydroascorbate, dehydroascorbate (DAsc) and nitrite.

Intermediates Int₁ and Int₂ are treated¹⁰⁸ as 1:1 adducts of peroxynitrous acid with hydroascorbate. According to EPR data, the yield of ascorbyl radicals is 0.24% with respect to starting peroxynitrite and accumulation of these radicals in the course of reaction is accompanied by a decrease of absorption at 345 nm. Therefore, ascorbyl radicals are not primary products. No homolysis of ONOOH into hydroxyl radicals and nitrogen dioxide was detected under the experimental conditions.

Hughes and Nicklin²⁰² studied the oxidation of hydroxylamine in the presence of copper(II) salts. It seems that they were the first who observed catalysis of peroxynitrite reactions by metal ions. They also postulated the formation of a complex between Cu(II) and both reagents.

It is assumed^{5, 22} that nitration of phenols and aromatic acids catalysed by transition metal (Fe³⁺, Cu²⁺, Mn³⁺) complexes proceeds involving reactive species similar to nitroyl cation:

Nitration of phenols catalysed by superoxide dismutase (SOD) has been best studied.^{127, 203} The rate of the reaction of

Scheme 8

peroxynitrite with Cu,Zn-SOD is about 10^5 litre mol⁻¹ s⁻¹ and the maximum yield of nitrophenols ($\sim 8\%$) is observed at pH 7.5 (see Fig. 5). In the absence of other phenols, the tyrosine residue of SOD is transformed to nitrotyrosine²⁰³ and Cu,Zn-SOD retains its catalytic activity. In the first stage, peroxynitrite reacts with copper; removal of copper from the SOD molecule causes nitration to cease. A complex of Fe³⁺ with EDTA is less catalytically active, however the yield of products exceeds 90% with respect to the starting peroxynitrite at pH 7.5.^{127, 128} Nitration is not accompanied by production of free radicals involving 'nitroyl-like' species that are formed in reactions (39)–(41). The differences between SOD and the complex of Fe³⁺ with EDTA were explained using Scheme 9.¹²⁷

In the reaction with [Fe³⁺(EDTA)] the role of the reactive intermediate is played by *cis*-peroxynitrite. SOD interacts only with *trans*-peroxynitrite due to specific features of the structure of Cu,Zn-superoxide dismutase. The copper ion in SOD is in a deep narrow cavity, therefore only *trans*-ONOO⁻ can reach the active site. Positively charged amino acids near the active site facilitate the motion of peroxynitrite anion into the cavity. The rate-limiting step of this reaction is *cis*–*trans*-isomerisation.¹⁵

Another mechanism of catalysis is realised in the case of nitration of tyrosine in the presence of porphyrin complexes of manganese(III) and iron(III).^{204–207} Metal-containing porphyrins (MPs) are rapidly oxidised by peroxynitrite (rate constants depend on the porphyrin structure and range from 2.5×10^4 to 5×10^7 litre mol⁻¹ s⁻¹)^{204, 208–211} to relatively stable intermediates Mn(IV)=O and Fe(IV)=O from which Mn(III) and Fe(III) regenerate at the stage of catalytic decomposition of peroxynitrite.

Reduction of Mn(IV)=O and Fe(IV)=O in the presence of phenols is a fast process and MPs catalyse nitration of phenols and oxidation of peroxynitrite. The Mn- and Fe-containing porphyrins cause more than five-fold (pH 7.4) and twelve-fold (pH 9.1) increase in the yield of nitration products (see Ref. 204).

It was established^{204, 212} that the first stage of catalytic nitration of tyrosine and other phenols involves the oxidation of MP(3+) by peroxynitrite to MP(4+). The oxidised porphyrin rapidly reacts with phenols, thus regenerating MP(3+) and

converting phenols into phenoxyl radicals that recombine with nitrogen dioxide formed in the first stage at a high rate ($k = 3 \times 10^9$ litre mol⁻¹ s⁻¹).¹⁹⁴ Introduction of ascorbic acid into the system inhibits formation of nitrophenols, Mn(IV)=O and Fe(IV)=O are reduced to stable (3+) form, NO₂[•] radical is reduced to NO₂⁻ and phenoxyl radical is reduced to the starting phenol.²⁰⁴

VI. Biochemical role of peroxynitrite

The possibility of *in vivo* production of peroxynitrite in fast recombination [$k = (4.3–19) \times 10^9$ litre mol⁻¹ s⁻¹]^{32–38} of nitrogen monoxide (product of enzymatic oxidation of L-arginine)^{213, 214} and superoxide anion O₂^{•-} (conventional product of aerobic cell metabolism²¹⁵) was first reported by Beckman *et al.*³ Activated macrophages are assumed to be responsible for production of peroxynitrite.^{216–218} If the intracellular concentration of SOD is 10 μmol litre⁻¹ and the rate constant for the reaction of SOD with superoxide is 2.3×10^9 litre mol⁻¹ s⁻¹ (see Ref. 219), the loss rate of O₂^{•-} is 2×10^4 s⁻¹ and the whole superoxide is transformed to oxygen and hydrogen peroxide.^{16, 39} If the intracellular concentration of nitrogen monoxide is 10⁻⁸ mol litre⁻¹, the loss rate of superoxide in the reaction with NO is two orders of magnitude lower (2×10^2 s⁻¹) than in the reaction with SOD. No peroxynitrite is formed under these conditions. The local concentration of NO near activated macrophages is much higher ($5 \times 10^{-6}–10^{-5}$ mol litre⁻¹) and peroxynitrite is produced at a rate of $(2–4) \times 10^4$ s⁻¹, which is twice as high as the rate of the reaction of O₂^{•-} with SOD.

Since the extracellular concentration of SOD is probably lower than $5 \times 10^{-6}–10^{-5}$ mol litre⁻¹, it does not preclude formation of peroxynitrite near activated macrophages.^{16, 39} Nitration of SOD by peroxynitrite reduces its activity and, as a consequence, increases the yield of peroxynitrite, thus switching off the signal function of NO. Peroxynitrous acid and its anion can penetrate inside cells through lipid membranes moving along anion channels or by diffusion^{132, 220–222} and thus toxic effects of peroxynitrite can manifest themselves inside cells. Peroxynitrite is produced *in vivo* in the reaction of NO with superoxide; polluted air and cigarette smoke are also possible sources of this compound.²²³

Biological value of peroxynitrite is due to its high and polyfunctional reactivity with respect to various biomolecules.

The key mechanisms of biochemical action of peroxynitrite are as follows.

1. Interaction with sulfide and thiol groups^{24, 83, 117, 118, 224, 225}

mediates the activity of many enzymes and receptors.^{226–230} Toxic effects of peroxynitrite are often associated with its ability to oxidise the methionine residue in the active site of α -1-protease (elastase inhibitor), which causes inactivation of enzyme.²³¹

2. Protonation under physiological conditions and subsequent homolysis to hydroxyl radicals and NO_2 produces oxidative stress and apoptosis; this is related to neurotoxicity and molecular mechanisms of attack on immunocompetent cells.^{218, 226, 232–235}

3. Oxidation of the alkyl and alkene C–H bonds in polyunsaturated fatty acids causes oxidative damage of lipid membranes.^{132, 220, 221, 236, 237}

4. Metal-ion (Cu^{2+} , Zn^{2+} , Fe^{3+} , Mn^{3+}) catalysed nitration of phenols and aromatic amino acids. Many DNAs^{56, 177, 238, 239} and enzymes are nitrated and oxidised, e.g., SOD^{15, 218, 234, 240–242} (its activity reduces; the concentrations of superoxide and peroxynitrite increase, thus producing oxidative stress); actin and neurofilaments^{226, 243} (cytoskeleton and myofibrillae are damaged); cytochrome *c*, cytochrome P450 and mitochondrial ATPase^{137, 212, 243–246} (inhibition of oxidative phosphorylation).

Peroxyntirite in organisms is a carrier of the bound form of nitrogen monoxide, a key transmitter in central and peripheral nervous system, and can induce damage to neurons in the case of strokes and neurodegenerative disease.^{15, 216, 247, 248} The effect of peroxynitrite, a possible terminal neurotoxic agent, is responsible for neurotoxic action of NO .²⁴⁹ For instance, amyotrophic lateral sclerosis can be due to nitration and oxidation of proteins, which damage the nuclei of motor neurons in spinal cord.^{5, 250}

Oxidation of low density lipoproteins (LDLPs) in arterial walls is thought to be the key step leading to atherosclerosis. Peroxynitrite initiates the oxidation of lipids^{132, 220, 237, 251} and oxidises LDLPs^{6, 251–258} to a potentially active atherogenic form, which results in accumulation of cholesterol esters in cells. Besides, peroxynitrite rapidly oxidises α -tocopherol, which precludes the oxidation of LDLPs.²⁵³ Nitration of tyrosine at *ortho*-position is the major route of peroxynitrite attack on protein molecules, which manifests itself in increased content of *o*-nitrotyrosine in patients with atherosclerosis.^{6, 251, 257, 258}

Diffusion of peroxynitrite across cell membranes inhibits mitochondrial electron transfer²⁵⁹ and damages cation channels.²⁶⁰ High cytotoxicity of peroxynitrite to *Trypanosoma cruzi*²⁶¹ and bactericidal activity against *Escherichia coli*²⁶² are due to deactivation of thiol-containing enzymes and inhibition of cell respiration.²²⁹

Since peroxynitrite is produced *in vivo* and can damage cells, an enzyme system for deactivating or utilising it should exist. It was shown that myeloperoxidase (MPO), horse raddish peroxidase and lactoperoxidase rapidly react with peroxynitrite. For instance, the reaction with MPO results in compound MPO-II.¹³⁹

The character of the dependence of the rate for reaction (42) on the pH value indicates that the enzyme reacts only with peroxynitrous acid. Thus, MPO can reduce the concentration of peroxynitrite by converting it into important bactericidal agent NO_2^- and protect SOD from the action of peroxynitrite, thus increasing the lifetime of NO generated in neutrophils.

Another possible way of peroxynitrite utilisation is the reaction with hydroascorbate anion. The concentration of HAsc^- is $\sim 10^{-3} \text{ mol litre}^{-1}$ in lungs and neutrophils and $10^{-2} \text{ mol litre}^{-1}$ in neurons, ranges from 3×10^{-5} to

$1.5 \times 10^{-4} \text{ mol litre}^{-1}$ in plasma and is $7 \times 10^{-3} \text{ mol litre}^{-1}$ in leucocytes and $1.3 \times 10^{-3} \text{ mol litre}^{-1}$ in liver.^{263–266} Therefore, with allowance for the rate constant for reaction (38), ascorbate can be treated as efficient intracellular scavenger of peroxynitrite.

Increasing interest in chemistry of ONOOH and nitrogen oxides is due to very important role played by these compounds in physiological processes (respiration, regulation of blood pressure and sexual function, growth of malignant cells, etc.). Both positive role (bactericidal and antimicrobial effects) and negative role of peroxynitrite are considered.^{4–11, 226, 247, 251, 258, 262, 267}

VII. Conclusion

The chemistry of peroxynitrite emerged more than 100 years ago. However, systematic, comprehensive investigations of the kinetics and mechanisms of reactions involving this compound began only in the last decade. Complexity of the studies of peroxynitrite reactions is due to its instability at physiological pH values, diversity of transformation pathways and to the influence of impurities (nitrite, hydrogen peroxide, metal complexes, CO_2) on the rates and mechanisms of reactions. Recently, application of methods for studying fast reactions and the kinetic distribution method made it possible to achieve some advances in studies of the kinetics and mechanisms of peroxynitrite decomposition and isomerisation, its reactions with hydrocarbons and DMSO, catalytic action of CO_2 and metal complexes. Considerable literature is devoted to biochemical aspects of the action of peroxynitrite.

At the same time a number of key problems concerning the mechanisms of influence of peroxynitrite are still to be solved. Pathways of isomerisation and decomposition of the compound belong to the most debatable issue. Recently, the homolytic mechanism of isomerisation involving intermediate formation of $\cdot\text{OH}$ and NO_2 radicals, which was accepted in earlier studies, has cast some doubt.^{38, 104} Experimental and theoretical arguments *pro et contra* the homolytic mechanism in different types of reactions are available. Undoubtedly, this is due to polyfunctional reactivity of peroxynitrite, which underlies high chemical and biochemical activity of the compound.

An interesting classification of the mechanisms of peroxynitrite reactions with a broad spectrum of organic substrates was reported¹⁴⁷ by researchers from Japan. It includes five reaction classes. These are (1) electron transfer with involvement of the reactive species NO^+ , NO_2 and $\cdot\text{OH}$ (nitration, hydroxylation and dimerisation of phenols, oxidation of phenols to quinones, dealkylation of *N,N*-dialkyl-*p*-toluidine); (2) *O*-electrophilic substitution involving ONOOH (formation of *N*-oxides in the oxidation of amines, oxidative cleavage of $\text{C}=\text{C}$ double bond and oxidation of alcohols to ketones); (3) *N*-electrophilic substitution (formation of triazoles from aromatic 1,2-diamines and *S*-nitrosation); the reactive species are ONOOH and NO^+ ; (4) *O*-nucleophilic substitution involving ONOO^- and HOQ^- (epoxidation of quinones and oxidation of aldehydes); and (5) radical mechanisms involving NO_2 and $\cdot\text{OH}$ (oxidation of lipids and alcohols, hydroxylation of activated aromatic compounds).

Analysis of the results presented in the present review and obtained in our kinetic studies of the reactions of peroxynitrite with hydrocarbons and DMSO (see Sections V.2 and V.3) suggest the following.

1. High oxidation potential and high electrophilic and nucleophilic activity allows peroxynitrite to react with a broad spectrum of substrates.

2. The variety of pathways and mechanisms of peroxynitrite reactions and the nature of the active centers in the peroxynitrite molecule are determined by not only the reaction conditions (pH, presence of transition metal impurities, CO_2 , hydrogen peroxide, nitrite) but also the properties of substrates:

- (a) with highly reactive substrates, whose reactions with peroxynitrite proceed faster than the latter decomposes, either peroxynitrous acid or its anion can act as reactive species;

(b) reactions with substrates of low reactivity proceed by radical mechanisms involving $\cdot\text{OH}$ -like reactive species (hydroxyl radical, radical pair or the excited form of peroxynitrous acid), which was proved taking the oxidation of inert alkane molecules under mild conditions as examples.

It is the reactivity of substrates that can reconcile the research group headed by Koppenol^{16, 38, 61, 108} (they assume a bimolecular interaction of peroxynitrite with many substrates) with the groups headed by Goldstein^{40, 62, 65} and Hurst^{64, 88} who prefers the mechanisms involving $\cdot\text{OH}$ -like reactive species.

3. Volatile substances, e.g., low-molecular-mass hydrocarbons, can react with peroxynitrous acid (but not its anion!) not only in solution, but also in the gas phase.

4. The ability of ONOOH to distribute between different phases (aqueous, gas phase and lipophilic phase) and generate OH radicals in each phase is of great importance for understanding the mechanisms of peroxynitrous acid initiated oxidation of lipid fragments in cells and diffusion of peroxynitrite across cell membranes.

High chemical and biological activity of peroxynitrite requires further systematic studies on the kinetics and mechanisms of reactions, including the reactions with biomolecules and their models under physiological conditions.

The authors express their gratitude to Dr. Yu V Geletij (Emory University, Atlanta, USA) for help in providing access to recent literature on the subject and for numerous discussions on the material, Prof. I V Komissarov (Donetsk Medical University) and Dr. V P Tretyakov (L M Litvinenko Institute of Physical Organic and Coal Chemistry, Ukraine) for valuable comments.

This review has been written with the financial support of the INTAS (Grant Nos 93-1060 and 99-209).

While the manuscript was in preparation, a new review²⁶⁸ has appeared. This indicates incessant interest of researchers in the subject in question.

VII. Conclusion	407

Abstract. The state-of-the-art in the design of piezoelectric immunosensors is analysed. The analytical conditions, types of immunochemical reactions detected by piezogravimetric sensors and methods for immobilisation of bioreceptor molecules on the electrode surface of piezoelectric resonators are considered. Special attention is given to the use of immunosensors for the detection of microorganisms and low- and high-molecular-mass compounds in liquid media. The bibliography includes 172 references.

I. Introduction

In the past decade, the use of immunosensors has become one of the most attractive and promising trends in bioanalytical chemistry. A distinguishing feature of this type of analytical devices is their ability to determine compounds of interest in complex mixtures with a high degree of sensitivity and selectivity and without any sample pretreatment. Immunosensors, like any other bioprobes, are built up of two major closely interconnected operational units, *viz.*, a bioselective material (a receptor) and a detector (a physical transducer). The receptor comes into contact with the tested substance, while the detector transduces the signal generated in the course of the biochemical reaction into an analytical response which can further be transformed and presented in a digital form.

High selectivity and high sensitivity of immunoassays are attained through the use, as key reagents, of antibodies (Ab), *i.e.*, protective proteins formed in the organisms of higher animals in response to external stimuli (antigens, Ag).^{1,2} The neutralising effect of Ab is based on their ability for highly specific recognition of complementary antigens and formation of immune Ag–Ab complexes with their subsequent elimination from the organism.

Traditional immunological methods enable determination of even minute concentrations of antibodies or antigens (high-molecular-mass immunogens and low-molecular-mass haptens);

however, they require complex time-consuming procedures. In contrast, immunobiosensors detect antigen–antibody interactions within a course of tens of seconds. The processes accompanying the operation of immunosensors are very similar to those occurring in living organisms. The formation of immune complexes is concomitant with changes in the voltage, current, optical (*e.g.*, refractive index) and acoustic characteristics, *etc.*; therefore, biochemical interactions can be recorded with the help of a vast array of physical, *e.g.*, optical, electrochemical, acoustic (including piezoelectric), *etc.*, transducers.

The interaction of an analyte with a piezoelectric sensor is associated with changes in the frequency (f), amplitude and phase of the transducer oscillations.³ Piezoelectric sensors are highly sensitive to changes in both mass and some physicochemical properties (*e.g.*, viscosity, density, elasticity, conductivity, *etc.*) of the receptor layer and the fluid in contact with the sensor.^{4,5} Especially well-studied are immunosensors operating on a microbalance principle. In order to enhance the stability and accuracy of measurements and to reduce the acquisition time from sensors operating at high damping fluid loads, modern devices employ high-precision sensitive digital systems for measuring frequency signals and efficient noise filtration methods. However, this trend demands special consideration and is beyond the scope of the present review.

The role of analytical signals in gravimetric sensors is played by the decrease in the oscillation frequency of the sensor (Δf) caused by the increasing mass of the receptor layer in the course of selective immunochemical coupling.

Apart from very high (at the picogram level) sensitivity of gravimetric immunosensors, the latter enable direct on-line detection of biochemical reactions without the use of labelled (fluorescent, enzymatic, radioactive, luminescent, *etc.*, probes) materials employed in classical solid-phase immunoassays, *e.g.*, Enzyme-Linked Immunosorbent Assay (ELISA), and related processes. The presence of non-polar organic solvents, which usually diminish the sensitivity of procedures that employ labelled materials, is not critical for the direct interaction of antibodies with antigens sensed with piezoelectric detectors.⁶ Other advantages of gravimetric immunosensors include fast response, handling ease, portability and possibility to be incorporated into multisensor and information gathering and processing systems.

Piezoelectric detection compares favourably and even exceeds in sensitivity many popular optical, spectrophotometric, electrochemical, fluorescent, immunoenzymatic, *etc.*, procedures for monitoring immunochemical reactions and is only slightly inferior

to reflexometry.^{7,8} In contrast to solid-phase immunoanalysis based on the use of non-recoverable reagents, immunosensors can easily be regenerated for repeated use. This capability makes their broader application in routine assays more expedient, primarily because the cost of a single assay is significantly reduced.

Some theoretical aspects of performance of piezoelectric biosensors and their specific applications for the detection of a vast array of analytes were reviewed.^{6,8–19} Two processes are taken into consideration in estimating analytical responses of biosensors, *viz.*, the increase in the coating weight due to formation of heterogeneous immune complexes and the transformation of this weight increase into electrical signals.

The development of various types of gravimetric sensors (*e.g.*, test systems, detectors for flow-injection analysis, *etc.*) based on highly specific interactions [antibodies–antigens, enzymes–substrates, receptors–ligands (hormones, cytokines), avidin–biotin, protein A–antibodies, DNA–DNA or RNA, transport proteins–various molecules and ions] will significantly expand the area of their application. Such sensors can find use in medicine, food industry, perfume production, pharmaceutical chemistry, agriculture (veterinary medicine, horticulture, plant growing), biotechnology, mining industry, military engineering and ecological monitoring of toxicants as well as soil and waste water pollutants of bacterial origin.

Unfortunately, in Russia the theoretical aspects of the design of mass-sensitive immunosensors are still very poorly investigated, whereas in other countries this trend of research is developing rapidly.

The present review is devoted to the description of different types of immunoassay based on the use of piezoelectric transducers with special reference to conditions for their implementation and methods for immobilisation of bioreceptor molecules. Special attention is given to the efficiency and outlooks in the application of gravimetric immunosensors for the detection of microorganisms as well as high- and low-molecular-mass biologically active substances in liquid media.

II. Some functional characteristics of gravimetric piezoelectric immunosensors in gaseous and liquid media

An acoustic microbalance is a piezoelectric quartz resonator, which operates on the bulk acoustic wave principle. It represents a thin disc from a natural or synthetic crystal of quartz with metal (gold, silver, aluminium, nickel, chromium) electrodes plated on both sides of the disk by thermal spraying.^{18–21} To minimise thermal effects, the disc is cut up along the shear plane of the crystal (the so-called AT-cut) manifesting the highest thermal stability in the temperature range 10–50 °C.¹²

Only the area between the electrodes appears to be piezoelectrically active; the mass sensitivity of a piezoelectric resonator decreases appreciably with an increase in the distance from the centre. Especially popular are crystals with a quartz plate diameter of 10–16 mm and gold (less often, silver) electrodes operating at intrinsic oscillation frequencies from 5 to 15 MHz. Some literature reports describe the use of resonators with improved frequency characteristics of the order of 30 (see Refs 22 and 23), 70 and even 110 MHz.^{24,25} Thin crystals resonating at high frequencies are more sensitive to mass fluctuations, but suffer from drawbacks of fragility and high noise levels.

The application of an external alternating electric potential to a piezoelectric material produces internal mechanical stress between the electrodes which leads to the deformation of the crystal. The resonance is achieved by including the crystal in an oscillation circuit where electric and mechanical oscillations are near to the fundamental frequency of the crystal. The intrinsic frequency of a resonator depends on many factors some of which are constant, *e.g.*, size and structure of the plate (thickness, density, roughness, type and shape of the cut, *etc.*), while some

are variable, *e.g.*, masses of metal electrodes and external factors (density or viscosity of gaseous and liquid media in which the measurements are performed, composition, ionic strength and pH of test solutions, *etc.*).^{4,5,10,11} The oscillation frequency of an AT-cut crystal decreases linearly with an increase in the mass of the materials deposited on the electrode surface in accordance with the Sauerbrey equation:²⁶

$$\Delta f = -\frac{2.3f_0^2 10^6 \Delta m}{A},$$

where Δf is the change in the oscillation frequency of the crystal (in Hz), f_0 is the intrinsic oscillation frequency of the crystal (in MHz), Δm is the mass of the receptor layer coated onto the electrode surface (in g) and A is the surface area of the electrode (in cm²).

However, this ratio is valid only for small mass increments. Overloading not only diminishes the sensitivity of assays, but also results in the stripping of signals; therefore, commercial piezoelectric microbalances are usually set to operate in the range from $\sim 1 \text{ ng cm}^{-2}$ to $\sim 100 \text{ } \mu\text{g cm}^{-2}$.

1. Specificity of immunosensors in gaseous media

The first attempt to use antigens as electrode coatings for piezoelectric microbalances dates back to 1972;²⁷ however, the interest of investigators in this field was awakened some time later. A report²⁸ on a highly sensitive (at the ppb level) detection of the pesticide parathion in air, which was based on the use of anti-parathion antibodies immobilised on a piezoelectric crystal, was published in 1986. Traces of moisture present in the thin-film coating of a sensor favoured the occurrence of immunochemical reactions in the gaseous phase. Piezoelectric sensors based on immobilised proteins (antibodies) were successfully employed for the detection of atmospheric pollutants including sulfur dioxide, carbon monoxide, hydrogen chloride, nitrogen dioxide, ammonia, organophosphorus pesticides, *etc.*^{28–32}

However, some literature reports refuted the occurrence of specific immunochemical reactions in antibody-based dry films used as biosensor coatings for detecting pesticide content in the air.³³ It is noteworthy that piezoelectric immunosensors are no longer employed for the analysis of gases due to the difficulty of analytical signal recording resulting from minute changes in the mass of the biosensor coatings during direct detection of low-molecular-mass compounds.

2. Some functional features of biosensor systems in liquid media

Early attempts to use piezoelectric biosensors for conducting measurements in liquid media were unsuccessful, since the crystals ceased to oscillate after being immersed into a solution. To overcome this problem, the mass gain was measured in the gaseous phase after incubation of the sensor with the test solution and subsequent drying. In this case, the frequency shifts were governed by the Sauerbrey equation. This procedure is commonly referred to as the dip-and-dry method.^{10,27,34,35} An alternative approach includes the construction^{36,37} of a different in principle excitation circuit for the analysis of fluids; this is based on the use of a flow detection cell where the test solution is exposed to only one side of the crystal.^{5,21,38,39}

The resonance frequency of a crystal immersed into a solution is strongly affected by the properties of the liquid phase; in this case, the Sauerbrey equation is not fulfilled. There exists no general equation which would take into account the contribution of all environmental factors to the overall response of a piezoelectric sensor in a liquid medium. Such a signal depends on the structure of the interface between the sensor coating and the surrounding solution. Such boundary effects are levelled off when only one side of the resonator is exposed to the solution and if crystal optically polished are used.

With consideration of the above limitations, piezoelectric immunosensors are used either as analytical test systems or as detectors for flow-injection analysis.

The pioneering studies that used piezoelectric immunosensors for a comparison of activities and specificities of antibodies in liquid media were carried out using the dip-and-dry method.²⁷ Since the 1980s, this trend was developing more intensively culminating in the elaboration of several methods for the detection of different subclasses of antibodies⁴⁰ and an indirect/competitive procedure for identification of antigens.⁴¹ In the 1990s, the range of detectable compounds increased considerably at the expense of biosensors for the detection of a vast array of microorganisms,^{42–52} blood cells,^{53–56} albumin,^{38,57} atrazine,^{17,58,59} human transferrin,⁶⁰ insulin,⁶¹ cocaine⁶² and immunoglobulin M (IgM).^{63,64} The major problems in conducting routine assays by this method are related to the conditions of exposure of biosensors to test solutions and their subsequent drying as well as the nature of the solvent adsorbed onto the sensor coating.

The range of substances detected by piezoelectric sensors in liquid media is rather broad and includes high- and low-molecular-mass compounds and cells. An original procedure was developed⁴² for the detection of microconcentrations of *Candida albicans* in the range from 10^6 to 5×10^8 cells ml^{-1} . High specificity of assay was confirmed by the absence of interactions of other yeast species or other antigen types with the sensor coating. Later, this approach was used for the detection of a vast array of pathogenic microorganisms (*Salmonella typhimurium*,⁴⁴ *Salmonella paratyphi*,⁴⁵ *Listeria monocytogenes*,^{46,47} *Vibrio cholera*⁴⁸), viruses (diarrhea,⁴⁹ herpes^{50,51}) and blood cells (human granulocytes,⁵³ T-lymphocytes,⁵⁴ erythrocytes^{55,56}).

Despite the relatively low reproducibility of experimental results due to hydration and the differences in the degree of the solvent adsorption on the receptor surface, the dip-and-dry method did not lose its significance to this day. Some recent publications describe different applications of this technique for the detection of microorganisms,^{52,65,66} proteins^{67–69} and toxicants.^{70,71} Its main advantage is in the possibility to use immunosensors as convenient quick-operating test systems for extralaboratory diagnostics and screening of environmental objects. The reliability of determination increases, while the limit of detection decreases with an increase in the time of exposure of the biosensor to the test sample, proper washing and drying of the biolayer to the constant weight.

A two-component sensor system one component in which is a detector and the other one is a reference sensor was developed in order to minimise the non-specific interactions between the sample components and the receptor layer of the sensor.⁶⁹ In this system, immobilisation of bioreceptor molecules on the sensor surface is preceded by the blockage of the sensitive area of the reference sensor.

The use of piezoelectric immunosensors in flow-injection analyses seems to hold more promise. In this case, the time required for a single assay is reduced to several minutes and the signal is followed in real time.⁷² This enables much higher reproducibility of the experimental data (measurement of relative changes in the frequency shift) and reduces the effects of non-specific interactions, since compounds adsorbed on the biosensor surface are easily removed by washing with the carrier solution. This, in its turn, allows re-usability of biosensors after regeneration of the biosensitive layer at the end of each measurement cycle.

The measurements are performed in a low-volume flow cell through which the test solution is pumped at a predefined speed. The cell volume varies from 35 to 100 μl .^{5,39,73}

More recent developments include a vast array of flow-type immunosensors for the detection of high- (bacteria, viruses, phages; antibodies, protein antigens, nucleic acids) and low-molecular-mass analytes (drugs, metabolites, ecotoxins).

III. Types of immunoassay

Immunoanalytical techniques based on piezoelectric immunosensors are classified according to the following criteria:

- nature of the receptor layer (antibodies, antigens, hapten–protein conjugates);
- type of biochemical reactions that induce the analytical signal (direct, competitive or displacement detection; mass amplified assays based on analyte modification);
- mechanism of generation of the analytical signal (increase or decrease in the mass of the bioreceptor layer);
- measurement technology (one- or two-step detection; dip-and-dry method, flow-injection analysis).

The classifications based on the type of the biochemical reaction and mechanism of generation of the analytical signal are especially popular. Among those, immunological methods based on the use of piezoelectric quartz transducers for conducting direct, indirect/competitive and displacement assays are among the most extensively studied techniques.^{13,16} Sandwich assay and approaches aimed at increasing the masses of adsorbed molecules and, hence, the analytical signal of the sensor, were developed for augmenting the sensitivity of immunoassays.

1. Direct detection

This one-step procedure is the simplest among other methods and is based on the interaction of the receptor layer of the biosensor with the analyte. The decrease in the resonance frequency due to formation of an immune complex on the electrode surface is directly proportional to the concentration of the analyte (Fig. 1). This kind of analysis is performed both in dip-and-dry and flow formats. Sensor electrodes are modified by antigens, monoclonal antibodies or polyclonal antibody-containing sera.

To increase the selectivity of assays, the sensor is pretreated with a solution of a non-ionic detergent or an inactivated protein which does not cross-react with test sample components [bovine serum albumin (BSA), gelatin, *etc.*], but is bound to the non-specific sites localised on the receptor surface of the biosensor. For example, the receptor layer of a DNA-based biosensor only weakly reacts with BSA molecules to produce a feeble frequency signal. In contrast, the analytical signals generated by anti-DNA antibody-containing sera from patients with autoimmune disease amounted to hundreds of Hertz.⁷⁴

Direct detection is the most efficient approach to identification of high-molecular-mass objects (somatic cells, microorganisms, protein macromolecules, antibodies, nucleic acids, glycoproteins, glycolipids and other antigens), since their sorption is accompanied by a significant increase in the mass of the receptor layer.

It is believed that direct binding of small molecules cannot be detected by piezoelectric immunosensors. For example, the sorption of a substance (4.4 ng cm^{-2}) onto a crystal with the intrinsic oscillation frequency of 10 MHz and the sensitivity of $0.227 \text{ Hz ng}^{-1} \text{ cm}^{-2}$ was accompanied by frequency changes that amounted to 1 Hz.¹³ The antibody monolayer (capacity of 500 ng cm^{-2}) contained 7×10^{-12} moles of binding sites. The

Figure 1. A schematic representation of a direct antibody assay.

(1) Antigen (hapten), (2) antibody, (3) non-specific components of the mixture.

maximum binding of a low-molecular-mass (~ 1000 Da) antigen corresponds to 2.7×10^{-12} mol cm $^{-2}$ and can induce only minor changes in the resonance frequency of the biosensor equal to several Hertz, which corresponds to the noise level. Nevertheless, the use of direct detection for identification of low-molecular-mass compounds, such as the herbicide atrazine⁷¹ and 2,4-dichlorophenoxyacetic acid^{13,75} having the detection limits from 0.24 to 0.27 $\mu\text{g litre}^{-1}$, has been described. The discrepancies between the magnitudes of experimentally determined and calculated frequency shifts can be attributed to changes in the viscoelastic properties of boundary layers of the fluid as a result of complexation with low-molecular-mass analytes.

Indirect/competitive, sandwich and other assay types are routinely used for the detection of low-molecular-mass molecules.

2. Competitive analysis

The first single-step indirect/competitive analysis of haptens based on piezoelectric sensors was carried out⁴¹ in 1980 and had a number of specific features. Whereas in routine immunochemical assays the competition for binding sites usually takes place between free and radiolabelled analytes, in the case of piezoelectric immunosensors the role of competing reagents is played by the free (non-bound) analyte, which is present in the solution, and the hapten–protein conjugate immobilised onto the bioreceptor layer (Fig. 2). The magnitude of the analytical signal of the sensor is inversely proportional to the hapten concentration in the test sample.

Figure 2. A schematic representation of an indirect/competitive assay. (1, 2) Immobilised and free haptens, respectively; (3) antibody.

This approach is especially convenient for the detection of low-molecular-mass haptens, *e.g.*, vitamins, drugs, hormones, metabolites, herbicides, *etc.* Competitive assays exceed direct detection in sensitivity,^{18,58} however the range of measured concentrations is narrower by one or two orders of magnitude.

Not only hapten–protein conjugates, but also antibodies can be used for the formation of receptor layers in competitive assays. In the latter case, a fixed amount of the hapten–protein conjugate is added to each test sample; such modification has got the name ‘alternative competitive analysis’ (Fig. 3). The conjugated and free haptens are equiprobably bound to the active sites of the immobilised antibodies; therefore, the lower the concentration of the free analyte in the sample, the greater the amount of the conjugated hapten bound to the receptor layer of the sensor. In this way, sorption of a conjugated analyte contributes to a significant enhancement of the frequency response.

Figure 3. A schematic representation of an alternative competitive assay. (1) Antibody, (2) hapten, (3) hapten–protein conjugate.

This type of immunoanalysis was successfully employed¹⁷ for the quantitation of triazine derivatives. The magnitude of the frequency shift induced by the binding of the triazine–protein conjugate to the receptor layer was inversely proportional to the triazine concentration in the range from 0.01 to 1 $\mu\text{g litre}^{-1}$. Despite its obviously lower sensitivity, the alternative method offers a broader concentration range in comparison with the competitive approach.

3. Two-stage sandwich assay

This assay is based on the use of secondary or species-specific antibodies which interact with the antibodies of the immune complex as with antigens specifically raised against them.^{40,76} Thus secondary antibodies enhance the analytical signal by forming sandwich complexes with test antibodies (Fig. 4), which significantly increases the selectivity and sensitivity of the assay. The sandwich technology was successfully employed⁷⁷ for determination of cholera toxin concentration in solutions (1×10^{-4} nmol litre $^{-1}$).

Figure 4. A schematic representation of a sandwich assay. (1) Antigen, (2) specific antibody, (3) non-specific antibody, (4) secondary antibody.

Sandwich assays are performed in two steps. In the first step, the antibodies (both specific and non-specific) are bound to an immobilised antigen. This is followed by an addition of secondary antibodies which react only with their specific antibodies to form sandwich-like complexes. The detection of allergen-specific immunoglobulin (IgE) in blood sera of patients with allergic dermatitis is a classical example of clinical application of this technique.⁶⁸ The allergenic protein (Der p) isolated from dermatophagoids was immobilised on the electrode surface of a biosensor. The interaction of the sensor with an antigenic blood serum from an allergic patient resulted in the binding of different antibody classes to the receptor layer; this was followed by differentiation of adsorbed antibodies upon exposure of the sensor to secondary anti-human IgE. The ability of secondary antibodies for specific recognition enables the differentiation between bound allergen-specific antibodies and representatives of other classes of blood serum immunoglobulins (*e.g.*, IgG, IgM).

A method⁷⁸ for determination of human serum albumin (HSA) based on the complexation of HSA with two types of antibodies is yet another illustrative example of a successful application of sandwich analysis. Noteworthy, the analytical signal generated by the sensor exceeded that obtained by the direct detection method threefold.

If direct detection of antigens is performed by the competitive method, the sandwich assay is complete in one step. This approach was used to determine the testosterone content ($13.6 \mu\text{g ml}^{-1}$) in a biological fluid.^{13,76}

4. Mass amplified assay

In addition to sandwich assays, the sensitivity of low-molecular-mass assays can be enhanced through the use of other approaches.

Figure 5. A schematic representation of a modified antibody assay. (a) Competitive assay, (b) sandwich assay, (1) modified antibody, (2) analyte.

One of them includes modification of sorbates by colloidal,^{79,80} latex, *etc.*, particles.^{81–83} Such methods are singled out into an independent group termed as ‘mass amplified assay’ and are based on the increment in the analyte mass.¹³ A schematic representation of such analyses is shown in Fig. 5.^{82,83} Modification of antibodies by colloidal particles caused significant increases in the sizes and masses of the adsorbed molecules. The assays were performed in the competitive (Fig. 5a) and sandwich (Fig. 5b) formats.

In the former case, the antibody molecules modified by solid colloidal particles could bind either to free analyte molecules (in solution) or to analyte molecules immobilised on the surface of the sensor electrode. Thus, the binding of the antibodies to the receptor layer was inhibited by high concentration of the analyte. The magnitude of the analytical response was inversely proportional to the concentration of the test antigen.

In the latter case, the reaction was complete in two steps (I and II); the protein molecules modified by colloidal particles interacted, similarly to secondary antibodies, with the analyte molecules bound to the receptor layer. In both cases, the frequency signal of the sensor was strongly enhanced by the colloidal particles deposited on the sensor surface. Gold, lead, cadmium and zinc sulfide sols as well as chromium, titanium and iron oxide sols are generally used as colloidal particles.

Latex agglutination is a convenient procedure for enhancing analytical signals. This approach was used³⁸ for the detection of *Escherichia coliform* species in solution within the concentration range 10^6 – 10^8 cells ml^{-1} . Latex particles able to modify *E. coli* specific antibodies were added to the reaction mixture.⁸⁴ After conjugation of the cells with antibodies immobilised on the sensor electrode, the anti-*E. coli* antibodies immobilised onto latex particles formed sandwich complexes with the cells bound to the antibodies on the electrode surface.

5. Displacement analysis

This format is especially suitable for determination of stabilities of affinity complexes (Ab–Ag, DNA–protein, DNA–RNA, *etc.*) in kinetic dissociation studies and for measurement of analyte concentrations. Whereas competitive analysis is a method of choice in determining minor concentrations of small molecules, macromolecules are more conveniently detected by displacement analysis. The method is based on the measurement of decrement in the mass of heterogeneous complex in the course of its dissociation induced by excess concentration of one of the reaction components. The analysis is performed in two steps (Fig. 6).

Determination⁴⁷ of *Listeria monocytogenes* in milk (2.5×10^5 – 2.5×10^7 cells ml^{-1}) is an example of this type of an immunoassay. The antibodies present in the sample were conjugated to a protein antigen isolated from *Listeria* sp., which was

Figure 6. A schematic representation of a displacement immunoassay. (1) Antigen, (2) specific antibody.

previously immobilised on the sensor electrode. This caused a decrease in the oscillation frequency of the sensor. Then, a displacement of the antibodies from the heteroimmune complex by *Listeria* cells added to the sample occurs. The amount of the displaced antibodies was directly proportional to the concentration of *Listeria* cells in the sample. A similar approach was used to determine the content of *Pseudomonas aeruginosa* in milk and drinking water.⁸⁵

IV. Methods for immobilisation of biomolecules

The sensitivity, selectivity and reproducibility of the assays of high- and low-molecular-mass compounds based on piezoelectric immunosensors strongly depend on the method used for the immobilisation of receptor molecules on the electrode surface.

The main requirements to the quality of bioreceptor layers are as follows:⁸⁶

- firm fixation of receptor molecules on the electrode surface;
- retention of high activity of immobilised biomolecules;
- uniform distribution of active binding sites on the electrode surface;
- physical and chemical stability (including regeneration stability) of the electrode layer in contact with the fluid during the measurement cycle;
- minimum mass of the receptor layer (the smaller the mass of the coating, the greater the mass increment of the analyte that can be established with the help of a microbalance).

The nature of the metal electrode should also be taken into consideration in deciding upon the immobilisation technique. Owing to their high chemical stability, piezoelectric resonators with gold electrodes are the most frequently used type; therefore, virtually all immobilisation techniques have been designed to operate with gold electrodes. However, in the past decade crystals with silver electrodes were gaining increasing attention by virtue of their low cost and higher sorptive capacity.^{87,88} It was found⁶⁸ that immunosensors with silver electrodes modified by lipoic acid with *N*-(3-dimethylaminopropyl)-*N'*-ethylcarbodiimide hydrochloride as a coupling reagent manifested 1.5 times higher sensitivity than sensors with gold electrodes. However, silver electrodes suffer from the disadvantage of being highly reactive and demands additional protection. This can be achieved, for example, through the use of polyethyleneimine supports able to form uniform layers and affording complete coverage of the electrode surface.

All currently known methods used for immobilisation of protein molecules may conventionally be divided into three groups:^{13,16} physical sorption, incorporation into matrices and chemical sorption.

Each of these techniques has advantages and drawbacks of their own. Very often, different methods are used in combination, but the choice of a procedure best suited for meeting a specific goal is always arbitrary. The degree of immobilisation of biomolecules

and the stability of the receptor layer should always be checked experimentally.

1. Physical sorption

Physical sorption is the simplest and fastest method for immobilisation of protein molecules on the surface of crystal electrodes under mild conditions. This is ensured by non-specific interactions or hydrogen bonds,⁸⁹ which enable the preservation of high functional activity of protein molecules^{70, 73, 90} and the formation of low-density layers.⁹¹ The number of active antibody sites is usually kept constant, although in some cases^{92–94} their functional activities can decrease as a result of conformational changes in the protein molecules. The amount of the adsorbed protein and, as a consequence, the sensitivity of the sensor are determined by the nature of the metal and the hydrophobicity of the protein, which, in its turn, depends on pH, ionic strength, temperature⁹⁵ and time of exposure of the sensor in the solution with antibodies. It was found⁹⁶ that after 4-day incubation the receptor layer could withstand up to 20 measuring cycles without any decrease in the analytical response.

Physical sorption is often used, *e.g.*, for the preparation of receptor coatings based on goat anti-ricin antibodies,⁷³ *Vibrio cholera*⁴⁸ and herpes virus antibodies,^{49, 50} recombinant fragments of specific antibodies against human immunodeficiency virus (HIV),^{97, 98} *etc.* The quantity of immobilised antibodies and cells can be estimated with a sufficient degree of accuracy from the difference between the frequency shifts in modified and pure piezoelectric quartz crystals.

The main disadvantages of such immobilisation include low sorptive capacity and low stability of coated surfaces, which diminishes the reproducibility of immunoassays and reduces the service lives of immunosensors. As the method in question does not provide well-developed surfaces required for covalent immobilisation, the sensitivities of biolayers are rather low.⁹¹

The use of physical sorption is not confined to the direct formation of bioreceptor coatings of sensor electrodes; it also favours the formation of intermediate protein layers which provide strong binding to both the metal surface of the electrode and the immunoreagent molecules. Protein A,^{61, 86, 87, 90, 98–100} which forms stable complexes with gold in neutral media (its binding constant is equal to 10^8 litre mol⁻¹) (see Ref. 101), is often used for the formation of intermediate layers. At the same time, protein A, which represents a polypeptide constituent of *Staphylococcus aureus*, can actively and specifically bind to immunoglobulins (to IgG, in particular) without affecting the active sites of antibodies which retain their high activities in the immobilised state.^{90, 102} Such immobilisation ensures not only high sensitivity and high binding capacity of the bioreceptor layer, but also its high elasticity, which is especially important for stable performance of piezoelectric immunosensors.¹⁰³ Immunosensors designed for the detection of insulin¹⁰⁴ and some viral and bacterial species¹⁰⁵ the bioreceptor coating in which was formed by protein A molecules demonstrated high sensitivity and stable performance even after a period of several months.

Further improvements of this technique included structural modification of proteins aimed at increasing the strength of binding of protein molecules to the gold surface. To achieve this, amino acid residues (*e.g.*, cysteine) containing SH groups were incorporated into the structure of the recombinant protein A (B5C1) by genetic engineering methods.¹⁰² The resulting intermediate layer based on the synthetic protein manifested higher binding capacity in comparison with the native protein A, which made it possible to increase the service life of the immunosensor without any loss in activity.

2. Incorporation into matrices

Incorporation of proteins into gels^{106–108} or polymeric matrices,^{51, 53, 54, 109, 110} which enables immobilisation at the expense of physical interactions, is rather a popular approach.

To obtain a polymeric matrix, a drop of a polymer solution in an organic solvent is placed onto the surface of a cleaned electrode and let dry until complete evaporation of the solvent. Immobilisation of antibodies is achieved by immersion of the sensor into an antibody-containing solution; then, antibodies are included into the polymeric layer. Such immobilisation was used³⁵ to determine the content of HSA. In earlier studies, biosensors based on polymeric matrices were actively employed for determination of blood cells, *e.g.*, human T-lymphocytes,⁵⁴ erythrocytes^{55, 56} and granulocytes;⁵³ however, the analytical signals generated by them were unstable in repeated measurements. The strength of binding of biomolecules can be increased through additional use of glutaraldehyde. To obtain a receptor layer, a solution of polyethyleneamine (PEA)^{70, 111} or polyethyleneimine (PEI)⁷⁰ in methanol is added dropwise to the surface of a crystal electrode and, after removal of the solvent, is incubated sequentially with glutaraldehyde and appropriate biomolecules, *e.g.*, antibodies or hapten–protein conjugates. In this case, the selective layer of the sensor retains its activity up to a period of 38 days.

Polymeric matrices prepared by electropolymerisation⁴⁵ or by the glow discharge method²¹ (which excludes the use of toxic solvents) are more efficient, but are still seldom used. Protein molecules in such polymeric films are linked by covalent bonds.^{21, 45, 112, 113}

Natural biopolymers (*e.g.*, proteins, polysaccharides) are also used for immobilisation of receptor molecules. A method for the formation, on the electrode surface, of hydrogels based on proteins (BSA) and antibodies has been described.⁷⁰ The biosensitive layer thus prepared was distinguished for high sensitivity and stability.

In recent years, polymeric films were especially often used as electrode modifiers (base layer) increasing the adhesion of biomolecules, since hydrophobisation and functionalisation of receptor surfaces enhance the stability of the bioreceptor layer.

3. Chemical sorption

This method is used for the preparation of dense and strong saturated layers that manifest high stabilities in liquid media.¹¹⁴ It is especially suitable for flow or flow-injection analyses. Covalent coupling provides firm fixation of biolayers on the electrode surface, which minimises the losses upon long-term exposure to fluid media, provides higher reproducibility of analytical signals and improves re-usability of immobilised solid phases after regeneration. Besides, chemical sorption allows preservation of functional activities of proteins over long periods of time (up to two years). However, in some cases the number of active sites in covalently coupled antibodies decreases under toxic effects of chemical reagents.¹¹⁵ Chemisorption usually employs gold (less often, silver) electrodes, and never aluminium or chromium electrodes.

Cross-linking, which is singled out into a separate group by some authors,^{108, 109, 116} represents a modified version of chemical sorption. It makes use of a vast array of mono- and heterobifunctional cross-linking reagents, such as hydrazide- and succinimide-containing derivatives. Glutaraldehyde, which reacts smoothly with amino groups to form additional methylene bridges in the protein molecule, is used more often than other reagents.^{68–71, 77, 111, 117–120}

Cross-linking is performed using different procedures. After short-term incubation of antibodies with a cross-linking reagent at room temperature, a drop of the reaction solution is added to the surface of a crystal electrode and air-dried.¹¹⁸ In the alternative approach, a drop of an antibody solution placed onto the electrode is exposed in a closed cell saturated with glutaraldehyde vapour at low temperature.⁷⁰ The fundamental difference between these two techniques is in different effects of the cross-linking reagent in homogeneous and heterogeneous media. Whereas after mixing of experimental solutions methylene bridges are formed throughout the whole bulk of the fluid, glutaraldehyde reacts exclusively with protein molecules on the surface of the liquid

Figure 7. A scheme of immobilisation of biomolecules by chemical sorption.

Immobilisation steps: I, activation of the metal surface; II, modification of functional groups; III, immobilisation of the protein molecule.

phase. This enables preservation of the native conformation of the active sites of the antibodies inside the layer and increases the sensitivity of the receptor coating of the sensor.

Virtually all chemical immobilisation procedures are complete in three steps (Fig. 7).

The surface of sensor electrodes is activated by application of a thin film (base layer) which is firmly fixed on the metal surface and contains reactive functional groups essential for subsequent immobilisation of protein molecules. In addition, the film coating protects the surface of metal electrodes from oxidation and premature destruction by corrosive media.

The formation of base layers from self-assembled monolayers (SAM) is of particular interest. Its advantages include homogeneity of base layers, their uniform distribution and spatial accessibility of their active sites and functional groups for the binding to receptor molecules as well as high mechanical strength and chemical stability.^{119, 120} An ideal monolayer consists of densely packed filaments firmly bound to smooth (*e.g.*, metal) surfaces.^{121, 122}

Treatment with siloxane derivatives, *e.g.*, (γ -aminopropyl)-triethoxysilane (APTS) and (γ -glycidoxypentyl)trimethoxysilane (GOPS) containing reactive amino and hydroxy groups, respectively, is widely used^{36, 71, 123–127} for the formation of SAM-based base layers. The surfaces thus modified bind biomolecules either directly (as in the case of GOPS) or after treatment with glutaraldehyde. The coupling of antibodies to siloxane films *via* amino and hydrocarbon groups of bifunctional cross-linking reagents¹¹⁶ favours the formation of dense ($74\text{--}220\text{ ng cm}^{-2}$) surface layers. High (from 78% to 92%) binding capacity of the latter in reactions with antigens is responsible for the wide applicability of this immobilisation technique.

The use of sulfur-containing compounds (*e.g.*, thiols and disulfides) that are adsorbed irreversibly on gold surfaces by coordination bonds between sulfur and gold atoms is yet another popular approach to the preparation of SAM. Alkanethiol-based films are among the most extensively studied types of SAM. As the orientation and stabilisation of monolayers is provided by van der Waals interactions between the methylene groups, the use of alkanethiol chains containing more than ten methylene groups permits one to obtain highly ordered monolayers of the crystal type.¹²¹

A similar approach was used to prepare SAM based on poly-L-lysine,¹²⁸ hydrophobic lipids,^{129, 130} cysteamine,¹³¹ cysteine⁷² and *p*-aminophenol,⁴⁵ which provide amino groups for modified layers; thiopropionic and lipoic acids,^{68, 72, 121} mercaptoundecanol¹³² containing reactive carboxy and hydroxy groups and dithiobis(succinimidylpropionate)^{72, 132} the NHS groups in which are directly involved in the binding of biomolecules.

High elasticity, which imparts conformational mobility to receptor molecules during their interactions with test objects and ensures successful transmission of signals to piezoelectric transducers, is a crucial requirement to piezoelectric sensor coatings. Therefore, in the second chemisorption step the activated surface of the sensor electrode is modified with a cross-linking reagent, such as glutaraldehyde, cyanogen bromide, thiol acids, hydrazine, 1,4-diepoxybutane, *etc.*¹¹⁵ To prepare more elastic bilayers with enhanced ligand-binding properties, high-molecular-mass biopolymers, *e.g.*, proteins A and G,⁷⁰ BSA⁷⁰ or polysaccharides: dextran¹³² or periodate-oxidised dextran,⁷² are used as cross-linking reagents. The formation of a receptor layer where covalently linked dextran is used as a spacer is schematically represented in Fig. 8.

Figure 8. A scheme of formation of a receptor layer where dextran is used as an intermediate layer between the electrode coating and the protein molecule.

Carbohydrate chains covalently attached to the protective coating on the sensor confer conformational 'flexibility' on the biomolecules that are bound to them.^{109, 115} Dextran activated by periodate oxidation were used^{72, 133} to prepare three-dimensional dense base layers with enhanced ligand-binding properties. However, this method has a number of disadvantages: it is time- and labour-consuming and requires the use of toxic reagents.

Biomolecules (protein A, lectins, avidin–biotin complex) used for modification of electrode surfaces present additional interest as flexible spacers. Therefore, the assignment of immobilisation methods to different groups is always arbitrary and combinations of various methods are used more and more often for the preparation of bioreceptor layers. The formation of the avidin–biotin complex is described by an affinity constant equal to $10^{15}\text{ litre mol}^{-1}$, which points to its stronger ($\sim 10^3$ -fold) binding in comparison with immunochemical fixation. Moreover, biotin is endowed with the ability to bind easily and firmly to antibodies without any appreciable loss of activity. Therefore, bioreceptor layers based on the avidin–biotin complex, which retains stability over a broad range of pH upon long-term exposure to liquids, are widely employed in immunochemical studies.^{57, 132, 134}

The third step includes direct covalent binding of protein molecules to reactive groups of spacers.

To salient advantages of chemical sorption of biomolecules one can relate the great diversity of immobilisation techniques and the possibility to use them in combination, which, in its turn, favours the development of strategic approaches to the preparation of highly selective layers with predefined characteristics and the design of biorecognising receptors for the detection of analytes.

The disadvantages of the above-considered immobilisation methods (cross-linking, covalent binding, incorporation into

polymeric matrices, immobilisation on biomolecules) include relatively high masses of receptor layers and, as a consequence, the need for step-by-step control over mass increases in order to prevent the losses in the assay sensitivity and to provide stable performance of piezosensors. In some cases, continuous monitoring of receptor layers may be required, since no versatile procedure exists allowing the attainment of high immobilisation levels with simultaneous preservation of activities of immobilised antibodies. Therefore, immobilisation conditions should be optimised individually for each specific measurement.

V. Conditions for regeneration of bioselecting coatings

Re-usability of biolayers after each measurement cycle is a valuable feature of immunosensors, especially those designed for flow-injection screening of large panels of test samples where the same crystal has to be used many times.

It is known that formation of heterogeneous immune complexes is a reversible process; therefore, regeneration is confined to their dissociation under the influence of various factors that cause a shift in the reaction equilibrium towards the initial compounds. The increase in the ionic strength is one of such factors. Considering that immune complexes are stabilised by hydrogen bonds and van der Waals interactions, any increase in the ionic strength brings about conformational changes in the active sites of antibody molecules with simultaneous desorption of the analyte from the bioreceptor layer and restoration of the initial number of binding sites in the immobilised biomolecules. Acid or alkaline solutions [0.2 M glycine/HCl buffer (pH 2.5),^{58, 67, 68, 134} 0.2 M glycine,⁶ 0.001 M HCl,^{13, 67, 68} 0.1 M HCl,⁶ 0.5 M H₂Cr₂O₇,¹³ 1 M HCOOH,⁷¹ 0.001–0.1 M NaOH (see Ref. 6)] as well as 30%–50% methanol⁶ and denaturing reagents [6–8 M (NH₂)₂CO (see Ref. 44) and guanidine⁶] are generally used for regeneration; their action suppresses the interactions of the active sites with the analyte. It is found that dilute solutions sometimes fail to induce complete dissociation of immune complexes, whereas more concentrated reagents can diminish the sensitivity of biosensors as a result of damage of the layer consisting of immobilised ligands. From this standpoint, restoration of their initial sensitivities and preservation of mass after each measurement are the main requirements to regeneration of biolayers. The regenerating effect of 0.15–3 M KSCN, which depends on the nature of the immunoreagents and enables up to 20-fold utilisation of the bioreceptor layer without any detriment to its activity, has been described.^{126, 127}

Selective biochemical interactions, which yield more stable complexes than those formed upon immunochemical coupling, can be used, along with chemical reagents, for decomposition of immune complexes. Thus synthetic peptides able to react with adsorbed antigens (*e.g.*, viruses) and to be easily eliminated from the receptor surface can be used for regeneration of biolayers.⁵¹ In this case, the biosensors retained their activities over 18 measurement cycles. A sorbed protein analyte can be eliminated on treatment with a proteinase. For example, a solution of non-specific proteinase K induced hydrolytic elimination of antibody molecules in a neutral medium without any effect on the immobilised ligands of the biolayer.⁶

When long-term performance causes partial inactivation and destruction of the sensor biolayer as a result of which the reproducibility of analytical signals diminishes, the metal surfaces of sensor electrodes should be cleaned and washed properly with highly concentrated solutions of alkali and acids, *e.g.*, 0.5–1.2 M NaOH (pH 11–13); 0.5–1.2 M HCl (pH 1–2), or concentrated hydrochloric acid. The choice of conditions for complete regeneration of the sensor surface depends on the nature of the metal electrode and the method used for the formation of the base layer. For example, if antibodies are immobilised on a gold electrode using protein A, the protein layer is completely eliminated by sequential washing of the sensor with 1.2 M NaOH,

1.2 M HCl and concentrated HCl.⁵⁸ Siloxane films are easily destroyed by treatment with concentrated HCl. A solution of H₂Cr₂O₇, which allows complete purification of gold electrodes of piezoelectric resonators from thiol within a course of 15 min, can be used as an efficient regenerating reagent. The elimination of (γ-aminopropyl)triethoxysilane-containing base layers requires long-term incubation of the sensor in a hot solution of H₂Cr₂O₇.¹³ (γ-Aminopropyl)triethoxysilane- and tetraethoxysilane layers are easily eliminated from the surfaces of silver electrodes with 0.1 M HCl (pH 2), which acts directly on the oxide film of the metal.^{13, 125–127, 135} After washing and drying, piezoelectric resonators can be repeatedly used for the formation of biosensitive layers of another specificity.

Thus, the choice of conditions for regeneration of bioreceptor layers and complete purification of metal surfaces of resonator electrodes depends on the nature of the metal and the method used for immobilisation of biomolecules; in each case, the conditions are selected experimentally. The possibility of performing two-level regeneration of resonators is a salient advantage of piezoelectric immunosensors, since it enables their repeated application and versatile performance, which eventually reduces the cost of the analysis.

VI. Applications of piezoelectric immunosensors

The areas of application of piezoelectric immunosensors for the detection of high- and low-molecular-mass analytes in liquid media are extremely diverse and include biochemical, clinical and analytical studies; certification of foodstuffs and pharmaceutical substances; monitoring of environmental objects and so on (Table 1).

The majority of modern piezoelectric immunosensors are designed for the detection of 'large-sized' analytes, such as protein molecules, lipid–protein complexes, nucleic acids and viruses as well as for identification of somatic and bacterial cells in biological fluids, drinking water and foodstuffs. Determination of concentrations of such objects with the help of piezoelectric immunosensors proved to be more convenient in comparison with traditional microbiological or immunological methods. Piezoimmunosensors are used in the clinical diagnostic practice for identification of blood constituents (erythrocytes, T-lymphocytes, granulocytes) and the most common pathogenic bacteria.^{5, 6, 11, 13, 16, 17} Design of sensors for detecting pathogenic viruses (*e.g.*, herpes,^{50, 51, 139} hepatitis,^{136–138} human immunodeficiency,^{97, 98} *etc.*) is yet another promising trend. A good correlation with the results obtained by ELISA was established upon screening of blood sera for the human immunodeficiency virus.^{67, 68, 97} Piezoelectric immunosensors are used in veterinary medicine for identification of infectious pathogens in animals^{65, 96} and poultry⁵² and monitoring the quality of agricultural products.^{13, 96}

An important role in the variability of microorganisms residing in human body and environmental objects is played by bacteriophages. Therefore, phages are presently used for the solution of many practical tasks including deciphering of the human genetic code, prophylaxis and treatment of infectious diseases and detection of pathogenic microorganisms in environmental objects. The most recent trends are towards the development of highly sensitive piezoimmunosensors based on resonators with intrinsic oscillation frequencies from 39 to 110 MHz; they are designed for the direct detection of phages M13 in liquids²⁵ and screening of phage libraries.^{140, 141}

New, in principle, applications for piezoelectric immunosensors are described in the review.¹⁴² A highly selective immunosensor was proposed based on immobilised monoclonal antibodies for discrimination of serogroups A, B and D of *Salmonella*. Such sensors manifest extremely high specificities in the recognition of antigens differing structurally at the level of immunodominant monosaccharides, *viz.*, optically isomeric 3,6-dideoxyhexoses (paratose, abequose, tyvelose). These findings open up fresh opportunities for the use of gravimetric immunosensors for

Table 1. Use of piezoelectric immunosensors in clinical diagnostics and ecological monitoring.

Analyte	Type of assay, method for immobilisation of biomolecules	Detection limit	Ref.
Microorganisms			
Hepatitis A and B viruses	direct assay, Ab were immobilised by protein A	10^5 particles ml^{-1}	136, 137
Hepatitis C virus	hepatitis C virus RNA was immobilised on cysteamine SAM through avidin (streptavidin)	—	138
Herpes virus	direct assay, Ab were immobilised by protein A	5×10^4 particles ml^{-1}	50, 51, 139
Potato X-virus	direct assay, chemisorption of Ab on a siloxane substrate	4×10^{-8} – 6×10^{-3} mg ml^{-1}	125
Phage library	displacement analysis, biotinylated antigens were immobilised by streptavidin	$(1-5) \times 10^{11}$ particles ml^{-1}	140
Bacteriophages M13	direct assay, antibodies were immobilised by a bifunctional cross-linking reagent	10^9 particles ml^{-1}	25
Bacteriophages	—	5×10^{12} particles ml^{-1}	141
<i>Salmonella</i> sp. from serogroups A, B and D	direct assay, antibodies were immobilised by a bifunctional cross-linking reagent	10^5 – 10^8 cells ml^{-1}	142
Proteins			
Immunoglobulin G (IgG)	direct assay, Ab were bound to protein A	10^{-6} – 10^{-2} mg ml^{-1}	143
Human IgG	direct assay, chemisorption of the protein complex IgG–Ab on a polystyrene substrate	$5 \mu\text{g ml}^{-1}$	144
HSA	Ab were immobilised on an ethylene diamine substrate, obtained by the glow discharge method	16 – $128 \mu\text{g ml}^{-1}$	21
	direct assay, Ab were immobilised on polystyrene	5 – 100 mg ml^{-1}	35
Immunoglobulin M	direct assay, chemisorption of Ab on poly(2-hydroxyethyl methacrylate)	10 ng ml^{-1}	145
Antibodies to human immunodeficiency virus	direct assay, immobilisation of a synthetic HIV-peptide or recombinant human proteins	tests yes/no	97, 98
Staphylococcal enterotoxin B (SEB)	competitive method, Ab were adsorbed on gold	$0.1 \mu\text{g ml}^{-1}$	146
Cholera toxin	sandwich method enhanced by ganglioside-modified liposomes	10^{-4} nmol litre $^{-1}$	147
C-Reactive protein	latex agglutination	20 – $66.7 \mu\text{g litre}^{-1}$	81
Ricin	direct assay, Ab were immobilised by physical sorption	$0.5 \mu\text{g litre}^{-1}$	73
Complement factors C1, C6	direct assay, chemisorption of Ab on a polyethyleneimine substrate	$0.83 \text{ nmol litre}^{-1}$	148, 149
Ferritin	direct assay, Ab were immobilised on a cysteamine monolayer by cross-linking	0.1 – 100 ng ml^{-1}	131
α -Fetoprotein	direct assay, Ab were immobilised on a cysteamine monolayer by cross-linking	$1.5 \text{ nmol litre}^{-1}$	150
Surface antigen of hepatitis B	the same	$4.7 \text{ nmol litre}^{-1}$	151
Immunoglobulin E	direct assay, physical sorption of the protein antigen	0 – 300 IU ml^{-1} , 0.15 – 17.5 IU ml^{-1}	67, 68
	direct assay, affinity attachment to an aptamer based on single-stranded DNA	$0.05 \text{ nmol ml}^{-1}$	152
Anti-DNA antibodies	direct assay, native and denatured DNA were immobilised by chemisorption	0.1 – $25 \mu\text{g ml}^{-1}$, 0.03 – 8 IU ml^{-1}	74
Insulin	sandwich format, adsorption of Ab	$0.17 \text{ nmol litre}^{-1}$	104
Transferrin	agglutination enhanced by poly(ethylene glycol)	$2.1 \text{ nmol litre}^{-1}$	153
Immunoliposomes	competitive assay, immobilisation of hapten	10^{-8} – $10^{-5} \text{ mol litre}^{-1}$	154
Low-molecular-mass compounds			
Oxalic acid	competitive assay, Ab were covalently immobilised on polyethylenamine substrate	$1.9 \mu\text{g ml}^{-1}$	70
	Ab were immobilised into a BSA-based hydrogel	50 ng ml^{-1}	70
2,4-Dichlorophenoxyacetic acid	competitive assay, Ab were covalently immobilised on an aminobenzenethiol substrate	0.24 – $0.27 \mu\text{g litre}^{-1}$	155
Cortisol	direct assay, Ab were bond to protein A	$36 \mu\text{g litre}^{-1}$ ($100 \mu\text{mol litre}^{-1}$)	117
3-Indolylacetic acid	competitive assay	$3 \text{ nmol litre}^{-1}$	156
Atrazine	the same	0.025 ng ml^{-1} ($5 \times 10^{-4} \mu\text{mol litre}^{-1}$)	58, 59
	direct assay	0.01 ng ml^{-1}	71
Cocaine	direct assay, Ab were bond to protein G	$33 \mu\text{mol litre}^{-1}$	62
	competitive assay, the hapten was attached to the monolayer of mercaptoundecanoic acid	$10^{-4} \mu\text{mol litre}^{-1}$	157
β -Estradiol	immobilisation of an estrogen component capturing the receptor–estradiol complex	$8 \text{ nmol litre}^{-1}$	158

Table 1 (continued).

Analyte	Type of assay, method for immobilisation of biomolecules	Detection limit	Ref.
Atropine	—	0.05 nmol litre ⁻¹	159
Polynuclear aromatic hydrocarbons	competitive assay, Ab were covalently immobilised on a siloxane substrate	0.01 µmol litre ⁻¹	160, 161
Nonylphenol	the same	0.8 ng ml ⁻¹	162
Cotinine	"	0.1 µmol litre ⁻¹	74
Salicylic acid	"	2.9 µmol litre ⁻¹	126
Sulfamethoxazole	"	6 × 10 ⁻⁴ µmol litre ⁻¹	127

validation of structural data for carbohydrate-containing biopolymers and design of diagnostic systems.

Piezoelectroimmunosensors are used for identification of protein molecules, *e.g.*, of antibodies in blood serum (IgG, IgM, IgE). In order to promote efficient treatment of allergic and autoimmune diseases, patients' blood sera are screened for immunoglobulins (IgE)^{67, 68, 152} and anti-DNA antibodies. Receptor layers containing native or denatured DNA were used⁷⁴ in direct flow-injection assays of anti-DNA antibodies in blood sera of patients with systemic lupus erythematosus.

Piezoelectroimmunosensors were used as valuable tools for the detection of a vast variety of clinically important analytes, such as α -fetoprotein¹⁵⁰ and ferritin,¹³¹ the tumour-associated protein markers. Unfortunately, the recently developed sensors cannot be used for the analysis of human blood samples because the range of quantifiable ferritin concentrations is very narrow. Further experiments should be aimed at expanding the quantifiable concentration range, since normal blood levels of this protein in healthy females and males are usually equal to 90 and 200 ng ml⁻¹, respectively.

DNA-Based piezoelectroimmunosensors are used for hybridisation of nucleic acids.^{163–165} A recently developed gravimetric immunosensor^{166, 167} proved to be the instrument of choice in the estimation of genetically modified organisms.

Not only protein molecules and DNA, but also carbohydrate-lipid biopolymers [lipopolysaccharides (LPS)], are used as receptor layers. Biologically active LPS, which represent the major outer membrane constituents of Gram-negative bacteria, are responsible for the O-antigenic specificity and toxicity of bacteria. A method for the study of interactions between immobilised bacterial endotoxins (LPS) and synthetic LPS-binding peptides has been developed.¹³⁵ The data obtained point to a high potential of gravimetric immunosensors based on immobilised LPS in estimating the efficiency of antitoxic agents (antidotes).

The widening assortment of competitive immunoanalytical techniques based on piezoelectric sensors gave a new impetus to the appearance of publications devoted to the analysis of low-molecular-mass substances (drugs, hormones, alkaloids, pesticides and their metabolites, ecotoxins, vitamins, *etc.*).^{168, 169}

Residual concentrations of pesticides, which belong to one of the most widespread classes of low-molecular-mass toxicants, can also be controlled with the help of piezoelectroimmunosensors.⁶

Considering that veterinary antibiotics are used as widely as pesticides and that accumulation of drug components and their toxic metabolites in agricultural products is a potential hazard to human health, the use of piezoelectroimmunosensors for the monitoring over the content of toxic substances in foodstuffs (milk, meat, eggs) and environmental objects (waste waters; rivers, brooks, subterranean waters) is a currently central task. Immunosensors for detecting antimicrobial sulfamide drugs in aqueous solutions and milk have been developed.^{127, 170} In addition, piezoelectroimmunosensors can be used in drug tests for adulterants.

A gravimetric immunosensor for measuring the content of cotinine (a nicotine metabolite and a specific marker of the functional status of smokers in sociological tests) in urine samples

has been designed.⁷⁴ Screening of analytes revealed that cotinine content in the urine of active smokers varied from 4 to 6 mg litre⁻¹, while that in non-smokers was as low as 0.5–0.7 mg litre⁻¹. The sensitivity of the new piezoelectroimmunosensor was comparable to those attained in polarisation immunofluorescent studies.

The operating characteristics of piezoelectroimmunosensors for detecting hydrophobic ecotoxins (*e.g.*, polyaromatic hydrocarbons^{160, 161}) were improved in the presence of organic solvents.^{6, 155}

The broad application of nonylphenol ethoxylates as detergents and emulsifying agents in the commercial production of cleansers, dyes, some herbicides and tanning agents led to the pollution of the environment with their degradation products. Especially hazardous and toxic is nonylphenol possessing carcinogenic, estrogenic, *etc.*, activities. A flow-injection method for measuring the nonylphenol content in water aimed at monitoring industrial effluents and water reservoirs has been developed.¹⁶²

The possibility of ecological monitoring of toxicants (*e.g.*, ocadaic acid) produced by some algae species has been demonstrated.⁷⁰

The ever increasing number of publications illustrates the strong inclination of investigators to expand the area of application of piezoelectroimmunosensors. It is of note that flow-type immunosensors are efficient tools not only for the detection of analytes of different molecular masses, but also for monitoring the changes in the viscoelastic properties of boundary layers in immune reactions carried out in solutions⁷⁵ and for following biochemical reactions in real time. This unique capability of piezoelectroimmunosensors enables kinetic studies of affinity reactions, such as antigen–antibody and protein–nucleic acid interactions, hybridisation of complementary DNA chains, receptor–ligand interactions, *etc.* Recent investigations in this field are documented in the reviews.^{6, 15, 126} Besides, piezoelectroimmunosensors hold much promise as potent tools for quantitation of cross-linking reactions between structurally related antigens and antibodies,¹⁷⁰ hybridisation of DNA^{163–165} and epitope mapping.¹⁷¹

Combination of piezoelectroimmunosensors with impedance measurements is a useful approach to the study of viscoelastic properties of films and fluids exposed on the surface of piezoelectric crystals. In this case, the alternating voltage having a frequency close to the intrinsic frequency of the resonator is applied to the piezoelectric crystal and the auxiliary electrode. The electrode potential and the current passing through the crystal are measured simultaneously. Their ratio (impedance) permits real-time monitoring of degradation processes in thin polymeric films in the presence of biomolecules; conformational changes; phase transitions, swelling and other immunochemical reactions.^{22, 172}

Moreover, the possibility to combine piezoelectroimmunosensors with other (*e.g.*, optical and electrochemical) methods including surface plasmon resonance and atomic force microscopy will further extend our knowledge of the actual events related to biochemical interactions at the cell level.

VII. Conclusion

The analysis of publications of the past decade demonstrates that the novel scientific trend related to the development and practical applications of piezoelectric immunosensors in bioanalytical chemistry has aroused an ever increasing interest of investigators all over the world.

The combination of a low cost with enhanced sensitivity, selectivity and re-usability makes piezoelectric immunosensors a valuable alternative to existing optical, electrochemical, etc., devices for conducting routine tests. As regards long-range outlooks, piezoelectric immunosensors can occupy a more prominent place as analytical tools for flow-injection detection of analytes of different molecular masses and genetically modified products, monitoring of immunochemical interactions and control over the growth of bacterial populations and changes in viscoelastic properties of liquid media. The development of diagnostic kits that are based on piezoelectric immunosensors and are specifically designed for early diagnosis of infectious, autoimmune and oncological diseases is still a topical task in modern clinical and veterinary medicine. Especially promising is the use of piezoelectric immunosensors for detecting drugs (doping control) and screening of urine, saliva and other biological fluids for alkaloids, hormones and other abused drug components.

In Russia, investigations aimed at the development of mass-sensitive immunosensors are still in their infancy. It remains to be hoped that the data presented herein will shed additional light on the broad prospects for future applications of piezoelectric immunosensors and will demonstrate their major advantages including real-time monitoring of molecular interactions without the use of any labels and complicated sample pretreatment procedures.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 06-03-32226).

Mesoporous titanium silicates as catalysts for the liquid-phase selective oxidation of organic compounds[†]

O A Kholdeeva, N N Trukhan

Contents

I. Introduction	411
II. Types of mesoporous titanium silicates and their synthesis	412
III. Methods of physicochemical characterisation of mesoporous titanium silicates	415
IV. Catalytic properties	422
V. Conclusion	429

Abstract. The data on the synthesis, physicochemical and catalytic properties of mesoporous titanium silicate materials published to date are surveyed. The relationship between the structure of these materials and their catalytic properties in the liquid-phase selective oxidation of organic compounds with peroxides is considered. The emphasis is placed on the problems of stability of mesoporous titanium silicate catalysts and the possibility of their recycling. The bibliography includes 264 references.

I. Introduction

Oxygen-containing organic compounds are important intermediates and products of both base and fine organic syntheses.^{1–9} Nearly a quarter of the major chemicals in the modern chemical industry are produced through the catalytic oxidation processes and the share of such processes is constantly increasing.^{8,9} Meanwhile, the stoichiometric ‘environmentally unfriendly’ oxidation of substrates with such agents as manganese or chromium oxides, metal permanganates or bichromates, nitric acid, *etc.*, still remains the major route to oxygen-containing products in the fine industrial synthesis.^{7,10–17} The stoichiometric oxidation consumes large amounts of expensive and toxic oxidants, which unavoidably gives rise to the problem of hazardous waste utilisation.

However, over the last decade, there has been a marked trend towards replacement of traditional stoichiometric oxidation procedures by catalytic ones, which are substantially more environmentally friendly and cost-effective. Among them, catalytic processes based on the environmentally safe oxidants, such as molecular oxygen and hydrogen peroxide, arouse the greatest interest.^{6–25} The active oxygen content in H₂O₂ is 47% and mere water is the only by-product of the H₂O₂ reduction. Although hydrogen peroxide is more expensive than oxygen (100% H₂O₂ costs 0.7 USD per kg),²⁵ the use of H₂O₂ often proves preferable in small-scale fine organic synthesis. First, the process equipment required for the oxidation with hydrogen peroxide is less expensive than that for the oxidation with oxygen, since the latter is

typically operated at elevated temperatures and pressures.^{7–10,26} Second, the processes based on the oxidation with aqueous H₂O₂ are commonly considered to be safer than those utilising oxygen under pressure. The feasibility of the implementation of hydrogen peroxide as an oxidant for a number of large-scale processes, such as caprolactam synthesis (Sumitomo Chemical Co.) or propylene oxidation (BASF and The Dow Chemical Co.) is currently surveyed by leading chemical companies.²⁵

Presently, water-soluble metal salts or complexes are dominantly used as catalysts for the liquid-phase oxidation.^{4–10,27} However, available catalysts for the selective homogeneous oxidation typically provide high activity and selectivity but low productivity due to the degradation of the catalytic sites in oxidative media. Furthermore, the separation of reaction products from the catalyst and recycling of the latter become a challenging task. Even in the case of two-phase oxidation, *i.e.*, when the catalyst is initially present in the aqueous phase, whereas the substrate and product are in an organic medium, contamination of the target product with toxic transition metal derivatives cannot be completely suppressed, since the interaction of the catalyst (or products of its decomposition) with organic components of the reaction mixture (*i.e.*, solvent or oxidation products) can yield metal complexes soluble in the organic phase.

The problem of the catalyst separation from the reaction products can be, in principle, solved only by the use of heterogeneous catalytic processes. However, it is known that the liquid-phase oxidation is often accompanied by the leaching of active components from solid catalyst, such that the oxidation process actually proceeds homogeneously in the bulk of the solution and all the above issues related to the product isolation and purification remain.^{10,13,16,28–33} Therefore, the development of novel solid catalysts providing the high activity and selectivity simultaneously with the stability against the action of reaction media is one of the most current challenges to the modern liquid-phase catalytic oxidation. The incorporation of transition metal ions or their complexes into frameworks or cavities (channels) of ordered micro- and mesoporous materials, *i.e.*, the design of so-called redox molecular sieves composed of isolated active sites homogeneously distributed over a solid matrix represents a promising possible route to the solution of this problem.^{7–10,13,16,28,29,34–37}

[†] The review is dedicated to the memory of V N Romannikov, who stimulated activities on the synthesis and studies of mesostructured silicate and metal-silicate materials at the Institute of Catalysis of the Siberian Branch of the RAS in the end of 1990s.

A real breakthrough in the liquid-phase catalytic oxidation was achieved in the mid-1980s by the Italian company Enichem with the invention of a microporous titanium silicate catalyst TS-1.³⁸ This catalyst is characterised by the structure of silicalite ZSM-5 (structural type MFI), in which the titanium(IV) ions are isomorphously substituted for a part of silicon atoms. This structure contains a three-dimensional framework of channels with a diameter of 5.3–5.6 Å. TS-1 was followed by another microporous titanium silicate catalyst, TS-2 (ZSM-11, structural type MEL, channels of 5.3–5.4 Å).^{39,40} Presently, TS-1 is still the best catalyst for the heterogeneous liquid-phase oxidation of various classes of organic compounds with aqueous hydrogen peroxide (Scheme 1).^{41–49} The oxidation of phenol with hydrogen peroxide over TS-1 was implemented industrially in 1987; using this process, about 10 000 t of hydroquinone and pyrocatechol are produced yearly.^{41,45} The main drawback of the microporous titanium silicates is the small size of the pores, which prevents their utilisation for the conversion of large organic molecules. In particular, the system TS-1–H₂O₂ is an active oxidant only for substrates with a kinetic diameter smaller than 6 Å (which includes unbranched alkanes and olefins, phenols, *etc.*).^{41–45} The problem of the selective catalytic oxidation of large organic molecules remains unsolved.

Scheme 1

Over the recent years, several titanium-containing zeolites and disordered titanium silicates with pores larger than in TS-1 have been synthesised, *viz.*, Ti-Beta (6.4 × 7.6 Å),^{50,51} Ti-APSO-5 (7.3 × 7.3 Å),⁵² Ti-MOR (6.7 × 7.0 Å),^{53,54} ITQ-7 (6.1 × 6.5 Å),⁵⁵ Ti-MWW (7.1 × 18.2 Å),^{56–59} Ti-DMS1 (11.2 Å),⁶⁰ *etc.* They were successfully utilised in the catalytic oxidation of some cyclic alkenes and alkanes (*e.g.*, cyclohexene, cyclooctene, norbornene, methylcyclohexane, *etc.*) and unsaturated alcohols,^{50–56,59–67} which cannot be oxidised over TS-1. Nevertheless, these catalysts are unable to overcome the problem of oxidation of larger molecules. Furthermore, some of them are sensitive to the action of aqueous hydrogen peroxide.^{28,29,31,68}

Over the last decade, a new class of materials, *viz.*, mesoporous silicates containing ions of various transition metals, including titanium, has become in the focus of interest: the number of publications devoted to their synthesis, characterisation and application as oxidation catalysts is rapidly increasing.^{32,45,69–91} The specific surface area of such materials can be as high as 1000 m² g^{−1} or even more. Large organic molecules can freely penetrate into the pores of these materials under the conditions of liquid-phase heterogeneous catalysis, in contrast to the pores of microporous materials. The design of such materials takes the first place among the current strategic tasks of fine organic synthesis oriented on the use of hydrogen peroxide.¹⁶

A number of reviews^{32,33,45,74,76–79,81–85,90,91} (not mentioning numerous original papers) devoted to the synthesis and elucidation of the properties of mesoporous metal silicates have

recently appeared. The first one was published in 1996.^{74,76} In the same year, a detail review devoted to microporous titanium silicates by Notari appeared,⁴⁵ which generalised rather scarce experimental data on mesoporous silicate materials available by that time. In 1997, two reviews by Corma^{77,78} on the synthesis of mesoporous molecular sieves (including metal silicates) and their applications in catalysis and another review by Schneider and Baiker,⁸¹ who considered mixed titanium–silicon oxides (aerogels), were published.

In the present review, we undertake an attempt to generalise and analyse the experimental results published to date (prior to the beginning of 2005) concerning the synthesis of mesoporous titanium silicates (both structurally ordered and amorphous) and analysis of their physicochemical properties and consider possible applications of these materials as catalysts for the selective liquid-phase oxidations. The emphasis is placed onto the relationship between the physicochemical characteristics of mesoporous titanium silicates and their catalytic properties and onto the problems of their stability and possibility of their recycling.

II. Types of mesoporous titanium silicates and their synthesis

There are two fundamentally different types of mesoporous metal silicate (including titanium silicate) materials, *viz.*, ordered and disordered. The first type includes various mesostructured materials (MMM, MCM-41, MCM-48, HMS, FSM-16, SBA-15, *etc.*), which are often referred to as mesoporous molecular sieves (Fig. 1*a*). The second type includes amorphous mixed oxides (*i.e.*, aerogels and xerogels) (Fig. 1*b*). Titanium can be either incorporated into the porous silicate matrix during its synthesis^{41,66–77} or grafted onto the surface of a preprepared matrix using the so-called post-synthesis, which means a treatment of a mesoporous silicate with titanium salts or complexes, such as TiCl₄, Ti(OPr)₄, [(C₅H₅)₂TiCl₂], [Ti₆(μ₃-O)₆(μ-O₂CC₆H₄OPh)₆.(OEt)₆], *etc.*^{7,28,92–99}

Figure 1. A schematic representation of the structure of a mesostructured material with hexagonally packed cylindrical mesopores (channels) (*a*) and of an aerogel (*b*);

a_0 is the lattice parameter, d_m is the diameter of a mesopore, h_w is the thickness of the silicate wall ($h_w = a_0 - d_m$), d_{100} is the interplanar spacing.

1. Mesostructured titanium silicate materials

Mesostructured silicates are known starting from the early 1990's.^{100,101} They represent highly ordered systems produced through the hydrothermal synthesis from inorganic precursors and surfactants.^{70–78,82,83,86–91} The mesopores emerging in such materials following the removal of surfactants by calcination or extraction have precisely determined sizes in the nanometre range (typically, from 20 Å to 200 Å) and form channels. The packing of the mesopores can be either hexagonal (MCM-41, HMS, MMM, FSM-16 or SBA-15) (see Fig. 1*a*), or cubic (MCM-48 or SBA-1) or lamellar (MCM-50), depending on the surfactant : Si ratio and conditions of the hydrothermal synthesis.^{74–77,83} The silicate

walls separating the channels of mesopores from each other are amorphous, but nevertheless the structure of these materials is characterised by long-range ordering[‡] owing to the ordered arrangement of the hollow channels. The specificity of the structure of these materials is reflected in the terms 'mesophase' or 'mesostructured', which imply long-range ordering (in the distance range from 1 nm to 1000 nm) at the absence of short-range ordering (at the atomic level). This feature distinguishes these materials from zeolites that are both short-range and long-range ordered.

Mesoporous mesophase metal silicates (and titanium silicates, in particular) are typically prepared through the hydrothermal synthesis by the crystallisation of a gel containing a source of the structural element (an Si compound), a structure-forming agent (*i.e.*, a surfactant) and a transition metal compound. The crystallisation is often carried out under elevated pressures and temperatures (25–200 °C). The duration of the crystallisation can vary from a few hours to several weeks.

The first report on the synthesis of an ordered mesoporous titanium silicate material, Ti-MCM-41, was published in 1994.⁶⁹ Later, several methods for the synthesis of a number of mesostructured titanium silicate materials (*e.g.*, Ti-MCM-41,^{69, 70, 72, 77} Ti-MCM-48,^{95, 102, 103} Ti-HMS,^{73, 87, 104} Ti-MMM,^{88, 105, 106} KIT-1,⁹³ Ti-TUD-1,¹⁰⁷ Ti-MSU-1,¹⁰⁸ Ti-FSM-16,¹⁰⁹ Ti-SBA-15,^{95, 96, 99, 110–113} Ti,Al-SBA-15,¹¹⁴ Ti-SBA-1,¹¹⁵ Ti-MMM-2,¹¹⁶ *etc.*) have been elaborated. The basic types of mesostructured titanium silicate materials are summarised in Table 1.

The type of interaction between the inorganic component (I) and the surfactant (S) is the key factor governing the formation of a mesophase material with a specific structure. The following interaction types are possible: electrostatic (S^+I^- or S^-I^+),^{76, 77, 82, 83, 88, 104} indirect electrostatic (S^+A-I^+ or $S^-C^+I^-$, where A^- and C^+ are auxiliary anions and cations, respectively),^{104, 117, 118} hydrogen ($S^0 \cdots I^0$)^{73, 87, 104, 108} and covalent (S^0-I^0)¹¹⁹ bonding.

The synthesis of mesostructured silicate and metal silicate materials (MCM-41, MCM-48, MMM, *etc.*) mediated by the electrostatic interactions between cationic surfactants (S^+) and polysilicate anions (I^-), *i.e.*, through the reaction pathway S^+I^- , is realised in alkaline media.^{69, 70, 77, 88, 102–106} The first mesostructured silicates of the structural type MCM-41 were synthesised in 1992 by the R&D team of the Mobil company using exactly this method.^{100, 101}

Alkyltrimethylammonium halides or hydroxides with the common formula $C_nH_{2n+1}(CH_3)_3NX$ ($n = 12–18$; $X = Cl^-$,

Br^- , OH^-) are usually employed as surfactants. The value of n determines the diameter of the resultant mesopores. Trimethylcetylammmonium bromide $n-C_{16}H_{33}(CH_3)_3NBr$ is used most frequently giving rise to the mesopores of 3–4 nm. If the reaction pathway S^+I^- is utilised, at least a part of oxygen atoms in the inorganic walls of the material carry a negative charge. In contrast to uncharged SiOH groups, charged SiO^- groups cannot take part in the formation of strong Si–O–Si siloxane bonds through the polycondensation under the hydrothermal treatment, which gives rise to discontinuities within the silicate walls and to a low stability of the materials against hydrolysis.^{88, 120} Due to the low hydrolytic stability, such a catalyst degrades structurally during the liquid-phase oxidation thus losing its activity.^{88, 106, 121–126} Attempts aimed at the additional structural stabilisation of the MCM-41 type catalysts with various chemical means (in particular, by addition of water-soluble organic or inorganic salts to the reaction mixture during the synthesis) often resulted in the collapse of the mesostructure and formation of disordered materials (see, for example, Refs 127 and 128).

The thermo- and hydrostability of MCM-41 can be enhanced by an additional hydrothermal treatment of the starting material with water.^{129, 130} This procedure, however, leads to an increase in the thickness of the silicate walls (h_w), which is unacceptable for metal silicate catalysts, since a part of active sites can be trapped within the walls and thus become inaccessible for the substrates (see Section III). Alternatively, the stability of the silicate walls towards the reaction (aqueous) medium can be enhanced by their surface silylation with hydrophobic species, such as $(CH_3)_3SiCl$, $(CH_3)_3SiNHSi(CH_3)_3$, *etc.*,^{131–138} or by specific doping, for instance, with aluminium.⁸⁸ The surface hydrophobicity of Ti-MCM-41 can also be increased by the removal of the template using extraction under supercritical conditions ($CO_2 + MeOH$).¹³⁹ Recently, a micromesoporous titanium silicate Ti-MMM-1, which combines structural motifs of TS-1 and Ti-MCM-41 in one phase, was synthesised using two types of surfactants, *viz.*, tetramethylammonium hydroxide and trimethylcetylammmonium bromide on the first and second steps of the synthesis, respectively.¹⁴⁰

The HMS type mesoporous silicate materials are formed at a pH close to 7 owing to the van der Waals interaction of uncharged surfactants (most typically, amines) with silicate particles (*i.e.*, the interaction type is $S^0 \cdots I^0$).^{73, 80, 87, 104, 141} The synthesis of Ti-HMS is usually carried out at room temperature.^{73, 87, 104} These materials are characterised by larger thickness (and, respectively, by higher strength) of the silicate walls as compared to those synthesised through the reaction pathway S^+I^- . The small size of particles constituting the HMS type materials is responsible for the so-called 'texture mesoporosity'.⁷³ It has to be stressed, however, that the degree of structural ordering in such materials is rather low.^{74, 104, 105}

[‡] The long-range ordering can be reliably detected using X-ray diffraction at small angles (less than 6–8 deg), high-resolution electron microscopy and adsorption techniques (see Section III).

Table 1. The main types of mesoporous mesostructured titanium silicate materials.

Material	Surfactant	Lattice type	Mesopore diameter /nm	Wall thickness /nm	Ref.
Ti-MCM-41	$C_{16}H_{33}(CH_3)_3NOH$ or $C_{16}H_{33}(CH_3)_3NBr$	hexagonal	2.9–3.5	1.0–1.5	69, 72, 104
Ti-MMM	$C_{16}H_{33}(CH_3)_3NBr$	"	3.4–3.8	0.8–1.0	88, 106
Ti-MMM-2	$C_{16}H_{33}(CH_3)_3NBr$	"	3.2	1.0	116
Ti-MCM-48	$C_{16}H_{33}(CH_3)_3NBr$	cubic	2.3	—	102, 103
Ti-HMS	$C_{12}H_{25}NH_2$	hexagonal	2.7	1.9	73, 87, 104
Ti-SBA-1	$C_{16}H_{33}(CH_3)_3NBr$	cubic	2.0	—	115
Ti-SBA-15	$(EO)_{20}(PO)_{70}(EO)_{20}$ (see ^a)	hexagonal	10.6–10.9	1.6–2.0	110
Ti-MSU-1	$C_{11}H_{23}O(CH_2CH_2O)_{12}H$	"	3.0	—	108
Ti-TUD-1	$(C_2H_5O)_3N$	see ^b	4.5–5.7	2.5–4.0	107

^a Triblock copolymer polyethylene oxide–polypropylene oxide–polyethylene oxide (Pluronic P123). ^b A disordered three-dimensional framework of mesopores with similar sizes.

Recently, mesoporous silicate materials were synthesised through the reaction pathway $S^{0...I^0}$ with polyethylene oxide-based (PEO) oxygen-containing polymers as non-ionogenic surfactants.^{108, 142} These surfactants are substantially less expensive than ionogenic alkylammonium salts and non-ionogenic alkylamines and, furthermore, they are non-toxic. Mesoporous titanium silicate Ti-MSU-1 was synthesised by addition of tetraethyl orthosilicate (TEOS) to a solution of amphiphilic surfactant Tergitol 15-S-12 [$C_{11-15}H_{23-31}O(CH_2CH_2O)_{12}H$] containing 5% of Ti.¹⁰⁸ The catalyst Ti-MSU-1 possesses a disordered hexagonal-like system of mesopores with a mean diameter of 3.0 nm. An alternative method for the synthesis of Ti-MSU-1 consists of the preparation of an aqueous solution of sodium silicate at pH > 9 followed by its mixing with acidic aqueous solution of non-ionogenic surfactant, *i.e.*, an amphiphilic diblock copolymer A_nB_m (A is a hydrophilic fragment, B is a hydrophobic fragment).⁸ The required heteroelement is then added to the reaction mixture (at a pH from 4 to 10). The materials obtained by this method are characterised by disordered arrangements of mesopores with similar diameters (from 1.5 nm to 30 nm, depending on the type of the surfactant used) separated from each other by walls with a thickness of >0.5 nm; the specific surface area of these materials is 300–1400 m² g⁻¹. Such materials are thermostable but no information on their hydrolytic stability is available.

Mesoporous silicate materials SBA-3 and SBA-15 are synthesised in strongly acidic media at pH ≤ 1.5 (Refs 75, 104, 118, 143–146) through the reaction pathway $S^+A^-I^+$ using the electrostatic interaction of surfactant cations and uncharged silicon dioxide particles with partly protonated surface silanol groups [*i.e.*, I^+ can be formulated as $H_2O^+Si(OH)_3$] mediated by auxiliary anions ($A^- = Cl^-$ or other anions). Alkylammonium salts,^{75, 104, 118} oligomeric alkylpolyethylene oxide with the general formula $C_nH_{2n+1}(EO)_mH$ ($n = 12–18$, $m = 2–25$) and block copolymers of oligomeric polyalkylene oxides $(EO)_n(PO)_m(EO)_p$ ($0 < n < 100$, $5 < m < 150$, $0 ≤ p < 100$) can be used as surfactants.^{118, 142–147} This approach makes it possible to achieve nearly the same degree of ordering of the mesostructure and control over the structural parameters as in the systems produced by the reaction pathway S^+I^- . The resulting materials are characterised by exceptionally high hydrostability,^{86, 142–146} since silicon dioxide particles involved into the formation of the mesostructure contain no ionised oxygen atoms that prevent complete polycondensation of siloxane links within the silicate walls.

Therefore, according to the available literature data, the silicate walls of mesoporous mesophase materials, which are stable against the action of water, can be formed only in strongly acidic media. However, the introduction of metal cations (Ti, Al, V, *etc.*) into silicate matrices becomes a problem in these media.^{86, 95, 104, 113} In particular, aluminium remains virtually unbound within the silicate walls being present in the forms that are readily leached.⁸⁶ The synthesis of Ti-MCM-41,¹⁰⁴ Ti-SBA-15¹¹³ and Ti-SBA-1¹¹⁵ in strongly acidic media requires a large excess of titanium, since its incorporation into the silicate walls is hindered by high solubility of Ti-containing species at this pH.¹⁰⁴ This issue can be overcome only by increasing pH to a value that provides sufficient level of the hydrolysis of dopant transition metal ions. In the majority of cases, this is achieved at a pH from 2.5 to 4.

The first attempt to incorporate titanium into a silicate matrix at a pH of 2.6–3.2 was undertaken in the beginning of 2000 with the synthesis of Ti-SBA-15 using $(EO)_{20}(PO)_{70}(EO)_{20}$ as a surfactant.¹¹⁰ Recently, a novel mesophase material, Ti-MMM-2, which manifests both thermohydrostability and resistivity to the leaching of the active component (titanium), has been synthesised using this approach with $C_{16}H_{33}(CH_3)_3NBr$ as a surfactant.^{116, 148} The

Ti-MMM-2 structure is generated in two steps. In the first step, a mixture containing positively charged silicon hydroxy complexes, titanium compounds and a surfactant is prepared while the pH is maintained in the range of 0.5–1.5. In the second step, a certain amount of a basic sodium silicate solution is added to the reaction mixture to increase and maintain the pH to a value in the range from 2.5 to 7.0. Then the mixture is subjected to a hydrothermal treatment.

Recently, two new methods for the synthesis of Ti-SBA-15 have been reported, the first one combines the hydrothermal treatment with the microwave irradiation,¹¹¹ the second is based solely on the microwave irradiation.^{149, 150} Most frequently, titanium is grafted onto the surface of presynthesised silicate SBA-15 in the post-synthesis step.^{95, 96, 99, 111, 112}

In the vast majority of published works, expensive tetraethyl orthosilicate was employed as a source of silicon. In recent years, there have been several reports on the use of less expensive and more available silicon sources, *viz.*, water-soluble inorganic sodium silicates $Na_2Si_2O_5$ and Na_2SiO_3 ,^{106, 110, 116, 142, 144, 145} and 'liquid glass' (28%–30% of SiO_2 and 9%–10% of Na_2O).¹²¹ Alternatively, H_2SiF_6 (Ref. 151) and colloidal dispersions of SiO_2 (Refs 121, 130) can be used. As a titanium source, titanium alkoxides, $Ti(OEt)_4$, $Ti(OPr)_4$, $Ti(Obu)_4$, and so on were utilised. The hydrolysis of organotitanium derivatives has to be strictly controlled in order to prevent their polymerisation.^{152, 153}

Inorganic titanium compounds, *e.g.*, $TiCl_3$,¹¹³ $TiCl_4$, $K_2TiO(C_2O_4)_2$, $(NH_4)_2TiF_6$,¹⁵⁴ $(NH_4)_3[Ti(O_2)F_5]$,¹⁵⁵ $Ti(SO_4)_2$ (Refs 110, 116, 148, 154) have recently started to be used in the synthesis of mesoporous mesophase titanium silicates. However, partial formation of oligomerised particles of titanium oxide was observed in all those cases except for the use of $(NH_4)_3[Ti(O_2)F_5]$ in the synthesis of Ti-MCM-41¹⁵⁵ and of the system $Ti(SO_4)_2-H_2SO_4$ in the synthesis of Ti-MMM-2.¹¹⁶ The addition of complex-forming agents (*e.g.*, H_2O_2 , acetylacetone, polyalcohols, aminoalcohols, *etc.*) often decelerates the hydrolysis and, respectively, suppresses the undesired polymerisation of titanium species.^{107, 113, 145, 153} Additionally, this technique makes it possible to increase the content of titanium in the silicate matrix up to an Si:Ti ratio of 1.9.¹⁵³ A synthesis of Ti-MCM-41 from a structure-forming precursor simultaneously from silicon and titanium, *viz.*, a copolymer of diethoxysiloxane with diethyltitanate $[(C_2H_5O)_2SiO]_n[(C_2H_5O)_2TiO]_m$, has recently been reported.¹³¹

The question on the formation mechanism of mesoporous mesostructured silicates remains a subject of debate.^{74, 76, 77, 82, 83, 88–90, 101} The model of 'liquid crystalline ordering' was one of the first mechanisms proposed.¹⁰¹ According to this mechanism, surfactant molecules self-assemble first into spherical micelles and then into cylinders. The latter are further arranged to form a hexagonal packing. The resultant 'liquid crystals' are then covered with a shell of inorganic particles.

According to another hypothesis,¹⁵⁶ no ordered phase of 'liquid crystals' is involved. The surfactant molecules assembled into cylinders interact with inorganic particles, which gives rise to the growth of a silicate layer atop the external surface of micelles and only after that the cylinders are arranged into a hexagonal packing.

Nevertheless, the majority of authors adopt the cooperative mechanism, which implies that electrostatic interactions between inorganic ions and surfactant molecules play the key role and govern the morphology of the resultant mesostructure.¹⁵⁷ This mechanism is depicted schematically in Fig. 2. In the first step (Fig. 2a), the ion pairs combining inorganic particles and surfactant molecules are formed due to the electrostatic interactions. In the second step (Fig. 2b), the ion pairs self-assemble into cylindrical micelles. Depending on the conditions, the cylinders are further arranged yielding a hexagonal (Fig. 2c), cubic or lamellar structure. In the last step, the inorganic particles are condensed giving rise to the emergence of a strong framework.

According to an alternative suggestion, the inorganic silicate particles self-assemble into layers separated from each other by

§ Triblock copolymers polyethylene oxide–polypropylene oxide–polyethylene oxide, such as $(EO)_{20}(PO)_{70}(EO)_{20}$ or $(EO)_{20}(PO)_{30}(EO)_{20}$, are most typically used as non-ionogenic surfactants.

Figure 2. A scheme depicting the cooperative mechanism of the formation of mesostructured silicates; (a–c) — see text.

rows of cylindrical micelles formed by the surfactant molecules.¹⁵⁸ Upon ageing, the layers become puckered and undergo cross-linking around the micelles thus yielding a hexagonal packing. Yet another model assumes that layers of surfactant and inorganic silicate particles are initially formed in the synthesis of MCM-41.¹⁵⁹ In the course of the polymerisation of silicate particles, the charge density is redistributed, which gives rise to the contortion of the layers and transformation of the lamellar mesostructure into the hexagonal one. However, the detailed consideration of modern concepts concerning the mechanisms of the mesostructure formation lies beyond the scope of the present review.

2. Amorphous mesoporous mixed oxides $\text{TiO}_2\text{—SiO}_2$

Amorphous mixed oxides $\text{TiO}_2\text{—SiO}_2$ (*i.e.*, aerogels and xerogels) represent another important class of mesoporous titanium silicate materials.^{81, 84, 85, 160–172} In terms of the structure, aerogels and xerogels can be described as long chains composed of primary silica particles (globules) touching each other only in a few points (see Fig. 1b).¹⁷³ Aerogels are characterised by a mean pore size of > 100 Å, whereas the mean pore size of xerogels is 5–20 Å. The typical specific surface area of xerogels is 300–700 $\text{m}^2 \text{g}^{-1}$. Aerogels manifest larger specific surface areas ($> 1000 \text{ m}^2 \text{g}^{-1}$) and simultaneously very high porosity (the specific volume of pores can be as high as 3–3.5 $\text{cm}^3 \text{g}^{-1}$).

Mixed oxides $\text{TiO}_2\text{—SiO}_2$ are routinely prepared by the sol–gel technology^{81, 173–175} that includes five major steps: (1) hydrolysis of silicon and titanium alkoxides, (2) polycondensation of alkoxides and growth of sol particles, (3) sol aggregation into an alcogel network, (4) gel ageing and (5) drying. The significant difference between the hydrolysis rates of silicon and titanium alkoxides makes certain problems in the preparation of materials with a homogeneous distribution of titanium ions over the silicon sol–gel matrix. These difficulties can be overcome by the utilisation of prehydrolysed TEOS^{84, 160, 161, 171} or tetramethyl orthosilicate (TMOS), which is more reactive towards hydrolysis, or by modification of titanium tetraisopropoxide with peroxide or

chelating agents, such as acetylacetone, cyclohexane-1,4-diol, *etc.*^{164, 165, 167–171, 176}

Aerogels are produced from alcogels by their drying under the conditions of a gradual increase in the temperature and solvent vapour pressure up to supercritical values. This results in the elimination of the ‘liquid–vapour’ interface and the related reduction of capillary pressure, which under the normal drying conditions in narrow pores can reach values equivalent to hundreds atmospheres and thus decrease the initial volume of the gel several-fold. The supercritical drying can be classified into high-temperature and low-temperature ones.^{81, 163, 167} In the former case, alcohols are used as solvents, whereas CO_2 is utilised in the latter case. The drying under the supercritical conditions makes it possible to avoid significant structural modifications of the starting alcogel. Xerogels are produced by the ordinary thermal drying of alcogels.

Prior to the 1980s, mixed oxides $\text{TiO}_2\text{—SiO}_2$ were synthesised with the use of either acidic or basic catalysis. The use of basic catalysts gives rise to gels composed of large particles with wide pores between them, whereas, finely structured gels composed of small particles separated from each other by narrow pores are formed under the conditions of acid catalysis. The latter structure is extremely fragile and breaks down to a significant extent even upon drying in supercritical CO_2 . As a result, the specific volume of pores in aerogels prepared with the use of acidic catalysts typically does not exceed 1 $\text{cm}^3 \text{g}^{-1}$.¹⁶⁸

In 1982, a new convenient method for the control over the structure of synthetic silica gels was suggested. It employs a two-step sol–gel procedure with the subsequent utilisation of acidic and basic (amine) catalysts in the first (partial hydrolysis and condensation) and second (polycondensation) steps, respectively.¹⁷⁷ This synthetic scheme enables stricter control over the structure of the resultant gel. In the first step, the chain-length distribution of alkoxide oligomers can be efficiently adjusted and various forms of particles can be deliberately generated (from active monomers to virtually completely condensed colloidal particles). In the second step, further growth of particles generated and the gel formation process can be finely tuned. The use of basic catalysts in this step provides more efficient polycondensation and enhances both the strength of the resultant material and its porosity. This technique was successfully applied to the synthesis of mixed aerogels $\text{TiO}_2\text{—SiO}_2$ affording materials with the specific pore volume of 2 $\text{cm}^3 \text{g}^{-1}$.^{178, 179} As has been established recently,^{126, 180, 181} a partial or complete replacement of traditional silicon alkoxides by less expensive ethyl silicate-40 (ES-40, the commercially available form of ethoxypolysiloxane; acidic hydrolysis of ES-40 yields low-molecular-weight polysilicate hydroxide¹⁷⁴) enables the preparation of aerogels $\text{TiO}_2\text{—SiO}_2$ with the specific pore volume as high as 3 $\text{cm}^3 \text{g}^{-1}$.

A substantial drawback of mixed oxides (primarily, of aerogels) is the collapse of their porous structure under the action of polar solvents (water, in particular). As has been demonstrated in a number of studies, the surface hydrophobisation of aerogels or the introduction of hydrophobic additives during the sol–gel synthesis often increases their activity and stability towards the reaction media.^{182–187} Methods for the production of composite mesoporous materials utilising presynthesised TS-1 as a component for the subsequent step of the sol–gel synthesis¹⁸⁸ are currently under development.

III. Methods of physicochemical characterisation of mesoporous titanium silicates

1. X-Ray diffraction

X-Ray diffraction (XRD) gives valuable information in studies of the hydrothermostability of mesostructured titanium silicates.^{88, 110, 116, 121, 125} XRD patterns of mesostructured materials, such as Ti-MCM-41, Ti-MMM, Ti-HMS and Ti-SBA-15, which are characterised by the hexagonal packing of cylindrical (or hexagonal prismatic) mesopores, reveal an intense peak (100)

and three weaker reflections, (110), (200) and (210).^{72, 77, 83, 86, 87} These reflections are indexed in a hexagonal lattice with the unit cell parameter given by $a_0 = 2d_{100}/\sqrt{3}$. Owing to the high degree of structural order in the mesoporous mesophase materials, the lattice parameter a_0 is constant. For the mesostructured systems under consideration this means that the diffraction patterns reveal narrow peaks with full widths at half maximum ($w_{h/2}$) of $(0.07-0.09)^\circ 2\theta$, which is close to the instrumental broadening. According to the experimental finding, the structure of Ti-MMM is more ordered than that of Ti-MCM-41 and Ti-HMS, as described in the literature.¹⁰⁴⁻¹⁰⁶ The peaks observed in the XRD pattern of Ti-MMM are substantially narrower with $w_{h/2} = (0.08-0.18)^\circ 2\theta$ and have symmetrical shapes. Meanwhile, the widths of the (100) reflection are $w_{h/2} = (0.40-0.70)^\circ 2\theta$ and $> 0.50^\circ 2\theta$ for Ti-MCM-41 and Ti-HMS, respectively; in the latter case, only one reflection is observed in the pattern, whereas the former also reveal feebly marked (110), (200) and (210) peaks (Fig. 3).^{75, 104}

Figure 3. The X-ray diffraction patterns of the mesostructured titanium silicates Ti-MMM (a) and Ti-HMS (b).^{104, 105}

It was established that the lattice parameters of calcined ordered titanium silicates (TS-1, Ti-ZSM-48, Ti-MCM-41 and Ti-HMS) linearly increase with an increase in the titanium content (up to 2%–2.5%).^{35, 45, 87, 104} This experimental fact can be rationalised assuming that the substitution of titanium for silicon is isomorphous. Since the ionic radius of titanium is larger than that of silicon, the substitution should give rise to a dilatation of the unit cell. Based on this observation, it was concluded¹⁸⁹ that the maximum titanium content, which can be accommodated in the TS-1 silicate matrix, is 2.5 mass %. A further increase in the titanium content does not result in a lattice dilatation, which indicates the appearance of non-structural titanium in TS-1. An increase in the titanium content in Ti-MMM and Ti-MCM-41 above 3 mass% gives rise to a significant loss in their structural order, which is manifested in the broadening of peaks in the XRD patterns.^{88, 105, 190} It is of note that this is not accompanied by any noticeable changes in the lattice parameter a_0 .¹²⁵

A recently developed method of structure simulation based on the quantitative analysis of intensities of diffraction reflections made it possible to recover the electron density distribution maps for a number of hexagonal mesostructured materials and reveal important information on the shape of the mesopores, the thickness and electronic structure of the silicate walls and the structure–chemical composition relation for these materials.^{88, 120, 191}

Mixed oxides $\text{TiO}_2\text{--SiO}_2$ are amorphous as regards X-ray diffraction due to the both lack of short- and long-range order.

2. Low-temperature nitrogen adsorption

Low-temperature (at 77 K) N_2 adsorption gives quantitative information concerning the texture of titanium silicate mesoporous materials, including specific surface area (A_m), specific volume (V_m) and mean diameter of the mesopores (d_m). The cylindrical shape of the mesopores in titanium silicates Ti-MCM-41, Ti-MMM, Ti-HMS and Ti-SBA-15 determines a characteristic shape of the adsorption isotherm,^{73, 74, 77, 83, 192} which is classified as type IV according to the IUPAC nomenclature (Fig. 4). Assuming zero scatter in the pore diameters, the range of pressures $\Delta(P/P_0)$, at which the capillary condensation should occur upon nitrogen adsorption, is rather narrow (0.06–0.08). Exactly these small values of $\Delta(P/P_0)$ are typical of type Ti-MMM materials (Fig. 4a), which fully supports the higher degree of their ordering as compared to, for instance, Ti-HMS, where $\Delta(P/P_0) > 0.2$ (Fig. 4b).^{105, 106} The strict constancy of the diameters of all cylindrical mesopores along their lengths requires the adsorption and desorption curves of nitrogen adsorption isotherms to be identical, at least, for $d_m \leq 4.5$ nm.^{88, 193} Investigations into the N_2 adsorption demonstrated that the texture porosity of Ti-HMS is substantially higher than that of Ti-MCM-41. In particular, the specific volumes of mesopores (with a diameter of 10–30 nm) between fine particles of Ti-HMS and Ti-MCM-41 are 1.11 and 0.03 $\text{cm}^3 \text{g}^{-1}$, respectively.⁷³

Figure 4. The isotherms of N_2 adsorption on the mesostructured titanium silicates Ti-MMM (a) and Ti-HMS (b).¹⁰⁵

Most typically, aerogels (they also manifest the type IV adsorption isotherms) do not contain micropores, whereas both micro- and mesopores are usually present in xerogels. Most frequently, xerogels manifest the type I isotherms. In order to estimate the texture parameters of mixed oxides $\text{TiO}_2\text{--SiO}_2$ (including aerogels and mesoporous xerogels), which are characterised by a broad size distribution of pores (Fig. 5), a modification of the Kelvin equation is normally applied, which takes into account the thickness of the multilayer of adsorbed molecules (it is the so-called BJH, or Barrett–Joyner–Halenda, method). This calculation, however, neglects pores smaller than 17 Å.⁸⁴

Figure 5. The size distribution of pores in the aerogel $\text{TiO}_2\text{--SiO}_2$ (20% TiO_2) calculated from the desorption part of the N_2 adsorption isotherm (273 K, 1 atm).¹⁶⁴ STP is standart temperature and pressure.

The BJH method is employed by the majority of authors for the calculation of texture parameters of mesostructured titanium silicates. Nevertheless, Fenelonov *et al.*¹⁹⁴ proposed a more accurate method for estimating the specific surface area, volume and size of the mesopores in such materials based on the combined structural and adsorption approach. It assumes that the following relations are held for a hexagonal (honeycomb) structure:

$$a_0 = d_m + h_w,$$

$$d_m = a_0(\varepsilon_m)^{1/2},$$

where ε_m is the porosity determined from the specific area of mesopores and real density (ρ) according to the equation

$$\varepsilon_m = \frac{V_m \rho}{1 + V_m \rho}.$$

The specific volume of mesopores can be estimated from the nitrogen adsorption isotherms measured at 77 K by standard procedures. For the determination of the specific volume V_m , external surface area (A_{ext}) and total surface area (A_{Σ}), the widely adopted comparison method is utilised.¹⁹⁴ The specific surface area of mesopores (A_m) is calculated by the equation

$$A_m = A_{\Sigma} - A_{\text{ext}}.$$

Table 2 lists the values of the texture parameters of four titanium silicates, *viz.*, Ti-HMS, Ti-MMM, Ti-MMM-2 and Ti-SBA-15 with the hexagonal packing of the mesopores, determined by the method described above. These results unambiguously indicate that the degree of structural ordering decreases along the series $\text{Ti-SBA-15} \sim \text{Ti-MMM} > \text{Ti-MMM-2} > \text{Ti-HMS}$. It was found that the size of the mesopores and the thickness of the silicate walls in Ti-SBA-15 are substantially larger than those in Ti-MMM and Ti-MMM-2. The thickness of the walls in Ti-MCM-41 increases with an increase in the titanium content.¹⁹⁵

3. Water adsorption

The adsorption and, consequently, catalytic properties of titanium silicates (*i.e.*, their activities and selectivities) as well as their stability against reaction media are determined to a large extent by their surface structures. According to the published data,^{45, 74, 77, 87, 101, 196, 197} microporous TS-1 possesses a hydrophobic surface, in contrast to mesoporous materials, such as Ti-MCM-41, Ti-HMS, *etc.*, which are characterised by hydrophilic surfaces owing to the presence of a large amount of the SiOH groups. Several types of such groups can occur on the surface of mesostructured silicates, in particular, free, H-bonded and coupled ones.¹⁹⁸ Only free and coupled SiOH groups are active towards the silylation upon hydrophobisation.

The surface hydrophobicity (or hydrophilicity) of titanium silicates can be evaluated using thermogravimetry by measuring mass losses due to water removal from the surface upon controlled heating.^{133, 134} Another modification of the thermogravimetric analysis consists of measuring the mass gain by evacuated or calcined samples in air with a certain humidity.¹³² According to this method, the ability of mesoporous materials to absorb water decreases in the series aerogel $\text{TiO}_2\text{--SiO}_2 > \text{Ti-MMM-2} > \text{xerogel } \text{TiO}_2\text{--SiO}_2 > \text{Ti-SBA-15} > \text{Ti-MMM} \gg \text{hydrophobised aerogel } \text{TiO}_2\text{--SiO}_2$ (Fig. 6). The saturation of identical

cylindrical pores with water proceeds faster and thus the adsorption equilibrium is established over a shorter time.

4. ^{29}Si NMR with the magic-angle spinning

The ^{29}Si nuclear magnetic resonance spectroscopy with line narrowing by the magic-angle spinning (NMR-MAS) provides important supplementary information on the structure of walls in titanium silicates, in particular, on their surface hydrophobicity (hydrophilicity) and the degree of polymerisation of siloxane links (including the possibility of the real-time synthesis monitoring).^{77, 83, 84, 104, 118, 130, 134, 138, 179, 197, 199} Despite some ambiguities in the deconvolution of overlapping signals in the ^{29}Si NMR-MAS spectra into single components, this technique makes it possible to quantify the number Q^n of sites with specific coordination types, *i.e.*, $\text{Si}(\text{OSi})_n(\text{OH})_{4-n}$ ($n = 2-4$) in silicates (Fig. 7). The ratio between Q^n values depends on the degree of condensation of silicon in the silicate walls, which, in turn, is a function of the material preparation procedure. Using this technique, it was demonstrated that fluorides promote the polymerisation of silicon compounds; the addition of fluorides into the reaction mixture during the synthesis enables the preparation of materials with a higher degree of condensation. In particular, in the case of SBA-15, the ratios $Q^3:Q^4$ are 0.34–0.62 and 0.74–0.78 in the presence and in the absence of fluorides, respectively.¹⁹⁹ The solid-state ^{29}Si NMR-MAS was used to establish that the silicate M41S undergoes a structural change under the conditions of hydrothermal treatment such that the degree of polymerisation of siloxane links in the walls increases.¹³⁰ The ^{29}Si NMR-MAS technique is widely applied to quantify the degree of surface silylation of mesostructured materials after their hydrophobisation.^{134, 138, 186, 200}

Figure 7. The ^{29}Si NMR-MAS spectrum of the titanium silicate Ti-MCM-41 (2.0% Ti).¹⁰⁴

Similar ratios of Q^n were found for mixed oxides with a low titanium content synthesised by the traditional method in an acidic medium with TEOS as a silicon source^{201, 202} and by the two-step method (see Section II) from ES-40.¹⁸¹ Meanwhile, smaller Q^4 and larger Q^2 and Q^3 were determined by ^{29}Si NMR-MAS for the $\text{TiO}_2\text{--SiO}_2$ samples prepared by the two-step method from TEOS.¹⁷⁹ Based on these results, it was concluded that the utilisation of ES-40 in the synthesis of mixed oxides $\text{TiO}_2\text{--SiO}_2$ increases the degree of silicon self-condensation (which correlates with the number of sites with the coordination type Q^4). It was found that the proportion of Q^4 relative to Q^3 in mixed oxides $\text{TiO}_2\text{--SiO}_2$ increases by approximately 20% (from 40% to 60%) with an increase in the titanium content, while the number of sites with the coordination type Q^2 remains virtually constant (<10%).¹⁸¹ A similar effect was observed by other authors,^{104, 200} which allowed them to conclude that the introduction of a small amount of titanium increases the degree of silicon condensation. However, if the titanium content exceeds a certain

critical value, the degree of silicon condensation decreases and the respective signals in the ^{29}Si NMR-MAS spectra become broader.²⁰⁰

5. Electron microscopy

Scanning electron microscopy (SEM), transmission electron microscopy (TEM) and high-resolution electron microscopy (HREM) are used for the elucidation of the texture and morphological properties of titanium silicates, including the size and shape of particles and pores. As has been established, the particles of Ti-HMS and Ti-MCM-41 are characterised by different morphologies. The former represent small spherical particles with a diameter of 0.2–0.3 μm .⁷⁴ Electron micrographs of Ti-MMM (Fig. 8a), Ti-HMS and Ti-MCM-41 (Ref. 73) samples clearly reveal a long-range-ordered porous structure with a hexagonal packing of identical mesopores. In contrast, a micrograph of Ti-MMM-2 (Fig. 8b)¹¹⁶ reveals domains of ordered mesopores, the degree of their ordering being substantially lower than that in Ti-MMM.

Figure 8. The electron micrographs of Ti-MMM (a), Ti-MMM-2 (b), xerogel $\text{TiO}_2\text{--SiO}_2$ (c) and aerogel $\text{TiO}_2\text{--SiO}_2$ (d).^{116, 181}

Microdomains of crystalline TiO_2 smaller than 1–2 nm in mixed titania–silica, which are invisible for X-ray diffraction, can be identified using HREM.^{81, 183, 203} According to TEM, samples of aerogels $\text{TiO}_2\text{--SiO}_2$ with the titanium content of 2 mass % – 17 mass % represent porous aggregates of interconnected amorphous particles (Fig. 8d).^{81, 181, 203} The size of primary aerogel particles is 3–5 nm and their shape is close to spherical. The size of primary SiO_2 particles in xerogels $\text{TiO}_2\text{--SiO}_2$ is virtually the same as in aerogels, but the xerogels are characterised by a significantly denser packing of the primary particles within the aggregates, which gives rise to a substantial contraction of the interparticle distance (Fig. 8c). Furthermore, the morphology of particles resemble a ‘crumbled glass’.^{81, 181, 203, 204} According to SEM, the use of a combined method for the preparation of mixed oxides $\text{TiO}_2\text{--SiO}_2$ involving suspending a mixed sol in an organic solvent (decanol or hexane) followed by its gelation affords spherical particles with a mean diameter of 50 μm .¹⁷¹

6. Diffuse reflectance optical spectroscopy

Diffuse reflectance ultraviolet (DRUV) spectroscopy is the simplest method for the determination of the electronic state of $\text{Ti}(\text{IV})$ ions in a solid silicate matrix. The charge transfer from a ligand X ($\text{X} = \text{HO}^-$, SiO^- or TiO^-) to a vacant d-orbital of the Ti^{4+} ions (ligand-to-metal charge transfer, LMCT) can be calculated from

the optical electronegativities (χ_{opt}) of the ligand X and the Ti^{4+} ion:

$$\nu = 30000 [\chi_{\text{opt}}(\text{X}) - \chi_{\text{opt}}(\text{Ti})].$$

With an increase in the coordination number of Ti(IV) from 4 to 6, the value of $\chi_{\text{opt}}(\text{Ti})$ increases from 1.85 to 2.05.⁸⁴ Therefore, in the case of Ti(IV) ions in the octahedral environment, the LMCT band should be red-shifted with respect to Ti(IV) ions in the tetrahedral environment.

According to numerous literature data,^{45, 68, 74, 77, 84, 87, 104, 197} the band position in the DRUV spectra of titanium silicates depends, in addition to the coordination number of Ti(IV), on the proximity of other titanium ions, *i.e.*, on the degree of dispersion of the titanium ions over the silicate matrix. The band at 205–208 nm observed in the spectrum of evacuated TS-1 is assigned to isolated titanium ions in the tetrahedral coordination environment.^{41, 45, 197, 205, 206} A treatment of TS-1 with water vapour or ammonia gives rise to an increase in the Ti coordination number, which is manifested in a reversible red-shift of the spectral maximum to 210–225 nm.^{68, 207, 208} The DRUV spectra of mesoporous titanium silicates with the titanium content below 2.5% typically reveal a main peak centred at 220–230 nm sometimes with a shoulder at 250–280 nm.^{74, 77, 84, 87} Table 3 summarises the literature data on the DRUV spectra of TS-1, Ti-MCM-41, Ti-MMM-2, mixed oxides $\text{TiO}_2\text{--SiO}_2$ and anatase (TiO_2). The band centred at 220–230 nm in the spectra of mesoporous titanium silicates is usually attributed to isolated Ti(IV) ions in the penta coordinated, octahedral (Refs 45, 72, 74, 77, 110, 116, 207, 208) or distorted tetrahedral coordination environment.^{104, 107, 209} This assignment is supported by the fact that there is no substantial blue-shift of the band upon the thermal dehydration of Ti-MCM-41 and Ti-HMS.¹⁰⁴ Since the bands corresponding to octahedral Ti(IV) in anatase and rutile are observed at 310–330 nm and 400 nm, respectively,^{45, 84, 197} the red-shift of the main band to this region or emergence of a shoulder in the spectra of titanium silicates is typically interpreted as clusterisation of octahedrally coordinated titanium ions due to the formation of the Ti–O–Ti bonds.^{41, 68, 77, 110, 167, 205, 209, 210} This interpretation agrees with the red-shift of the main band observed with an increase in the titanium content.^{87, 105, 106} Meanwhile, taking into account that the intensity of the band at 270 nm is reduced upon the thermal dehydration or evacuation of titanium silicates, it can be attributed to isolated titanium ions in a highly hydrated or distorted octahedral environment.^{68, 87, 104, 207, 211}

Table 3. Spectral parameters of selected titanium silicates.

Material	Parameter (method)			Ref.
	position of the maximum of the LMCT band /nm (DRUV)	pre-edge peak intensity (%) (XANES)	the average Ti–O bond length /Å (EXAFS)	
TS-1	205–208	75	1.80–1.81	45
$\text{TiO}_2\text{--SiO}_2$	220–240	58–75 ^a (32) ^b	1.81–1.82	84, 181
Ti-MCM-41	220–230	77 ^a (33) ^b	1.81	77
Ti-MMM-2	221	(30) ^b	—	116

^a Data for evacuated samples. ^b Data for the samples in air.

Figure 9. The DRUV spectra of mesoporous titanium silicates with similar titanium loadings.^{11, 125, 126} (1) Ti-MMM (1.89% Ti), (2) aerogel $\text{TiO}_2\text{--SiO}_2$ (1.68% Ti), (3) Ti-SBA-15 (2.05% Ti).

Figure 9 compares the DRUV spectra of Ti-MMM, aerogels $\text{TiO}_2\text{--SiO}_2$ and Ti-SBA-15 with similar titanium contents.[†] According to the spectral assignment described above, Ti-MMM and the aerogel contain isolated titanium ions with the coordination numbers of 4, 5 and/or 6. In the case of Ti-SBA-15, the band is red-shifted and broadened. Taking into account that the spectrum does not change after calcination of the sample, this indicates the presence of clusterised titanium ions.¹¹⁰

7. XANES and EXAFS

XANES spectroscopy (X-ray Absorption Near-Edge Structure) is substantially more expensive than DRUV, and thus it is utilised less frequently. Nevertheless, it gives important supplementary information on the coordination environment of titanium in titanium silicates. XANES spectra at the Ti K-edge of both ordered titanium silicates, such as TS-1,^{45, 197, 207} Ti-Beta,⁴⁵ Ti-MCM-41,^{72, 77, 92, 212, 213} Ti-HMS¹⁰⁴ and Ti-MMM-2,¹¹⁶ and amorphous mixed oxides $\text{TiO}_2\text{--SiO}_2$ ^{84, 181, 214, 215} containing only finely dispersed titanium ions reveal a distinct pre-edge peak (due to the electronic transition $1s \rightarrow 3d$) with the intensity strongly dependent on the degree of hydration of titanium ions (*i.e.*, on their coordination numbers). Dehydrated titanium ions in the tetrahedral coordination environment give rise to the pre-edge peak with an intensity of ~75%–80% of the X-ray absorption edge jump and the full width at half maximum of ~1.5 eV. Meanwhile, the pre-edge peak with the intensity of ~30% corresponds to penta(hexa) coordinated titanium ions, which are formed in the reaction of tetrahedral titanium ions with water.^{45, 77, 92, 104, 197, 200, 207} The XANES spectra of rutile and anatase manifest three weak pre-edge peaks, which thus correspond to clusterised octahedral titanium ions.^{45, 197, 214} Therefore, if a XANES spectrum of a mesoporous titanium silicate material manifests these three weak peaks, then it might be concluded that the sample contains clusterised octahedral titanium ions.^{110, 214, 216, 217} Figure 10 depicts the XANES spectra of mesoporous titanium silicates Ti-MMM-2 and Ti-SBA-15 and of aerogel $\text{TiO}_2\text{--SiO}_2$. The shape and intensity of the pre-edge peaks in the spectra of Ti-MMM-2 and aerogel indicate the presence of isolated penta(hexa) coordinated Ti(IV) ions in these samples, whereas Ti-SBA-15 undoubtedly contains oligomerised titanium ions. Therefore, the XANES results are fully consistent

[†]The DRUV spectra are given in the Kubelka–Munk units $F(R) = (1 - R)^2/2R$ (R is the reflectivity index).

Figure 10. The XANES spectra of mesoporous titanium silicates measured in air.^{110, 116, 190}

(1) Ti-SBA-15 (2.05% Ti), (2) Ti-MMM-2 (1.68% Ti), (3) aerogel TiO₂–SiO₂ (3.68% Ti).

with the aforementioned DRUV spectral data.^{110, 116, 181} According to Table 3, the intensity of the pre-edge peak in the XANES spectra of Ti-MCM-41 and mixed oxides TiO₂–SiO₂ increases upon evacuation, which implies that the titanium ions are present in the samples dominantly in the isolated octahedral sites under atmospheric conditions but are converted into the tetrahedral state upon complete dehydration.^{77, 84, 104, 214}

The elucidation of titanium silicates by means of EXAFS spectroscopy (Extended X-Ray Absorption Fine Structure) reveals information on the number of oxygen atoms and Ti–O bond lengths in the first coordination sphere of the titanium ions and on distances between the titanium ions and second-coordination-shell neighbours. According to EXAFS results, the mean Ti–O bond lengths are 1.79–1.84 Å, 1.89–1.91 Å and 1.94–2.06 Å for tetra-, penta- and hexa-coordinated titanium ions, respectively.^{72, 84, 218}

8. X-Ray photoelectron spectroscopy

Using X-ray photoelectron spectroscopy (XPS), the electronic state of elements and chemical composition of the near-surface layer of catalysts with a thickness of up to 4–5 nm can be probed. The Ti(2p), Si(2p) and O(1s) core-level photoemission lines in titanium silicates have been studied by several authors.^{74, 84, 197} The absence of the Ti(2p) component at a binding energy of 457.4 eV typical of Ti³⁺ ions in the XPS spectra indicates that titanium is present exclusively as Ti⁴⁺ ions. The Ti(2p) core-level photoemission line shows up in the spectra as a spin–orbit doublet Ti(2p_{3/2})/Ti(2p_{1/2}) (Fig. 11). The exact position of the Ti(2p_{3/2}) photoemission line is indicative of the coordination environment of the titanium ions. The photoemission line in a binding energy range of $E_b = 458.4–458.6$ eV is commonly attributed to titanium in the octahedral coordination (as in TiO₂), whereas the line at 459.9–460.2 eV is assigned to isolated titanium ions with the tetrahedral coordination (Refs 45, 72, 74, 84, 197, 219, 220). The XPS spectra of Ti-MCM-41 and Ti-HMS reveal a photoemission line centred at $E_b = 459.9$ eV,⁷⁴ whereas the main component in the spectrum of TS-1 is located at $E_b = 460.2$ eV.⁴⁵ In the case of a catalyst Ti-SBA-15 (with 2.05–7.17 mass % of Ti), the Ti(2p_{3/2}) photoemission line is located at 458.3 eV, which is consistent with the octahedral environment of Ti(IV) ions similar to that in anatase (see Fig. 9).^{45, 74, 96} As a rule, XPS data fully agree with the DRUV spectral results.^{96, 110} A quantitative analysis of intensities of the

Figure 11. The XPS spectra of the mesoporous titanium silicate Ti-SBA-15 with the Ti loading of 2.05% (1) and 7.17% (2).¹¹⁰ (a) O(1s) core-level photoemission line, (b) Ti(2p) core-level photoemission line.

Ti(2p_{3/2}) and Si(2p) core-level photoemission lines yields the Ti:Si atomic ratio on the surface of titanium silicate catalysts.^{84, 110, 197, 219}

As for O(1s) core-level photoemission lines, the peak at $E_b = 532.9–533.3$ eV is attributed to the silicon-bound oxygen atoms, since the oxygen line of SiO₂ appears exactly at this position.^{221, 222} In TiO₂, the respective line is observed at $E_b = 529.8–530.0$ eV and thus this region is attributed to the titanium-bound oxygen atoms.^{45, 74, 221, 222} In the XPS spectra of mixed oxides TiO₂–SiO₂, in addition to the two above lines at $E_b = 530.6$ eV (which corresponds to the Ti–O–Ti bonds) and 532.7 eV (which corresponds to the Si–O–Si bonds), the third line at an intermediate binding energy (531.4 eV) is observed, which is thus assigned to the Ti–O–Si bonds.²¹⁹ The disappearance of this line upon calcination of the samples at 1000 °C is interpreted as a structural transformation of the sample giving rise to TiO₂ agglomerates.

9. Electron spin resonance spectroscopy

Electron spin resonance (ESR) spectroscopy is widely used for the detection and elucidation of properties of paramagnetic transition metal ions incorporated into molecular sieves. Capabilities of this method as regards titanium silicates are limited, since the titanium ions are characterised by the oxidation state 4+ and thus are diamagnetic. Structural information concerning Ti ions can be obtained after reduction of titanium silicate samples with CO, H₂, UV- or γ -radiation, *i.e.*, when the diamagnetic Ti(IV) ions are converted into the paramagnetic Ti(III) ions. This ESR-based approach was utilised to confirm the isomorphous substitution of Ti(IV) for Si(IV) in TS-1.^{223, 224} The ESR spectrum of TS-1 reduced by carbon monoxide manifests an axially symmetric signal with a split $g_{\parallel}$ -component [$(g_{\parallel})_1 = 1.98$, $(g_{\parallel})_2 = 1.97$] and $g = 1.913$ attributable to titanium(III) in the axially distorted tetrahedral coordination. This means that its precursor, *i.e.*, titanium(IV) ions, were also located in tetrahedral sites.²²³ So far, there have been only a few ESR studies on the state of titanium ions in mesoporous titanium silicates.^{225, 226} In particular, the ESR spectrum of γ -irradiated Ti-MCM-41 reveals, in addition to the aforementioned axial signal of tetrahedral titanium ions, an axial signal characterised by values of $g_{\parallel} = 1.898$ and $g_{\perp} = 1.967$ typical of Ti(III) in the distorted octahedral environment.²²⁵

The ESR technique is widely utilised in structural studies of catalytically active particles in particular, of Ti superoxide radicals **1**,^{207, 226–229} which are generated from titanium peroxo complexes **2**.²²⁷

In particular, titanium silicate TS-1 in the presence of H_2O_2 produces an intense anisotropic ESR signal with the following parameters of the g -tensor: $g_{xx} = 2.0030$, $g_{yy} = 2.0099$ and $g_{zz} = 2.0238$. This signal is attributed to superoxotitanium species $\text{Ti}(\text{O})_2$.²⁰⁷ The interaction of TS-1, Ti-Beta, Ti-MCM-41 and amorphous TiO_2 – SiO_2 with aqueous H_2O_2 yields two types of superoxotitanium species (*viz.*, **A** and **B**).^{228, 229} The superoxo particles **A** ($g_{xx} = 2.0023$, $g_{yy} = 2.0090$, $g_{zz} = 2.0266$) and **B** ($g_{xx} = 2.0023$, $g_{yy} = 2.0090$, $g_{zz} = 2.0238$) are characterised by rhombic g -tensors. It was suggested that the type **A** particles are produced from $(\text{SiO})_4\text{Ti}$ species localised inside the silicate walls, whereas the type **B** particles are formed from $(\text{SiO})_3\text{Ti}(\text{OH})$ species localised on the external surfaces of the walls. The fraction of the type **A** species decreases in the series TS-1 > Ti-Beta > amorphous TiO_2 – SiO_2 , whereas the fraction of the type **B** species decreases in the series Ti-MCM-41 > amorphous TiO_2 – SiO_2 > Ti-Beta > TS-1. It was proposed that the type **A** species are involved in the selective oxidation of styrene to the respective epoxide.

10. Raman spectroscopy

The Raman spectra of mesoporous silicate TS-1, which contains only isomorphously substituted isolated titanium ions within the silicate walls, reveal vibrational bands at 799 – 828 cm^{-1} , 467 cm^{-1} , 375 cm^{-1} and 290 cm^{-1} .¹⁹⁷ An increase in the titanium content gives rise to the appearance of four new bands at 140 – 145 cm^{-1} (it is the most intense band; its detection limit as regards TiO_2 is 0.05 mass %), 386 – 400 , 513 – 516 and 637 – 639 cm^{-1} . These bands are attributed to non-structural titanium; likely, they can be interpreted as the initial stage of anatase formation.^{45, 74, 84, 109, 197, 230, 231} Apparently, Raman spectroscopy is one of the most sensitive techniques that enables detection of early stages of the emergence of TiO_2 crystallites in mesoporous titanium silicates.^{110, 111} In particular, the Raman spectrum of Ti-SBA-15 with Ti contents 7.17 mass % manifests an intense peak at 145 cm^{-1} (Fig. 12). Meanwhile, neither X-ray diffraction nor electron microscopy give any evidence of the emergence of the TiO_2 phase in this sample.¹¹⁰

Figure 12. The Raman spectra of mesoporous titanium silicates.¹¹⁰ (1) Ti-MMM (1.89% Ti), (2) Ti-SBA-15 (2.05% Ti), (3) Ti-SBA-15 (7.17% Ti), (4) TiO_2 (anatase). The * mark corresponds to plasma excitation.

11. IR spectroscopy

There are two most informative regions in the IR spectra of titanium silicates: 3200 – 3800 cm^{-1} and 950 – 970 cm^{-1} . Two peaks at 3728 – 3748 cm^{-1} (narrow) and 3222 – 3540 cm^{-1} (broad) are observed in the region of stretching vibrations of the O–H groups.^{132, 197, 220} These bands are attributed to vibrations of the free and H-bonded silanol Si–OH groups, respectively.

The band at 960 cm^{-1} observed in titanium-containing zeolites is often assigned to the Ti–O–Ti bonds sites,^{45, 197, 206} an increase in its intensity with an increase in the titanium content in TS-1 is interpreted as a manifestation of titanium trapping in the silicate walls. However, in the case of mesoporous mesophase titanium silicates, the assignment of this band to the Ti–O–Ti bonds is not ambiguous, since spectra of metal-free mesoporous silicates reveal a band in the same region ascribed to Si–O vibrations of the Si–O–R groups.^{45, 72, 74, 77} Notwithstanding, the intensity ratios of the bands at 960 cm^{-1} and 800 cm^{-1} (the latter is attributed to symmetrical stretching vibrations of the SiO_4 groups) in the spectra of mesostructured titanium silicates is substantially larger than in their titanium-free analogues.⁷⁴

In the case of mixed oxides TiO_2 – SiO_2 , the relative degree of dispersion of titanium over a silicate matrix $D_{(\text{Ti}-\text{O}-\text{Si})}$ can be estimated on the semiquantitative level by analysing the intensity distributions of deconvoluted spectral components at 940 – 960 cm^{-1} (vibrations of the Ti–O–Si groups) and 1210 cm^{-1} (vibrations of the Si–O–Si groups).^{81, 164, 179, 181} Using this technique, it was demonstrated that the level of titanium dispersion decreases with an increase in its content in the mixed oxides.

12. IR spectroscopy of adsorbed CO molecules

The accessibility of active titanium sites for reagents is one of the most important parameter of mesoporous titanium silicate catalysts. Since the typical size of nanopores lies in the nanometre range, the diffusion hindrances to the transport of reagents towards the active sites can be quite decisively ruled out, however a part of the sites can appear trapped inside the silicate walls and thus become inaccessible for reagents. In this regards, the thickness of the silicate walls is an important characteristics of mesostructured titanium silicates. It is known that the wall thickness depends on the preparation procedure. For instance, the walls in Ti-MMM and Ti-MMM-2 are only 0.8 – 1.0 nm thick,^{87, 116, 125} which approximately corresponds to the size of two SiO_4 tetrahedra (the size of an SiO_4 tetrahedron is $\sim 0.4\text{ nm}$).¹⁷³ This means that all titanium sites in these materials should be accessible for reagents. Meanwhile, in the case of Ti-SBA-15, the wall thickness is already 1.5 – 2.0 nm ¹¹⁰ and thus a part of titanium sites can be located inside the walls and become inaccessible for reagents. Presently, there are no direct methods to strictly quantify the accessibility of titanium sites for reagents; however, this parameter can be estimated on a qualitative level using IR spectroscopy of adsorbed CO molecules.¹¹⁰ Three types of bands are observed in the IR spectra of adsorbed CO molecules, *viz.*, at 2135 cm^{-1} (attributed to physisorbed CO), 2153 cm^{-1} (CO forming complexes with the silanol groups)²³² and 2179 cm^{-1} (CO interacting with the Ti cations localised on the surface of the silicate matrix).^{233, 234}

This method was applied to a comparative analysis of Ti-MMM and Ti-SBA-15. It turned out that the band centred at 2179 cm^{-1} in the spectrum of Ti-SBA-15 is substantially less intense than that in Ti-MMM (Fig. 13), *i.e.*, the concentration of surface titanium ions accessible for reagents is lower in this sample.¹¹⁰ As has been established in a similar way, aerogels TiO_2 – SiO_2 are characterised by a larger amount of surface Ti ions than xerogels TiO_2 – SiO_2 .^{181, 204}

Figure 13. The IR spectra of CO adsorbed on mesoporous titanium silicates at 100 K (the region of C–O vibrations).¹¹⁰ (1) Ti-MMM (1.89% Ti), (2) Ti-SBA-15 (2.05% Ti).

IV. Catalytic properties

Numerous reports on the use of mesostructured titanium silicates and mixed oxides $\text{TiO}_2\text{--SiO}_2$ as catalysts for the selective liquid-phase oxidation of organic substrates have appeared over the last decade. Selected examples of such reactions are given in Table 4. The oxidation of non-functionalised and substituted alkenes, organic sulfides and alkylphenols has been studied most thoroughly. These reactions assisted by mesoporous titanium silicates are considered in more detail below. The problems concerning the efficiency of oxidant utilisation and the stability of catalysts under the reaction conditions, including the possibility of their recycling, are also discussed.

1. Oxidation of alkenes

Mesoporous titanium silicate Ti-MCM-41 has proven to be an efficient catalyst for the selective epoxidation of alkenes with aqueous hydrogen peroxide or alkyl hydroperoxides. Ti-MCM-41 is less active than TS-1 with respect to the oxidation of small molecules with hydrogen peroxide under similar conditions, which is explained by its higher hydrophilicity that prevents efficient adsorption of non-polar substrates.^{45, 69, 72, 77} Furthermore, some reactions easily realisable with TS-1 (in particular, propylene epoxidation, oxidation of linear alkanes and primary amines) are virtually impossible over Ti-MCM-41 and Ti-HMS.^{74, 254, 255} On the other hand, a clear advantage of Ti-MCM-41 and other mesoporous titanium silicates is that they are capable of catalysing the oxidation of bulky organic molecules, which cannot penetrate into the pores of microporous catalysts. In particular, only linear alkenes are efficiently oxidised over TS-1, whereas the majority of mesoporous titanium silicates actively catalyse the oxidation of cyclohexene (typically yielding the respective epoxides and/or diols as primary products).^{105–107, 122, 134, 137, 151, 166–168, 179, 182–185, 212, 235} The introduction of aluminium into the structure of SBA-15 with subsequent titanium deposition enables the deep oxidation of cyclohexene into adipic acid in a 88% yield at a 96% substrate conversion.¹¹⁴

Another advantage of Ti-MCM-41 and other mesoporous titanium silicates over microporous titanium silicates consists of the possible use of relatively large organic hydroperoxides as oxidants.^{41, 69, 72, 77, 78, 81, 166–168, 182–185, 200, 236, 238, 245–253} For instance, mesoporous titanium silicate Ti-MCM-41 manifested higher activity towards the oxidation of α -terpineol and norbornene with *tert*-butyl hydroperoxide as compared to zeolite Ti-Beta^{72, 236} (Table 5). If alkyl hydroperoxides are used as oxidants, titanium silicate catalysts provide higher selectivity of the epoxidation and manifest higher stability, although the oxidation rate is, as a rule, lower than in the case of the oxidation with H_2O_2 .¹²² In some cases, mesoporous titanium silicates

Ti-MCM-41	8	32 9	11	42 6
Ti-Beta	8	8 6	11	18 13

prepared by the deposition of titanium onto a silicate matrix in the post-synthesis step demonstrated higher activities than Ti-MCM-41, which can be due to the higher accessibility of titanium sites in the supported catalysts.^{87, 107, 238}

A naturally occurring terpene, (–)-caryophyllene can be oxidised with hydrogen peroxide over Ti-MMM or Ti-MMM-2 to 4,5-monoepoxide derivative with a selectivity of 70%–80% at an alkene conversion of 70%–75% in 4 h.^{105, 116} It is of note that no reaction is observed in the presence of TS-1.¹¹⁶

The oxidation of α -pinene with *tert*-butyl hydroperoxide over Ti-HMS or Ti-MCM-41 yields the respective epoxide with 100% selectivity, although the substrate conversion does not exceed 11%.²³⁷ The epoxide ring can be opened to afford the respective diol using Ti-MCM-41 modified with acid sites (by doping with Al, Fe or B).²³⁷ The oxidation of styrene with hydrogen peroxide catalysed by titanium silicates, such as Ti-MCM-48, Ti-MCM-41 or Ti-HMS, proceeds with the cleavage of the C=C bond to yield benzaldehyde with a selectivity of 77%–85% at a substrate conversion of 10%–28%.^{102, 104} The catalyst Ti-MCM-48, which contains a three-dimensional framework of cylindrical mesopores, manifested higher activity than Ti-MCM-41 towards the oxidation of a number of higher alkenes with hydrogen peroxide.^{103, 134}

MCM-41 modified with titanium in the post-synthesis step is more active than Ti-MCM-41 towards the oxidation of unsaturated terpenic alcohols. The difference in their activities is smaller in the case of alcohols with the OH group located closer to the C=C double bond.²³⁸ Supported titanium catalysts MCM-41 manifest high activity and selectivity in the epoxidation of methyl esters of unsaturated fatty acids with *tert*-butyl hydroperoxide and, furthermore, the epoxidation proceeds stereospecifically.²⁵¹ In the case of Ti-MCM-41, the difference in the oxidation rates of *E*- and *Z*-isomers is substantially smaller than with Ti–SiO₂,

which is probably due to the higher accessibility of channels present in MCM-41 for the *E*-isomer (methyl elaidate) as compared to the *Z*-isomer (methyl oleate).

The catalytic properties of mixed oxides $\text{TiO}_2\text{--SiO}_2$ are best studied by the example of the epoxidation of olefins and oxidation of unsaturated alcohols and ketones with alkyl hydroperoxides (see Table 4). Aerogels synthesised by the low-temperature supercritical drying are more active than both xerogels and aerogels prepared by the high-temperature supercritical drying.¹⁶⁷ The use of aqueous H_2O_2 as an oxidant leads to the titanium leaching from the silicate matrix and the collapse of the porous structure. Therefore, organic hydroperoxide in non-aqueous solvents should preferably be used.¹⁶⁷

In a number of cases, it was possible to improve the selectivity of epoxidation by surface hydrophobisation of mixed oxides and mesostructured titanium silicates (Table 6). The hydrophobisation was accomplished by the surface silylation with hydrophobic reagents^{131–134} or by the introduction of hydrophobic modifiers directly into the silicate matrix during its synthesis.^{182–185} It was shown that the porous structure and activity of hydrophobised mesoporous titanium silicates is better sustained after several cycles of operation. Although hydrophobisation generally decreases the surface of mesopores and often decreases their diameter as well, hydrophobised catalysts exhibit improved activity and selectivity of the oxidation of alkenes and alkanes with respect to their non-hydrophobised precursors.^{131, 133, 134, 182, 184, 187} In addition, the efficiency of H_2O_2 (Refs 131, 134 and 182) and alkyl hydroperoxide utilisation is enhanced.¹³³

Table 6. The effects of the surface hydrophobisation on the performance of titanium silicate catalysts in the epoxidation of cyclohexene.

Catalyst	Reaction time /h	Oxidant	Cyclohexene conversion (%)	Epoxide selectivity ^a (%)	Ref.
Aerogel $\text{TiO}_2\text{--SiO}_2$	2	Bu^tOOH	18	80	184

Ti-MCM-41	0.5	Bu^tOOH	63	91	133
Hydrophobised Ti-MCM-41 ^c	0.5	Bu^tOOH	87	99	133
Ti-MCM-41	3	H_2O_2	0.72	0	134
Hydrophobised Ti-MCM-41 ^d	3	H_2O_2	13	14	134

^a Based on the substrate. ^b The aerogel was modified with phenyl groups during the sol–gel synthesis. ^c The surface of Ti-MCM-41 was silylated with $(\text{CH}_3)_3\text{SiNHSi}(\text{CH}_3)_3$. ^d The surface of Ti-MCM-41 was silylated with $(\text{CH}_3)_3\text{SiCl}$.

The selectivity of epoxidation in the oxidation of unsaturated alcohols, in particular, cyclohexenol, with *tert*-butyl hydroperoxide in the presence of aerogel $\text{TiO}_2\text{--SiO}_2$ was substantially improved by the surface modification of the catalyst with amine and 3-acetoxypentyl groups either during the sol–gel synthesis^{245, 246} or by addition of an amine directly into the reaction mixture.²⁴⁸ The type of the modifier affects the ratio of *cis*- and *trans*-epoxides among the reaction products.

Numerous literature data indicate that the catalytic activity of mesoporous titanium silicates in the alkene oxidation reactions is mainly determined by the state and accessibility of titanium sites. However, it can also be affected by other factors, such as size and shape of crystallites (particles), concentration of surface defects, surface hydrophobicity/hydrophilicity and acid–base properties,

concentration of dopant ions, and so on.^{73, 84, 104, 179} As in the case of titanium-containing zeolites (TS-1, Ti-Beta, *etc.*),^{67, 256} the activity of mesoporous titanium silicates is likely to be strongly affected by the presence of sodium ions therein. The coordination number of titanium ions in the initial catalyst plays no decisive role in the catalytic properties of titanium silicates as regards oxidation with hydrogen peroxide, since tetra-coordinated titanium is unavoidably converted into penta- and hexa-coordinated species in the presence of water (see Sections III.6 and III.7).^{99, 116} Meanwhile, in the case of oxidation with alkyl hydroperoxides in non-polar solvents, titanium silicates originally containing tetra-coordinated titanium can manifest higher activity as compared to titanium silicates comprising titanium ions with the coordination numbers of 5 and 6.^{77, 84, 85} So far, no direct experimental evidence have been obtained that ordered titanium silicates are more active in the oxidation of alkenes and unsaturated alcohols than amorphous mesoporous titanium silicates with a similar titanium loading (provided that titanium is uniformly distributed over the matrix).^{98, 249, 257}

2. Oxidation of thioethers

Mesostructured titanium silicates Ti-MCM-41, Ti-HMS, Ti-MMM and Ti-MMM-2 are efficient catalysts of the oxidation of bulky organic sulfides to the respective sulfoxides and sulfones.^{70, 71, 77, 105, 106, 116, 240, 241} For the oxidation of methyl phenyl sulfide, the activity of titanium silicate catalysts decreases in the series $\text{Ti-MMM} \sim \text{Ti-MMM-2} \gg \text{Ti-SBA-15} > \text{TS-1}$,^{110, 116} the maximum selectivity of the sulfoxide formation is 76% at the 100% substrate conversion. The activity of TS-1 rapidly decreases in the following series of substrates: dimethyl sulfide $\gg$ diethyl sulfide $>$ methyl phenyl sulfide $>$ ethyl phenyl sulfide $\gg$ diphenyl sulfide (for the latter substrate, the conversion is nearly zero).²⁵⁸ Type Ti-Beta zeolites are more active than Ti-MCM-41 in the oxidation of methylphenyl sulfide, whereas the reversed series of activities is observed for bulkier sulfides, *e.g.*, for isopentyl phenyl sulfide.²⁴⁰

The catalyst Ti-HMS manifested a high activity in the oxidation of benzo- and dibenzothiophenes with hydrogen peroxide;²⁴¹ these reactions are considered as a prospective method for the removal of sulfur-containing compounds from motor fuels alternative to the hydrodesulfurisation.

3. Oxidation of substituted phenols

Mesoporous titanium silicates are efficient catalysts of the oxidation of sterically hindered phenols, such as 2,6-di-*tert*-butylphenol, 2,3,5-trimethylphenol, 2,3,6-trimethylphenol, *etc.*, with hydrogen peroxide to quinones and diquinones (Refs 73–75, 77, 99, 104, 116, 125, 126, 146, 148, 149). According to the experimental results, Ti-HMS is more catalytically active than Ti-MCM-41 towards the liquid-phase oxidation of methyl methacrylate, styrene and 2,6-di-*tert*-butylphenol.^{73, 104} It is of note that the difference in the activities of the catalysts becomes more distinct in the case of bulkier phenols. Probably, this is partly due to the higher texture mesoporosity of Ti-HMS, which facilitates the free transport of bulky substrates.^{73, 104}

According to the recently published results, the oxidation of 2,3,5-trimethylphenol with hydrogen peroxide over microporous Ti-APO-5²⁵⁹ and mesoporous Ti-HMA²⁴² affords 2,3,5-trimethyl-1,4-benzoquinone (which is an intermediate of the vitamin E synthesis) in yields of 85% and 58%, respectively. However, the authors gave no evidence of the heterogeneity of the process and the lack of titanium leaching. In general, the problem of titanium leaching from solid matrices and of structural degradation of the catalysts in the course of oxidation is not adequately addressed by many authors, although it represents the main factor restricting wide practical application of titanium-containing catalysts. The oxidation of 2,3,6-trimethylphenol (TMP) with hydrogen peroxide and *tert*-butyl hydroperoxide has been comprehensively studied^{110, 116, 125, 126} in the presence of diverse mesoporous titanium silicates, including mixed oxides

TiO₂–SiO₂ (both aerogels and xerogels), Ti-MMM, Ti-MMM-2 and Ti-SBA-15.

A new method for the synthesis of 2,3,6-trimethyl-1,4-benzoquinone (TMBQ) by the oxidation of TMP with hydrogen peroxide in the presence of mesoporous titanium-containing catalysts has been elaborated recently, which provided a selectivity as high as 98% at the 100% TMP conversion.¹⁸⁰ The main by-product of this reaction is 2,2',3,3',6,6'-hexamethyl-4,4'-biphenol; its yield increases with a decrease in temperature of the reaction mixture and an increase in the [TMP]:[Ti] ratio. No further substrate conversion occurs after withdrawal of the catalyst by the rapid filtration of the reaction mixture (Fig. 14). This, coupled with the results of the chemical analysis, gives strong evidence that the oxidation proceeds exclusively on the catalyst surface and that there is no noticeable leaching of Ti(IV) from the silicate matrix.^{125, 126}

Figure 14. The kinetics of TMP oxidation with hydrogen peroxide in the presence of Ti-MMM.¹²⁵

Reaction conditions: 0.1 mol litre⁻¹ of TMP, 0.7 mol litre⁻¹ of H₂O₂, 1.3 × 10⁻² mmol of Ti, 3 ml of MeCN, 80 °C;

(1) without filtration, (2) the catalyst is removed by filtration in 5 min after the start of the reaction.

The activity of different types of mesoporous titanium silicates (aerogel TiO₂–SiO₂, xerogel TiO₂–SiO₂, Ti-MMM, Ti-MMM-2 and Ti-SBA-15) towards the oxidation of TMP per active catalytic site decreases with an increase in the titanium loading of the catalysts (Fig. 15a). This dependence can be rationalised taking into account that the level of dispersion of titanium over the silicate matrix decreases with an increase in the titanium loading, which gives rise to the formation of less reactive Ti–O–Ti bonds, as evidenced by the red-shift of the absorption band in the DRUV spectra. As has been already stated above, the degree of dispersion of titanium is one of the main parameters determining the catalytic activity of titanium silicates: the higher the degree of dispersion, the higher the activity (Refs 77, 84, 125, 126, 167, 168, 203).

The activity of catalysts with similar concentrations of titanium decrease in the following series: aerogel TiO₂–SiO₂ > Ti-MMM ~ Ti-MMM-2 > xerogel TiO₂–SiO₂ >> Ti-SBA-15 > TS-1. This activity series correlates well with the size of mesopores in the respective materials and also with the apparent activation energies of the reaction (*E*_a).^{125, 181, 260} In particular, the activation energies are 81 kJ mol⁻¹ and 60 kJ mol⁻¹ over the aerogel TiO₂–SiO₂ and Ti-MMM catalysts, respectively. Therefore, the oxidation of TMP with hydro-

Figure 15. The performance of aerogels TiO₂–SiO₂ with various titanium loadings (a) and different mesoporous titanium silicates with similar titanium concentrations (b) in the catalytic oxidation of 2,3,6-trimethylphenol with hydrogen peroxide.^{110, 116, 125, 126, 181}

Reaction conditions: 0.1 mol litre⁻¹ of TMP, 0.013 mmol of Ti, 0.35 mol litre⁻¹ of H₂O₂, 3 ml of MeCN, 80 °C;

(1) the yield of TMBQ, (2) the conversion of TMP in 20 min after the start of the reaction, (3) the activity.

gen peroxide in the presence of these catalysts proceeds in the kinetic regime and is not limited by diffusion processes. In the case of the xerogel TiO₂–SiO₂, which is characterised by substantially smaller pores, the activation energy is *E*_a = 29 kJ mol⁻¹, which is rather typical of diffusion limited processes.²⁶⁰ Ti-SBA-15 represents an exception to this correlation, since its activity is substantially lower as compared to other mesoporous titanium silicates despite the large size of the mesopores therein. Probably, this is due to both the low degree of titanium dispersion and large thickness of the silicate walls in this material, which is in accord with the IR spectral analysis of adsorbed CO molecules (see Section III.12).¹¹⁰ It is important to note that the structural ordering of mesoporous titanium silicates does not correlate with their activities. For instance, Ti-HMS is more active than Ti-MCM-41,¹⁰⁴ whereas Ti-MMM-2 and Ti-MMM manifest similar activities,¹¹⁶ although Ti-MCM-41 and Ti-MMM are more structurally ordered than Ti-HMS and Ti-MMM-2, respectively.

4. The efficiency of H₂O₂ utilisation

The activity of mesoporous titanium silicate catalysts in the oxidation correlates with the rates of H₂O₂ decomposition in the absence of organic substrates: aerogel TiO₂–SiO₂ >

Figure 16. The kinetics of decomposition of H_2O_2 in the presence of Ti-SBA-15 (1), Ti-MMM (2) and aerogel $\text{TiO}_2\text{-SiO}_2$ (3).²⁰⁴ Reaction conditions: 1.29 mmol of H_2O_2 , 0.013 mmol of Ti, 3 ml of MeCN, 80 °C.

$\text{Ti-MMM} > \text{Ti-SBA-15}$ (Fig. 16).²⁰⁴ The efficiency of hydrogen peroxide utilisation (H_2O_2 selectivity) can be estimated as the ratio of the rates of H_2O_2 consumption by the target oxidation of an organic substrate and the concomitant non-productive decomposition of H_2O_2 over the catalyst. Since this ratio clearly depends on the substrate type and/or reaction conditions, the efficiency of H_2O_2 utilisation is also a function of these parameters (Fig. 17). The more active the substrate, the higher the efficiency of H_2O_2 utilisation. In particular, the efficiencies of H_2O_2 utilisation are 45% and 75% in the oxidation of cyclohexene and more nucleophilic caryophyllene, respectively.

The H_2O_2 selectivity is an important parameter of a catalytic process. In order to improve the efficiency of H_2O_2 utilisation, large-scale industrial oxidation processes of petrochemical synthesis are usually accomplished with a large excess of an organic substrate (which is typically less expensive than the oxidant). In contrast, substrates often appear more expensive than oxidants in fine chemical synthesis processes, such that it appears more cost-effective to use an excess of H_2O_2 (which partly decomposes non-productively) in order to enhance the substrate conversion and minimise the costs of product isolation and purification.^{26, 47} In certain cases, the efficiency of H_2O_2 utilisation can be improved by the surface hydrophobisation of mesoporous titanium silicates.^{131, 133, 134, 182}

Figure 17. The efficiency of H_2O_2 utilisation in the oxidation of various organic substrates over Ti-MMM.²⁰⁴ Substrates: (1) methylphenylsulfide (20 °C), (2) cyclohexene (50 °C), (3) caryophyllene (50 °C), (4) 2,3,6-trimethylphenol (80 °C).

5. The problem of stability of titanium silicate catalysts

As has been mentioned above, the leaching of the active component and consequent loss of activity of catalysts is one of the most serious problems in the practical use of liquid-phase catalytic oxidation with aqueous H_2O_2 . The stability of titanium silicates against the titanium leaching depends both on the properties of the titanium silicate itself (the degree of dispersion of titanium over the silicate matrix, thickness of the silicate walls, surface hydrophobicity, etc.) and the reaction conditions (solvent type, H_2O_2 concentration, temperature, composition of the reaction products, etc.).¹²⁴ In particular, titanium is leached from Ti-MCM-41^{122, 250} and mixed oxides $\text{TiO}_2\text{-SiO}_2$,^{167, 203} if methanol is used as a solvent. Meanwhile, aerogels and xerogels $\text{TiO}_2\text{-SiO}_2$ and Ti-MMM proved stable against the titanium leaching in acetonitrile media.^{105, 106, 125, 126} Notwithstanding, the activity of the catalysts decreased substantially upon recycling, despite the lack of titanium leaching.

According to the systematic investigations into the factors affecting the stable functioning of mesoporous titanium silicate catalysts upon repetitive use, the main reason for the loss of activity of Ti-MMM catalysts and mixed oxides $\text{TiO}_2\text{-SiO}_2$ is the negative impact of water (or aqueous hydrogen peroxide) on the hydrophilic surface of the catalysts.^{106, 110, 125, 126} As has been established by small-angle X-ray diffraction and N_2 adsorption, the structure of Ti-MMM degrades as a result of treatment with water (Fig. 18). The structural decomposition of Ti-MCM-41 in

Figure 18. X-Ray diffraction patterns of Ti-MMM (a), Ti-SBA-15 (b) and Ti-MMM-2 (c) before (1) and after their treatment with H_2O (2) or with 30% aqueous H_2O_2 in MeCN (3).^{110, 116, 125}

Figure 19. The DRUV spectra of Ti-MMM (1.89% Ti) (a),¹²⁵ Ti-MMM-2 (1.67% Ti) (b)¹¹⁶ and Ti-SBA-15 (2.05% Ti) (c).¹¹⁰ (1) Prior to treatment, (2) after the treatment with 30% aqueous H_2O_2 in MeCN, (3) after the second treatment with the same solution, (4) after the treatment with a 74% solution of H_2O_2 in MeCN. Treatment conditions: 1.3×10^{-2} mmol of Ti, $0.35 \text{ mol litre}^{-1}$ of H_2O_2 , 3 ml of MeCN, 80°C , 1 h.

the course of phenol hydroxylation¹²³ and upon its treatment with water vapour was revealed by X-ray diffraction.¹²¹ In the case of mixed oxides TiO_2-SiO_2 , a decrease in the specific surface area and volume of the mesopores was detected following their treatment with a 30% solution of H_2O_2 in MeCN.¹²⁶ The collapse of the porous structure gives rise to 'oligomerised' forms of titanium, which are inert in the oxidation, as evidenced by the irreversible red-shift of the band in the DRUV spectra of Ti-MMM and mixed oxides TiO_2-SiO_2 after their treatment with H_2O_2 in MeCN (Fig. 19). The emergence of 'oligomerised' forms of titanium was also registered by DRUV spectroscopy in zeolites Ti-Beta and Ti-MWW after several catalytic cycles,^{53, 68} although Ti-MWW exhibited slightly higher stability against the hydrogen peroxide action than Ti-Beta. A similar conclusion on the conversion of isolated titanium ions into 'oligomeric' agglomerates in the course of the oxidation with H_2O_2 was derived from the comparative analysis of the XANES spectra of Ti-MCM-41 before and after the reaction.^{123, 212}

A decrease in the water concentration in the oxidation of TMP increases the catalyst stability but gives rise to an overall loss of its activity (Fig. 20). The surface hydrophobisation of titanium silicate catalysts gives rise to similar effects.²⁰⁴ Although a decrease in water concentration in the reaction mixture has a positive effect on the oxidation of non-polar substrates (e.g., alkenes), the efficient oxidation of polar substrates requires a certain amount of H_2O . Water is involved in the formation of the Ti-OH bonds manifesting high reactivity towards H_2O_2 ,^{261, 262} thus promoting the generation of active oxidising species, viz., titanium hydroperoxo complexes.^{43, 45, 263} As has been established recently,²⁶⁴ water also promotes the adsorption of H_2O_2 on titanium sites in TS-1.

In contrast to Ti-MMM, Ti-MMM-2 and Ti-SBA-15 synthesised in weakly acidic media can be considered as hydrothermostable materials. According to the X-ray diffraction data, no structural changes with Ti-MMM-2 and Ti-SBA-15 are observed after their boiling in water for several hours (see Fig. 18). The DRUV spectrum of Ti-SBA-15 does not change at all after treatment with 30% aqueous of H_2O_2 in acetonitrile at 80°C . In the case of Ti-MMM-2, the DRUV band is only insignificantly broadened, although its position remains constant (see Fig. 19). Furthermore, the DRUV spectrum of Ti-MMM-2 reveals no changes, if hydrogen peroxide treatment is performed at a lower temperature (e.g., at 20°C), which implies that the initial state of the titanium ions in the samples is not affected. The state of the titanium ions in Ti-MMM-2 also remains unaffected after treatment with boiling water, in contrast to, for example, Ti-MMM¹²⁵

Figure 20. The performance of Ti-MMM (1.89% Ti) in the oxidation of 2,3,6-trimethylphenol with 30% (a) and 84% (b) aqueous solutions of H_2O_2 .¹²⁵

For the reaction conditions, see caption to Fig. 15.

(1) TMBQ selectivity, (2) TMP conversion in 30 min (a) and in 100 min (b) after the start of the reaction.

and Ti-TUD-1,¹⁰⁷ which exhibit red-shifts of the respective bands in the DRUV spectra. In contrast to Ti-SBA-15, the silicate walls in Ti-MMM-2 are sufficiently thin and titanium is smoothly dispersed over the matrix. These factors are responsible for the high catalytic activity of this material, which is comparable to that of hydrolytically unstable Ti-MMM in the first catalytic cycle. The structural stability provides the steadiness of the catalytic properties of the material. In contrast to Ti-MMM, Ti-MMM-2 can be repeatedly used in the reaction without significant losses of activity (Fig. 21), which makes it a promising catalyst for the oxidation of large organic molecules.

Figure 21. The performance of Ti-MMM-2 (1.67% Ti) in the oxidation reactions of methyl phenyl sulfide to the respective sulfoxide (a), of caryophyllene to the respective epoxide (b) and of 2,3,6-trimethylphenol to 2,3,6-trimethyl-1,4-benzoquinone (c) with hydrogen peroxide.¹¹⁶ Reaction conditions: (a) 0.1 mol litre⁻¹ of MeSPH, 0.12 mol litre⁻¹ of H₂O₂, 6 × 10⁻³ mmol of Ti, MeCN, 20 °C; (b) 0.1 mol litre⁻¹ of caryophyllene, 0.11 mol litre⁻¹ of H₂O₂, 6 × 10⁻³ mmol of Ti, MeCN, 50 °C; (c) see caption to Fig. 15. (1) The product yield, (2) substrate conversion in 35 min (a), 4 h (b) and 30 min (c) after the start of the reaction.

V. Conclusion

A large number of mesoporous titanium silicates, both ordered and amorphous, have been synthesised over the last decade and reliable procedures of their detail structural characterisation using a combination of physicochemical instrumental methods have been elaborated. The use of small-angle X-ray diffraction, electron microscopy and low-temperature nitrogen adsorption gives valuable insights into the real structure of these materials (including such parameters as the size, shape and packing type of the mesopores, degree of ordering, thickness of the silicate walls, particle size, and so on). The degree of surface hydrophobicity/hydrophilicity of titanium silicate materials can be assessed using the gravimetric analysis of water adsorption/desorption or ²⁹Si NMR-MAS spectroscopy. The combined application of spectroscopic techniques (DRUV, XANES, IR, Raman, XPS, ESR, and some others) sheds light upon the structure of active titanium sites in the catalysts (*i.e.*, the coordination environment and degree of their dispersion over the silicate matrix). IR spectroscopy of adsorbed CO molecules gives qualitative comparative information on the accessibility of titanium ions in various materials, however methods for the quantitative analysis of this parameter are yet to be developed.

Mesoporous titanium silicates are promising catalysts for the oxidation of large organic molecules with peroxides owing to the suitable pore size and high specific surface area. Using such catalysts, the selective oxidation of different classes of organic substrates has been successfully implemented, in particular, the oxidation of alkenes to epoxides and diols, of unsaturated alcohols, ketones and esters to epoxides, of organic sulfides to sulfoxides and sulfones, of alkylphenols to quinones and dibenzoquinones, *etc.* It has to be stressed that both the characteristics of specific catalysts (titanium loading, concentration of dopant ions, thickness of the silicate walls, specific surface area, diameter and specific volume of mesopores, *etc.*) and the reaction conditions have to be taken into account in the comparative analysis of the literature data on the catalytic activities of different types of mesoporous titanium silicates in the oxidation reactions. All available information obtained by the set of physicochemical instrumental techniques should be consistently analysed in order to understand the differences in the activities of specific catalysts.

Systematic investigations into the mutual relationships between the structural, texture and catalytic properties of mesoporous mixed oxides TiO₂–SiO₂ and mesostructured titanium silicates established that it is the degree of dispersion (isolation) of titanium ions over the silicate matrix and the accessibility of the active titanium sites for reagents, which is in turn determined by

the size of pores and the thickness of the silicate walls, that are the key factors governing their activity as catalysts. In contrast, the coordination number of titanium ions is apparently of low importance in the case of the oxidation with aqueous hydrogen peroxide, since tetrahedral titanium ions are effectively converted into penta- and hexa-coordinated species in the presence of water. So far, there have been no direct experimental evidence that ordered mesoporous titanium silicates are any superior to amorphous titanium silicates with similar titanium loadings in terms of the catalytic activity. The surface acid–base properties of titanium silicates strongly affect their activity and selectivity towards certain reactions. The systematic investigations into this phenomenon can shed light upon the origin of the selectivity manifested by mesoporous titanium silicates in the oxidation of various classes of organic substrates.

For the majority of presently known mesoporous titanium silicates, the problem of their stability against hydrolysis is a very urgent question, which restricts wide practical applications of these materials to the liquid-phase oxidation of different substrates with aqueous hydrogen peroxide. The surface hydrophobisation is a promising means to improve upon the structural stability of the catalysts. Hydrophobised catalysts manifest higher activity towards the oxidation of non-polar and weakly polar compounds (*e.g.*, alkanes and alkenes) than their non-hydrophobised precursors. The reverse trend is observed for the oxidation of polar substrates (*e.g.*, alkylphenol or naphthols). A substantial progress in solving the problem of the hydrolytic instability of mesoporous titanium silicates has been made with the synthesis of a thermohydrostable catalyst Ti-MMM-2, which compares well with Ti-MCM-41 and Ti-MMM in terms of activity but is, unlike them, stable against the action of water.

The authors are grateful to Professor V B Fenelonov and PhD M S Melgunov for valuable comments and to PhD M P Vanina for the help in the manuscript preparation.

Molecular assemblies of polymethine dyes

B I Shapiro

Contents

I. Introduction	433
II. Polymethine state of dyes	434
III. Dye aggregation in solution	434
IV. Dye aggregation on silver halide microcrystals	440
V. Conclusion	453

Abstract. Aggregation processes of polymethine dyes in solutions and a heterogeneous system of AgHal microcrystals are considered. The mechanism of formation of nanoaggregates is discussed. The relationship between the aggregation and the structure of dye molecules is demonstrated. The aggregation is shown to depend on the composition and habit of AgHal microcrystals and the emulsion factors of real photographic systems. The structures and energy levels of aggregates are surveyed. The mechanism of photographic action of aggregates and ways of increasing their photochemical activity are discussed. The bibliography includes 272 references.

I. Introduction

Polymethine (cyanine) dyes became of practical interest after they have been used extremely successfully as spectral sensitizers of silver halide photographic materials. Spectral sensitisation was discovered by H Vogel more than 130 years ago.¹ It should be noted that Vogel was the first to demonstrate the uniqueness of polymethine dyes as spectral sensitizers. In spite of numerous attempts to employ other classes of dyes, only cyanines have found use in photographic technology.

In the course of development of spectral sensitisation, optimal polymethine dyes (Dy) were selected. Initially, dyes have been used primarily in the molecular (M) form. More recently, these dyes began to be used in the aggregated state. As demonstrated in numerous publications (see, for example, the reviews^{2–6}), polymethine dyes capable of forming supramolecular structures, the so-called J-aggregates, have the highest photographic efficiency. Nowadays, most black-and-white and colour photographic materials are spectrally sensitised in the visible spectral region with J-aggregates of polymethine dyes.

The J-aggregation of polymethine dyes is a bright example of self-organisation of organic matter, which is somewhat similar to biological processes. Drawing the analogy between the dye aggregation and self-organisation in living matter, it should be

noted that helical structures can also appear in the former case.⁷ It should be emphasised that J-aggregation is a simpler phenomenon than self-organisation in living organisms, at least because molecules of the same (or related) compounds interact with each other, unlike genes or protein molecules whose helices contain different nucleotides or amino acids, respectively. Hence, the dye aggregation has attracted attention of researchers attempting both to understand general features of aggregation and to find application of the resulting self-organised systems. As mentioned above, some of these systems have long been in use in photographic processes.

Complicated organised structures of organic molecules (molecular assemblies) are of considerable interest primarily because such structures hold promise for processing and storage of large data sets. This phenomenon is used by nature. Reliable information libraries, such as DNA molecules in living organisms, are bright examples. It should be noted that biological self-organisation processes occur in aqueous solutions containing dissolved salts. Life originated from a salt solution of the primeval ocean. The present review shows that salts play an exceptionally important role also in the polymethine dye aggregation.

In the period of extensive development of optical methods for data recording and storage, molecular assemblies consisting of organic dyes have attracted considerable interest. Of all classes of organic dyes, polymethine dyes are distinguished by a high intensity of light absorption and tendency to aggregation.

It is commonly accepted that J-aggregation of cyanine dyes in solutions was virtually simultaneously discovered by Jelly⁸ and Scheibe.⁹ However, Sheppard has observed this phenomenon much earlier.^{10,11} He revealed systematic changes in the absorption curves of cyanine dyes in various solvents and found substantial changes in absorption in aqueous solutions. Jelly and Scheibe also found that absorption maxima are either shifted to shorter wavelengths (H-aggregation) or sharply shifted to longer wavelengths (J-aggregation) relative to the absorption maximum of the molecular form with increasing concentration of dye solutions.

The J-aggregation process is most typical of polymethine dyes. Hence, before proceeding to problems of aggregation, it is worthwhile to consider the specific features of polymethine dyes, which distinguish these compounds from other classes of dyes both by the optical properties and tendency to self-organisation as highly ordered aggregates. The case in point is the so-called polymethine state associated with the specific structural features of polymethine dyes.

II. Polymethine state of dyes

Polymethine dyes (PMD) contain either of the following three main chromophoric systems: the amidinium ion (A), the carboxyl ion (B) and the bipolar amidic system (C)

Schemes A–C show the limiting (resonance) structures of the chromophores. These π -conjugated systems are characterised by the presence of an odd number of methine groups between the charged polar atoms or groups.^{2,3} Positively charged quaternary nitrogen atoms serve as such polar structural elements in amidinium-ion systems; negatively charged oxygen atoms, in carboxylion systems. In formally neutral amidic systems, heteroatoms at the ends of the chromophoric system have opposite charges, *viz.*, the positive charge on the quaternary nitrogen atom and the negative charge on the oxygen atom. Generally, the terminal nitrogen and oxygen atoms are involved in heterocyclic fragments, such as benzothiazole, benzoxazole, benzimidazole, quinoline, indolenine, rhodanine, thiohydantoin, *etc.* The formula of dyes of the amidinium-ion type can be represented as

Figure 2. Absorption spectra of aqueous solutions of 1,1'-diethyl-2,2'-cyanine chloride.² The concentrations of the solution at 25 °C /mol litre⁻¹: (1) 1.3×10^{-5} , (2) 1.3×10^{-3} , (3) 7.1×10^{-3} , (4) 1.4×10^{-2} .

common π -electron system is present, which is manifested in a bathochromic shift of the absorption band, a decrease in its width and, consequently, an increase in intensity. Absorption in the J-band region is due to the cooperative action of all molecules involved in the aggregate, and the absorbed energy is distributed throughout the aggregate. This process is typical of the exciton motion, *i.e.*, the transfer of the excited state, which is formed upon light absorption by one molecule in the close-packed aggregate, from one molecule to another in a time shorter than the oscillation period of the dye. The aggregation of cyanines in solution was reviewed in detail by Herz.^{16, 17}

It is worthwhile to consider the spectroscopic manifestation of interactions between molecules in aggregates in terms of McRae–Kasha's model^{18, 19} for a dimer as the simplest case. The probability of the electron transition from the ground state (*G*) to the excited state (*E*) split due to an intermolecular interaction depends on the angle α between the direction of the transition dipole moments and the axis of the aggregate (the axis through the centres of the molecules in the aggregate, see Fig. 3). For $\alpha = 90^\circ$, the spectral transition to the higher split excited state is most probable. This corresponds to sandwich-type dimers of cyanine dyes characterised by an absorption band hypsochromically shifted relative to the M-band. The transition to the lower split

Figure 3. Diagram of the energy levels of the monomer of the dye and its dimers depending on the angle between the direction of transition dipole moments and the axis of the aggregate;^{18, 19} *G* is the ground state, *E* is the excited state.

state is forbidden. If $\alpha = 0^\circ$, the transition to the lower split excited state is preferable, which corresponds to a bathochromic shift of the absorption band of the dimer. In the general case, for example, at $\alpha > 54^\circ$, the transition to the higher split state with a hypsochromic shift of the absorption band is more probable. For $\alpha < 54^\circ$, the transition to the lower split state with a bathochromic shift is preferable.

This model was extended to larger aggregates (H- and J-aggregates). Based on X-ray diffraction data and results of calculations for aggregates of cyanine dyes, it was concluded that the structural parameter, *viz.*, the packing angle in the aggregate, is of most importance for the spectral properties of such aggregates.^{3, 20, 21}

The structure of an aggregate can be pictorially represented as a deck of cards (Fig. 4). The shift angle in a slipped deck of cards is the above-mentioned packing angle determining the spectral absorption of the aggregate. Calculations demonstrated that $\alpha = 60^\circ$ corresponds to H-aggregates, whereas $\alpha = 30^\circ$ and 19° correspond to J-aggregates. The smaller the angle α , the larger the bathochromic shift of the absorption band of J-aggregates.

Figure 4. Schematic representation of the structures of H- and J-aggregates of cyanine dyes;⁶ α is the packing angle of the aggregate.

The two-dimensional structure of J-aggregates considered by Kuhn, the so-called brickwork structure with the packing angle $\alpha = 19^\circ$ (Fig. 5a), is substantiated the most.^{21–24} Calculations by the molecular orbital (MO) method demonstrated that 3–5 cyanine molecules are sufficient for the appearance of the J-band in the absorption spectrum of a brickwork structure.^{20, 25, 26}

It should be noted that the aggregation of some dyes, for example, of *meso*-methyl-substituted thiacyanines, (particularly, on silver halides) is characterised by double absorption bands. One peak is hypsochromically shifted relative to the M-band, whereas another peak of approximately equal intensity is shifted bathochromically. For such aggregates, a herringbone structure is considered (Fig. 5b).²⁷ In the latter, dimers of the dye serve as the main structural units, which are repeated (translated)

Figure 5. Brickwork (a) and herringbone structures (b) of J-aggregates and the scheme of energy level splitting in dimeric fragments of the aggregates (c).²⁷

many times. Due to splitting of the energy levels of the dye in the dimer (according to Davydov), two spectral transitions occur (Fig. 5c). The intensity ratio of these transitions is determined by the angles α and β .²⁷ For $\beta = 90^\circ$, two transitions have equal intensities.

A dimer is the simplest dye aggregate. The formation of dimers was described in early publications (see, for example, the review¹⁶). Dimers are formed by cyanines containing polymethine chains with different lengths (dyes **1**, $n = 0-3$). The formation of dimers from anionic monomethinecyanines has also been documented.²⁸⁻³⁰ The M- and D-forms are in thermodynamic equilibrium. This is exemplified by thiacyanine ($n = 0$) in Fig. 6. The intensity of the M-band increases, whereas the intensity of the D-band decreases with decreasing dye concentration and increasing temperature, the curves passing through an isosbestic point.

Figure 6. Absorption spectra of aqueous solutions of the triethylammonium salt of 5,5'-dichloro-3,3'-di(γ -sulfopropyl)thiacyanine;²⁸ A is the optical density; the concentration of the solution/mol litre⁻¹: (1) 1×10^{-5} , (2) 1×10^{-6} , (3) 1×10^{-7} ; the cell length/cm: (1) 0.1, (2) 1.0, (3) 10.

Van der Waals forces and dispersion interactions of π -conjugated systems play the major role in the formation of dimers.¹⁶ Dimerisation of cyanines was studied in detail by West and Pears.³¹ It was found^{17,31} that dimerisation in aqueous solutions increases with increasing length of the polymethine chain and with increasing hydrophobicity due to elongation of N -alkyl substituents and, on the contrary, dimerisation decreases with increasing degree of non-planarity of dye molecules, in particular, due to bulky substituents. The free energy of dimerisation of cationic cyanines changes only slightly (by 5–7 kcal mol⁻¹).³¹ For anionic dyes containing sulfoalkyl groups at the nitrogen atoms in heterocyclic moieties, the changes in the free energy of dimerisation are larger.²⁸ Apparently, stability of dimers of anionic cyanine dyes is determined by a strong intermolecular Coulombic interaction between the sulfo group of one molecule and the positive charge on the chromophore of another molecule. The possibility of formation of mixed dimers containing cationic thiacyano- and dicarbocyanines in aqueous solutions was discussed.³¹

It should be noted that the formation of dimers in aqueous solutions leads to fluorescence quenching with a simultaneous increase in the role of triplet states.¹⁶ The only exception is dimers of oxacyanine, which exhibit stronger fluorescence in solutions compared to its monomers.³² Apparently, this is associated with the difference in the structure of two isomers of cyanines involved in the dimers.

Larger aggregates, *viz.*, trimers, tetramers and n -mers, including H-aggregates (Fig. 7), are formed as the dye concentration of in solution increases and the temperature decreases,³³ the hypsochromic shift of the absorption band of aggregates being increased. As a rule, H-aggregates, like dimers, show no lumines-

cence. However, the appearance of narrow H-bands (H^*) was observed.³⁴ Colloidal particles can be H^* -aggregates exhibiting strong luminescence.^{33,34}

The J-aggregation of cyanine dyes is of particular interest. Most earlier studies investigated cationic dyes. The formation of J-aggregates from individual molecules occurred. This process was poorly controlled and led to the uncontrolled growth of J-aggregates up to the formation of colloidal particles.^{16,17} The results of investigation of J-aggregation of imidacarbocyanine molecules performed by Herz^{16,17} are presented in Fig. 8 as an example.

Equilibria between the monomeric and aggregated forms of dyes can be studied by analysing absorption spectra at different dye concentrations. According to the law of mass action, the equilibrium between the monomeric and J-aggregated forms can be written as follows:¹⁶

$$n c_M \rightleftharpoons c_J, \quad (1)$$

$$K = \frac{c_J}{c_M^n},$$

$$\log(nc_J) = \log(nK) + n \log c_M, \quad (2)$$

where n is the number of monomers in the J-aggregate and K is the equilibrium constant. The plot of $\log(nc_J)$ vs. $\log c_M$ should be linear with a slope of n . The change in the free energy of aggregation is determined from the temperature dependence of K .

For imidacarbocyanine in an aqueous electrolyte solution, $n = 4$.^{16,17} Herz hypothesised¹⁶ that, under experimental conditions, colloidal particles can be formed, and $n = 4$ corresponds to the single spectroscopic unit rather than to the size of J-aggregates. The same value of n was obtained for the J-state of cationic naphthothiacyanine²⁵ in an aqueous solution and for 1,1'-diethyl-2,2'-cyanine.³⁵ Small values of n were determined from spectroscopic data in some other studies.¹⁶ It should be noted that irreversibility of the equilibrium in a monomer–J-aggregate system is the main problem in determining the number of molecules in J-aggregates and the thermodynamic parameters of aggregation. Generally, small J-aggregates (consisting of a few molecules) grow into colloidal particles. The identification of

Figure 8. Dependence of absorption of benzimidacarbocyanine at 25 °C on its concentration in a 10^{-3} M NaOH aqueous solution.¹⁶ The concentration of the solution /mol litre $^{-1}$: (1) 0.5×10^{-6} , (2) 1.0×10^{-6} , (3) 5.0×10^{-6} , (4) 1.0×10^{-5} , (5) 1.0×10^{-4} , (6) 4.0×10^{-4} ; c_M and c_J are the concentrations of the monomeric and aggregated forms of the dye, respectively.

states by spectroscopic methods is complicated by the fact that particles of different sizes give similar absorption maxima. Hence, reversibility of the equilibrium and colloidal stability of solutions in time are the main criteria in the determination of the state of dyes.

A new method of J-aggregation (from dimers rather than from individual molecules) was examined in the studies.^{36,37} This method typical of anionic cyanine dyes is referred to as the block construction of aggregates.³⁷ The equilibrium between dimers and J-aggregates of the pyridinium salt of 3,3'-di(γ -sulfopropyl)-4,5,4',5'-dibenzo-9-ethylthiacarbocyaninebetaine is illustrated in Fig. 9. It can be seen that the equilibrium is thermodynamically reversible because the spectral curves pass through an isosbestic point. The tendency of dyes to aggregation is enhanced with decreasing temperature and increasing concentration. These results are consistent with the characteristic features of aggregation of thiacyanines.^{28,36}

To determine the sizes of J-aggregates, the plot of $\log(nc_J)$ vs. $\log c_D$ was constructed (Fig. 10). The slope of the line [corresponding to the number (m) of dimers in the J-aggregate] is 2, *i.e.*, the J-aggregate consists of two dimers or four monomers. Probable structures of J-aggregates formed from two dimers are shown in Fig. 11.^{21–23} In all cases, the formation of J-aggregates from dimers is associated with the shift of the molecules in dimers with respect to each other. It was hypothesised that a brickwork structure is most preferable. It was demonstrated that J-aggregates of thiacyanine [triethylammonium salt of 5-chloro-3,3'-di(γ -sulfopropyl)-4',5'-benzothiacyaninebetaine] also consist of two dimers, *i.e.*, of four dye molecules.³⁶

In studies of the equilibria between different forms of anionic thiacyanine dyes in aqueous solutions the following, at first glance, paradoxical conclusion was reached: the block construction of J-aggregates from dimers is the most preferable method for

Figure 9. Absorption spectra of thiacarboaniline in aqueous solutions. The concentration of the solution /mol litre $^{-1}$: (1) 10^{-4} , (2) 3.3×10^{-5} , (3) 1×10^{-5} , (4) 0.5×10^{-5} ; the cell length /cm: (1) 0.1, (2) 0.3, (3) 1.0, (4) 2.0.

the construction of 'ideal' J-aggregates of the same size (monostructural J-aggregates). This new approach to the construction of J-aggregates was used for the preparation of mixed J-aggregates from dyes containing polymethine chains of different lengths.^{37, 38} To our knowledge, Scheibe *et al.*³⁹ observed for the first time the appearance of new bands in the absorption spectrum of a system consisting of two dyes, *viz.*, 1,1'-diethyl-2,2'-cyanine and its 2-benzoselenazole analogue. In the spectrum of a complex mixture of solvents, benzene–amyl alcohol–water, an additional absorption band was found between the bands of J-aggregates of individual dyes. The appearance of new bands for analogous dyes containing long alkyl groups in the spectra of Langmuir–Blodgett films was described by Penner and Mobius.⁴⁰ Mixed amalgam-type aggregates were obtained⁴¹ in Langmuir–Blodgett films for 3,3'-diethyl-9-phenylthiacarbocyanine dyes substituted in heterocycles. It should be noted that J-aggregates composed of two types of dyes were formed in heterogeneous systems at the water–organic solvent interface.

The main scheme of the block construction of J-aggregates from molecules of different dyes in water involves the preliminary formation of dimers of these dyes due to a shift of the J-aggregate $\rightleftharpoons$ dimers equilibrium toward the dimers (upon heating of their solution) followed by the formation of complex aggregates (upon cooling of the systems).^{37, 38} The absorption spectrum of a mixture consisting of solutions of thiocarbocyanine and thiadicarbocyanine is a summary curve of the bands of the starting dyes (Fig. 12, curve 1). Heating of the solutions to 50–80 °C leads to destruction of J-aggregates of individual dyes and the appearance of bands corresponding to absorption of dimers of dyes (see Fig. 12, curve 2). After subsequent cooling of the solutions, the dimers form new J-aggregates including different molecules (see Fig. 12, curve 3). The absorption band of mixed J-aggregates appears at longer wavelengths compared to the band of J-aggregates of thiocarbocyanine and is hypsochromically shifted relative to the absorption band of J-aggregates of thiadicarbocyanine. This phenomenon is common to thiacyanines, which can form J-aggregates in aqueous solutions and contain an extensive π -conjugated system in the heterocycles. Therefore, mixed aggregates with desired spectral properties can be prepared by choosing appropriate pairs of dyes.

Apparently, the resulting mixed J-aggregates are homogeneous structures analogous to solid solutions of dyes, which is confirmed by the character of their fluorescence spectra. Intrinsic luminescence bands (Fig. 13 *b*) correspond to individual absorp-

Figure 12. Absorption spectra of a 1 : 1 mixture of aqueous solutions of thiocarbocyanine and thiadicarbocyanine ($c = 1 \times 10^{-4}$ mol litre $^{-1}$) after mixing at 20 °C (1), upon heating to 50 °C (2) and after cooling to room temperature (3).^{37, 38}

Figure 13. Absorption spectra (*a*) and fluorescence spectra (*b*) of J-aggregates of thiocarbocyanine (1) and thiadicarbocyanine (2) and their mixture (3) in aqueous solutions.^{37, 38}

tion bands of J-aggregates of the starting dyes and their mixture (Fig. 13 *a*). Therefore, the block construction of J-aggregates in solution is an efficient method for the preparation of J-aggregates of cyanine dyes containing polymethine chains with different lengths and mixed J-aggregates. Hence, this method can be considered as a promising approach to the formation of complex organised structures, *viz.*, molecular assemblies with new optical properties.

A different type of aggregates composed of dimers was obtained in studies of cyanine dyes, which substantially differ in the length of the polymethine chains, *viz.*, thiacyanines and thiadicarbocyanines.⁴² In this case, mixed J-aggregates are not formed, absorption bands of dimers of thiadicarbocyanines disappear and the absorption spectra show new absorption bands. This is illustrated in Fig. 14, which shows the absorption spectra

Figure 14. Absorption spectra of aqueous solutions of triethylammonium salts of 5'-chloro-3,3'-di(γ -sulfopropyl)-4,5-benzothiacyanine (1) and 3,3'-di(γ -sulfopropyl)-9,11-(β , β -dimethyltrimethylene)-10-methylthiadicarbocyanine (2) and their mixture (3) at room temperature.⁴² The concentration of the dyes $c = 1.0 \times 10^{-5}$ mol litre $^{-1}$; (4) the difference spectrum of the starting dyes and their mixed solutions.

of aqueous solutions of triethylammonium salts of 3,3'-di(γ -sulfo-*propyl*)-4,5-benzo-5'-chlorothiacyanine and 3,3'-di(γ -sulfo-*propyl*)-9,11-(β,β -dimethyltrimethylene)-10-methylthiadibenzocyanine. The thiacyanine existed in the dimeric ($\lambda_{\text{max}} = 421 \text{ nm}$) and monomeric ($\lambda_{\text{max}} = 442 \text{ nm}$) forms (curve 1). The thiadibenzocyanine also existed in the dimeric ($\lambda_{\text{max}} = 588 \text{ nm}$) and monomeric ($\lambda_{\text{max}} = 655 \text{ nm}$) forms (curve 2). Curve 3 represents the absorption spectrum of mixed equimolar solutions of the dyes. After mixing of solutions of the dyes, the intensity of the dimer band of the thiadibenzocyanine substantially decreases and new absorption bands appear at $\lambda_{\text{max}} = 444$ and 678 nm , which is shown by curve 4 (obtained by subtracting curves 1 and 2 from curve 3). This interaction between thiacyanines and thiadibenzocyanines has a general character regardless of the nature of substituents in the heterocyclic moieties of the dyes.⁴² Therefore, interaction between dimers of two dyes is pronounced. It was hypothesised that this is associated with the presence of dimer(1)–dimer(2) interactions involving different dyes. Apparently, splitting of the dimer band of the dicarbocyanine dye is due to splitting of the electron levels of the dimer in a 'heterocontact dimer' due to the perturbing action of the dimer of the thiacyanine dye. It was concluded that the formation of 'heterocontact' aggregates is energetically more favourable than the formation of dimers and J-aggregates of individual dyes. Therefore, in this case, as in the case of formation of mixed J-aggregates, dimers are the main building blocks of organised polymolecular structures. However, the formation of mixed J-aggregates is, apparently, hindered due to a substantial difference in the geometry of the interacting molecules and, consequently, the so-called suprastructures with incommensurate elements are formed.⁴³

The influence of electrolytes and surfactants on aggregation of cyanines was examined in several studies (see, for example, Refs 16, 20 and 44). It is evident that the aggregation of charged cyanine dye molecules is influenced by electrolytes. Generally, the introduction of inorganic electrolytes stimulates aggregation.¹⁶ This is related to the salting out of the dye from a solution under the action of an electrolyte. The charge of the ion opposite to the charge of the dye molecule plays a great role. In aqueous solutions of anionic dyes,⁴⁵ the electrolyte concentration stimulating aggregation decreases and the J-aggregation rate increases with increasing charge of the cation.[†] It was hypothesised that the self-aggregation becomes more probable in the presence of framework-forming auxiliary partners (for example, ions). Figuratively speaking, ions can serve as 'nails' facilitating the building of J-aggregates. In addition, ions involved in J-aggregates can promote their stabilisation.

Organic surfactants (unlike inorganic electrolytes) hinder the self-association of dyes in water.⁴⁶ This influence is characteristic also of micelle-forming non-ionic surfactants.¹⁶ This property lies at the basis of the spectroscopic method for the determination of the critical micelle concentration. It should be emphasised that dye aggregation can, on the contrary, occur in the pre-micellar region of surfactant concentrations.

The influence of surfactants on aggregation was examined.^{7, 47–50} The presence of long hydrocarbon fragments at the nitrogen atoms in the imidazobenzocyanine molecule is found to favour the formation of helical structures of J-aggregates, in which the hydrocarbon tails serve as a framework at which a helical packing of the dye molecules is assembled as a nanotube. An example of such structures characterised by a two-band spectrum of the J-aggregate is shown in Fig. 15.⁵⁰

Unlike the deaggregating action of micelle-forming surfactants, polymeric surfactant ions (polyelectrolytes) stimulate aggregation. The spectral shifts caused by interactions of polyelectrolytes with both anionic and cationic dyes were studied in detail (see references in the review¹⁶).

Figure 15. Cylindrical model of the helical structure of imidazobenzocyanine.⁵⁰

The influence of gelatine on aggregation of cyanine dyes in solutions was studied in depth. The appearance of a new band at longer wavelengths after the addition of traces of gelatine to aqueous solutions of carbocyanines was observed for the first time by Sheppard⁵¹ and Solov'ev.⁵² More recently, Dickinson,⁵³ Borin⁵⁴ and Boyer *et al.*⁵⁵ performed systematic studies of the influence of the gelatine concentration, the temperature and pH on aggregation of cationic dyes in aqueous gelatine solutions. It was found that J-aggregation of dyes is initiated in the presence of a small amount of gelatine ($\sim 0.01\%$), and a further increase in the gelatine concentration in solution leads to destruction of J-aggregates to give monomers. In a 1% gelatine solution, J-aggregates are absent. In addition, pH of an aqueous gelatine solution should be higher than pH of the isoelectric point of gelatine. It should be noted that the solutions contained not only J-aggregates but also other 'short-wavelength' aggregates of dyes. More recently, Hermel and Seeboth⁵⁶ studied the influence of the molecular mass distribution of gelatine and the effect of liquid-crystalline *N*-substituted butylaniline on aggregation of oxacar-

[†] See also the publication by T D Slavnova, A K Chibisov, H Gorner *J. Phys. Chem. A* **109** 4758 (2005).

bocyanine. Krasovskii *et al.*⁵⁷ investigated the properties of the anionic analogue of this dye containing sulfopropyl groups at the nitrogen atoms in aqueous solutions near the gel-formation threshold of gelatine. It was found that J-aggregates are more readily formed in low-molecular-weight gelatines. However, mixtures of monomeric and several aggregated forms (dimers, H- and J-aggregates) were obtained in these systems as well. It was demonstrated^{51,52} that traces of gelatine act as aggregation centres because adsorption of dyes occurs on particular groups of gelatine.

Gelatine was demonstrated⁵⁸ to promote J-aggregation of anionic dyes from dimers according to the mechanism of block construction. In this case, gelatine serves as the third component facilitating aggregation.

A study of the dependence of J-aggregation on the type of gelatine showed⁵⁹ that the aggregation is substantially influenced by the positively and negatively charged groups. In acidic gelatines, J-aggregation occurs much more readily than in alkaline gelatines. In acidic gelatines containing positively charged quaternary nitrogen atoms at a pH under study, J-aggregation starts at higher temperatures and lower gelatine concentrations. J-Aggregation is slowed down as the number of acidic groups in the gelatine molecule increases. It was concluded that the quaternary nitrogen atoms in acidic gelatines serve as J-aggregation centres of anionic dyes. The ability of gelatine to catalyse J-aggregation was exploited for the preparation of gelatine layers containing nanoparticles of J-aggregates consisting of several dye molecules.

In recent studies, considerable attention was given to the formation of J-aggregates in films of various polymers, including electroconducting polymers. Composites containing J-aggregates are promising materials for the construction of electroluminescent displays and the preparation of electrorefractive layers, nonlinear optical systems and other systems used in nanoelectronics. Mal'tsev *et al.*^{60–62} investigated J-aggregates as a light-emitting medium in electroconducting polymers. The authors observed electroluminescence of J-aggregates of mono-, tri-, penta- and heptamethinecyanines in the visible and IR spectral regions. The photoelectrical, nonlinear optical and photorefractive properties of J-aggregates in polyimide films were investigated.^{63,64} The nonlinear optical properties of J-aggregates of thiocarbocyanine dyes in multilayer polymer films were studied.⁶⁵ Films containing J-aggregates of cyanine dyes were used for generation of ultra-short laser pulses and nonlinear optical transformations.^{66–70} The J-aggregation of thiocarbocyanine dyes in polymer films was investigated.⁷¹ Data on J-aggregation in polymeric matrices were obtained primarily for pseudoisocyanine in polyvinyl alcohol,^{72,73} polystyrene sulfonate and polyacrylic acid.^{74–76}

IV. Dye aggregation on silver halide microcrystals

The most detailed information on aggregation of cyanine dyes was obtained in long-term studies of spectral sensitisation of AgHal-based photographic materials. It is known that J-aggregation more readily occurs at the AgHal/solution interface.^{2,16} The use of cyanine dyes for spectral sensitisation of photographic silver halide emulsions provides a substantial increase in additional light sensitivity in the region, where AgHal microcrystals do not absorb light. Dyes capable of forming supramolecular structures, *viz.*, J-aggregates, are characterised by the highest photographic efficiency.^{2–6,77}

The J-aggregation process is determined primarily by the molecular structure of the dye (the lengths of the polymethine chain, the structure of heterocyclic rings and the presence of substituents in these moieties and in the chain), the nature of the halogen atom, the habit and size of emulsion microcrystals, the presence of ions and compounds adsorbed on AgHal (stabilisers, surfactants, colour-forming components, *etc.*), pBr and pH.^{2,3,16,17,20,77,78}

The J-aggregation by itself is not a sufficient condition for high efficiency of spectral sensitisation. Many J-aggregating dyes

are inefficient under particular conditions. The photographic efficiency of J-aggregates cannot be attributed only to a change in the position of the energy levels of dye molecules upon J-aggregation. The experience showed that the surface state of AgHal microcrystals and the topography of impurity centres play a decisive role. The surface defects and impurity centres are of importance in J-aggregation and location of photogenerated electrons and holes. Interactions between J-aggregates of a dye and impurity sites can lead to a decrease in the photographic activity of the dye. Generally, this is attributed to desensitisation and self-desensitisation of dyes.^{79,80} Desensitisation causes a decrease in the intrinsic (blue) light sensitivity of AgHal. Self-desensitisation leads to a decrease in the light sensitivity in the absorption zone of dyes. The efficiency of spectral sensitisation can substantially be increased by introducing supersensitisers (compounds, which inhibit or completely exclude self-desensitisation of dyes).

1. Relationship between aggregation and the structure of dyes

The relationship between the structure of dyes and their tendency to form aggregates in solutions and on the surface of AgHal were studied in depth (see references in the publications^{2–6,77–80}). The available data are rather contradictory due to complexity of a photographic system.

Among cyanine dyes unsubstituted in heterocyclic fragments and the outer polymethine chain, mono- and trimethinecyanines are most prone to aggregation on the surface of AgBr(I) emulsion grains.^{2,3,77} Generally (with rare exception^{81–83}), di- and tri-carbocyanines (penta- and heptamethinecyanines) form H-aggregates rather than J-aggregates on AgHal substrates.^{17,77} This may be related to the requirements of a highly ordered arrangement of molecules in J-aggregates, whereas the uniformity of the states of the molecules is less probable due to an increase in the number of *cis-trans* isomers with increasing length of the polymethylene chain of dyes.⁸⁴ As a result, any deviation from the uniformity of structural elements, in particular, due to *cis-trans* isomerism, hinders aggregation. For example, only rigid fixation of the chain by polymethylene bridges in thiadi- and -tricarbo-cyanine molecules preventing *cis-trans* isomerism results in J-aggregation of dyes containing such a long polymethine chain in solutions and on AgHal.^{37,38,83,85}

Derivatives of partially hydrogenated rings (thiazoline and pyrrolidine) show almost no tendency to form J-aggregates. Analogous dyes containing conjugated heterocyclic fragments (thiazole and 1,3,4-thiadiazole) have a weak tendency to form aggregates, whereas this tendency is substantially stronger in the case of compounds containing fused heterocyclic systems with a high degree of π -electron delocalisation (such as benzoxazole, benzoselenazole, benzothiazole, quinoline, *etc.*). J-Aggregation in AgHal emulsions accompanied by a shift of absorption bands to longer wavelengths increases in the thiazoline < thiazole < benzothiazole < naphthothiazole series. This indicates that interactions of π -electrons in heterocyclic systems play a considerable role in the formation of polymolecular states. The phenyl groups in the thiazole or thiadiazole moieties have an analogous effect on J-aggregation.⁷⁷ Indo- (see Ref. 78) and imidacarbocyanines,⁸⁶ as well as indo- and thiadiazolo-1,3,4-dicarbocyanines,⁷⁷ also show a tendency to form J-aggregates.

Merocyanines rarely form J-aggregates on AgHal, although dimethinemerocyanines containing indolenine and pyrazolone moieties and malonodinitrile derivatives⁸⁴ give J-bands in emulsions. Sensitisation and absorption spectra of a number of dimethinemerocyanines, derivatives of unsymmetrical cyclic compounds (in particular, 3-alkylrhodanine and 1,3-dialkylthiohydantoin), show J-bands whose intensity increases with increasing duration of storage of melted sensitised emulsions.⁷⁷

The introduction of substituents into different classes of dye molecules has a similar effect on their aggregation. For example, J-aggregation is substantially enhanced in the presence of chlorine atoms in heterocyclic fragments of various carbocyanines or the

methyl and ethyl groups in the *meso* positions of thia-, oxa- and selenacarboxyanines.^{2, 77, 78} Taking into account considerable differences in the tendency of structurally similar dyes to form J-aggregates, small modifications would be expected to change the mutual orientation of the molecules responsible for their interactions. The specificity of the influence of an increase in the bulkiness of substituents was observed even in a single series of dyes. For example, the ability of 9-ethyl-6,6'-dimethoxycarboxyanines to form J-states is substantially higher than that of the corresponding 6,6'-diethoxy and, particularly, 6,6'-dipropoxy derivatives, whereas the tendency to form H-states substantially increases in this series.⁷⁷

It is commonly accepted that the ability to form aggregates is enhanced in the presence of halogen (except for iodine) atoms and COOR, CN and some other electron-withdrawing groups in the heterocyclic rings of indo-, imida, quino(2,2')- and oxacarboxyanines containing unsubstituted chains due to a strengthening of π - π -electron interactions between the molecules.⁸⁷ The influence of other substituents is very specific.

In the quino-(2,2')-cyanine series, *N,N'*-dimethoxides are much less prone to J-aggregation than ethoxides.⁷⁸ Sheppard *et al.*⁸⁸ demonstrated that this property is inherent also in methoxides of cyanines prepared from other bases, in particular, from benzothiazole and benzoxazole. *N,N'*-Dimethoxides of quino-, oxa-, thia- and selenacarboxyanines are less efficient due to their high ability to form photochemically inactive H-polymers.⁷⁷ If methoxides and ethoxides of thia-, imida- and indocarboxyanines are characterised by a similar tendency to undergo polymerisation, they are similar in the sensitising action. The intensity of the J-band sharply decreases with increasing number of carbon atoms in the alkyl groups at the nitrogen atoms (C_2H_5 – n - C_4H_9) in the series of 5,5'-disubstituted 9-ethylthiacarboxyanines,⁷⁸ whereas the intensity of this band remains virtually unchanged in the case of imidacarboxyanines.⁷⁷ In the series of dimethinemercocyanines, *viz.*, rhodanine and thiohydantoin derivatives,⁷⁸ the ability to form J-aggregates, on the contrary, either appears or is enhanced.

Among carboxyanines containing alkyl and sulfoalkyl substituents, dyes containing sulfoalkyl groups at the nitrogen atoms are more prone to aggregation, the photographic activity of J-states being much higher than that of dyes containing alkyl substituents with different structures.³

As mentioned above, the ability of dyes to form various polymolecular states is enhanced in the presence of methyl and ethyl groups at the *meso* position of the polymethine chain of thia-, oxa- and selenacarboxyanines. A comparison of the sensitisation and absorption spectra of dyes and the experimental relative quantum yields of sensitisation for several groups of dyes demonstrated that the introduction of methyl and ethyl groups at the *meso* position of carboxyanines leads to the formation of the photochemically active H_1 - and J_1 -states of 9-methylcarboxyanine and the J_2 - or J_3 -states of 5,5'-disubstituted 9-ethylthiacarboxyanines in the adsorption layer.^{77, 78} More recently, it was found that the common polymolecular herringbone structure characterised by two spectral transitions rather than two different states (H_1 and J_1) are formed for 9-methyl-substituted thiacarboxyanines.^{80, 89} In these studies, as well as in other investigations (see references in the publication²⁰), the introduction of alkyl groups at the *meso* position was demonstrated to have a substantial effect on the enhancement of J-aggregation, the replacement by the ethyl group being more favourable for the *cis* configuration, whereas the presence of structurally identical dye molecules facilitates their self-assembly as J-aggregates.

The dependence of the ability to form aggregates not only on the number of isomers, but also on such factors as the planarity of cyanine molecules and the absence of internal rotational motion was examined^{84, 86, 90} and the contribution of these factors to the colour and the ability to undergo polymerisation and be sensitised was investigated. The compactness of molecules and a small deviation from planarity are particularly favourable for aggrega-

tion because planar molecules more readily form close-packed relatively rigid structures, which are less susceptible to thermal decomposition. Brooker *et al.*⁸⁶ classified dyes into free, compact and overcrowded. The first two groups involve planar molecules and the third group includes nonplanar molecules. The fact that substituents violating the planarity of molecules hinder aggregation is well illustrated by 1,1'-diethyl-2,2'-cyanine derivatives. The tendency of this compact dye to form aggregates is weakened by 3,3'-alkyl substituents, which push the heterocyclic rings out of the plane of the molecule. In some cases, the required compactness and the related ability to form aggregates can be achieved by fixing the heterocyclic moieties by bridging groups, thus forming a rigid cyclic structure of the molecule. This is typical of *N,N'*-ethylenebenzimidazolocyanine, which readily forms J-aggregates on the surface of AgHal. By contrast, the sterically hindered and nonplanar *N,N'*-diethyl-substituted analogue cannot undergo aggregation.^{17, 91}

Carboxyanine derivatives of *N,N'*-dialkylbenzimidazoles were studied in detail.^{77, 78} The introduction of alkyl substituents at position 9 of these dyes causes a substantial deviation from coplanarity and decreases the ability to form J-aggregates. Likewise, the introduction of bulky substituents, such as NO_2 , SO_2CF_3 or SCF_3 , at position 5 of the heterocycle suppresses the formation of J-aggregates of compact *N,N'*-dialkylbenzimidazole molecules on the surface of AgHal.

The introduction of the CH_3O and C_6H_5 groups at the *meso* position of the chain and of aryloxy groups at positions 8 and 10 can assist aggregation of oxa- or thiacarboxyanines, which are aggregated poorly, if at all, because it becomes possible to form compact structures from all-*trans* or mono-*cis* configurations.^{25, 26} Taking into account the role of substituents in the chain and at the nitrogen atoms of the ring, it was hypothesised that small deviations from the plane of the dye molecule due to the presence of ethyl and other groups, can facilitate the formation of J-states with a brickwork structure from compact planar dye molecules.^{92, 93}

Therefore, the factors favourable for the planarity of a molecule, an elongation of the π -conjugated system of the dye and the uniformity of the isomeric composition of the molecule are responsible for the ability to form J-aggregates. However, these are necessary but not sufficient conditions for J-aggregation. Since J-aggregates are particular three-dimensional packings of dye molecules, J-aggregation depends on the volume of the substituents both in the rings and the chain, which can cause steric hindrance to interactions of the π -conjugated systems of dyes in aggregates.

2. Influence of emulsion factors on aggregation of spectral sensitisers

The nature of the halogen atoms in AgHal microcrystals of photographic emulsions is one of the most important factors influencing J-aggregation. It is known^{2, 3} that the adsorption strength of cyanine dyes on AgHal powders decreases in the series $AgI > AgBr > AgCl$. For many dyes, J- and H-aggregation decreases in the following series: $AgBr(I) > AgBr > AgBr(Cl) > AgCl$.^{77, 78} Meyer⁹⁴ was the first to find that the introduction of 3 mol.% of silver iodide into crystals of a silver bromide emulsion substantially enhances J-aggregation of 9-ethyl-3,3',5,5'-tetramethylthiacarboxyanines accompanied by an increase in the light sensitivity of photolayers.

The influence of the nature of halide ions in monodisperse emulsions containing cubic and octahedral crystals was investigated⁹⁵ and J-aggregation of microcrystals of the same habit of silver chloride bromide and silver bromide iodide emulsions was demonstrated to be better compared to silver chloride emulsions.

Aggregation of dyes upon adsorption on AgHal microcrystals of different habits was studied in depth.^{77, 95–106} It was noted^{100, 101} that absorption spectra of some dyes in emulsions prepared by the ammonia method differ from those prepared by the ammonia-free method. In neutral emulsions, the conditions

for aggregation of dyes are more favourable than those in ammonia emulsions. This may be associated not with the presence or absence of ammonia in the emulsion but with the different habits of microcrystals (a spherical habit in ammonia emulsions and a tabular habit in neutral emulsions).

Dye aggregation on cubic and octahedral AgHal microcrystals has been studied in sufficient detail. It was found that aggregation of cyanines on the (100) faces differs from that on the (111) faces. Experimental data and a theoretical justification for the predominant J-aggregation on the surface of octahedral crystals were reported.^{95–99, 102, 105} 9-Methylthiacarbocyanines, which form J₂-aggregates on the (111) faces giving a band at $\lambda_{\text{max}} = 625$ nm and aggregates on the (100) faces characterised by two absorption bands at $\lambda_{\text{max}} = 590$ and 520 nm, were primarily used as model compounds.

It was found^{97, 102} that readily aggregating dyes (imida- and 5,5'-dichloro-9-ethylcarbocyanines) form, at low concentrations, J-aggregates predominantly on octahedra. Adsorption of cyanines is determined by Coulombic interactions between the negatively charged (111) surface and the positively charged terminal nitrogen atoms of a polymethine chromophore. The fact that the distances between the molecules in the aggregate are similar to those between the ions on the surface of octahedral AgBr microcrystals satisfies the requirement for a closer packing, which is also favourable for J-aggregation. In spite of steric and electrostatic hindrance, readily aggregating dyes whose aggregation is facilitated by water molecules are primarily adsorbed in the J-state on the (100) faces. Tani¹⁰² found that not only J-aggregation but also H-aggregation of cyanines is stronger on the (111) faces than on the (100) faces.

It was noted⁹⁹ that J-aggregation of dyes, in particular, of 9-methylthiacarbocyanines, occurs predominantly on the (100) faces of AgCl analogous to that observed on the (111) faces of AgBr. It was hypothesised that J-aggregates are additionally stabilised by denser solvate shells. This is due to the difference in the influence of Cl[−] and Br[−] ions on the structure of water on the surface. In the presence of chloride ions, the solvation effect is enhanced,⁹⁶ and, consequently, hydrophobic binding of dye molecules with each other is possible.

On the contrary, experimental data on the enhancement of J-aggregation of dyes on cubic microcrystals were reported.^{103–107} A small amount of a dye is sufficient for J-aggregation because the (100) faces contain a small number of crystal lattice defects.¹⁰⁴ Octahedral microcrystals contain a larger number of surface defects. Hence, H-aggregation occurs at low concentrations, whereas higher concentrations of dyes are necessary for J-aggregation. Kazmierczak and Markocki¹⁰⁶ studied the photographic action of thia-, oxa- and selenacarbocyanines at different pAg and pH of emulsions. It was found that particular elements of the dye molecules can facilitate J-aggregation on either (100) or (111) faces. Carbocyanines containing methoxy or phenyl groups at position 5 of heterocyclic fragments show a tendency to form J-aggregates on the (100) faces. Unsubstituted dyes are more prone to J-aggregation on the (111) faces. 5,5'-Dichloro- or 5,5'-dimethyl-substituted carbocyanines behave analogously. Some dyes form J- or H-aggregates regardless of the habit of AgHal microcrystals.

Grishina¹⁰⁸ found that the influence of different structural elements of anionic and cationic thiacyanines on J-aggregation has a general character and is independent of the habit and homogeneity of AgHal microcrystals. More stable J-aggregates are formed on the (100) faces compared to those on the (111) faces.

The size of emulsion microcrystals is yet another important factor determining J-aggregation of spectral sensitizers. However, the available published data do not allow one to reveal general features of dye aggregation depending on the dispersion of silver halide microcrystals in photographic emulsions.

Of all sensitisation bands, the J-band is most dependent on the additives. The concentration of Ag⁺ ions in emulsions and pH of the medium have a considerable effect on J-aggregation. In an

aqueous medium under ambient conditions, the surface of AgBr is stoichiometric to the lattice ions at pAg 5.3. The surface of AgBr acquires a negative charge as the concentration of Br[−] ions increases. The limiting surface area, which can be occupied by adsorbed bromide ions, is ~20% of the surface area of the microcrystals, a particular concentration of Br[−] ions corresponding to each habit.³ Adsorption of dyes leads to a shift of the equilibrium between the bromide ions in solution and on the surface and an increase in pAg. The amount of the adsorbed dye and the strength of adsorption on the surface of AgBr depend on the structure of the dye. For example, merocyanines and cationic dyes, which bind silver ions, are adsorbed in larger amounts at lower pAg. Adsorption of cyanines binding bromide ions is favoured by an increase in pAg.³ However, it was demonstrated⁹⁹ that adsorption of certain cationic carbocyanines depends only slightly on the change in pAg in a rather wide range and substantially decreases only at rather high silver ion concentrations (pAg < 4).

The influence of pAg on adsorption of cyanines having different structures is often determined by the influence of this factor on J-aggregation in the adsorption layer. An enhancement of the tendency to form J-aggregates upon adsorption of dyes on an AgBr powder from ethanol was observed in the presence of an excess of both Br[−] and Ag⁺ ions.^{109, 110}

In investigations of spectral sensitisation of photographic emulsions,^{5, 110} the degree of dye aggregation not necessarily changes with decreasing concentration of bromide ions (during washing of sensitised layers with water with the aim of increasing the light sensitivity). More recent studies demonstrated¹¹¹ that J-aggregation of many cyanines is suppressed in the presence of an excess of silver ions, a considerable amount of dyes being displaced to gelatine. The addition of an AgNO₃ solution (to pAg 3–4) to a monodisperse emulsion before the addition of a spectral sensitizer led to suppression of J-aggregation of quino-2-cyanines compared to J-aggregation in the starting emulsion. This was not observed in the case of other mono- and trimethine-cyanines.¹¹² Therefore, J-aggregation of cyanine dyes depends not only on pAg but also on the way of changing this parameter.

Cyanine dyes are bases whose protonation constants differ by 14 orders of magnitude¹⁷ depending on the structure of the dye and, as a consequence, the influence of pH on aggregation is substantially different for dyes having different structures. Generally, an increase in pH leads to a particularly substantial weakening of the J-band of basic cyanines as pH is lowered. The following factors cause a decrease in the effect of pH on J-aggregation: the cubic habit of microcrystals, high concentrations of I[−] ions in the substrate, an excess of Hal[−] ions in the solution, a high molar absorption coefficient of the dye and the absence of competitive adsorbents.^{113, 114} It should be taken into account that pAg and pH can substantially depend on the presence of sensitizers and other additives in emulsions. For example, the addition of a sensitizer to an acidic emulsion followed by an increase in pH does not lead to a weakening of J-bands of thiacyanines.

For dye aggregation, not only pAg, pH and the nature of the adsorbent but also the nature of gelatine, which is used in photographic emulsions as a dispersion medium, are of considerable importance. The influence of gelatine was examined in a number of studies (see, for example, Ref. 20). The absorption spectra of dyes substantially depend on the gelatine concentration. Small amounts of gelatine serve as aggregation sites, while the carboxy groups of gelatine can serve as adsorption sites for dyes in solution. The influence of gelatine on J-aggregation, in particular, the dependence of J-aggregation on the concentration of gelatine and its type, was studied.²⁰ Dye aggregation starts on particular sites of gelatine molecules. The concentrations of these sites in different types of gelatines are different.

The influence of gelatine on J-aggregation of cyanine dyes is associated with pH,²⁰ because gelatine is a polyelectrolyte, different types of gelatine having somewhat different isoelectric points.

The influence of the main stabiliser of photographic emulsions of 4-hydroxy-6-methyl-1,3,3a,7-tetraazaindene (sta-salt) on aggregation of different dyes was studied in detail by Shapiro *et al.*^{79,80,115–118} The action of the sta-salt on quino-2,2'-cyanine was examined. In the study of an emulsion containing cubic AgBr microcrystals with dimensions $0.17\ \mu\text{m}$ subjected to gold and sulfur sensitisation, the sta-salt was demonstrated to cause a transformation of the J-band ($\lambda_{\text{max}} = 575\ \text{nm}$). At low concentrations of the sta-salt, this band is shifted to shorter wavelengths; an increase in the concentration of the sta-salt to $(2-5) \times 10^{-3}$ mol per mole of AgBr gives rise to two distinct absorption bands at $\lambda_{\text{max}_1} = 570\ \text{nm}$ and $\lambda_{\text{max}_2} = 580\ \text{nm}$; at the sta-salt concentration of $\geq (8-10) \times 10^{-3}$ mol per mole of AgBr, one J₂-band appears at longer wavelengths. However, the character of aggregation and the efficiency of supersensitisation substantially depend on the order of addition of the sta-salt and a dye. The action of the sta-salt was related^{115–118} to adsorption on surface defects, on which J-aggregation starts. Aggregation is suppressed by stabilisers belonging to heterocyclic thio derivatives (benzothiazole-2-thiol and 1-phenyltetrazole-5-thiol).¹¹⁹

The addition of various surfactants to emulsions causes changes in the absorption spectra of J-aggregating sensitizers.^{120,121} It was concluded that J-aggregates of anionic cyanine dyes are more stable against surfactants, which are used as precipitants of the solid phase, than those of cationic dyes.

The addition of colour-forming non-diffusing components (CNC) to an emulsion medium impairs J-aggregation of cationic cyanine dyes.^{77,78} This is attributed to desorption of the sensitizer from the surface of emulsion microcrystals. J-Aggregates of betaine dyes are even more stable against the desorption action of CNC; for these dyes, spectral sensitisation in the J-band is retained in the presence of CNC.⁷⁷ This fact was also noted by Lifshits and co-workers (see references in the publications^{77,78}), who demonstrated the stability of cyanine dyes against CNC to increase upon fusion of benzene and thiophene rings. The sensitising action of J-bands of benzimidacarbocyanines in the presence of CNC is enhanced by the Hal, CF₃, CN and CO₂R substituents in heterocyclic fragments. This may be associated with an increase in the strength of bonds in J-aggregates on AgHal microcrystals.

Bis-quaternary salts, in particular, benzimidazole derivatives,^{122–124} contrary to CNC, facilitate J-aggregation. In the presence of bis-quaternary salts, the J-band is shifted to longer wavelengths and its intensity slightly increases. Such changes were observed, for example, in the spectra of 3,3'-di(γ -sulfopropyl)-9-ethyl-4,5,4',5'-dibenzothiacarbocyanine betaine. An increase in the intensity of J-bands, including the appearance of J₂- and J₃-bands, was observed also for other carbocyanines, which show a weak tendency to form long-wavelength aggregates characterised by the highest photographic efficiency. According to the results of the study,¹²⁴ co-adsorption of dyes and bis-quaternary salts results in an increase in the strength of adsorption of polymethine dyes against the desorption action of CNC. The influence of bis-quaternary salts of α -picoline on J-aggregation of cyanine dyes was examined.^{125,126} The addition of a bis-quaternary salt of α -picoline at concentrations similar to the concentrations of the dye was demonstrated to enhance J-aggregation. This phenomenon is arbitrarily called catalysis of aggregation.

J-Aggregation is enhanced in the presence of inorganic I[−], CN[−] and SCN[−] anions.^{2,77,78} These anions form poorly soluble salts with Ag⁺ ions and, being located in the adsorption layer, provide prerequisites for a close packing of dyes, resulting in a substantial increase in aggregation adsorption. The influence of these anions on J-aggregation and photographic efficiency of thiamonomethinecyanines adsorbed on cubic AgCl microcrystals and planar AgBr(I) microcrystals was examined.¹²⁷ It was found that J-aggregates of thiamonomethinecyanines are formed in the presence of the I[−], CN[−] or SCN[−] ions and the efficiency of spectral sensitisation substantially increases. The most pronounced effect was observed in the presence of SCN[−].

In the presence of SCN[−], adsorption is increased and J-aggregation of thiamonomethinecyanines and oxa-, imida- and thiocarbocyanines on cubic AgCl microcrystals is enhanced.^{128–131} The factors responsible for the observed changes were revealed.¹²⁸ Electronic photographs of microcrystals of the starting emulsion and the emulsion treated with a KSCN solution were published. Surface etching occurs on microcrystals treated with rhodanide ions, and pronounced outgrowths are observed at the vertices and edges of AgCl cubes. An increase in the structure imperfection due to formation of a new phase (apparently, of AgSCN) is favourable for nucleation and growth of J-aggregates. This is accompanied by a substantial increase in the spectral sensitivity at the maximum of the J-band. The introduction of SCN[−] ions into an AgCl emulsion before the addition of a dye solution⁸³ is favourable also for J-aggregation of thiadicarbocyanine dyes, which serve as spectral sensitizers for the IR spectral region, thus substantially shifting the spectral sensitivity range to the IR region.

J-Aggregates consisting of two different dyes are of particular interest. It should be noted that data on such J-aggregates are scarce. The formation of mixed J-aggregates from two thiadicarbocyanine dyes having different structures was documented.¹³² Absorption spectra of photographic layers sensitised by individual thiadicarbocyanines and their composites are shown in Fig. 16*a*. Each dye forms its own J-aggregate. The simultaneous

Figure 16. Absorption spectra of photographic layers sensitised by 3,3'-diethyl-5,5'-dimethoxy-8,10-dimethylenethiacarbocyanine tosylate (1), the pyridinium salt of 3,3'-di(γ -sulfopropyl)-5,5'-dimethoxy-9-ethylthiacarbocyanine (2) and their composite (3) (a) and the spectrograms of the corresponding layers (b);¹³² D is the blackening density.

addition of equimolar concentrations of dyes to an emulsion gives rise to a new J-band (curve 3 in Fig. 16a), the intensities of the J-bands of individual dyes being decreased. The spectrograms obtained on the corresponding photographic layers (Fig. 16b) are clear evidence of the formation of a new photochemically active J-band, whose maximum is between the sensitisation maxima of the individual J-bands of two dyes. The principal conclusion¹³² was that the position of the sensitisation maximum can be varied over a wide range by changing the concentrations of dyes involved in mixed J-aggregates.

Mixed J-aggregates of thiocarbo- and thiadicarbocyanines were examined in the study.¹³³ The results are presented in Fig. 17. The method of formation of mixed J-aggregates allows the selection of J-aggregates. In this case, a new J-aggregate inherits the properties of the parent dyes. For example, mixed J-aggregates containing carbo- and dicarbocyanines combine the efficiency of carbocyanines with the spectral sensitisation zone in the IR spectral region characteristic of dicarbocyanines.¹³⁴ The formation of mixed J-aggregates from oxacarbocyanines having different structures was observed for the first time in the study.¹³⁵ The problem of supersensitisation in mixed J-aggregates of thiadicarbocyanine dyes was discussed.¹³⁶

In the studies,^{137,138} the possibility of the formation of mixed and heterocontact J-aggregates from thiadicarbocyanine and monomethinecyanine dyes both in an aqueous gelatine solution and on the surface of AgBr(I) crystals with (S + Au)-chemical sensitisation was examined. The structures and properties of

mixed J-aggregates formed on the surface of AgHal were studied.¹³⁹

From the aforesaid, the following conclusion can be drawn. Since J-aggregation of dyes occurs on the surface of AgHal microcrystals, the J-aggregation process often more substantially depends on the surface state than on changes in the structure of the dye. The surface state of microcrystals in an emulsion is determined primarily by their habit. It is known¹¹¹ that the (111) surface has a larger number of jogs and kink-sites, *i.e.*, it is more imperfect than the (100) surface. Hence, the (111) surface contains a larger number of sites with an excessive energy at which nucleation of J-aggregates can occur. Therefore, the nucleation of aggregates should occur more easily on the (111) surface. However, J-aggregation, like crystallisation, includes two steps, *viz.*, nucleation and crystal growth (growth of J-aggregates). Presumably, the subsequent growth of J-aggregates, which determines the position of the absorption maximum of the J-band, occurs more readily on the less imperfect (100) surface on which the smaller number of J-aggregates are nucleated. It is the contribution of these two steps that determines J-aggregation of a particular dye. If a dye is not prone to J-aggregation, nucleation more readily occurs on the (111) surface. However, an increase in the size of aggregates on this surface is unlikely. On the contrary, if a dye is prone to aggregation, nucleation does not limit the process and ordered J-structures more readily grow on the (100) surface of the crystal. Apparently, the different contributions of these processes to the formation of J-aggregates account for the seemingly contradictory published data on the ease of aggregation on the (111) and (100) surfaces.

Evidently, the charge state of the surface of AgHal microcrystals is determined by the concentrations of the Ag^+ and Hal^- ions in an emulsion. In the presence of an excess of Ag^+ , adsorption of molecules of certain dyes (particularly those containing sulfur atoms) on the surface is facilitated, which hinders J-aggregation. Compounds adsorbed on the surface of AgHal (surfactants, thio derivatives and various heterocyclic bases), particularly those which are capable of forming poorly soluble complexes and salts with silver ions, should play a great role. Apparently, stabilising and antifogging compounds and inorganic ions belong to this class.

Therefore, J-aggregation is determined not only by the molecular structure of dyes but also by parameters combined under the general name 'emulsion factors'.

3. Structures of dye aggregates adsorbed on AgHal microcrystals

The aggregate structures both in solution¹⁴⁰ and in crystals¹⁵ were studied in depth. It was noted that J-aggregation in solution is similar to crystallisation. In particular, two steps are distinguished: nucleation and aggregate growth.¹⁴¹

As mentioned above, dye molecules differ in the ability to form aggregates depending on their structure. In the general case, J-aggregation more readily occurs on the surface of solid phases than in solution. The numbers of monomeric fragments involved in J-aggregates of dyes in aqueous solutions were determined by different methods.^{3,16-18,20,142} The degree of polymerisation of aggregates can vary from 2 to 10^6 depending on the molecular structure of the dye and the method used for the determination. The main methods for the determination of the number of molecules in J-aggregates in solution were described in the publications.^{3,16,24}

In early studies, a knowledge of the structures of J-aggregates was based on X-ray diffraction data obtained by Hoppe¹⁴³ for aggregates of 2,2'-cyanine dyes. These results are as follows:

- individual dye molecules are extended parallel to each other;
- short axes of dye molecules are inclined to the axis of the aggregate; the deviation from the normal is 35° ;
- the normal distance between the molecules along the axis of the aggregate is $\sim 3.6 \text{ \AA}$.

Figure 17. Absorption spectra of photographic layers sensitised by the triethylammonium salt of 5,5'-dichloro-3,3'-di(γ -sulfopropyl)-9,11-(β , β -dimethyltrimethylene)-10-methylthiadicarbocyanine (1), the pyridinium salt of 3,3'-di(γ -sulfopropyl)-4,5,4',5'-dibenzo-9-ethylthiadicarbocyanine (2) and their composite (3) (a) and the spectrograms of the corresponding layers.¹³³

Figure 18. Models of structures of J- (*a*, *b*) and H-aggregates (*c*) of cyanine dyes.^{144, 145}

A slipped-deck-of-cards structure: a staircase structure (*a*) and a ladder structure (*b*).

In early studies, Scheibe *et al.*^{144, 145} proposed models for structures of J-aggregates as a slipped deck of cards, *viz.*, a staircase and a ladder, with consideration for the results obtained by Hoppe (Fig. 18 *a, b*). The authors reached a conclusion that dye cations are adsorbed on edges of AgHal in close-packed monolayers. Based on the degree of light polarisation in absorption bands of quino-2,2'-monomethinecyanine aggregates on freshly cleaved mica crystals, the angle α between the plane of the molecules and the axis of the aggregate was estimated as $\sim 55^\circ$. At the same time, the plane of the molecule in the structure of H-aggregates (a hypsochromic shift) is perpendicular (in the authors' opinion) to the axis of the aggregate (Fig. 18 *c*).

The above-considered structures of J-aggregates were generally accepted until the late 1960s. Bird and co-workers³³ refined the basic staircase structure proposed by Scheibe with the use of the point-dipole theory. These results contribute to the development of an idea, according to which the main structures of H- and J-aggregates are, in principle, identical. However, $\alpha < 54^\circ 44'$ in J-aggregates and $\alpha > 54^\circ 44'$ in H-aggregates. The initial version of the point-dipole theory was inapplicable to precise quantitative calculations of J-aggregates. Hence, this theory was improved based on the quantum-chemical model of interactions between molecules in aggregates taking into account electron cloud overlap (an electron gas model). This theory was applied to large aggregates of various dyes, and, although the results of calculations were inaccurate, they allowed one to obtain correct orders of the angles.

Presumably, aggregates of cyanine dyes in solution differ from those adsorbed on a substrate in that the structure of adsorbed aggregate is related to the crystal lattice structure of the adsorbent and molecules in adsorbed aggregates are packed less closely than in solution. This is evidenced by the results of spectroscopic studies. J-Aggregates of the same dye give a narrower J-band in solution compared to that in the adsorbed state. Apparently, this is associated with the affinity of particular fragments of cyanine dye molecules for local regions of the surface of AgHal.⁹³

Bird and co-workers^{146–148} applied an improved point-dipole model to a specific case of benzothiazole dyes on an AgBr substrate. Circular dichroism measurements of adsorbed J-aggregates demonstrated that dye molecules are oriented in a particular fashion on different faces of AgBr microcrystals.¹⁴⁷ It was postulated^{146, 147} that the long axis of the dye molecules in aggregates is oriented predominantly on the surface of microcrystals along the [110] direction. In this case, rows of Ag^+ ions on the surface of a cube are at a distance of 4.08 Å, whereas rows on the surface of an octahedron are at a distance of 3.54 Å, *i.e.*, at a distance similar to the standard intermolecular distance in the graphite lattice (3.4 Å) found²⁰ for the packing of planar aromatic molecules. Bird suggested that chemisorption of dyes is accompanied by the formation of bonds between the Ag^+ ions of the AgBr lattice and the sulfur atoms of the benzothiazole moieties of the molecules, which form a structure of a slipped-deck-of-cards type and are adsorbed so that the sulfur atoms are oriented toward the surface of microcrystals and the NR groups border the solution. As a consequence, the formation of particular aggregate structures of dye molecules with a lateral shift by 3, 2, 1 or 0 ionic

radii can be formed on the octahedral surface. An application of this chemisorption model to cubic microcrystals presents certain difficulties.

The slip angles of dye molecules along the aggregate axis (z) in the structures formed on the octahedral surface are 19, 30, 60 and 90° . According to Bird's theory, the slip angles of 90 and 60° corresponding to Scheibe's staircase structures are assigned to H-aggregates; the slip angles of 30 and 19° , to J-aggregates. These angles are well consistent with the spectral shifts of absorption bands of aggregates.²⁰ The results of calculations performed within the framework of the molecular-exciton theory¹⁴⁹ confirmed the aggregate structures for thiocarbocyanine and its homologue. The largest bathochromic shift for linear J-aggregates corresponds to the angle of 19° between the long molecular axis of the dye and the axis of a J-aggregate.

The same slip angles ($90, 60, 30$ and 19°) were expected along the [110] direction on the (111) surface of AgCl. However, in this case the dye molecules should be located closer to each other than along the [110] direction on the octahedral surface of AgBr, because the rows of ions along the [110] direction on AgCl are located at a distance of 3.4 Å.

The researchers encountered obstacles when generalising Bird's model to the (100) surface of cubic AgBr, because the distance between the rows of silver ions along the [110] direction is larger (4.08 Å) than the graphite-like distance for aromatic structures. Bird proposed a model,¹⁵⁰ in which the assumed $\text{Ag}^+ \cdots \text{S}$ bond is deformed and, hence, the angle between the long axis of the dye molecules and the [110] direction is 24.4° . Smith demonstrated¹⁵¹ that a rotation of the molecule by only 5° is necessary for the aggregate structure to be identical to that present on the (111) surface; however, the angle α is equal to 21.7° .

A study of the aggregate structures of some sensitising dyes adsorbed on AgI, AgBr or AgCl by electron diffraction demonstrated²⁰ that the 1,1'-diethyl-2,2'-cyanine and 3,3',9-trimethylthiocarbocyanine molecules are inclined to the surface of AgHal, and the inclination angle depends on the nature of Hal^- . It was concluded²⁰ that the molecules are arranged in a regular fashion corresponding to strong adsorption forces. If adsorption forces are weak, the aggregate structure is disordered.

Based on the data on aggregation of thia- and oxacarbocyanines and taking into account the steric factors, it was concluded^{20, 152, 153} that the formation of the epitaxial $\text{Ag}^+ \cdots \text{S}$ bond proposed by Bird is highly improbable and this bond is of secondary importance in adsorption. The sizes of dye molecules do not necessarily correspond to the crystal lattice parameters of silver halide. The distances between the rows of molecules and the slip angles in the aggregates are determined by the molecular geometry and intermolecular interaction forces rather than by chemisorption forces, which, in turn, depend on the structure of dyes (the nature of heterocycles and substituents both in the chain and heterocycles and the length of the polymethine chain).

A model of physical adsorption of dyes on the surface of silver halide was proposed.¹⁵⁴ The adsorption is considered as a function of the crystallographic lattice parameters of AgHal. In the studies,^{147, 154} the adsorption of dyes was considered taking into account that the ideal (111) and (100) surfaces do not exist because of Coulombic restrictions. It is known that such surfaces contain a large number of steps parallel to the [110] direction. The orientation of the molecules of aggregated cyanine dyes formed upon adsorption is determined by the presence of steps on the surface of AgBr microcrystals. The rate of J-aggregation of pseudocyanine was higher on a larger number of defect sites of the (111) surface. The average size of J-aggregates is smaller and absorption occurs at shorter wavelengths compared to those on the (100) surface and other surfaces. The dichroism was studied as a function of the deviation of the growth direction of a dye aggregate *vs.* the [110] direction and as a function of the deviation of the real crystal surface from the perfect surface. The orientation of J-aggregates of pseudocyanine along the [110] direction was preferable. However, this tendency was not revealed for other eleven known thia-

oxa- and imidacarbocyanines. Presumably, a complex variation of the arrangement of the dye molecules on the surface steps with different *hkl* indices vs. the dye structure and the absence of a pronounced orientation along the [110] direction are evidence that chemisorption plays an insignificant role.

Maskasky¹⁵⁵ also cast doubt on the occurrence of chemisorption in the case of aggregation of oxa- and imidacarbocyanines on cubic and planar AgCl and AgBr microcrystals. The orientation of J-aggregates on AgCl along the [110] and [100] directions studied by low-temperature luminescence microscopy remained unexplained within the framework of the theory of chemisorption. It was hypothesised that J-aggregates are located along surface defects of microcrystals (surface steps).

It was established that chemical bonding and Coulombic attraction make a particular contribution to aggregation of most dyes. However, van der Waals forces between a polarisable substrate and delocalised π -electrons of dyes contribute the most to adsorption.³ This accounts for the fact that the heats of adsorption of cyanines on more polarisable AgBr and AgI are higher than that on AgCl.^{156, 157} However, the model of chemisorption appeared to be useful in considering certain problems of spectral sensitisation, such as the dependence of absorption spectra of adsorbed dyes on the habit and halide composition of microcrystals,^{98, 147, 148, 158} the mechanism of supersensitisation,⁶ the influence of substituents in the chromophore chain on the spectral shifts and the relationship between the structure of aggregates and their adsorption.^{90, 146–148, 159–161}

Taking into account the model of chemisorption, Reich²⁷ explained the observed two-band spectrum in the case of adsorption of 3,3'-bis(β -carboxyethyl)-5,5'-dichlorothiarcobocyanine on AgBr and AgCl microcrystals. He proposed a model of J-aggregates consisting of two non-parallel stacks of dye molecules, in which one stack is adsorbed along the [110] direction of AgHal microcrystals, whereas another stack is adsorbed along the [101] direction to form a herringbone structure (see Fig. 5*b*). The results of calculations of the energy splitting in electronic spectra of aggregates are consistent with the experimental data for a herringbone structure with $\alpha = 30^\circ$ within each stack for an octahedral surface and with $\alpha = 35^\circ 5'$ for a cubic surface (the spectra contain broad bands in the visible spectral region).

Adsorption isotherms were used in early studies of aggregation. However, it is known that these isotherms do not allow one to establish unambiguously whether dyes are adsorbed as individual molecules or aggregates. This problem can be solved only by comparing adsorption isotherms and reflection spectra.^{3, 20, 159} The initial weak rise of adsorption isotherms up to an inflection point for carbocyanines of the type

X = S, Se, NR, CH=CH, O; A[−] — counterion;
R¹–R³ — substituents.

is accounted for by the fact that the molecules are initially adsorbed on the microcrystal surface by their planes. Further adsorption results in that the dye molecules take edgewise orientation and form a monomolecular layer of a close-packed aggregate, which is accompanied by the appearance of an inflection point in the isotherm.¹⁰³ Another explanation is that the dye molecules are adsorbed on the long edge of the molecule perpendicular to the microcrystal surface even at low concentrations, but the molecules are disordered. An increase in the dye concentration gives rise to larger ordered aggregates.

Based on the results of investigation of the shifts of spectral absorption bands and their comparison with the shifts calculated by a quantum chemical method, Kuhn and co-workers^{22, 162, 163} proposed a generalised two-dimensional model of a brickwork

arrangement of dye monomers (see Fig. 5*a*). In the case of a two-dimensional aggregate structure and the appropriate angle α , one type of aggregates can be transformed into another type (H-aggregates are transformed into J-aggregates with decreasing α and *vice versa*). A quantitative examination of X-ray spectra¹⁶⁴ of *meso*-alkyl-substituted thiarcobocyanines revealed the existence of J-aggregates formed in a brickwork fashion from sandwich dimers, which consist of monomers with the oppositely directed *meso*-alkyl groups.

It is rather difficult to determine the degree of polymerisation in the case of formation of adsorbed J-aggregates. It is hardly correct to extrapolate large self-association numbers for dyes in solution (an order of 10²) to adsorbed J-aggregates, because the properties of aggregates depend only slightly on the number of molecules in the aggregates if the self-association number is rather large. A reasonable conclusion is that the number of molecules in aggregates is small and the lower limit for the size of J-aggregates corresponds to the ratio of the sensitizer concentration to the supersensitizer concentration in mixed aggregates, at which the J-band of a supersensitizer disappears. According to estimates, J-aggregates of a pseudocyanine should contain at least three molecules. It is known that adsorbed dyes form several aggregates, which substantially differ in absorption and position of the energy levels.^{115–118}

Tani *et al.*^{165–168} made an attempt to determine the number of molecules in J-aggregates of *meso*-ethyl-substituted thiarcobocyanine by a spectroscopic method from the ratio of the half-widths of absorption bands of the monomer to those of an adsorbed J-aggregate of the dye. The calculated numbers of the molecules vary from 5 to 15. Studies by the desorption method demonstrated¹⁶⁹ that J-aggregates of thiarcobocyanine on the (111) surface included 10–37 molecules; on the (100) surface, 34–53 molecules.

In the studies,^{129–131} the sizes of J-aggregates of thiamonomethinecyanines¹²⁹ and oxa-, imida- (see Ref. 130) and thiarcobocyanines¹³¹ in an AgCl emulsion containing cubic microcrystals were estimated from the ratio of the half-widths of absorption bands of the monomers to those of adsorbed J-aggregates of the dyes. The calculated numbers of the molecules were 2–7, 3–4, 6–27 and 6–12 for thiarcocyanines, oxacarbocyanines, imidacarbocyanines and thiarcobocyanines, respectively.

Recently, due to an improvement of experimental technique, it has become possible to study the sizes of J-aggregates by direct observation using atomic force microscopy (AFM). It was found¹⁷⁰ that molecules of triethylammonium salt of 3,3'-di(γ -sulfopropyl)-5,6,5',6'-dibenzo-9-ethylloxacarbocyanine and sodium salt of 5,5'-dichloro-3,3'-di(γ -sulfopropyl)-9-ethylthiarcobocyanine form linear rows along the [210] direction on the surface of cubic AgBr microcrystals. These rows of J-aggregates form larger structures, *viz.*, columns with sizes from 20 × 60 to 30 × 60 nm,² the macrostructures of J-aggregates of oxacarbocyanine being longer than those of J-aggregates of thiarcobocyanine.

The structure of J-aggregates of quino-2,2'-cyanine on the surface of cubic AgBr microcrystals was also studied by this method.¹⁷¹ The dye molecules in a two-dimensional packing of J-aggregates are inclined at an angle of 10° to the [010] direction. The supramolecular structure of thiarcobocyanines on AgBr was studied by AFM.^{172–174} The differences in the molecular packing of H- and J-aggregates were clearly seen depending on the dye structure. Brickwork- and herringbone-type structures of aggregates were observed for the first time. The brickwork and herringbone structures of H-aggregates are shown in Fig. 19. This figure also shows a model reconstruction of thiarcobocyanine aggregates. Therefore, different aggregate structures, which have been considered earlier in the literature, were confirmed by experimental methods for the first time.

The sizes of columns of J-aggregates determined by AFM agree well with the results of investigation of these aggregates by analytical colour fluorescence electron microscopy (ACFEM).

Figure 19. Structures of aggregates of thiocarbocyanine dyes determined by the AFM method;¹⁷³

(a) an H-aggregate of 5,5'-dichloro-3,3'-diethyl-9-methylthiocarbocyanine tosylate, an image area is $5.6 \times 5.6 \text{ nm}^2$; (b) a brickwork structure of 5,5'-dichloro-3,3'-diethyl-9-ethylthiocarbocyanine tosylate, an image area is $3.6 \times 4.2 \text{ nm}^2$; (c) a herringbone structure of 3,3'-dimethyl-4,5,4',5'-dibenzo-9-methylthiocarbocyanine tosylate, an image area is $4.1 \times 4.5 \text{ nm}^2$.

Studies by ACFEM demonstrated¹⁷⁵ that the dimensions of columns depend on the nature of the dye. The size distribution of J-aggregates of oxa- and thiocarbocyanines depending on the location of J-aggregates on the (100) face of AgBr was also studied by ACFEM.¹⁷⁶ It was found that large J-aggregates are predominantly formed in zones bordering the vertices of microcrystals; large and small J-aggregates, in zones bordering the edges; small J-aggregates, in the middle region of the face. The sizes of aggregates were determined in pixels (1 pixel = $3.3 \times 4.1 \text{ nm}^2$). The sizes of large, medium and small aggregates were 5–6, 3–4 and 1–2 pixels, respectively. J-Aggregates of cyanine dyes on AgBr microcrystals were also studied by ACFEM.¹⁷⁷ The surface area of J-aggregates was $\sim 30 \times 70 \text{ nm}^2$. The size of J-aggregates increased without change in their number with increasing amount of the adsorbed dye. It was demonstrated that aggregates on the surface of cubic AgBr are extended along the [110] or [210] direction.

The ACFEM method was used to study J-aggregation and the orientation of quino-2,2'-cyanine and oxacarbocyanine on the

(100) and (111) surfaces of cuboctahedral AgBr microcrystals.¹⁷⁸ It was found that the luminescence colour of J-aggregates changes under the action of the electron flux during measurements. No differences in luminescence on the (100) and (111) surfaces were revealed. The formation of J-aggregates on different faces of AgHal was revealed from luminescence studies.^{178, 179} J-Aggregation of thia- and indocarbocyanine dyes on cubic and planar AgBr microcrystals was investigated by ACFEM.¹⁸⁰ Based on the results of this investigation, it was concluded that the sizes of J-aggregates of 5-substituted thiocarbocyanines on cubic microcrystals are larger than those of unsubstituted dyes. It was noted that an increase in the sizes of J-aggregates of dyes with time occurs according to the mechanism of Ostwald ripening.

Thus, the structures of J-aggregates in solution and the structures of aggregates adsorbed on the surface of AgHal were studied in depth. The main structures of J-aggregates of cyanine dyes were calculated and determined experimentally. J-Aggregates were demonstrated to be highly organised and their structures are determined by the geometry of the dye molecules, the surface of AgHal microcrystals and the surface concentration of the dye. However, due to a complexity of photographic systems, the aggregate structures formed in a particular photographic emulsion cannot always be determined with high precision. Nowadays, it is impossible to take into account, in full measure, all various interrelating factors in real emulsion systems, the role of the dye structure, the method of the addition of the dye to photographic emulsions, the role of supersensitisers and aggregating additives and the surface state of microcrystals. Nevertheless, the main factors responsible for J-aggregation, which can be used to initiate the formation and control the growth of J-aggregates, were revealed. It is impossible to control these processes without knowledge of the surface state of AgHal emulsion microcrystals.

4. Energy levels of aggregated forms of dyes

The positions of the energy levels of aggregates responsible for their physicochemical properties depend primarily on the electronic structures of individual dye molecules and the mutual geometric arrangement of the molecules in aggregates.

Two π -electrons are located in the highest occupied molecular orbital (HOMO) of a monomeric dye in the ground state. Absorption of a light quantum by a dye without a change in the spin leads to excitation of one π -electron from HOMO to the lowest unoccupied molecular orbital (LUMO) and the molecule is converted into the first excited singlet state (Dy^*). The energy of transition from the ground state to the first excited singlet state is equal to the energy difference between LUMO and HOMO. The positions of the energy levels of LUMO (ϵ_{LUMO}) and HOMO (ϵ_{HOMO}) relative to the electron bands of AgHal determine the efficiency of spectral sensitisation by a dye.^{2, 3}

The positions of the energy levels of organic dyes can be found experimentally and calculated by quantum chemical methods. Since it is difficult to determine the energy levels of dyes adsorbed on AgHal by experimental methods,³ quantum chemical methods have gained wide acceptance.

First attempts to relate the energy levels (calculated by the Hückel method) of the simplest cyanines to their photographic efficiency were made in the studies.^{181, 182} More recently, systematic studies by Tani and Kikuchi^{183, 184} and Sturmer and Gaugh^{185, 186} were published. The charge distributions in molecules were calculated by semiempirical all-valence-electron methods at the CNDO/2 level and by the Pariser–Parr–Pople method.^{187, 188} These methods give satisfactory estimates for the energies of spectral transitions, charge distributions, dipole moments, redox potentials and $\text{p}K_{\text{a}}$ of dyes. When studying the excited state, Forster¹⁸⁹ provided a qualitative verification of the spectra of cyanine dyes based on the selection rules for electron transitions. The calculated data were summarised by Kachkovskii.^{14, 190}

According to experimental data, the ionisation energies are 4.4–5.9 eV,^{191, 192} and the electron affinities are 3.0–3.3 eV.¹⁹³

Experimental methods for the determination of ionisation potentials and electron affinities, which characterise the ground and excited states of adsorbed dyes, are very complicated and give ambiguous results. Electrochemical methods for the determination of reduction and oxidation potentials have gained wide acceptance. These potentials correlate with $\varepsilon_{\text{LUMO}}$ and $\varepsilon_{\text{HOMO}}$, respectively.^{3, 6, 20} The polarographic half-wave reduction ($E_{1/2}^{\text{red}}$) and oxidation ($E_{1/2}^{\text{ox}}$) potentials of dyes in solution are generally measured. These potentials correlate with $\varepsilon_{\text{LUMO}}$ and $\varepsilon_{\text{HOMO}}$, respectively. The polarographic potentials for different types of dyes vary in the following ranges: $E_{1/2}^{\text{red}}$ from -0.6 to -2.2 V and $E_{1/2}^{\text{ox}}$ from 0.2 to 1.3 V (relative to a saturated silver chloride electrode).^{186, 192}

Adsorption of individual dye molecules on AgHal leads to changes in the positions of $\varepsilon_{\text{LUMO}}$ and $\varepsilon_{\text{HOMO}}$ because the energy levels of dyes are subjected to the perturbing action of surface defects of the substrate and impurity centres. Sets of values rather than one value are typical of $\varepsilon_{\text{LUMO}}$ and $\varepsilon_{\text{HOMO}}$ of adsorbed dyes.^{194, 195} Consequently, the mean potentials are dealt with. Therefore, the use of polarographic potentials, which are thermodynamic (*i.e.*, mean) values, is quite justified.

Taking into account aggregation, which also leads to changes in the positions of the energy levels, the situation is complicated. Evidently, the positions of the levels $\varepsilon_{\text{LUMO}}$ and $\varepsilon_{\text{HOMO}}$ of an aggregated dye relative to the conduction and valence bands of AgHal are of most importance for spectral sensitisation. Calculations of $\varepsilon_{\text{LUMO}}$ and $\varepsilon_{\text{HOMO}}$ of aggregates present considerable difficulties because it is necessary to take into account a combination of molecules characterised by a particular electron density distribution, the mutual orientation of the molecules and the influence of the substrate. Hence, the results of all calculations are approximate.

The molecular-exciton theory in the point-dipole approximation gives qualitative estimates of the shifts of the maxima in absorption spectra of J-aggregates with respect to the position of the maximum in the spectrum of the monomer depending on the intermolecular distance in the aggregate, the number of monomers in the aggregate and the packing angle.^{33, 93} When studying the spectroscopic characteristics of J-aggregates, Kuhn and co-workers^{22, 162, 163} developed a perturbation method based on the Schrödinger equation in the π -electron approximation. The calculations adequately reproduce the bathochromic shifts of absorption bands for one- and two-dimensional brickwork arrangements of molecules.

The energy change in an aggregate depending on the angle α was estimated by the Pariser–Parr–Pople method.^{196–198} It was demonstrated that there is a complex correlation between the energy change and the spectral shift. The plot of the energy of the spectral transition has a pronounced minimum at acute angles α for all dyes (Fig. 20). The angle α at the minimum energy of the spectral transition is $\sim 29^\circ$, $\sim 24^\circ$ and $\sim 21^\circ$ for tri-, penta- and heptamethinecyanines, respectively. For thia-, oxa- and imidacar-

Figure 20. Plot of the energy of the spectral transition *vs.* the packing angle of molecules in J-aggregates for thia-, oxa- and imidacarbocyanines and quino-2,2'-carbocyanine.¹⁹⁸

The angle α at the minimum energy is $19 \pm 2^\circ$.

bocyanines and pinacyanol, the angle α is $19 \pm 2^\circ$; for pyridocarbocyanine, $22 \pm 2^\circ$.¹⁹⁸

Calculations for narrow J-bands are generally performed with the use of a statistical exciton model,^{199–208} according to which the random disorder in the environment is averaged by a moving Frenkel exciton in a J-aggregate. In terms of this model, the electronic structure of isolated polymethine dye molecules involved in J-aggregates is ignored. Egorov^{209–212} reduced the problem of electronic excitation of an aggregate to the problem of an elementary electron transfer, which provided an insight into the nature of the J-band.

The determination of the energy levels of J-aggregates by experimental methods presents considerable difficulties. In the review by Dietz,²¹³ the results of investigations of the energy levels in dye aggregates and the methods for their determination were generalised and analysed. The ionisation potentials, electron affinities and basicities were considered. The difficulties in measuring the redox potentials of dyes adsorbed on silver halide microcrystals were mentioned. It was concluded that the validity of the extrapolation of the polarographic half-wave potentials, which were measured in solution, to adsorbed dyes is not evident.

Nelson^{214–216} determined the ionisation energy of pinacyanol adsorbed on CdS as an aggregate. This energy is ~ 4.5 eV, which is comparable with the ionisation potential of the monomeric form. For some cyanine dyes, the ionisation potentials remain virtually constant ($5 \text{ eV} \pm 4\%$). Dyes differ in the length of the polymethine chain and the nature of heterocyclic groups. Taking into account a small difference in the experimental values, it was concluded that the level $\varepsilon_{\text{HOMO}}$ changes only slightly upon J-aggregation.

In the review by Dietz,²¹³ considerable attention was given to investigations of the luminescent properties of adsorbed polymethine dye J-aggregates, which are important for the determination of the energy levels of aggregated dyes. It is commonly accepted that luminescence of aggregates on a substrate is due to bimolecular electron–hole recombination. Usual resonance fluorescence excited in the J-band is observed for adsorbed J-aggregates. Luminescence of J-aggregates and dimers can be explained in terms of the exciton theory of splitting of the excited states due to aggregation.²⁰ Fluorescence quenching is caused by poly- and monophenols and OH^- ions. The degree of polymerisation of dyes in J-aggregates can be estimated by mathematical processing of fluorescence data.

Cooper demonstrated^{217, 218} that two bands appear in low-temperature fluorescence spectra of quino-2,2'-cyanines in solution and emulsions. These bands correspond to allowed bands of J-aggregates in the absorption spectrum with maxima at $\lambda_{\text{max}1} = 570.5$ nm and $\lambda_{\text{max}2} = 575$ nm. Based on a comparison of the intensities of resonance fluorescence of two aggregates adsorbed on a chemically sensitised AgBr emulsion, Cooper concluded that the electron transition to the conduction band of AgBr from photoexcited J₂-aggregates is more efficient than from J₁-aggregates because the latter have a more intense fluorescence band, while the intensity of the adsorption band is lower. Measurements of the microwave photoconductivity of photographic layers performed by Kellogg *et al.*²¹⁹ confirmed this fact. It was demonstrated that the low efficiency of fluorescence of J₂-aggregates corresponds to the higher efficiency of the formation of electrons in the conduction band in an AgBr emulsion. Due to the presence of impurities, the intensities of two bands change in a different way. The intensity at shorter wavelengths decreases more substantially than that at longer wavelengths. It is assumed that the difference in the photographic activity of these aggregates is associated primarily with the difference in the arrangement of molecules in J-aggregates rather than with the change in the number of molecules in the aggregates.

Based on a comparison of the results obtained in photographic studies of supersensitisation of quino-2,2'-cyanine J₁- and J₂-aggregates upon the addition of oxathiocarbocyanines with different $E_{1/2}^{\text{ox}}$ (from 0.54 to 0.98 V *vs.* SCE) and upon fluorescence

quenching in supersensitised aggregates, it was concluded^{115–118,220} that the difference in ϵ_{HOMO} for J₁- and J₂-aggregates and the positions of ϵ_{LUMO} in these aggregates relative to each other and relative to the conduction band of AgBr can be rather precisely estimated by combining these methods. An analysis of the dependence of the supersensitisation coefficient on $E_{1/2}^{\text{ox}}$ of the supersensitiser demonstrated that the position of ϵ_{HOMO} for J₂-aggregates can be estimated on the electrochemical potential scale at 0.8 V (vs. SCE), whereas the level of ϵ_{HOMO} of J₁-aggregates is lower. Fluorescence of J₁- and J₂-aggregates at 77 K is excited both in the absorption region of the dye (500–530 nm) and in the main absorption region of AgBr (337 nm). This implies that the levels of S_1 (ϵ_{LUMO}) of aggregates are lower than the conduction band bottom of AgBr. The triplet states of dyes change only slightly upon aggregation,²¹³ and the splitting of the triplet levels upon dimerisation and polymerisation is small.³⁴

In studies by Sviridov and co-workers,^{221–223} the changes in the positions of the energy levels of dyes upon J-aggregation were estimated by photochemical oxidation of poly- and monomolecular forms of carbocyanine dyes on the surface of WO₃ films. It was demonstrated that aggregates act as reducing agents for the monomeric form in oxidation of thiocarbocyanine dyes, whereas nonaggregated dyes serve as a reducing agent in the case of imidacarbocyanines. Therefore, the level ϵ_{HOMO} of thiocarbocyanines increases upon aggregation, whereas the level ϵ_{HOMO} of imidacarbocyanines decreases. For oxacarbocyanines, the levels ϵ_{HOMO} of J-aggregates also increase. An increase in the energy levels ϵ_{HOMO} of thiocarbocyanine J-aggregates compared to the energies of the occupied electronic levels of monomers was observed by Kawasaki *et al.*,^{224–226} who used electrochemical oxidation. In the case of J-aggregation, the oxidation potential becomes more negative (by ~ 0.2 V).

Cramp *et al.*,^{227,228} and Ehrlich²²⁹ were the first to study cyanine dye aggregates by flash photolysis. Chibisov *et al.*,^{230,231} employed flash photolysis to study the positions of the energy levels of dyes in J-aggregates. It was demonstrated that excitation of dyes to the J-band is accompanied by ‘whitening’ of this band and the formation of induced short-wavelengths absorption bands belonging to radical dications of dyes followed by band relaxation of J-aggregates. The relaxation rate correlates with $E_{1/2}^{\text{ox}}$ of dyes. Therefore, ϵ_{HOMO} for J-aggregates of different dyes can be related to $E_{1/2}^{\text{ox}}$.

Lenhard and Hein^{232,233} performed experimental studies on the changes in the positions of the energy levels (the redox potentials) for J-aggregation of thiadicarbocyanine containing a bridging substituent in the chain. The aggregation state of the dye was varied by introducing a deaggregating agent. An energy level diagram was constructed. According to this diagram, aggregation of thiadicarbocyanine leads to only a weak change in ϵ_{HOMO} , and the level ϵ_{LUMO} decreases by 0.32 eV.

In conclusion, let us note that substantial changes in the positions of the levels ϵ_{HOMO} and ϵ_{LUMO} upon aggregated adsorption (by about 0.2–0.3 eV) explain to a large extent the behaviour of cyanine dye J-aggregates as either sensitisers or desensitisers of silver halides. Hence, to predict and verify the methods for intensification of spectral sensitisation, it is important to know the positions of the energy levels of J-aggregates.

5. Mechanism of the photographic action of dye aggregates

In the pioneering studies performed by Spence and Carroll²³⁴ as well as by West and Carroll,²³⁵ the photochemical activity of dyes was quantitatively estimated and the molecular state was demonstrated to be photochemically active. More recently, Natanson and Klimzo^{4,5} found that the photochemical activity of J-aggregates generally increases as the corresponding band is shifted to longer wavelengths, and the activity of H-bands decreases as the band is shifted to shorter wavelengths. It should be noted that the photochemical activity of J-aggregates of well-aggregating dyes is higher than the activity of the molecular state. As a rule, the

sensitising ability of J-aggregates characterised by a narrow band is higher than that of J-aggregates with a broad band.⁴

If J-aggregates are formed on the surface of AgHal microcrystals only at rather high dye concentrations, these aggregates were demonstrated^{4,5} to be photographically less active than monomers. The lower photochemical activity of J-aggregates of some sensitising dyes compared to that of dyes in the M-state is attributed to a higher probability of secondary dye desensitisation and self-desensitisation competing with the formation of a latent photographic image.^{6,80}

Processes responsible for desensitisation lead to a decrease in the intrinsic light sensitivity of photographic emulsion layers. Photoexcitation of dyes also causes desensitisation. This process is referred to as dye self-desensitisation.^{3,6} The difference between dye desensitisation and self-desensitisation is related to the differences in the photoprocesses upon photoexcitation of AgHal and dyes.^{6,236} As a rule, a decrease in the light sensitivity due to self-desensitisation is more pronounced in the region of additional light sensitivity compared to the intrinsic light sensitivity.^{6,236}

Aggregated forms of dyes are characterised by self-desensitisation according to the hole mechanism (type II dye self-desensitisation):⁶ recombination of dye holes and photoelectrons trapped on the surface of AgHal microcrystals. These processes are most typical of dye J-aggregates, in which holes are translated to considerable distances. The type II desensitisation process, unlike type II self-desensitisation, involves a larger number of steps (Fig. 21).⁶ Photoexcitation of AgHal can result in that some holes are trapped on the surface of AgHal microcrystals by the dye to form dye holes and some holes can be trapped by hole-acceptor impurity centres (see Fig. 21a). The type II self-desensitisation process is, apparently, simpler because dye holes inevitably appear upon spectral sensitisation, *i.e.*, in the case of electron transfer from Dy* to AgHal (see Fig. 21b). Therefore, the number of dye holes can be larger. Hence, the probability of self-desensitisation can be higher than the probability of desensitisation and, as a consequence, its influence on spectral sensitivity can be larger than the influence of desensitisation on intrinsic light sensitivity. It should be noted that if the level ϵ_{HOMO} of a dye is lower than or

Figure 21. Schemes of desensitisation (a) and type II self-desensitisation (b).¹¹⁸

IC_e is an impurity site as an electron acceptor; IC_p is an impurity site as a hole acceptor; e is a photoelectron; p is a photohole; $h\nu$ is a light quantum absorbed by AgHal; $h\nu_{\text{Dy}}$ is a light quantum absorbed by a dye.

close to the valence band top of AgHal, the dye holes can be injected directly to the valence band.

As opposed to type I desensitisation and self-desensitisation according to the electron-acceptor mechanism, no clear dependence for type II desensitisation and self-desensitisation on the polarographic half-wave oxidation potential $E_{1/2}^{\text{ox}}$, *i.e.*, the potential of a dye hole, was found.^{79, 80, 237} Moreover, structurally similar dyes, which form J-aggregates showing similar absorption maxima and having virtually equal $E_{1/2}^{\text{ox}}$, can differ substantially in the desensitising ability and efficiency of spectral sensitisation.^{6, 80}

In the studies,^{6, 79, 80} the efficiency of type II self-desensitisation was related not only to the energy factor but primarily to the kinetic factor. According to the modern views, sulfite sensitisation affords the $(\text{Ag}_2\text{S})_n$ clusters formed at surface defects of AgHal. Silver sulfide clusters form impurity centres, which exhibit properties of either electron acceptors (IC_e) or hole acceptors (IC_p) depending on n , the charge and the location site. Spectral sensitizer molecules are also adsorbed on the surface of AgHal, the molecules being partially self-organised to form rather elongated J-aggregates. According to the kinetic model of desensitisation,^{6, 79, 80} type II desensitisation and, particularly, self-desensitisation, should substantially depend on the spatial arrangement of the dye aggregates and the recombination centres at which photoelectrons are located. The rate constant of desensitisation (recombination) according to the hole mechanism (k_d) can be described by the equation

$$k_d = A_d \exp\left(-\frac{\alpha \Delta E^\circ}{RT}\right), \quad (3)$$

where A_d is the frequency factor, α is the coefficient and ΔE° is the electrochemical potential difference between the dye hole and the electron trapped by an impurity centre on the surface of AgHal

$$\Delta E^\circ = E_{1/2}^{\text{ox}} - E_{\text{IC}_e}^\circ.$$

It should be noted that the rate constant of recombination for organised systems of J-aggregates, unlike stochastic systems in which a dye exists in the molecular state, is more dependent on the frequency factor A_d than on the energy factor (ΔE°). The frequency factor is a function of the distance r between the J-aggregate and the electron-acceptor impurity centre.

If the transfer of a dye hole to IC_e occurs without the involvement of the valence band of AgHal on the surface across the tunnel junctions under a barrier with a width r , then

$$A_d \approx \exp(-r),$$

i.e., the frequency factor strongly depends on r . In addition, this factor is related to the mobility (μ) of dye holes within the aggregate. The latter is determined by the structure of the J-aggregate, primarily, by the interplanar distance between the dye molecules in the aggregate and the packing angle. Consequently,⁶

$$A_d = f(\mu, r).$$

If self-organisation of dye molecules in J-aggregates is hindered, it starts at surface defects of AgHal, including impurity centres, *viz.*, chemical sensitisation products (Fig. 22 *a*). Due to a contact between J-aggregates and IC_e ($r \rightarrow 0$), the frequency factor and the recombination rate increase, which is manifested as a considerable dye self-desensitisation. On the contrary, if J-aggregation readily occurs and aggregates can be formed not only at defects of AgHal but also at other sites, the probability of contacts between the aggregates and IC_e decreases, the distance r increases (Fig. 22 *b*) and, as a consequence, the recombination rate decreases. Apparently, the difference in the photographic properties of dyes similar in the structure and energy levels is associated with the topography of aggregates formed on the surface of AgHal. Let us note once again that the probability of type II self-desensitisation, which depends on the dye structure, the habit of AgHal microcrystals, pAg and other factors, can be

Figure 22. Schemes of self-desensitisation of J-aggregates of dyes (*a*, *b*) and supersensitisation according to the 'isolation' mechanism (*c*).

substantially higher than the probability of desensitisation. Hence, self-desensitisation can to a large degree determine the efficiency of spectral sensitisation of AgHal by aggregating dyes.^{6, 80}

The efficiency of spectral sensitisation can be increased with the use of supersensitisers. Over many years, the results of studies on desensitisation and supersensitisation have not been generalised. Shapiro considered^{79, 80, 126} a generalised chemical concept of spectral sensitisation, in which particular attention is given to secondary oxidative dye self-desensitisation. According to this concept, supersensitisation is considered as deceleration of secondary dark dye self-desensitisation. There are at least three mechanisms of inhibition of type II hole self-desensitisation: (1) dye hole trapping by a supersensitiser; (2) 'isolation' of a hole from an impurity centre acting as a photoelectron acceptor (IC_e); (3) control over aggregation in such a way as to exclude the possibility of existing contacts between aggregates and IC_e .¹²⁶

The mechanism of dye hole trapping by a supersensitiser (the arbitrary reductive mechanism) was considered in detail by Gilman.²³⁸ This mechanism is most typical of J-aggregating dyes, in which holes can migrate to large distances within the aggregates. A bright example of the supersensitising action of the styryl fragment of 2-(*p*-diethylaminostyryl)benzothiazole on J-aggregates of 1,1'-diethyl-2,2'-cyanine iodide was given in the study.²³⁵ A slight change in the absorption band of J-aggregates in the presence of a supersensitiser led to a sharp increase in the photographic sensitivity (by more than an order of magnitude). Measurements of the photoconductivity of photographic layers also demonstrated a considerable increase in photoconductivity in the case of absorption in the J-band, which is indicative of an increase in the quantum yield of Dy^* -derived photoelectrons to the conduction band of AgHal. According to West and Carroll,²³⁵ photoexcitation of J-aggregates gives rise to excitons, whose rate of propagation in the dye layer is so high that the electron transfer to the conduction band of AgHal can be hindered. Hence, excitation is lost due to either thermal energy dissipation or dye fluorescence. The addition of a supersensitiser and inclusion of the latter in J-aggregates hinders exciton motion. Therefore, a super-

sensitiser acts as an exciton trap. Exciton trapping leads to an increase in the probability of electron transfer to AgHal. This phenomenon was considered in more detail by Gilman.²³⁸

According to Gilman, supersensitisation involves oxidation of a supersensitiser (S) by a photoexcited dye Dy_j^* or a dye hole ($Dy_j^{+\bullet}$)

resulting in relocation of a hole to the supersensitiser.

Supersensitisation according to reaction (4) gives rise to the radical anion Dy_j^- . The level ϵ_{LUMO} of the electron in Dy_j^- is higher than that in Dy_j^* due to interelectron repulsion of the extra electron. Hence, the probability of electron transfer to the conduction band of AgHal increases and, as a consequence, the efficiency of sensitisation increases. In the case of supersensitisation according to reaction (5), the probability of recombination processes decreases due to removal of a dye hole and, consequently, the spectral sensitivity can increase. For supersensitisation to occur according to the hole-acceptor mechanism, the supersensitiser must be oxidised more readily than the dye. Therefore, the condition for supersensitisation can be written as follows:²³⁸

$$E_{1/2(S)}^{ox} < E_{1/2(Dy)}^{ox}.$$

The 'isolation' mechanism of supersensitisation^{79, 80, 239, 240} involves selective adsorption of organic compounds on IC_e (generally, on Ag_2S centres), isolation of J-aggregates from IC_e and, consequently, a decrease in the probability of recombination processes (see Fig. 22c). Processes according to the 'isolation' mechanism can occur with supersensitisers, which are more difficult to oxidise than dyes,²³⁹ i.e.,

$$E_{1/2(S)}^{ox} > E_{1/2(Dy)}^{ox}.$$

Various heterocyclic compounds, which are selectively adsorbed on Ag_2S centres, primarily, the well-known stabiliser 4-hydroxy-6-methyl-1,3,3a,7-tetraazaindene, can be used as supersensitisers. Purine bases, for example, guanine and adenine, exert the supersensitising action.^{79, 80} Some monomethinecyanines and nullmethinemercyanines are efficient supersensitisers of the 'isolation' type.

It should be noted that the 'isolation' mechanism substantially differs from the mechanism proposed by Riester.²⁴¹ In the supersensitisation model developed by Riester, dye molecules are isolated from the total surface of AgHal, and the 'isolation' mechanism consists in isolating the molecules from the surface impurity centres, which are chemical sensitisation products. This isolation model takes place in core-shell emulsions and Ir^{3+} -doped emulsions. Photoelectron trapping inside AgHal microcrystals hinders electron-hole recombination. Taking into account this fact, desensitisation and self-desensitisation can be substantially decreased.^{242–244} The formation of an interlayer formed by a supersensitiser between J-aggregates and impurity centres was observed by luminescence techniques.^{245, 246}

Belous and Tolstobrov²⁴⁶ were the first to find that the intensity of luminescence of the Ag_2S cluster in the IR spectral region decreases in a dye- Ag_2S cluster system upon light absorption by dye J-aggregates adsorbed on Ag_2S . Fano attributed²⁴⁷ the observed antisensitisation to the antiresonance effect due to interference of the excited states of the dye and Ag_2S in the case of a direct contact between a sensitiser and an impurity centre. Antisensitisation sharply decreases and the intensity of sensitised luminescence of the cluster increases with increasing distance between the Ag_2S cluster and the dye. 4-Hydroxy-6-methyl-1,3,3a,7-tetraazaindene¹¹⁷ and its alkyl analogues, thiamonomethinecyanines, mercocyanines, styryl dyes and other compounds showing specific adsorption on Ag_2S centres were used as interlayers between dye aggregates and Ag_2S centres.^{248–251}

It was hypothesised^{248, 251} that selective adsorption of organic compounds on Ag_2S centres can be due to the presence of 1,3-dipolar structures involving (in the case of thiacyanines) the nitrogen atoms of heterocycles and the carbon atom of the methine group. It should be noted that the distance between the atoms determining the dipole is 2.6 Å, i.e., it is similar to that between the Ag^+ and S^{2-} ions in the Ag_2S clusters.^{6, 248–251}

It should be noted that a superadditive increase in the light sensitivity is observed if the two above-mentioned modes of inhibition of type II self-desensitisation occur simultaneously.^{79, 80} The superadditive effect of supersensitisation is evidence of the difference between the mechanisms of supersensitisation of photographic layers by two types of compounds in successive steps of dye-hole self-desensitisation. In this case, either dye holes are initially trapped by a readily oxidisable supersensitiser followed by isolation of holes from the photographically active centres with compounds, which are difficult to oxidise and which are adsorbed on these centres, or, alternatively, supersensitisers act in the reverse order.

The third mode of supersensitisation by J-aggregating dyes consists in controlling J-aggregation¹²⁶ by adding such organic compounds to a photographic emulsion that either facilitate aggregation or are involved in 'recrystallisation' of aggregates thus facilitating the growth of more ordered structures of J-polymers. As a result, the distance r (see Fig. 22b) can increase (contacts between J-aggregates and IC_e are absent) or more ordered J-aggregates are formed. In the latter, the probability of energy dissipation of photoexcitation of J-aggregates between structurally different aggregates decreases. For example, bis-quaternary salts of heterocyclic bases of the following general formula can act as regulators of J-aggregation:

where Z and Z' are the groups of atoms, that form the pyridine, quinoline or benzimidazole rings, $n \geq 2$ and X^- is the anion.

It was demonstrated^{122, 123, 125, 126} that the addition of bis-quaternary salts to a photographic emulsion at concentrations comparable with that of the J-aggregating dye enhances the ability of the latter to form J-aggregates, causes a bathochromic shift of the absorption maximum and leads to an increase in the efficiency of spectral sensitisation. In the studies,^{125, 126} the influence of bis-quaternary salts was interpreted as facilitating J-aggregation. Apparently, the fact that the pair positive charges on the nitrogen atoms are not equal to the pair negative charges on the halide ions in the case of adsorption of bis-salts on AgHal microcrystals results in such a relief of the surface potential on the surface of AgHal at which J-aggregation is facilitated not only on defect sites but also on other regions of the surface and which is favourable for ordering of the aggregate structures.

The replacement of the alkyl groups at the nitrogen atoms of cyanine dyes by sulfoalkyl groups⁷⁸ (i.e., the transformation into dyes having a betaine structure) facilitates J-aggregation. Apparently, the presence of dipolar betaine structures in anionic dyes can promote both nucleation of J-aggregates on the dipolar surface of AgHal microcrystals (Ag^+ and Hal^- ions) and subsequent aggregate growth.

It is known that J-aggregation is affected by various photo-graphically inactive compounds, for example, ketones, nitriles, aromatic alcohols (phenols), etc., which also cause a bathochromic shift of J-bands and an increase in the efficiency of spectral sensitisation.¹²⁶ Generally, the bathochromic shifts of J-bands are related to either a decrease in the packing angle of dye molecules or to an increase in the number of sensitiser molecules involved in aggregates. Both parameters should depend on the aggregation rate. Rapid aggregation should lead to the random formation of particles of different sizes on surface defects of AgHal. Organic compounds cause 'recrystallisation' of J-aggregates. In this case, organic compounds introduced into an emulsion in large amounts

(0.1–1.0 mol per mole of AgHal) serve as a medium (a solvent) facilitating 'recrystallisation'. The latter can give rise to more ordered J-aggregates with bathochromically shifted absorption bands and far removed from IC_e ($r > 0$, see Fig. 22 b), and lead to an increase in the photographic activity of aggregates. J-Aggregation is often facilitated by an increase in the temperature of a molten emulsion and its storage at high temperature before coating.

The formation of numerous new defects, which stimulate J-aggregate growth at sites that are not bound to impurity centres, on the surface of AgHal microcrystals before the introduction of a spectral sensitiser should facilitate J-aggregation. These numerous defects occur, for example, in the synthesis of AgHal microcrystals with a variable halide composition, particularly, of AgBr(I). Hence, an increase in the concentration of iodide ions in AgBr(I) emulsions to a particular limit generally promotes J-aggregation.² This can also account for the influence of the thiocyanate and cyanide ions on J-aggregation. It was demonstrated²⁵² that the addition of iodide ions to an AgBr emulsion leads to the formation of silver iodide at the vertices and edges of microcrystals, thus promoting J-aggregation. According to the results of the studies,^{78, 253} SCN^- and CN^- ions have the same effect. In the studies,^{128–131} it was also demonstrated that J-aggregation of dyes on AgHal increases in the presence of SCN^- . There are also other procedures for controlling the surface imperfection of AgHal.¹²⁵ In addition, J-aggregation can be controlled by decreasing the rate of release of dyes into solution. This can be achieved by adding poorly water-soluble dyes as aqueous sols or by readsorbing dyes from the substrate (SiO_2 , etc.) on AgHal.^{3, 254, 255}

Type I self-desensitisation according to the electron-acceptor mechanism is possible for IR dyes, which form J-aggregates.⁶ It is known that the electron affinity of a dye increases with increasing length of the polymethine chain resulting in a considerable decrease in the efficiency of spectral sensitisation.^{83, 133} According to the modern views,⁶ dyes in the ground state serve as intermediate carriers of electrons to oxygen atoms and protons, *i.e.*, dyes catalyse oxidation by oxygen involving protons of water molecules. The intermediate involvement of dyes in type I self-desensitisation can be determined by such factors as the electron affinity of the molecule and the positive charge of the chromophoric moiety of the dye. In this case, the probability of secondary oxidation processes should increase with increasing electron affinity of dye molecules (which is characterised by the polarographic half-wave reduction potential) and particularly with increasing length of an electron acceptor in aggregates.

The following suggestion was made:^{134, 256} if an efficient procedure were available for assembling unstable silver atoms (or subcentres of a latent image) to form stable particles of a latent image during exposure, the spectral sensitivity of a photomaterial would be substantially increased due to a decrease in the contribution of dye self-desensitisation to spectral sensitisation. The main idea of this method is that the chemical enhancement, *i.e.*, the development of a photomaterial already in the step of exposure, is employed. In this case, latensification of a latent image occurs during exposure. For this purpose, it is necessary to provide a reducing medium in the photographic layer by adding a reductone. The algorithm of this process can be as follows: before exposure, *i.e.*, before the formation of catalytic silver particles, a reductone does not reduce AgHal, apparently, due to kinetic factors. However, after blanket exposure and the formation of silver particles, a reductone reduces pre- and subcentres of a latent image to form stable developed centres of a latent image. This can be described by the following processes:

Ascorbic acid is a natural reductone, which has long been used in photographic processes.³ The action of ascorbic acid on infrared photographic layers is a bright example of the efficiency of reducing supersensitisers.^{233, 257–260} Several mechanisms of action of ascorbic acid were described in the literature. It was hypothesised²³³ that an IR dye is oxidised on the surface of AgHal to form a radical dication thus enhancing desensitisation according to the mechanism of photoelectron trapping. The authors observed the appearance of a new hypsochromically shifted absorption band of the radical dication of an IR dye, whose intensity decreased in the presence of ascorbic acid. Consequently, ascorbic acid (in the authors' opinion) reduces the radical dications of the dye to the dye in the ground state, which leads to a decrease in desensitisation. According to the above-considered mechanism, the influence of ascorbic acid occurs before the light action.

The influence of ascorbic acid on numerous IR dyes containing polymethine chains of different lengths in an AgBr(I) emulsion was studied in detail.²⁶¹ Short-wavelength bands of radical dications were found in none of reflection spectra of the dyes, for which a supersensitising effect of ascorbic acid was observed. Hence, it was concluded that the action of ascorbic acid is not associated with reduction of the desensitising radical dication of the dye. It was suggested²⁶ that ascorbic acid acts as an inhibitor of dye self-desensitisation immediately after the light step.²⁶¹

Ascorbic acid was demonstrated¹³⁴ to be adsorbed on silver sulfide sensitivity centres. Latensification of a latent photographic image under the action of ascorbic acid is efficient because silver particles formed on Ag_2S centres are subjected to the primary enhancement by ascorbic acid. Other reductones responsible for the superadditive effect in the photographic development, such as metol, phenidone, dodecyl gallate, *etc.*, behave analogously. Apparently, their action is also associated with specific adsorption on Ag_2S centres and latensification of a latent photographic image.

A new method of inhibition of type II self-desensitisation according to the hole mechanism was considered.^{80, 134, 256} This method is based on the use of a new type of supersensitisers which undergo transformation as a result of oxidation by dye holes accompanied by decomposition of the initial core. This gives rise to a molecule containing a new core, which acts as a reducing agent for AgHal. Chemical transformations of the oxidised form of a supersensitiser lead to the injection of one electron (or several electrons) into AgHal microcrystals, resulting in an enhancement of a latent photographic image. The scheme of the process is as follows:⁸⁰

where BH is a supersensitiser and R^- is a base. According to this scheme, the supersensitiser BH is oxidised by a dye hole to form the radical cation BH^{++} , which reacts with the base R^- to give the radical B^+ . The latter can act as a reducing agent for silver halide, *i.e.*, can inject the second electron into AgHal, resulting in the growth of the centre of a latent photographic image.

The above two-electron scheme was used in the studies.^{262–264} The formate anion (HCO_2^-) served as a hole acceptor. Oxidative decomposition of organic compounds accompanied by electron injection into AgHal was experimentally performed by Muentner and co-workers.^{265–271} Carboxy-substituted amines were gener-

ally used as hole acceptors. Decomposition of the resulting radical cations can occur in decarboxylation, deprotonation, C—C bond cleavage, etc.

In essence, all the above-considered supersensitisation processes under the action of reductones involve reductive latensification of a latent photographic image. This process can be initiated by either a reductone present in a photographic layer (for example, by ascorbic acid) or a reductone formed upon oxidative decomposition of a supersensitiser.

Nowadays, the unique properties of silver halide as a catalytic light-sensitive system are used in full measure only in the dark step of the photographic process (in the step of development). Nevertheless, the use of the unique catalytic properties of AgHal in the light step of the photographic process (as the 'primary development') holds promise. This strategy of spectral sensitisation would be expected to lead to a considerable increase in the light sensitivity of photomaterials.

Various approaches to the explanation of the photographic action and supersensitisation of polymethine dye aggregates were considered in the literature in sufficient detail. A unified theory of spectral sensitisation was developed. This theory is based on redox reactions in a photographic layer, which occur after dye photoexcitation in the secondary dark steps. Of all aggregated forms, the J-aggregated state of cyanine dyes is the most photographically efficient form.

V. Conclusion

Dye aggregates and, primarily, J-aggregates are nanosize molecular ensembles. Aggregates possess collective properties due to formation of a common π -conjugated system, which is reflected in changes in the electronic levels of dyes involved in aggregates, optical absorption bands and the chemical and photochemical activity. Evidently, all these properties depend on the aggregate structure, which is, in turn, determined by the mode of their formation. Nowadays, the architecture, more precisely, the nanoarchitecture of molecular ensembles of dyes can be considered. As in the traditional architecture, the appearance and functional possibilities of nanoarchitectural ensembles are determined by elements of the nanoarchitecture and their combination. In the nanoarchitecture of molecular ensembles of polymethine dyes, molecules, dimers and larger species serve as such elements. It should be noted that numerous elements are available because the class of polymethine dyes is characterised by a great variety of molecular structures and the diversified optical and electronic properties.^{2,3}

The nanoarchitecture of molecular ensembles of polymethine dyes is based on their specific structural features, which determine the tendency of dyes to undergo self-association. A new principle of the construction of complex organised systems from blocks (dimers, which are the simplest organised elements) rather than from individual 'bricks' (molecules) is of particular interest. Presumably, the block principle of construction is widespread in the Nanoworld and occurs in more complicated biological structures.

Investigations of molecular ensembles of polymethine dyes belong to the field of nanochemistry and nanotechnology.²⁷² It should be noted that the notions of nanoscience and nanotechnology are frequently mixed in the literature, although they are obviously different. Molecular ensembles of polymethine dyes are successfully used in nanotechnology for the preparation of photographic materials. Dye J-aggregates have been efficiently used in photographic processes as optical sensors in the spectral sensitisation for approximately seven decades.

Nowadays, in the framework of nanotechnology, aggregates composed of a small number of coloured organic compounds are of particular importance due to the extensive development of optical methods for data recording, processing and reading. In particular, methods for the controlled formation of molecular ensembles of polymethine dyes having desired structures and

required optical and electronic properties are of interest for the use in systems of optical conversion of data, including 'optical' computers.

Molecular and crystal design of nonlinear optical organic materials

K Yu Suponitsky, T V Timofeeva, M Yu Antipin

Contents

I. Introduction	457
II. Methods for the assessment of molecular hyperpolarisabilities	458
III. Characteristics of π -conjugated systems related to the efficiency of the second harmonic generation	464
IV. Possible ways to improve thermal stability and optical transparency of NLO materials	476
V. The design of NLO crystals	485
VI. Conclusion	489

Abstract. The results of theoretical and experimental studies on the second-order molecular and crystal nonlinear optical susceptibilities of organic and several classes of organoelement compounds are summarised. Modern methods used in these studies are briefly characterised, their advantages and drawbacks are outlined as regards their application to the systematic search for efficient nonlinear optical materials. Recent achievements and the main challenges in the field are thoroughly discussed and an optimum algorithm of the design of such materials is proposed. The bibliography includes 479 references.

I. Introduction

Investigations into the nonlinear optical (NLO) materials is an actively developing field of the materials science.^{1–10} These materials have to comply with specific requirements, such as manifestation of high quadratic nonlinear optical susceptibilities and thermal stability and transparency in the operational range of wavelengths. Inorganic materials that are most frequently implemented in various devices meet these requirements to a certain degree. However, as early as the 1970s it was realised^{11–15} that organic compounds containing donor and acceptor (D/A) substituents linked through a π -electron system (the so-called D– π –A molecules) are capable of manifesting 1–2 orders of magnitude higher NLO efficiencies (NLO susceptibilities) due to the π -electrons weakly bound to the nuclear framework. This explains the great interest of researchers to the experimental elucidation of nonlinear optical susceptibilities of such compounds and the search for methods enabling prediction of the hyperpolarisabilities and structural simulations of highly efficient NLO molecules. Over the last two decades, the assortment of molecules under study has expanded substantially.^{16–22} A con-

siderable progress has been attained in the field of quantum-chemical calculations of the hyperpolarisabilities of molecules^{23–27} thereby providing valuable insight into the optimum molecular structures and helping to establish the structure–property relationship. The effects of the nature of the π -conjugated system have been monitored using series of polyphenylenes, polyenes, polyynes, their diphenyl-substituted analogues and molecules with heterocyclic π -systems.^{28–36} Various donor and acceptor substituents, in particular, NO₂, C(O)R, CN, OR, NR₂ as well as heterocyclic fragments and their combinations, have been studied in detail.^{37–43}

Only one of numerous possible NLO effects, *viz.*, the second harmonic generation (SHG), which is a special case of the sum frequency generation (SFG) is concerned in the present review. Incident photons with a frequency ω are absorbed by an NLO medium; the majority of photons are re-emitted at the same frequency but, for a small fraction of the incident radiation, the frequency of the generated photons is doubled (Scheme 1). This implies that the nonlinear optical effects can only be detected with powerful radiation sources, such as lasers.

Scheme 1

The dependence of the dipole moment (μ), which describes the perturbation of a system within the dipole approximation, on the external field strength (E) can be represented as a series^{44, 45}

$$\mu_i = \mu_i^0 + \alpha_{ij}E_j + \beta_{ijk}E_jE_k + \gamma_{ijkl}E_jE_kE_l + \dots, \quad (1)$$

where μ_i^0 is the i th component of the dipole moment of the unperturbed system; α_{ij} is the linear polarisability; β_{ijk} and γ_{ijkl} are nonlinear polarisabilities. The polarisabilities are frequency-dependent, which, strictly speaking, has to be reflected in their notation: for instance, $\beta_{ijk}(-\omega_1, -\omega_2, \omega_1, \omega_2)$, where ω_1 and ω_2 are incident radiation frequencies. The second harmonic generation is a particular case as a first-order nonlinear effect and thus it is described by the third term of the series (1), *i.e.*, by the parameter $\beta(2\omega, \omega, \omega)$ [or $\beta(\omega)$], which is a third-rank tensor. Typically, the notation β refers to molecules, *e.g.*, it is used in the studies of the second harmonic generation in solutions or gases or in theoretical calculations. In those cases, the proportionality coefficient is referred to as hyperpolarisability. In the case of crystal, the term

second-order nonlineal optical susceptibility is used, which is denoted as $\chi^{(2)}$ or d . Static hyperpolarisabilities extrapolated to the zero frequency [referred to as β_0 , $\beta(0,0,0)$ or $\beta(0)$] are often used for comparative analyses. It is related to the dynamical values by means of the following expression:²³

$$\beta(\omega) = \beta(0)[1 + A\omega^2 + \dots]. \quad (2)$$

The coefficient A depends exclusively on the nature of the molecule. The static hyperpolarisabilities are significantly easier to calculate and they are sufficient for the analysis of trends along various series of compounds, as will be demonstrated below. For the sake of easy comparison and interpretation, the molecular hyperpolarisabilities are usually represented as their vector components

$$\beta_{\text{vect}} = (\beta_x^2 + \beta_y^2 + \beta_z^2)^{1/2}, \quad (3)$$

where

$$\beta_i = \beta_{ixx} + \beta_{iyy} + \beta_{izz}.$$

Such representation is used due to the fact that β_{vect} can be determined experimentally from measurements of the hyperpolarisabilities of molecules. Sometimes, the hyperpolarisability is represented as the tensor norm

$$\|\beta\| = \left(\sum_{ijk} \beta_{ijk}^2 \right)^{1/2}. \quad (4)$$

In many cases, the tensor is degenerated into a vector due to a particular symmetry of the molecule. Thus, all even-order optical susceptibilities of any system with an inversion centre are strictly zero.

In order to compare and interpret the experimentally measured hyperpolarisabilities reported by different research groups, one has to critically assess them for several reasons. First, there are several independent representations of the NLO parameters related to modifications of the formulas (3) and (4), which is not always clearly specified in original papers.[†] Second, different research groups use different reference values of the same standard sample in the measurements. This problem has been specially addressed.⁴⁶ Nevertheless, even after detailed critical assessment, quantitative comparisons of results reported by different research groups is not recommended (see Section 6 in Ref. 46).

Following this guideline, below we compare only those results that were obtained by one research group within the same cycle of measurements. Such an approach made it possible to establish quantitative relationships between polarisabilities of different molecules and correlate their NLO activities with the molecular structure. The relationship between the hyperpolarisability of a molecule and its structure can be deduced from the quantum mechanical description of hyperpolarisability. The Hamiltonian of a system (*e.g.*, a molecule) in an external electric field can be represented as

$$\hat{H} = \hat{H}_0 + \hat{H}',$$

where $\hat{H}_0$ is the Hamiltonian of the unperturbed system and the term $\hat{H}'$ describes the effect of the field applied. If $\hat{H}'$ can be considered as a small perturbation, the hyperpolarisability (assuming only one excited state, which is referred to as the two-level model, and one-dimensional character of the tensor β , which is equivalent to the existence of one prevailing component, *e.g.*, β_{xxx}) can be written in a compact form as³

$$\beta_{xxx} = \frac{3\omega_{ge}^2 \Delta\mu_{ge} |\mu_{ge}|^2}{2\hbar^2(\omega_{ge}^2 - \omega^2)(\omega_{ge}^2 - 4\omega^2)}, \quad (5)$$

[†] In the present review, the notation β is adopted for the hyperpolarisability. By default, β without any additional indices, which was not explicitly commented, means vector component of hyperpolarisability [see Eqn (3)] in the static limit.

where ω_{ge} is the frequency of the transition from the ground (*g*) to the excited (*e*) state, μ_{ge} is the respective transition dipole moment and $\Delta\mu_{ge}$ is the difference between the dipole moments of the molecule in the ground and excited states. This formula clearly shows that β becomes larger with an increase in μ_{ge} and $\Delta\mu_{ge}$. This is achieved for molecules containing donor and acceptor groups linked through a π -conjugated system. Mobile π -electrons in such molecules are readily redistributed upon perturbation with an electric field.

Importantly, as follows from the above relationship, NLO parameters of organic molecular crystals have a straightforward correlation with molecular hyperpolarisabilities. Since intermolecular interactions are significantly (2–3 orders of magnitude) weaker than the intramolecular ones,⁴⁷ the nonlinear susceptibility of a crystal can be represented as a sum of hyperpolarisabilities of the constituent molecules over the unit cell^{48–50}

$$d_{IJK} = \frac{1}{V} f_I f_J f_K \sum_{n=1}^Z \left(\sum_{i=1}^3 \sum_{j=1}^3 \sum_{k=1}^3 \cos \theta_{II}^n \cos \theta_{JJ}^n \cos \theta_{KK}^n \beta_{ijk} \right). \quad (6)$$

Here, V is the unit cell volume; indices I, J and K refer to the crystallographic coordinate system; indices i, j and k define the components of β in the molecular coordinate system; the trigonometric terms $\cos \theta_{II}^n$, $\cos \theta_{JJ}^n$ and $\cos \theta_{KK}^n$ define the transition matrix between these coordinate systems; f_I, f_J, f_K are the factors accounting the local field effects.

The experimental determination of the optical susceptibilities of crystals or polymers, which are of the greatest practical importance, is laborious (especially for single crystals), therefore, the design of NLO materials is based to a large extent on the knowledge and application of the relationship between the NLO susceptibilities of a crystal and hyperpolarisabilities of the constituent molecules.

The present review surveys the approaches to the design of NLO active materials at the molecular and crystal level. We limit ourselves to the consideration of organic and selected classes of organoelement compounds. Supplementary information on the use of organometallics in nonlinear optics can be found elsewhere.^{51, 52}

II. Methods for the assessment of molecular hyperpolarisabilities

1. Experimental methods for measurement of molecular hyperpolarisabilities

One of the most popular method for the determination of molecular hyperpolarisabilities in solution or gas phase based on the measurements of the electrical field-induced second harmonic (EFISH) was developed in the early 1970s.^{53–56} Prior to the measurement, molecules of the compound under study are oriented along a static electrical field. The third-order macroscopic optical susceptibility (Γ) obtained directly from the measurements relates to the respective microscopic value (γ) through the following expression

$$\Gamma = N\gamma f_0 f_\omega f_{2\omega},$$

where N is the number of molecules per unit volume, $\gamma = \gamma_e + \gamma_v + \gamma_r$ is the sum of electronic (γ_e), vibrational (γ_v) and orientational (γ_r) terms; $f_0, f_\omega, f_{2\omega}$ are the local field factors. The hyperpolarisability relates to the orientational term as

$$\gamma_r = \frac{\mu\beta_{\text{vect}}}{5kT}.$$

The orientational contribution can be separated using the temperature dependence $\gamma_r(T)$, and thus the scalar product of the dipole moment and the vector part of the hyperpolarisability $\mu\beta_{\text{vect}}$ can be determined. Often, the orientational term predominates, therefore other two terms can be neglected.⁵⁵ In order to retrieve the absolute value of β_{vect} , one should know the angle between the vectors μ and β_{vect} and the value of dipole moment.

The former can be estimated by means of quantum-chemical calculations, whereas the latter can be determined both theoretically and experimentally.

This means that the accuracy of the resultant value of β depends on the reliability of the quantum-chemical approximation applied and the accuracy of the determination of μ . Other tensor components β_{ijk} remain unknown and thus the formula (6) can only be applied to the calculation of the components of the NLO susceptibility tensor provided that the molecular hyperpolarisability is dominated by a single component (e.g., β_{xxx}).

Yet another problem relates to the transition from the macroscopic (Γ) to the microscopic (γ) level of description, which requires an explicit allowance for the local field factors. In the case of weakly polar solute molecules and non-polar solvents, for which the intermolecular interactions can be neglected, the local field factors can be described within the Onsager model. However, the compounds that are of the greatest interest for nonlinear optics are polar and poorly soluble in non-polar solvents. Solute molecules in a polar solvent are additionally polarised by their solvate environment; furthermore, the formation of molecular associates, in particular, due to the H-bonding, is highly probable. Also there is a concentration dependence of the hyperpolarisability. Such effects have been studied in detail in the case of *p*-nitroaniline (*p*-NA, **1**). Measurements of the molecular hyperpolarisability were performed for solutions in polar methanol⁵⁷ and non-polar melt of *trans*-stilbene⁵⁸ and for a melt of *p*-NA itself.⁵⁷ The ratios obtained

$$\frac{\beta_{p\text{-NA}}^s}{\beta_{p\text{-NA}}^m} \approx \frac{\beta_{p\text{-NA}}^s}{\beta_{p\text{-NA}}^{\text{melt}}} = 0.33$$

(the superscripts s, m and melt denote the values for the solutions in stilbene and methanol and the melt, respectively) suggest a strong influence of the intermolecular interactions on the measured values. Both in the methanolic solution and the melt, *p*-nitroaniline molecules form H-bonded associates, which induce additional polarisation of the molecules thus giving rise to an increase in their hyperpolarisability. A similar relation has been obtained for *trans*-4-dimethylamino-4'-nitrostilbene (DANS, **2**) in *trans*-stilbene and acetone solutions^{58, 59}

$$\frac{\beta_{\text{DANS}}^s}{\beta_{\text{DANS}}^a} = 0.3$$

(the superscript a and s correspond to the acetone and stilbene solutions, respectively).

The concentration dependences of β were studied for systems with both weak (e.g., nitrobenzene–benzene or nitrobenzene–CCl₄) and strong intermolecular interactions prone to the formation of H-bonds (e.g., water–methanol).⁵⁷ For polar and H-bonded systems, it was suggested to describe β with the following equation

$$\beta = \beta_0 + \beta_{\text{dip}}^0(1 - c) + \beta_{\text{solvent}} f_s, \quad (7)$$

where β_0 is the hyperpolarisability of the isolated molecule, the second term quantifies the dipole–dipole interactions and the last term describes specific solute–solvent interactions; c and f_s are empirical parameters. This equation provides only a qualitative description of the real situation. For any specific case, additional measurements are required to estimate the two latter terms quantitatively, which becomes a separate problem.

Yet another experimental method exploits the phenomenon of incoherent scattering of the incident radiation by single molecules, the so-called Hyper Rayleigh Scattering (HRS), which was discovered in 1965.⁶⁰ For the measurements of the second harmonic generation, this method came in use only during the last decade owing to studies of *p*-NA, 4-methoxy- and 4-hydroxy-4'-nitrostilbenes by Clays and Persoons.^{61, 62} The hyperpolarisabilities of these molecules measured using HRS were in agreement with the earlier EFISH results.

A clear advantage of HRS over EFISH is that⁶³ it does not require external static electrical fields for orienting the molecules, i.e., for the induction of a non-centrosymmetric medium. This allows probing of molecules with the zero dipole moment (in particular, octupolar molecules and ions, which are described in more detail below). Furthermore, HRS can yield several components of the molecular hyperpolarisability tensor. Most typically, components β_{ZZZ} and β_{XZZ} in a laboratory coordinate system are determined, which relate to the molecular parameters as follows⁶⁴

$$\langle \beta_{ZZZ}^2 \rangle = \frac{1}{7} \sum_i \beta_{iii}^2 + \frac{6}{35} \sum_{i \neq j} \beta_{iii} \beta_{ijj} + \frac{9}{35} \sum_{i \neq j} \beta_{ijj}^2 + \frac{6}{35} \sum_{ijk} \beta_{ijj} \beta_{jkk} + \frac{12}{35} \beta_{ijk}^2, \quad (8)$$

$$\langle \beta_{XZZ}^2 \rangle = \frac{1}{35} \sum_i \beta_{iii}^2 - \frac{2}{105} \sum_{i \neq j} \beta_{iii} \beta_{ijj} + \frac{11}{105} \sum_{i \neq j} \beta_{ijj}^2 - \frac{2}{105} \sum_{ijk} \beta_{ijj} \beta_{jkk} + \frac{8}{35} \beta_{ijk}^2. \quad (9)$$

Nevertheless, the principal of the aforementioned problems related to the use of EFISH are also typical of HRS, although to a lesser extent. First, even with HRS one cannot determine all the tensor component β_{ijk} . The second problem is due to the neglect of the solvation and association effects. For instance, the following ratios of hyperpolarisabilities were determined for acetonitrile and nitrobenzene in the gas (g) and liquid (l) phases⁶⁵

$$\frac{\beta_{\text{MeCN}}^g}{\beta_{\text{MeCN}}^l} = 0.53, \quad \frac{\beta_{\text{PhNO}_2}^g}{\beta_{\text{PhNO}_2}^l} = 0.77.$$

In the liquid phase, molecules stronger interact with each other and thus are stronger polarised as compared to the gas. More polar molecules are characterised by larger β , which is reflected in the ratios outlined above.

Huyskens *et al.*^{66, 67} applied HRS to study the dependence of hyperpolarisability of *p*-NA and its *N,N*-dimethyl derivative on the solvent nature, in particular, polarity. They tested 50 different solvents and deduced the following formula representing the hyperpolarisability in a solution as a sum of the hyperpolarisability of an isolated molecule (gas-phase) β^g and corrections for the dipole–dipole interactions (the second term) and association (the third term)

$$\beta = \beta^g + \gamma_0 a \sqrt{\frac{\mu}{V}} + (1 - \gamma_0) b \sqrt{\mu}, \quad (10)$$

where γ_0 is the fraction of solute molecules not involved into H-bonding; a and b are empirical coefficients; μ is the dipole moment of the molecule in the gas phase; V is the solvent molar volume. Apparently, Eqn (10) is equivalent to Eqn (7), which was proposed to correct EFISH results for the solvation and association effects. Unfortunately, parametrisation of these equations for any particular compound is very demanding experimentally.

The problem of the interpretation of the solvation effects becomes especially important when the molecular hyperpolarisability has to be further used to estimate the NLO susceptibility of a crystal, in which the molecule is polarised by the crystal field evidently different from that experienced by the molecule in a solution or in a melt.

2. Theoretical approaches to the determination of the molecular hyperpolarisabilities

The major advantage of quantum-chemical methods for the determination of molecular hyperpolarisabilities is that^{68–70} they enable calculation of all the tensor components β_{ijk} . It has to be however noted that the problem of transferability of theoretical values for an isolated molecule to the molecule in a solid phase remains open and deserves a special consideration.

There are two basic approaches to the calculation of β . Within the first approach, the terms describing the interaction of a system

with an electromagnetic field are explicitly included into the Hamiltonian of the system. The second approach exploits the idea that the eigenfunctions of a molecule constitute a complete set and any state of the molecule perturbed by an electric field can be factorised in this basis.

In the first approach referred to as the Finite Field (FF) theory, the Hamiltonian of a system perturbed by an electrical field with a strength E is represented as

$$\hat{H} = \hat{H}_0 - eE\hat{r}, \quad (11)$$

where $\hat{H}_0$ is the Hamiltonian of the unperturbed system and $\hat{r}$ is the dipole moment operator. The polarisability can be deduced as the derivative of the dipole moment $\mu(E)$ or energy $W(E)$ with respect to the field (E). For the first hyperpolarisability, the following expression can be written

$$\beta_{ijk} = \frac{\partial^2 \mu_i(E)}{\partial E_j \partial E_k} = - \frac{\partial^3 W(E)}{\partial E_i \partial E_j \partial E_k}. \quad (12)$$

The differentiation can be performed either numerically or analytically. In the latter case, an acronym CPHF (Coupled Perturbed Hartree–Fock) is often used instead of FF.

This approach was further developed by Zyss^{71–73} in a combination with the semiempirical approximation INDO/S. The hyperpolarisabilities were calculated as numerical derivatives of the dipole moment with respect to the electric field for a series of mono and disubstituted benzenes [**1**, *o*-NA (**3**), **4**, **5**] and compared to the available experimental data. A direct comparison of contributions made by σ - and π -electrons into the value of hyperpolarisability indicates that it is the π -electrons that are of predominant importance, which is fully in accord with earlier concepts. According to the values obtained for molecules **1**, **4** and **5**, β drastically increases with an increase in the conjugated chain length.

The theoretical values of β reported by Zyss^{71–73} are underestimated by approximately one order of magnitude as compared to the experimental data, however, they correctly reproduce the experimental trends along the series of compounds studied (Table 1).

Kurtz *et al.*⁷⁵ utilised the MNDO approximation with the AM1 and PM3 parametrisation schemes and adopted the FF-based algorithm of the calculation of different-order polarisabilities for the MOPAC code. Matsuzawa and Dixon^{76,77} comprehensively tested this implementation by calculating hyperpolarisabilities of about 150 conjugated polar molecules with the PM3 parametrisation.

As shown in Fig. 1, a reasonably good agreement between the theoretical and experimental values was obtained, although the

Figure 1. The correlation of calculated (FF/PM3 method) and experimentally determined (EFISH measurements)^{78,79} hyperpolarisabilities of D/A-substituted π -conjugated molecules.

values for molecules with high hyperpolarisabilities were systematically underestimated by the calculation.

Based on the FF theory, Cardelino *et al.*⁸⁰ suggested to simulate the perturbation field with a set of point charges.

If the separation between the opposite charges $\pm q$ is sufficiently large ($L > 160 \text{ \AA}$), the probe molecule placed into the centre of the system experiences the influence of a constant electric field

$$E = \frac{1}{4\pi\epsilon_0} \left(2 - 2^{2/3} \right) qL^{-2}, \quad (13)$$

the field strength being varied from 0 to $7 \text{ V \AA}^{-1}$.

The calculated values of β obtained for molecules **1**, **3**, *m*-NA (**6**) and **7–9** using this model^{80–83} are in good agreement with the experimental ones (Table 2).

The Sum Over States (SOS) method is also widely applied to the theoretical evaluation of NLO susceptibilities of molecules.

Table 2. Calculated (modified FF/AM1 method, in the static limit) and experimental values of the molecular hyperpolarisabilities (10^{-30} esu) of D/A-substituted benzene derivatives.

1	3.4	6.4–46.9	5	50.6	433.2

^a Hereinafter in this Section: a range of β values is given, if several experimental values were reported in the literature for the molecule;^{46,74} in the case of incident wavelength-dependent calculations, only the experimental data measured at the same wavelength are given; in the case of calculations in the static limit (as in this case), the whole range of experimental values is given. ^b Results of EFISH measurements from Ref. 73.

According to this method, the hyperpolarisability can be represented as⁸⁴

$$\beta(\omega)_{ijk} = -\frac{e^3}{8\hbar^2} \sum_n \sum_{n'} \left\{ \left(r_{gn'}^j r_{n'n}^i r_{gn}^k + r_{gn'}^k r_{n'n}^j r_{gn}^i \right) \times \right. \quad (14)$$

$$\times \left[(\omega_{n'g} - \omega)^{-1} (\omega_{ng} + \omega)^{-1} + (\omega_{n'g} + \omega)^{-1} (\omega_{ng} - \omega)^{-1} \right] +$$

$$+ \left(r_{gn'}^j r_{n'n}^i r_{gn}^k + r_{gn'}^k r_{n'n}^j r_{gn}^i \right) \left[(\omega_{n'g} + 2\omega)^{-1} (\omega_{ng} + \omega)^{-1} + \right.$$

$$+ \left. (\omega_{n'g} - 2\omega)^{-1} (\omega_{ng} - \omega)^{-1} \right] + \left(r_{gn'}^j r_{n'n}^k r_{gn}^i + r_{gn'}^k r_{n'n}^j r_{gn}^i \right) \times$$

$$\times \left[(\omega_{n'g} - \omega)^{-1} (\omega_{ng} - 2\omega)^{-1} + (\omega_{n'g} + \omega)^{-1} (\omega_{ng} + 2\omega)^{-1} \right] \Big\},$$

where the dipole moment operator r and the transition frequencies ω with subscripts correspond to transitions between the ground (g) and excited (n, n') states.

The dependence of the hyperpolarisability on ω is explicitly included in the Eqn (14), which is an advantage of this approach. However, an accurate calculation of β requires that the summation was performed over all excited states, which is associated with enormous computational costs. This approach is of low efficiency, especially as regards calculations for large and medium-sized molecules (*e.g.*, *p*-NA). The contributions of separate electron transitions into the total β value can be isolated and arranged in the descending order of their magnitudes. Then, the summation in the Eqn (14) can be aborted after reaching a preset accuracy level. Utilising of the SOS method makes it possible to analyse separate contributions thereby providing a valuable insight into the origin of the nonlinear susceptibility of a molecule, which is a prerequisite for establishing the structure–property relationship. Nevertheless, it should be kept in mind that the total contribution of neglected terms can prove significant impact despite the smallness of each separate term.

The SOS method within the CNDO/CI approximation was applied by Lalama *et al.*,⁸⁵ Morrell and Albrecht⁸⁶ for the evaluation of the hyperpolarisability of *p*-NA. The values of β (in esu) obtained in these two studies, 6.53×10^{-30} (Ref. 85) and 34.3×10^{-30} (Ref. 86) are significantly different due to the different parameter sets used, however, they both lie within the range of reported experimental values $(6.4–46.9) \times 10^{-30}$ (Refs 57, 58, 74 and 87) measured in different solvents, at different incident wavelengths and using different reference values of d_{11} (for the quartz standard): 0.8×10^{-9} (Refs 57, 58) or 1.2×10^{-9} esu (Refs 74, 87).

The SOS method was further optimised by Morley and co-workers.^{88–90} They parametrised the method for 22 π -conjugated molecules using the CNDO/CIS approximation. The formula (14) was modified by its transformation to a special coordinate system with the origin placed into the centre of gravity of the electron density distribution of the molecule in its ground state. The theoretical results for nitrobenzene (**10**), aniline (**11**), *p*-NA and molecules **12–15** obtained by this method reproduce the experimentally established trends, although the values themselves differ by a factor of 3–4 in some cases (Table 3). Here, it would be appropriate to mention the large scatter in the reported experimental data, which limits the reliability of the parametrisation. The method described above was implemented in the CNDOVSB software code.⁸⁹

Table 3. Calculated (SOS method within the PPP and CNDO approximations) and experimental values of dynamic ($\hbar\omega = 1.17$ eV) hyperpolarisabilities (10^{-30} esu) of D/A-substituted benzene and stilbene derivatives.

Molecule	β_{PPP}	β_{CNDO}	$\beta(\text{experiment})$
10	5.4	0.62	1.9–2.4
11	2.5	3.66	0.6–1.2
1^a	35.9	12.18	9.6–46.9
12	300.0	69.15	225–295
13	39.1	9.25	21
14	179.3	126	180–260
15	687.9	355	470–790

^a The experimental data for *p*-NA were measured at $\hbar\omega = 0.656$ eV; the photon energy values $\hbar\omega = 1.17$ and 0.656 eV correspond to the incident wavelengths of 1064 and 1907 nm, respectively.

Li, Marks and Ratner^{91,92} combined the SOS method with the PPP/CIS approximation; some of their results are compared with the experimental data and CNDO-based theoretical estimates in Table 3. It is clearly seen that the calculated data agree qualitatively with the experimental ones. The PPP-based theoretical estimates agree with the experiment somewhat better than the CNDO-based ones, although the former approximation is by definition less accurate. Probably, the deficiency in the theory is compensated for by better parametrisation.

Verification of the adequacy of the SOS approach was carried out by Kanis *et al.*^{39,93,94} for 203 polar organic molecules using the ZINDO code^{95–98} (the SOS method coupled with the INDO approximation), the results obtained are shown in Fig. 2.

Figure 2. The correlation of calculated (SOS/INDO method)^{95–95} and experimentally determined (EFISH measurements)^{78,79} hyperpolarisabilities of D/A-substituted π -conjugated molecules.

Some common trends can be revealed from the comparison of theoretical (based on the FF and SOS approaches) and experimental results (see Figs 1 and 2). The agreement for lower values of β is better than for higher values (in the latter case, the calculated values are always smaller than the experimental ones). Taking into account that the reported experimental data refer to SHG measurements in solutions,^{78,79} this discrepancy can be rationalised assuming the aforementioned solvation and association effects, which become important for easily polarisable molecules, *i.e.*, for molecules susceptible to the environmental effects. Apparently, the correlation between the theoretical and

experimental values is better described by a function $k\sqrt{x}$ ($y > 1$) rather than a linear dependence.

The majority of calculations of the hyperpolarisabilities with *ab initio* quantum-chemical methods are based on the finite field (FF) formalism. For the calculation of the frequency dependent hyperpolarisabilities $\beta(2\omega, \omega, \omega)$, it is necessary to use the time-dependent Schrödinger equation. Such an approach employing the Hartree–Fock approximation was elaborated by Sekino and Bartlett⁹⁹ and tested on a number of small molecules. The calculated values were found to be ~ 1.5 – 2 times smaller than the respective experimental data. Karna and Dupuis^{100, 101} improved the computational algorithm and accomplished test calculations for molecules CHHal_3 . The algorithm was implemented in the HONDO code.¹⁰¹ Despite good agreement in polarisabilities $\alpha(\omega, \omega)$, the theoretical values of $\beta(2\omega, \omega, \omega)$ were several-fold smaller than the experimental ones. Most probably, this is due to the fact that the reported experimental values refer to measurements in solutions.

Further developments of the theoretical approaches to the determination of molecular hyperpolarisabilities are based on the account of the electron correlation. Sekino and Bartlett proposed¹⁰² a multiplicative static correlation correction to $\beta(2\omega, \omega, \omega)$ calculated at the Hartree–Fock (HF) level. Within the ACES II software code developed by the authors, the correlated dynamical hyperpolarisability was obtained based on the value of $\beta(2\omega, \omega, \omega)$ calculated by the Hartree–Fock method and the values of $\beta(0)$ calculated both by the Hartree–Fock and by higher-level electron correlation methods {the perturbation (MP2) or Coupled Clusters theory [CCSD and CCSD(T)]} according to the formula

$$\beta_{\text{cor}}(2\omega, \omega, \omega) = \beta_{\text{cor}}(0) \frac{\beta_{\text{HF}}(2\omega, \omega, \omega)}{\beta_{\text{HF}}(0)}. \quad (15)$$

Rice *et al.*¹⁰³ suggested to account the electron correlation in the calculations of the dynamic hyperpolarisabilities with an additive correction

$$\beta_{\text{cor}}(2\omega, \omega, \omega) = \beta_{\text{cor}}(0) + [\beta_{\text{HF}}(2\omega, \omega, \omega) - \beta_{\text{HF}}(0)]. \quad (16)$$

Further, Rice and Handy,^{104, 105} Aiga and co-workers^{106–109} elaborated a method for the calculation of the dynamic hyperpolarisabilities within the MP2 approximation with the simultaneous account of the electron correlation and frequency dependence. The validity of the additive scheme was verified¹⁰⁵ by comparing its results with the results of strict *ab initio* calculations of $\beta(2\omega, \omega, \omega)$ for formaldehyde and ammonia. The use of the additive correction underestimates the *ab initio* values for CH_2O and NH_3 by 4% and 13%, respectively, at the incident wavelength of a ruby laser. Hammond and Rice compared¹¹⁰ the additive and multiplicative corrections in the case of HCl molecule by accounting the electron correlation with the CCSD(T) method. The frequency dependent values were calculated within the Hartree–Fock and MP2 methods. The latter approach yielded better (by 3%–8%) agreement with the experimental data and in this case, the additive correction performed slightly better (by 1%) than the multiplicative one. On the other hand, the multiplicative scheme appears preferable if the frequency dependence is taken into account by the Hartree–Fock method (the difference is 4%).

Yet another approach to the assessment of hyperpolarisability with account of the electron correlation was elaborated^{111, 112} based on the CCS, CC2, CCSD and CC3 methods. The following values of $\beta(2\omega, \omega, \omega)$ were obtained for hydrogen fluoride with the t-aug-cc-pVTZ basis set (in a.u. at $\omega = 0.0656$ a.u.):

Method	CCS	CC2	CCSD	CC3	Experiment ¹¹³ (gas phase)
$-\beta(2\omega, \omega, \omega)$	7.760	12.030	8.789	8.321	10.9 ± 0.95

It has to be mentioned that the hydrogen fluoride molecule represents a ‘stumbling block’ as regards the comparison of the theoretical and experimental results. Even after a vibrational correction (-1 a.u.)^{114, 115} is added, the theoretical estimation remains beyond the confidence interval of the experiment. Notwithstanding, the similar vibration-corrected calculations for a series of small molecules, including H_2O , CO, MeCN and HCl, give values of $\beta(2\omega, \omega, \omega)$ in quantitative agreement with the experiment (Table 4).^{116–120}

High-level *ab initio* calculations make it possible to estimate $\beta(2\omega, \omega, \omega)$ to within 10%. It has to be stressed that the accurate

reproduction of experimental data is the only reasonable criterion for the adequacy of the theoretical method applied. However, the experimental measurements are dependent on the selection of the reference values. Unfortunately, no unambiguous criteria for the correct selection of such standard values have been proposed so far.^{23, 65, 121, 122} Furthermore, the application of highly accurate calculations is restricted to the size of molecules under study. It is evident that the molecules considered above, composed of two–six atoms, are exclusively of theoretical interest.

Thus, two major directions of modern theoretical investigations into the NLO properties of molecules can be distinguished. The first direction implies the development of high-level *ab initio* methods and their verification by comparing the calculation results with the accurate experimental data from gas-phase measurements. Such calculations should use sufficiently broad basis sets that include polarisation and diffusion functions,¹²³ take into account the electron correlation and vibrational corrections,^{124, 125} which can amount up to several per cent of the total value¹²⁶ (this correction is typically neglected in lower-level calculations).

The second direction consists of the use of less accurate but faster methods for the calculation of hyperpolarisabilities enabling studies of larger molecules for the prediction of trends in their NLO properties and selection of promising systems for the experimental study. For instance, Beck and Grummt analysed¹²⁷ 200 different conjugated polar molecules using the FF and SOS methods with semiempirical approximations (AM1, PM3, CNDO/S). They concluded that the semiempirical methods adequately reproduce the experimentally observed trends, and the discrepancies between the theoretical and experimental values are due to the lack of treatment (or insufficient model treatment) of the environmental effects rather than mere theory deficiencies.

The density functional theory (DFT) is widely employed for the evaluation of NLO properties of molecules, in particular, hyperpolarisabilities, since it provides the most efficient means (in terms of computational costs) to account the electron correlation.¹²⁸ Nevertheless, the reliability and validity of DFT-derived results remain disputable. Some authors criticise^{129–132} theoretical hyperpolarisabilities calculated using very well known functionals, such as SVWN, BLYP and B3LYP.^{128, 133} Meanwhile, other research groups (see, for instance, Refs 134–138) advocate the validity of the DFT calculations. Tables 5–9 compare theoretical hyperpolarisabilities of small molecules, benzene diyne derivative **16**, triazines **17–19**, NH₂/NO₂-substituted π -conjugated molecules (compounds **1**, **12**, **20**, **21**), D/A-substituted

D = MeO (a), HO (b), Me (c), HC(O) (d).

The application of DFT gives rise to a problem of an inexact asymptotic behaviour of the majority of functionals at distances far from nuclei (*i.e.*, in the region of vacant molecular orbitals): they decrease exponentially rather than as $\sim 1/r$. The functionals with improved asymptotic behaviour [*e.g.*, LB94, HCTH(AC) or BP86-GRAC] often perform better in terms of agreement with the experimental data and accurate *ab initio* quantum mechanical calculations (see Tables 5, 6).

However, an HCTH(AC)-based calculation incorrectly predicts the hyperpolarisability of acetonitrile, whereas the use of the B97-1 functional yields more accurate estimates. An incorrect ratio of the hyperpolarisabilities of molecules **17** and **18** was obtained in a theoretical study of triazine derivatives with the

LB94 functional (see Table 7). The hybrid functionals B3LYP and B97-1 perform somewhat better than LDA and BLYP (see Table 6).

Table 8 summarises computational results for a number of molecules with extended π -conjugated bridges. According to the tabulated data, the values predicted by DFT (in particular, in the case of the LB94 functional with improved asymptotic behaviour) are significantly larger than those predicted by MP2. Based on this conclusion, Champagne *et al.*¹³¹ warned against the use of DFT for the evaluation of hyperpolarisabilities. However, we should point out that the hyperpolarisabilities increase by factors of 12 and 5 on going from molecule **1** to **12**, as estimated with B3LYP and MP2, respectively. Meanwhile, according to the experimental measurements, the ratio of hyperpolarisabilities of D/A-substituted stilbenes and benzenes varies in the range from 6 to 10, depending on substituents and experimental conditions (see Table 9). This means that the increase in β with an increase in the conjugation chain length is somewhat underestimated by MP2 and overestimated by B3LYP in the above calculations by Champagne *et al.*¹³¹ It is also of note that β of *p*-NA has been accurately determined experimentally in the gas phase (1787 ± 73 a.u., EFISH, $\lambda = 1064$ nm)⁶⁵ and it is unclear, why Champagne *et al.*¹³¹ did not compare their theoretical results with this experimental value. From Table 8, it is apparent that the B3LYP-based estimate is closer to the experimental value than that of MP2.

As has been mentioned above, the B3LYP functional performs slightly better than the non-hybrid ones and, in this particular case, also proves superior to LB94 (which estimates the increase in hyperpolarisability on going from **1** to **12** to be 19-fold). Unfortun-

nately, the lack of experimental data for **21** prevents the respective analysis of the increase in hyperpolarisability on going from **20** to **21**. We suggest that the use of DFT gives rise to the overestimation of hyperpolarisabilities in the case of extended easily polarisable π -systems, such as polyenes. At the same time, the π -systems containing aromatic rings are less polarisable and can be adequately described within DFT.

Regardless of the aforementioned drawbacks, the majority of functionals correctly reproduce the experimental trends in β (see Tables 5–8). It thus follows that the B3LYP and, especially, B97-1 functionals are slightly superior to others.

It is important to keep in mind the major purpose of the use of various computational methods. Most often, in the search for promising materials for NLO applications it is reasonable to monitor relative changes in hyperpolarisabilities along a specific series of compounds. Apparently, DFT provides the optimum efficiency for this task.

III. Characteristics of π -conjugated systems related to the efficiency of the second harmonic generation

1. Qualitative criteria of hyperpolarisability.

Hyperpolarisability as a function of the conjugated chain length

The condition that an NLO active molecule should contain strong donor and acceptor substituents linked by an easily polarisable π -bridge can be considered as a basic prerequisite in the search for NLO compounds. The optimum combination of the π -system and D/A-substituents provides the maximum NLO efficiency.

Marder *et al.*^{141–145} proposed a convenient criterion for the description of NLO active molecules, which characterises the degree of delocalisation of the electron density over the π -system as a function of the nature (weak/strong) of D/A-substituents, *viz.*, Bond Length Alternation (BLA), calculated as a mean difference between the lengths of formally ordinary and double bonds. This difference can be determined from either experimental data on the molecular structure or quantum-chemical calculations. A series of substituted polyenes was analysed in order to verify the applicability of the criterion.

The distribution of bond lengths in the polyenes shifts either towards the non-polar form (a non-polar solvent, weak D/A-substituents) or towards the zwitter-ionic form (a polar solvent, strong D/A-substituents).

The BLA criterion was used¹⁴¹ to monitor the effects of the strength of D/A-substituents on the degree of the electron delocalisation over the polyene π -chain. The criterion makes it possible to arrange any D/A-substituents in a common scale of their relative strengths and depict the molecular hyperpolarisability as a function of the substituent strength.

Within the two-level model, the static hyperpolarisability can be represented as

$$\beta = \frac{3}{2} (\mu_e - \mu_g) \frac{\mu_{ge}^2}{E_{ge}^2}, \quad (17)$$

where $(\mu_e - \mu_g)$ is the difference between the dipole moments of the molecule in the ground and excited states, μ_{ge} is the transition dipole moment and E_{ge} is the corresponding energy [this is a static analogue of the formula (5)]. Terms in the right part of Eqn (17) are related to the ground state wavefunction (Fig. 3), which in turn correlates with BLA according to the definition of the criterion.^{141, 142}

Hyperpolarisabilities of molecules with identical substituents (*viz.*, NMe_2 and CHO) as a function of BLA and another similar criterion, Bond Order Alternation (BOA), were analysed theoret-

Figure 3. Dependences of $(\mu_e - \mu_g)$ (1), μ_{eg}^2 (2), E_{eg}^{-2} (3) and β (4) on the ground-state wavefunction of a polyene system represented by the BLA parameter.

It is commonly adopted that $BLA > 0$ for molecules in the neutral form and $BLA < 0$ for zwitter-ions. A–E are arbitrarily selected regions.

ically using the SOS/INDO/CISD and FF/AM1 methods.^{144–146} Solvent effect were simulated by applying an electric field. The dependence β vs. BOA fully consistent with the curve 4 in Fig. 3 was obtained. The function β vs. BLA was also analysed¹⁴⁷ for the case of octupolar molecules (see below).

The values of β for molecules **24** with the donor substituent (D) varied over the series H, Me, OH, OMe, NH₂ and NMe₂ were estimated within the CPHF/6-31G approximation. The resultant values of β increase with an increase in the donor strength of the substituent along the above series, but it does not reach the maximum probably remaining in the region A (see Fig. 3).

Yet another criterion, BACS (Bridge Atomic Charge Sum), which characterises the effects of substituents and/or environment on the degree of conjugation over the π -chain linking donor and acceptor groups in molecules of the type **25**, was suggested.^{148–150} It is defined as the sum of charges on the atoms constituting the chain.

$$BACS = q_{C_i} + q_{H_j}$$

Solvent effects were also simulated by adjusting the external electric field strength. D/A-substituted polyenes and five-membered heterocycles (**26a–c**, **27a–c**) were selected as model systems. The optical characteristics were calculated within the FF/AM1 approximation. The linearity between BACS and BLA criteria was demonstrated for the case of polyenes,¹⁴⁸ which implies that BACS also correlates with the ground state wave-

function. It was established^{149,150} that the dependences β vs. BACS for the substituted heterocycles studied are similar to those for polyenes. Thus, it may be concluded that the curve 4 in Fig. 3 describes the general trend in hyperpolarisability of any π -conjugated system on going from its neutral to the zwitter-ionic form.

X = NH (a), O (b), S (c).

Yet another parameter utilised to represent the ground state wavefunction within the VB-*m*CT model is worth mentioning. A molecule can be represented as a combination of its valence-bond structure (VB) that characterises of the neutral form and *m* charge-transfer (CT) states corresponding to different zwitter-ionic forms (Scheme 2).

The ground-state wavefunction (ψ_g) can be written in the basis of VB (φ_{VB}) and CT (φ_{CT}) functions as

$$\psi_g = \varphi_{VB} \sqrt{1 - ml} + \sqrt{l} \sum_{j=1}^m \varphi_{CTj}, \quad (18)$$

where *m* is the number of zwitter-ionic states, *l* is the parameter quantifying the degree of mixing between the neutral and the zwitter-ionic forms. The latter parameter was selected by some researchers^{151–156} as a criterion for the evaluation of β , whereas another criterion, MIX, was preferred in a series of works^{157–160} for linear molecules. MIX relates to *l* in a simple way

$$MIX = 2l - 1.$$

The linearity between *l* and MIX, on the one side and BLA, on the other was demonstrated for linear,^{151,157–160} quadrupolar,¹⁵² octupolar^{153–155} and tetrahedral molecules.¹⁵⁶ Furthermore, Laage *et al.*¹⁶¹ applied the MIX criterion to the description of hyperpolarisabilities of charged D/A-substituted polyenes.

It has to be noted that the criteria considered above, despite their convenience, have specific limitations and are only of a qualitative character. For instance, the use of BLA for molecules containing heteroatoms is hardly justified. The BACS criterion is more suitable for the comparative analyses of results obtained for different π -conjugated chains but it has to be kept in mind that the values of atomic charges depend on the computational method

and basis sets selected.¹⁶² Probably, the criteria *I* or MIX are more versatile, however, their determination requires special calculations, whereas molecular geometry parameters and atomic charges are listed in default outputs of all major quantum-chemical codes. The common feature of all the criteria considered above is that they correlate with the ground state wavefunction, which primarily defines the efficiency of the second harmonic generation. All the above-mentioned criteria can only be used for the visualisation of the wavefunction.

As has been shown both theoretically (*e.g.*, see Ref. 163) and experimentally,^{78,79} an elongation of the conjugation chain gives rise to a significant increase in the molecular hyperpolarisability. Zhu and Jiang¹⁵⁰ estimated the increase in β with an increase in the number of units (n) in the conjugation chain. Comparative data for molecules with polyheterocyclic chains are shown in Fig. 4. The quinonoid-type polyheterocycles **26a–c** reveal high NLO activity, whereas that in the case of polyheterocycles **27a–c** is significantly lower and the activity increases more slowly with the chain elongation. According to the computation, β increases in the series pyrrole < furan < thiophene, but this empirical observation was not explained.

Figure 4. Hyperpolarisability as a function of the number of conjugated chain units for NH_2/NO_2 -substituted polyheterocycles (1–6) and polyenes (7);

(1) polythiophene (**27c**), (2) quinonoid analogue of polythiophene (**26c**), (3) polyfuran (**27b**), (4) quinonoid analogue of polyfuran (**26b**), (5) polypyrrole (**27a**), (6) quinonoid analogue of polypyrrole (**26a**), (7) polyenes.

Similar results were obtained by Morley,¹⁶⁴ who applied the software code CNDOVSB to calculate the polarisabilities of NMe_2/NO_2 -substituted polyheterocycles. The same series of ascending β (pyrrole < furan < thiophene) was obtained. Morley speculated¹⁶⁴ that such a sequence is due to the combined effect of the degree of charge transfer and energy gap between the ground and excited states.

Investigation into the dependence of hyperpolarisabilities of NMe_2/NO_2 -substituted polyenes, polyynes and polyphenylenes on the conjugation chain length under assumption of planarity of the molecules using the SOS/CNDO/CI method (Fig. 5), for molecules with sufficiently long π -chains ($n > 7$), showed that β increases in the series polyphenylenes < polyynes < polyenes. Furthermore, in the case of polyphenylenes, the increase β stops for $n > 8$.^{165–168}

Champagne, Jacqemin *et al.*^{169–174} investigated a number of molecules containing polymethinimine (PMI) π -chains. Since the fragment $\text{CH}=\text{N}$ can be simultaneously regarded as a chain unit and a D/A-pair, they analysed^{169,170} molecules $\text{H}-(\text{CH}=\text{N})_n\text{H}$, *i.e.*, molecules without supplementary substituents. Under assumption of the planar *trans*-structure of the chain, the values of the hyperpolarisability were estimated for n varied from 1 to 20 and the hyperpolarisability increment per $\text{CH}=\text{N}$ unit in an infinite chain was determined

$$\Delta\beta = \beta(n) - \beta(n-1).$$

Figure 5. Hyperpolarisability as a function of the number of conjugated chain units for NMe_2/NO_2 -substituted oligomers; (1) polyenes, (2) polyynes, (3) polyphenylenes.

If the lengths of formally ordinary and double carbon–nitrogen bonds are kept fixed,¹⁷⁰ the absolute values of hyperpolarisability significantly diminish with an increase in BLA, in agreement with the general dependence $\beta(\text{BLA})$ (see Fig. 3). Moreover, the increment of $|\beta|$ increase with a chain elongation also decreases

BLA / Å	0.100	0.126	0.150	0.190	0.220
$\Delta\beta_{zzz}(\infty)$ (a.u.)	-2753 ± 129	-1461 ± 51	-869 ± 28	-434 ± 7	-293 ± 2

The authors explained this by a decrease in the degree of the electron density delocalisation. In another study of the same system,¹⁷¹ the bond lengths were allowed to vary in the geometry optimisation procedure and the BLA values were adjusted by allowance for the solvent effects. As expected, BLA somewhat decreased with chain elongation: from 0.132 Å to 0.095 Å and from 0.137 Å to 0.092 Å on going from $n = 2$ to 18 for an isolated molecule and acetonitrile solution, respectively.

The ratio β/M , where M is the molecular mass, was suggested as a convenient criterion to compare unsubstituted PMI (4.2 in units of 10^{-30} esu) with other types of compounds.¹⁷² For instance, $\beta/M = 0.76$, 0.16 and 0.10 for D/A-polyenes,¹⁷⁵ *p*-NA¹⁷⁶ and 3-methyl-*p*-NA,¹⁷⁷ respectively.

PMI and polyenes with identical D/A-substituents were directly compared in a theoretical study within the CPHF/6-31G approximation^{173,174} (Table 10, Fig. 6). The authors considered¹⁷³ the effects of different D/A-substituents and their mutual arrangement (which is especially important for PMI) at a constant length of the PMI and polyene chains ($n = 4$).

$\text{F}-(\text{CH}=\text{N})_4\text{NH}_2$	1495.5	$\text{F}-(\text{CH}=\text{CH})_4\text{NH}_2$	1109.9
$\text{H}_2\text{N}-(\text{CH}=\text{N})_4\text{F}$	−456.6	$\text{F}-(\text{CH}=\text{CH})_4\text{OH}$	707.5

According to the data listed in Table 10, the PMI chain provides higher optical efficiencies with weakly polarising substituents (OH/F, NH_2/F). However, the situation is reversed upon the introduction of strong D/A-groups (*i.e.*, OH/ NO_2 or NH_2/NO_2). The authors explained this by a combined action of three factors: the degree of the electron density delocalisation and the asymmetry in the electron density distribution relative to the unsubstituted polyene either intrinsic (due to the alternating

Figure 6. Component of hyperpolarisability parallel to the conjugated chain (β_1) as a function of its length for $\text{H}_2\text{N}-(\text{CH}=\text{CH})_n\text{NO}_2$ (1), $\text{O}_2\text{N}-(\text{CH}=\text{N})_n\text{NH}_2$ (2) and $\text{H}_2\text{N}-(\text{CH}=\text{N})_n\text{NO}_2$ (3). Calculation within the CPHF/6-31G approximation.

$\text{N}^{\delta-}=\text{C}^{\delta+}$ fragments) or extrinsic (induced by D/A-substituents). The higher NLO efficiency of polyenes in the case of strong D/A-substituents (NH_2/NO_2) can be explained by the higher degree of the π -electron delocalisation in polyenes with respect to PMI, which dominates over the asymmetry contribution. The situation is reversed in the case of weak D/A-pairs: the asymmetry effect prevails. The best result upon PMI substitution can be achieved by attaching donor groups from the side of nitrogen atoms (see Table 10), since the asymmetry effects of the D/A-groups and $\text{CH}=\text{N}$ fragments are oppositely directed in this case. A study of changes in hyperpolarisability of NO_2/NH_2 -substituted PMI and polyenes with chain elongation¹⁷⁴ (see Fig. 6) indicated that the attachment of donor groups from the side of nitrogen atoms enhanced the polarisability only for short and medium-length PMI chains ($n < 11$), which is in agreement with the data presented in Table 10. The opposite effect was observed for long PMI chains: the absolute value of β continued to increase for $\text{H}_2\text{N}-(\text{CH}=\text{N})_n\text{NO}_2$, whereas it started to decrease for $\text{O}_2\text{N}-(\text{CH}=\text{N})_n\text{NH}_2$.

These results can be rationalised within the concept of auxiliary D/A-substituents. The terminal nitrogen atom in a PMI chain carries a partial negative charge; the attachment of a donor group to it increases its donor ability, and thus this acts as an auxiliary donor. The partially positively charged terminal carbon atom behaves similarly with respect to acceptor groups attached. In such a situation, the asymmetry induced by the D/A-pair is opposite to the intrinsic asymmetry due to the $\text{CH}=\text{N}$ fragments. For relatively short PMI chains ($n < 4$), the D/A-pair asymmetry prevails. Upon an increase in the chain length, the induced asymmetry becomes weaker and thus the intrinsic asymmetry due to the $\text{CH}=\text{N}$ fragments starts to dominate, which gives rise to a decrease in the hyperpolarisability at $n > 10$; the effect of substitution vanishes for $n \rightarrow \infty$. If D/A-substituents are attached to the opposite terminal atoms, both asymmetry effects act in the same direction. However, the terminal $\text{N}^{\delta-}$ and $\text{C}^{\delta+}$ atoms of the PMI chain deactivate the acceptor and donor properties of the substituents attached, which gives rise to β lower than that of analogous D/A-polyenes. This concept is also supported by results obtained for molecules **28–37** (Table 11).^{4, 178–182}

Table 11. Calculated values of static hyperpolarisabilities (10^{-30} esu) for molecules **28–37**.

Molecule	β	Calculation method	Ref.
28	28.0	FF/PM3	178–180
29	36.8	FF/PM3	178–180
30	33.9	SOS/PPP/CI	4
31	25.6	SOS/PPP/CI	4
32	46.7	SOS/PPP/CI	4
33	47.6	SOS/PPP/CI	4
34	4.87	CPHF/6-31G	181, 182
35	3.94	CPHF/6-31G	181, 182
36	6.35	CPHF/6-31G	181, 182
37	4.26	CPHF/6-31G	181, 182

The bridging nitrogen atom in molecule **28** acts as a weak acceptor, and the central CH group acts as a donor. This deactivates the terminal D/A-substituents. In contrast, the central fragments in molecule **29** enhance the strength of D/A-substituents, which gives rise to an increase in the hyperpolarisability.^{178–180} The heterocyclic nitrogen atoms in molecules **30–33** withdraw the electron density thus increasing the partial positive charge on the adjacent carbon atoms.⁴ This attenuates the donor properties of molecules **30** and **31** but enhances the acceptor properties of molecules **32** and **33**. An analogous situation is observed in molecules **34–37**.^{181, 182}

Jacqemin *et al.*^{183–186} published the first estimates (calculated with the CPHF/6-31G method) of the hyperpolarisabilities of molecules $(\text{X}-\text{Y})_n$, where X, Y = B, P, Si, N, C characterised by the *trans*-cisoid structure [except for the $(\text{B}=\text{N})_n$ molecule, which is linear]. In particular, they estimated the values of β/M (Table 12). It is apparent that the PMI systems considered above manifest significantly higher NLO activities.

Table 12. Calculated values of β/M (10^{-30} esu) for $(\text{X}-\text{Y})_n$ oligomers.

2. Molecules with heteroatoms

Fragments containing heteroatoms, in particular, heterocyclic π -systems, are widely used in the design of NLO-active compounds as both π -bridges and the D/A groups.^{187–190}

The NLO properties of azulene-containing molecules, their heteroanalogues and related reference compounds (**38–44**) have been studied.^{191–193}

The azulene bicyclic system can be used as either a donor or an acceptor or as a unit of a π -bridge. The donor properties of azulene were estimated based on the EFISH measurements in dioxane ($\lambda = 1907$ nm)¹⁹¹ and SOS-based calculations (INDO, $\lambda = 1907$ nm).¹⁹² Its behavior as a π -bridge was considered theoretically using the FF method (AM1 in the static limit).¹⁹³ The donor properties of azulene are comparable to those of RR'N groups (R, R' = Alk or Ar, see molecules **38–41**), which are among the strongest π -donors. Diazaazulene derivatives **42–44** manifest higher hyperpolarisabilities than DANS (Table 13), which indicates the higher NLO activity of azulene-containing molecules. Probably, this is due to the lower energy barrier to the electron delocalisation and enhanced donor and acceptor ability of the substituents attached to the five- and seven-membered rings of azulene, respectively.

Table 13. Calculated hyperpolarisabilities of azulene-containing molecules, their hetero analogues and reference compounds.

The spectral properties of unsubstituted five-membered heterocycles C_4H_4X ($X = O, S, Se$ and Te) were studied theoretically using *ab initio* calculations at different levels.^{194–196} The hyperpolarisability increases in the following series: thiophene < furan < selenophene < tellurophene. It is of interest that the results of theoretical studies of the D/A molecules with π -systems built up of such heterocycles (see above) manifest the reversed trend, *viz.*, thiophene > furan. As it will be discussed in more detail below, both thiophene and furan can act as a π -bridge of choice depending on the specific structure of the D- π -A molecule. It is of note that the sequence of ascending β for unsubstituted heterocycles partly correlates with the aromaticity series: thiophene > selenophene > tellurophene > furan.¹⁹⁷ The correlation is violated by the position of furan. However, the aromaticity of furan is still a subject of debate: it is estimated to be in the range from 20% to 60% of the benzene value, depending on the theoretical method utilised.¹⁹⁸

For unsubstituted fused heterocycles, β increases¹⁹⁹ and the aromaticity decreases²⁰⁰ on going from benzothiazole to benzoxazole.

Most probably, the following trend is observed: the less aromatic unsubstituted heterocycle is characterised by larger β due to the lower energy barrier to the electron density redistribution.

Jen and co-workers^{201–205} analysed the effects of thiophene for benzene substitution in π -conjugated chain on the spectral properties.

According to the results obtained (Table 14, molecules **2, 45–49**), the substitution for the phenylene fragment from the donor side is more efficient, since the electron-rich thiophene fragment acts as an auxiliary donor in this case. If the bridge is built up of two thiophene fragments, the value of β increases further, since only a readily polarisable conjugated system appears between the D/A groups. The introduction of strong π -acceptors, such as a tricyanoethylene substituent, gives rise to an even further increase in the hyperpolarisability. On the other hand, it has to be

Table 14. Spectral properties [$10^{48} \mu\beta_0$ (esu); $\lambda_{\max}$ /nm] of heterocyclic molecules.

Dirk *et al.*²⁰⁶ proposed to use thiazole as a structural unit of π -bridges. The substitution of this five-membered heterocycle for the benzene ring doubles β (see Table 14, molecules 50 and 51). The authors explained this increase by the lower energy barrier to the electron delocalisation in the case of thiazole. Meanwhile, molecule 51 is less optically transparent.

The hyperpolarisabilities of biaryls 52–54 increase²⁰⁷ in the series 52 (imidazole) < 53 (oxazole) < 54 (thiazole), although they remain lower than β of their biphenyl analogue 55. Similar trends in β on going from π -systems containing nitrogen heterocycles to oxygen and further to sulfur heterocycles were obtained for molecules 56–58 and 59–61.^{208, 209}

It is evident that the aforementioned trends can be explained only by a combined account of the effects of the energy barrier to the electron delocalisation and the π -electron density excessiveness or deficiency (relative to that in benzene) in these heterocyclic systems.

A detailed theoretical background for the results considered above was given^{210–212} taking heteroanalogues of D/A-substituted stilbenes as model molecules. Breitung *et al.*²¹² also analysed five-membered heterocyclic compounds containing two heteroatoms, for which the non-equivalence of positions 2 and 5 in the heterocycles has to be addressed. Albert *et al.*²¹⁰ considered a series of molecules 62–73. Their spectral properties were assessed using the SOS/INDO method ($\hbar\omega = 0.1$ eV) for molecular geometries optimised at the AM1 level (Table 15).

65	53.8	423	71	36.1	419
66	53.2	425	72	27.7	414
67	62.5	430	73	24.4	409

Note. For molecule 12, $\lambda_{\text{max}} = 363$ nm, $\beta_{\text{vec}} = 31.7 \times 10^{-30}$ esu.

According to the data summarised in the left part of Table 15, the heterocyclic substitution for one of the benzene rings at the donor side increases the hyperpolarisability, which is in accordance with the lower aromaticity of the heterocycles. However, the energy of aromatic stabilisation decreases in the series benzene > thiophene > pyrrole > furan,^{213, 214} whereas the hyperpolarisability increases in the series 12 (benzene) < 62 (thiophene) < 63 (furan) < 64 (pyrrole). The latter series conforms to the sequence of ascending π -electron excessiveness.²¹⁵

Therefore, heterocycles act as auxiliary donors; apparently, this factor prevails over the aromatic stabilisation effects. Moreover, both factors act in the same direction. Upon replacement of carbon atoms in the benzene ring from the acceptor side by the nitrogen atoms (molecules 65–67), β further increases. The resultant π -electron-deficient ring enhances the effect of the NO_2 group and, moreover, provides a lower delocalisation barrier. If nitrogen atoms are introduced at the position Z (no such compounds are mentioned in Table 15), the hyperpolarisability increases even further. Meanwhile, if the five-membered heterocycle is located at the acceptor side (right part of Table 15), the order of ascending β is reversed, i.e., 68 > 69 > 70, which corresponds to the decrease in the π -electron excessiveness and does not correlate with the changes in the energy barrier to the aromatic delocalisation. Still, all three molecules 68–70 manifest higher NLO activity than molecule 12, which is due to the lower aromatic delocalisation barrier therein with respect to benzene. In this case, the effects of the π -electron density excessiveness are of low importance. It seems strange that the hyperpolarisability of molecule 68 is larger than that of 62. This violates the concept of auxiliary D/A-substituents and is not supported by other theoretical²¹¹ and experimental^{201–205} estimates.

Moylan *et al.*²¹⁶ analysed β as a function of the thiophene location in the π -chain using compounds 74 ($10^{30} \beta = 686 \pm 21$ esu; $\lambda_{\text{max}} = 708$ nm) and 75 ($10^{30} \beta = 867 \pm 35$ esu; $\lambda_{\text{max}} = 719$ nm) as examples.

According to the EFISH measurements (at $\lambda = 1907$ nm in chloroform), higher NLO activity is observed for molecule **75**, which contains the thiophene fragment substituted with an acceptor group, despite molecule **74** is more polar, *i.e.*, it possesses a higher dipole moment. This discrepancy can be explained²¹⁶ based on the β (BLA) dependence (see Fig. 3) assuming that both molecules are located in the region *B*. This implies that an increase in the polarity of the π -system, for instance, induced by a stronger D/A group or by a change in the thiophene position, gives rise to a decrease in β . Thus the authors concluded that the concept of auxiliary D/A groups is not versatile. Nevertheless, it remains unclear, why the authors²¹⁶ did not study molecules with weaker substituents. Following the authors' logic, such molecules should fall into the region *A* (see Fig. 3), such that the thiophene location from the side of the donor should appear preferable. This is supported by the experimental data^{201–205} for weaker D/A groups. In our opinion, the results by Moylan *et al.*,²¹⁶ once again corroborate the above statement that the optimum combination of D/A groups and a π -system in a D- π -A molecule is required for the efficient manifestation of the NLO properties. According to the dependences shown in Fig. 3, the majority of NLO active molecules studied fall into the region *A* where all the aforementioned concepts are valid. Meanwhile, for molecules in the region *B*, all these regularities (not only the concept of auxiliary D/A groups) are violated thus giving rise to a decrease in β .

The hyperpolarisabilities of a series of analogues of NH₂/NO₂-substituted stilbene derivatives²¹¹ are listed in Table 16. The calculations were accomplished using different methods, but all qualitative trends were fully consistent.

X = NH, A = CH, B = N: Y = S (**76**), O (**77**), NH (**78**);
Y = NH, A = N, B = CH: X = S (**79**), O (**80**), NH (**81**).

X = S: Y = S (**82**), O (**83**), NH (**84**); X = O: Y = S (**85**), O (**86**), NH (**87**); X = NH: Y = S (**88**), O (**89**), NH (**90**).

These results support the above-mentioned regularities regarding the replacement of the benzene ring by heterocyclic fragments. The hyperpolarisability increases in the following

Table 16. Calculated values of β_0 (CPHF/4-31G) for NH₂/NO₂-substituted stilbenes and their heterocyclic analogues under the assumption of their planarity.²¹¹

Molecule	$10^{30} \beta_0$ (esu)	Molecule	$10^{30} \beta_0$ (esu)
9	26.0	82	32.9
64	45.2	83	29.0
70	21.6	84	23.0
76	50.8	85	36.9
77	45.3	86	32.1
78	37.3	87	27.5
79	18.0	88	47.1
80	20.2	89	40.8
81	26.3	90	35.0

series **82** < **85** < **88**, **83** < **86** < **89**, **84** < **87** < **90** and decreases in the series **82** > **83** > **84**, **85** > **86** > **87**, **88** > **89** > **90**. In the case of five-membered rings with two heteroatoms, β manifests the following trends: **76** > **77** > **78**, **79** < **80** < **81**. It is of interest that the hyperpolarisability increases in the series **79** < **80** < **70** < **84** < **81** < **87** < **90**. The electron density deficiency decreases in the series thiazole > oxazole > imidazole.²¹⁵ Some authors²¹⁷ consider imidazole already as a weakly electron-rich fragment. Apparently, this is supported by the presented set of molecules where the imidazole ring adjacent to a donor group (**81**) results in higher NLO activity than benzene (**70**) and thiophene (**84**) rings. It is also important to stress that the charges on the carbon atoms in positions 2 and 5 of azoles are different. In molecule **81**, the donor is attached to the carbon atom in position 5, which has a lower positive charge than that in position 2, which is more favourable. Unfortunately, no examples with the reversed situation were considered.²¹¹ Such a study has been carried out by McMahon and co-workers,²¹² who considered D/A-substituted stilbene analogues with one Ph ring replaced by thiazole using the SOS method ($\lambda = 1907$ nm).

Molecule	91	92	93	94	95
$10^{30} \beta$ (esu)	36	54	118	42	57

Therefore, the difference in the π -density at the carbon atoms in positions 2 and 5 differently affects the hyperpolarisabilities of molecules.

The maximum value of β is achieved upon the introduction of a π -electron deficient thiazole ring from the side of an acceptor in a way that the latter is bound to the more positive carbon atom at position 2. This was also rationalised by the contribution made by the heterocycle into the total dipole moment of the molecule directed from the acceptor to the donor. The dipole moment vector in the heterocycle is directed approximately from the nitrogen atom to the sulfur atom and thus, in the case of molecule **93**, it makes a certain positive contribution to the total dipole moment. A similar situation is observed in molecule **95**, but the heterocycle, being π -electron deficient, behaves as a 'counter-acting' donor.

It is interesting to note that the replacement of one of the benzene rings by the thiazole fragment both from the donor and acceptor sides gives rise to an increase in the hyperpolarisability of the D/A-substituted stilbene analogue, *i.e.*, the aromaticity effects prevail. For molecules **76** and **79** (see Table 16), where the thiazole fragment substitutes one of the pyrrole rings in molecule **90**, the hyperpolarisability decreases in a different series, *viz.*, **76** > **90** > **79**, which means that the π -electron deficiency of the thiazole ring becomes the dominant factor. Two reasons can be suggested to explain this apparent discrepancy: first, molecules **76** and **79** contain pyrrole as the second aromatic ring involved into the π -system (rather than benzene in molecules **92–95**), and second, different D/A pairs were used. This changes the balance between the aromaticity and the π -electron deficiency effects.

Results similar to those discussed above²¹² were obtained by Jug *et al.*²¹⁸ for imidazole and oxazole analogues of D/A-substituted stilbenes **96–99** (CPHF-based calculations within the VWN/TZVP-FIP approximation).

X = NH, Y = CH, Z = N (**96**); X = NH, Y = N, Z = CH (**97**);
X = O, Y = CH, Z = N (**98**); X = O, Y = N, Z = CH (**99**).

The following values of β_0 were obtained:

Molecule	96	97	98	99
$10^{30} \beta_0$ (esu)	77	78	84	99

The examples discussed above, despite the existence of specific discrepancies, demonstrate the general approach to the design of efficient NLO molecules based on the concept of auxiliary electron donors (acceptors) and fragments with low energy barriers to the electron delocalisation. Notwithstanding, the prediction of a net balance of particular factors on the hyperpolarisability remains a challenging task. In addition, the effects of aromaticity delocalisation barrier and electron deficiency/excessiveness can vary, depending on the computational method or experimental conditions. However, regardless of the method applied, the results can always be rationalised based on the interplay of three factors, *viz.*, the energy barrier to the delocalisation (aromaticity), the π -electron density deficiency/excessiveness and the charge distribution within the heterocycle (*i.e.*, the orientation of the dipole moment of the ring).

It is of note that the hyperpolarisability can be used as a criterion of the combined influence of the π -electron density deficiency/excessiveness and aromatic stabilisation.

Over the recent years, considerable efforts have been put forth to study the NLO properties of organic cations due to the fact that the probability of the crystallisation in non-centrosymmetric space groups for salts is higher than for neutral molecules. This implies that the molecular design step should include an analysis of ions. The hyperpolarisability of a series of cations **100–104** was measured by means of HRS in MeCN (with PF_6^- as a counterion).^{219–222}

The cations reveal the same trends in the spectral properties as analogous D- π -A molecules.

Cation	100	101	102	103	104
λ_{max} /nm	470	477	553	537	579
$10^{30} \beta_0$ (esu)	110	108	130	130	227

The aryl substitution for an alkyl group at the N^+ atom and the elongation of the conjugation chain gives rise to an increase in β and narrowing of the optical transparency range. The cations manifest rather high hyperpolarisabilities. However, an important question arises: what a system is actually probed in these cases. The acceptor ability of the pyridinium cation should depend on the strength of its interaction with a counteranion,²²³ which in turn depends on the experimental conditions, such as the nature of the solvent and of substituents at the N^+ atom and solution concentration. The exact structure of a cation-anion complex can be unambiguously determined in the crystalline state (which has indeed been done for a number of samples), whereas it is impossible for solutions. Thus it remains unclear, whether the regularities revealed reflect changes in the structure of the cation itself or they are due to the counterion effects. Yet another important problem has also to be addressed: how one can utilise the results of measurements in solution to predict the NLO susceptibility of a crystal, which can feature a totally different mutual orientation of the cation and anion? However, taking into account that the basic trends obtained are very similar to those for neutral D- π -A molecules (β increases with an increase in the acceptor strength and the length of the conjugation chain), it might be assumed that the counterion-induced effects are insignificant and the experimental results can well be interpreted in the same way as for the neutral molecules. Quantum-chemical calculations could help to clarify this problem, but no theoretical studies of this kind were carried out.^{219–222}

According to the literature data, vinylene (sometimes, acetylene) and thiophene (or other heterocyclic) fragments are combined in the vast majority of molecules considered as promising NLO materials. In addition, phenylene fragments are also often used as structural blocks of π -bridges. Examples of diverse NLO active molecules are discussed below and their spectral properties are summarised in Table 17.

The molecules considered incorporate heterocyclic fragments (**105–108**), phosphorus-containing groups (**109, 110**), branched π -chains (**111, 112**) and azo-groups (**109, 113**). Unfortunately, the results obtained for them cannot be directly compared; however, the general trend of an increase in β with an increase in the conjugation chain length, strength of D/A substituents, λ_{max} and a decrease in the aromaticity degree are evident. Table 17 also indicates that the molecules transparent in the visible region ($\lambda_{\text{max}} < 400$ nm) typically manifest rather low values of β (*e.g.*, **106a, 108a,b**). Criteria for the selection of specific combinations of fragments should include, in addition to achieving the maximum possible hyperpolarisabilities, high optical transparency, thermal stability and synthetic accessibility. An elongation of a π -bridge typically diminishes the thermal stability and narrows the optical transparency range. The introduction of strong D/A substituents (NR_2 , NO_2 , CN) induces a bathochromic shift of the absorption band. In overall, the design of D- π -A molecules by combining different D/A groups and building blocks of π -bridges is aimed at

achieving a desired level of the thermal stability and optical transparency while keeping sufficiently high values of β .

3. Zwitter-ionic molecules

One of the approaches to the design of NLO active molecules implies the use of aromatic D/A groups either directly attached to each other or linked through a short π -bridge.²³⁸ Among this class of compounds, merocyanine dyes are studied most intensely. The ground state of merocyanines can be represented as a superposition of the non-polar quinonoid form (e.g., **114**) and the zwitter-ionic form (e.g., **115**) that makes a significant contribution.

Merocyanines exhibit negative solvatochromism and are exceptionally sensitive to the nature of the solvent.

The first study of the NLO properties of merocyanine was accomplished by Levine *et al.*²³⁹ The absorption maximum was observed at λ_{max} of 605 nm and 440 nm in pyridine and water, respectively. According to the EFISH measurements in pyridine and methanol (which is close to water in terms of polarity), β is negative in both solvents but its absolute value is larger in methanol (-51×10^{-30} esu vs. -34×10^{-30} esu). Similar results were obtained for dyes **116**–**118**; their experimentally measured spectral characteristics are compiled in Tables 18 and 19.

A comprehensive theoretical study of merocyanines was performed by Albert *et al.*²⁴⁷ (SOS/INDO, $\hbar\omega = 0.65$ eV). In particular, they reported functions β vs. ground state wavefunction for molecules **116b**, **119**, **120** (Fig. 7).

Molecule **119** contains no aromatic groups; both the neutral and zwitter-ionic forms of **120** are stabilised by one aromatic ring, whereas in the zwitter-ionic form of **116b**, both six-membered rings are aromatic. The curves obtained have generally the same shape as function β (BLA) depicted in Fig. 3. In the case of molecule **116b**, this dependence differs drastically from those for **120** and **119** because of the aromatic stabilisation of the zwitter-ionic form. This form makes a dominant contribution to the ground state of the molecule already in weakly polar solvents, and an increase in the solvent polarity gives rise to an increase in $|\beta|$.

Figure 7. The dependences of β_{vect} (1), transition dipole moment for the transition from the ground to the first excited state (μ_{ge}) (2) and the respective transition energy (ΔE_{ge}) (3) on the external field strength for molecules **119** (a), **120** (b) and **116b** (c).²⁴⁷

The spectral properties of heterocyclic zwitter-ionic molecules **121–129** were the subject of both theoretical (CNDOVSB, $\hbar\omega = 0.95$ and 0 eV; SOS/INDO/S, $\hbar\omega = 0.65$ and 0 eV; CPHF/6-31G) and experimental investigations.^{248–250}

There is qualitative agreement between the results obtained by different methods. According to calculations at the CPHF/6-31G level presented in Table 20, the NLO activities of molecules **121–129** are 3–5 times higher than those of the well-known NLO molecules **1** and **2**. This difference was explained by a larger change in the dipole moment ($\Delta\mu$) upon the transition into the excited state. And this effect is achieved for relatively small molecules, whereas an increase in $\Delta\mu$ for normal D– π –A systems can only be achieved by an elongation of a π -conjugated chain.

Table 20. Spectral properties and dipole moments of heterocyclic zwitterionic molecules in the ground (μ_g) and excited (μ_e) states.

Abe *et al.*²⁵⁰ carried out an experimental (measurements of HRS) and theoretical investigation into the behaviour of molecule **124** in solvents of different polarities. The experimental measurements indicated that the hyperpolarisability slightly decreases in more polar solvents. The theoretical values were calculated using the CPHF/6-31G method and the solvent effects were taken into account within the Onsager model by varying the dielectric permittivity (ϵ) from 1 to 90. It was found that the hyperpolarisability decreases from the maximum value of $|\beta| = 33 \times 10^{30}$ esu at $\epsilon = 2$ to nearly zero with an increase in ϵ up to 90. It is of note that the opposite results were obtained for merocyanines, as discussed above. Probably, this difference is due to the fact that the isolated molecule **124** in the ground state falls into the region close to the minimum of $\beta(\epsilon)$ (see Fig. 7), *i.e.*, the contribution of the zwitter-ionic form is significantly larger than that for merocyanines and thus $|\beta|$ decreases with an increase in the solvent polarity.

Abe *et al.*²⁵¹ analysed (within the CPHF/6-31G approximation) the spectral properties of molecules **130–136** taking molecule **129** as a reference. An extended conjugated chain was introduced from the side of an acceptor group rather than between the D/A substituents. In addition, some molecules with non-aromatic D/A groups were considered (see Table 20).²⁵¹ Upon introduction of additional π -substituents into the pyridinium fragment, the hyperpolarisability first increases but then starts to decrease after a certain threshold length of the conjugation chain (*cf.* molecules **129** and **134–136**). This phenomenon was explained by competing effects of $\Delta\mu$ and $\lambda_{\max} \sim 1/E_{ge}$. The value of $\Delta\mu$ remains virtually constant on going from **129** to **134**, whereas the transition energy E_{ge} decreases, which results in an

increase in β . Upon further elongation of the π -chain, E_{ge} changes insignificantly, whereas $\Delta\mu$ decreases resulting in a respective decrease in β . Upon introduction of an additional donor group, β decreases (molecules **130** and **132**), since both $\Delta\mu$ and $\lambda_{\max}$ decrease. In contrast, the introduction of an acceptor group (molecules **131** and **133**) leads to the opposite effect due to an increase in $\Delta\mu$ and $\lambda_{\max}$.

Interesting results were reported by Albert *et al.*^{252, 253} for a series of merocyanine dyes and their analogues (molecules **137–140**).

$R^1 = R^2 = H$ (a); $R^1 = H$, $R^2 = Me$ (b);
 $R^1 = R^2 = Me$ (c); $R^1 = Me$, $R^2 = Bu^t$ (d);
 $R^1 = R^2 = Bu^t$ (e).

Using the Hückel method within the two-level model [see Eqn (17)], they demonstrated that an increase in the torsion angle θ at the central double bond from 0° to 90° gives rise to an increase in the difference between the dipole moments of the molecule in the ground and excited states as well as in the transition dipole moment and to a decrease in the transition energy ($E_{ge} = 0$ at $\theta = 90^\circ$). This combination of factors should lead to the existence of a maximum value of β at $\theta = 70–89^\circ$. Figure 8 compares the function $\beta(\theta)$ for unsubstituted molecule **137a** with freely variable θ with the hyperpolarisabilities of molecules **137a–e** in which the respective torsion angles are determined by steric repulsion of substituents. Both the dependences have similar behaviour. The maximum value of β is in the range of $70–80^\circ$ and significantly exceeds that for the planar structure.

Figure 8. Hyperpolarisability of molecule **137a** (solid line) (SOS/INDO, $\hbar\omega = 0.1$ eV, AM1 optimisation) as a function of an angle between the six-membered rings (θ) and the hyperpolarisabilities of molecules **137a–e** (small circles marked as 1–5, respectively).

Calculations for molecules **141** and **142** with the FF/AM1 method yielded similar results.^{254, 255} Here, the maximum value of β is reached at θ of 60–80°.

Albert *et al.*²⁵³ also analysed the effects of the elongation of a π -conjugated chain (*cf.* molecules **139** and **140**) on β . The chain fragments were introduced in such a way as to retain the steric effects of substituent resulting in the non-planar structure. Selected results are shown in Table 21. Variation of the torsion angle in molecule **139** by introducing various substituents gives rise to the same type dependence as that for molecule **137** discussed above. It is worth mentioning that the molecule **139e** with the conjugation chain elongated from the side of the acceptor group is characterised by higher β as compared to molecule **140** (the elongation from the donor side), which is probably due to the more efficient stabilisation of the zwitter-ionic (benzenoid) form. A decrease in β with an elongation of the conjugation chain in the series of molecules **139e–g** was explained in a similar way. Unfortunately, trends in β upon chain elongation in **140** were not considered by the authors;²⁵³ however, based on the results discussed above, it might be assumed that β should decrease with an increase in the length of the conjugation chain owing to smaller contribution of the zwitter-ionic form to the ground state of the molecule.

Table 21. Spectral characteristics of molecules **138–140**.²⁵³

Molecule	R ¹	R ²	n	$\lambda_{\max}$ /nm	$10^{30} \beta$ (esu)
138	—	—	—	1206.8	352.8

139g	Bu ^t	Bu ^t	3	971.0	754.5
140	—	—	—	991.6	1119.4

The effects of deviation from planarity for quinonoid molecules were also considered by other research groups.^{256, 257} Bartkowiak *et al.*²⁵⁶ analysed the hyperpolarisabilities of molecules **143a,b** as a function of their conformations using the SOS and FF methods within the AM1 approximation and found that the maximum β is reached at angles θ between the six-membered rings of 60° and 75° for **143a** and **143b**, respectively

According to the results of X-ray crystallographic studies,^{258–260} the angle θ lies in the range of 55–70° for molecules similar to **143** containing phenyl substituents in the *ortho*-positions of the pyridine ring ($R^2 = \text{Ph}$), which is close to the optimum value for the manifestation of the NLO properties. Gangopadhyay *et al.*²⁵⁷ selected 7- R^1 -7'- R^2 -8,8'-dicyanoquinodimethane as a reference molecule.

Figure 9. A graphical representation of hyperpolarisabilities (FF/AM1) of various 7- R^1 -7'- R^2 -8,8'-dicyanoquinodimethane derivatives.

They constructed 22 molecules with the torsion angle varying from 0° to 86° by introducing donor groups with different steric volumes (Fig. 9). Assuming that the strengths of donor groups differed insignificantly, it was concluded that the maximum of β reached at $\theta \sim 60^\circ$ suggests the preferred non-planar conformation.

It is of note that in the majority of ordinary D- π -A molecules, the deviation from planarity results in a decrease in the hyperpolarisability due to a break of the π -conjugation chain.^{261–264}

Ravi and Radhakrishnan²⁶⁵ proposed to describe the balance between the quinonoid and zwitter-ionic forms of a molecule with a criterion QBC (Quinonoid-Benzenoid Character) defined as

$$\text{QBC} = 1 - 6 \sum_{i=1}^3 |1.400 - r_i|,$$

where 1.400 Å is taken as the standard value of the bond length in benzene; r_1, r_2, r_3 are the bond lengths in the six-membered quinonoid ring. The value of QBC can be varied by adjusting the electric field strength. 7,7'-Diamino-8,8'-dicyanoquinodimethane was used as a reference molecule. The calculations were carried out using the SOS/AM1/CISD method. Table 22 summarises the values of hyperpolarisabilities, energies of transitions to the excited states and QBC. It is seen that the absorption maximum appears in the visible region at the QBC corresponding to the maximum value of β ; upon further increase in QBC, β decreases only to 50% of its maximum value, whereas the absorption band shifts to the UV range. It has to be pointed out that the actual values of QBC for quinonoid molecules investigated by X-ray crystallography^{266–269} lie in the range 0.75–0.82, which corresponds to the range of optical transparency.

Table 22. The values of the QBC parameter, hyperpolarisability (10^{-30} esu) and energies of transitions into the first and second excited states for 7,7'-diamino-8,8'-dicyanoquinodimethane.

QBC	β_{vect}	Transition energy /eV	QBC	β_{vect}	Transition energy /eV
0.088	−9.7	2.83 (0.006)	0.358	−75.4	2.65 (0.390)
		3.42 (1.130)			3.72 (0.471)
0.118	−18.5	2.80 (0.044)	0.436	−86.5	2.67 (0.457)
		3.39 (1.065)			3.75 (0.032)
0.190	−35.4	2.77 (0.195)	0.592	−94.0	2.87 (0.583)
		3.44 (0.841)			3.71 (0.050)
0.232	−46.2	2.71 (0.264)	0.730	−67.4	3.17 (0.571)
		3.50 (0.718)			3.75 (0.000)
0.286	−58.6	2.66 (0.326)	0.790	−47.7	3.37 (0.479)
		3.59 (0.599)			3.78 (0.000)

Note. Transition oscillator strengths are given in parentheses.

Rao and Bhanuprakash studied²⁷⁰ molecules **144**–**147** with D/A groups linked by a σ -bridge, $\text{CH}_2\text{--CH}_2$ using the FF/AM1 method.

D = $p\text{-NH}_2\text{C}_6\text{H}_4$, A = $p\text{-NO}_2\text{C}_6\text{H}_4$ (**a**);

D = $p\text{-C}_6\text{H}_4\text{O}^-$, A = $\text{C}_5\text{H}_5\text{N}^+$ (**b**).

The following values of hyperpolarisability were found

Molecule	144a	145a	146a	147a	144b	145b	146b	147b
$10^{30}\beta$	6.3	6.3	6.1	4.2	−625.0	−437.3	−683.5	−301.8
(esu)								

Molecules **144a**–**147a** contain traditional D/A substituents, whereas molecules **144b**–**147b** are of the zwitter-ionic character. The calculated values of β indicate substantial weakening of interactions between the NH_2 and NO_2 groups in molecules **144a**–**147a** since σ -fragments break the conjugation. In contrast, in the case of zwitter-ionic molecules **144b**–**147b**, the σ -bridge stabilises the zwitter-ionic form, which gives rise to an increase in β , i.e., the introduction of a σ -bridge is formally equivalent to a rotation of the phenyl rings (see Fig. 9).

Changes in the hyperpolarisability due to the replacement of a benzene ring by a heterocycle were considered.^{271–273} In contrast to non-quinonoid D– π –A molecules, whose hyperpolarisabilities increase owing to the lower energy barrier to the electron delocalisation in heterocycles with respect to benzene, the opposite trend is manifested by quinonoid molecules. This can be explained in the same way: the higher the energy barrier to the electron delocalisation, the higher the stability of the zwitter-ionic form.

IV. Possible ways to improve thermal stability and optical transparency of NLO materials

The possibility of the use of organic compounds for the second harmonic generation is determined by a number of parameters and, as has been mentioned above, it often happens that an enhancement of one parameter deteriorates others. Therefore, the molecular design of NLO materials has to include simultaneous optimisation of several key molecular characteristics. For instance, most tables in the previous section listed data on the optical transparency of molecules (λ_{max}) in addition to the values of their hyperpolarisabilities. The results discussed above indicate that the function $\beta(\lambda_{\text{max}})$ increases with an increase in the strength of D/A substituents or the length of the π -system or with the introduction of less aromatic fragments in place of more aromatic ones. Several studies were related to investigations within different classes of compounds, such as imidazoles,²⁷⁴ tolans,²⁷⁵ pyrazoles,²⁷⁶ thiazoles,²⁰⁷ coumarins.²⁷⁷ The dependences

$$\beta = k \log \lambda_{\text{max}} + a$$

obtained are nearly linear with the coefficient k varying from 5 to 8. A number of approaches to the search for optimal combinations of the desired properties have been proposed.

1. Linear molecules with one-dimensional hyperpolarisability

Polyene systems are among the most efficient NLO-active π -systems. Unfortunately, they are characterised by rather low thermal and chemical stabilities (moreover, these characteristics are getting worse with an increase in the length of the π -system²⁷⁸) and absorption maxima in the visible range. Several attempts to improve these characteristics have been undertaken. Thus it was suggested²⁷⁹ to use spiro-conjugated chains (molecules **148** and **149**). Their comparison with polyene and quinonoid polyphenylene-type molecules **150** and **151** showed (Table 23) that the

Table 23. Calculated spectral characteristics (SOS/INDO/CI) of spiro-conjugated, polyene and polyphenylene D/A molecules with geometries optimised using the AM1 method and experimental optical characteristics of molecules with σ -fragments (HRS measurements in CHCl_3 at $\lambda = 1064$ nm extrapolated to the zero frequency).

Molecule	$10^{30}\beta_0$ (esu)	λ_{max} /nm	Molecule	$10^{30}\beta_0$ (esu)	λ_{max} /nm
148	1.7	398	152a	69.2	405
149	2.9	430	152b	69.8	395
150	17.6	594	152c	86.4	407
151	16.6	668	152d	80.0	406
			152e	174.4	500

hyperpolarisabilities of spiro-systems are lower by an order of magnitude while the range of their optical transparency is significantly wider.

Jerome and co-workers^{280,281} proposed to brake the conjugation chains of conjugated molecules by introducing σ -fragments in order to broaden the range of their optical transparency (see Table 23). The values of hyperpolarisability were both calculated and measured, and qualitative agreement of theoretical and experimental results was observed.

X = CMe_2 (**a**), SiMe_2 (**b**), $(\text{SiMe}_2)_2$ (**c**), S (**d**), $\text{CH}=\text{CH}$ (**e**).

It should be taken into account that the experimental NLO efficiency of molecule **152e** can be strongly overestimated since its absorption maximum is very close to the second harmonic. According to the results obtained, the introduction of a central σ -fragment gives rise to a significant hypsochromic shift of the absorption band but the hyperpolarisability decreases severalfold. The spectral parameters of molecules **152a,b** are close to each other, whereas molecule **152d** manifests a slightly higher hyperpolarisability and its absorption band is shifted to the visible range, which suggests weak involvement of the sulfur lone-pair electrons into the delocalised π -system. It is noteworthy that the value of β for molecule **152c** is larger than those for molecules **152a,b,d**. This can be explained by the involvement of both σ - and $\sigma-\pi$ delocalisation mechanisms in polysilanes.^{282–284}

Sudharsanam *et al.*²⁸⁵ utilised the S–S fragment for the break of conjugation chains in a series of molecules **153**. The hyperpolarisabilities of these molecules were measured by HRS method at $\lambda = 1064$ nm in CHCl_3 using a value of 17×10^{-30} esu for **1** as a reference.

Molecule	153a	153b	153c	153d
$10^{30} \beta$ (esu)	36	102	98	44
$\lambda_{\max}$ /nm	304	319	321	317

The data obtained show that the introduction of stronger D/A groups affects β to a larger extent than $\lambda_{\max}$. The values of $\lambda_{\max}$ remain sufficiently low, so that the molecules remain optically transparent in the whole visible spectral range. The authors adopted value 55.4×10^{-30} esu as a reference for **2** for a comparative analysis of the hyperpolarisabilities, however, this value was determined under different conditions and is strongly underestimated. For instance, according to measurements performed under the same conditions,²⁸⁶ the value of β for **2** is almost 9 times larger than for **1**, *i.e.*, it would be more appropriate to use the value of $\sim 150 \times 10^{-30}$ esu for the sake of comparison. Thus the hyperpolarisability of **2** is ~ 1.5 times larger than that for its disulfide analogue, while molecule **2** is less optically transparent ($\lambda_{\max} = 427$ nm in CHCl₃).

The use of sterically stabilised polyenes **154–156** was suggested^{287–289} as a way to improve the thermal stabilities of D- π -A systems with polyene π -bridges.

The absorption spectra were measured in 1,4-dioxane, the polarisabilities were determined using EFISH measurements in chloroform ($\lambda = 1907$ nm); the decomposition temperatures (T_d) of molecules **154–156** were 170, 317 and 343 °C, respectively, as estimated by differential scanning calorimetry (DSC).

The following values of spectral parameters were obtained for the sterically stabilised π -conjugated molecules:

Molecule	154	155	156
$10^{30} \beta$ (esu)	453	378	—
$\lambda_{\max}$ /nm	563	538	518

The above data clearly demonstrate that the introduction of cyclohexene fragments simultaneously brings about some increase in the optical transparency and a significant increase in the thermal stability. As expected, this occurs at the cost of a decrease in β , since $\lambda_{\max}$ also decreases.

Luo, Hua *et al.*^{290, 291} investigated sterically stabilised π -conjugated molecules **157–160**. Their absorption spectra were measured in chloroform and the hyperpolarisabilities were determined using HRS measurements in methanol ($\lambda = 1064$ nm).

Molecule	157	158	159	160
$10^{30} \beta$ (esu)	1393	1564	1086	2890
$\lambda_{\max}$ /nm	493	474	508	490

Despite the molecules stabilised with a cyclohexene fragment contain longer π -chains, they are characterised by slightly shorter absorption wavelengths and higher β .

It was shown^{292, 293} that the thermal stabilities of molecules **161** increase upon transition from thiophenes to their analogues containing thiophene 1,1-dioxide moiety ($\lambda_{\max}$ were determined for CHCl₃ solutions).²⁹³

Molecule	161a	161b	161c
$\lambda_{\max}$ /nm	326	390	406
M.p. /°C	118	137	226

Molecule	162a	162b	162c	162d
$10^{30} \beta$ (esu)	61.4	116.1	84.7	175.7

This also leads to an increase in the hyperpolarisability, as evidenced by the theoretical calculations (FF/AM1 in the static limit)²⁹² for molecules **162**, due to the loss of aromaticity in the five-membered heterocycles. The latter factor, on the other hand, narrows the optical transparency range of these molecules. Likely, the acceptor properties of the SO₂ group are also partly responsible for the increase in β . This suggestion is supported by rather high hyperpolarisabilities of molecules **163** (measurements in CH₂Cl₂ at $\lambda = 1907$ nm extrapolated to the zero frequency).²⁹⁴

Molecule	163a	163b	163c
$10^{30} \beta$ (esu)	3070	2320	4880
$\lambda_{\max}$ /nm	704	660	738

The use of amino or alkylamino groups as donors is preferable for achieving high values of β , however, these compounds are less thermally stable than, for instance, their alkoxy analogues.^{295, 296} With this regard, Moylan *et al.*^{297–299} and other researchers (see Refs 300–302) proposed to use a diarylamino group and showed that its introduction significantly increases thermal stability without narrowing of the optical transparency range (Table 24).

The use of tetra- or pentafluorophenyl groups (molecules **169–171**) as acceptors instead of π -acceptor groups results in broadening of the optical transparency range and an increase in the thermal stability^{303–305} (Table 25, molecules **169a,c,e**, **170a** and **169b,d,f**, **170b**). The data from Table 25 also indicate that it is difficult to unambiguously predict the trend in β upon transition

Table 24. Optical and thermal characteristics of D/A-substituted stilbenes and their analogues.

from the nitrophenyl to the pentafluorophenyl acceptors (molecules **169e,f** and **170a,b**). The result depends on the structure of the π -system and the donor type, in addition to the mere strength of the acceptor group to be replaced. It is also evident that the use of NPh_2 groups instead of NAlk_2 leads to a significant increase in the thermal stability (molecules **169a–d**, **171a,b**).

^a The value of $\mu\beta$ is given.

An original approach to increase thermal stability of potential NLO molecules was suggested by Nesterov *et al.*^{306, 307} They used $D-\pi-A-D'$ molecules in which the amino groups liable to the formation of H-bonds were introduced as auxiliary donors D' . Although the melting point of a compound does not correlate directly with crystal lattice energy, nor with the presence of H-bonds in the structure, the literature data (see, for instance, Refs 308–311) indicate that crystals of similar molecules differing from each other only by the presence/absence of H-bonding sites possess higher melting points provided that the crystal structure involves H-bonds. In particular, crystals built up of H-bonded molecules **172a–174a** melt at significantly higher temperatures than crystals built up of molecules **172b–174b**, which do not form H-bonds.

Molecule	172a	172b	173a	173b	174a	174b
M.p./°C	188	114	216	157	275	145

Table 26 summarises the results of theoretical calculations of dipole moments and hyperpolarisabilities (FF/AM1 in the static limit) and experimental characterisation (measurements of λ_{max} in THF)^{306, 307} for imines **175** and their $D-\pi-A-H$ analogues.

It is evident that the substitution of the amino group for a hydrogen atom results in a decrease in the hyperpolarisability, this is also accompanied by a decrease in the dipole moment. The latter factor as well as the availability of active sites prone to H-bonding increase the probability of crystallisation of these compounds in a non-centrosymmetric space group. Indeed, five out of nine compounds studied crystallise in such groups.

2. Molecules with two- and three-dimensional hyperpolarisability

In the case of molecules possessing two- and three-dimensional hyperpolarisabilities, non-diagonal components of the tensor β becomes significant making an additional contribution to the value of β .^{312, 313} In particular, for 1,3-dinitro-4,6-diaminobenzene, the diagonal component β_{zzz} is an order of magnitude

Table 26. Melting points, spectral characteristics and crystallographic data for imines **175** and their $D-\pi-A-H$ analogues.

smaller than β_{zzz} .³¹⁴ The so-called V- or X-shaped molecules **176–182** were a subject of a series of studies.^{315–319} By comparing characteristics of molecules **176** and **179** with those of molecules **177**, **178** and **180** one may conclude that the attachment of a second donor group, at least, doubles β and enhances the thermal stability but somewhat narrows the range of the optical transparency (Table 27). In contrast, a comparison of characteristics of molecules **181** and **182** indicates that the introduction of a second acceptor group broadens the range of optical transparency in addition to increase in β and T_d .

Table 27. Spectral characteristics and decomposition temperatures of molecules **176–182**.

Molecule	$10^{30} \beta_0$ (esu)	λ_{max} /nm	T_d /°C
176	88.8 ± 6.6	468	332
177	175 ± 3	486	404
178	197 ± 2	496	348

187a	1277	−76	−671	530	76	190c	1.9
187b	725	−25	579	1279	77	191a	2.1
						191b	1.2
						191c	1.6

Note. The FF/MP2/6-31 + G*³²⁰ and FF/AM1³²¹ methods were used for molecules **183a**–**187b** and **188a**–**191c**, respectively.

The results of this work are compiled in Table 28. Provided that the coordinate system is selected so as the axis Y is perpendicular to the molecular plane, the components β_{xxz} , β_{yyz} and β_{zzz} make the dominant contributions to the total hyperpolarisability β_{tot} . The optimisation of the hyperpolarisability

$$\beta_{tot} = \beta_{xxz} + \beta_{yyz} + \beta_{zzz}$$

for such molecules requires a consistent selection of D/A-substituents and the angle φ between the directions of the charge transfer. In particular, the absolute value of β increases on going from molecules **183** to **184** due to a change in φ . A comparison of characteristics of molecules **185b** and **187b** with those of **185a** and **187a**, respectively, indicates that an increase in the strength of a D group (*i.e.*, the use of the amino instead of the hydroxy group) gives rise to a decrease in β , whereas the reversed trend is observed for molecules **186a** and **186b**. It is also worth noting that the relative significance of contributions β_{xxz} and β_{zzz} changes on going from molecule **186** to **187**. A study of didonor/diacceptor-substituted six-membered rings³²¹ (see Table 28) gave similar results. Molecules with donor groups occupying adjacent positions possess higher values of β .

Sudharsanam *et al.*³²² considered molecules **192** and **193** (FF/AM1 in the static limit). Molecule **192** possesses a severalfold higher NLO activity and a broader range of optical transparency. However, it is non-planar. Meanwhile, β should prominently increase if $\theta \rightarrow 0$.³²³ Analysis of molecule **194** with the strictly planar structure revealed a rather high β (SOS/INDO/CIS, $\lambda = 1064$ nm).

Calix[4]arenes, like V-shaped systems discussed above, also incorporate several D/A pairs in one molecule. These molecules were a subject of several investigations.^{324–326} They can adopt the following conformations:

195a–d

$R^1 = R^2 = R^3 = R^4 = p\text{-NO}_2\text{C}_6\text{H}_4\text{-N=N}$ (a); $R^1 = \text{H}$, $R^2 = R^3 = R^4 = p\text{-NO}_2\text{C}_6\text{H}_4\text{-N=N}$ (b); $R^1 = R^2 = \text{H}$, $R^3 = R^4 = p\text{-NO}_2\text{C}_6\text{H}_4\text{-N=N}$ (c); $R^1 = R^2 = R^3 = \text{H}$, $R^4 = p\text{-NO}_2\text{C}_6\text{H}_4\text{-N=N}$ (d).

196

Interestingly, the absorption band maximum remains constant for all the conformers,³²⁴ which implies that this parameter is weakly affected by the mutual orientation of the D/A-phenyl fragments. In contrast, the value of hyperpolarisability strongly depends on the conformation, which is evidenced by the experimental and theoretical data presented in Table 29.

According to the calculations, 1,2- and 1,3-alternates are characterised by values of β close to zero, which is in agreement with the zero hyperpolarisability experimentally found for the 1,3-conformer. This is due to the complete mutual cancellation of the NLO activity of different D/A-phenyl fragments. The ratio of activities cone/partial cone depends on the inclination angle of the phenyl rings. Brouyere *et al.*³²⁶ additionally compared the hyperpolarisability of NO_2/OH -substituted calix[4]arene in the cone conformation with those of *o,o'*-dimethyl-*p*-nitrophenol and its dimer built up of two parallel molecules. As can be judged from Table 29, additive schemes are applicable to the evaluation of β neither for the dimer nor for calix[4]arene (with a correction for the non-parallel arrangement of the rings), which clearly implies interaction between the π -systems. Further arguments in favour of the substantial influence of the intermolecular π - π interactions on the spectral properties were presented by other authors.^{327–329}

Similar conclusions were derived^{330,331} for NO_2/OH -substituted calix[4]arenes **195a–d** in the cone conformation.

Molecule	195a	195b	195c	195d	196
$10^{30} \beta$ (esu)	296.6	275.2	302.6	233.1	186.7
λ_{max} /nm	374	378	382	378	387

The experimental values (HRS, THF, $\lambda = 1064$ nm) for tetrahydroxycalix[4]arene successively substituted with *p*-nitrophenylazo groups (molecules **195**) were compared with that of the monomeric analogue **196**. The value of λ_{max} for calix[4]arenes is virtually independent of the number of acceptor groups and is slightly smaller than that of the monomer, whereas β is larger. The observed variations in β are probably due to different mutual orientations of the fragments in the calix[4]arene molecule, which is determined by the steric interaction of the substituents.

It is important that the absorption band is blue-shifted and β is increased on going from the monomer to calix[4]arenes (*i.e.*, tetramers). It should be noted that it is possible to achieve a significantly higher NLO activity by sequential coupling of monomers, however at the cost of narrowing of the optical transparency range.

Paracyclophane derivatives **199–201** represent yet another example of molecules possessing non-standard conjugated systems (to be compared with reference molecules **197** and **198**).^{332–334}

Table 29. Calculated and experimental values of β (10^{-30} esu) and λ (nm) for D/A-calix[4]arenes in different conformations.

Conformation	Donor	β_{EFISH} (calculation)	β_{HRS} (calculation)	β_{EFISH} (experiment)	β_{HRS} (experiment)	λ_{max} (calculation)	λ_{max} (experiment)
Cone	OH	22.9	23.8	—	—	290	—
Partial cone	OH	12.5	12.8	—	—	290	—

Monomer ^a	OMe	12.5	13.1	12.0	—	301	302
Dimer ^a	OMe	18.3	18.3	—	—	284	—

Note. The calculated values of β were obtained³²⁶ using the SOS method within the INDO/CIS approximation;

$$\beta_{\text{EFISH}}(\text{calculation}) = \beta_{\text{zzz}} + \frac{1}{3}(\beta_{\text{zxx}} + \beta_{\text{zyy}} + \beta_{\text{xxz}} + \beta_{\text{yyz}} + \beta_{\text{xzx}} + \beta_{\text{yzy}}); \beta_{\text{HRS}}(\text{calculation}) = \sqrt{\frac{35}{6}} \langle \beta_{\text{HRS}}^2 \rangle, \text{ where } \langle \beta_{\text{HRS}}^2 \rangle = \langle \beta_{\text{zzz}}^2 \rangle + \langle \beta_{\text{xzz}}^2 \rangle.$$

see Eqns (8), (9); experimental measurements were performed in CHCl_3 at $\lambda = 1064$ nm.^{324,325}

^a Data for *o,o'*-dimethyl-*p*-nitrophenol.

X = NHex₂, Y = NO₂ (**200**); X = NO₂, Y = NHex₂ (**201**);
Hex = n-C₆H₁₃.

The experimental data in Table 30 unambiguously confirm the through-space electron density transfer between the two phenyl rings. The hyperpolarisability of molecule **199** estimated within the additive scheme as a sum of values for molecules **197** and **198** appears three times smaller than the experimental value. Molecule **199** manifests relatively high β and remains optically transparent in virtually entire visible range. On the other hand, the additive model applied to molecules **200** and **201** describes the vector part of the hyperpolarisability tensor ($\beta_j = 1$) relatively well but fails to estimate the septor component ($\beta_j = 3$), which makes the predominant contribution. It is of note that the charge transfer in substituted paracyclophanes was also confirmed by the topological analysis of the electron density distribution based on high-precision X-ray diffraction studies.³³⁵ The introduction of an OH group (which is a strong donor) into one of the benzene rings of the paracyclophane molecule gives rise to the emergence of a critical point (3, -1) between carbon atoms of different benzene rings,³³⁵ which is indicative of a chemical interaction according to the Bader theory.[‡] Meanwhile, the correspondent critical points

are observed neither in unsubstituted paracyclophane nor in its quinonoid analogue, which means that in these cases, no direct through-space charge transfer is involved.^{336, 337}

Bahl *et al.*³³⁸ reported experimentally measured spectral characteristics (HRS in CHCl₃, $\lambda = 1064$ nm) of naphthalene derivatives **202–204**.

Molecule	202	203	204
$10^{30} \beta$ (esu)	26	32	18
$\lambda_{\max}$ /nm	298	308	312

Probably, the reason for the larger value of β in the case of molecule **202** as compared to molecule **204** is again the direct through-space interaction. According to X-ray crystallographic results,³³⁸ the phenyl rings in molecule **203** are nearly parallel to each other and rotated by 62.6° relative to the central naphthalene fragment. The absorption bands of molecules **202** and **203** are blue-shifted with respect to that of molecule **204** and their hyperpolarisabilities are 1.5–2 times larger. Therefore, it may be concluded that the involvement of the direct through-space electron density transfer increases β but does not result in narrowing of the optical transparency range.

Octupolar molecules that are characterised by a three-fold symmetry axis and zero dipole moments represent yet another promising class of molecules for the design of NLO materials. Some representatives of this class were considered by Zyss and Ledoux.^{339, 340} The vector part of the tensor β is zero for octupolar molecules, whereas the septor part remains significant³⁴¹ thus determining the macroscopic spectral properties of the compound. Due to the absence of dipole–dipole interactions, octupolar molecules crystallise in non-centrosymmetric space groups with higher probability than other classes of molecules, which is one of their major advantages.^{342, 343}

Under the assumption of non-interacting substituents (*i.e.*, provided that the effects of D/A pairs are additive), the hyperpolarisability increases by a factor of 1.5 on going from a dipolar to the respective octupolar molecule (featuring the same substituents and π -bridge).³⁴⁴

Bredas *et al.*³⁴⁵ performed a comparative analysis of the spectral characteristics of *p*-NA and triaminotrinitrobenzene (TATB). The hyperpolarisabilities β estimated as norms of the respective tensors [Eqn (4), FF/AM1] were equal to 12.1 and 22.2×10^{-30} esu, and absorption band maxima were located at 4.6 eV and 5.3 eV for *p*-NA and TATB, respectively,³⁴⁴ which means that TATB is characterised by a broader optical transparency range.

Andraud *et al.*³⁴⁶ compared the spectral characteristics of dipolar and octupolar systems for a series of molecules **205a–d** and **206a–d**.

Table 30. Spectral characteristics [$10^{30} \beta$ (esu)] of monosubstituted stilbenes and D/A-substituted paracyclophanes.

Mole- cule	β	$\lambda_{\max}$ /nm	Mole- cule	$ \beta_j = 1 $	$ \beta_j = 3 $	$ \beta_{j=1}^{\text{ad}} $	$ \beta_{j=3}^{\text{ad}} $
197	9	320	200	190	430	170	620
198	9	345	201	260	580	290	0
199	60	378					

Note. All measurements were performed in chloroform; the results of EFISH measurements extrapolated to the zero frequency are given for molecules **197–199**; the measurements were performed at $\lambda = 1907$ nm for **197** and **198** and at $\lambda = 1064$ nm for **199**;³³² HRS results measured at $\lambda = 1320$ nm are given for molecules **200** and **201**.^{333, 334}

[‡] R Bader *Atoms in Molecules: A Quantum Theory* (Oxford: Clarendon Press, 1990)

$n = 1$ (a), 2 (b), 3 (c), 4 (d).

Molecule	205a	205b	205c	205d	206a	206b	206c	206d
$10^{30} \beta$ (esu)	18.5	29.0	40.4	52.0	27.4	44.4	58.6	72.0
$\lambda_{\max}$ /nm	391	426	455	480	396	434	458	484

The results obtained [SOS/INDO/S, β estimated according to the Eqn (4)] reveal some general trends also typical of one-dimensional polar molecules. In particular, β and $\lambda_{\max}$ increase with an elongation of the conjugation chain. A systematic comparison of molecules **205a–d** and **206a–d** indicated that octupolar molecules are characterised by higher NLO activities and small bathochromic shifts of the absorption bands.

Spectral and thermal properties of octupolar molecules were also studied by Cho *et al.*^{347–351} The experimental HRS data extrapolated to the zero frequency within the three-level model are presented in Table 31 together with the results of thermogravimetric analysis (TGA). Additionally, the spectral characteristics of dipolar molecules **207** and octupolar molecules **208a–i** were compared.³⁴⁷

X = NO₂; Y = *p*-Et₂NC₆H₄–CH=CH (a);

p-Hex₂N–(C₆H₄–CH=CH)₂ (h),
p-Et₂NC₆H₄–N=N–C₆H₄–CH=CH (i).

The hyperpolarisabilities β of octupolar molecules **208** are larger than those of their dipolar counterpart **207**. Furthermore,

Table 31. Spectral and thermal characteristics of molecules **207** and **208**.

208i	246	485	—	1064	THF

the octupolar molecules manifest broader optical transparency ranges. As expected, the hyperpolarisability increases and the optical transparency range becomes narrower with an elongation of the conjugation chain (*cf.* molecules **208d,e** and **g**) and the introduction of stronger acceptors (*cf.* **208b** and **c**). It is of note that the introduction of the phenyl fragments in place of the Et groups at the nitrogen atom (*cf.* **208e** and **f**) gives rise both to a significant increase in β and a hypsochromic shift in the absorption band. The replacement of a CH=CH fragment (**208h**) by N=N (**208i**) results in a decrease in β due to a decrease in the degree of conjugation of the π -bridge. It seems unusual that the hyperpolarisabilities of molecules **208g** and **208h** differing only in the alkyl substituents differ as much as by a factor of 3. In the experimental measurements, solvents with similar polarities were used and, as has been mentioned above, the measured values were extrapolated to the zero frequency. Most probably, this discrepancy reflects the inadequacy of the three-level model to the extrapolation of the experimental data measured at different incident wavelengths. An analysis of the literature data shows that the use of two- and three-level models for the extrapolation of hyperpolarisability values can indeed yield incorrect results.³⁵²

A similar dependence of β on the structure of dipolar and octupolar molecules was obtained for a series of compounds **209** and **210**. Molecules with long conjugation chains (*e.g.*, **209e,f**) manifest larger β and $\lambda_{\max}$ (Table 32). A comparison of hyperpolarisabilities of molecules **209a** and **209b** confirms the validity of the concept of auxiliary D/A groups. The introduction of a donor into the electron-rich thiophene ring is energetically more favourable than the introduction of an acceptor. Molecules **210a–d** contain σ -fragments, such as CH₂ and CH₂–CH₂, providing high optical transparencies of these compounds ($\lambda_{\max} < 300$ nm), and the introduction of the CH₂–CH₂ fragment proves more efficient. The introduction of an acceptor sulfo group instead of a donor amino group (*cf.* molecules **209c,e** and **209d,f**) both increases β and broadens the optical transparency range. According to the results³⁵⁸ devoted to the design of 1,3,5-substituted benzene derivatives with acceptor groups at the terminal positions of π -conjugated substituents, these molecules are optically transparent in a broader range. For instance, $\lambda_{\max}$ is equal to 317 nm ($\beta = 39 \pm 5 \times 10^{-30}$ esu) for 1,3,5-(*p*-CF₃C₆H₄C $\equiv$ C)₃-2,4,6-(MeO)₃C₆, according to the HRS measurements in CHCl₃ at $\lambda = 800$ nm.

Chemical structures of four nido-pentaborane derivatives are shown:

- 215**: A nido-pentaborane derivative with a square pyramidal boron core. The open square face is capped by a carbon atom (C) bonded to a nitro group (NO₂) and an amino group (NH₂). The other four vertices of the square face are capped by BH groups. The remaining two vertices of the pentagonal face are capped by HB and BH groups.
- 216**: A nido-pentaborane derivative with a square pyramidal boron core. The open square face is capped by a CH group and a BH group. The other four vertices of the square face are capped by BH groups. The remaining two vertices of the pentagonal face are capped by O₂N-B and NH₂-B groups.
- 217**: A nido-pentaborane derivative with a square pyramidal boron core. The open square face is capped by a CH group and a BH group. The other four vertices of the square face are capped by BH groups. The remaining two vertices of the pentagonal face are capped by H₂N-B and NO₂-B groups.
- 218**: A nido-pentaborane derivative with a square pyramidal boron core. The open square face is capped by a CH group and a BH group. The other four vertices of the square face are capped by BH groups. The remaining two vertices of the pentagonal face are capped by H₂N-C and NO₂-B groups.

These results show again that the hyperpolarisabilities of carboranes and *p*-NA are comparable. This suggests the conjugation between substituents and the carborane cage and three-dimensional delocalisation of electrons over the carborane core. This suggestion is supported by the results of the topological analysis of the electron density distribution function in carborane derivatives (based on the experimental high-precision X-ray diffraction data)³⁷⁶ and by mandatory utilisation of the resonance structures for the description of chemical bonding in carboranes within the concept of three-centre bonds.³⁷⁷ Furthermore, according to calculations of magnetic properties³⁷⁸ and an analysis of chemical properties,³⁷⁹ carboranes can be regarded as aromatic systems. A significant increase in β upon introduction of another carborane cage into the conjugation chain (molecules **216** and **219**) gives an additional argument in favour of the analogy between the two- and three-dimensional aromaticity. It can seem strange that molecule **220** is characterised by smaller hyperpolarisability than molecule **215**, despite the presence of a longer conjugated bridge. The probable reason for this is the higher degree of aromaticity of 10-vertex carboranes as compared to 6-vertex ones.³⁸⁰

The above data clearly show that the use of carboranes as building blocks of conjugation bridges gives rise to relatively high values of hyperpolarisability with a simultaneous broadening of the optical transparency range. Taking into account the high thermal stability of carboranes, they should be recognised as a very promising class of compounds for applications in nonlinear optics.

V. The design of NLO crystals

The search for crystalline materials with high nonlinear optical susceptibilities d_{ijk} includes two principal steps. In the first step, most promising compounds are selected based on the information regarding their molecular spectral properties. In the second step, d_{ijk} has to be estimated, which can be done with a number of theoretical³⁸¹ and experimental^{3,382} methods.

1. Experimental methods for the determination of the NLO susceptibilities of crystals

The NLO susceptibility of a crystal can be measured both for single crystals and polycrystalline powders. In the former technique, the interference pattern (also referred to as the Maker fringes) produced by the second harmonic radiation transmitted through a single crystal is registered and the intensities in its maxima are compared to a standard reference.^{383–385} This method enables independent determination of all components of the susceptibility tensor. For the determination of specific components d_{ijk} , polished parallel-sided plate crystals are used, which were carefully cut along the respective crystallographic directions.

Generally, the incident wave with a frequency ω and the secondary wave with a frequency 2ω propagating in a crystal are characterised by different phase velocities, so that the interaction area is small and thus the measured intensity of the second harmonic is low. Nevertheless, in the majority of organic crystals, there are specific crystallographic directions, the so-called synchronism directions,³ along which the phase velocities are identi-

cal and thus the second harmonic intensity is amplified proportional to the squared distance traveled by the secondary wave in the crystal. This makes it possible to significantly improve the accuracy of the measurements. However only the effective susceptibility coefficient (d_{ef}) can be determined in this way, whereas every single component of the susceptibility tensor become inaccessible. However, it is the effective susceptibility that is of greatest practical importance. Provided that the refractive index of the material and all the tensor components d_{ijk} are known, the synchronism directions can be approximately found and the value of d_{ef} can be assessed.

A method for the determination of the NLO susceptibility in polycrystalline powders is based^{386–388} on the registration of intensity of the second harmonic transmitted through a cell filled with a powder under study and its comparison with a reference signal. Such measurements are significantly simpler since they do not require time-consuming manipulations with optical-quality single crystals, *i.e.*, their growth, cutting and polishing.

A detailed description of both experimental methods can be found elsewhere.^{3,382} Here, we only mention their major advantages and drawbacks as regards their application to the design of NLO materials.

It is evident that the Maker fringe method provides comprehensive information on the NLO properties of a material. Its main disadvantage consists of the necessity to grow and process relatively large optical-quality crystals (with a volume of up to $\sim 1 \text{ cm}^3$), which is very demanding. Therefore, this method is not applicable to the systematic search for the NLO materials. The powder method is by far simpler; it makes it possible to find out whether a crystal possesses synchronism directions and assess its potential in a rather straightforward way. The drawbacks of this method include the relatively low accuracy (50% at most) and the lack of information on single components of the susceptibility tensor.

It has to be noted that the experimental determination of the NLO susceptibility of a crystal does not generally require the detailed knowledge of its crystal structure. In particular, only space group is required for the interpretation of the Maker fringes. Nevertheless, X-ray diffraction data are indispensable, since the measured susceptibility cannot be ascribed to a specific material if its crystal structure is unknown. First of all, this is due to the frequently occurring polymorphism. In particular, a powder under study can actually be a mixture of several polymorph modifications of one compound. Second, it often happens that solvent molecules enter the crystal structure and thus the experimental NLO susceptibility has to be attributed to a solvate rather than pure compound.

Theoretical methods for the evaluation of NLO susceptibilities are typically based on the oriented gas model^{48,49} [see Eqn (6)], which assumes that the susceptibility of a crystal can be represented as a sum of molecular hyperpolarisabilities. The calculation of single components d_{ijk} of the crystal susceptibility tensor requires the knowledge of the hyperpolarisabilities of constituent molecules, local field factors (the approximate formula $f_i f_j f_k = 3$ can be employed in the case where no experimental data to estimate these factors are available)³⁸⁹ and orientation of the constituent molecules in the unit cell.

The basic difference between the existing methods consists of the degree of neglect of the intermolecular interactions. The utilisation of Eqn (6) based on the values of β of an isolated molecule means the complete neglect of the intermolecular interactions. Zyss and Oudar⁴⁹ derived formulas for the calculation of d_{ijk} for the most common space groups under the assumption of the two-dimensional character of the hyperpolarisability, which is suitable for all nearly planar molecules. These formulas have relatively simple forms for monoclinic space groups but become increasingly complicated for higher symmetries. Furthermore, the original paper contains several misprints. This approach was further refined and implemented in the software code NLOP.^{50,390} This code operates with the full molecular hyper-

polarisability tensors and thus it makes possible to calculate the optical properties of any molecular crystal without restrictions to molecular geometry and space group. Furthermore, the probability of errors due to manual calculations with formulas from Ref. 49 is minimised [e.g., see Ref. 391, where d_{xyz} of 2,5-di(benzylidene)cyclopentanone was overestimated twice due to a misprint in the original formula]. According to the calculations for model molecules **221**–**224**, for which the experimental values of d_{ijk} are also available, the theoretical approach agrees with the experiment at a semiquantitative level provided that the crystal structures reveal no specific strong intermolecular interactions (Table 35).^{50,390} No doubt, this is sufficient for a preliminary evaluation of the potential of a compound under study and its appropriateness for a more thorough analysis.

Recently, the oriented gas model was improved by the introduction of a supermolecule concept, which means that the hyperpolarisabilities of molecular associates rather than isolated molecules are taken as input for the calculation of d_{ijk} . This makes it possible to include the dependence of the NLO properties of a molecule on its intermolecular environment into consideration to a certain accuracy level defined by the size and shape of the associate.

In particular, dimers of *p*-NA,³⁹⁶ 2-methyl-4-nitroaniline (MNA, **225**)³⁹⁷ and urea (**226**)³⁹⁸ were considered. The structure of the H-bonded *p*-NA dimer was obtained by the geometry optimisation at the HF/6-31+G** level; those of the MNA dimer (formed by weak stacking interactions) and the H-bonded urea dimer were taken from the experimental X-ray crystallographic data.^{399,400} The hyperpolarisabilities β_z of the dimers calculated within the supermolecule approximation and by the additive scheme were 27.6×10^{-30} esu and 15.4×10^{-30} esu for **1** (CPHF/6-31+G**), 10.5×10^{-30} esu and 15.3×10^{-30} esu for **225** (CPHF/6-31G with the frozen core) and 0.26×10^{-30} esu and 0.38×10^{-30} esu for **226** (CPHF/DZV), respectively.

As has been noted in the previous Section, in the case of molecular associates formed by the stacking interactions between π -systems, the additive scheme for the calculation of hyperpolarisabilities is violated. In particular, the values of β for a stacking dimer of *p*-NA at a distance between the benzene rings of 3.5 Å are 20.5×10^{-30} esu and 24.6×10^{-30} esu, as calculated within the supermolecule approximation and by the additive scheme, respectively.³²⁷ Therefore, it becomes apparent that the additive scheme can be violated in different ways, depending on the dimer structure: the chain-like structure is more favourable than the columnar structure. However, in the case of urea, the super-

molecule value of β for the H-bonded (chain-like) dimer is 1.5 times smaller than the additive one. Several authors^{177,401,402} considered larger molecular clusters of MNA and urea. For a cluster of urea composed of 7 molecules (generated on the basis of crystallographic data),⁴⁰¹ the additive NLO susceptibility was smaller than the supermolecule value only by 15%. In the case of molecular associates of MNA (generated on the basis of crystallographic data), the additive susceptibility was 5 times smaller than the supermolecule value along the crystallographic axis *a* (which approximately conforms to the direction of the molecular dipole moment) but 30%–50% larger than the supermolecule value in the perpendicular directions. On average, the additive scheme underestimated the NLO susceptibility by a factor of two as compared to the supermolecule model.

As has been mentioned above (see Section II), the desired level of accuracy should be considered as the basic appropriateness criterion in the selection of the theoretical method to be applied. The theoretical evaluation of the NLO properties at a semiquantitative level is well sufficient for the majority of tasks related to the systematic search for promising NLO compounds. In such a case, either the mere additive scheme or the supermolecule model based on a small molecular associate, depending on the presence of short intermolecular contacts in the molecular structure, will provide adequate results.

2. Methods for the design of NLO crystals

As has been mentioned above, only non-centrosymmetric crystals are capable of generating the second harmonic. Therefore, the major problem within the design of NLO crystals consists of the search for compounds that crystallise in non-centrosymmetric space groups. The use of chiral molecules is one of the most evident ways to meet this requirement. However, a non-centrosymmetric space group is the only necessary condition for the manifestation of the NLO activity, whereas the sufficient condition implies an optimum arrangement of molecules in a crystal in such a way that individual contributions of molecular hyperpolarisabilities are mutually enhanced.⁴⁹ Unfortunately, many chiral crystal packings are actually pseudo-centrosymmetric (with two crystallographically independent molecules in a unit cell) (see, for example, Refs 307, 403–405). The efficient design of NLO crystals is thus hampered by two major factors. First, there are currently no general approaches to the prediction of crystal structures.^{406–408} Second, the vast majority of organic compounds tend to crystallise in centrosymmetric space groups.^{409,410} The latter fact is traditionally explained by the influence of dipole–dipole interactions favouring the antiparallel orientation of the molecular dipole moments.¹⁶ Nevertheless, the role of dipole–dipole interactions in the formation of crystal structures remains a subject of debate. Some authors^{411,412} argue that the contribution of these interactions is small, while other authors^{413,414} consider it significant. Interestingly, both the viewpoints are substantiated by statistical analyses of crystal structures retrieved from the Cambridge Structural Database (CSD).⁴¹⁵ Adopting the latter viewpoint, it becomes apparent that it is necessary to introduce specific intermolecular interactions which would prevent antiparallel orientation of dipoles in order to obtain a non-centrosymmetric crystal. Even assuming that the

dipole–dipole interactions are insignificant and the inversion symmetry of the majority of crystals is a net result of diverse factors, the involvement of specific forces overcoming these factors is a prerequisite for the formation of a non-centrosymmetric crystal. It would be appropriate to mention here that the NLO active molecules, which are in the focus of the present discussion, are typically characterised by large dipole moments, often exceeding 10 D,[§] and thus the effects related to the dipole–dipole interactions are more pronounced for them than for a ‘statistical average’ case.

Several approaches to the problem of construction of non-centrosymmetric crystals exploiting specific intermolecular interactions counteracting the forces that favour the centrosymmetric structures have been suggested. These include the utilisation of molecules containing fragments prone to H-bonding; the use of salts composed of charged ions for which the electrostatic interactions become significant; co-crystallisation with an inert component giving rise, for instance, to a ‘dilution’ of the structure and consequent attenuation of the dipole–dipole interactions between molecules of the NLO-active component. Various combinations of these approaches are also possible. But another question then arises: what kind of crystal packing should be anticipated, taking into account that rather strong specific intermolecular interactions are involved? Presently, this question cannot be unequivocally answered. A comprehensive survey of this problem would be a subject of a separate review. With this regard, below we attempt to critically assess this important problem only with a few representative examples.

The importance of H-bonds as a key factor in the design of crystal structures is well documented.^{410, 416–422} The following regularities of H-bonding in the crystal structures were formulated: (1) the most active proton donors and acceptors have to be involved in H-bonding; (2) H-bonds are preferably formed between the most efficient donor and acceptor.

As for crystalline NLO-active compounds, the principal role played by H-bonds in the formation of non-centrosymmetric structures has been addressed in numerous studies.^{306, 307, 423–429} However, in all these cases, the conclusions were derived after the completion of X-ray crystallographic study and subsequent analysis of the crystal packings. It is also of note that weak intermolecular forces, such as van der Waals or C–H...X interactions, are always present in the crystal structures in addition to stronger ones. In the studies cited above, the strong specific interactions were responsible only for the formation of a basic motif of the crystal packing, whereas the mutual arrangement of these motifs was governed by weaker forces. Even if a certain basic motif is retained to a high confidence level over a wide series of compounds upon the variation of substituents, the prediction of fine effects of weaker interactions on the supramolecular organisation in the crystal is hardly possible. For instance, a comparative analysis of the crystal structures of more than 40 conjugated molecules with NH₂/NO₂-substituents retrieved from CSD showed that, in all cases, an aggregation of molecules along a specific direction to form H-bonded polar chains can be suggested, whereas the mutual orientations of such chains cannot be easily controlled.⁴³⁰ Lyssenko *et al.*⁴³¹ reported the crystal structures of compounds **227a** and **b** differing from each other only in alkyl groups. Both the structures are built up of identical non-centrosymmetric H-bonded layers. Nevertheless, the neighbouring layers are stacked in parallel and thus are related by a translation in the structure of **227a**, whereas they are antiparallel and related by an inversion centre in the structure of **227b**. No specific interactions stabilising this particular chiral packing in the case of **227** were revealed.⁴³¹

R = Me (**a**), Et (**b**).

The problem of interpretation of quantum-chemical calculations on H-bonded associates occurring in crystal structures was specifically addressed by Turi and Dannenberg.^{432–435} Their aim was to verify the predictive power of calculations by systematically checking whether the energetically most favourable associate, as predicted by means of quantum chemistry, actually occurs in the real crystal structure of the compound. They considered the following H-bonded associates of cyclohexane-1,3-dione and acetic acid

The crystal structure of the associate **228** is composed of molecules in the enol form adopting the *anti*-conformation. At the same time, according to the quantum-chemical calculations (HF/6-31G** and AM1), the stability of an isolated molecule decreases in the series ketone form > enol form/*syn*-conformation > enol form/*anti*-conformation. The relative gain in energy upon the formation of H-bonded associates with respect to the monomers in the ketone form can be analysed based on the results of AM1 calculations compiled in Table 36.

Table 36. Total energies (kcal mol^{−1}) for associates **228**, **230** composed of *N* molecules.

<i>N</i>	Molecule		<i>N</i>	Molecule	
	228	230		228	230
2	1.5	0.1	6	−3.1	−3.0
3	−0.7	−1.4	7	−3.5	−3.3
4	−1.9	−2.2	∞	−5.7	−4.9
5	−2.6	−2.7			

It is seen that at least three cyclohexane-1,3-dione molecules should associate to an H-bonded chain of either *syn*- or *anti*-conformers to become energetically more favourable than the same number of non-interacting isolated molecules in the ketone form. Furthermore, the chain of *anti*-conformers **228**, which actually occurs in the crystal, becomes the most energetically favourable structure only after association of no less than six molecules. H-bonded molecular associates of acetic acid (**229**, **231**) was yet another subject of studies by Turi and Dannenberg.^{434, 435} The simulation of acetic acid dimers was unsuccessful in explaining its crystal structure. No H-bonded dimer with the expected structure

[§] Unfortunately, to the best of our knowledge, no statistical studies regarding the distribution of centrosymmetric and non-centrosymmetric space groups for highly polar compounds have been reported so far.

is realised in the crystal because one of the $C=O\cdots H-O$ H-bonds is replaced by the $C=O\cdots H-CH_2$ bond, which gives rise to the H-bonded chain **231** as the main motif of the crystal packing. A calculation of a three-dimensional cluster that included several chains and 36 molecules in total was required to demonstrate that such a structure is indeed energetically more favourable than that composed of H-bonded dimers. This result clearly illustrates the importance of cooperative effects in the formation of associates and implies that the energy additivity can be violated upon the attachment of a next molecule to the existing cluster.

Similar conclusions were derived based on the analysis of crystal packings of nitroanilines, urea and *p*-benzoquinone.^{436–438} It is of note that the quantum-chemical simulations described above were accomplished only for compounds with known crystal structures. For instance, the following statement is valid for carboxylic acids (distinctive features of their crystal structures were comprehensively analysed for the first time by Leisero-witz⁴³⁹): it is impossible to judge on the association pattern of molecules even in one dimension, not mentioning the full three-dimensional crystal structure, based exclusively on the molecular structure.^{410, 440}

Nevertheless, in specific cases, the theoretical approach based on the atom – atom potential method makes it possible to establish the relative energies of centrosymmetric and non-centrosymmetric dimers. The formation of a non-centrosymmetric crystal structure can be anticipated if the latter proves preferable.^{81, 82}

Unfortunately, in overall, the predictive power of contemporary methods for the theoretical crystal packing simulation is rather low. According to recent results devoted to testing of modern specialised software tools for the crystal structure prediction,^{441–444} the correct structure is typically present among 5–10 energetically most favourable structures suggested by the codes, but in many cases it is not the most favourable structure.

Certain regularities in the formation of crystal structures can be revealed using a statistical analysis of the structural information stored in CSD for specific classes of compounds. Within the framework of the search for compounds that are crystallised in non-centrosymmetric space groups, Etter and Huang⁴⁴⁵ accomplished such statistical analyses for nitroanilines, co-crystallisation products in the system phenol–pyridine⁴⁴⁶ and benzoic acids.⁴⁴⁷

For NH_2/NO_2 -substituted molecules of the type

non-centrosymmetric packings are observed in 46% of all cases. Meanwhile, according to CSD, the probability of the crystallisation of an achiral compound in a non-centrosymmetric space group is only 11%.⁴⁴⁵ NH_2/NO_2 -substituted compounds typically reveal H-bonded non-centrosymmetric chains as the basic structural motif. Etter and co-workers⁴⁴⁶ reported results of the NLO susceptibility measurements using the powder method for 22 co-crystallisation products in the system phenol–pyridine. The second harmonic generation was observed for four samples, which amounts to 18% of all cases, *i.e.*, slightly exceeds the statistical average value. According to analysis of the crystal packings of benzoic acid,⁴⁴⁷ centrosymmetric structures occur in 98% of all cases provided that the H-bonded dimer **232** acts as the basic structural block. On the other hand, if infinite H-bonded chains are observed, non-centrosymmetric packings occur with a probability of 52%. The probability of the formation of such chains is substantially higher for *ortho*-substituted acids due to,

first, probable intramolecular H-bonding and, second, steric effects favouring the exit of the COOH group out of the ring plane.

The formation of centrosymmetric dimers can be prevented^{448, 449} by esterification of acids, *e.g.*, by the synthesis of 3-(4-nitrophenyl)-2-phenylacrylates. The compounds, in which *p*-MeO–C₆H₄ and Me groups substitute for the proton, crystallise in non-centrosymmetric space groups. Furthermore, the crystal packing occurring in the case of the Me-derivative appears to be close to the optimum one.

Studies on hydrazones were reported.^{450, 451} According to measurements of the NLO susceptibilities of powders, 20 out of 28 synthesised compound crystallised in non-centrosymmetric space groups.

Several compounds from this series were examined using X-ray crystallography. It was shown that in the vast majority of cases, λ -shaped non-centrosymmetric H-bonded chain **233** is formed as the basic structural motif, although the reasons responsible for the emergence of this particular structure were not identified.

Partly, this issue was clarified in studies of $D-\pi-A-D'$ -imines^{306, 307} (see Section IV). As in the case of hydrazones, the crystal structures of imines were found to be built up of λ -shaped chains. Based on a detailed analysis of the crystal packing of imines, the authors^{306, 307} solidly argued the formation of non-centrosymmetric groups. An isolated single H-bonded chain contains voids that tend to be filled with molecules constituting neighbouring chains thus giving rise to their non-parallel mutual arrangement, which excludes the formation of an antiparallel centrosymmetric packing.

X-Ray crystallographic data on other hydrazone derivatives^{452–456} support the conclusions derived in other studies (Refs 450 and 451). It is worth mentioning that this series of crystal structures obeys the aforementioned main rule of H-bonding. Indeed, if an Ar–D group contains no auxiliary active H-bonding sites, the intermolecular $N-H\cdots O(NO)$ bonds are formed in all cases. On the other hand, the pattern of hydrogen bonds is altered upon introduction of donor OR groups; this can result in the formation of both non-centrosymmetric and centrosymmetric space groups.

Crystal structures of salts composed of the organic cation, 2-amino-5-nitropyridinium ($2A5NP^+$), and an anion (An^-) of either organic or inorganic nature were investigated.^{457–467} According to the results obtained, the probability of occurrence of a non-centrosymmetric space group correlates with the shortest $H_2N\cdots NH_2$ distance (Table 37). If this distance is longer than 4 Å, then a non-centrosymmetric packing is realised, whereas in the distance range of 3.8–4.0 Å, both centrosymmetric and non-centrosymmetric structures are possible. The authors suggestedly explain this correlation by an attenuation of the effects of dipole – dipole interactions with an increase in the $H_2N\cdots NH_2$ distance. In our opinion, this explanation is insufficient since it ignores the fact that it is the strong hydrogen bonds present in all structures that form the basic structural motifs therein. Additionally, it is currently impossible to predict *a priori* the $H_2N\cdots NH_2$ distance

Table 37. Correlation between the shortest $\text{H}_2\text{N}\cdots\text{NH}_2$ distance (r) and probability of the occurrence of a non-centrosymmetric space group in the crystal structures of $2\text{A5NP}^+ \cdot \text{An}^-$.

An^-	$r/\text{\AA}$	Space group	An^-	$r/\text{\AA}$	Space group
HSO_4^-	3.454	$Pbca$	Cl^-	4.702	$P2_1$
InCl_6^{3-}	3.465	$P2_1/a$	Br^-	4.807	$P2_1$

for a specific compound and, respectively, to conclude on the most probable packing type.

Gangopadhyay *et al.*^{468–471} analysed compounds **234–237** for which non-centrosymmetric packing occurs only for a certain length of the alkyl fragments. The authors distinguished three major contributions to the lattice energy: H-bonds, dipole–dipole and dispersion interactions.

In the case of dinitro derivatives, only dipole–dipole and dispersion interactions contribute to the lattice energy due to the formation of intramolecular H-bonds. According to calculations with the atom–atom potential method, the dispersion contribution increases and dipole–dipole contribution decreases with an elongation of the alkyl group. The authors established that a balance between these interactions is settled in the case of the formation of a non-centrosymmetric structure. The dipole–dipole interactions evidently induce a centrosymmetric molecular packing. But what kind of structure is induced by the dispersion interactions? If one assumes that the dispersion interactions induce a non-centrosymmetric structure, it becomes puzzling, why that compounds resume to crystallise in centrosymmetric space groups upon further increase in the alkyl chain length after the balance point. As has been mentioned above, the effects of the dispersion forces on the packing of molecules in a crystal are difficult to predict, which is probably the main reason for the poor efficiency of modern approaches to the crystal structure prediction.

Yet another approach to the design of NLO crystals employs the polymorphism phenomenon^{472,473} and implies the search for the optimum conditions for the growth of a particular modification that crystallises in a non-centrosymmetric space group. Kuleshova and Antipin^{474,475} analysed some of the most common centrosymmetric–non-centrosymmetric polymorph pairs ($P2_1/c-P2_12_12_1$; $P2_1/c-P2_1$; $P2_1/c-Pc$; $P2_1/c-Pna2_1$) based on the structural information retrieved from CSD and derived several

general conclusions. Typically, if one of the two polymorphs crystallises in a chiral space group, the crystal structures of both modifications include chiral structural fragments (*e.g.*, layers or chains). In such a case, the polymorphism relates to different mutual arrangements of these fragments induced, as has been discussed above, by weaker intermolecular interactions. These polymorphs are often accompanying and can be prepared under identical experimental conditions (solvent, temperature, concentration). This detailed analysis is definitely useful but it nevertheless does not answer the most important question: how can a non-centrosymmetric modification be purposefully prepared? Unfortunately, two (or more) polymorphs of a compound very often appear to be centrosymmetric.^{476,477}

Probably, one of the best substantiated approaches to the design of non-centrosymmetric crystals elaborated by Leiserowitz and Lahav^{478,479} employs ‘tailor-made’ additives that selectively inhibit the growth of undesired polymorph modifications. Such an approach is based on the assumption that nuclei of all possible modifications are present in the solution but only the most stable nucleus survives to give rise to the resultant crystal. If a small amount of an additive capable of interacting with the most rapidly growing crystal faces of a certain polymorph and thus inhibiting its growth is introduced to the mother liquor, this will greatly favour the formation of other modifications.

VI. Conclusion

The optimum route to the design of NLO materials should be based on the knowledge and effective utilisation of the contemporary experimental and theoretical methods for the elucidation of structure and properties of NLO-active compounds.

It is evident that the combinatorial approach to the search for new materials by synthesis and experimental testing (for instance, by the powder method) can hardly be accepted as the optimum one. In this case, the step of the evaluation of molecular hyperpolarisabilities (which is actually of no practical importance) is skipped, but it is extremely costly in terms of time and chemicals expenses. Furthermore, the powder method yields only the effective value of the NLO susceptibility and gives no information on factors affecting this value, which makes further purposeful optimisation impossible.

In our opinion, it would be logical and convenient to subdivide the problem of the design of highly efficient NLO materials into two successive steps: molecular design and crystal design.

Taking into account the recent advancement of experimental techniques for the determination of the NLO properties of molecules in solution, the major factor limiting the accuracy of the experimental results relates to the fact that the measurements are performed not for the isolated target molecule, but rather for a product of its interactions with solvent molecules, which is characterised by an unknown structure. The measured hyperpolarisability of a molecule can change severalfold, depending on the solvent. The gas-phase experiments provide a higher accuracy but the majority of polar organic compounds promising for NLO applications do not vaporise due to the decomposition. There are a lot of issues related to different ways of data representation [see formulas (3) and (4)] and the use of different reference values for standard samples. This complicates any comparative analysis of the experimental results obtained by different research groups. However, the data obtained by one research group within the same cycle of measurements can well be compared and analysed at a semiquantitative level. Furthermore, the independently measured characteristics of a certain compound can often be referenced to the respective parameters of a previously studied molecule measured under identical conditions. Therefore, in the present review, we systematically compared and analysed the NLO properties of a broad assortment of molecules reliably determined either theoretically or experimentally, taking the above constraints into account. The reported experimental and theoretical values for the same

molecule are typically in accordance with each other to at least a semiquantitative level. According to the literature data, DFT calculations based on hybrid functionals, such as B3LYP or B97, is the theoretical method of choice for the systematic exploration of the NLO properties of molecules.

The molecular design of NLO materials should differentiate between zwitter-ionic and neutral molecules (*i.e.*, molecules with a negligible contribution of the zwitter-ionic form into the ground state). In a schematic diagram showing hyperpolarisability as a function of intermixing between the neutral (ψ_{VB}) and zwitter-ionic (ψ_{CT}) forms (Fig. 10), zwitter-ionic and neutral molecules are located in the right-hand (*i.e.*, in the range of negative β) and left-hand parts, respectively. The hyperpolarisability of a neutral molecule is governed by the following key parameters: the strength of D/A groups, the energy barrier to the electron delocalisation over the π -system (aromaticity), the length of the conjugation system and the degree of its electron-deficiency(excessiveness). These parameters jointly determine the overall degree of the electron delocalisation over a D- π -A molecule. The majority of NLO molecules in the neutral form fall into the region to the left from the maximum. This gives a key to the construction of molecules with the optimum structure.

Figure 10. Hyperpolarisability as a function of key parameters (X); X is an increase in the strength of D/A groups, an elongation of the conjugation chain, a decrease in the degree of aromaticity of the π -system and an increase in the degree of electron-deficiency(excessiveness) of the π -system from the acceptor(donor) side.

In contrast, zwitter-ionic molecules containing aromatic D/A groups typically fall into the region to the left from the negative maximum, and thus a decrease in the degree of conjugation between the D/A groups, which additionally stabilises the zwitter-ionic form, gives rise to an enhancement of the NLO properties.

The results discussed in the present review indicate that the algorithm of the search for a molecular structure providing an ultimate hyperpolarisability is generally established.

Nevertheless, any NLO material should meet a number of additional requirements, including optical transparency (the lack of resonance absorption at the second harmonic frequency), thermal and chemical stability, stability towards laser irradiation, accessibility of large (up to 1 cm³) optical-quality single crystals, *etc.* Two former properties can already be estimated at the molecular level (see Section IV). Unfortunately, it turns out that, as a rule, the modifications of molecules resulting in an enhanced hyperpolarisabilities simultaneously give rise to narrower ranges of the optical transparency and lower stabilities. Therefore, the greatest research efforts are currently put forth to locate the proper compromise between the desired spectral and thermal properties, on the one hand and sufficiently high hyperpolarisabilities, on the other.

The most important task within the design of crystals manifesting NLO properties consists of the elaboration of methods for growing of non-centrosymmetric crystals with the optimum molecular packings. Since X-ray crystallography is still the only source of unambiguous information on crystal structures, the current approach to the design of NLO active crystals is based on

the 'trial-and-error' method. The contemporary theoretical methods for the crystal structure simulation are capable of providing the required information only to a limited extent.

The extended array of structural information stored in CSD makes it possible to analyse the regularities of molecular packings along series of closely related compounds and thus make probabilistic predictions. A complex approach combining the CSD-based data mining with available software capabilities of crystal structure simulations and quantum-chemical calculations on molecular associates can be of much help to reduce the probability of errors and increase the number of fruitful trials within the 'trial-and-error' approach.

Summarising all the above results and discussion we propose the following stepwise algorithm for the optimum design and construction of NLO materials.

1. Preliminary selection of molecules and evaluation of their hyperpolarisabilities on the basis of quantum-chemical calculations. The preliminary selection should take into account the literature data on the relationship between the structure of molecules and their spectral and thermal properties. An allowance should be made for the possibility of their crystallisation in non-centrosymmetric space groups. It is also advisable to perform in this step crystal packing simulations and a statistical analysis of the structural data on related compounds from CSD.

2. The synthesis of the selected compound and growing of its single crystals suitable for the X-ray crystallographic characterisation. The crystal structure determination and analysis aimed at the exploration of possibilities to obtain a non-centrosymmetric structure. The crystal structure simulation also can prove useful in this step for a more detailed interpretation of the X-ray crystallographic results. The achievable accuracy of crystallographic data gives indirect information on the accessibility of large optical-quality crystals of the compound.

3. The evaluation of components d_{ijk} of the NLO susceptibility tensor within the oriented gas model or supermolecule approximation. This can be done, for instance, using the software code NLOP. The results obtained can be supplemented with experimental measurements of NLO susceptibility on powders, which additionally enables the determination of the synchronism directions and evaluation of the radiation stability of the material.

4. Growing of large optical-quality single crystals of those compounds that successfully passed all the previous steps for the determination of their NLO susceptibility along different crystallographic directions, including the synchronism direction, using the Maker fringe method. Based on the results obtained the final conclusion concerning the potential of the material for NLO applications can be derived.

This review was written with a partial financial support from the Russian Foundation for Basic Research (Project Nos 02-07-90322 and 03-03-32716), the Federal Programme for the Support of Leading Scientific Schools (NSh-1060.2003.3) and the NASA Alliance for Nonlinear Optics (NAG5 6532).

V. Conclusion	504

Abstract. The experimental NMR techniques for studies of translational diffusion in anisotropic systems and the results of their applications to thermotropic liquid crystals are reviewed. The main approaches to the theoretical description and computer simulations of diffusion are discussed. The experimental results are compared with computations. The bibliography includes 194 references.

I. Introduction

Liquid crystals (LC) represent substances that exist, under certain conditions, in a particular state that is intermediate between the solid and liquid states.

Liquid crystals or mesophases are formed by asymmetric rod-like or discotic molecules.¹ Depending on the method of preparation of LC, thermotropic and lyotropic systems are distinguished. The former result from thermal influence on mesogenic solid crystals, while the latter are formed upon dissolution of mesogenic molecules in certain solvents. Liquid-crystalline ordering stems from the anisotropic pair potential among mesogenic molecules. As a result of this interaction, molecules tend to align preferentially along the same spatial direction called a director. Quantitatively, this orientational order is characterised by the order parameter $S = 0.5\langle 3\cos^2\vartheta - 1 \rangle$, where ϑ is the angle between the molecular symmetry axis and the director. Depending on the spatial arrangement of the mesogenic molecules, LC are subdivided into nematic, cholesteric, smectic and columnar phases.¹ Nematics exhibit one-dimensional orientational order. In smectic and columnar phases, in addition to the orientational order, a positional molecular order is present (molecules are arranged to form layered or column-like structures, respectively).

Molecules in liquid crystals exhibit high translational mobility. Combination of spatial ordering of the molecules with their high mobility opens the prospects for the practical applications of

LC, which, in turn, stimulates the interest in fundamental studies of mesophases.^{1–7}

In contrast to isotropic liquids where the self-diffusion is described by a scalar diffusion coefficient D , the translational self-diffusion in LC is characterised by a tensor $\mathbf{D}$.^{8–11} In LC with the axial symmetry, two of the three principal components D_{xx} , D_{yy} , D_{zz} of the diffusion tensor are equal in magnitude.^{11,12} Conventionally, diffusion coefficients $D_{\parallel}$ and $D_{\perp}$ denote diffusion along and perpendicular to the director, respectively.

Diffusion in LC has been studied by a variety of experimental techniques including nuclear magnetic^{8,9,11,13} and electron spin^{14–16} resonances, quasielastic neutron scattering (QENS),^{17–26} forced Rayleigh scattering,^{27–35} optical microscopy^{36–42} and radioactive tracer method.^{43–45} NMR is currently the predominant method in diffusion studies of liquid crystals primarily because in most of the other techniques it is the diffusion of the molecular labels that is measured, which reflects only indirectly the diffusion of the molecular species in LC.

The past decade has witnessed significant advances in the NMR techniques. Novel procedures for the diffusion studies in LC have been developed;^{46–60} that based on the magnetic pulsed field gradient spin-echo technique is unique because it is molecularly selective and requires neither foreign probes nor changing the LC properties.^{61–67} Molecular positions and their changes are encoded by the NMR frequency, which becomes a function of the position in the presence of a magnetic field gradient.

The development of new techniques has allowed much more accurate measurements in a far broader range of diffusion coefficients. This has stimulated studies of ‘difficult’ and less conventional LC phases and determination of the diffusion tensor components in the phase transition region. With these new improved techniques it was also shown that some previous diffusion data were erroneous. New experimental results have motivated the development of new theoretical models and computer simulations of the diffusion process in liquid crystals.

In the present review, the experimental NMR techniques for diffusion studies in thermotropic liquid crystals are considered. The experimental results are compared with those derived from theoretical modelling and computation. The previous exhaustive review of diffusion studies in liquid crystals was published more than 20 years ago by Krüger⁸ and was followed by brief recent surveys^{9,10} and a methodological review.¹¹

II. NMR methods for measuring diffusion in liquid crystals

In ordinary liquids, the NMR spectra consist of narrow lines because anisotropic spin interactions are all motionally averaged to zero due to rapid isotropic tumbling of the molecules. In contrast, in liquid crystals this local motional averaging is incomplete³ and anisotropic spin couplings, such as the dipole–dipole or quadrupole interactions, are averaged to non-zero residual value. Hence, experimental NMR spectra usually exhibit line broadening and splitting. Spectral broadening translates into a quick decay of spin coherences in the time domain, which has a direct detrimental bearing on field-gradient NMR experiments for diffusion.

1. Pulsed-field-gradient NMR experiments

The determination of diffusion in conventional NMR experiments in isotropic liquids usually employs the pulse gradient spin echo (PGSE)^{64–67} or the pulse gradient stimulated spin echo (PGSTE)[†] (Ref. 68) radio-frequency (rf) pulse sequences depicted in Fig. 1. Irrespective of the specific experiment, NMR detects displacement *via* gradient-assisted de- and re-phasing of spin coherences. Diffusion coefficients can be measured only if the spin coherences are sufficiently de-phased by the applied field gradient.

In isotropic liquids, the resulted spin echo amplitude is described by the well-known Stejskal–Tanner^{62,69} expression

$$A(g, \delta, \Delta) \sim \exp \left[-D\gamma^2 g^2 \delta^2 \left(\Delta - \frac{\delta}{3} \right) \right], \quad (1)$$

where g and δ are the strength and the length of the applied gradient pulses, respectively, Δ is the diffusion time (the delay between gradient pulses), D is the self-diffusion coefficient and γ is the gyromagnetic ratio of the observed nuclei.[‡] In anisotropic systems, this expression is modified to accommodate for the diffusion anisotropy [Eqn (2)]:^{11,69,70}

Figure 1. Pulse sequences for conventional pulsed-field-gradient spin echo (a) and stimulated echo (b) NMR experiments; δ is the length of the gradient pulses, Δ is the time delay between the gradient pulses.

[†] In the absence of motion, all de-phased magnetisation can be recovered in the form of echo signal.⁶⁸

[‡] Since dephasing is proportional to γ^2 , the majority of NMR diffusion measurements have been carried out on high- γ nuclei, mainly ^1H .

$$A(g, \delta, \Delta) \sim \exp \left[-\gamma^2 \delta^2 \left(\Delta - \frac{\delta}{3} \right) g D g \right]. \quad (2)$$

The quick decay due to relaxation processes sets an upper limit for the length of applicable gradient encoding/decoding pulses and, thereby, a lower limit for the measurable diffusion coefficients. Whether or not the line broadening can be suppressed depends on the dominant spin interaction and the magnitude of the residual coupling.

2. Spin interactions and the NMR spectral shape

The residual spin interactions depend on the orientation of local LC director with respect to the applied static magnetic field B_0 . If this orientation varies at short distances, spectral splitting by residual couplings may even vanish due to molecular reorientation induced by translational displacement. The director orientation with respect to the direction of the external magnetic field can be homogeneous or randomly distributed in the sample. Low-viscous LC can be prepared in a homogeneous state with the same director orientation all over the sample volume by applying suitable electromagnetic fields. For example, in many nematics the molecular axes orient spontaneously along the field vector in the magnetic field. This is a consequence of the positive anisotropy of the magnetic susceptibility $\Delta\chi = \chi_{\parallel} - \chi_{\perp}$ of molecules ($\chi_{\parallel}$ and $\chi_{\perp}$ are susceptibilities parallel and perpendicular to the director, respectively). The contribution to the free energy

$$\Delta G = -\frac{1}{6} \Delta\chi B_0^2 (3 \cos^2 \vartheta - 1)$$

(ϑ is the angle between the director and the field vector) due to coupling to a magnetic field B_0 is minimised for the director alignment parallel to the field. Although $\Delta\chi$ is relatively small, the collective effect in the bulk sample is sufficient to overcome thermal fluctuations. Such oriented systems are contrasted to ‘powder’ samples with the random angular orientation of the director.

The appearance of the spectrum also depends on the involved spin couplings. The pairwise dipole–dipole interactions usually act in LC among a manifold of nuclei. Hence, even in uniformly oriented LC samples [e.g., in 4-cyano-4'-pentylbiphenyl (5CB)] ^1H NMR spectra of dipole–dipole coupled ^1H nuclei are wide because they consist of many overlapping split lines (Fig. 2).

Figure 2. ^1H NMR spectrum of nematic 4-cyano-4'-pentylbiphenyl (5CB).

The exception is LC where the director of a sample is oriented at the ‘magic angle’ ϑ_m to B_0 , since at this condition the splitting and the resulting spectral broadening are suppressed.[§] Single-spin quadrupole interactions for spin $I = 1$ nuclei in a macroscopically

[§] At $\vartheta_m = \arccos(1/\sqrt{3}) \approx 54.7^\circ$ (ϑ_m), the angular factor in the dipole–dipole interaction term is equal to zero; hence, the corresponding contribution to the spectral line width vanishes.

oriented LC may result in spectra split into sharp lines. For example, the ^2H NMR spectrum of partially deuterated 4-cyano-4'-octylbiphenyl (8CB)

consists of quadrupolar split doublets (Fig. 3).

Figure 3. ^2H NMR spectrum of partially deuterated smectic 4-cyano-4'-octylbiphenyl (8CB).

Powder samples exhibit, irrespective of the type of the involved spin interaction (dipole–dipole and quadrupolar), large broadening but often, for the latter case, with a discernible ‘powder pattern’ line shape with the characteristic singularities.⁷¹

3. Measurement of diffusion coefficients in liquid crystals

Diffusion in thermotropic liquid crystals has been addressed by a broad range of NMR techniques,^{8,9,11} including static-field-gradient method,^{47,59,60} as well as various techniques combining pulsed field gradients with a ‘nematic’ echo sequence,^{72–74} multiple-pulse spin decoupling,^{11,49–55,75–77} magic-angle sample orientation,^{46,56–58,73,78–82} deuterium stimulated (alignment) echo,⁵³ soft-pulse excitation⁸³ and multiple-quantum NMR.^{55,84,85} The optimum choice depends on the type of spin interaction, spectral shape and macroscopic sample orientation. Thus, conventional PGSE and PGSTE techniques have been used for weakly oriented solutes in liquid crystalline matrices.^{3,8,86–88}

a. Sample alignment at the magic angle

The simplest and earliest method for the diffusion coefficient measurement involves the preparation of a homogeneously oriented sample, which is then placed by its director at the magic angle (54.7°) with respect to the magnetic field B_0 .⁷⁹ In LC with the uniaxial symmetry of the orientational order, this rotation suppresses the dipole-dipole broadening. The limitation of the method is the required uniform orientation at a given oblique angle to the magnetic field; hence, this technique is not available in liquid-crystalline phases that reorient in the magnetic field or cannot be uniformly oriented. Hence, this approach has mainly been used for studies of viscous smectic phases formed upon cooling of nematic phases.[¶] For nematic phases, the electric field has been employed to hold the director along the magic angle.⁷⁸

In yet another approach, fast switching of the B_0 direction in a field-cycling spectrometer⁴⁶ creates the magic-angle condition. A

late offspring of magic-angle technique, appropriate for studies of unoriented powder-like LC samples, is a diffusion experiment performed under magic angle spinning (MAS) conditions⁸⁹ with the gradient field set along the spinning axis.

b. Suppression of anisotropic spin interactions by echo techniques

In the case of small anisotropic dipole–dipole ($I = 1/2$) or quadrupole couplings ($I = 1$), one may apply the solid or quadrupole echo^{90,91} instead of a conventional spin echo. In some cases, the so-called nematic echo^{92,93} generated in a $90^\circ - \tau - \beta - \tau$ sequence with $\beta < 54.7^\circ$ has been observed in ^1H NMR and employed in diffusion experiment.^{73,74,94} For ^2H NMR experiments, the stimulated echo sequence with modified pulse flip angles has been suggested to suppress the effect of the quadrupolar coupling on the echo amplitude.⁵³

c. Spin decoupling

Line broadening effects for systems of nuclei with $I = 1/2$ are in most cases significant due to homonuclear dipolar interactions. In solids, static dipolar line broadening is usually suppressed by appropriate radio frequency pulse sequences.⁹⁵ The same strategy has been explored for anisotropic diffusion experiments. The problem is that dipolar decoupling sequences perform inefficiently in the presence of a large frequency offset induced by the applied field gradient.⁹⁶ Hence, initially only very short (and, hence, weak due to instrumental limitations) gradient pulses in-between the rf pulses of the homonuclear decoupling sequence have been applied.^{75,76} As a consequence, only relatively fast diffusion could be measured this way. A better choice is to apply magic-echo (Fig. 4)^{53,97} decoupling during evolution periods of the stimulated echo pulse sequence.⁹⁸ In this sequence, longer windows are available for gradient pulses. Magic echo, originally devised to remove multi-spin dipole–dipole coupling, has also been shown to suppress simultaneously static quadrupole effects.⁹⁹ Hence, this strategy has been applied to quadrupolar spins with non-vanishing dipolar couplings.^{53–55} The disadvantage of the experiment is the limited time available for gradient encoding: at most, one-third of the coherence evolution periods.

Figure 4. Stimulated echo sequence combined with magic-echo decoupling for measuring diffusion coefficients in the presence of static dipole–dipole and/or quadrupole interactions in LC.⁵³

Decoupling in the presence of uninterrupted gradient pulses^{100,101} is more effective. However such experiments can only be made accurate if the resonance frequency offset effects of decoupling are correctly dealt with. This can be achieved using slice selection by a soft 180° pulse (Fig. 5), which limits the active sample volume to the region with sufficiently small frequency offset.^{49–51} Applied to homonuclei,^{49,51} this strategy suffers from two shortcomings: down-scaling of the gradient by the decoupling sequence, which limits the efficiency of gradient encoding and a decrease in the signal intensity as a result of slice selection. In the case of heteronuclei,⁵⁰ there is no down-scaling of gradient and the slice selection scheme can be ‘multiplexed’ thereby collecting the signal from most of the sample volume.

¶ Once oriented by the magnetic field in the nematic phase and subsequently transformed upon cooling to the smectic state, many samples preserve a homogeneous director orientation even when turned away from B_0 .

Figure 5. Pulse sequence for diffusion measurements using stimulated echo experiment with homonuclear decoupling (by MREV8 sequence)⁹⁵ applied simultaneously with the field-gradient pulses.⁴⁹

d. Multiple-quantum NMR

An additional possibility, explored not only in the case of $I = 1$ nuclei,⁵⁴ but also in the situation of dipolar coupled spins $I = 1/2$,^{84,85} is to perform an experiment where gradient pulses are employed during the evolution of multiple-quantum spin coherences. The highest-order coherences are not influenced by static quadrupolar and dipolar effects and, hence, exhibit longer decay.¹⁰² As an additional advantage, the field gradient affects higher-quantum coherences proportional to their quantum order thereby increasing the efficiency of gradient encoding/decoding.

e. Strong field gradient

Instead of suppressing line broadening, one may try a ‘brute force’ approach, *viz.*, to increase the strength of the gradient field. One way is to use a small gradient coil in combination with a high-current generator.^{103–111} The other solution is to exploit static gradients such as the one present in the fringe field of a conventional NMR superconducting magnet.^{112,113} The rf pulse sequence in this case is similar to that shown in Fig. 1 b, but with the gradient field constantly present instead of the pulsed gradient.^{47,59,60,114} An obvious disadvantage is small signal-to-noise ratio, which is a consequence of the limited range of excitation of the applied rf pulses and of the spectral broadening by the gradient during detection. Moreover, one cannot conveniently vary the gradient strength and direction.

f. Spectral selective excitation

Spatial slice selection can be replaced by spectral slice selection by long selective rf pulses.⁸³ It has been shown that weak rf pulses can excite sharp proton signals in ^1H NMR spectra of liquid crystals,¹¹⁵ which can be exploited for measurements of their diffusion coefficients.⁸³ Just as for spatial slice selection, the signal loss is a disadvantage of this approach.

g. Relaxation

Diffusion coefficients can be estimated from the NMR spin relaxation rate measurements.^{116–123} An access to diffusion *via* relaxation, however, requires the separation of contributions to the relaxation rates of intra- and intermolecular interactions as well as contributions of different modes of molecular reorientations. The contribution of the intermolecular interaction to spin relaxation processes originates from the modulation of dipole–dipole interactions upon molecular diffusion.^{124–127} Diffusion coefficients extracted from the relaxation data characterise the translational motion on the molecular length-scale in contrast to the micrometre-scale diffusion coefficients obtained by the field-gradient techniques.

h. Spectral shape analysis

Chiral mesophases (cholesterics) exhibit helical spatial modulation of the molecular orientation. If the NMR spectral shape is dominated by the anisotropic spin interactions, the resonance frequency turns out to be spatially encoded even without the application of an external field gradient.^{128–137} Modulation of the spin resonance frequency as a result of molecular diffusion is

reflected in the shape of the NMR spectrum, akin to chemical exchange effects.¹³⁸ Note, this approach can only measure the diffusion component along the modulation direction, *i.e.*, along the helical axis.

4. Accessing the diffusion tensor components

Characterisation of the diffusion tensor $\mathbf{D}$ requires experiments performed at several field gradient orientations with respect to the director. In a homogeneously oriented sample, $D_{\parallel}$ and $D_{\perp}$ can be measured either by using orthogonal gradient coils^{52,53,55,57,58,139} or by changing the sample orientation provided that the director is not re-oriented by the magnetic field.^{46,60,78,82} The other option, applicable in non-oriented samples, exploits the spectral broadening itself by anisotropic spin interactions, such as quadrupole coupling⁹⁰ or chemical shift anisotropy.^{51,140} Since the anisotropic interactions provide correspondence between the spectral resonance frequency and the domain orientation, the intensity decay at different frequencies in the spectrum for just one gradient direction reveals the principal components of the diffusion tensor $\mathbf{D}$.

If diffusion within individual domains of non-oriented powder samples cannot be orientationally assigned (as is typical of the ^1H nuclei), the diffusional decay becomes the composite of decays for different gradient orientations.^{11,141} If the orientational distribution is completely random and other effects, such as restricted diffusion, do not complicate the evaluation, the diffusion tensor can also be extracted either from the composite decay or from diffusion–diffusion correlation (or exchange) experiments using orthogonal field gradient pulses.^{142–144}

III. Theoretical models and computer simulations of diffusion in liquid crystals

1. Diffusion models in nematics

Several theoretical approaches have been developed to describe the translational diffusion in nematic liquid crystals. The hydrodynamic theory of Franklin¹⁴⁵ evaluates the molecular diffusion in terms of viscosity coefficients, friction constants and detailed molecular geometry. Using this approach, the temperature dependence of the anisotropic radio-tracer diffusion in the nematic phase of *p*-azoxyanisole (PAA) was correctly predicted.¹⁴⁵ In contrast, the results obtained for nematic 5CB were found to be incompatible with this model.^{52,55} Since the approach involves many parameters not readily available with sufficient accuracy, its predictions cannot be easily verified by experiments.

In yet another approach, the diffusion coefficients in nematic phases have been derived *via* a parameterised form of the momentum time-autocorrelation function in the system of perfectly ordered clusters and subsequent transformation of the diffusion tensor from the cluster frame to the laboratory frame.¹⁴⁶ The theory relates the components of the diffusion tensor to the molecular geometry (molecular axial ratio) and the order parameter S . It predicts that the arithmetic (isotropic) average of the diffusion coefficient

$$\langle D \rangle_a = \frac{2D_{\perp} + D_{\parallel}}{3} \quad (3)$$

is independent of orientational order and geometry and changes continuously across the nematic–isotropic phase transition. The model has previously been applied with varying success to nematic liquid crystals. Particularly, a satisfactory agreement with the results in PAA was found.¹⁴⁶

Hess and co-workers¹⁴⁷ have applied the affine transformation from the isotropic diffusion of hard spheres to the space of aligned uniaxial ellipsoids to derive the diffusion coefficients in terms of the molecular axial ratio and the phase order parameter. In contrast to the previous approach, the geometric average

$$\langle D \rangle_g = D_{\parallel}^{1/3} D_{\perp}^{2/3} \quad (4)$$

rather than the isotropic average $\langle D \rangle_g$ is predicted to be independent of the molecular shape and order and to coincide at the phase boundary with the diffusion coefficient in isotropic phase. This model has been successfully tested using molecular dynamics computer simulations^{147, 148} and describes well experimental NMR results.^{52, 53}

A mean-field kinetic approach to anisotropic translational diffusion in nematics has also been proposed.¹⁴⁹ Similarly to the affine transformation model, the predicted value of $\langle D \rangle_a$ increases with the increase in the molecular order.

2. Diffusion models in smectics

The diffusion in the smectic A phase has been modelled under the assumption of a periodic temperature-independent potential $V(z)$ along the smectic director^{150–152}

$$V(z) = \frac{V_1}{2} \cos\left(\frac{2\pi z}{d}\right), \quad (5)$$

where d is the layer spacing. Thus, diffusion parallel to the director requires the molecule to overcome not only the viscous drag of the medium, but also the potential barrier. In-layer diffusion remains essentially unaffected. Molecular diffusion along the director is given by the equation

$$(D_{\parallel})^{\text{sm}} = (D_{\parallel})^{\text{nem}} \left[I_0\left(\frac{V_1}{2RT}\right) \right]^{-2}, \quad (6)$$

where I_0 is the modified Bessel function of the first kind and of the zero order. For the non-zero potential amplitude, V_1 , this model predicts a discontinuity of $D_{\parallel}$ at the nematic–smectic A phase transition. This approach has successfully described diffusion data obtained by QENS and NMR methods in some smectic LC with a pronounced discontinuity of $D_{\parallel}$ at the nematic–smectic phase transition.^{8, 94}

Recently,⁵⁵ this model has been modified to include a temperature-dependent potential in the parameterised form:

$$V_1(T) = V_0 \left(1 - \frac{T}{T^*}\right)^{\gamma} \quad (7)$$

in keeping with the temperature dependence of McMillan's smectic order parameter.¹⁵³ The value of the parameter T^* is close to the smectic–nematic transition temperature. This modified model provided a correct description of the experimental results in smectic A phases with a weak second order nematic–smectic phase transition as is typical of systems exhibiting a significant nematic range.^{55, 80, 81}

3. The temperature dependence of the diffusion coefficients

Arrhenius-type descriptions are commonly applied to the temperature dependence of the individual components of the diffusion tensor in liquid crystals.^{8, 9}

$$D_{\parallel, \perp} = D_{\parallel, \perp}^0 \exp\left(-\frac{E_{\parallel, \perp}}{RT}\right). \quad (8)$$

However, the energy parameter E does not have a simple physical meaning in the case of liquid crystals, in contrast to solids where it corresponds to the height of the potential barrier for particle jumping between the lattice sites. The values $E_{\parallel, \perp}$ in mesophases may be dependent on the temperature through the order parameter, especially near the phase transitions.⁵² Thus, although Eqn (8) has often been found to fit well the experimental data recorded in mesophase temperature ranges, the numerical results lack physical interpretation.

4. Computer simulation of the diffusion by molecular dynamics

In molecular dynamics (MD) simulation of diffusion in liquid crystals,^{148, 149, 154–164} the diffusion coefficients were determined either from the mean-square molecular displacements or from the

velocity autocorrelation functions. The results are commonly compared to those predicted based on the affine transformation model and to experimental data.

A non-monotonic temperature dependence of $D_{\parallel}$ in nematic phase was observed,^{148, 164} which was attributed to the competition between a decrease in molecular ordering and mobility. The geometric average of the diffusion coefficient $\langle D \rangle_g$ was found to be continuous and linearly temperature-dependent across the nematic–isotropic phase transition. In contrast, the isotropic average $\langle D \rangle_a$ depends on molecular order,¹⁶⁴ as illustrated in Fig. 6.^{163, 164}

Figure 6. The temperature dependences of the diffusion tensor components and their averages as obtained from MD simulation.¹⁶⁴ (1) $D_{\parallel}$, (2) $D_{\perp}$, (3) $\langle D \rangle_a$, (4) $\langle D \rangle_g$.

Calculations of mean-square displacements were performed in a system of soft-core spherocylinders (cylinders with hemispherical caps) interacting by an inverse-power pair potential.¹⁵⁴ The obtained data showed that, in the smectic A phase, diffusion takes place exclusively along the layer. In an MD simulation of a Gay-Berne mesogen,¹⁶³ $D_{\parallel}$ was shown to change abruptly for the phase sequence isotropic–smectic A, which is characteristic of a first-order phase transition, and $D_{\parallel} < D_{\perp}$. However, if the system also exhibits an extended nematic phase, starting from $D_{\parallel}(\text{smec A}) \approx D_{\parallel}(\text{nem})$ in the vicinity of nematic–smectic A transition, the $D_{\parallel} > D_{\perp}$ nematic property permeates the smectic A phase and may become inverted at lower temperatures. The coefficient $D_{\perp}$ essentially follows the same temperature trend well described by the Arrhenius law over the whole range of smectic and nematic phases. This type of diffusion was observed experimentally in liquid crystals of 8CB.⁵⁵

MD simulation has been performed in the columnar phase of the discotic molecules of hexakis(pentyloxy)triphenylene.¹⁶⁵ The diffusion process exhibited a solid-like jump behaviour in the plane perpendicular to the columnar axis. The translational dynamics of the molecules along the axis was described by the model of column sliding.

IV. Experimental studies of diffusion in thermotropic liquid crystals

Early NMR diffusion experiments in thermotropic nematic^{8, 72, 74, 75, 77, 88, 166} and smectic systems^{8, 73, 76, 79, 80} often merely recorded the fact that the diffusion is anisotropic. The experimental accuracy, reproducibility and the range toward slow diffusion were limited, as has been demonstrated recently

Figure 7. Data on anisotropic diffusion in 5CB as obtained by spin-decoupling-based NMR diffusion experiments ($\circ$ — D_{iso} , $\bullet$ — $D_{\parallel}$, Δ — $D_{\perp}$),⁵² in comparison with the results obtained by other techniques: PGSE NMR [(1) D_{iso} ,¹⁶⁷ [(2) D_{iso} , (2') $D_{\parallel}$, (2'') $D_{\perp}$];¹⁶⁸ fringe-field NMR (3) D_{iso} ,¹⁶⁹ field cycling NMR [(4) D_{iso} , (4') $D_{\parallel}$, (4'') $D_{\perp}$];⁴⁶ PGSE NMR with the sample reorienting in the electric field [(5) D_{iso} , $\blacktriangle$ — $D_{\parallel}$];⁷⁸ forced rayleigh scattering [(6) D_{iso} , (6') $D_{\parallel}$, (6'') $D_{\perp}$];²⁷ [(7) D_{iso} , (7') $D_{\parallel}$, (7'') $D_{\perp}$];³⁵ QENS ($\square$ — D_{iso} , $\blacksquare$ — $D_{\parallel}$, $\diamond$ — $D_{\perp}$).¹⁹

(Fig. 7).⁵² The early works performed up to 1982 have been comprehensively reviewed by Krüger,⁸ and hence are only briefly recalled here.

A parameter that can be measured with the acceptable accuracy is the activation energy, since it may be obtained from the strong temperature dependence of the diffusion coefficient. The values of the activation energies $E_{a\parallel} \approx E_{a\perp}$ that have been obtained in nematic liquid crystals were comparable to those in isotropic phases. In smectics, the relationships $E_{a\parallel} > E_{a\perp}$ and $E_{a\perp}(\text{smec}) \approx E_{a\perp}(\text{nem})$ have generally been observed, which is consistent with the model of in-layer continuous diffusion in liquids and a jump process between the layers typical of solids.

The diffusion anisotropy $D_{\parallel}/D_{\perp}$ in nematic phase ranges between 1.2 and 4. Within the experimental accuracy, the values of the majority of average diffusion coefficients $\langle D \rangle_a$ in the nematic phase at the clearing point determined earlier were close to the isotropic diffusion coefficients. The ratio $D_{\parallel}/D_{\perp}$ in smectics was found to vary in a wider range from $D_{\parallel}/D_{\perp} \geq 1$ to $D_{\parallel}/D_{\perp} \ll 1$.

1. Diffusion in nematic and cholesteric phases

Nematic phases were frequently chosen for testing new techniques for the determination of diffusion coefficients in liquid crystals, the nematic phase of 5CB being the most popular model compound. Recently, the diffusion coefficients in 5CB obtained by different methods have been compared (see Fig. 7).⁵² While earlier results strongly disagree, obviously due to methodological problems, more recent studies by advanced NMR techniques, including multiple-pulse-decoupling PGSTE,^{52,55} fringe-field-gradient stimulated echo⁴⁷ and spectral-slice-selection PGSTE⁸³ demonstrate a good agreement.

The most accurate values of the diffusion tensor components in 5CB over a wide temperature range (Fig. 8) have been obtained by multiple-pulse-decoupling PGSTE NMR.^{52,55} The temperature dependence of the diffusion coefficient D_{iso} in the isotropic

Figure 8. Values of $D_{\parallel}$ (1), $D_{\perp}$ (2), $\langle D \rangle_a$ (3), $\langle D \rangle_g$ (4) and D_{iso} (5) in 5CB obtained by multiple-pulse spin-decoupling-based NMR experiment.⁵² Solid lines are the fits by the affine transformation model.¹⁴⁷

phase is described with high accuracy by the Arrhenius equation. Although the temperature dependence of both $D_{\parallel}$ and $D_{\perp}$ in the nematic phase at the points far from the nematic–isotropic phase transition can be approximated by the Arrhenius-type relationship (with the activation energies $E_{a\parallel} < E_{a(\text{iso})} < E_{a\perp}$), the two curves $D_{\parallel}(T)$ and $D_{\perp}(T)$ converge fast toward the isotropic value closer to the phase transition. This suggests that the anisotropy of the translational diffusion reflects the orientational ordering of the molecules, which decreases sharply on approaching the isotropic phase. The temperature dependence of the isotropic average $\langle D \rangle_a$ [see Eqn (3)] also deviates from the simple Arrhenius relationship in the vicinity of the phase transition. At the phase transition, there is an appreciable discontinuity between D_{iso} and $\langle D \rangle_a$. This behaviour contradicts that predicted from a model of a momentum time-autocorrelation function used for the diffusion coefficient calculations.¹⁴⁶ In contrast, calculations using the affine transformation model¹⁴⁷ are consistent with experimental results. In particular, the values of the geometric average $\langle D \rangle_g$ [see Eqn (4)] are on the line extrapolated from the isotropic phase. An analogous behaviour was observed in the nematic phases of 8CB (Refs 53, 55) and *N*-(4-ethoxybenzylidene)-4'-butylaniline (EBBA)⁵⁵ where the same types of multiple pulse techniques were employed.

Diffusion measurements have been performed in 4-(*n*-octyl-oxy)-4'-cyanobiphenyl (8OCB) and 4,4'-di-(*n*-octyl)azoxybenzene (OAB) using fringe-field-gradient NMR.^{59,60} The temperature dependences of $D_{\parallel}$ in the nematic phase and at the isotropic–nematic phase transition resemble that in 5CB and 8CB. Since the temperature dependences of the $D_{\perp}$ component of the diffusion tensor were not measured and since the nematic phase in OAB exists in a limited temperature range, no comparison with the theoretical models was performed.

The temperature dependences of the principal components of the diffusion tensor were reported for homologous series of di(alkyl)azoxybenzenes and (alkoxy)cyanobiphenyls^{46,82} using the field-cycling technique. A characteristic alternation of diffusion coefficients and activation energies as functions of the chain

length, *i.e.*, the familiar odd-even effect, has been observed. Unexpectedly, it was found⁸² that both $D_{\parallel}$ and $D_{\perp}$ were larger than D_{iso} , which is probably due to systematic errors caused by methodological problems.

An anomalous temperature dependence[†] of the components of the diffusion tensor was also found in nematic 4-pentylphenyl 2-chloro-4-(4-pentylbenzoyloxy)benzoate.¹⁰⁰ This behaviour is most probably an artefact due to interference between the heteronuclear decoupling and the field gradient as discussed in Ref. 50.

Conventional PGSTE NMR has been applied for studying the diffusion behaviour in a cholesteric phase formed by 5CB doped with an optically active chiral component, *viz.*, 4-cyano-4'-(2-methyl)butylbiphenyl (CB15).¹⁶⁸ The orientation of molecules in a cholesteric phase corresponds to that in the nematic phase with the director helically twisted in space. The pitch axis of the twisted structure is aligned perpendicular to the direction of the magnetic field of a spectrometer. This experiment demonstrates the existence of the translational diffusion anisotropy (ratio $D_{\parallel}/D_{\perp} \approx 1.7$) with the diffusion coefficients dependent on the diffusion time.

In a number of diffusion studies in cholesteric phases, NMR spectral shape analysis has been used, which allowed measurement of only $D_{\perp}$, *i.e.*, diffusion along the pitch axis. It was shown that $D_{\perp}$ increases with pitch length and depends on the diffusion time.^{128–130} The Arrhenius-type temperature dependence was commonly observed with apparent activation energies close to those in nematic phases and with relationship $D_{\perp} < D_{\text{iso}}$ at the clearing temperature (Fig. 9).^{128, 131}

Figure 9. The temperature dependence of the diffusion coefficients in the isotropic and cholesteric phases of a mixture of substituted phenylbenzoates and chiral dopants.¹³¹ (1) $D_{\perp}$, (2) D_{iso} .

While diffusion coefficients in the isotropic phases of liquid-crystalline compounds commonly display simple Arrhenius-type temperature dependences,^{47, 52, 55, 167, 169–174} accurate measurements performed in the vicinity of the isotropic–nematic phase transition on the isotropic side indicated a noticeable deviation from this conventional behaviour.^{106, 175} This effect has been attributed to the formation of locally ordered nematic clusters (cybotactic groups) in isotropic surroundings.

[†] The experimental values of the activation energies in this nematics were related as $E_{\parallel} > E_{\perp}$, which is not typical of nematics.

2. Smectic phases

Smectics A exhibit high molecular mobility within the layers comparable to that in conventional liquids. Diffusion anisotropy in smectics typically becomes $D_{\parallel}/D_{\perp} < 1$,^{8, 57, 76, 79} as opposed to that in nematics. At the nematic–smectic phase transition, $D_{\perp}$ changes nearly continuously, while $D_{\parallel}$ and its apparent activation energy change abruptly as a result of molecular jumps between adjacent smectic layers.^{8, 55, 60} However, smectic A materials that exhibit a broad temperature range of the nematic phase display a different behaviour (Fig. 10): for them, the nematic-like relationship $D_{\parallel}/D_{\perp} > 1$ is typically found in the vicinity of the phase transition point.^{55, 56, 58, 59, 81} Upon cooling deeper into the smectic phase, the diffusion ratio may change to the opposite, more common for smectics.^{59, 73} As concerning the activation energies, the relation $E_{\parallel} \geq E_{\perp}$ is always fulfilled.

Figure 10. The temperature dependences of the diffusion coefficients in isotropic, nematic and smectic A phases of 8CB.⁵⁵ Lines are fits by the affine transformation model¹⁴⁷ in the nematic phase and by a model with a temperature-dependent periodic potential in the smectic A phase.^{55, 150} (1) $D_{\parallel}$, (2) $D_{\perp}$, (3) D_{iso} .

Fringe-field-gradient stimulated echo has been applied¹¹⁴ to measure the diffusion coefficients in different smectic A, C* and C_A* phases[‡] of the liquid crystal of 1-methylheptyl 4'-[4-(n-decyl-oxy)benzoyloxy]biphenyl-4-carboxylate. A continuous decrease in the diffusion coefficient in the direction of the layer normal was observed in smectic A and C* phases, while an abrupt decrease by nearly two orders of magnitude was found on the transition to C_A* phase. Similarly, slow interlayer diffusion in smectic C_A* phase compared to phase C* has been detected using ²H NMR spectral shape analysis.^{137, 176} This finding was explained by steric effects arising from the anticlinical molecular arrangement in adjacent layers, which hinder the interlayer diffusion.

Experimental results obtained in smectic A phases^{55, 59, 60} have been compared to the available theoretical models. Some results⁵⁹ were consistent with the model developed by Volino *et al.*,^{150, 151} which predicts an abrupt decrease in $D_{\parallel}$ at the transition from nematic or isotropic phases to smectic A phases (Fig. 11).

[‡] C* and C_A* are chiral smectic phases C with synclinically and anticlinically ordered molecules, respectively.

Figure 11. Diffusion coefficients of OAB obtained in the isotropic, nematic and smectic A phases.⁵⁹ (1) $D_{\parallel}$, (2) $D_{\perp}$, (3) D_{iso} .

However, for systems with a weak second-order nematic-to-smectic phase transition, a model with the temperature-dependent potential (see Eqn 7 and Fig. 10) should be assumed for the analysis of the experimental data. The behaviour of 8CB⁵⁵ and 8OCB⁶⁰ was correctly described in that way.

3. Columnar phases of discotic molecules

In contrast to conventional thermotropics built by rod-like mesogenic units, columnar phases are formed by discotic flat molecules.¹⁷⁷ For the columnar hexagonal phase of a discotic thermotropic hexapentylxytriphenylene, it was shown that the diffusion is very slow⁵⁴ in contrast to early indications.¹⁷⁸ The diffusion in the direction perpendicular to the columnar axes was measured by ^2H PGSTE NMR. A low magnitude of the diffusion coefficient [$D_{\perp} = (1-4) \times 10^{-14} \text{ m}^2 \text{ s}^{-1}$] and a high activation energy ($E_{\perp} = 115 \text{ kJ mol}^{-1}$) suggested solid-like or, perhaps, collective diffusion mechanisms in discotics.⁵⁴

4. Polymeric liquid crystals

Anisotropic diffusion with the relationship $D_{\parallel} > D_{\perp}$ relative to the α -helical chain axis and with apparent activation energies dependent on the main-chain length has been observed in LC phases formed by rod-like polypeptides.¹⁷⁹⁻¹⁸¹ In the polymeric LC phase formed by flexible poly(diethylsiloxane) molecules, the diffusion was found to be faster than that in the isotropic phase.¹⁸² This was attributed to a decrease in the degree of entanglement between the polymer chains that become orientationally correlated in the anisotropic phase.¹⁸²

5. Liquid crystals confined in porous media

The effect of confinement on the diffusion properties of LC embedded in porous glass matrices (with the pore size varied from 7.5 to 140 nm) was studied for the nematic 5CB as an example.⁴⁷ A strong decrease in the diffusion coefficient with the decrease in the pore size was observed. The PGSE NMR measurement of self-diffusion in nematic EBBA confined in porous glasses was used to estimate the size of the nematic clusters in the isotropic pre-transition region adjacent to the nematic phase.¹⁰⁶

6. Diffusion of small solute molecules in mesophases

Due to their low orientational order, small organic molecules dissolved in liquid crystals exhibit long decays of spin coherences. Therefore, conventional PSGE or PGSTE experiments can be used to assess their diffusion coefficients.^{8, 14, 72, 86, 87, 183-189} In nematic phases, the solute diffusion is fast and the diffusion anisotropy is small, as compared to the diffusion of molecules forming a mesophase.^{8, 9} This contrasts the strong translational diffusion anisotropy $D_{\parallel}/D_{\perp} \ll 1$ observed in smectic phases.⁸

Recently, the diffusional behaviour of xenon in liquid crystals has been studied in detail.¹⁹⁰⁻¹⁹⁴ PGSE ^{129}Xe NMR has been used to probe diffusion of xenon dissolved in nematic^{190, 191, 194} and smectic (A and C*) phases.¹⁹²⁻¹⁹⁴ No diffusion anisotropy and very weak anisotropy ($D_{\parallel}/D_{\perp} > 1$) were observed in the nematic phases of ZLI-1132¹⁹⁰ and EBBA/ZLI-1167,¹⁹¹ respectively. In contrast, significant anisotropy was found in smectic phases of ferroelectric liquid crystals, where $D_{\parallel}/D_{\perp} \ll 1$.^{192, 193}

V. Conclusion

A number of new diffusion techniques applicable to liquid crystals have been developed during the past decade. In contrast to techniques applied for isotropic liquids, these advanced approaches with various degrees of sophistication have not yet become routine tools. However, when applied with insight, the new techniques provide much higher accuracy and significantly extend the range of the accessible diffusion coefficients.

Self-diffusion data provide detailed and easily interpreted information on the molecular organisation and dynamics in mesophases. The anisotropic diffusion tensor and the activation energy in liquid crystals are very sensitive to structural changes at the phase transitions. Observing the changes in components of the diffusion tensor at the phase transitions allow a thorough evaluation of, and discrimination among, the theoretical models as well as the assessment of the computer simulation data. For conventional thermotropic phases, such as nematics and smectics A, the accurate diffusion data obtained with advanced NMR methods are well understood in terms of available theoretical models. For other systems, including highly ordered columnar and smectic phases generally exhibiting slow diffusion, only limited data are available as yet.

Metal derivatives of tetrazoles

P N Gaponik, S V Voitekhovich, O A Ivashkevich

Contents

I. Introduction	507
II. Metal derivatives of unsubstituted and 5-substituted tetrazoles	508
III. Metal derivatives of neutral <i>N</i> -substituted tetrazoles	520
IV. Metal derivatives of <i>C,N</i> -substituted tetrazoles generating anionic centres in the substituent	525
V. Applications of metal tetrazole derivatives	531
VI. Conclusion	533

Abstract. Published data on the synthesis, structure, properties and applications of metal derivatives of tetrazoles are generalised and described systematically. Compounds based on the anionic and neutral tetrazole forms, *C*- and *N*-mono- and *C,N*-disubstituted tetrazoles are considered. The bibliography includes 464 references.

I. Introduction

In recent years a new direction has been developed in the tetrazole chemistry, which has appeared at the border with inorganic chemistry and is related to the synthesis and studies into the structure and properties of metal tetrazole derivatives (MT). This is due to the practical and theoretical significance of these unique compounds and diversity of their properties, depending on both the nature of the metal atom and the functional groups attached to the tetrazole ring.

Tetrazoles are a peculiar class of heterocyclic compounds exhibiting properties of both acids and bases.^{1–3} Therefore, they can exist in neutral, anionic and cationic forms. The metal atom (M) in MT can be bound to the heterocycle by a covalent, ionic or coordination bond or can be incorporated into a neutral molecule, anion or cation. When considering the enormous array of existing data in terms of these peculiar features, one can distinguish several main types of MT (**1**–**5**) (R^A is the substituent generating the anionic centre, X is an inorganic or organic ligand, A is the anion, MA is the metal-containing anion).

Compounds **1a,b** are formed upon deprotonation of 5-substituted tetrazoles and, in the case of alkali and alkaline earth metals, are mainly ionic (**1a**). For other metals, a more or less covalent bond of the type **1b** is formed; this also occurs for mixed-ligand complexes (**1c**). Compounds **2** are π -complexes in which neutral mono- and disubstituted tetrazoles are present as ligands. A separate type of MT is represented by chelates **3** formed by *C*- and *N*-substituted tetrazoles in which substituents generate the anionic centre. The metal atom in MT **4** and **5a** is directly linked to the carbon atom of the tetrazole ring, while in tetrazolium salts **5b**, the metal is a part of the anion.

Owing to the availability and good prospects for the practical use, derivatives of types **1**–**3** are most studied. And only in the last decade, more than 300 relevant papers were published. However, numerous data on the synthesis, structures and properties of these compounds have not been described systematically as yet. Data on transition metal compounds of tetrazoles and tetrazolate anions published before 1987 have been surveyed.⁴ Two reviews devoted to complexes of 1,5-disubstituted tetrazoles⁵ and thermo- and photochromic iron(II) complexes with 1-alkyltetrazoles⁶ have been published. In addition, a recent review⁷ devoted to organo-metallic complexes of azoles contains some data on the tetrazole derivatives.

The purpose of the present review is to describe systematically and generalise the existing data on the synthesis, structure, properties and applications of MT of types **1**–**3** prepared using anionic and neutral forms of unsubstituted and *N*-substituted tetrazoles. Organometallic compounds **4** and tetrazolium compounds **5**, which are somewhat different and much less studied, are beyond the scope of the review. However, judging from the latest publications, the attention to these derivatives increased owing to

the prospects of their use in organic synthesis⁸ and analytical chemistry.^{3,9}

The information is systematised according to the type of tetrazole that forms MT, because the structure of the tetrazole derivative, *i.e.*, the presence, positions and the nature of substituents in the ring, determines the formation of metal–tetrazole bonds of different nature and, hence, dictates the methods used to synthesise the MT. The attention is focused on the synthetic aspects and applications of MT. Structural features and properties of MT are also discussed.

II. Metal derivatives of unsubstituted and 5-substituted tetrazoles

5-Substituted tetrazoles are the most readily available tetrazole derivatives.^{1–3,10} This accounts for the considerable interest in them as the starting compounds in the synthesis of MT. Due to their unique structures and properties, tetrazoles of this type form diverse metal derivatives; the methods of their synthesis can be divided into two groups. The first one includes the reactions of 5-substituted tetrazoles with bases, metal salts or other metal-containing compounds and transformations of the MT formed. Due to acidic properties of 5-substituted tetrazoles, the pK_a of which ranges from -0.8 to 6 depending on the nature of substituent R ,^{1–3,11,12} it is possible to prepare salts **1a** and similar metal derivatives **1b,c**. In some cases, tetrazoles are not deprotonated, complexes **2** ($R^2 = H$) being formed with involvement of the lone pair of the tetrazole nitrogen. The second group of methods comprises heterocyclisations of linear polynitrogen structures with metal salts or complexes; this gives metal derivatives **1a–c**.

1. Synthesis of metal derivatives from tetrazoles

The reactions of 5-substituted tetrazoles **6** with bases (alkali and alkaline earth metal hydroxides,^{13–18} alkoxides^{19–25} or hydrides^{16,26}) afford tetrazolates **1a**. In most cases, the reaction is carried out in water, ethanol or acetonitrile, and the resulting salts are often used for subsequent transformations without isolation from the reaction medium.

M is alkali or alkaline earth metal; $X = H, OH, OAlk$.

This reaction is also suitable for the synthesis of poly(5-vinyl-tetrazole) (PVT) salts. However, the reaction in water or ethanol does not proceed to completion despite an excess of the base.²⁷ In other organic solvents, sodium poly(5-vinyltetrazolate) (**7**) with a metal content of 99.9% of the stoichiometric amount was obtained.²⁸

In the presence of complex-forming compounds, this reaction may give salts with a more intricate composition. In particular, the reaction of tetrazole with lithium hydroxide in DMSO afforded lithium tetrazolate **8**, incorporating a DMSO molecule, in 33% yield.²⁹ Treatment of 5-phenyltetrazole with potassium hydride and 18-crown-6 in THF at room temperature gave 5-phenyltetrazolate of the potassium complex with 18-crown-6 (**9**) in 94% yield.²⁶ The structures of compounds **8** and **9** were determined by X-ray diffraction analysis.

The substituent at the heterocycle carbon atom can also exhibit acidic properties; in this case, the tetrazole forms salts of different types. For instance, 5-nitraminetetrazole (**10**) is converted into salts **11** and **12** containing singly and doubly charged tetrazole anions, respectively.^{30–33} According to X-ray diffraction data, in caesium³¹ and lithium (hydrate)³³ salts **11**, the negative charge is delocalised over the anion. Salts **12** are often prepared using more readily available 5-aminotetrazole (**13**) instead of tetrazole **10**. Upon nitration with polynitro compounds in the presence of an alkali, compound **13** is converted into 5-nitraminetetrazolate(2–) salts (**12**) (yields 68%–91%).³⁰

$M = Li, Na, K, Rb, Cs$.

5-Substituted tetrazole **14** reacts with potassium hydride as a dibasic acid to give dipotassium salt **15** in a quantitative yield.³⁴

A series of MT **1c** have been prepared by the reaction of 5-substituted tetrazoles **6** with organometallic bases and oxides, in particular, tributyltin oxide^{1,2} and diphenylthallium²¹ and phenylmercury¹ hydroxides dissolved in lower alcohols. MT **16–19**

$X = 1,3-C_6H_4, (CH_2)_n$ ($n = 1, 2, 4$).

obtained in this way may have more complex structures in the crystalline state due to the additional coordination of the metal atom to the tetrazole ring. According to X-ray diffraction data, compound **17** is a dimer formed through the N(1),N(2)-binding of the tetrazole ring to the metal atom, and MT **18** [$X = (CH_2)_4$] is polymeric owing to the tridentate coordination of the heterocycle by the N(1), N(2), N(3) atoms to different metal atoms.²¹

The use of the methods to prepare compounds **1b**, where M is a transition metal, is virtually unexplored. The reaction of 5,5'-bitetrazole with copper(II) oxide or copper(II) basic carbonate gave³⁵ copper(II) bitetrazolate. These reactions proceed more smoothly in the presence of ammonia or ethylenediamine, which are incorporated into the final product.^{35–37} Thus the reaction of potassium 5-nitraminotetrazolate (**11**, $M = K$) with nickel(II) hydroxide in aqueous ammonia furnished triammine(5-nitraminotetrazolato)nickel(II) (yield 80%) having dimeric structure **20** according to X-ray diffraction data.³⁷

The reaction of tetrazoles **6** with metal chlorides, sulfates, acetates and other salts is a convenient method for the preparation of MT **1b**. Due to poor solubility, the target compounds are formed on mixing aqueous or aqueous ethanolic solutions of reactants at room temperature. This procedure was used to prepare silver (**21**)³⁸ and copper(II) tetrazolates³⁹ and nickel(II) and copper(II) 5-vinyltetrazolates⁴⁰ having a stoichiometric composition. Due to the possibility of inclusion of a reagent into the final product, the composition of the resulting salt depends on the starting reactant ratio. In particular, tetrazole reacted with excess silver nitrate to give the double salt $2 Ag(HCN_4) \cdot AgNO_3$ (**22**).³⁸

According to X-ray diffraction, the structure of tetrazolate **21** is a 3D network of three- and four-coordinate silver ions linked by tri- and tetradentate tetrazolate ligands. In salt **22**, the silver atoms are two- and three-coordinate, while the tetrazole ring is linked to the metal atoms through four nitrogen atoms. The Ag–N bond lengths in these compounds are in the range of 2.197(4)–2.410(4) Å.³⁸ Note that participation of all four nitrogen atoms of the tetrazole ring in metal coordination is a rare case. This coordination mode has also been found recently by X-ray diffraction analysis in the structure of copper(I) 5-methyltetrazolate.⁴¹ More often, the tetrazolate anion acts as a bidentate bridging ligand or a monodentate ligand. According to X-ray diffraction data, both types of coordination exist in the mixed-ligand copper(II) complex **23**, prepared by the reaction of 5-phenyltetrazole with copper acetate in aqueous ethanol in the presence of 2,2'-bipyridine.⁴²

The reaction of salts MX_2 ($M = Cu, Cd, Zn$; $X = Cl, OAc$) with Schiff bases **24** in methanol resulted in the complexes $M(HL)_2(MX_2)_n$, where $n = 0–2$, HL is the singly deprotonated ligand, and the complexes ML, where L is the doubly deprotonated ligand. The diversity of compositions of the complexes obtained is due to the ability of metal atoms to substitute the hydrogen atoms in the tetrazole ring and the hydroxy group, polydentate nature of the heterocycle and participation of the azomethine group in the coordination, as indicated by IR spectroscopic data.⁴³

$R = 2,4\text{-Cl}_2\text{C}_6\text{H}_3, 2\text{-MeO-}3,5\text{-Cl}_2\text{C}_6\text{H}_2, 2,4\text{-(MeO)}_2\text{C}_6\text{H}_3, 4\text{-Me}_2\text{NC}_6\text{H}_4, 2\text{-HOC}_6\text{H}_4, 2\text{-HO-}5\text{-BrC}_6\text{H}_3, 2\text{-HO-}5\text{-NO}_2\text{C}_6\text{H}_3.$

Depending on the reaction conditions, *meta*- and *para*-5,5'-phenyleneditetrazoles **25** react with Cd, Zn and Mn(II) salts to give essentially different, as regards both composition and structure, complexes **26**, **27**,⁴⁴ **28**,⁴⁵ **29**.⁴⁶ The structures of compounds **26–29** were determined by X-ray diffraction. Compounds **26–28** in which the doubly charged anions derived from tetrazole **25** function as bridges are two- and three-dimensional coordination polymers. Conversely, compound **29** is a mononuclear aqua complex containing no metal–tetrazole coordination bond. In the structure of complex **28**, one-dimensional channels were found which occupy up to 35% of the void volume and encapsulate tetrameric cyclic water clusters and DMF molecules. On heating to 150 °C, water and DMF are removed from the channels, which accounts for the interest of researchers in this type of compound for the preparation of inclusion compounds and sorbents. A coordination polymer with a composition similar to complex

$L = N_4CC_6H_4CN_4.$

26 is formed upon the reaction of 3-(tetrazol-5-yl)benzoic acid with zinc chloride under hydrothermal conditions.⁴⁷

The 5-(4-pyridyl)tetrazole anion also acts as a bridging ligand forming two-dimensional coordination polymers **30–32** upon the reaction with Cd⁴⁸ and Zn⁴⁹ ions under hydrothermal conditions. The products were characterised by X-ray diffraction. Under the same conditions, Cu(II) ions are reduced and the process ends in the formation of Cu(I) complex **33**, having a 3D structure.⁴⁹

The high thermal stability, insolubility in most of solvents and photophysical properties of complexes **28** and **30–33** induce interest in these compounds as promising fluorescent materials.^{45, 48, 49}

Not only derivatives of tetrazolate anions **1b** can be isolated as the reaction products of 5-monosubstituted tetrazoles with transition metal salts, but also complexes **2** containing the molecular form of tetrazoles. This is true first of all for palladium salts. Unlike copper(II) and nickel(II) chlorides, palladium(II) chloride reacts with 5-vinyltetrazole in water⁴⁰ or chloroform⁵⁰ to give the molecular complex Pd(CH₂=CH–CN₄H)₂Cl₂. However, 5,5'-bitetrazole and 5-monosubstituted tetrazoles containing a pyridyl or pyrimidyl group react under the same conditions to give complexes **34–36** in which the tetrazole ring occurs in the anionic or neutral form.⁵¹

X = CH, N.

The preparation of nv-complexes of neutral 5-substituted tetrazoles with other metal salts has been reported. In particular, the synthesis of compound **37** by the reaction of mercury(II) salts or oxide with 5-hydrazinotetrazole in aqueous perchloric acid has been described.⁵²

A complex of *N*-(tetrazol-5-yl)benzamidine hydrochloride (**38**), viz., CoLCl₂ (L is ligand **38**),⁵³ and complexes of 2,2,5,5-tetramethyl-4-(tetrazol-5-yl)-3-imidazole-1-oxyl 3-oxide (**39**),⁵⁴ viz., NiLCl₂(H₂O) and CuLCl₂ (L is ligand **39**), have been prepared. According to IR spectroscopy, diffuse reflectance spectroscopy and magnetochemical measurements, neutral ligands in these complexes are coordinated in the bidentate mode, namely, by a nitrogen atom of the tetrazole ring and either the amidine nitrogen atom (compound **38**) or the oxygen atom of the N→O group (compound **39**). In the complexes of tetrazole **39**, weak interaction between the unpaired electrons of the metal and the ligand was found.⁵⁴

Refluxing in ethanol of divalent metal salts with Schiff bases prepared from 1,1'-diacetylferrocene, 5-aminotetrazole or some other azoles gives rise to MT having apparently chelate structure **40** in which the metal atom can be additionally coordinated by the anion.^{55–57}

X–Y = SCH, NHCH, NHN; M = Co, Cu, Ni, Zn;
A = NO₃, SO₄, C₂O₄.

Note that in the studies cited above,^{40, 50–57} involvement of the molecular form of 5-substituted tetrazoles in the coordination was proposed relying on the results of spectroscopic studies and chemical analysis. X-Ray diffraction data confirming the existence of complexes of neutral tetrazoles have been obtained only for compounds **41**⁵⁸ and **42**.⁵⁹ Complex **41** in which 5-phenyl-tetrazole is coordinated by the metal ion through the N(3) atom has been prepared in 94% yield by the reaction of the ligand with titanium(IV) chloride at room temperature. Studies of the mass spectra of this complex and its behaviour in a THF solution indicate that the tetrazole ligand is bound rather weakly to the metal ion; this restricts the suggested use of compound **41** for the synthesis of titanium nitride.⁵⁸ In complex **42** obtained by the reaction of 5-aminotetrazole with cadmium picrate on heating in water, neutral tetrazole is also coordinated in the monodentate mode, but by the N(4) atom.⁵⁹

Poly(5-vinyltetrazole) behaves with respect to metal salts like monomeric 5-substituted tetrazoles. It reacts with nickel(II) and copper(II) chlorides in water to give the salts $[M\{\text{CH}_2\text{CH}(\text{CN}_4)\}_2]_n$, while with palladium chloride, molecular complexes $[\text{Pd}\{\text{CH}_2\text{CH}(\text{CN}_4\text{H})\}_3\text{Cl}_2]_n$ are formed.⁴⁰ The reaction of poly(5-vinyltetrazole) with excess copper(II) nitrate is accompanied by a decrease in the solution pH to give a water-insoluble complex containing three tetrazole fragments per metal ion.⁶⁰ A specific feature of the complexation of PVT with copper(II) ions is the formation of complexes, under certain conditions, with a high local concentration of copper stabilised by both coordination bonds and hydrogen bonds between the tetrazole units. The mutual strengthening of these bonds results in the cooperative stabilisation of the whole system.⁶¹ The reaction of PVT with chromium(III) chloride is accompanied by a slight decrease in pH; this gives soluble complexes in which the chromium atom coordinates both the tetrazole ring and water molecules.⁶² A method for the synthesis of iron poly(5-vinyltetrazole) complex from the monomer has been reported.⁶³ Some of the Fe^{2+} ions arising upon electrochemical dissolution of an iron electrode (with potassium

peroxydisulfate as the electrolyte) form a redox system, $\text{Fe}^{2+} - \text{S}_2\text{O}_8^{2-}$, which initiates the radical polymerisation of 5-vinyltetrazole; other Fe^{2+} ions interact with the tetrazole ring as complex-forming agents. This yields the polymer $[\text{Fe}\{\text{CH}_2\text{CH}(\text{CN}_4)\}_2]_n$ insoluble in water or organic solvents.

The replacement of neutral tetrazole in the reactions with transition metal salts by water-soluble ammonium and alkali or alkaline earth metal tetrazolates rules out the possibility of formation of complexes **2** and is used successfully for the synthesis of MT **1b**. This method was employed to prepare silver 5-nitroaminotetrazolate (**12**, $\text{M} = \text{Ag}$),⁶⁴ a number of fluorine-containing silver tetrazolates $\text{Ag}(\text{RCN}_4)$, where $\text{R} = \text{CF}_3$, NF_2CF_2 , NF_2CFCl , and transition metal tetrazolates $\text{Ni}(\text{RCN}_4)_2 \cdot 2\text{MeOH}$, $\text{Cu}(\text{RCN}_4)_2 \cdot 2.5\text{MeOH}$ and $[\text{Fe}(\text{RCN}_4)\text{Cl}] \cdot \text{MeOH}$, where $\text{R} = \text{NF}_2\text{CF}_2$.⁶⁵ The transformation of 5-aminotetrazole (**13**) via sodium salts **43** or copper salts and the 5-nitrotetrazolate anion afforded nickel(II) (**44**)⁶⁶ and mercuric (**45**)⁶⁷ 5-nitrotetrazolates (Scheme 1). The presence of inner-sphere water and the monodentate mode of coordination of the tetrazolate anion in complex **44** were established by X-ray diffraction analysis.

Sodium 5,5'-azoditetrazolate pentahydrate (**46**),⁶⁸ which is also readily prepared from tetrazole **13**, serves as a convenient starting compound for the synthesis of other 5,5'-azoditetrazolates. Recently, a large group of 5,5'-azoditetrazolates of other alkali and alkaline earth metals, aluminium, yttrium, some lanthanides (La, Ce, Nd, Gd),⁶⁹ and thallium(I)²¹ have been synthesised by this method (as hydrates) and characterised by X-ray diffraction analysis. It is noteworthy that these compounds easily eliminate water even at room temperature. This makes the salts sensitive to friction or impact; therefore, handling these salts requires special care.⁶⁹

The reaction of sodium salt of 2-(tetrazol-5-yl)-4,4,5,5-tetramethyl-4,5-dihydroimidazol-1-oxyl 3-oxide (**47**) with manganese(II) and nickel(II) acetates gave ionic complexes **48** and **49** (Scheme 2) in which (according to X-ray diffraction data) the paramagnetic tetrazolate anion acts as a bidentate chelating or bridging ligand. Due to intermolecular hydrogen bonds, these complexes form high-dimensional heterospin structures whose magnetic properties are of obvious interest.⁷⁰

A number of neutral water-soluble highly stable gadolinium(III) **50**, **51** and zinc **52** complexes with 5-(2-pyridyl)- and 5-(2-pyridyl 1-oxide)tetrazoles have been prepared by the reactions of metal salts with potassium or barium tetrazolates obtained *in situ* from tetrazoles and the corresponding carbonates in water. Compounds **50–52** were prepared in 48%–76% yields. According to X-ray diffraction data, in these complexes tetrazoles are bidentate ligands forming stable five- and six-membered chelate rings. In gadolinium compounds **50**, **51**, the second coordination sphere includes additional water molecules, which

Scheme 1

Scheme 2

makes the complexes readily soluble and provides high proton relaxation ability.⁷¹

Synthesis of MT by the reaction of 5-R-tetrazolates with transition metal salts is of interest due to the fact that the resulting compounds are capable of subsequent transformations involving the initial tetrazolate. In particular, cobalt(II) and nickel(II) nitrates react with sodium 5-R-tetrazolates in aqueous solutions to give metal tetrazolates as the solid phase, which is gradually dissolved on treatment with excess 5-R-tetrazolate anion. The dissolution is accompanied by an increase in the solution viscosity and gives rise to water-soluble polymers. The rate of dissolution depends substantially on the nature of substituent R; in particular, it increases in the order $\text{NH}_2 < 4\text{-MeC}_6\text{H}_4 < \text{CH}=\text{CH}_2 < \text{Ph} < \text{H} < \text{Bu} < \text{Et} < \text{Me}$. In the case of $\text{R} = \text{NO}_2$, CF_3 , the process stops after the formation of solid products insoluble in an excess of the ligand. Presumably, polymeric complexes are formed in the case of azoles with $\text{p}K_{\text{a}}$ and $\text{p}K_{\text{BH}^+}$ values in the 3.5 to 12 and -4 to 5 ranges, respectively.⁷²

The tetrazolate anion has a fairly high nucleophilicity and can replace some groups in coordination compounds; this is used for the synthesis of mixed-ligand complexes. In these processes, the tetrazolate anion is introduced in the reaction as alkali metal tetrazolates or is generated *in situ* from 5-R-tetrazole and a base. The ligand being replaced is, most often, a halogen atom. The reaction of complex $[\text{AuCl}(\text{PPh}_3)]$ and tetrazole in the presence of sodium hydroxide in acetone according to this synthetic protocol gave complex 53 in 52% yield.⁷³ The reaction of chlorotris(3,5-di-*tert*-butylpyrazolato)titanium(IV) with sodium 5-phenyltetrazolate in THF (23°C , 48 h, 74%) resulted in tris(3,5-di-*tert*-butylpyrazolato)-5-phenyltetrazolatotitanium(IV) (54). The replacement of two chlorine atoms in analogous niobium(V) and tantalum(V) dichloride complexes requires more drastic conditions (refluxing), and in the latter case, only one chlorine atom is substituted despite the use of excess tetrazolate.⁷⁴ According to X-ray diffraction data, the tetrazole ring in the resulting complexes 53–55 is coordinated as a monodentate ligand.

$\text{M} = \text{Nb}$, $\text{L} = 2\text{-(5-phenyltetrazolato)}$ (a); $\text{M} = \text{Ta}$, $\text{L} = \text{Cl}$ (b).

When sodium 5-perfluoroalkyltetrazolates 56 react with (pentacarbonyl)bromomanganese, the bromide ion and some of the

carbon monoxide molecules are substituted. On the basis of IR spectroscopic data, it was assumed that the tetrazolate anion forms a π -complex in solution, which is transformed into σ -complex **57** upon removal of the solvent. Attempts to grow single crystals of the obtained compounds from a diglyme solution in the presence of sodium bromide resulted in ionic complex **58** (for $R = F$) with the N(2),N(3)-bridging bidentate coordination of the heterocycle (X-ray diffraction data).⁷⁵

A similar bridging bidentate coordination of the tetrazole ring has been proposed on the basis of mass spectrometry and ^{19}F and ^1H NMR spectroscopy for complex **59** synthesised by the reaction of silver 5-(difluoroamino)difluoromethyltetrazolate with Me_3SnCl in THF.⁶⁵

A series of homo- and heterobridged rhodium complexes with the tetrazolate anion and other ligands have been prepared by replacement of the chloride ions or acetylacetonate molecules in rhodium diene compounds $[\text{RhCl}_2\text{L}_2]$ (**60**), $[\text{Rh}(\text{acac})\text{L}]$ (**61**), *et al.*^{76,77}

cod is cycloocta-1,5-diene; tfbb is tetrafluorobenzo[5,6]bicyclo[2.2.2]octa-2,5,7-triene.

These reactions of tetrazole with rhodium compounds readily proceed at room temperature in the presence of triethylamine, and in the case of rhodium acetylacetonate, no base is required. However, in the synthesis of the complex with a bridging diphenylphosphide group, the best results are attained with lithium tetrazolate. The resulting compounds are of interest for the synthesis of trinuclear complexes, for example, $[\text{Rh}_3(\mu_3\text{-HCN}_4)(\mu\text{-Cl})\text{Cl(CO)}_6]$, which represent (according to X-ray diffraction data) unusual examples of metal–metal interaction; the tetrazolate anions in these complexes are bound in the tridentate bridging mode.⁷⁶

Similarly, the substitution of 5-(2-pyridyl)tetrazole and 2,6-bis(tetrazol-5-yl)pyridine for chlorine in the complexes RuL_2Cl_2 (L is 2,2'-bipyridine, 4,4'-dimethyl-2,2'-bipyridine)⁵¹ and $\text{Ru}(\text{tpy})\text{Cl}_3$ (tpy is 2,2':6',2''-terpyridine)⁷⁸ gave ruthenium-containing tetrazoles **62** and **63** in 55%–84% yields. The UV-spectroscopic and electrochemical studies have shown that the introduction of a tetrazolyl group having strong σ -donor properties into the $\text{Ru}(\text{tpy})\text{Cl}_3$ complex results in destabilisation of the ground energy state and decreases the metal oxidation potential.

This is also accompanied by a decrease in the emission energy and an increase in the luminescence time from 1 to 80 ns.⁷⁸

The 5- R -tetrazolate anion replaces the acetoxy group in 2- and 4-mercuriomethylquinolinium salts. The ^1H NMR characteristics of compounds **64** prepared in this way in 76%–96% yields indicate that only one N -isomer is formed in each case; however, the available data are insufficient for assigning the reaction products to either N(1)- or N(2)-isomeric tetrazoles.²⁴

The presence of an active hydrogen atom in 5-substituted tetrazoles accounts for their ability to replace the alkyl and cyclopentadienyl groups in organometallic compounds susceptible to hydrolytic decomposition. For example, 5-phenyltetrazole replaces one methylcyclopentadienyl ligand in $(\text{CpMe})_3\text{M}$, where $\text{CpMe} = \eta\text{-C}_5\text{H}_4\text{Me}$, $\text{M} = \text{Yb, Er}$, at room temperature to give binuclear complexes **65** in 60%–78% yields. According to X-ray diffraction data, the phenyltetrazolate anion in these complexes is coordinated by three nitrogen atoms as a bridging and chelating ligand.⁷⁹ Attempts to prepare a similar praseodymium complex failed: complete substitution took place to give the salt $\text{Pr(PhCN}_4)_3$. For $\text{M} = \text{Dy or Gd}$, the reaction gave crystals of complexes containing, apart from the methylcyclopentadienyl ligand, a cyclopentadienyl ligand, the formation of which was attributed to the presence of a small amount of cyclopentadiene in the starting methylcyclopentadiene.

M = Yb, Er.

In the case of trialkylaluminium, the reaction smoothly proceeds in toluene and, depending on the reactant ratio, may give the substitution products of the 5-phenyltetrazolate anion for one, two or three alkyl groups, *viz.*, compounds **66**.⁸⁰

R = Me, $n = 1-3$; R = Et, Buⁱ, $n = 1$.

Yet another possibility of MT synthesis is provided by displacement of neutral ligands (water, THF, ammonia) from various complexes. Water present as a ligand in cobalt(III) ammine complexes **67** and **68** is bound weaker to the central atom than the ammonia molecules and can be easily replaced by the tetrazolate anion. This underlies the preparation of cobalt(III) tetra- (**69**) and pentaammine (**70**) complexes, which contain a metal-coordinated 5-substituted tetrazole ring.⁸¹⁻⁸⁷

R = H, Me, NH₂, NO₂, CH₂N₃, C(NO₂)₃, (NNO₂⁺)(NH₄⁺), Ph,

3-NO₂C₆H₄, [X = NH₂, NO₂, N₃, (NNO₂⁺)(NH₄⁺)].

In the case of 5-phenyl-⁸² and 5-(3-nitrophenyl)tetrazoles,⁸⁵ compounds [Co₂(NH₃)₈(RCN₄)(H₂O)₂](ClO₄)₅ · n H₂O, where R = Ph, 3-NO₂C₆H₄, were isolated in addition to the expected complexes **69**. With microwave heating, 5-phenyltetrazole replaces not only water in complex **67**, but also the ammonia molecule to give compound [Co(NH₃)₃(PhCN₄)₃].⁸² More readily available precursors of cobalt(III) aqua ammine complexes, *viz.*, tetraamminecarbonatocobalt salts,^{81, 83, 84, 86} are often used in these syntheses instead of the Co(III) complexes themselves.

Compounds **71** and **72** [M = Cu(II), Zn(II)] potentially useful as initiating explosives were prepared from similar ammine complexes of other metals.⁸⁸

M = Cu, Zn.

5-(4-Pyridyl)tetrazole⁸⁹ and 5-(4-cyanophenyl)tetrazole⁹⁰ react with the complexes [CpFe(CO)L(THF)]CF₃SO₃ in the presence of triethylamine. They replace the coordinated THF molecule to give compounds **73** containing, according to ¹H and ¹³C NMR spectroscopy, a Fe—N(2) σ-bond.

L = CO, PPh₃, P(OMe)₃; X = N, CCN; Cp = η-C₅H₅.

2. Synthesis of metal derivatives of tetrazoles by heterocyclisation

Among heterocyclisation reactions, [3 + 2]-cycloaddition of azides to systems containing C≡N bonds is most significant for the synthesis of tetrazoles.^{1-3, 10} This method allows one to prepare both 5-substituted tetrazoles and their metal derivatives.⁹¹ The starting compounds include nitriles and organic or inorganic azides, in particular, sodium or ammonium azide prepared *in situ*. Sodium azide, like other alkali metal azides, is less reactive than ammonium azide and reacts only with activated nitriles containing electron-withdrawing substituents. The reaction occurs smoothly at room temperature or on moderate heating to give 5-R-tetrazolates **74**^{65, 75, 92} and **75**⁹³ in quantitative yields.

Salt **47** containing a paramagnetic anion has been obtained in a somewhat lower yield (77%) by treatment of the appropriate nitrile with a mixture of sodium azide and ammonium chloride in DMF.⁷⁰ An attempt to prepare caesium 5,5'-bitetrazolate from dicyanogen and excess caesium azide was unsuccessful.⁹³ 5,5'-Bitetrazole salts, in particular, sodium salt **76**, can be synthesised by the reaction of sodium cyanide and azide with manganese dioxide in the presence of copper(II) salts.¹³

Under hydrothermal conditions (water, 130 °C), dicyanoethylene reacts with sodium azide in the presence of zinc chloride and sodium hydroxide⁹⁴ to give the sodium salt of *trans*-1,2-di(tetrazol-5-yl)ethylene (**77**) (yield 35%). According to X-ray diffraction, salt **77** is a one-dimensional coordination polymer in the crystalline state.

In this synthesis, zinc chloride acts as a catalyst of cycloaddition, which is typical of Lewis acids. This route is suitable for the preparation of complexes of some other metals.^{95–107}

The synthesis of MT from cyanopyridine isomers has been studied rather comprehensively. Depending on the temperature of the reaction carried out in the presence of zinc chloride, 3-cyanopyridine (**78**) forms zinc 5-(3-pyridyl)tetrazolate (**79**)⁹⁵ or hydroxy complex **80**,⁹⁶ which are polymeric (according to X-ray diffraction data).

The complex $(3\text{-C}_5\text{H}_4\text{NCN}_4)\text{CdN}_3$ was isolated in 55% yield upon the reaction of nitrile **78** with sodium azide and cadmium chloride in water at 120 °C. According to X-ray diffraction data, the metal atoms in this compound are linked by bidentate azide and tetradentate pyridyltetrazolate [N(1), N(2), N(4) and N(Py) atoms] bridges to form an intricate 3D structure.⁹⁶

According to this procedure, nitrile **81** was converted into 5-(4-pyridyl)tetrazolate complexes of zinc **32**⁹⁵ and **82**,⁹⁶ manganese **83**,⁹⁷ cadmium **84**⁹⁷ and **85**⁴⁸ and calcium **86**.⁹⁷ Recently, it has been shown in relation to the synthesis of complex **83** that cycloaddition can also be accomplished at room temperature.⁹⁸ After a 2-h reaction of 4-cyanopyridine with manganese nitrate and sodium azide in a water–methanol mixture, the yield of complex **83** was 48%.

Complex **85** is a three-dimensional coordination polymer in which each cadmium cation has a nearly square planar environment composed of four anions (two *trans*- Cl^- and two *trans*- HO^-); the other two *trans*-positions are occupied by the nitrogen atoms of two tetrazole ligands. The latter function as tridentate ligands, being coordinated through the N(2), N(3) and N(Py) atoms. This complex has high thermal stability (stable up to 450 °C) and is attractive as a material with light-blue fluorescence and phosphorescence.⁴⁸

Similarly, 2-cyanopyridine (**87**) has been converted into zinc (**88a**)⁹⁵ and manganese (**88b**)⁹⁵ 5-(2-pyridyl)tetrazolate dihydrate. Complex **88b** was prepared [like a similar copper(II) derivative **88c**] using a somewhat unusual protocol, *viz.*, by refluxing a methanolic solution of 2-aminomethylpyridine and benzaldehyde with subsequent addition of sodium azide and the corresponding metal salts followed by slow evaporation (the yield was 20%). The mononuclear blocks of complexes **88** are linked to one another by hydrogen bonds to form a 2D framework.⁹⁹

M = Zn (**a**, 85%), Mn (**b**, 54%; 20%), Cu (**c**, 15%); X = ClO_4 , BF_4 .

Tetrazolates **89**,¹⁰⁰ **90a**,¹⁰¹ **90b**,¹⁰² **91**¹⁰³ and **92**¹⁰⁴ have been prepared from the appropriate nitriles and metal salts; all these compounds were studied by X-ray diffraction. Complexes **90** are smoothly formed at room temperature in high yields (81%–84%), which is apparently due to good solubility of the starting nitrile in water and the electron-withdrawing properties of the substituent attached to the cyano group. Complex **92** has a high thermal stability (stable up to 345 °C) and is a second harmonics generator 80 times as active as urea.¹⁰⁴

Dinitriles react with sodium azide in water in different ways. Indeed, in the presence of zinc chloride and 1,10-phenanthroline, 4,5-dicyanoimidazole is converted after 24 h at 160 °C into crystals of one-dimensional polymeric complex of 4,5-di(tetrazol-5-yl)imidazole **93** (yield 53%).¹⁰⁵ Similar treatment of 1,2-

dicyanohydrazine is accompanied by cleavage of the N–N bond to give (5-aminotetrazolato)hydroxyzinc (**94**).¹⁰⁶ In the case of terephthalonitrile and 3,4-dicyanopyridine, the reaction in the presence of manganese salts is limited to azidation of only one cyano group to give complexes **95**¹⁰⁷ and **96**⁹⁸ in which the tetrazolate anion is not involved in coordination (X-ray diffraction data). A similar structure has been found for some other tetrazole-containing manganese aqua complexes.^{46,97}

Other methods based on cycloaddition of azides to nitriles require introducing the metal into the reaction as a nitrile or azide complex, which somewhat restricts their synthetic scope. However, these approaches are quite efficient in the synthesis of different-ligand metal complexes **1c** in which one of the ligands is represented by 5-substituted tetrazole.^{108,109}

A series of iron(II) complexes of this type **97a–h** have been synthesised; high yields are attained at room temperature for several hours.^{90,110} Presumably, the process starts with a nucleophilic attack by the azide ion on the nitrile carbon atom to give the N(1) derivative, which is rapidly converted in the N(2)-isomer.¹¹⁰ Despite the excess of sodium azide, in the case of binuclear nitrile complexes, the reaction stops after the formation of monotetrazole derivatives **97f–h**.⁹⁰ The coordination to the N(2) atom of the tetrazole ring in these products was confirmed by X-ray diffraction data for complex **97c** and by similarity of the spectro-

scopic (¹H and ¹³C NMR) characteristics to those of other complexes **97**.¹¹⁰

X = CN: L = CO (**a**), PPh₃ (**b**), P(OMe)₃ (**c**), 2,6-Me₂C₆H₃CN (**d**);
X = NO₂: L = P(OMe)₃ (**e**); X = CNFeCp(L)(CO)⁺CF₃SO₃[−]:
L = CO (**f**), PPh₃ (**g**), P(OMe)₃ (**h**).

On the basis of kinetic studies, a similar mechanism has been proposed also for the formation of cobalt(III) complexes **98** from the nitrile complexes and sodium azide.¹¹¹

R = Me, Ph.

The kinetics and mechanism of isomerisation have been studied in substantial detail for *N*-coordinated pentaamminocobalt(III) 5-*R*-tetrazolates **99a,b**.^{112–115} The isomerisation is due to higher thermodynamic stability of N(2)-coordinated complexes compared to the 1-isomers. This is indicated, in particular, by quantum chemical calculations for silver(I) 5-chlorotetrazolate complexes.¹¹⁶

R = Me, Ar.

The cycloaddition of the azide ion to nitrile complexes prepared by N-cyanation of histidine has been used to introduce Mn(II)-,¹¹⁷ Fe(II)-¹¹⁸ and Fe(III)-coordinated¹¹⁹ tetrazolyl group into myoglobin derivatives.

Complex-type tetrazolates can be synthesised not only from coordinated nitriles, but also from their synthetic precursors. Recently, it has been found^{120,121} that the reaction of cyclopropenyl complex **100** with an excess of trimethylsilyl azide yields ruthenium(II) tetrazolate complex **101**. A ruthenium nitrile complex is formed as an intermediate in this reaction.

Bis-tetrazolate complex **102** was prepared in a similar way from the corresponding binuclear ruthenium complex.¹²² Coordination by the N(2) atom of the tetrazole ring has been proposed for compounds **101** and **102** on the basis of X-ray diffraction data.¹²¹

Reactions of metal azide complexes are often used for the synthesis of MT. In recent years, the addition of organic derivatives of stannyl azides to nitriles, resulting in tetrazoles with an organotin substituent at N(2), has been studied in detail. Researchers focused the attention on the use of this reaction for the synthesis of bis-, tris- and tetrakis- and functionally substituted 2-(trialkylstannyl)tetrazoles **103**.^{58, 123–130} Note that the compounds synthesised have a fairly complex structure in the crystalline state due to coordination of different nitrogen atoms of the heterocycle to the metal, as followed from X-ray diffraction data for compounds of this series.^{58, 126–130}

The first Os(III) tetrazolate complex **105** was prepared from terpyridine-stabilised complexes of osmium in different oxidation states using three methods. X-Ray diffraction data confirm the *trans*-geometry of the complex compound, the N(2)-coordination of the 5-methyltetrazolate anion and coplanarity of the tetrazole ring and terpyridine.^{140–142}

Organometallic compounds containing alkyne and vinylidene fragments can also be used as the starting compounds in the synthesis of tetrazolate complexes by cycloaddition. On treatment of molybdenum complexes **106a,b** with sodium azide at room temperature, complexes **107** were isolated as the major products. Presumably, the reaction proceeds through the intermediate coordination of azides and nitriles to the metal and intramolecular 1,3-dipolar cycloaddition. According to X-ray diffraction data, complex **107** (R = Ph) contains two cluster molybdenum atoms [the Mo–Mo bond length is 2.7913(6) Å], one being bonded to the heterocycle N(1) atom, while the other, to the α-carbon atom; substantial electron delocalisation occurs in the Mo–C–C(5) fragment.¹⁴³

R = Ph;

R = Pr, C(Me)=CH₂, Ph, MeC₆H₄.

3. Physicochemical properties and chemical transformations

Salts of 5-substituted tetrazoles are rather stable compounds; however, some of them are known to be sensitive to mechanical impact or heating. The sensitivity of these salts is mainly determined by the nature of the substituent at C(5) in the tetrazole ring and the nature of the cation. Electron-withdrawing substituents

increase the N(1)–N(2) bond polarity and hence decrease the thermal stability of the heterocycle.¹⁴⁴ Tetrazole salts with alkali and alkaline earth metal cations are rather stable. Lithium tetrazolate melts at 318 °C, and sodium and potassium tetrazolates melt at 284 and 228 °C, respectively. Calcium tetrazolate melts at 282 °C, whereas analogous strontium and barium salts explode (before melting) at 374 and 344 °C, respectively.²⁰ Metal tetrazole derivatives stable up to 400–450 °C are also known.¹⁰⁰

Sodium tetrazolate monohydrate undergoes a polymorphic transformation after dehydration at 192 °C, melts at 284 °C and decomposes with explosion above 323 °C. Decomposition is accompanied by nitrogen evolution to give sodium hydrocyanamide.¹⁷ Silver tetrazolate (**108**, M = Ag) decomposes at 224 °C with heat evolution to give silver cyanamide, which also decomposes at 600 °C to give metallic silver.³⁸

Study of the combustion of mixtures of tetrazole with alkali and alkaline earth metal tetrazolates resulted in the discovery of new types of combustion, *viz.*, liquid-flame^{19, 145–147} and layer-by-layer combustion,¹⁴⁷ which are distinguished by a high self-organisation level and a number of specific features. This opens up prospects for the design of new types of non-expendable gas generants and for the development of self-propagating high-temperature synthesis techniques in combustion waves.

A different fragmentation pathway is observed for 5-substituted tetrazole salts. For example, sodium 5-aminotetrazolate (**109**) decomposes to give sodium azide and cyanamide in the first stage (290–460 °C). Secondary reactions include decomposition of sodium azide with nitrogen evolution and cyclotrimerisation of cyanamide to give melamine and its condensation products.²² A similar mechanism is observed in the first stage of thermal decomposition of PVT sodium salt (**7**), which takes place at 340–400 °C with heat evolution and gives rise to polyacrylonitrile and sodium azide.²⁸

Complex tetrazolates and some salts of 5-substituted tetrazoles are promising as initiating explosives (IE) and serve as components of gas generating compositions (see Section V); therefore, their thermal transformations have been studied rather comprehensively. The mechanism of thermal decomposition giving condensed or gaseous products depends appreciably on the conditions of thermolysis, the nature of the metal and the reactivity of gaseous products.^{31, 32, 37, 69, 86, 88, 148}

Among the chemical transformations of metal derivatives of 5-substituted tetrazoles, N-alkylation reactions have a high practical value, because they underlie the most facile and general method for the synthesis of *N*-substituted tetrazoles.^{1–3} The use of 5-substituted tetrazole salts in the synthesis of *N*-mono- and *C,N*-disubstituted tetrazoles by alkylation is more expedient than the use of neutral 5-substituted tetrazoles. This is due to higher nucleophilicity of the tetrazole ring in tetrazole salts resulting from their ionic structure. The mainly ionic type of the metal–tetrazole bond follows from X-ray diffraction data obtained in recent years for alkali and alkaline earth metal tetrazolates.^{29, 69, 70, 93, 149–152} A distinctive feature of the structure of these salts is a symmetric structure of the tetrazole ring in which the C–N(1) and N(1)–N(2) bond lengths are equal to C–N(4) and N(3)–N(4) bond lengths, respectively. This structure of the

heterocycle accounts for the high aromaticity of the tetrazolate anion (which is the highest among the tetrazoles); therefore, the nature of the cation has an insignificant influence on the selectivity of alkylation of metal tetrazolates and, in most cases, a mixture of 1- and 2-substituted tetrazoles **110** and **111** is formed. The product ratio is mainly determined by the electronic and spatial structure of the R^1 substituent at the C atom.

A more pronounced influence of the nature of the metal should be expected for salts and complexes of p- or d-elements with a covalent bond between the metal and the ring nitrogen atom. Indeed, the selectivity of alkylation of cobalt(III) 5-R-tetrazolate complexes **112** in which the tetrazole ring is bound to the metal through the N(2) atom (X-ray diffraction data) differs sharply from the selectivity of alkylation of alkali metal tetrazolates. In the former case, only 1,5-disubstituted tetrazoles **110** without any isomeric tetrazoles **111** were found among the reaction products with alkyl halides in chloroform and nitrobenzene at 36–57 °C. A ^1H NMR study of the alkylation kinetics has shown that the reaction occurs in two stages *via* a 1,5-disubstituted tetrazole complex.¹⁵³

$R^1 = Me, PhCH_2, Ph, CF_3, 4-FC_6H_4, 3-FC_6H_4$; $R^2 = Me, PhCH_2$;
 $L = HONC(Me) = C(Me)NO$.

The alkylation of iron(II) complexes **73** also proceeds selectively. At lower temperatures, the process ends in the formation of complexes of 1,5-disubstituted tetrazoles **113** isolated from the reaction mixture in high yields (67%–98%).^{89, 90, 110}

$X = CCN$: $L = CO, PPh_3, P(OMe)_3$; $X = N$, $L = CO$;
 $X = CCNFeCpL(CO)^+ CF_3SO_3^-$: $L = PPh_3, P(OMe)_3$.

Several examples of alkylation of complex tetrazolates used for the synthesis of *N*-substituted tetrazoles has been described.^{69, 121} However, the selectivity of these reactions has not been discussed. The alkylation of 5-substituted 2-(tributylstannyl)tetrazoles has been studied in more detail. Methylation of these compounds with some reagents is selective and gives 1,5-disubstituted tetrazoles.^{1, 2} However, in the case of other alkylating reagents, mixtures of 1- and 2-substituted tetrazoles have been obtained. This behaviour of stannyl derivatives is attributed to different degrees of their association in solutions. In recent years, alkylation of stannyltetrazoles has been employed for the syn-

thesis of poorly accessible disubstituted tetrazoles. Thus the reaction of *o*-phenylenedi(2-tributylstannyltetrazole) (**114**) with an excess of 1,2-dibromoethane in methanol resulted in cyclophane **115**.¹⁵⁴ In dibromoethane, alkylation of tetrazole **114** is accompanied by dehydrohalogenation to give *N*-vinyltetrazoles.¹⁵⁵

Arylation of 2-tributylstannyltetrazoles **116** with diphenyliodonium chloride at room temperature afforded 5-aryl- and 5-hetaryl-2-phenyltetrazoles **117**.¹⁵⁶ The reaction was selective unlike a similar reaction of sodium 5-phenyltetrazolate in which approximately equal amounts of 1,5- and 2,5-diphenyltetrazoles are formed.²³ On refluxing with acetic anhydride, tetrazoles **116** are converted into 2-R-5-methyl-1,3,4-oxadiazoles **118**. The reaction proceeds apparently with formation of *N*-acyltetrazoles and their recyclicalisation.¹²⁵

117: $R = Ph, 4-MeC_6H_4, 4-BrC_6H_4, 1H-indol-3-yl, 1H-indol-3-ylmethyl$;
118: $R = Ph, 1-acetylindol-3-yl, 1H-indol-3-yl(phenyl)methyl$.

Most complexes and salts of 5-substituted tetrazoles are sensitive to the action of acids. Upon the reaction with an equimolar amount of acids under mild conditions, N(2)-coordinated ruthenium(II) **100**¹²¹ and iron(II) **73**^{89, 90, 110} complexes are protonated at the N(4) atom of the heterocycle. Under more drastic conditions, this type of compounds are destroyed to give tetrazoles **6**, which is used for the synthesis of the latter.^{1-3, 10, 98, 157-162}

The behaviour of MT towards oxidising and reducing agents has not been systematically studied. However, the tetrazolate anion is known to be stable against these reagents, only substituents being affected. Thus upon dissolution in hydrazine, alkali and alkaline earth metal 5,5'-azoditrazolates are reduced to give 5,5'-hydrazoditrazolates **119**.¹⁵²

$M = Li, Na, Ba$; $n = 1, 2$.

The action of oxone ($2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$) on sodium 5-(ethoxycarbonyl)tetrazole **120** allows a hydroxyl group to be introduced into the heterocycle at N(2) position.¹⁶³

Other known transformations of this type of MT have been used to prepare bi- and polynuclear metal-containing tetrazoles the structures of which were determined by X-ray diffraction analysis. Silver tetrazolates react with triphenylphosphine in dichloromethane to give polymeric complex **121** through bridging N(1),N(3)-coordination of the heterocycle.⁷³ Silver 5-trifluoromethyltetrazolate reacts with triphenylantimony in acetone to give binuclear complex **122** with the N(2),N(3)-coordination of the heterocycle.⁶⁵

Mono- and dimethylaluminium 5-phenyltetrazolates **66** (R = Me; $n = 1, 2$) react with trimethylaluminium to give bi- and tetranuclear complexes $[(\text{PhCN}_4)_2\text{AlMe} - \text{AlMe}_3]$ and compounds **123**, respectively.⁸⁰

Worthy of note is also radical polymerisation of sodium 5-(methacrylamido)tetrazole (**124**) to give polymer **125**. Copolymerisation of this salt with 0.08 mol.% of *N,N'*-methylenebis(acrylamide) affords a polymeric gel absorbing up to 200 g of water per gram.¹⁸

III. Metal derivatives of neutral *N*-substituted tetrazoles

The introduction of an *N*-substituent into the tetrazole ring, instead of the hydrogen atom capable of migration (prototropy) and dissociation, gives rise to two isomeric *N*-substituted tetrazoles **110** and **111**,¹⁻³ which behave as weak bases ($-\text{p}K_{\text{BH}^+} = 2-4$); note that 1-substituted tetrazoles are much more basic than the 2-isomers.¹⁶⁴ In these compounds, the N(4)

atom is the most basic; however, the sequences of variation of the proton affinity (according to quantum-chemical calculations) are different: $\text{N}(4) > \text{N}(3) > \text{N}(2) > \text{N}(1)$ for 1-substituted tetrazoles; $\text{N}(4) > \text{N}(1) > \text{N}(3) > \text{N}(2)$ for 2-isomers.^{165, 166}

In early studies, complexes of 1-substituted tetrazoles have been prepared by procedures based on the use of non-aqueous solvents and forced removal of water from the starting salt hydrates.^{4,5} Only in the 1980s, did publications appear (see, for example, Ref. 4) describing the synthesis of transition metal complexes with *N*-substituted tetrazoles directly from metal salt hydrates in organic solvents, their mixtures with water and even in water. The solvent is selected considering its electron-donating activity, the ability to dissolve the reactants and precipitate or function as a crystallisation medium for the final product. Most often, the complex is isolated by partial concentration of the reaction mixture, its storage for a certain period of time or cooling. In most cases, the reactions of 1-substituted tetrazoles in weakly coordinating solvents (alcohols, acetone, diethyl ether, acetonitrile, *etc.*) smoothly proceed at room temperature to give solid complexes.

2-Substituted tetrazoles are more sensitive to the conditions under which the complex formation is carried out, in particular, to the presence of water in the reaction mixture.^{167, 168} In addition, the formation of solid complexes of 2-substituted tetrazoles is prevented by their high solubility. Therefore, high concentrations of components and dry solvents are required to obtain such complexes (although in some cases, the presence of a minor amount of water is allowed). In some cases, the reaction mixture must be heated and then concentrated. Many *N*-substituted tetrazoles are liquids, which allows preparing complex-type compounds by the reaction of the starting components without a solvent.

Complexes of 1-substituted tetrazoles **110** ($\text{R}^1 = \text{H}$) have been studied in most detail, first of all, due to the discovery, for these derivatives, of spin transitions accompanied by thermo- and photochromism (Fe^{2+} complexes) and ferromagnetic ordering of the electron spins (Cu^{2+} compounds). More than a hundred complex-type compounds have been prepared and characterised; their compositions vary over a broad range, being mainly dependent on the nature of the metal cation and the counter-ion (Table 1). In some cases, the compositions of the complexes formed are affected by the starting reactant ratio, the solvent, and the nature and the size of the substituent in 1-substituted tetrazole. For example, metal (Cu^{2+} , Co^{2+} , Ni^{2+}) chlorides and 1-alkyl-, 1-vinyl- and 1-allyltetrazoles form the ML_2Cl_2 complexes irrespective of the reactant ratio. Copper(II) bromide and thiocyanate behave in a similar way. In the case of weakly coordinating anions (BF_4^- , ClO_4^- , PF_6^- , *etc.*), the greatest number of coordinated ligands corresponds to the formula ML_6X_2 ($\text{M} = \text{Zn}, \text{Fe}, \text{Cu}, \text{Co}, \text{Ni}$). Metal nitrates occupy an intermediate position, being capable of forming compounds with a $\text{MX}_n:\text{L}$ ratio of 1:2, 1:3, 1:4 and 1:6. For 1-substituted tetrazoles containing bulky substituents (Bu^t , Ph, Mes, 3-Cl-4- FC_6H_3), complexes with a smaller number of coordinated tetrazoles, in particular, equimolar complexes, CuLCl_2 , $\text{CuL}(\text{BF}_4)_2$, have been isolated. In some cases (for $\text{L} = 1\text{-propyl-}$, 1-chloroethyl- or 1-phenyltetrazole), during the growth of single crystals, additional uncoordinated tetrazole molecules were incorporated in the crystals.

2-Substituted tetrazoles **111** ($\text{R}^1 = \text{H}$) behave in complexation reactions in a different way. It has been shown in relation to 2-alkyltetrazoles and copper(II) chloride that, depending on the reactant ratio, the resulting complexes may be described as CuLCl_2 , CuL_2Cl_2 or $\text{Cu}_3\text{L}_4\text{Cl}_6$ (Table 2), the last-mentioned complexes being also formed during recrystallisation of CuL_2Cl_2 or during their synthesis with low reactant concentrations. The greatest number of coordinated 2-substituted tetrazole molecules is four in the case of copper(II) tetrafluoroborate or two with the nitrate.

nuclear oxychloride $Cu_4OL_4Cl_6$ complexes, as a result of hydrolysis of copper chloride and due to high thermodynamic stability of this type of cluster. Such a transformation has also been observed²²⁴ on attempted synthesis of the 1-ethyltetrazole complex with copper(II) bromide carried out by slow concentration of a solution of the reactants in 96% ethanol, which gave single crystals of the $Cu_4OL_4Br_6$ complex.

The structures of complexes of *N*-substituted tetrazoles have been studied by spectroscopic techniques and by X-ray diffraction analysis. Most often, 1-substituted tetrazoles are monodentate ligands, complex formation involving the N(4) atom. Hence, the environment of the copper atom in the halide complexes CuL_2X_2 , where $X = Cl, Br$; L is 1-R-tetrazole ($R = Me$; Et; $CH_2=CHCH_2$; CH_2CHY , $Y = Cl, Br, N_3$), is completed to a square bipyramid due to contacts with halogen atoms coordinated to the neighbouring copper atom,^{179, 182, 184, 185, 195, 202, 207} i.e., halide ions are bridges connecting the CuL_2X_2 fragments into layers (structure **126**). The *trans*-coordinated tetrazole ligands occur in the interlayer space; the size of the substituent in the ligand determines the interlayer spacing. All complexes of copper(II) halides with 1-monosubstituted tetrazoles having such structure are low-temperature ferromagnets.^{185, 198, 199, 202, 225} According to electronic and IR spectroscopy, this type of a layered polymeric structure is also characteristic of cobalt(II) and nickel(II) chloride complexes with 1-ethyl-¹⁸² and 1-allyltetrazoles¹⁹⁵, ML_2X_2 . Recently,¹⁹⁶ this has been confirmed by X-ray diffraction analysis carried for cobalt 1-allyltetrazole complex.

The key difference between the structures of these copper(II) and cobalt(II) complexes is that in the latter compound, the bridging bonds have the same length (2.54 Å), whereas in the copper complex these bonds are markedly dissimilar due to the Jahn–Teller effect (2.30 and 2.99 Å). It was found, however, that the cobalt complex is a weak ferromagnet with $T_N = 102 \pm 1$ K having spontaneous magnetisation of $\sigma_s(5 \text{ K}) = 710 \pm 5 \text{ G cm}^3 \text{ mol}^{-1}$. In the case of bulky substituents ($R = \text{Bu}^t, \text{Ph}, \text{Mes}$), the CuL_2Cl_2 complex exists as linear polymeric structure **127** due to chloride bridges, while the tetrazole ligands are coordinated in the *cis*-position.^{194, 212, 216}

1-(2-Methoxyethyl)tetrazole (**110**, $R^1 = \text{H}$, $R^2 = \text{CH}_2\text{OMe}$) shows an unusual ligand behaviour compared to other 1-alkyltetrazoles. It reacts with copper(II) bromide in methanol or ethanol to give two isomeric complexes, α - and β - CuL_2Br_2 , which differ substantially in physicochemical properties and structure.²⁰⁶ The α -form obtained from methanol is a 2D structure **128** in which the copper ions are connected by the N(4),N(2)-bridging tetrazole ligands and the bromide ion is monodentate. In this species, no magnetic interaction occurs between the copper ions. Conversely, the β -form, which crystallises from ethanol, exhibits ferromagnetic properties ($C = 0.41 \text{ cm}^3 \text{ K mol}^{-1}$, $J/k_B = 16.4 \text{ K}$, $\theta = 30.5 \text{ K}$) and has structure **126**.

A substantial influence of the substituent on the structure of the complex is also observed for 2-substituted tetrazoles. Indeed, complexes $\text{Cu}(2\text{-R-tetrazole})_2\text{Cl}_2$ ($R = \text{Me}, \text{Et}$) have a layered polymeric structure **129** joined by bridges formed by some of the chlorine atoms and tetrazole ligands coordinated through the N(4) and N(1) atoms. The second tetrazole ligand is coordinated in the monodentate mode through the N(4) atom.^{217, 218} As the substituent bulk increases ($R = \text{Pr}, \text{CH}_2 = \text{CHCH}_2$), both tetrazole ligands become bridging and are coordinated by the N(4) and N(1) atoms (structure **130**).²¹⁹

Note that complexes **128**–**130** are the first examples of layered polymeric structures formed by *N*-substituted tetrazoles through two nitrogen atoms of the heterocycle. The complexes CuLCl_2 and $\text{Cu}_3\text{L}_4\text{Cl}_6$ are polymeric chains **131** and **132**, respectively, formed owing to the bridging coordination of chlorine atoms;^{220–222} in **132**, the neighbouring copper atoms are additionally linked by the tetrazole ring [N(3), N(4) atoms]; hence, a half of the tetrazole ligands in the structure are bridging.²²²

The main feature of the metal nitrate complexes is related to different coordination modes of nitrate anions even in compounds with similar compositions. According to X-ray diffraction data, in three copper(II) complexes, **133**,²¹³ **134**,²⁰⁴ **135**,¹⁸⁶ in which 1-substituted tetrazole ligands are coordinated through the N(4) atom and occupy *trans*-positions, the nitrate anions are coordinated as

monodentate, bidentate and bridging ligands. Moreover, compound **135** is a 2D coordination polymer. The linear chain packing of mononuclear complexes **134** gives rise to a weak ferromagnetism ($\theta = 0.30 \text{ K}$ and $C = 0.44 \text{ cm}^3 \text{ K mol}^{-1}$).

No structural data for the thiocyanate or chloride complexes $\text{CuL}_2(\text{NCS})_2$ and CuLCl_2 (L is 1-substituted tetrazoles) have been reported. The IR and EPR data indicate a bridging type of the $\text{Cu}–\text{NCS}–\text{Cu}$ bond, while in the case of CuLCl_2 , a bridging coordination of 1-substituted tetrazoles through the N(3) and N(4) atoms is assumed.¹⁶⁷ The salts of bivalent metals ($\text{Fe}, \text{Ni}, \text{Cu}, \text{Zn}$) with weakly coordinated anions (BF_4^- , ClO_4^-) react with an excess of 1-substituted tetrazole to give mononuclear complexes containing MN_6 coordination octahedra. The coordination involves the N(4) atom of the ring. In compounds with fewer coordinated tetrazole molecules, the copper coordination sphere contains anions (according to IR spectroscopic and X-ray diffraction data).^{215, 226}

The structures and properties of six-coordinate iron(II) complexes FeL_6X_2 (see Table 1) have been studied in most detail; these compounds possess unique properties related to the extremely high sensitivity of their electronic characteristics to relatively weak impact of temperature, pressure or light with a definite wavelength. This induces easy reversible spin transitions (ST)

between the ground diamagnetic low-spin ($\text{LS}, S = 0$) and paramagnetic high-spin ($\text{HS}, S = 2$) states the nature of which for iron(II) complexes has been studied in fair detail and considered in reviews^{6, 227, 228} and references cited therein. Characteristics of the ST (a broad range of temperatures, 45–200 K, the character and sharpness of transitions, the presence of hysteresis and the width of the hysteresis loop) are determined by structural features of the complexes. Numerous publications describe X-ray diffraction, magnetochemistry, and Mössbauer, EXAFS, photoelectron, FT IR and Raman spectroscopic studies of the structures, physicochemical properties and their variation in the series of related iron(II) complexes and those diluted over broad ranges with isomorphous zinc^{229–232} and nickel²³³ complexes (Refs 169–176, 181, 188–192, 199, 200, 234–250). It was found that the ST may be accompanied by a structural phase transition, which results in shortening of the $\text{Fe}–\text{N}$ bond in the coordination polyhedron by $\sim 0.2 \text{ Å}$ and distortion of the polyhedron symmetry.^{6, 228, 249, 251} Therefore, ST characteristics may be sensitive to the external pressure.^{6, 191, 251}

The obtained data suggest that the change in the magnetic and optical properties upon spin transitions in Fe(II) complexes with 1-substituted tetrazoles is largely related to the cooperative mechanism of transfer of the electronic effects and is determined by the efficiency of intermolecular contacts, including hydrogen bonds, π - π and other interatomic interactions between the structural fragments of the compounds. Recent theoretical descriptions of spin transitions for a series of iron(II) complexes with 1-(2-haloethyl)tetrazoles in terms of physical²⁵² and quasi-chemical²⁵³ models of the intermolecular interactions are in fairly good agreement with experimental data.

These results have stimulated the research aimed at the development of methods for the synthesis and study of the properties of iron(II) complexes with binuclear monosubstituted tetrazoles, the structure of which could ensure effective cooperative interactions through bridging ligands. A number of recent publications have been devoted to the iron(II) complexes FeL_3X_2 , where L is di(tetrazol-1-yl)alkanes **136** ($m = 2$, $\text{X} = \text{BF}_4$;²⁵⁴ $m = 4$: $\text{X} = \text{ClO}_4$,²⁵⁵ PF_6 ²⁵⁶) and **137** ($\text{R} = \text{H}$, $\text{X} = \text{ClO}_4$;²⁵⁷ $\text{R} = \text{Me}$, $\text{X} = \text{BF}_4$).²⁵⁸ A broader set of these compounds based on tetrazoles **136** ($m = 1-8, 10, 12$) have been described in dissertations.^{169, 259} However, it was noted¹⁶⁹ that for $m = 6, 8, 12$, complexes $\text{FeL}_3(\text{BF}_4)_2$ with a sufficient purity could not be isolated.

An important feature of iron(II) complexes with bistetrazoles is that they form one-^{254, 257} and three-dimensional^{255, 256, 259, 260} polymeric structures. This stimulated further investigations into the self-assembly of supramolecular structures and self-organisation of molecules through coordination to transition metal ions. Of special note is the structural, chemical and functional diversity of the resulting objects. A series of 2D polymeric complexes based on tetrazolylamine **138** described as ML_2X_2 ($\text{M} = \text{Fe}, \text{Cu}, \text{Co}, \text{Zn}$; $\text{X} = \text{BF}_4^-$ and $\text{M} = \text{Fe}, \text{Zn}$; $\text{X} = \text{ClO}_4^-$) and a series of double compounds $[\text{Cu}_{0.01}\text{M}_{0.99}\text{L}_2](\text{BF}_4)_2$ ($\text{M} = \text{Zn}, \text{Fe}$); $[\text{Fe}_x\text{Zn}_{(1-x)}\text{L}_2](\text{BF}_4)_2$ ($x = 0.0062-0.970$)²⁵⁹ have been synthesised and studied. Research into the formation of this type of supramolecular structures is needed to study systematically the mechanism of transfer of electronic effects.^{252, 259}

It has been noted^{6, 259} that spin transition characteristics depend essentially (apart from the nature of the ligand and counter-ion) on the formation conditions of the crystals of complexes. The investigation of compounds such as $\text{FeL}_6(\text{CF}_3\text{SO}_3)_2 \cdot \text{L}_2$ (L is 1-propyltetrazole),¹⁷³ $\text{FeL}_3(\text{PF}_6)_2 \cdot \text{Solv}$ [L is **136** ($m = 4$), Solv is 0.5 MeOH or H_2O],²⁵⁶ $\text{FeL}_3\text{X}_2 \cdot \text{MeCN}$ [L is **136** ($m = 5$), $\text{X} = \text{BF}_4, \text{PF}_6$]²⁵⁹ has shown that inclusion of uncoordinated tetrazole or solvent molecules into the structure changes substantially the characteristics of spin transitions.

The structures and physicochemical properties of several complexes of other transition metals with bis-tetrazoles similar in composition to iron(II) complexes have been studied, in particular, the complex $\text{CuL}_3(\text{ClO}_4)_2$ [L is **136** ($m = 2$)],²⁶¹ the Ni(II) and Cu(II) complexes with 1,4-di(tetrazol-1-yl)butane (**136**, $m = 4$).²⁵⁵ The first representatives of coordination polymers based on 2-substituted bis-tetrazoles **139** have been prepared and characterised: one-dimensional $\text{ZnL}_3(\text{ClO}_4)_2$ complex [L is **139** ($m = 2$)],¹⁶⁸ one- and three-dimensional polymers, $\text{CuL}_3(\text{ClO}_4)_2$ and $\text{ZnL}_3(\text{ClO}_4)_2 \cdot 2\text{EtOH}$ [L is **139** ($m = 3$)],²⁶² and five copper complexes with 1,4-di(tetrazol-2-yl)butane (**139**, $m = 4$).²⁶³ The

synthesis of the last-mentioned compounds shows an essential dependence of the composition and structure of MT on the nature of the solvent used.

Generally, binuclear tetrazoles function most often as bridging ligands and give coordination compounds containing fewer ligands than in the case of mononuclear *N*-substituted tetrazoles. Apart from those mentioned above, a number of such compounds with 1,1'-*m*-phenyleneditetrazole (**140**) have been obtained, in particular, ML_2X_2 , where $\text{M} = \text{Ni}, \text{Co}, \text{Cu}$; $\text{X} = \text{NO}_3, \text{ClO}_4$;¹⁹⁹ CuL_2X_2 , where $\text{X} = \text{NO}_3, \text{BF}_4$, and CuLCl_2 .²⁶⁴ An equimolar ratio has also been found for copper(II) chloride complexes with *para*- and *ortho*-isomers of compound **140**²⁶⁴ and with bis-tetrazoles based on diphenyl ethers **141a-c**.²⁶⁵

$\text{X} = \text{H}$ (a), NO_2 (b), tetrazol-1-yl (c).

Bis-tetrazole **141c** reacts with copper(II) chloride to give compounds $\text{CuL}_{0.5-0.75}\text{Cl}_2$ with composition depending on the reactant ratio.²⁶⁵ It was shown by X-ray diffraction that 1,2-bis(1-methyltetrazol-5-yl)ethane functioning as a bridging ligand with respect to copper(II) chloride forms polymeric complex **142** containing both monodentate and bridging chlorine atoms.²⁶⁶

The presence of second substituent in the tetrazole ring (tetrazoles **110, 111**) and a substituent capable of complexation has a pronounced influence on the compositions and structures of the coordination compounds. Unlike 1-monosubstituted tetrazoles, which form the complexes CuL_2Cl_2 and CuL_6X_2 ($\text{X} = \text{BF}_4, \text{ClO}_4$) (see Table 1), 1,5-disubstituted tetrazoles form compounds CuLCl_2 (see Ref. 177) and CuL_4X_2 (see Ref. 267) under the same conditions. For 1:1 complexes, a bidentate bridging tetrazole coordination is assumed, which is in line with the results of quantum-chemical calculations of the proton affinity¹⁶⁵ and

with experimental data on quaternisation,²⁶⁸ indicating that 1,5-disubstituted tetrazoles contain two clear-cut nucleophilic centres [N(4) and N(3)], coordination through these atoms being energetically favourable.²⁶⁹ According to X-ray diffraction data,⁵ the ligand in $\text{Ag}_2\text{L}_4(\text{NO}_3)_2$, where L is perhydroazepino[1,2-*e*]tetrazole, is coordinated in the bidentate bridging mode, two ligand molecules being coordinated through the N(3) and N(4) atoms, while the other two ligand molecules, through N(4). However, in the polymeric-chain complex CuLCl_2 , where L is 5,5-dimethyl-5,6-dihydro-tetrazolo[5,1-*a*]isoquinoline,²⁷⁰ as well as in palladium(II) chloride complexes with isomeric 5-vinyl-1(2)-methyl-tetrazoles,^{271, 272} only the N(4) atom of the tetrazole ring is involved in coordination (X-ray diffraction data). In the case of steric restrictions (aryl substituent in position 5), palladium chloride forms a bond with the N(3) atom.²⁷³ X-Ray diffraction data have been obtained, indicating that perhydroazepino[1,2-*e*]tetrazole can also function as a bidentate ligand giving formally nine-coordinate complex of samarium(III) **143**.²⁷⁴

N-Substituted tetrazole **144** containing an acetohydrazide group, which can act as a chelating ligand, forms complexes ML_2X_2 with metal nitrates and perchlorates; various types of coordination of this tetrazole to the metal are encountered in the complexes. According to X-ray diffraction data, coordination through the N and O atoms of the acetohydrazide group and the N(4) atom of the tetrazole ring giving linear polymeric chains is found in copper(II)²⁰⁸ and cadmium(II)²⁰⁹ perchlorate complexes. IR data indicate that the same coordination mode is also characteristic of zinc(II),²⁰⁹ nickel(II) and cobalt(II)²⁰⁸ coordination compounds. In the case of lead(II)²¹⁰ and nickel(III)²⁰⁸ complexes, the interaction occurs only through the hydrazide fragment. It was shown by X-ray diffraction analysis²¹⁰ that polymeric chains of the lead nitrate complex are formed due to the tridentate chelating-and-bridging coordination of the nitrate group.

R = NH_2 (a), Me (b), $\text{CH}=\text{CH}$ (c).

The amino groups of 1-*R*-5-aminotetrazoles **145a-c** can also coordinate the metal atom. A number of complexes of these ligands with transition metals have been prepared and studied.^{40, 84, 88, 275} It was found²⁷⁵ that in the compound $\text{NiL}_2\text{Cl}_2(\text{H}_2\text{O})_{0.5}$, where L is tetrazole **145a**, the exchange interaction between the unpaired electrons of the Ni^{2+} ion is ferromagnetic. According to X-ray diffraction data,²⁷⁶ the complex CuL_2Cl_2 is a 2D coordination polymer in which 1,5-diamino-tetrazole functions as a bridging ligand coordinated by the N(4) atom of the ring and the nitrogen atom of the 1-amino group. It is also worth noting that in the octahedral complex $[\text{Co}(\text{NH}_3)_4\text{L}_2] \cdot (\text{ClO}_4)_3$ (L is tetrazole **145b**), the monodentate tetrazole ligands are coordinated in different ways, namely, by the N(3) or N(4) atom.²⁷⁷ Several compounds of this type, viz. $[\text{Co}(\text{NH}_3)_4\text{L}_2] \cdot (\text{ClO}_4)_3$ and $[\text{Co}(\text{NH}_3)_5\text{L}](\text{ClO}_4)_3$ (L are ligands **145a, b**^{88, 278} or perhydroazepino[1,2-*e*]tetrazole),²⁷⁹ prepared from cobalt ammine complexes **69**, have been reported (see Section II). Their physicochemical properties were studied in detail.^{84, 88, 278, 279}

It was shown by X-ray diffraction²⁸⁰ that 1-methyl-5-dimethylaminotetrazole reacts with copper(II) chloride as a bidentate

chelating ligand to give complex **146**. 2-Pyridyltetrazole ligands are also coordinated in the bidentate mode when react (in 1 : 1 ratio) with palladium and ruthenium chlorides to give five-membered metallacycles **147** and **148**, respectively.⁵¹

A compound with two pyridyltetrazole fragments and copper(II) chloride form a trinuclear linear complex **149** (X-ray diffraction data) in which the ligand occupies a bridging position between two neighbouring copper atoms.²⁸¹

In a search for new metal-containing mesogens, complexes of long-chain 2-alkyltetrazoles containing additionally a 4-pyridyl fragment have been synthesised. The coordination in these complexes was found²⁸² to involve the pyridine nitrogen atom, as for example, in compounds **150**.

$\text{R}^1 = \text{Alk}$; $\text{R}^2 = \text{H}, \text{OMe}$.

It was shown²⁸² that only silver complexes **150** ($\text{R}^1 = n\text{-C}_9\text{H}_{19}, n\text{-C}_{14}\text{H}_{29}$; $\text{R}^2 = \text{H}$) exhibit mesomorphic properties, smectic S_A phases arising in the temperature range of 174–204 °C. It is noteworthy that analogous ligands containing no pyridine rings are coordinated through the tetrazole N(4) atom and form palladium(II) complexes giving no liquid-crystalline phases.²⁸³

According to X-ray diffraction data,^{284, 285} in copper(II) complexes **151–153**, the exocyclic oxygen atom also participates in the coordination of the metal ion to binuclear tetrazoles. Note that 1,5-bis(1-methyltetrazol-5-yl)-3-oxapentane isolated as perchlorate reacts with copper(II) chloride to yield complex **151** or **153**, depending on the nature of the solvent. In complex **151**, the intermolecular interactions of the $\text{C}-\text{H}\cdots\text{Cl}$ and $\text{C}-\text{H}\cdots\text{N}$ types are responsible for the formation of infinite one-dimensional chains.²⁸⁵

On the basis of IR spectra of disulfide **154** and the complexes $\text{MO}_2\text{L}_2\text{Cl}_2$ ($\text{M} = \text{Mo}, \text{W}$; L is compound **154**), it was concluded that the ligands are coordinated through one of the sulfur atoms.²⁸⁶

The complex formation of the tetrazole analogues of peptides deltorphin,²⁸⁷ β -casomorphin,²⁸⁸ enkephalin²⁸⁹ and tetraalanine²⁹⁰ has been studied by potentiometric and spectroscopic methods. The stability constants of the copper(II) complexes formed in aqueous solutions were determined; it was shown that the introduction of a 1,5-tetrazolyl fragment, which mimics the *cis*-amide group, into the peptide gives rise to peptide agents that efficiently chelate copper(II) ions under physiological conditions. The site of introduction of the tetrazolyl fragment into the amino acid residues has a crucial influence on the coordinating ability of the compounds. The obtained data may underlie the simulation of the peptide–metal binding sites.

IV. Metal derivatives of *C,N*-substituted tetrazoles generating anionic centres in the substituent

N-Substituted tetrazoles containing electron-withdrawing proton-containing substituents in the 5-position of the ring are capable of tautomeric transformations. They can be deprotonated to give various anionic forms that react with metal cations to give, as a rule, chelate complexes **3**. In recent years, the ways of synthesis of MT of various dimensions based on tetrazole-containing cyanoacetates **155** have been studied in detail. Depending on the nature of reactants and synthesis conditions, these tetrazoles react with alkali metal compounds to give (according to X-ray diffraction data) salts or complexes.^{291,292}

The reactions of these ligands or enol forms of compounds **156** with transition metal salts occur in different ways. By varying the nature of substituents and using metal ions with appropriate coordination properties, one can obtain mono- and binuclear complexes and also polymeric structures of different dimensionality. The composition and dimensionality of the ML_m complexes are presented in Table 3.

Table 3. Composition and dimensionality of the complexes ML_m derived from ligand **156**.

^a In these cases, $\text{R}^2 = \text{H}$, in other cases, $\text{R}^2 = \text{CN}$.

The second tetrazole ring can also act as an electron-withdrawing substituent in the carbon chain. Thus, bistetrazole **157** reacts with zinc acetate in methanol to give a complex (in 78% yield), representing, according to X-ray diffraction data, a one-dimensional coordination polymer with rather short (2.257 Å) intermolecular $\text{Zn} \cdots \text{N} \equiv \text{C}$ bonds.²⁹⁸

Bis(tetrazolylmethyl ketone) **158** undergoes double deprotonation in the reaction with zinc acetate to give the tetranuclear chelate Zn_4L_4 , which crystallises from THF as cryptatoclathrate (according to X-ray diffraction data); this dissociates in solution.²⁹⁹ In the 3D structure of this compound, each zinc ion is connected to three ligands, and the coordination sphere is a distorted trigonal bipyramid. When made to react with iron(III) chloride in the presence of triethylamine, compound **158** forms the complex Fe_2L_3 with D_3 symmetry and the (Δ, Δ) – (Λ, Λ) –*fac*-configuration of the Fe(III) coordination polyhedron (octahedron), and the *p*-phenylene ligand of this type forms a tetranuclear adamantane-like chelate complex.²⁹⁹

The reactions of acyl derivatives of *N*-alkyl-5-aminotetrazoles with metal salts proceed in a similar way, the amide group being deprotonated. For example, 5-acetylamino-1-benzyltetrazole reacts with copper(II) acetate to give complex **159** (in 74% yield), which is self-assembled into a stair-like one-dimensional supramolecular structure owing to the intermolecular interaction between the coordinatively unsaturated copper(II) ion and the nitrogen atom of the amide group. The copper(II) environment in this complex is a tetragonal bipyramid.²⁹⁵

The introduction of an α -pyridyl group into these ligands changes considerably their coordination properties. *N*-(2-Alkyl-tetrazol-5-yl)pyridine-2-carboxamides and -thioamides **160** were shown^{300, 301} to react with copper(II), zinc(II), cobalt(II) and nickel(II) acetates at 20 °C to give a series of mono-, bi- and tetranuclear complexes differing appreciably in the structure of the coordination unit, which decompose only at temperatures above 250 °C [note that during the synthesis Co(II) was oxidised to Co(III)]. For the Ni_4L_8 complexes and their solvates with metal–metal distances of 5.56–5.57 Å, a weak intramolecular ferromagnetic interaction has been found^{300, 302}

$\xrightarrow[\text{MeOH}]{\text{M(OAc)}_2}$

ML_3
 M_2L_4
 M_4L_8

A ditetrazole derivative of this type, *N*(2),*N*(6)-bis(1-methyl-tetrazol-5-yl)pyridine-2,6-dicarboxamide (**161**), has been used^{303, 304} for the synthesis of transition metal oxo complexes. This compound undergoes double deprotonation, and the doubly charged anion exists in solution as two rotamers, L^{A} and L^{B} ; these species selectively form oxo complexes of two different types, Fe_2MOL_3 [$\text{M} = \text{Fe(II)}, \text{Cu(II)}, \text{Co(II)}, \text{Ni(II)}$] and $\text{Zn}_8\text{O}_2\text{L}_6$. These complexes are considered as models of metalloproteins and promising oxidation catalysts.

The structures and properties of trinuclear oxo-centred complexes have been studied in most detail using a variety of spectroscopic, electrochemical and spectroelectrochemical methods and X-ray diffraction analysis. In these compounds, the ligand acquires the shape of a helix and binds all three metal atoms by five electron-donating nitrogen atoms, giving rise to complexes stable in solution and in the solid state (m.p. > 250 °C with decomposition). These complexes show unusual electronic properties of the central $\text{Fe}_2^{\text{III}}\text{M}^{\text{II}}\text{O}$ core, which imply the possibility of fine tuning of the parameters of the reversible electron transitions $\text{Fe}^{\text{III}} \rightleftharpoons \text{M}^{\text{II}}$ by external action. According to X-ray diffraction data, compounds **162** ($\text{M} = \text{Fe}, \text{Ni}, \text{Cu}$) correspond to the D_3 point group of symmetry, three metal ions being indistinguishable in these structures. The metal–metal distances (3.267–3.287 Å) are somewhat shorter than those in similar complexes with carboxylate bridges (3.306–3.308 Å). Mixed-valence iron complex **162** can be easily converted into $[\text{Fe}_3^{\text{III}}\text{OL}_3]$ by treatment with cerium(IV) nitrate; the reaction of $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ with the ligand under consideration in the presence of triethylamine at room temperature affords the ionic complex $(\text{HNEt}_3)[\text{Fe}^{\text{III}}\text{L}_2]$ (yield 87%).³⁰⁴

The triazene ligand $\text{RNHN}=\text{NR}$ (R is 2-methyltetrazol-5-yl) is also easily deprotonated in the reaction with nickel chloride. The resulting dark red crystals of mononuclear complex **163** are thermally stable despite the high content of nitrogen, and undergo no changes below 250°C .³⁰⁵

**163**

Like the initial 5-aminotetrazole (**13**), its 1- and 2-methyl derivatives react with tetranitromethane in alkaline media to give 5-nitraminotetrazole salts **164**, **165** (yields 65%–85%), which vigorously decompose at temperatures of $248\text{--}325^\circ\text{C}$. In the case of *N*-cyanoethyl derivatives, this reaction occurs smoothly only for the 2-isomer. The nitration of 5-amino-1-cyanoethyltetrazole is accompanied by dealkylation to give salts **12**.³⁰⁶

**164****165**

M = Li, Na, K, Rb, Cs (**164**); R = Me, $\text{CH}_2\text{CH}_2\text{CN}$; M = Na, K (**165**).

Silver(I) complexes based on *N*-nitraminotetrazole anions **110** ($\text{R}^1 = \text{H}$, $\text{R}^2 = \text{NHNO}_2$) and **111** ($\text{R}^1 = \text{H}$, $\text{R}^2 = \text{NHNO}_2$; $\text{R}^1 = \text{NHNO}_2$, $\text{R}^2 = \text{Me}$) have also been reported.⁶⁴ These 1:1 complexes were prepared in almost quantitative yields from ammonium salts of tetrazoles and silver nitrate in water; they are stable under ambient conditions and susceptible to explosive decomposition on heating; their decomposition temperatures lie in the range of $180\text{--}275^\circ\text{C}$.

Of substantial value for MT synthesis are *N*-substituted 5-mercaptotetrazoles **166**, which may exist in thiol **166a** and thione **166b** tautomeric forms, form **166b** predominating in the condensed state.³⁰⁷ These compounds are readily deprotonated to give tetrazolethiolate anion, which is a stable 6π -electron cyclic system.

**166a****166b**

Depending on the reagents and reaction conditions, 5-mercaptotetrazoles **166** (R = Ph, 4-MeC₆H₄, 3-MeC₆H₄, 4-ClC₆H₄) form complexes involving both deprotonated (L) and neutral (HL) forms, for example, $\text{Bi}(\text{HL})_2\text{Cl}_3$, $\text{Bi}(\text{HL})(\text{H}_2\text{O})\text{Cl}_3$,³⁰⁸ $\text{VO}_2(\text{HL})_2\text{Cl}(\text{H}_2\text{O})$, $\text{NbL}_2(\text{H}_2\text{O})\text{Cl}_3$ and $\text{TaL}_5(\text{H}_2\text{O})$.³⁰⁹ Complexes with a neutral form of the ligand are prepared by reactions of tetrazoles **166** with a metal salt in ethanol or aqueous ethanol solution with heating and with maintaining of the required pH. The nature of the substituent R and metal cation also influence the composition of the complex and the form of existence of the ligand in the complex. The data from IR, electronic and ^1H NMR spectroscopy provided the conclusion³¹⁰ that neutral 1-substituted mercaptotetrazoles are coordinated in the thione form **166b**. It was also shown that 5-mercapto-1-phenyltetrazole (**167**) displaces triphenylarsine from copper(I) triphenylarsine complexes to give complexes **168** involving the neutral form of the tetrazole ligand, which is coordinated in the thione form through the sulfur atom.³¹⁰

**167****168**

X = Cl, Br, I.

However, no structural data are still available for this type of complexes. In some cases,^{308,311} data on the composition and properties of complexes have been improperly interpreted.

Complexes with mercaptotetrazole anions are mainly prepared by substitution of an appropriate thiolate anion (taken as the ammonium or sodium salt) for a halide ion. They can also be prepared by the reaction of the metal salt with a neutral ligand in the presence of an amine. A number of neutral and ionic complexes of 1-methyl- and 1-phenyltetrazole-5-thiones have been prepared by this method; their molecular structures have been studied by X-ray diffraction: $(\text{Ph}_3\text{P})_3\text{Cu}_4(\text{MeN}_4\text{CS})_4 \cdot \text{CH}_2\text{Cl}_2$ (**169**), $[\text{Ph}_3\text{PAu}(\text{MeN}_4\text{CS})]_2$ (**170**), $\text{Ph}_3\text{PAu}(\text{PhN}_4\text{CS})$ (**171**), $(\text{Ph}_3\text{P})_2\text{Ag}(\text{PhN}_4\text{CS}) \cdot \text{CH}_2\text{Cl}_2$ (**172**), $(\text{Ph}_3\text{P})_2\text{Hg}(\text{MeN}_4\text{CS})_2$ (**173**), $(\text{AsPh}_4)_2[\text{Hg}(\text{MeN}_4\text{CS})_4]$ (**174**), $(\text{AsPh}_4)_2[\text{Pd}(\text{MeN}_4\text{CS})_4]$ (**175**), $\text{AsPh}_4[\text{Au}(\text{PhN}_4\text{CS})_2]$ (**176**), $\text{AsPh}_4[\text{Au}(\text{PhN}_4\text{CS})_4]$ (**177**),³¹² $\text{NEt}_4[\text{Au}(\text{MeN}_4\text{CS})_4]$ (**178**),³¹³ $\text{PPh}_4[\text{Au}(\text{MeN}_4\text{CS})_4] \cdot 0.5 \text{H}_2\text{O}$ (**179**),³¹⁴ $(\text{Ph}_3\text{P})_2\text{Ag}(\text{PhN}_4\text{CS}) \cdot \text{MeOH}$ (**180**).³¹⁵ Note that tetranuclear complex **169** is formed upon crystallisation of the dimeric compounds $[\text{Ph}_3\text{PCu}(\text{MeN}_4\text{CS})]_2$ existing in solution and has an unusual asymmetric structure. One copper atom not bound to triphenylphosphine is coordinated only by three sulfur atoms and the other three copper atoms are tetracoordinated by the P, N and S atoms.

**169**

In complexes **170–180**, 1-R-5-mercaptotetrazoles are coordinated to the metal atom in the monodentate mode through the sulfur atom. Complex **170** is a dimer owing to the intermolecular Au–S bonds, while the other compounds are monomers. Unexpectedly, the M–P bonds in all triphenylphosphine complexes were found to be shorter than the M–S bonds. On the basis of Raman spectra and quantum-chemical calculations for tetrazole **167**, its sodium salt and the complex $\text{Ag}(\text{PhN}_4\text{CS})$, one can conclude that in the absence of other ligands, this tetrazole is bound to silver(I) by two donor atoms, S and N(4).³¹⁶

The substitution reaction in gold(III) complex **181** on treatment with sodium 1-methyltetrazole-5-thiolate was found³¹³ to involve Au–N bond cleavage, protonation of the dimethylamino group and the formation of zwitter-ion complex **182** in which the gold atom (X-ray diffraction data) has a distorted square planar environment (AuCS_3). Compound **181** exhibits an antitumour activity; therefore, studies of the ligand exchange in this complex and the biological activities of the products obtained arouse considerable interest.^{313,317} The replacement of chloride ions in complex **181** by successive treatment with diphenylthiocarbazone and 5-mercapto-1-methyltetrazolate anion to give mixed-ligand complex has been carried out.³¹⁷

The 5-mercapto-1-methyltetrazolate anion also reacts as a monodentate ligand to form technetium(III) and (V) complexes **183–185**.³¹⁸ During the synthesis of nitride complex **185**, Tc(VI) is reduced to Tc(V), which is also typical of reactions with other

S-donor ligands. According to X-ray diffraction data, ionic complexes **184** and **185** have a square pyramidal structure, while neutral complex **183** has a trigonal bipyramidal geometry in which the triphenylphosphine and acetonitrile molecules are coordinated in the axial positions. An attempt has been made³¹⁹ to carry out quantum-chemical prediction of the spin state of transition metal complexes, including the technetium(III) complex **183**.

By exchange of thiosulfate ligands in complex **186** for the 1-methyltetrazole-5-thiolate anion, binuclear nitrosyl iron complex **187** has been synthesised.³²⁰ On the basis of IR and Mössbauer spectroscopy data, it was concluded that in this complex, tetrahedrally coordinated iron atoms are bound to each other by two $\text{N}=\text{C}-\text{S}$ bridges. Complex **187** is stable in air and can be used as a model to study the mechanism of transformations of the nitrosyl adducts of $[\text{2Fe},\text{2S}]$ -proteins *in vivo*.

The synthesis and structure of the complexes of organotin 1-R-5-thiotetrazoles **188** have been studied in detail. The complexes are obtained at room temperature according to the following scheme:

R^2	n	X	Yield (%)	Ref.
Ph ^a	3	Na	88	321
Me	3	Na	67	322
Me	3	NH ₄	59	323
Bu	3	Na	74	322
CH ₂ Ph	3	NH ₄	74	323
Ph	3	Na	70	322
Me	2	NH ₄	26	323
Bu	2	Na	58	322
CH ₂ Ph	2	NH ₄	79	323
Ph	2	Na	69	322
Me ^b	2	Na	52	322

^a In this case, $\text{R}^1 = \text{Me}$, and in other cases, $\text{R}^1 = \text{Ph}$; ^b only one chloride ion is replaced under the synthesis conditions to give $\text{Me}_2\text{SnCl}(\text{SCN}_4\text{Ph})$.

These compounds can also be prepared by cycloaddition of organic isothiocyanates to R_3SnN_3 but this route is seldom used. Syntheses of the complexes $\text{Bu}_3\text{Sn}(\text{SCN}_4\text{Me})$ and $\text{Bu}_3\text{Sn}(\text{SCN}_4\text{Ph})$ have been reported.³²²

All the obtained complexes have been studied by ^1H , ^{13}C and ^{119}Sn NMR and Mössbauer spectroscopy and X-ray diffraction analysis. In solution, these compounds are monomers, the tin atom has a tetrahedral coordination and is bound to the tetrazole ligand through the donor sulfur atom. In the solid state, X-ray diffraction analysis shows the formation of an additional weaker intramolecular bond, $\text{Sn}-\text{N}(4)$, the length of which is 2.94–3.28 Å [for example, in compounds **189** ($\text{R} = \text{Me}$),³²¹ **190** ($\text{R} = \text{Me}$),³²⁵ **191** ($\text{R} = \text{Me}$),³²⁶ **192** ($\text{R} = \text{Bu}$)]. In the complexes $\text{R}_3\text{Sn}(\text{SCN}_4\text{Ph})$ [$\text{R} = \text{Me}$ (**191**),³²⁶ Bu (**192**)], the tetrazole ligand forms an intermolecular $\text{Sn}-\text{N}(3)$ bond thus increasing the coordination number of the central atom to 6. This bond (2.6–2.7 Å) is essentially shorter than the intramolecular bond (3.2–3.3 Å). As a result, the complex is a trimer for $\text{R} = \text{Me}$ and a linear polymer for $\text{R} = \text{Bu}$.

The presence of a hydroxy group in the benzene ring of 5-mercapto-1-phenyltetrazole was found³²⁷ to have a substantial influence on the structure of di- and trialkyltin compounds. A series of such compounds **193** have been prepared and studied by IR and ^1H NMR spectroscopy.

$n = 3$: $\text{R} = \text{Ph}$ (**a**), Bu (**b**); $n = 2$: $\text{R} = \text{Me}$ (**c**), Bu (**d**).

Complexes **193a–d** have also been studied by X-ray diffraction. The presence of an intermolecular $\text{Sn}-\text{N}$ bond in complex **193b** and intermolecular $\text{O}-\text{H}\cdots\text{X}$ hydrogen bonds ($\text{X} = \text{O}, \text{N}, \text{S}$) in the crystal structures of compounds **193a,c** gives rise to polymeric chains and two-dimensional networks. In addition, strong $\pi-\pi$ interaction of the hydroxyphenyl fragments was found in complexes **193b,c**. In compound **193c**, the intramolecular $\text{Sn}-\text{N}$ bond (2.704 Å) is shorter than that in related complex **190** ($\text{R} = \text{Me}$) (2.947 Å).

The 5-mercapto-1-phenyltetrazolate anion can be coordinated only through the tetrazole $\text{N}(4)$ atom. According to X-ray diffraction data,³²⁸ the unit cell of the crystalline mixed-ligand complex **194** contains two independent molecules **A** and **B**, which are formally bond isomers.

Organotin complexes **195** were prepared from 1,4-phenylenedi(tetrazolethiols) by two methods;³²⁹ the same ligands were used to synthesise lead- and mercurio-thiotetrazoles.

195: R = Me (**a**, 77%), Et (**b**, 53%), Bu (**c**, 55%), Ph (**d**, 40%);
196: M = Pb, $n = 3$ (**a**, 33%); M = Hg, $n = 1$ (**b**, 80%).

According to X-ray diffraction, the supramolecular structure of compound **195c** is a 2D polymer consisting of 32-membered rings $(\text{NC}_4\text{SSnN}_2\text{CSSnN}_3)_2$. The asymmetric cell contains two trigonal bipyramidal *trans*- NSSnN_3 fragments. The tin atom is bound to the ligand through sulfur and is coordinated by the N(4) atom of the tetrazole ring of the neighbouring molecule. Conversely, trimethyltin derivative **195a** crystallises with two methanol molecules and gives a linear polymeric structure due to hydrogen bonds, the tin atom having a trigonal bipyramidal environment, *trans*- SOSnN_3 . The polymer is formed by 14-membered rings $(\text{SnSCN}_2\text{HO})_2$ connected by phenylene bridges. A similar coordination polyhedron geometry and a polymeric structure were also found for complex **195b** by Mössbauer spectroscopy. Complex **195d** is monomeric and might contain a weak intramolecular Sn–S bond. According to ^{119}Sn NMR data obtained in DMSO, the metal atom in compounds **195c,d** has a tetrahedral coordination environment, while in the case of methyl and ethyl derivatives **195a,b**, the coordination number of tin increases to 5 due to coordination of the solvent. According to ^{207}Pb NMR data, a similar coordination mode is observed for the lead atom in compound **196a**.

Interesting data have been obtained³³⁰ for the compound $\text{Ph}_3\text{PbSCN}_4\text{Ph}$ synthesised by the exchange reaction of Ph_3PbCl with the ammonium salt of tetrazole **167**. The compound has a one-dimensional polymeric structure formed due to the intermolecular Pb–N(2) contact (the bond length is 3.339 Å). The unusual orientation of the tetrazole ring with respect to the lead atom [the intermolecular Pb–N(2)–N(1)–N(4) dihedral angle is 126.1°] prompted the hypothesis of π -coordination of the tetrazole ring to the metal atom.

Due to the rather high acidity of 5-mercaptotetrazoles **166** ($\text{p}K_a = 2.8\text{--}3.6$),¹¹ their metal complexes, for example, com-

pounds **188**,³³¹ **189**,³²⁴ **194**,³²⁸ **197**,³³² **198**,³³³ **199**,³³⁴ **200**,³²⁸ **201**,³³⁵ can be prepared by the reaction of these tetrazoles with basic reagents.

X-Ray diffraction data confirm the different coordination modes of the anion of tetrazole **167** in compounds **197**.³³² The coordination number of the cations increases from 5 to 8 following an increase in the ionic radius on passing from Na^+ to Cs^+ . In K^+ , Rb^+ and Cs^+ complexes, four-membered MSCN rings are formed upon bidentate coordination of the ligand by the S and N(4) atoms, while in Rb^+ and Cs^+ compounds, $\text{Rb}\cdots\text{C}$ and $\text{Cs}\cdots\text{C}$ contacts with the carbon atom of the phenyl group were also found. As was to be expected, the alkali metal ion in complexes **198**³³³ and **201**³³⁵ is coordinated by the crown ether and, in the case of the sodium compound, no direct reaction between the metal and tetrazole takes place. Conversely, in the crystal structure of **201**, the potassium ion has a contact with the N(4)–C(5)–S fragment of the tetrazole ligand [bond lengths: K–N(4) 2.934(4) Å, K–C 3.469(4) Å, K–S 3.373(2) Å]; in this respect, this complex bears the similarity with the complexes of organotin compounds considered above where the Sn–S and Sn–N distances are in the range of 2.617–3.255 Å.

A series of Pd(II) and Pt(II) complexes with 1-R-5-mercaptotetrazoles **202**³³⁶ and **203**¹³³ have been obtained by 1,3-cycloaddition of the azido complexes of these metals to organic isothiocyanates.

Compound	M	R	X or X ₂	Yield (%)
202a	Pd	Et	PMe ₃	88
202b	Pd	CH ₂ CH=CH ₂	PMe ₃	75
202c	Pd	PhCH ₂	PMe ₃	81
202d	Pd	Ph	PMe ₃	59
202e	Pd	Ph	PMe ₂ Ph	93
202f	Pd	2,6-Me ₂ C ₆ H ₃	PMe ₃	45
202g	Pd	2,6-Me ₂ C ₆ H ₃	PEt ₃	72
202h	Pt	Et	PMe ₃	91
202i	Pt	Ph	PMe ₃	92
202j	Pt	Ph	PEt ₃	64

Compound	M	R	X or X ₂	Yield (%)
202k	Pd	Ph	Et ₂ P(CH ₂) ₂ PEt ₂	76
202l	Pt	Ph	Et ₂ P(CH ₂) ₂ PEt ₂	66
202m	Pt	2,6-Me ₂ C ₆ H ₃	Et ₂ P(CH ₂) ₂ PEt ₂	92
203a	Pd	Et	PMe ₃	61

The binuclear complex 1,4-[PhC≡CPd(PEt₃)₂SCN₄]₂C₆H₄ was synthesised in a similar way from *p*-phenylene diisothiocyanate in 37% yield.¹³³ Treatment of azide complex **204** with alkyl isothiocyanates results in unusual binuclear palladium complexes **205**, which may contain an intramolecular metal–metal bond.

According to X-ray diffraction data, the Pd–Pd distance in complex **205** (R = Prⁱ) is equal to 2.9704(6) Å, which is smaller than twice the covalent radius of palladium (1.380 Å), but larger than the length of the single Pd–Pd bond (2.55–2.8 Å) in other binuclear palladium complexes.³³⁷

R = Et, Prⁱ, Buⁿ, CH₂=CHCH₂.

The data from IR and ¹H, ¹³C and ³¹P NMR spectroscopy and X-ray diffraction analysis of compounds **202b,d,h,m** and **203b** are indicative of S-coordination of thiotetrazoles in these complexes. The Pd–S bond lengths (2.325–2.365 Å) are typical of analogous neutral and anionic Pd and Au tetrazolethiolate complexes **170**, **171**, **175**–**177** prepared in a different way. Note that coordination of the tetrazole ring through the nitrogen atom has previously been suggested based on IR and ¹H NMR spectra for Pd(II) complexes **206** prepared by cycloaddition of azide complexes to phenyl thiocyanate.¹³² Apparently, spectroscopic data alone are inadequate to draw this conclusion, as the vibration frequency of the C=S fragment bound to nitrogen atoms has not been reliably assigned as yet.³¹⁶

R = H, Et.

A number of MT based on tetrazolyldihydroborate anions have been synthesised; they were formed as salts **207**³³⁸ and **208**^{339,340} from sodium and potassium borohydrides and tetrazoles.

Compounds **207** and **208** react with bivalent metal salts in methanol and water, respectively, to give crystalline complexes [M{H₂B(SCN₄Me)₂}₂] [**209**; M = Co (**a**), Ni (**b**)]³³⁸ and

[M{H₂B(CHN₄)₂}₂(H₂O)₂](H₂O)₂ (**210**; M = Co, Zn, Cd, Mn, Fe).^{341–343} The reaction of compound **208** with nickel(II)³⁴² and copper(II)³⁴³ salts in water results in loose amorphous precipitates, which can be dissolved in ammonia and then crystallised as polymeric complexes [M{H₂B(CHN₄)₂}₂(NH₃)₂]_n (**211**; M = Cu, Ni).^{341,342} The structures of the resulting complexes were investigated by various spectroscopic methods and X-ray diffraction. It was shown³³⁸ that the dihydrobis(1-methyl-5-thiotetrazol-4-yl)borate anion is coordinated as a bidentate ligand (*k*²-S,S) in complex **209a** and as a tridentate ligand (*k*³-S,S,HB) in complex **209b**, i.e., rather strong Ni...H–B interaction is manifested. Conversely, in compounds **210**, dihydrobis(tetrazolyl)borate anion acts as a bridging ligand, being coordinated through the N(4) atoms of both rings and forming a 2D structure. Complexes **211** also have a 2D structure with polyhedron distortion due to the Jahn–Teller effect typical of copper. The coordination polyhedron is formed by four nitrogen atoms of two bis(tetrazolyl)borate ligands and two ammonia molecules in *trans*-positions.^{341–343}

The properties and structures of two MT prepared by an unusual method, namely, by recyclisation, have been reported.^{344,345} 5-Aminothiatetrazoles are known to isomerise into 5-mercaptotetrazoles on treatment with an aqueous solution of sodium hydroxide. Using 5-(1-naphthylamino)-1,2,3,4-thiatetrazole as an example, it was shown³⁴⁴ that this isomerisation occurs more efficiently under the action of barium hydroxide in toluene in the presence of hexamethylphosphoramide. This gives solvated complex **212** in which the ligands form chelate rings due to coordination of the tetrazole ring through sulfur and nitrogen atoms.³⁴⁴

An unexpected transformation of aminoazidofurazan induced by sodium nitrite yields rather stable (m.p. = 255 °C) sodium salt of 5-cyano-1-hydroxytetrazole (**213**).³⁴⁵ In the crystal structure of the hydrate of salt **213**, the sodium atom in the NaN₃O₄ polyhedron is coordinated by the nitrogen atom of the nitrile group, by the N(3) and N(4) atoms of three anions and by oxygen atoms of four water molecules.

It is noteworthy that, being rather strong OH acids, 1-hydroxytetrazoles are capable of ready formation of stable salts with metals or nitrogen bases. A sequence of transformations of ethyl 1-hydroxytetrazole-5-carboxylate (**214**) has been reported;³⁴⁶ compound **214** readily forms a silver salt and, like other 1-hydroxytetrazoles, reacts with bromoacetone in the presence of potassium carbonate to be reduced to ethyl tetrazole-5-carboxylate, which was isolated as the silver salt. The structure of silver compounds of this type has not been determined as yet.

V. Applications of metal tetrazole derivatives

A key application of MT is organic synthesis, where they are used as the starting and intermediate compounds for the preparation of practically valuable substances. First, this is synthesis of *N*-substituted tetrazoles from various metal tetrazolates.^{1–3, 15, 16, 23, 347–349} By using metal derivatives **1b** and **2** containing covalently bound metal, it is possible in some cases to obtain selectively one of the possible *N*-substituted tetrazole isomers **110** and **111**.^{69, 89, 110, 121, 347–349} This approach is successfully used not only to prepare simplest *N*-alkyltetrazoles, but also for the synthesis of *N*-aryl- and *N*-hetaryltetrazoles^{23, 156, 186, 350} and for introduction of tetrazolyl groups into complex biologically active compounds.^{351, 352} The replacement of traditional alkylating agents in these processes by other halogen-containing compounds provides the route to 2-phosphinetetrazoles,³⁴⁸ 2,5-disubstituted triazolo[3,4-*b*][1,3,4]thiadiazoles,³⁵³ tetrazolylmethylaminoglyoximes and furazans³⁵⁴ difficult to prepare by other methods. Alkylation of metal 5-mercaptotetrazolates plays an important role in the synthesis of biologically active compounds incorporating a 1-*R*-tetrazole-5-thiolate fragment.^{355–365} Treatment of *N*-alkylstannyltetrazoles **16**, **103**^{88, 157–159, 161, 162} and metal tetrazolates^{75, 94} with acids is the final stage of a popular synthesis of 5-substituted tetrazoles **6** from nitriles. More readily available alkali and alkaline earth metal bis-tetrazolates, for example, salts **46** and **76**, are often used to prepare the corresponding ammonium and hydrazinium salts and salts of organic bases.^{366–368}

Metal derivatives of tetrazoles find use as catalysts. For example, iron(III) complexes **215a,b** demonstrated²⁹⁴ high efficiency as oxidation and dehydrogenation catalysts in the epoxidation of olefins and dehydrogenation of dihydropyridine with dioxygen and aldehydes. Owing to the use of mentioned compounds, these processes smoothly occur at room temperature and atmospheric pressure.

215a,b

$R^1 = \text{Bu}^t$, $R^2 = \text{CN}$, $R^3 = \text{OMe}$ (**a**); $R^1 = \text{Bu}^t$, $R^2 = \text{H}$, $R^3 = \text{Ph}$ (**b**).

Palladium(II) acetate complexes with *m*-phenylenedi(1*H*-tetrazole)³⁶⁹ and 1-(2-iodo-phenyl)tetrazole,³⁷⁰ prepared *in situ*, proved to be good catalysts in the Suzuki and Heck coupling reactions.

Many energetic MT able to pass from the combustion mode to detonation are promising as initiating explosives (IE) for safe initiating means including those operating from a low-voltage current sources or on exposure to laser radiation.^{31, 83} First of all, these are cobalt(III) amino tetrazolate complexes **69–71**,^{83, 87, 148, 371} which have a substantially lower impact sensitivity and are less toxic than traditional IE, namely, lead azide, fulminating mercury or lead trinitroresorcinolate.⁸⁷ Compound **69** ($R = \text{NO}_2$) is successfully used in light igniting charges applied in the pyrocontrol of guided missile systems.⁸³ Good operation parameters were found for non-hygroscopic and low-toxic complex **70**, which has a reduced sensitivity to the static electric discharge. The use of this compound as a key component in perforating equipment meant for operation in deep oil and gas wells markedly increases oil and gas condensate production rates and decreases the time of development of exploratory and producing wells.⁸³

An extremely high susceptibility to laser pulse was found recently for the complexes of 5-hydrazinotetrazole with mercury(II) perchlorate **37** and 5-aminotetrazole with silver(I) perchloramide **216**.^{52, 83, 371} For complex **37**, the initiation threshold by a neodymium laser ($\lambda = 1.06 \mu\text{m}$, pulse duration $\tau_q = 30 \text{ ns}$) is $\sim 5 \text{ mJ cm}^{-2}$. This complex has found use for the production of film light-sensitive charges employed for the formation of shaped shock waves and blast hardening of steels.⁸³ Other MT of type **1** proposed as IE include silver¹⁴⁸ and mercury salts of 5-nitrotetrazole,^{67, 148} caesium salts of 5-nitrotetrazole and 5,5'-azoditrazole,³⁷² cobalt(III), nickel(II), copper(II) and zinc(II) complexes with ammonia and 5-nitrotetrazole **71**, **72**⁸⁸ and cobalt(III) complexes with ammonia and *N*-substituted tetrazoles **217**, **218**.^{87, 277–279} These MT show a number of advantages over the conventional IE; many of them can be considered as promising low-toxic explosives valuable for the development of environmentally safe (green) energetic materials (see, for example, Ref. 279).

$R^1 = \text{NH}_2$; $R^2 = \text{Me}$, NH_2 ; $R^1 - R^2 = (\text{CH}_2)_5$.

It has been shown³⁷³ that 5,5'-bitetrazole or bis(tetrazol-5-yl)amine or their barium, strontium and copper salts can underlie the development of low-smoke pyrotechnic compositions to be used in colour fireworks.

An important field of MT application is gas generation. Of most interest in this respect are salts of 5-substituted tetrazoles as they are safer than azides used previously.³⁷⁴ The compositions proposed for the use in car safety pads usually include an oxidant represented by metal oxides or salts (perchlorates, nitrates, etc.), and a fuel. As such fuels, 5-aminotetrazole,^{375–379} 5-nitraminotetrazole,^{380–382} 5,5'-bitetrazole^{35, 36, 379, 383} and salts with alkali, alkaline earth and transition metal cations [copper(II), zinc, cobalt(II), iron(III)] were patented. In addition, some of these compounds are catalysts of carbon monoxide and nitrogen oxide burning and conversion into carbon dioxide and nitrogen, respectively. Minor additives of these salts, in particular, those based on unsubstituted 5-aminotetrazole, decrease the toxicity of other gaseous products to a reasonable extent.^{377, 378} The formation of environmentally safe gaseous products from aminotetrazole-based compositions, for example, potassium salt of 5-aminotetrazole, has been proposed as a fire extinguishing means, instead of Freons or other halogenated compounds used currently in fire extinguishers.^{384, 385} The use of 5-substituted tetrazole salts **1a,b** ($M = \text{Na}$, K , Ca , Zn), which produce nitrogen at temperatures above 300°C or above 230°C , for the design of fire-resistant thermoset³⁸⁶ and thermoplastic³⁸⁷ polymers has been patented. Copper(II) 5-methyltetrazolate and other salts of 5-substituted tetrazoles and 5,5'-bitetrazole with melting points above 200°C have been proposed^{388, 389} for the manufacture of high-quality moulds for casting of foamed materials. The decomposition of tetrazoles accompanied by gas evolution and change in the state of the plastic surface underlies the laser beam marking of polymeric articles containing tetrazole derivatives, including their alkali and alkaline earth metal, zinc and copper salts.³⁹⁰

The ability of tetrazoles to form stable complexes with various metal ions is widely used in photoprocesses and for corrosion protection of metals.^{316, 391–395} 5-Substituted tetrazoles and their

salts as well as 5-mercapto-1-phenyltetrazole and its derivatives are used as light-sensitive materials and reagents that improve sharpness, enhance the mechanical and thermal stability of the image and prevent bleaching.^{396–399} 5-Mercapto-1-phenyltetrazole is the most effective metal corrosion inhibitor in the series of heterocyclic compounds. On a metal surface, this compound forms inert, insoluble and stable complexes with metal ions, which prevent the material from destruction.^{400–402} The film of these complexes inhibits corrosion of copper,^{403–407} nickel,⁴⁰⁸ iron,⁴⁰⁹ steel,^{410–413} bronze,^{406,414} and Cu–Zn⁴¹⁵ and Fe–B⁴¹⁶ alloys in acidic media. Treatment of silver,^{417,418} copper⁴¹⁹ and brass⁴²⁰ surfaces with compositions containing 5-mercapto-1-phenyltetrazole prevents them from dimming even in the presence of corrosive reagents such as sulfur-containing gases. It has been noted⁴²⁰ that this treatment is more efficient than that with agents used traditionally. 5-Phenyltetrazole and its potassium and sodium salts are fairly effective copper and steel corrosion inhibitors in aqueous solutions of sodium sulfate and chloride.^{421,422} In addition, tetrazoles inhibit not only electrochemical but also microbiological corrosion of metals.⁴²³

The interaction of tetrazoles with the surface of various parts and articles, resulting in a substantial change in their physico-chemical properties has been used for the manufacture of printed circuit cards,^{424–428} semiconductor devices,⁴²⁹ layered materials;⁴³⁰ for stabilisation of CdS colloid solutions⁴³¹ and Mo–S–Cu thermochromic films formed on the copper surface,⁴³² and for surface modification of silver nanoparticles.⁴³³ The use of tetrazolylacetic acid as a bidentate ligand allows the design of polynuclear heterometallic clusters, Cu₁₂Gd₆ and Cu₁₂Nd₆ (Ref. 434).

The formation of coloured metal complexes of azotetrazoles **219** and **220** stable in solution is used for spectrophotometric determination of traces of iron(III),⁴³⁵ bismuth(III)⁴³⁶ and palladium(II)⁴³⁷ in various mixtures and articles.

The high stability of the 5-diazotetrazole complex with copper(II) ions also underlies the voltammetric method for quantitative determination of copper present in low concentration (10^{–9} mol litre^{–1}).⁴³⁸ The ability of 1-substituted tetrazoles **110** to form easily separable crystalline complexes with copper(II) chloride, which liberate free tetrazole ligand upon hydrolysis, has been used⁴³⁹ for purification of this class of compound. This method is especially convenient for the production of low-volatile *N*-substituted tetrazoles sensitive to mechanical impact and capable of polymerisation. Since isomeric 1- and 2-substituted tetrazoles differ in the complexation properties, this process proved to be convenient for the separation of isomer mixtures.

Immobilisation of tetrazoles on a polymeric matrix furnishes sorbents for selective binding of copper⁴⁴⁰ and europium,⁴⁴¹ filtering materials⁴⁴² and hydrogels^{443–445} suitable for purification of biological fluids and water from heavy metals and radionuclides. The ability of salt **7** to form hydrogel compositions under the action of Cr³⁺ ions is exploited in the application of this compound as a thickening agent in slurry explosives.⁴⁴⁶

Owing to high ionic conductivity and stability, lithium salts with heterocyclic anions, in particular, 5-cyanotetrazolate anion,⁴⁴⁷ and alkali metal salts with 1-methyltetrazole-5-thiolate anion^{334,448–451} are promising as components of polymeric electrolytes in galvanic and electrochemical (photovoltaic) current sources.

5-Substituted tetrazoles are known to be bioisosteres of the carboxy group, possessing a comparable acidity and lower toxicity. Tetrazoles are ionised in the physiological pH range, the tetrazolates thus formed being much more lipophilic than the corresponding carboxylates. This explains the interest in tetrazoles for the design of new effective drugs.¹⁰ The structures of such drugs can incorporate the tetrazole ring in the form of a salt having higher solubility in water and ability to crystallise. Examples are Losartan Potassium (**221**),¹⁰ which is a representative of new-generation antihypertensive drugs, and Pemirolast Potassium (**222**)⁴⁵² and MDL-427 (**223**),¹⁴ which are effective as antiallergenic and antiasthmatic drugs.

The complexes prepared by the reaction of the widely used antibacterial agent cephazolin or its sodium salt with metal(II) chlorides, ML₂Cl₂ and MClCl (**224**), Ag₂L₂Cl₂ (L is the deprotonated cephazolin), exhibit higher antibacterial activities *in vitro* compared to cephazolin with respect to *Staphylococcus aureus*, *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus mirabilis* and *Salmonella enteritidis*.^{453,454}

A similar activity should be expected of complexes of another tetrazole-containing antibiotic, cefamandole, with copper,⁴⁵⁵ cadmium⁴⁵⁶ and zinc⁴⁵⁷ salts. An antibacterial activity was also found for silver tetrazolate⁷³ and complexes **40**.^{55–57} Platinum(II) complexes **225** possess a cytotoxic action with respect to malignant cells; compounds **225d,e** are similar in activity to cisplatin, while complexes **225a–c** demonstrate a higher activity.⁴⁵⁸ Salt **7** shows a clear-cut polyelectrolyte activity toward an aseptic inflammatory process, which may be used to accelerate healing of wounds and to suppress scar formation.⁴⁵⁹ Trialkylstannyl derivatives of 5-aryl- and -hetaryltetrazoles **103** were patented as herbicides and animal parasite control means.⁴⁶⁰

Gadolinium(III) complexes **50** and **51**⁷¹ and the complexes GdL₃(H₂O)_n and Na[GdL(H₂O)] obtained from ligands **226**⁷¹ and **227**,⁴⁶¹ respectively, are promising for the use in medicine as contrasting agents for magnetic resonance diagnostics. They show a high proton relaxation ability, good solubility in water, high stability and low osmotic pressure. These complexes surpass conventional reagents in many performance characteristics.

For many MT, practically valuable properties were found, demonstrating good prospects for their use in various fields of science and engineering. These properties include photo- and thermochromism,^{6, 227, 228} ferromagnetism,^{185, 199, 202, 225, 276} mesomorphism,^{281, 282} nonlinear optical properties,^{100, 104} luminescence,^{44, 48, 49, 462, 463} and electrolytic production of nitrogen.⁴⁶⁴

VI. Conclusion

The ready availability of tetrazole and its derivatives containing four electron-donating atoms in the five-membered ring and existing as different isomeric forms and the high reactivity of the functional groups attached to the heterocycle ensured successful development of the investigations dealing with synthetic routes to, and physicochemical properties of, diverse MT. Numerous MT containing almost all known metals have now been obtained. The substituents in the tetrazole ring and the method used to prepare MT have a pronounced influence on the MT composition, structure and properties. Of course, the classification of MT proposed in this review is not all-round. There exist a number of compounds that cannot be assigned unambiguously to any type of metal tetrazole derivatives. Nevertheless, analysis based on this classification allows one to carry out deliberate selection of the rational routes to new MT with specified structure and properties. The successful development of synthetic methods forms the grounds for the practical use of many MT in various fields of science and engineering. For other compounds of this series, new practically valuable properties, not always predictable, have been found. Owing to the ability of tetrazole derivatives to be coordinated through different nitrogen atoms of the ring and donor atoms of substituents and to the structural, chemical and functional diversity of the MT formed, these compounds present considerable interest for the study of self-assembly of supramolecular structures and self-organisation of molecules through coordination to transition metal ions and the design of polymeric structures of different dimensionality. The subsequent systematic studies would provide information of what structural features of MT determine the appearance of particular useful properties and would enable targeted synthesis of such derivatives.

Abstract. Published data on modification of oxide materials with phosphonic and phosphinic acids and their derivatives are systematised and generalised. The regularities of formation of grafted modifier layers on the oxide surfaces are considered. It is shown that phosphonic acids and their derivatives can form dense well-ordered layers. The factors affecting the properties of such layers are analysed. The key applications of these modifiers are considered. The bibliography includes 146 references.

I. Introduction

Chemical modification of the surface of mineral supports is a common method for fabrication of a broad spectrum of surface-modified materials, such as chemical and biological sensors, modified electrodes, separation membranes, selective adsorbents, sorbents for HPLC, heterogeneous metal complex catalysts, implants, antiadhesants, anticorrosion coatings, *etc.*¹ The most widely used materials are based on silica, which can be best chemically modified with organosilicon compounds.^{2–5} However, at present the family of surface-modified materials has been considerably extended due to the use of other mineral supports (various oxides and metals) and some other modifiers. As a result, organosilicon compounds no longer play the role of universal modifiers.

Generally, the molecule of a modifier must contain three fragments (Fig. 1). These are a functional group that determines the chemical properties of the surface-modified material, an anchoring group responsible for immobilisation of the modifier molecule on the support surface through covalent bonding and a spacer (or linker) that connects the functional group to the anchoring group, thus completing the structure of the modifier molecule.

Figure 1. Structure of the surface of a chemically modified support.

Modification of the surface of oxide materials usually involves electrophilic substitution (a surface hydroxyl proton is replaced by the anchoring group of the modifier). From this it follows that the modifier molecule must contain a leaving group that forms a stable compound with proton.

The requirements for the anchoring group are as follows: the anchoring fragment should have a valence of at least two, because otherwise it cannot be bound to the surface; the reaction between the groups present on the support surface and the anchoring group should follow an unambiguous pathway and proceed as fast as possible; and the system of chemical bonds between the support and the grafted layer should be stable under the operational and storage conditions of the surface-modified material. It is also desired that the modifier be non-toxic[†] and the synthesis of this compound be not too complicated. Most often, silicon and phosphorus are used as the anchoring elements. Other anchoring elements include B, C, N, S, Ge, As, Sn, Sb, Hg and Pb.

The surface of silica is usually modified with silicon anchoring groups SiX_n because they meet the requirements mentioned above. The interaction of these groups with the surface hydroxyl groups of silica results in the formation of a hydrolytically stable system of chemical bonds $\text{Si}-\text{O}-\text{Si}-\text{C}$. The next in use are organophosphorus compounds to which this review is devoted. In order to provide strong bonds with the surface OH groups of oxide materials, the anchoring phosphorus atom in organophosphorus compounds should be bound to such reactive groups, as OH, OR or Hal; *i.e.*, the modifier molecule should be an organic phosphorus acid or its derivative. Trivalent phosphorus acids (phosphonous and phosphinous acids) are oxidised in air, which

[†] The use of alkyl compounds of tin or mercury as surface modifiers is permissible, but special care should be taken.

makes them undesired as modifiers because the properties of the grafted layer of a sample exposed to atmosphere will change with time in an uncontrollable and unpredictable manner. From this it follows that the most appropriate organophosphorus modifiers of oxide surfaces are phosphorus(V) acids (phosphonic and phosphinic acids) and their derivatives.

II. Modification of silica and mica surfaces

At present, 60% to 80% of all surface-modified materials are based on silica. This is due to considerable advantages of this material and first of all, to the possibility of varying its structural characteristics (specific surface area, pore diameter and volume, and particle shape and size) over a wide range. A great advantage of silica is also its low catalytic activity, which appreciably decreases the probability of undesired side reactions. Silicas are also well studied, readily available and cheap. Modification of silica with organosilicon compounds has long been known and well studied (see, *e.g.*, Refs 1, 2) and we will not dwell on it. Our attention will be focussed on the modification of silica with phosphonic acids.

The interaction of phosphonic acids with silica has been documented.^{6–10} When silica is refluxed with phosphonic acids for 2 h in chlorobenzene, a signal appears in the ³¹P NMR spectra, which differs from the signal of the acid adsorbed on silica and remains after washing the support with *n*-propanol and propan-2-ol. The signal was attributed⁶ to phosphonate groups formed on the silica surface. This is quite surprising because phosphonic acids do not undergo esterification (with, *e.g.*, ethanol) on reflux. The authors assumed that the interaction of phosphonic acids with the silica surface involves the formation of an intermediate containing a pentacoordinate silicon atom (here, the role of Lewis acid site is played by the silicon atom).

Boiling silica with *tert*-butylphosphonic acid in toluene results in grafting of the acid to the surface.⁸ The grafting density is 1.5 nm^{−2} (from this point on the term 'grafting density' means the number of molecules per nm² of the surface area). The granulometric composition of the support remained unchanged after modification. The grafted layer is hydrolytically stable in a neutral medium (the grafting density decreases by 15% after storage of the modified samples in distilled water for 2 days at room temperature); however, its stability in acidic and alkaline media is much lower.⁹

The interaction of silica with methylphosphonic and phenylphosphonic acids was studied (Ref. 10). ³¹P NMR experiments revealed the formation of a system of P—O—Si bonds on the silica surface.

Phosphonic acids interact with the silica surface much less readily than with the surfaces of most metal oxides. It was reported that long-chain phosphonic acids do not interact with the silica surface at all⁷ and that dialkyl esters of phosphonic acids behave analogously.^{9,10} Nevertheless, slow decomposition of dimethyl methylphosphonate into methanol and methyl methylphosphonate on hydroxylated silica under severe conditions is possible.¹¹ Methyl methylphosphonate can be partially grafted on the surface, however the grafting density is very low even under such conditions. Deydroxylated silica does not interact with dimethyl methylphosphonate.¹¹

The surface of silica was modified by dichloroanhydride of butylphosphonic acid and by dibutylphosphonic acid.⁹ The grafting density was ~1 nm^{−2} in both cases. The hydrolytic stability of the layers prepared was low, being similar to that of the layers formed in the modification of silica with phosphonic acids.⁹

Considerable attention is paid to chemical modification of the surface of mica crystals. Mica is a convenient object for wetting studies and for atomic force microscopy (AFM) studies of the surface, because its crystals can be broken with ease into smaller pieces with extended smooth facets. The facet surfaces contain oxygen–silicon tetrahedra and are very similar to the silica surface. It should be noted that the surface of a perfect facet of a

mica crystal contains only siloxane groups, and a real facet can contain defects (silanol groups).^{12, 13}

Octadecylphosphonic acid does not form a dense monolayer on the mica surface.¹⁴ Modification of the surface of a fresh facet on a mica crystal with octadecylphosphonic acid by melting followed by heating at 130 °C for 2 h leads to incomplete coverage of the mica surface. Besides, the modified regions can be multiply covered (additional octadecylphosphonic acid molecules are attached to the surface through van der Waals interactions with neighbouring molecules). Similarly to clean mica surface, non-modified areas are highly hydrophilic,[‡] whereas modified regions are hydrophobic and non-hygroscopic.

Treatment of mica facets with a solution of octadecylphosphonic acid in tetrahydrofuran results in the formation of self-assembled monolayers comprised of the acid molecules on the mica surface.¹⁵ An AFM study of the samples characterised by different modification time revealed the formation of 'islands' of strongly grafted molecules on the surface (surface coverage of about 25%) after 1 min of treatment, which begin to grow and merge, thus producing a dense monolayer. Only small surface defects (surface coverage of about 85%) remain unmodified after 30 min while after 120 min the surface becomes almost uniformly covered (surface coverage of about 95%).

Octadecylphosphonic acid forms round 'islands' on the mica surface in contrast to octadecyltrichlorosilane 'islands' that have a fractal morphology¹⁶ due to qualitatively different mechanisms of grafting of these compounds. Octadecyltrichlorosilane rapidly and almost irreversibly reacts with the mica surface and forms strong covalent bonds with surface hydroxyl groups and neighbouring modifier molecules. The modifier molecules are grafted at the positions where the anchoring groups contact the support surface. This leads to diffusion-controlled aggregation and fractal morphology of 'islands' thus formed. The octadecylphosphonic acid molecules are not linked to one another and interact with the silica surface slowly and (to a great extent) reversibly. This allows them to be involved in some kind of lateral diffusion and, as a consequence, makes possible molecular rearrangements within the grafted layer. The fact that most 'islands' are round suggests linear tension (analogue of surface tension for two-dimensional case) at the 'island' – bare surface interface. It should be noted that although the grafted layer formed after treatment of the surface with octadecylphosphonic acid is highly ordered, the alkyl chains are characterised by rather loose packing. Namely, each molecule occupies a surface area of nearly 0.25 nm² while the angle between the alkyl chains and the normal to the surface (tilt angle) is 40°. It is interesting that even at the shortest modification times (less than 1 min) the surface coverage is rather high (about 25%).

Contact angle measurements for the mica crystal surfaces modified with octadecylphosphonic acid¹⁵ revealed the following regularities. The cosine of the contact angle of the hexadecane on modified surface is a linear function of the surface coverage with the modifier molecules. The contact angle changes from 20° for bare mica crystal to 45° for the fully modified crystal. The contact angle on fully modified surface compares well with that obtained for well-formed thiolate monolayers, which indicates a high degree of ordering of the monolayer.

The cosine of the contact angle of water on the modified mica surface linearly decreases only to nearly 50% coverage and then reaches a maximum value.[§] The contact angle of water on bare mica surface is 3°.

The inflow and outflow contact angles were also determined, the former being about 5° larger than the static contact angle while the latter being very small (<10°). It should be noted that the contact angles of water on the mica surface decrease with time. This can be due to hydrolytic instability of layers formed.

‡ In air, a water film up to a nanometre thick is formed on these areas.

§ The maximum attainable contact angle for the monolayers under study is 90°.

An AFM study¹⁷ of *in situ* growth of octadecylphosphonate 'islands' on mica in tetrahydrofuran confirmed the conclusions made earlier.¹⁵ Namely, modification of the mica surface begins with nucleation followed by growth of 'islands' which then merge into a monolayer. No motions of 'islands' relative to one another were observed in the course of modification. It is likely that a proportion of octadecylphosphonic acid molecules is aggregated in solution; these aggregates grafted in the surface serve as nuclei. The growth of 'islands' is consistent with an accretion model, according to which disordered acid molecules present on bare mica surface (they cannot be detected by AFM) gradually diffuse towards an 'island', thus making its growth possible. Bubbling air through the solution led to a jumpwise increase in the surface coverage. This is due to the presence of octadecylphosphonic acid monolayer at the solution–air interface.¹⁷ To check this assumption, experiments involving multiple short-term (less than 1 s) dips of samples into the modifier solution. It was found that the surface coverage increases with the number of dips and the fraction of a monolayer per dip increases in proportion to the octadecylphosphonic acid concentration in the solution. This substantiates the assumption made above.

A comparative analysis of the growth of octadecylphosphonic acid monolayers on sapphire and mica surfaces was reported.¹⁸ It was found that mica is less reactive than sapphire. At room temperature, a monolayer providing a water contact angle of 90° is formed after 1 min on sapphire (from 5×10^{-5} M solution) and after several hours on mica. Octadecylphosphonic acid layers on sapphire are more ordered than on mica, namely, at room temperature the acid forms a highly ordered quasi-crystalline layer on sapphire while disordered liquid-expanded layers are formed under identical conditions on mica.

The thermal stability of grafted phosphonic acid layers is almost independent of the nature of support.¹⁹

III. Modification of alumina surface

Following silica, alumina is the next in significance among oxide supports used in the synthesis of surface-modified materials. As silica, alumina is relatively cheap and available. Significant drawbacks of Al₂O₃ compared to SiO₂ are a nonuniform surface and the dependence of the surface properties on the sample prehistory. Additionally, the presence of strong Brønsted or Lewis acid sites on the Al₂O₃ surface can cause undesired transformation of the modifier molecules. At the same time alumina offers certain advantages over silica, *e.g.*, higher mechanical stability and greater stability in alkaline media.

The importance of studies on the regularities of modification of Al₂O₃ surface is first of all determined by the fact that such valuable material as metallic aluminium is always covered with oxide film.

Phosphonic acids offer considerable advantages over organosilicon compounds in the modification of Al₂O₃ surface. This is first of all due to the presence of strong acid sites on the Al₂O₃ surface, which significantly facilitates the donor–acceptor interaction of phosphoryl group of the modifier with the Lewis acid sites (unoccupied sites or those formed from a proportion of Brønsted sites due to competitive displacement of other nucleophilic groups). This interaction makes the phosphorus atom more electrophilic and facilitates a subsequent reaction between the modifier and the surface hydroxyl groups. Besides, this donor–acceptor interaction helps the anchoring groups of the modifier molecules to block efficiently the surface acid sites, so the surface becomes more uniform and non-specific.

Conventional organosilicon modifiers (*e.g.*, ethoxysilanes) do not readily react with the alumina surface (see, *e.g.*, Ref. 20). High grafting density can be reached only with silanes that contain two or three leaving groups at silicon atom and can therefore form horizontal cross-links with neighbouring modifier molecules. The use of chlorosilanes for modification of alumina is complicated by the fact that hydrogen chloride evolved in the reaction causes

destruction of Al₂O₃ surface and uncontrollable changes in the structural and geometric parameters of the support and the surface acidity. The addition to the reaction mixture of a compound that can react with hydrogen chloride (*e.g.*, organic amine) leaves the situation unchanged, because this component is sorbed on specific (acid) surface sites and also causes uncontrollable changes in the properties of the modified support thus formed. It seems likely that good results would be obtained with silicon hydrides as modifiers; however, the interaction of these compounds with Al₂O₃ surface has been poorly studied. Additionally, such compounds (especially those having small substituents at silicon atom) are less available and less stable than chloro- and alkoxy-silanes. Therefore, it is not surprising that most studies on the modification of Al₂O₃ surface were carried out using phosphonic acids or their derivatives as modifiers.

1. Phosphonic acids

Phosphonic acids are one of three classes of compounds (in addition to thiols and trifunctional silanes) capable of forming dense self-assembled monolayers on support surfaces. Therefore, a large number of studies on the modification of Al₂O₃ surface are concerned with phosphonic acids. It should be noted that a self-assembled monolayer is the best grafted layer, because it provides the highest extent of screening of the support surface.

Self-assembled monolayers comprised of *n*-octadecylphosphonic acid molecules on the (1000) and (1 $\bar{1}$ 02) faces (C- and R-faces, respectively) of a sapphire single crystal were studied by AFM, contact angle measurements and FTIR spectroscopy.¹⁸ It was established that the formation of monolayer strongly depends on temperature. This was explained by a three-phase model for film deposition. At low temperature, close-packed molecular 'islands' nucleate and grow on almost bare substrate surface (two-dimensional transition vapour–solid),[‡] while at high temperature two-dimensional transition liquid–solid occurs and a film is formed on the surface.

A change in the contact angle in the surface modification implies the formation of a surface film, however AFM measurements failed to detect it. As the modification time increases, structures with poorly defined boundaries appear on the surface, which can be detected by AFM. These structures become larger as the treatment duration increases. The height of the structures (0.8 nm for the C-face and ~0.55 nm for the R-face) does not reach a value consistent with a fully extended octadecylphosphonic acid molecule (~2.5 nm). The water contact angle on the sapphire surface treated with octadecylphosphonic acid (1 min) is 90° and remains unchanged upon increase in the modification time. However, treatment of sapphire surface with *n*-hexadecylphosphonic acid for 1 min results in the formation of a layer for which the water contact angle is 31°; the contact angle increases to 36° as the treatment time increases to 0.5 h for the C-face and to 1 h for the R-face.

At low temperatures, the growth of a surface modifier layer is significantly different from that described above. At 2 °C, small 'islands' with well-defined boundaries are formed. The height of the 'islands' is about 1.1 nm. The surface coverage increases with time, but slowly, and the surface remains incompletely covered even after treatment for 15.5 h.

A FTIR study of the modified sapphire surface showed that treatment of the surface for 1 min at room temperature is followed by the formation of disordered ('liquid-expanded') layers, which become much more ordered after 1 h. Modification at 2 °C leads to the formation of highly ordered layers. The results obtained suggest a two-dimensional phase diagram for the grafted layer (in

‡ Two-dimensional transition means that molecules are transferred over a surface. In this case highly ordered close-packed regions of the grafted layer are treated as solid, disordered close-packed regions are treated as liquid and regions with a grafting density much lower than that characteristic of the monolayer are treated as vapour.

the 'temperature-grafting density' coordinates). The 'liquid-expanded' disordered state of the grafted layer in this system is only possible at temperatures above 11 °C. This temperature corresponds to a triple point.

The kinetics of growth of the modifier layer on the C- and R-sapphire faces are different. Namely, the growth rate on the C-face is higher and the growing layer is thicker; this is due to different surface energies of these faces. The R-face is formed by a layer of oxygen atoms while the C-face is formed by a layer of aluminium atoms (the surface area of the C-face is smaller than that of the R-face); the C-face contains a larger number of coordinatively unsaturated sites and is characterised by higher surface energy. Assuming epitaxial growth of a modifier layer, it is clear that the layer growing on the C-face will be thicker. The modification temperature can be shifted towards high-temperature region owing to proximity to the face edge or other surface defects. Generally, by varying the temperature it is possible to control the amount of defects within the grafted layer.

Self-assembled monolayers comprising the molecules of three phosphonic acids, namely, $\text{CF}_3(\text{CF}_2)_7(\text{CH}_2)_{11}\text{PO}_3\text{H}_2$,[†] $\text{n-C}_{16}\text{H}_{33}\text{PO}_3\text{H}_2$ and $\text{n-C}_{22}\text{H}_{45}\text{PO}_3\text{H}_2$ on the surface of aluminium covered with native oxide film were studied by IR spectroscopy, ellipsometry and contact angle measurements.²¹ It was shown that the layers formed by these three acids are characterised by significantly different structures and growth kinetics. For instance, the lack of ordering was observed for fluorinated phosphonic acid in all cases (layer becomes insignificantly more ordered with an increase in the modification time) while the layer thickness increases with time (from 1.8 nm after modification for 5 s to 2.3 nm after 24 h).

It should be noted that the behaviour of partially fluorinated phosphonic acids on the surface of oxidised aluminium is basically different from that of perfluorothiols on silver and gold surfaces.^{22–24} This was explained by two factors, namely, larger size of the anchoring group PO_3H_2 compared to the thiol group and low lateral mobility of phosphonate groups on Al_2O_3 surface compared to that of thiol group on the noble metal surfaces.²¹

At long treatment times, the acids $\text{n-C}_{16}\text{H}_{33}\text{PO}_3\text{H}_2$ and $\text{n-C}_{22}\text{H}_{45}\text{PO}_3\text{H}_2$ form ordered layers in which alkyl chains are in fully transoid conformation. Different behaviour of these acids and the partially fluorinated acid is due to the presence of a bulky, conformationally rigid perfluorinated segment in the last-mentioned molecule; this precludes the close packing of alkyl groups. Additionally, some contributions from low solubility of the partially fluorinated acid in ethanol (solvent for modification) and micellisation in solution (although the authors reported no unambiguous proofs of micellisation) are also possible.

The IR spectra of the samples modified with these three acids exhibit no AlOH bands, which is associated with the interaction of these groups with OH groups of phosphonic acid molecules accompanied by the formation of a surface alumophosphonate layer.

[†] Acid $\text{CF}_3(\text{CF}_2)_7(\text{CH}_2)_{11}\text{PO}_3\text{H}_2$ forms on Al_2O_3 surface a grafted layer characterised by minimum surface energy.

The modification of Al_2O_3 surface with fluorinated phosphonic acid approaches its equilibrium rapidly. This acid forms disordered 'islands' on the surface, which then merge. The formation of a monolayer takes $\sim 5\text{--}10$ min. A considerable increase in the water contact angle for the modified surface is observed after modification over a period of 5 s. Docosylphosphonic acid $\text{n-C}_{22}\text{H}_{45}\text{PO}_3\text{H}_2$ also modifies the surface following the 'island' mechanism; however, alkyl chains in the 'islands' formed are ordered. In this case the kinetics of modification is similar to that of fluorinated acid. At the same time hexadecylphosphonic acid $\text{n-C}_{16}\text{H}_{33}\text{PO}_3\text{H}_2$ initially forms a disordered 'liquid-like' layer on the aluminium surface, which becomes more ordered as the modification time increases. In this case the equilibrium is attained after about 4 h. (An increase in the rate of formation of self-assembled monolayers in the presence of fluorinated modifiers was also detected in the case of fluoro derivatives of trichlorosilanes^{25,26} and thiols.²⁷)

Contact angle measurements showed that water spills over the starting oxidised aluminium plates (contact angle equals zero). Surface modification imparts highly hydrophobic properties to the surface, that is, the contact angle for the surface modified with hexadecylphosphonic and docosylphosphonic acids is 110° (cf. 122° for partially fluorinated acid).

At low degree of modification, all modifier molecules are tridentate, *i.e.*, they form three covalent bonds with the oxidised aluminium surface. One of them is a donor-acceptor bond between the phosphoryl oxygen and the Lewis acid surface site.²¹ As the modification time increases, bidentate and even monodentate modifier molecules appear on the surface. This is confirmed by the fact that for the tridentate molecules in the transoid conformation of alkyl chains within the grafted layer the tilt angle should be 35° . The films studied at high degrees of modification are characterised by much larger angles that increase with increasing the modification time.

A theory developed by the authors of Ref. 28 treats the surface layers as gas-like, liquid-like and crystal-like ones (layers can also be represented using a two-dimensional state diagram). The triple point of the layer comprising docosylphosphonic acid molecules is much higher than room temperature while that of a layer comprised of hexadecylphosphonic acid molecules is near room temperature. The triple point of the fluorinated acid and the crystalline-like state of the grafted layer are apparently inaccessible. Efforts were made in order to reach the crystal-like state for a fluorinated acid film by heating the modified sample followed by cooling, however heating to moderate temperatures (at most 250°C) left the structure of the grafted layer unchanged, whereas heating above 250°C led to irreversible destruction of the grafted layer.

Adsorption and self-assembly of phosphonic acids on oxidised surfaces of metallic aluminium were studied by X-ray photoelectron spectroscopy, Auger spectroscopy and FTIR spectroscopy.²⁹ The surfaces of high-purity aluminium (99.999%) and an industrial alloy containing 98.87% of aluminium, 0.76% of magnesium, 0.29% iron and 0.08% silicon were modified. Prior to modification, the samples were thoroughly polished. As a result, the surface of bare aluminium was optically smooth while iron inclusions were seen on the alloy surface. It was shown that self-assembly of layers is possible on both types of surfaces. Full coverage of the bare aluminium and alloy surfaces was reached after 100 s. Studies of the alloy samples characterised by shorter modification time showed that adsorption of phosphonic acids first of all occurs on iron inclusions and then on the aluminium surface. Magnesium and silicon impurities do not affect the formation of the grafted layer.

A packing study of alkyl chains in the grafted layer revealed initial formation of disordered layers followed by gradual ordering with an increase in the modification time. The formation of fully ordered grafted layers takes about 70 h.²⁹ The tilt angle of alkyl chains was determined from IR spectroscopy data.^{30,31} Its value (31°) is similar to the corresponding angle for alkyl chains in

phosphonic acid bound to the surface in a tridentate fashion (35°). The somewhat lower magnitude of tilt angle may indicate the presence of coordinated groups of lower denticity on the surface. Unfortunately, the authors²⁹ did not report which alkylphosphonic acids were used for modification. This complicates the understanding of the results obtained.

Decylphosphonic acid can form films on the surfaces of bare aluminium and aluminium alloy 2024T3 containing inclusion phases of $\text{Al}_7\text{Cu}_2\text{Fe}$ of size up to a few micrometres. The structure of such films was studied by X-ray photoelectron spectroscopy.³² Prior to modification the samples were thoroughly polished and the oxide film was removed by bombarding them with argon ions. Immediately prior to modification the samples were exposed to air for a short time, which led to formation of a thin surface oxide layer.

X-Ray photoelectron spectra showed that the oxide layer on the alloy surfaces contain small amounts of copper. P(2s) X-ray photoelectron spectroscopy data revealed a uniform coverage of the aluminium and aluminium alloy surfaces with decylphosphonic acid molecules and the absence of preferred or reduced sorption of the modifier on inclusions. At the same time the contact angle for the modified bare aluminium sample was 110° , being only 97° for the alloy, which indicates a lesser ordering of the grafted layer on the alloy surface. The reason for this is to be clarified.

The influence of preliminary long-term exposure of samples to air, nature of solvent and random sorption of hydrocarbon contaminations on sample surface on the quality of coatings were also studied.^{32,33}

The interaction of alumina with phosphonic acids is often accompanied by the formation of a surface aluminium phosphonate phase.³⁴

For instance, a phosphonate phase is formed in the course of adsorption of phenylphosphonic acid from water at pH 4 and during treatment of alumina with bis(trimethylsilyl) phenyl phosphonate. However, the phosphonate phase was not detected when the modification was performed at pH 6.

An attempt to prepare a monolayer coating by treating Al_2O_3 surface with octadecylphosphonic acid was reported.⁷ However, breakdown of particles of the starting oxide and formation of only bulk phase of aluminium phosphonate were observed under the experimental conditions.

Adsorption of a range of organic molecules on the surface of magnetron-sputtered aluminium was studied.³⁵ Prior to modification the aluminium surface was exposed to air for a short time, which resulted in the formation of a thin oxide layer. Alkylphosphonic and alkanecarboxylic acids and aliphatic triethoxysilanes, trichlorosilanes, amines and epoxides were used as surface modifiers. The modification was carried out in toluene. It was found that phosphonic and carboxylic acids form well-ordered layers with the grafting density of about 5 nm^{-2} on aluminium surface, whereas trichlorosilanes form polymeric layers and other compounds form disordered layers with low grafting density. Under the experimental conditions, trichlorosilanes can destroy the aluminium surface and, in the limiting case, dissolve the sample. One can assume that this is due to hydrolysis of silanes with trace amounts of water present on the metal surface and in solvent (toluene).

Polarisation modulated IR reflection spectra revealed a low proportion of *gauche*-defects within the layers formed by phosphonic and carboxylic acids and a small tilt angle. Water contact angle measurements for acid treated aluminium surface showed that the contact angle remains unchanged after modification for 4–6 h in the case of carboxylic acids and after only 0.5 h in the case of phosphonic acids. The maximum contact angle values attained in these experiments were 120° for phosphonic acids and 117° for carboxylic acids. The water contact angles for surfaces of copper, silver and gold, modified with alkanethiols are 115° , 116° and 120° , respectively.³⁶ Taking into account that alkanethiols form highly ordered layers on the surfaces of these metals, one can consider that the layers formed by carboxylic and, especially, phosphonic acids are well-ordered. This is in good agreement with the published data³⁷ obtained for monolayer coatings formed by alkylphosphonic and alkylsulfonic acids.

The longer the alkyl group in the modifier molecule the larger the contact angle.^{37–39} At the same time, sessile drop measurements of the contact angle provide information on the state of the modifier layer at a depth of at most four methylene units.⁴⁰ From this it follows that the effect mentioned above can be explained only by an increase in the degree of ordering of the grafted layer with elongation of the alkyl chain.

Higher density and ordering of the grafted layers of phosphonic acids compared to those of carboxylic acids are due to the ability of phosphonic acids to displace contaminants from the support surface. According to X-ray photoelectron spectroscopy data, the aluminium surface is always covered with carbonaceous contaminants. One can assume that they block the adsorption sites suitable for grafting. It was established that undecanoic acid is incapable of displacing all contaminants from aluminium surface, whereas decylphosphonic acid does it. This is apparently a reason for the higher degree of ordering of the grafted layer. Higher ability of phosphonic acids to displace contaminants from the support surfaces compared to carboxylic acids is likely due to greater stability of the tridentate anchoring group compared to bidentate carboxyl group.[‡]

A methodology for the formation and derivatisation of self-assembled monolayers of α,ω -alkanediyl-diphosphonic acids on conventional engineering metals, such as soft and stainless steels, aluminium, copper and brass was reported.⁴¹ Diacids with different number of methylene units $[(\text{CH}_2)_{2n}, n = 1–6]$ between phosphonic groups were studied. The surface modification was carried out in ethanol at room temperature and the treatment time was 15–30 min. Prior to modification, 1 equiv. of sodium hydroxide was added to the diphosphonic acid solution in order to bind only one phosphonate group to the surface and to leave the second acid group in the solution. The degree of ordering of monolayers formed increased with an increase in the length of the polymethylene chain. For instance, short-chain acids formed disordered surface layers while dodecylidiphosphonic acid formed highly ordered layers. Modification of steel surface in ethanol led to the formation of monolayers while the process in water mainly lead to formation of polylayers. The nature of this phenomenon is still unclear.

Further modification of diphosphonic acid monolayers involved complexation of free phosphonate groups with Zn^{2+} , Cu^{2+} , Mg^{2+} , Mn^{2+} , Ni^{2+} , Pb^{2+} , ZrO^{2+} , VO^{2+} , Al^{3+} , Cr^{3+} , Fe^{3+} and Ce^{3+} cations. Layers thus modified could participate in complexation with organic acids and polymers containing acid groups. The cations served as linkers connecting the phosphonate groups of the grafted layer to carboxylate or phosphonate groups of the 'incoming' acids. The thermal stability of such layers is rather high. For instance, thermal decomposition of a layer

‡ The ability to displace contamination from sorption sites is governed by the energy of the bond between the displacing group and the surface (other conditions being equal, the higher the denticity the higher the bond energy).

formed by a diphosphonic acid in the presence of Zn^{2+} cation linker in air begins at 250 °C. When the process is completed, a phosphate phase was left on the surface.

The action of a copolymer of ethylene and methacrylic acid on diphosphonic acid monolayer films results in a very strong composite. Composites based on long-chain diphosphonic acids efficiently inhibit metal corrosion in 5% hydrochloric acid, whereas composites based on short-chain diphosphonic acids exhibit no protective effect; moreover, in some cases corrosion of metal surfaces is enhanced.⁸

It should be noted that metal-modified monolayers possess a surprisingly high stability against organic acids. In particular, complexation of such layers with such a strong acid as perfluorooctanoic acid did not lead to destruction of the grafted layer.

Thermal stability and stability in various solvents (in particular, water) are important parameters of grafted layers. They determine the possibility of using grafted layers in liquid and gas chromatography, in catalysis, for corrosion protection, etc.

The dependence of the grafting density of alkylphosphonic acids on $\gamma\text{-Al}_2\text{O}_3$ surface on the structure of alkyl group and on the amount of the modifier employed was studied.⁸ It was shown that alkylphosphonic acids readily interact with the oxide surface. In all cases the granulometric composition of oxide particles changed significantly, namely, relatively large oxide particles (100–200 μm) were transformed into small particles at most 2 μm in diameter. This is due to the fact that the interaction of alkylphosphonic acids with Al_2O_3 is not stopped at the stage of monolayer formation (grafting). The grafted phosphonic groups interact with the surface AlOH fragments to give aluminium phosphonate and the starting particles are destroyed, which is confirmed by high content of carbon in the samples obtained.

The dependence of the grafting density on the amount of modifier is strongly different for normal and branched alkyl groups. For instance, for *tert*-butylphosphonic acid the maximum grafting density is $\sim 2.5 \text{ nm}^{-2}$ and remains almost unchanged as the content of the modifier in the reaction mixture increases. In the case of isopropylphosphonic acid the grafting density slightly increases with an increase in the modifier concentration, whereas for *n*-butylphosphonic acid the grafting density increases to almost complete consumption of modifier in the reaction mixture.

A study⁸ of the hydrolytic stability of the grafted layers obtained showed that it is maximum, but not too high, in the range of neutral pH values (grafting density of the samples stored for 2 days in an aqueous medium at room temperature decreased by about 15%), being even lower in acid and alkaline media. The pore volume in the modified support was studied in relation to the type of the modifier and to the modification conditions. In most cases, modification strongly affects the pore volume in the support.

A thermogravimetric study of thermal stability of phosphonic acid monolayers on alumina surface was reported.¹⁹ The modified samples exposed to nitrogen atmosphere showed a dramatic mass loss in the temperature interval 200–600 °C due to degradation of the grafted layer. Interestingly, the degradation onset temperature (200–250 °C) and the maximum mass loss temperature (400–450 °C) depend only slightly on the support nature. The activation energy of the degradation process ($265 \pm 15 \text{ kJ mol}^{-1}$ for the samples under study) behaves analogously. According to IR spectroscopy and elemental analysis data, after degradation of the grafted layer the support surface is covered with small amounts of carbon (mainly in the form of carbides) and the total phosphorus (as phosphates). It is significant that the grafted layers in air remain almost as stable as in inert atmosphere; the only exception is a decrease in the maximum mass loss temperature by 50–100 °C.

The thermal stabilities of layers of phosphonic acids, alkylsilanes (RSiH_3) and alkyltrimethylchlorosilanes supported on

Al_2O_3 surfaces were compared.¹⁹ The thermal stability of the RSiH_3 layers is similar to that of the phosphonic acid layers while alkyltrimethylchlorosilane layers are much less stable.

A computer simulation study of the reaction of vinylphosphonic acid with the (0001) face of alumina and its energy characteristics was reported.⁴² In this system the acid molecules are attached to the support surface in a tripodal fashion.^{43,44} Because of this, three types of sorption sites capable of interacting in such a manner were studied.⁴² They differed in distances between adjacent hydroxyl groups and between the aluminium ion lying below the surface and the phosphorus atom. Additionally, bi- and monodentate interactions of vinylphosphonic acid with the surface were also simulated.

According to calculations, the binding enthalpy of vinylphosphonic acid depends on the geometry of the sorption site and on the distance from the phosphorus atom to the aluminium ion located under the surface plane. It was found that tripodal binding is characterised by the largest negative enthalpy, while monodentate binding by the smallest negative enthalpy. The arrangement of the vinyl fragment relative to the tridentate anchoring group has no effect on the enthalpy of reaction. The Al-O-P bonds that anchor the modifier molecule on the support surface are mainly ionic, with a small contribution of covalent bonding.

2. Phosphonates

Compared to phosphonic acids, phosphonates are much more rarely used for the modification of alumina. There are only a few studies on surface modification using this class of compounds. In particular, a study³⁴ on the modification of alumina with diethyl phenylphosphonate revealed the formation of monolayer diethyl phenylphosphonate film on the surface and the lack of bulk phase of aluminium phosphonate.[†] The modification of $\gamma\text{-Al}_2\text{O}_3$ surface with diethyl *n*-butylphosphonate also ceases at the stage of monolayer formation; no bulk phase of aluminium phosphonate was also observed. However, the grafting density attained under these conditions was low ($\sim 0.9 \text{ nm}^{-2}$).

The authors of a gas chromatographic study⁴⁵ of $\gamma\text{-Al}_2\text{O}_3$ surface modified with diethyl *n*-butylphosphonate reported a procedure for fabrication of coatings with high coverage (3.4 nm^{-2} , or about 70% of monolayer). The modified sorbents are significantly different from the starting Al_2O_3 and from alumina coated with squalane (20 mass %), being similar in properties to silica. This was attributed to the effect of the phosphoryl groups of grafted ester molecules that interact with the acid sites on the oxide surface, thus efficiently making the surface less accessible to the adsorbate.

The density of grafting of diethyl phosphonates on $\gamma\text{-Al}_2\text{O}_3$ surface was studied in relation to the grafting conditions.⁹ The highest grafting density ($4.5\text{--}5.0 \text{ nm}^{-2}$) was achieved upon heating of an alumina-ester slurry at 120 °C for 20 h. It should be noted that, despite all advantages, the procedure requires a consumption of large amount of the modifier. Similar grafting density values were also achieved using a method involving the coating of oxide surface with small amounts (sufficient for the formation of 2–3 monolayers) of modifier in a volatile solvent followed by evaporation of the solvent and heating of the support at 120 °C for 20 h. Changes in the pore volume in the support upon modification of Al_2O_3 with phosphonic acid esters were estimated.⁹ It was shown that this parameter decreases only slightly (by a few per cent) in the course of modification, which is comparable with the accuracy of its determination.

A number of studies are devoted to adsorption of esters of various phosphorus-containing acids (in particular, dimethyl

[§] Diphosphonic acid monolayers themselves almost do not inhibit metal corrosion by 5% hydrochloric acid.

[†] Seemingly, in this case it is possible to avoid destruction of the support, which is observed in the modification of Al_2O_3 with free phosphonic acids or their bis(trimethylsilyl) esters.

methyl phosphate) from the vapour phase on the surfaces of various oxides including Al_2O_3 . These studies are of considerable interest because the authors reported a comprehensive study of the interaction between these compounds and the oxide surface.

In particular, chemisorption of phosphoric acid, trimethyl phosphate, methyl and dimethyl methylphosphonates on bare and oxidised (111) faces of alumina was studied.⁴⁶ Preliminary chemisorption studies of dimethyl methylphosphonate on the (111) face of platinum,⁴⁷ (100) face of rhodium⁴⁸ and on alumina surface⁴⁹ showed that the process begins with the donor–acceptor interaction of the phosphoryl oxygen atom with the surface. The energy of the donor–acceptor bond formed can be rather high ($\sim 58 \text{ kJ mol}^{-1}$ according to Ref. 48). Desorption of such samples occurs only upon heating to high temperatures. Noteworthy is that not dimethyl methylphosphonate but products of its decomposition (H_2 , H_2O , CO , CO_2 , CH_4 and MeOH) are desorbed. Decomposition of ester molecule begins with cleavage of the $\text{P}=\text{O}(\text{C})$ bonds followed by cleavage of the $\text{P}-\text{C}$ bonds at higher temperatures. Taking sorption of trimethyl ester of phosphorous acid on the (110) face of iron as an example, it was shown⁵⁰ that sorption is accompanied by the formation of grafted methoxyl groups, which decompose to carbon monoxide and hydrogen at high temperatures.

Adsorption of dimethyl methylphosphonate on the (111) face of aluminium cleaned from the oxide film is accompanied by essential degradation of the ester molecule, as indicated by desorption of alkanes and alkenes from the surface and by the formation of a graphite-containing surface phase. A dimethyl methylphosphonate layer formed on the surface of oxidised aluminium is much more stable. According to X-ray photoelectron spectroscopy data, the ester bonds $\text{P}-\text{O}-\text{C}$ are rapidly cleaved to form $\text{Al}-\text{O}-\text{P}$ bonds while the $\text{P}-\text{C}$ bond remains stable up to 550 K. [It should be noted that exposures of the gaseous ester to the surface were rather low, namely, from 0.5×10^{-4} to 1.0×10^{-4} Torr s (see Ref. 49).]

Sorption of dimethyl (diisopropyl, diphenyl) methylphosphonates on Al_2O_3 surface was studied by tunnelling electron microscopy.⁵¹ The surface of Al_2O_3 was formed by plasma oxidation of Al films. Experiments were carried out in the temperature interval from 200 to 673 K; the diisopropyl and dimethyl esters were deposited from the gas phase (exposure of 1 Torr s) and the diphenyl ester was applied from 0.025 M solution in hexane.

At sorption temperatures below 295 K, adsorption of the esters on the surface involves formation of donor–acceptor bonds between the phosphoryl oxygen atoms and surface Al atoms. Above 295 K, decomposition of the dimethyl and diphenyl esters begins with cleavage of one ester bond $\text{P}-\text{O}-\text{C}$ and formation of one $\text{Al}-\text{O}-\text{P}$ bond. In other words, layers of grafted methyl methylphosphonate and phenyl methylphosphonate groups are formed on the surface. In the case of diisopropyl ester the process begins only at temperatures above 373 K, which seems to be due to considerable steric hindrance produced by the isopropyl groups. At temperatures above 473 K, the second methoxyl group of the grafted methyl methylphosphonate decomposes and a layer of methylphosphonate groups is formed on the surface (methylphosphonate groups are stable in inert atmosphere up to 750 K). Elimination of the second phenoxyl group from the grafted phenyl methylphosphonate occurs only at 673 K. The mechanism of the interaction of these three esters with Al_2O_3 surface was documented.⁵¹

A similar study⁴⁹ of adsorption of gaseous dimethyl methylphosphonate on the surface of Al_2O_3 film was carried out in the temperature range from 200 to 673 K at exposures from 3×10^{-4} to 10 Torr s. The results obtained were in excellent agreement with the published data⁴⁶ on sorption of dimethyl methylphosphonate. It was also pointed that sorption of methyl methylphosphonate proceeds by the same mechanism as sorption of carboxylic acids. In both cases, interaction of the surface hydroxyl group with the proton of carboxylic acid (or methyl methylphosphonate) and interaction of the carbonyl (or phosphoryl) oxygen atom with the

surface Lewis acid site is accompanied by the formation of a water molecule and a modifier molecule attached to the surface in bidentate fashion.

Sorption of dimethyl methylphosphonate without dissociation can proceed by two mechanisms.⁴⁹ One of them involves formation of hydrogen bonds between the phosphoryl oxygen atoms and surface hydroxyl groups while the other involves formation of a donor–acceptor bond of the same oxygen atom with a surface Lewis acid site. In the latter case the energy of the bond between the ester molecule and alumina surface (~ 100 – 120 kJ mol^{-1}) is about four times higher than in the former. A product of sorption proceeding by the first mechanism can be detected based on the shift of the IR absorption band of the surface hydroxyl groups from 430 to 415 cm^{-1} . Actually, such a product was detected in a study of low-temperature (200 K) sorption of dimethyl methylphosphonate. However, IR spectroscopy data showed that the surface of the starting oxide rapidly takes its initial appearance, from which it follows that almost all amount of ester is desorbed from the surface at this temperature.

One can assume that the preferred mechanism of molecular sorption involves formation of hydrogen bonds. This is in agreement with the fact that at 295 K some amount of chemisorbed ester (product of either donor–acceptor interaction or dissociative sorption) is present on the surface of non-dehydroxylated Al_2O_3 in addition to a rather low concentration of surface Lewis acid sites.

The IR spectra support the dissociative mechanism of sorption. In particular, this is confirmed by the detection of methanol formation. However, it is still unclear whether or not does dissociative sorption follow the donor–acceptor interaction. In order to answer this question, adsorption of trimethylphosphine oxide on the surface of Al_2O_3 was studied.⁴⁹ The Lewis basicity of this compound is similar to that of dimethyl methylphosphonate, however trimethylphosphine oxide cannot be dissociatively sorbed under these conditions. It was shown that trimethylphosphine oxide is bound to the surface to a temperature of 473 K, which indicates a strong interaction between the molecule and the surface. At the same time phosphonic acid esters are known to possess relatively low reactivities, so the interaction of inactivated ester molecule with such nucleophiles as the hydroxyl groups of Al_2O_3 surface is unlikely. From this it follows that dissociative adsorption is preceded by the formation of donor–acceptor bonds between the phosphoryl oxygen atom and surface Lewis acid site. Probably, in this case the ester groups displace the water molecules and hydroxyl groups bound to the Lewis acid sites. It was also shown that hydroxylation of the surface has little effect on the results of grafting, thus substantiating the last-mentioned assumption.

Dissociation of the second methoxyl group in methyl methylphosphonate grafted on the surface is difficult to proceed. Even at 673 K, only 60% of methoxyl groups are eliminated from methyl methylphosphonate attached to the surface.

3. Other phosphonic acid derivatives

Chemisorption of isopropyl methylphosphonofluoridate on Al_2O_3 was studied.⁵² It was shown that at room temperature the grafting of ester molecules on the surface is accompanied by selective elimination of HF. The grafted molecules gradually decompose, which results in liberation of propene and formation of a monolayer of methylphosphonate molecules on Al_2O_3 surface. At 295 K, the process is rather slow (only $\sim 2\%$ of grafted monoester groups are decomposed) but accelerates on heating.

Modification of $\gamma\text{-Al}_2\text{O}_3$ surface with phosphonodichloridates was reported.⁹ The dichloridates interact with the surface rapidly under mild conditions. It was found that this type of modification radically changes the granulometric composition of $\gamma\text{-Al}_2\text{O}_3$ particles. Namely, relatively large particles (100–200 μm in diameter) are transformed to fine dust (particles at most 2 μm in diameter). The pore volume in the support abruptly (by an order of magnitude) and uncontrollably (it can either increase or

decrease) changes in the course of modification. These data and an abnormally high grafting density of the phosphonodichloridate molecules ($\sim 6 \text{ nm}^{-2}$) indicate that the interaction is accompanied by degradation of the particulate surface layer and formation of aluminium phosphonate and, probably, aluminium chloride phases.

The interaction of $\gamma\text{-Al}_2\text{O}_3$ particles with 0.1 M aqueous potassium *n*-octylphosphonate $\text{n-C}_8\text{H}_{17}\text{P}(\text{O})(\text{OK})_2$ was investigated in the same study. It was shown that the salt slowly reacts with $\gamma\text{-Al}_2\text{O}_3$ surface (the grafting density of phosphonate groups is only 1.2 nm^{-2} after 100 h of modification). The modification is accompanied by dispersion of the oxide particles, which indicates degradation of the surface layer.

4. Phosphinic acids

Di-*n*-butylphosphinic acid interacts with $\gamma\text{-Al}_2\text{O}_3$ to give an aluminium dibutylphosphinate surface layer.⁹ The grafting density is very high (4.8 nm^{-2}). The interaction is accompanied by dispersion of the support, being indicative of degradation of the surface oxide layer.

The hydrolytic stability of the coating obtained is relatively high (phosphoryl oxygen atom forms a rather strong donor–acceptor bond with the Lewis acid site), namely, the grafting density remains almost unchanged after two days of treatment with aqueous dioxane in the range of pH values from 2 to 7. However, the grafting density appreciably decreases beyond the limits of this interval of pH values.

IV. Modification of titania surface

Interest of researchers in the chemical modification of titania surface is due to the wide use of metallic titanium owing to unique properties of the material (high strength, corrosion resistance, relatively low density). A significant advantage of titanium consists in its good biocompatibility, which makes it possible to use this material for fabrication of bone prostheses. Being a wide-band semiconductor, titania has found applications in solar energy converters and in photocatalysis.

Modification of TiO_2 surface (metallic titanium is always covered with a dioxide layer) makes it possible to vary the properties of titanium surface over a wide range. Here, conventional organosilicon modifiers are inappropriate because they do not form dense and stable coatings. At the same time organic phosphorus acids and their derivatives readily react with TiO_2 and form dense ordered layers on its surface. Moreover, as in the case of Al_2O_3 , these modifiers significantly improve the uniformity and non-specific character of titania surface, *i.e.*, its inability to be involved in any interactions except for the van der Waals ones.

1. Phosphonic acids

A pioneering study on the modification of TiO_2 surface with phosphonic acids dates back to the early 1980s.⁵³ In the last decade the emphasis was placed on the investigation of fine details of the grafted layer morphology.

Modification of TiO_2 surface with phenylphosphonic acid under different conditions makes it possible to obtain different coatings.³⁴ At room temperature, treatment of TiO_2 surface causes coordination of the phosphoryl oxygen atom to acid sites of the oxide surface followed by condensation of P-OH and Ti-OH groups (analogously to the interaction with alumina). Modification of TiO_2 with phenylphosphonic acid under severe conditions (boiling in water or toluene in a tube at 120°C for 24 h)

results in the formation of a bulk phase of titanium phosphonate. This phase can be detected in ^{31}P NMR spectra. The amount of titanium phosphonate formed in water exceeds that formed in toluene. The content of carbon in such samples corresponds to a grafting density of 10 nm^{-2} . Reduction of the surface treatment time to 5 h causes a decrease in the grafting density, which in this case corresponds to a monolayer coverage.

Modification of TiO_2 surface with bis(trimethylsilyl) phenylphosphonate under severe conditions can also lead to formation of bulk phosphonate phase, however the content of this phase is lower compared to the modification with phenylphosphonic acid.⁵⁴ The authors assumed that the formation of this phase involves migration of the trimethylsilyl group from the adsorbed modifier molecule to the oxygen atom of titanoxane fragment followed by cleavage of one Ti-O bond. Diethyl phenylphosphonate forms only a monolayer coating on TiO_2 surface under these conditions.

An IR spectroscopic study⁵⁴ of the structure of the grafted layers showed that the IR spectra of the samples modified with phenyl phosphonates exhibit neither P=O , Si-C , nor C-O absorption bands. Based on this fact, it was concluded that the molecules of phosphonic acid esters are mainly attached to the surface of TiO_2 in a tridentate fashion. At the same time the IR spectra of the samples modified with phenylphosphonic acid exhibit a P-OH band, which points to bidentate bonding of a fraction of the modifier molecules to the surface (heating of the modified samples at 120°C leads to disappearance of P-OH groups).

Photolysis of P-C bonds on the surface of the modified samples under the action of soft UV radiation (350 nm) was also investigated in the study cited.⁵⁴ It was found that irradiation of the samples placed in water causes cleavage of the P-C bonds and subsequent formation of a surface layer of titanium phosphate, whereas these bonds are retained upon irradiation of the samples placed in toluene.

Modification of TiO_2 surface with octadecylphosphonic acid⁷ does not lead to complete coverage; the surface coverage is $\sim 61\%$ of the monolayer (the use of short-chain alkylphosphonic acids causes the formation of dense monolayers).⁵⁵ Most likely, the octadecylphosphonic acid molecules are attached to the surface in a bidentate fashion (grafted layer contains free P-OH groups). According to ^{13}C NMR spectroscopy data, these layers are poorly ordered especially in the region of terminal chain segments.

A structure of monolayers formed by molecules of long-chain phosphonic acids deposited on the surface of nanocrystalline titania using Langmuir–Blodgett techniques was reported.⁵⁶ Unfortunately, the authors gave no indications of the character of the bonding between the acid molecules and the surface; because of this, it remains unclear whether or not this process can be considered as chemical modification of the surface.

A study of self-assembly of ordered monolayers of phosphonic acids on hydroxylated native oxide layer of metallic titanium⁵⁷ showed that monolayers resulted from surface modification performed at room temperature can be removed with ease by washing the samples with organic solvents, *e.g.*, hot tetrahydrofuran. (In this case low surface coverage was explained by inertness of the oxide film on the surface of metallic titanium to phosphonic acids.⁵⁸) Heating of the modified samples at 120°C significantly improves the stability of the grafted layers, however attempts to fabricate a dense coating in one step failed because of a high content of physisorbed acid molecules on the surface. By repeating the modification–heating–washing cycle it is possible to attain a higher surface coverage. A monolayer coating is formed only after six treatment cycles. Analysis of AFM micrographs showed that the acid molecules chemisorbed on TiO_2 surface form roundish ‘islands’. According to IR spectra, the ‘islands’ are characterised by ordered molecular arrangement similar to crystalline one.

Grafting of ω -carboxyalkylphosphonic acids[†] on TiO₂ surface occurs selectively and involves formation of a system of Ti—O—P bonds (carboxyl group remains unattached to the surface). Here, a high surface coverage is attained after a single modification cycle, which was explained by the interactions between carboxyl groups of the modifier molecules.⁵⁷ Monolayers thus formed are rather stable and cannot be removed by washing.

The selectivity of grafting of ω -carboxyalkylphosphonic acids RP(O)(OH)_2 with $\text{R} = (\text{CH}_2)_n\text{CO}_2\text{H}$ on the surface of titania through the phosphonic group was confirmed in a more recent study.⁵⁹ The conformations of $(\text{CH}_2)_n\text{CO}_2\text{H}$ chains in the grafted layer formed depends on the chain length. Ordered quasi-crystalline all-*trans* layers[‡] are formed only at $n \geq 16$ (proportion of *gauche*-defects in such chains is low). The acid with $n = 12$ also forms a sufficiently ordered layer with preferred *trans*-conformation of chains, but in this case the proportion of *gauche*-defects is high (at room temperature, alkylphosphonic acids with this chain length do not form ordered layers). Acids with shorter chain length form disordered layers. The possibility of polylayer formation on the surface was also reported; however, polylayers are removed by washing the samples with polar solvents (*e.g.*, acetone).

Ordered layers undergo a thermally induced transition from the quasi-crystalline to a 'liquid-like' state. The conformational mobility of alkyl chains in the layers formed by ω -carboxyalkylphosphonic acids is lower compared to that of the layers formed by alkylphosphonic acids with the same number of carbon atoms. This can be explained by the presence of hydrogen bonds between carboxyl groups (according to IR spectroscopy data, all carboxyl groups of the grafted layer are involved in the formation of hydrogen bonds). The hydrogen bonds are completely disordered, which dramatically differs layers formed by such acid molecules from the layers of ω -mercaptoalkylcarboxylic acids on gold nanoparticles.^{60, 61}

Similar results were obtained in a study⁶² on the modification of titania surface with carboxyalkylphosphonic acids $\text{HO}_2\text{C}(\text{CH}_2)_n\text{PO}(\text{OH})_2$, where $n = 2, 3, 11$ and 15 . The authors pointed to bidentate bonding of these compounds to the surface through the phosphonate groups because of a large proportion of surface P—OH groups (analogous results were obtained in another study⁵⁴).

A comparative analysis⁶³ of stability of the grafted layers formed on TiO₂ (anatase) surface treated with octadecylphosphonic acid and various octadecylsilanes [with SiH₃, SiCl₃, Si(OMe)₃ and SiMe₂Cl anchoring groups] revealed the formation of highly ordered monolayers with grafting densities of $4.3\text{--}4.8\text{ nm}^{-2}$ in all cases except for the modification with dimethyloctadecylchlorosilane. Treatment with the latter compound results in the formation of a disordered layer characterised by a low grafting density (about 1.5 nm^{-2}).

The kinetic curves of sorption are similar for all modifiers and show a fast anchoring of the modifier molecules to the surface followed by a slow increase in the grafting density and gradual ordering (in those cases where ordering does occur). The sorption curves obtained are correctly described by a first-order equation with two rate constants differing by 1–2 orders of magnitude. Based on the rate constant values, the anchoring groups can be ordered as follows with respect to their activities: $\text{SiCl}_3 \gg \text{PO}(\text{OH})_2 > \text{SiMe}_2\text{Cl} > \text{Si}(\text{OMe})_3 > \text{SiH}_3$. Two types of interaction between the modifier molecules and the support surface were proposed based on the analysis of the IR spectra of the samples obtained. The modifiers capable of forming horizontal cross-links (unsubstituted trichloro- and trimethoxysilanes) gave highly

ordered layers at low surface coverages (40%–50% of the limiting coverage). This was interpreted⁶⁵ as an indication of the 'island' mechanism of modification. Contrary to this, an ordered layer of octadecylphosphonic acid molecules was formed only at high grafting densities, which indicates a uniform surface coverage similar to the case of dimethyloctadecylchlorosilane that does not form ordered layers under the conditions studied. The thermal stability of the grafted layers is rather high, namely, their degradation begins at $\sim 200^\circ\text{C}$ in air and at 300°C in inert atmosphere.

The hydrolytic stabilities of the grafted layers formed on the surface of anatase treated with octadecylphosphonic acid, dimethyloctadecylchlorosilane and octadecylsilane were compared.⁶⁴ It was established that the layers formed upon modification of anatase surface with dimethyloctadecylchlorosilane are characterised by low stability, namely, the grafted layer is completely removed from the surface after 24 h of storage in a neutral medium at room temperature. The other two layers show higher hydrolytic stabilities, the phosphonate layer being much more stable. Nevertheless, the grafting density of the phosphonate layer decreased by about 15% after seven days of hydrolysis in a neutral medium at room temperature.

A study⁶⁵ on the enthalpies of the reactions of phosphonic acids with TiO₂ surface revealed an increase in the enthalpy with an increase in the length of alkyl group. The enthalpy can even take positive values; in this case, the modification reactions are driven by the entropy factor.

2. Phosphonic acid esters

Diethyl phenylphosphonate and bis(trimethylsilyl) phenylphosphonate are also used for the modification of TiO₂ surface.³⁴ In all cases the diethyl ester formed only monolayer coatings, whereas the bis(trimethylsilyl) ester under severe conditions (boiling with support in toluene) destroyed the oxide surface with the formation of bulk titanium phosphonate phase.

The possibility of using TiO₂ as photocatalyst gave an impetus to studies on the photodegradation of phosphonic acid esters on the surface of TiO₂. A study⁶⁶ on the kinetics of photodegradation of the dimethyl and diethyl methylphosphonates in aqueous solutions showed that only physisorption of these compounds occurs on the TiO₂ surface.

Gas-phase photodegradation of dimethyl methylphosphonate supported on glass coated with a TiO₂ layer (ester concentration in air varied from 1 to 90 ppm⁻¹) results in methylphosphonic acid which interacts with the oxide surface.⁶⁷ Activity of the photocatalyst drops owing to progressive poisoning of its surface with degradation products, but can be completely recovered after several cycles of washing with distilled water.

In a study⁶⁸ of the interaction of dimethyl methylphosphonate, dimethyl phosphite and trimethyl phosphate with the surface of highly disperse TiO₂ it was established that at low temperatures adsorption of these compounds on the surface is accompanied by the formation of hydrogen bonds with surface hydroxyl groups. At higher temperatures, dissociative adsorption with elimination of methoxyl groups is observed, which ceases at $T > 473\text{ K}$. At $T > 573\text{ K}$, the P—C bonds are cleaved, which results in the formation of a phosphate phase on the TiO₂ surface.

3. Phosphinic acids and their esters

The interaction of diphenylphosphinic acid and its ethyl and trimethylsilyl esters with TiO₂ surface was studied by IR and NMR spectroscopy.⁵⁴ From the spectra of the TiO₂ samples modified with ethyl diphenylphosphinate it follows that this modifier forms a monolayer coating on the surface of TiO₂ under the conditions studied. The spectra of the TiO₂ samples treated with diphenylphosphinic acid or trimethylsilyl diphenylphosphinate exhibit complex patterns and are difficult to interpret. The authors suggested the formation of some amount of titanium diphenylphosphinate on the surface in these cases.

[†] According to IUPAC nomenclature, these compounds are called ω -phosphonoalkancarboxylic acids.

[‡] Probably, the quasi-crystalline state of the grafted layer is stabilised through the formation of hydrogen bonds between carboxyl groups.

V. Modification of zirconia surface

The surface of ZrO_2 is similar in chemical properties to the surface of TiO_2 . At the same time there is a number of significant differences between them. In particular, the concentration of hydroxyl groups on the surface of ZrO_2 is nearly 1.5 times higher than on the surface of TiO_2 and the basicity of zirconia surface is also higher than that of amphoteric titania. These features manifest themselves in the modification of ZrO_2 surface with organic acids of phosphorus and their esters.

The structure of a grafted monolayer formed by octadecylphosphonic acid molecules on the surface of ZrO_2 powder has been a subject of detailed NMR studies (Refs 69, 70). ^{31}P NMR spectra indicate a significantly non-uniform structure of the monolayer formed (the peak is rather broad, which points to different fashion of denticity of the bonding between the phosphonate group and the surface). Phosphonate groups on ZrO_2 surface are not strictly immobilised, because the corresponding reorientation time varies in the range 0.1–1 s. This is likely due to high ionicity of the $\text{Zr}-\text{O}$ bond in the surface monolayer of zirconium phosphonate.

^{13}C NMR spectra provide indications of high ordering of alkyl chains in the grafted layer and of transoid conformation for a vast majority of $\text{C}-\text{C}$ bonds in these chains. At the same time the proportion of *gauche*-defects in the grafted layer is relatively high even at room temperature and increases on heating.

The structure of layers formed on the surface of non-porous ZrO_2 nanopowder ($S_{\text{sp}} = 40 \text{ m}^2 \text{ g}^{-1}$) treated with partially deuterated octadecylphosphonic acid (deuterium atoms were introduced at the carbon atom in α -position with respect to phosphonate group) was studied by ^2H NMR spectroscopy at 200–340 K.⁷¹ It was shown that at 340 K the mobility of the anchoring phosphonate group is sufficiently high to be detected by solid state ^2H NMR echo technique. It is believed that so high reorientation rates can be explained, in particular, by bulkiness of the phosphonate group and by monodentate fashion of its bonding to the surface. Simulation of NMR spectra also shows that phosphonate groups can be anchored to the surface of ZrO_2 in different mode.

A ^1H NMR study of phosphonate monolayers on zirconia surface showed the possibility of attainment of all-*trans*-arrangement of alkyl chains.⁷ Nevertheless, here we do not deal with crystalline layers because of rather loose chain packing and large vibrational amplitudes.

The effect of the temperature and alkyl chain length on the ordering of the films formed on the zirconia surface treated with alkylphosphonic acids $n\text{-C}_n\text{H}_{2n+1}\text{P}(\text{O})(\text{OH})_2$ ($n = 8-18$) was studied.⁷² It was found that the acids with $n < 16$ do not form ordered layers on the surface of ZrO_2 at room temperature. The acids with $n = 16$ and 18 form layers with almost all-*trans* alkyl chains at room temperature, but the transition temperature of the hexadecylphosphonic acid layer to the disordered state is only slightly higher than room temperature. The transition temperature of a monolayer formed by octadecylphosphonic acid molecules is about 50 °C; however, in this case the alkyl chains are disordered at lower temperatures compared to crystalline zirconium phosphonates with the closest packing of alkyl chains. Close packing of alkyl chains in the layer is hampered by the phosphonate group whose cross-section is $\sim 0.25 \text{ nm}^2$ (cf. 0.18 nm^2 for methylene unit).

In the monolayers studied the tilt angle is 31°. ⁷² This is somewhat smaller than the equilibrium value for alkylphosphonate bound to the surface in a tridentate fashion; however, this deviation can be compensated by strengthening of the van der Waals interactions between alkyl chains in the case in point.

Structures formed on the surface of ZrO_2 nanopowders (two samples with an average particle size of 5 and 30 nm were used) treated with ω -carboxyalkylphosphonic acids with the spacer length of 2, 3, 11 and 15 methylene units were studied.^{59, 60} The results obtained were to a great extent similar to those obtained

for TiO_2 (see Section IV), however there is a number of distinctions. First, no $\text{P}-\text{OH}$ groups were detected within the layer grafted on ZrO_2 ; this probably indicates a stronger anchoring of phosphonate groups to the ZrO_2 surface. Second, a trend to formation of polylayer coatings on ZrO_2 surface is observed (the second and other layers are bound to the surface and first layer through hydrogen and van der Waals bonds). These layers are stable to multiple washing with acetone, while washing with methanol or aqueous acetone results in removal of the second and subsequent layers.

The selectivity of bonding between the modifier molecules and ZrO_2 surface is also lower than in the case of TiO_2 surface. Namely, the surface of the ZrO_2 powder with a particle diameter of 5 nm contains a small amount of ω -carboxyalkylphosphonic acid molecules bound to the surface through the carboxyl group (this was not observed for the powder with a particle diameter of 30 nm).

The formation of octadecylphosphonic acid monolayers on the surfaces of ZrO_2 and zirconated silica was studied.⁷ In both cases ordered monolayers were formed, although the end groups of the grafted chains were disordered. The monolayer on zirconated silica is much more ordered than on ZrO_2 . The limiting surface coverage on ZrO_2 was not attained (maximum grafting density was $\sim 73\%$ of the limiting value). The grafting density on zirconated silica is only 26% of the theoretical value; this is probably due to nonuniform coating of the silica surface with the ZrO_2 layer (long-chain phosphonic acids do not interact with silica).

A number of structurally similar types of phosphonate groups were found on the surfaces of the modified ZrO_2 samples. This was associated with the presence of different types of sorption sites on the surface of ZrO_2 .⁷ The formation of a small amount of zirconium phosphonate on the surface of zirconated silica was detected by ^{13}C NMR spectroscopy.

The surface of ZrO_2 was also modified⁷³ with regioregular amphiphilic polythiophenes containing phosphonic group in side chains.⁸ It was found that such polythiophenes form self-assembled monolayers on the surface.

A comparison of the structures and hydrolytic stabilities of monolayers formed on the surface of monoclinic ZrO_2 crystal modified with octadecylphosphonic acid and dimethyloctadecylchlorosilane showed⁶⁴ that the acid forms highly ordered surface monolayers with a grafting density of $4-5 \text{ nm}^{-2}$ while the silane forms disordered layers with a grafting density of at most 2.2 nm^{-2} . Hydrolysis was performed using tetrahydrofuran–water mixtures (tetrahydrofuran was added in order to attain better wettability of the modified support). The hydrolytic stability of the layers formed by the modifier with the dimethylchlorosilyl anchoring group is low. Namely, the grafted layer is completely destroyed after 24 h in neutral medium at room temperature. Layers formed by octadecylphosphonic acid molecules are much stronger bound to the surface. Here, an insignificant mass loss (about 2%) was observed after a week of hydrolysis at pH values from 1 to 10 at room temperature. At 65 °C, the stability of layers somewhat decreases but remains rather high.

The thermal stability¹⁹ and the enthalpy of formation⁶⁵ of phosphonate layers on ZrO_2 surface are similar to the corresponding parameters of phosphonate layers supported on TiO_2 .

VI. Modification of iron oxide surfaces

Studies on the interaction of organophosphorus acids and their esters with iron oxide surfaces are mainly aimed at fabricating stable and thin anticorrosion coatings supported on iron and iron alloys.

§ Multilayered ordered structures that can be formed by such compounds have been documented.^{74, 75}

1. Phosphonic acids

Phosphonic acids are widely used for modification of the surfaces of iron (usually, coated with a native oxide layer) and iron oxides. Most studies on the modification of iron surface with phosphonic acids are carried out to solve certain applied problems; however, attention has also been paid to the problem of the structure of the grafted layer. The structure of the octadecylphosphonic acid layer grafted on amorphous Fe_2O_3 particles synthesised⁷⁶ by sonication of a solution of iron carbonyl in decane has been reported.⁷⁷ Thermogravimetric analysis of the modified Fe_2O_3 particles 5–10 nm in diameter showed that thermal decomposition of the grafted octadecylphosphonate layer occurs at 340 °C. It was established that the phosphonate group is anchored to the surface in at least bidentate fashion and that thermal desorption involves cracking of hydrocarbon chains of the modifier.

The magnetisation of the iron oxide particles coated with octadecylphosphonic acid is three times lower than that of identical samples modified with sulfonic acids and at least an order of magnitude lower than the magnetisation of the starting iron oxide or iron oxide modified with alkanolic acids.^{78,79} This was explained by the action of the phosphonic acid molecules that change the spin state of the near-surface Fe^{3+} ions by promoting their transition from the high-spin to the low-spin state (as a result of formation of donor–acceptor bonds between these ions and the phosphoryl groups of the modifier) and by the fact that unoccupied phosphorus d-AOs enhance the magnetic interaction between neighbouring Fe^{3+} ions.

The assumption that the decrease in magnetisation is due to breakdown of Fe_2O_3 particles under the action of phosphonic acid is apparently incorrect. Indeed, sulfonic acids are much stronger than phosphonic acids and surface modification with the former should result in greater reduction of the magnetisation, which is not observed actually. Additionally, the specific surface area of the Fe_2O_3 particles modified with octadecylphosphonic acid is almost the same as that of the particles modified with carboxylic acids (71.5 and 72 m² g^{−1}, respectively). An IR study of the structure of the grafted layer showed that it is highly ordered and that the packing of alkyl groups in this layer is similar to crystal packing.

A dramatic decrease in the magnetisation of the iron oxide particles modified with phosphonic acids was also detected in an EPR study.⁸⁰ No broadening of the microwave absorption line of the modified particles was observed on cooling (this behaviour is characteristic of superparamagnetic particles).

An electron microscopic study carried out by the same authors⁸⁰ showed that the modified particles do not dissolve in phosphonic acids. These results as well as EPR spectroscopy data suggested that the reason for different magnetisation of the starting and modified particles consists in different types of the interaction of surface iron atoms (as was mentioned in Ref. 77). Most probably, antiferromagnetic interactions realise on the surface of the particles modified with phosphonic acids,⁸¹ which eventually leads to superantiferromagnetic particles.⁸²

The procedure for self-assembly and derivatisation of monolayers of α,ω -alkanediphosphonic acid molecules on the surfaces of soft and stainless steels⁴¹ is similar to that described in Section III.

2. Phosphonic acid esters

Dimethyl methylphosphonate adsorbed on $\alpha\text{-Fe}_2\text{O}_3$ surface from the gas phase at 170 K readily interacts with the oxide surface by the dissociative mechanism involving elimination of methoxyl groups.¹¹ At 250 K, both methoxyl groups dissociate and a methylphosphonate layer is formed on the surface. Further heating leads to decomposition of the ester with evolution of volatile products (carbon oxides, water, methanol, hydrogen, formic acid) and formation of iron phosphate on the surface. Dissociative chemisorption with elimination of two MeO groups at temperatures above 250 K was also observed in the modification of the (110) face of iron crystal with trimethyl phosphate.⁵⁰

Modification of iron powder with diethyl esters of octyl- and tetradecylphosphonic acids is highly efficient.²⁰ The coatings obtained exhibited good corrosion resistance (no corrosion was observed even after a few weeks of storage in aerated 0.1 M NaCl solution). The conductivities of the modified powders remained rather high, being almost equal to the conductivity of untreated iron powder freshly cleaned from native oxide film. This indicates that the monolayer coating thus formed presents no difficulties to electron transport (electron tunnelling effect manifests itself at distances of the order of the thickness of monolayer coating). This differs the phosphonate coatings from the triethoxysilane-based ones. The latter also efficiently protect iron from corrosion, but reduce the conductivity by three to six orders of magnitude (probably, due to formation of a thick insulating polymer layer on the surface). The phosphonate coatings also have a high thermal stability, namely, they protect iron from oxidation in air up to 350–400 °C.

VII. Other oxides and metals

The action of diethyl methylphosphonate vapours on tin dioxide at 300 °C causes dissociative sorption of the ester with elimination of ethylene (from one EtO group) and formation of ethyl methylphosphonate layer grafted on SnO_2 surface.⁸³ Raising the temperature leads to elimination of the second EtO group. Diethyl methylphosphonate is used as a model compound in detecting organophosphorus compounds (in particular, warfare agents) using semiconductor (SnO_2) sensors.⁸³

A study⁵⁶ of monolayer films formed by eicosylphosphonic acid molecules deposited on SnO_2 surface using Langmuir–Blodgett technique showed that at a surface area per acid molecule of 0.23 nm² the tilt angle is 17°; reduction of the surface area to 0.2 nm² causes the tilt angle to decrease to 16°. Unfortunately, the nature of bonding between the acid molecules and the SnO_2 surface was not studied; therefore, it is unknown whether the chemical grafting of the acid molecules on the surface or physisorption occurs.

The formation of eicosylphosphonic acid layers on silver and gold supports was also investigated in the study cited,⁵⁶ and again the nature of sorption was not studied. However, one can assume that no chemical grafting occurs, because bare gold surfaces do not adsorb phosphonic acids⁸⁴ while a layer of phosphonic acid molecules physisorbed on a gold substrate can be removed with ease by washing with organic solvents (even isooctane). Taking into account the fact that monolayer films formed by alkanethiol molecules that readily interact with the surface of gold substrates exhibit not too high oxidation stability (oxidation causes desorption and degradation of the grafted layer), elaboration of methods for modification of gold surfaces remains topical.

A procedure involving deposition of submonolayers formed by copper atoms on the surface of gold supports followed by modification of the surface with phosphonic acids was proposed.⁸⁴ A grafted layer thus obtained is stable and cannot be removed from the surface using such solvents as isooctane, ethanol and water. Octadecylphosphonic acid monolayers on copper-plated gold surface show the water and hexadecane contact angles of 111° and 28°, respectively, which indicates a high density and ordering of the layers. This was also substantiated by IR spectroscopy data.

At the same time IR spectroscopy data revealed a larger tilt angle of alkyl groups of octadecylphosphonic acid molecules compared to alkanethiol molecules grafted on gold surface. This is likely due to the fact that the amount of copper on the gold surface is less than that required to provide a monolayer coating. According to X-ray photoelectron spectroscopy data, the copper : oxygen : phosphorus ratio at the surface is 2 : 3 : 1, i.e., there is one phosphonate group per two copper atoms.

The layer formed by octylphosphonic acid molecules on copper-plated gold surface is disordered and has a liquid-like structure.⁸⁴ The octadecyl- and octylphosphonic layers are 2 and

0.8 nm thick, respectively (ellipsometry data). Electroactive 11-ferrocenylundecylphosphonic acid can also be grafted on copper-plated gold surface. However it does not form ordered monolayers (probably, due to the bulkiness of the ferrocenyl group, which precludes the close packing of alkyl groups). The density of grafting of ferrocenylundecylphosphonic acid molecules on the surface is $4 \mu\text{mol m}^{-2}$ (see Ref. 84), which is somewhat lower than the value obtained for thiols ($4.3 - 5.6 \mu\text{mol m}^{-2}$).⁸⁵⁻⁸⁸

The formation of monolayers of α,ω -alkyldiphosphonic acid molecules on the surface of copper, brass, tantalum and chromium was reported.⁴¹ The properties of these monolayers are generally similar to those of corresponding monolayers formed on aluminium and titanium (see Section III). Monolayer films of ω -carboxyalkylphosphonic acids formed on tantalum surface⁸⁹ are similar to the layers prepared on aluminium surface (see Section III). Self-assembled monolayers formed by octadecylphosphonic acid molecules on tantalum surface was also studied.⁹⁰ A rather high degree of ordering of alkyl groups in these layers is similar to that observed for alkylthiol layers formed on gold surface.

Monolayer films formed by *n*-amyl- and *n*-tetradecylphosphonic acid molecules on zinc surface were prepared⁹¹ by treating a polished zinc plate with solutions of corresponding acids in ethanol or aqueous ethanol. Both acids form dense layers, rather highly ordered for C_{14} and much lower ordered (almost disordered) for C_5 . The water and hexadecane contact angles for the tetradecylphosphonic acid layer almost coincide with the values characteristic of fully methylated surface, thus confirming high density and ordering character of the layer. Nevertheless, such layers do not protect zinc from electrochemical corrosion.

Dimethyl methylphosphonate vapours interact with tungsten trioxide surface⁶⁸ similarly to the case for titania (see Section IV). The only significant difference between sorption of ester on these two substrates is the formation of much stronger hydrogen bonds between the ester phosphoryl group and the surface hydroxyl groups on WO_3 . This was attributed to a much higher Brønsted acidity of WO_3 surface compared to TiO_2 surface.

Information on the interaction of phosphonic acids with hafnia-coated silica surface is also available.^{92,93}

VIII. Applications of materials with surfaces modified with organophosphorus compounds

1. Separation membranes

One of the key avenues of practical use of phosphonic acids as modifiers of Al_2O_3 and TiO_2 surfaces is fabrication of organoceramic membranes. Such membranes were prepared⁹⁴ by chemical grafting of *n*-butylphosphonic acid on the surface of an alumina membrane. The modification was carried out in order to change the gas transport properties of the membrane, because efficient separation of gases with similar molecular masses using the initial mesoporous membrane with a pore diameter of 5 nm was impossible. Changes in the surface properties of the modified membrane provided a way to controllable variation of the contributions of different transport mechanisms and to improvement of the membrane's permeability and selectivity. *n*-Butylphosphonic acid modified membranes were used for separation of CH_4 , C_2H_6 , C_3H_8 , N_2 , H_2 and CO_2 at room temperature. The best results (high permeability and high selectivity coefficient) were obtained for the separation of a propane–nitrogen mixture. The authors pointed that the *n*-butylphosphonate layer can be removed from the surface by washing with alkali (in this case the properties of the initial membrane are recovered; if necessary, the membrane can be re-modified).

Membranes for separation of bovine serum albumin from native bovine serum by ultrafiltration were synthesised.⁵⁵ When using TiO_2 membranes, albumin is adsorbed irreversibly and cannot be removed from the membrane surface until complete denaturation. However, sorption of albumin becomes reversible

upon treatment of the membrane with *n*-butylphosphonic acid, which forms a monolayer with a grafting density of about $5 \mu\text{mol m}^{-2}$ on TiO_2 surface (this corresponds to a cross-section area of $\sim 0.3 \text{ nm}^2$). The acid modified membrane is highly hydrophobic, which precludes water transport across the membrane under the experimental conditions. Wetting the membrane with ethanol–water mixture makes the surface hydrophilic and transport of water or aqueous solutions across the membrane becomes possible. This is not accompanied by desorption of butylphosphonate groups from the surface. Albumin is not adsorbed on this membrane, being filtered with a nearly 100% efficiency.

Membranes made of alumina or silica cannot be used because of breakdown of the former and instability of grafted layers on the latter material.⁵⁵

The IR spectra of modified TiO_2 exhibit no $\text{P}=\text{O}$ and $\text{P}-\text{OH}$ absorption bands. This was interpreted as an indication of tridentate grafting of butylphosphonic acid molecules. The grafted layer can be removed from the surface by washing with a NaOH solution following a known procedure;⁹⁵ this is followed by recovery of the initial properties of the membrane.

Similar results were obtained for a ZrO_2 -based membrane.⁵⁵

2. Heterogeneous metal complex catalysts

Phosphonate anchoring groups are used for immobilisation of metal complex catalysts on solid supports. The activity of metal porphyrinate complexes immobilised on TiO_2 surface in the alkene oxidation reactions was studied.⁹⁶ Catalysts were prepared by grafting metal porphyrinates with phosphonate groups on TiO_2 surface. The authors also reported the possibility of grafting such complexes on the surface of TiO_2 electrodes, which can be used in electrochemical catalysis and in fabrication of electrochemical sensors.

The synthesis of heterogeneous metal complex catalysts based on bipyridyl complexes of rhodium and iridium grafted on TiO_2 surface was reported.⁹⁷ The complexes were grafted through phosphonate groups in the ligand side chains. These compounds exhibit a rather high catalytic activity similar to that of homogeneous analogues. The highest activity was obtained for the complexes immobilised on freshly prepared (by hydrolysis of tetraisopropoxytitanium) titania, whereas grafting on a commercially available oxide (specific surface area of $429 \text{ m}^2 \text{ g}^{-1}$) gave somewhat less reactive samples.

Phenylphosphine ligands are very often used for the synthesis of catalytically active metal complexes. The possibility of immobilisation of phosphines $\text{Ph}_2\text{P}(\text{CH}_2)_3\text{Si}(\text{OEt})_3$ on the surfaces of various inorganic oxides (MgO , TiO_2 , Al_2O_3 and SiO_2) was studied.⁹⁸ It was found that these phosphines can be easily grafted on the surfaces of Al_2O_3 and SiO_2 , but cannot be grafted on the surfaces of TiO_2 or MgO .⁹⁸ At the same time similar ligands with phosphonate anchoring groups⁹⁹ can be grafted on the surfaces of the last-mentioned two oxides.

The catalyst performance was studied⁹⁷ in relation to the pH of the medium. The highest performance was achieved at pH 5.6 and remained unchanged up to pH 12.5 for two days (the authors reported a slight increase in performance), thus indicating stability of the grafted layer at $5.6 \leq \text{pH} < 12.5$. However, at pH 12.9 the catalyst performance dramatically decreases with time due to degradation of the grafted layer.

3. Modified electrodes

Phosphonic acids are often used for modification of oxide electrode surfaces. In particular, the surface of TiO_2 (anatase) nanocrystals supported on conducting glass was modified with viologen (1,1'-dieicosyl-4,4'-bipyridinium dichloride) and eicosylphosphonic acid.¹⁰⁰ A mixture of eicosylphosphonic acid and viologen was deposited using Langmuir–Blodgett technique. At high dilution of viologen with the acid, only one viologen molecule with known orientation is adsorbed on each TiO_2 nanocrystal and no electron transfer between viologen molecules adsorbed on different nanocrystals occurs. This system can be used as photo-

sensitive electrode for a photoelectrochemical cell (such a cell is highly sensitive in the visible spectral region).

A rather large number of studies are devoted to modification of electrodes fabricated from indium–tin oxide (ITO) ceramics (91% In_2O_3 , 9% SnO_2). In particular, ITO electrodes can be modified with phosphonic acids to form a salt monolayer on the surface.¹⁰¹

The electrochemical properties of an ITO electrode modified with 2,5-bis(phosphonomethyl)hydroquinone and a ZrO_2 -coated ITO electrode were studied¹⁰² by cyclic voltammetry.[¶]

The molecules of 2,5-bis(phosphonomethyl)hydroquinone spontaneously and irreversibly react with the surface of the ITO electrode irrespective of the presence of a zirconium layer. The grafting density is $\sim 2.6 \mu\text{mol m}^{-2}$ (about 40% of theoretically possible value). The modified electrodes showed good characteristics in electrochemical molecular recognition of alkali metal and ammonium cations. Namely, they permitted the observation of unique redox peak potential shifts depending on the molar concentration of each type of cations in the range 0.01 – $1.0 \text{ mol litre}^{-1}$. The electrodes are selective to potassium cation in the presence of sodium cations. Initially, the electrochemical characteristics of the non-zirconated modified electrode almost coincides with those of the zirconated electrode, but gradually changes with time (probably, due to a lower hydrolytic stability of the grafted layer on the non-zirconated electrode). The grafted layer on the zirconated electrode was stable at $0 \leq \text{pH} < 12$.

The interaction of 6-(ferrocenyl)hexylphosphonic acid with the surface of an ITO electrode was studied.¹⁰³ This acid can be grafted on the electrode surface (the grafting density is $3.1 \mu\text{mol m}^{-2}$ or about 70% of the limiting value¹⁰⁴). The grafted layer is characterised by strong intermolecular interactions between ferrocenyl fragments. Monolayers thus obtained are stable in acetonitrile in both (ferrocene and ferricinium) forms, however protic solvents gradually destroy the grafted layer. As a result, the grafted molecules are desorbed from the surface (the process in ethanol at room temperature is slow while proceeds faster in water). Boiling of the modified samples in water leads to complete desorption of the grafted molecules from the surface.

Owing to strong intermolecular interactions between ferrocenyl fragments the modifier molecules are grafted on the support surface in 'island' fashion even at low surface concentrations. Attempts to obtain a more uniform grafting by 'diluting' 6-(ferrocenyl)hexylphosphonic acid with short-chain phosphonic acids failed. Apparently, ferrocenyl fragments interact with one another much stronger than with short alkyl chains. When dodecylphosphonic acid was used as diluent, a 'dilution' effect was observed, but attempts to efficiently isolate ferrocenyl fragments also failed. Apparently, acids with longer chains should be used in this case.

ITO electrodes are most often used as anodes in organic bilayer based electroluminescent devices, because ITO glass is transparent (optical transmission of 90%) and possesses good conducting properties; various metals can serve as cathodes. Unfortunately, the metals characterised by low work function of electron are highly reactive and readily oxidisable (e.g., calcium or a magnesium/silver alloy), which limits the lifetime of the devices.

Phosphonic acids are known to form self-assembled monolayers on the surface of ITO glass.¹⁰⁵ Using an ITO electrode coated with electron-acceptor 2-chloroethylphosphonic acid and an aluminium cathode, the threshold voltage was considerably reduced¹⁰⁶ to a value characteristic of a much less stable magnesium–silver electrode. The use of the modified ITO electrode eliminates the need of electrodes made of highly reactive metals and makes it possible to exclude a factor that limits the operational life of electroluminescent devices (because the grafted layer of such devices is stable under the operation conditions).

Modification of the ITO electrode with 2-chloroethylphosphonic acid led¹⁰⁷ to considerable improvement of the stability of

a light-emitting diode based on poly(5-methoxy-2-octyloxy-1,4-phenylenevinylene) owing to reduction of the onset voltage. Electronic effects at the polymer/ITO electrode interface in the electroluminescent devices based on an ITO electrode modified with 2-chloroethylphosphonic acid were also considered.¹⁰⁸

4. Biosorbents

Porous beads made of ZrO_2 modified with ethylenediamino- N,N,N',N' -tetrakis(methylenephosphonic) acid were used as pseudoaffinity sorbents for chromatographic separation of human immunoglobulin G from untreated blood serum.¹⁰⁹ The particle diameter varied from 25 to 38 μm . The effects of the temperature, of sodium chloride content in eluent and of the eluent pH on the maximum binding capacity of the protein and the equilibrium binding constant were studied. Measurements were carried out in the temperature range from 4 to 35 $^{\circ}\text{C}$ at sodium chloride concentrations in the eluent of 0.05, 0.1 and $0.2 \text{ mol litre}^{-1}$ and at pH values of 5.5, 6.0, 6.5, 7.0 and 8.0. Temperature changes in the range given above had almost no effect on the binding constant, whereas an increase in the salt concentration or in pH value led to a marked decrease in the maximum binding capacity and to an increase in the binding constant. The maximum binding capacity of immunoglobulin G at the lowest pH value (5.5) is 55 mg ml^{-1} (see[†]). The sorbent obtained allows immunoglobulins A, G and M in untreated serum to be separated. At a linear elution velocity of 4.32 cm min^{-1} , the yields of these immunoglobulins were respectively 29.5 ± 6.3 , 3.22 ± 0.70 and $6.84 \pm 0.70\%$, respectively. The purity of the immunoglobulins obtained from a single chromatographic run was $89.0 \pm 2.6\%$.

The decrease in the maximum binding capacity with the increase in the electrolyte (sodium chloride) concentration suggests that the binding of immunoglobulin to the sorbent the most important role is played by electrostatic interactions and, probably, hydrogen bonds. The mechanism of the interaction between immunoglobulin and the sorbent is still to be clarified.

At all temperatures studied, the shape of adsorption curves is correctly described by the Langmuir equation. The values of the binding constant indicate a moderate degree of affinity of the sorbent, which is characteristic of pseudoaffinity ligands.^{110, 111}

A more recent study on optimisation and modelling of chromatography on this sorbent was reported.¹¹² The maximum static binding of human immunoglobulin G on this sorbent was 55 – 65 mg ml^{-1} and the maximum dynamic binding was 12 – 20 mg ml^{-1} . It was emphasised¹¹² that ZrO_2 offers significant advantages over conventional silicas and polymeric supports, namely, high strength and excellent thermal and chemical stabilities, which also allows this material to be used as support.^{110, 113–115}

The phosphonic acid used for modification is¹¹² a highly efficient blocker of Lewis acid sites present on the surface of unmodified zirconia in a concentration of 4 – 5 mmol m^{-2} (see Ref. 116). The sorbent studied also possesses a high hydrolytic stability. Namely, the composition of the grafted layer remained unchanged in the range of pH values from 1 to 10. Possible mechanisms of the pseudoaffinity interaction of the sorbent with immunoglobulin G were also considered.¹¹²

5. Implants

Titanium is widely used for production of bone implants. One of the key problems concerned with titanium implants is passive integration. No chemical bonds are formed between the growing bone tissue and the implant, which deteriorates the strength of the system at the junction. To increase the adhesive force between the implant and the bone tissue, ethane-1,1,2-triphosphonic and methylenediphosphonic acids were grafted on titanium disks.¹¹⁷ These disks were used to study proliferation, differentiation and

[¶]This electrode was fabricated by pre-soaking of the starting ITO electrode with Zr(IV) -containing solutions.

[†]Amount of immunoglobulin per ml of sorbent.

protein production for rat osteoblasts (*in vitro* experiments). No statistically significant deviations of proliferation compared to blank run were observed. Thus, the phosphonic acids studied have no cytotoxic effect on osteoblasts. At the same time production of type I collagen on the modified samples increased significantly (up to 16%) compared to non-modified samples, which indicates a stronger binding of the modified implants to the surrounding bone tissue.

Similar results were obtained in a study¹¹⁸ of the possibility of using modified titanium samples in dental implantology (here, the situation is similar to osteoplastics). Ethane-1,1,2-triphosphonic and propane-1,1,3,3-tetrakisphosphonic acids were used as modifiers. The results obtained confirmed better biocompatibility of the modified implants, the samples modified with ethane-1,1,2-triphosphonic acid showed a greater sorption of calcium compared to the samples modified with propane-1,1,3,3-tetrakisphosphonic acid.

6. Magnetic materials for medicine

Magnetite nanoparticles (average diameter 6–8 nm) with grafted biocompatible layers formed by dodecyl- or hexadecylphosphonic acid molecules can find applications in magnetic resonance imaging.¹¹⁹

Using IR spectroscopy, it was shown that phosphonic acids form 'islands' with ordered arrangement of alkyl groups and high grafting density on the surface of magnetite nanoparticles. Thermogravimetric analysis (TGA) of the particles fabricated indicates that the phosphonate coatings are more stable than carboxylate ones. From the TGA data it follows that thermal desorption of molecules involves two steps. This was also observed for Fe₂O₃ (Ref. 77) and Ta₂O₅ particles (Ref. 120) and explained by (i) occurrence of two types of the interaction between the modifier molecules and the surface^{77, 120} and (ii) formation on the surface of particles of a modifier bilayer similar to the phospholipid layer of biomembranes.¹¹⁹

The latter assumption is substantiated by the following facts. First, complete interaction between acids and the surface is difficult to attain; therefore, it is clear that the excess amounts of the acids bound to the surface through weak hydrogen and van der Waals bonds will be desorbed with ease. Second, two-step desorption was observed for not only phosphonic but also carboxylic acids that are attached to the oxide surfaces in a similar fashion.⁷⁷ Third, transitions in the differential scanning calorimetry spectra occur at temperatures that correspond to TGA peaks, having a more convex shape in the temperature range corresponding to the second TGA peak. This was interpreted as a substantiation of the formation of a modifier bilayer on the surface of the oxide particles.

7. Anticorrosion coatings

Phosphonic acids are widely used for fabrication of anticorrosion coatings on aluminium, iron and iron alloys. Traditionally, aluminium is protected from corrosion by chromation, which is used in industry on a large scale. However, weak adhesion of chromated aluminium to paintwork materials and toxicity of hexavalent chromium compounds[‡] used for chromation give an impetus to search for and elaboration of alternative methods for protecting aluminium from corrosion. For instance, cellulose derivatives with phosphonate groups were proposed¹²¹ as protective coatings. The surface layers were formed by immersion of metal samples into dilute solutions of phosphorylated cellulose. According to scanning electron microscopy data, the surface defects of the starting metal are no longer detected after this treatment. Fourier transform IR data indicate that cellulose units in the surface layers are mainly aligned to the support surface. The

properties of the layers formed depend on the concentration of the modifier solution. The thickness of the newly formed layer is ~1 nm in a 0.1% solution and about 6 nm for a concentration of 2%. At concentration of 3% the layer thickness was not determined (according to electron microscopy data, the surface layer has a highly nonuniform structure).

Contact angle measurements showed¹²¹ that after the first immersion the contact angle somewhat decreases, but remains unchanged in the subsequent measurements. The plates modified with the 0.1% solution are characterised by the same contact angle values for the whole surface area of the sample. Modification with more concentrated solutions results in different contact angle values at different points, thus indicating an inhomogeneous structure of the layers formed using concentrated solutions. These conclusions are also confirmed by corrosion tests. For instance, a thin layer formed from a dilute solution of phosphorylated cellulose is a good protector of aluminium from corrosion, whereas thicker layers prepared from concentrated solutions provide no protection at all (apparently, because of inhomogeneous structure). In spite of positive results obtained¹²¹ it should be noted that chromation of aluminium is a more efficient technique.

It was also proposed to protect aluminium from corrosion using self-assembled layers of organic molecules.¹²² Numerous classes of modifiers were studied, namely, alkylphosphates, alkylphosphonic acids, tetraalkylphosphonium salts and alkyliminobis(methylphosphonic) acids, alkyltrimethoxysilanes, alkyltrimethoxysilanes, alkanolic acids, aliphatic alcohols, bromides, amines, thiols, sodium alkyl sulfates and sodium alkyl sulfonates. Among them, only monoalkylphosphate, phosphonic acid and trimethoxysilane layers showed good results in studies of their hydrolytic stability at pH values of 7 and 12. Because all other layers possess low hydrolytic stability, only these three types of modifiers were included in further studies.

Contact angle measurements (with water as the process liquid) showed that the silane layers have lower hydrophobicity and corrosion stability than the alkylphosphate and phosphonate layers that are characterised by similar values of the contact angle.

Phosphorus-containing grafted layers thus obtained were studied by IR spectroscopy¹²² and it was shown that the anchoring phosphorus-containing group is linked to the alumina surface by three oxygen atoms. For simple alkyl derivatives the degree of ordering of alkyl groups within the grafted layer increases with the treatment time and reaches a limiting value after about 70 h (this is in good agreement with the published data²⁹). High grafting density almost equal to the limiting value is reached after a few hours. At the same time bifunctional derivatives containing polar groups in their molecules provide no limiting coverage even after 24 h of modification. The authors failed to estimate the degree of ordering of such layers.

A large number of studies on the modification of metal surfaces with phosphonic acids are devoted to protection of metallic iron from corrosion. In particular, phosphonic acids are used for protection of heat exchangers as both inhibitors of corrosion and heat exchange stabilisers.^{123, 124} Due to low toxicity, high chemical stability and ability to inhibit corrosion of iron in neutral media phosphonic acids are widely used as additives to heat-transfer fluid (water).^{125, 126} Short-chain phosphonic acids are good inhibitors of corrosion of iron and steels.^{124, 127}

The anticorrosion effect of 1-hydroxyethylidenediphosphonic acid (HEDPA) in the presence of calcium cations[§] on the properties of metallic iron was studied.¹²⁸ Treatment of iron with a combination of HEDPA with calcium cations makes it possible to reduce the anodic current and to inhibit the reaction of oxygen reduction at cathode. Using electrochemical methods, X-ray

‡ Special care should be taken when using toxic Cr(VI) derivatives. As time passes, these compounds adsorbed on aluminum diffuse to the environment, thus polluting it.

§ The acid itself is a very poor inhibitor of corrosion of soft steel,¹²⁹ while the anticorrosion ability significantly increases in the presence of calcium ions.¹³⁰

photoelectron spectroscopy data and Auger spectroscopy, it was shown that the optimum ratio of the molar concentrations of calcium ions and HEDPA is 1 : 2. As the concentration of calcium cations increases, the corrosion potential is shifted to the cathode.¹²⁸

Synergistic inhibition of corrosion of a soft steel modified with zinc cations and 3-phosphopropionic acid in 0.006% chloride solution was studied¹³¹ by electrochemical and weight change methods. It was found that the grafted layer contains iron phosphonate complexes and zinc hydroxide (it slows the diffusion of iron phosphonate complexes and hydrogen cations through the grafted layer, which in turn inhibits corrosion).

The possibility of protecting iron from corrosion by treatment with phosphonic acids was studied by researchers from another group.¹³² The surface of iron was modified at pH 7 with alkylphosphonic and α,ω -alkanediylphosphonic acids from aqueous solutions using sodium hydroxide as alkalisng agent. It was found that the formation of a surface phosphonate layer changed the polarisation resistance potential and the surface capacitance of the iron sample. The formation of dense grafted layer led to significant inhibition of corrosion (anodic type of protective mechanism).

A study on the kinetics of modification of iron surface with phosphonic acids showed that the process begins with fast adsorption of phosphonic acids and formation of poorly ordered layers. The second stage involves ordering of the grafted layer, as indicated by slow increase in the polarisation resistance. The grafted layer becomes completely ordered after a few days of modification. The major difference between the layers formed by mono- and diphosphonic acids consists in that alkylphosphonic acids form a hydrophobic monolayer coating on the surface, whereas diphosphonic acids can form thin polylayers owing to relatively strong intermolecular interactions.

Piperidin-1-ylmethylphosphonic and piperazin-1,4-diylbis(methylphosphonic) acids were also used as inhibitors of iron corrosion.¹³³ The addition of these phosphonic acids causes a shift of the pitting potential in chloride solutions to the region of positive values, which inhibits the pitting attack. The corrosion potential is shifted to the region of negative values and the corrosion current and, hence, the corrosion rate decrease. This was explained by the formation of a dense protective film from phosphonic acid molecules on the electrode surface. It was found that the efficiency of both acids increases as their concentrations in solution increase and reaches a maximum at a concentration of $\sim 5 \text{ mmol litre}^{-1}$. Piperazin-1,4-diylbis(methylphosphonic) acid was also shown to be a more efficient inhibitor of corrosion compared to piperidin-1-ylmethylenephosphonic acid.

Inhibition of iron corrosion in hot potassium hydrocarbonate solution (it is often used for absorption of CO_2) was studied.¹³⁴ Since HEDPA is also a good inhibitor of soft steel corrosion,¹³⁵ it was interesting to consider the inhibiting effect of this acid on stainless steel corrosion. It was found¹³⁴ that HEDPA does inhibit corrosion of stainless steel. The addition of small amounts of 2-aminothiophenol to HEDPA significantly enhances the inhibiting effect. Diethanolamine also enhances the protective effect. The best results were obtained with a ternary mixture 2-aminothiophenol/HEDPA/diethanolamine (1 : 10 : 30 000); this mixture is also a good inhibitor of soft steel corrosion.

8. Maintenance of adhesion

In a study⁸⁹ on adhesion of organic compounds to metal surfaces it was pointed that ω -functionalised phosphonic acids possess good adhesive properties to aluminium. Phosphorylation provides a good alternative to chromation. In particular, the formation of a phosphonate monolayer on aluminium surface takes only 20 min.⁸⁹

Phosphonic acids can be used as components of base coatings for iron. Such coatings improve the adhesion of varnishes and paints to the metal surface. In a study¹³⁶ on novel base coating

systems for iron and soft steels the major components were dodecylphosphonic acid and a number of phosphonic acids containing thienyl groups. They form self-assembled monolayers on the passivated iron surface. The samples were coated by immersion into aqueous solutions of modifiers. Prior to modification, iron was treated with 10% HNO_3 solution for passivation.

The formation of self-assembled monolayers of thienylphosphonic acid molecules on the surface was confirmed by voltammetry and contact angle measurements. Measurements showed an efficient hydrophobisation of iron surface. The water contact angle is $18.5 \pm 4.0^\circ$ for passivated iron, $51.4 \pm 4.0^\circ$ for non-passivated iron and 121.2 ± 2.0 and $148.5 \pm 3.0^\circ$ for iron treated with 6-(3-bithienyl)hexylphosphonic acid and dodecylphosphonic acid, respectively. Large contact angles indicate the formation of dense and ordered layers on the iron surface. Despite the larger contact angle obtained for iron treated with dodecylphosphonic acid compared to iron treated with thienylphosphonic acids, the use of the last-mentioned compounds makes it possible to carry out polymerisation of thienyl groups and thus to improve the stability of the grafted layer.

Adhesion of organic compounds to the surface of titanium can also be improved by phosphorylation.⁸⁹

IX. Conclusion

The published data considered in this review show that phosphonic acids and their esters, as well as phosphinic acids are important and promising modifiers of oxide surfaces. Often, organophosphorus compounds provide the possibility of fabrication of highly ordered surface monolayers with grafting densities approaching the limiting values. By and large, phosphonic acids are more preferable than phosphinic acids because they form more ordered grafted layers and are more synthetically accessible. Despite the fact that phosphonic acid esters are less reactive than the parent acids, the former are quite often used for modification of oxides (in particular, alumina), because they do not destroy the surface of this support.

It should be noted that organophosphorus compounds are the best modifiers of titania and zirconia. They form grafted layers of better quality compared to organosilicon compounds. Phosphonic acids are similar to silanes in efficiency of the modification of alumina and iron oxide surfaces. Phosphorus-containing layers grafted on these oxides are more dense, but have a lower hydrolytic stability. If alumina is used under anhydrous conditions, it can be protected with organophosphorus compounds. Silica can be better protected with silanes rather than organophosphorus modifiers because the latter provide a lower grafting density and have a much lower hydrolytic stability, although can form highly ordered layers on the silica surface.

In spite of intensive research in the field in question, many problems are still to be solved, *e.g.*, the mechanisms of the interaction of phosphonic acid esters with the surface of TiO_2 . The effects of the crystal structure of Al_2O_3 and TiO_2 on the results of surface modification are also poorly studied. At present, only a narrow range of oxide surfaces can be modified with phosphonic acids and their esters. These are the mineral supports considered in this review.

Organophosphorus modifiers of oxide surfaces are thought to be quite promising for practical use in chemistry, biology and medicine. It is believed that they will be useful for fabrication of selective chemical sensors, in particular, those based on semiconductor SnO_2 ,^{137,138} efficient titania-based photocatalysts,¹³⁹ biocompatible titanium, tantalum and calcium-phosphate implants with grafted phosphonate layers,^{140,141} asymmetric heterogeneous metal complex catalysts;^{142,143} very thin and stable anticorrosion coatings;¹⁴⁴ specific sorbents for separation and concentration of biomolecules;¹⁴⁵ materials for molecular recognition,¹⁴⁶ *etc.*

Abstract. Methods for synthesis and the structures of high spin polynuclear carboxylate complexes of divalent manganese and iron are considered. The bibliography includes 153 references.

I. Introduction

Currently, polynuclear coordination compounds containing high spin atoms of transition elements have become the focus of keen attention of specialists of various profiles. Due to the presence of open-shell metal sites, these compounds are, as a rule, extremely reactive with respect to different donating organic and inorganic molecules, inducing their unusual chemical transformations in the coordination sphere of the metal core.¹ In addition, the presence of unpaired electrons on the metal atoms of polynuclear coordination compounds determines their unique magnetic and electro-physical properties. It is these particular properties that suggest that in the future this kind of compounds can be used as building blocks of electronic molecular devices.^{2–5}

Carboxylate complexes of high spin 3d-metals are special among a wide variety of polynuclear molecular systems. Their distinguishing feature is high solubility in organic solvents (particularly, the derivatives with alkanoate anions). This is quite important, because performing the reactions in organic solvents excludes hydrolysis, which, as a rule, results in decomposition of polynuclear molecules. Moreover, this provides an opportunity of chemical assembly of the molecules in relatively inert media (including non-polar ones), which significantly simplifies the methods of targeted synthesis of magneto-active polynuclear molecules.

Carboxylate complexes are not only the subject of fundamental investigations, but are also compounds of potential industrial importance. For instance, it has recently been shown that pivalate complexes with three and six Fe(III) atoms are promising components of a homogeneous catalytic Gif-system for hydrocarbon oxidation.⁶ High solubility of polynuclear complexes in hydro-

carbon solvents facilitates the transfer of the metal ions into non-aqueous media. This is of great importance for manufacturing diverse metal-containing films on surfaces of different supports. It is known that thermolysis of pivalate complexes results in elimination of the carboxylate ligands thus building up the metal core and yielding ultimately oxide materials.⁷ Currently, the methods of synthesis of molecular ferromagnets based on polynuclear carboxylate systems are being intensively developed. These compounds can potentially be used as materials for molecular electronics.^{8–15}

The present review describes the methods of synthesis of high spin polynuclear manganese(II) and iron(II) carboxylates. In spite of the obvious interest in these compounds, their synthetic chemistry is not well developed due to problems in the preparation and, especially, isolation of the complexes related to their extreme sensitivity to atmospheric oxygen. Manganese(II) and iron(II) carboxylate derivatives undergo much easier oxidation than similar cobalt(II), nickel(II) and copper(II) compounds, yielding various stable polynuclear Mn(III) and Fe(III) oxocarboxylate systems.^{16, 17} This feature largely determines specific demands as regards synthetic methods and physicochemical studies, which seriously impedes the development of this promising branch of inorganic chemistry.

II. Binuclear carboxylate complexes

Binuclear carboxylate complexes represent the most numerous class of Mn(II) and Fe(II) polynuclear structures. Their potential use as models with bridging carboxylate groups for mimicking active sites of enzymes is a reason for the increased attention to this class of compounds.^{18–27} Usually, these complexes contain high spin metal sites and therefore, magnetic methods can successfully be employed to reveal the structure–property relationships. This is extremely important for the development of advanced methods for calculations of the magnetic properties and for more efficient search for new ‘magnetic’ molecules.^{28–30} Such studies are undoubtedly valuable as a significant contribution to the development of approaches to control the magnetic properties of complexes by chemical methods.

Preparation of binuclear complexes requires special conditions such as to enable a carboxylate group to bind only two metal sites. Therefore, geometrical and electronic parameters of the carboxylate ligand [or rather the substituent R in the RC(O)O group] as well as other donating ligands in the complex should be adjustable. The number of donating ‘non-carboxylate’ ligands should not be too large to prevent the formation of mononuclear

Received 17 March 2006

Uspekhi Khimii 75 (7) 627–644 (2006); translated by D S Yufit

complexes. Therefore, it is necessary to measure out the number of donating ligands per metal atom when carrying out the synthesis.

The Mn(II) and Fe(II) binuclear complexes may be subdivided into complexes with one, two, three and four carboxylate bridges. The molecules of the first two groups usually contain a bridging ligand of another type (*e.g.*, a water molecule, a hydroxyl group, *etc.*).

'Singly bridged' manganese binuclear carboxylate complexes are formed in the reaction of manganese(II) inorganic salts with salts of the corresponding carboxylic acids in the presence of strong chelating ligands such as 2,2'-bipyridyl (2,2'-bipy), 1,10-phenanthroline (1,10-phen), *N,N,N',N'*-tetrakis(2-pyridylmethyl)-1,2-ethylenediamine (tpen) and others. The complexes $[\text{Mn}_2(\mu\text{-OOCCH}_2\text{NMe}_3)(2,2'\text{-bipy})_4(\text{H}_2\text{O})_2](\text{ClO}_4)_4$ (**1**), $[\text{Mn}_2\cdot\{(\text{OOC})_2\text{CH}_2\}(1,10\text{-phen})_3(\text{H}_2\text{O})_2(\text{Cl})]\text{Cl}$ (**2**) and $[\text{Mn}_2(\mu\text{-OAc})\cdot(\text{tpen})_2](\text{ClO}_4)_3$ (**3**) belong to this class.^{31–33}

The binuclear iron complexes $[\text{Fe}_2(\mu\text{-OOCPh})(\mu\text{-L})]\text{X}_2$ [HL is *N,N,N',N'*-tetrakis(1-ethylbenzimidazol-2-ylmethyl)-2-hydroxy-1,3-diaminopropane, X = BF_4 (**4**); HL is *N,N,N',N'*-tetrakis(1-methyl-4,5-diphenylimidazol-2-ylmethyl)-2-hydroxy-1,3-diaminopropane, X = ClO_4 (**5**)], in which iron ions are linked together by a bridging carboxylate group and by a bridging oxygen atom of polydentate ligand HL, are known. These complexes were obtained by the reaction of iron(II) salts with benzoic acid and the corresponding ligand in the presence of triethylamine.^{22, 23}

Similar reactions with less sterically hindered polydentate ligands, for example, *N,N,N',N'*-tris(1-methylbenzimidazol-2-ylmethyl)-*N'*-methyl-2-hydroxy-1,3-diaminopropane (HL), in which the number of donating nitrogen atoms is insufficient to fill the metal coordination sphere, result in the formation of complexes with coordinated solvent molecules or anions of salts. Thus the binuclear ionic complex $[\text{Fe}_2(\mu\text{-OOCPh})\cdot(\mu\text{-L})(\text{MeOH})_{1.5}(\text{H}_2\text{O})_{0.5}](\text{BF}_4)_2$ (**6**) was obtained by the reaction of $\text{Fe}(\text{BF}_4)_2 \cdot 6 \text{H}_2\text{O}$ with benzoic acid and HL. Treatment of this complex with a solution of NaSCN results in substitution of thiocyanate anions for the coordinated water and alcohol molecules and in the formation of a neutral complex $[\text{Fe}_2(\mu\text{-OOCPh})(\mu\text{-L})(\text{SCN})_2]$ (**7**).³⁴

Macrocyclic ligands normally produce mononuclear complexes due to their geometrical features. However, complexes containing two carboxylate-bridged metal atoms in the cavity of macrocycle are known. For instance, high spin manganese binuclear complexes **8** and **9** with one bridging carboxylate group and [2 + 2]-macrocyclic ligands were obtained by the condensation of 2,6-diformyl-4-methylphenol with *N,N*-bis(2-aminoethyl)methylamine in the presence of manganese(II) ions.^{18, 19}

R = Me (**8**), 2-O₂NC₆H₄ (**9**).

Two manganese atoms in molecules of complexes **8** and **9** linked by one bridging carboxylate group occur inside a distorted macrocycle and coordinate the donating atoms of the macrocyclic ligand.

Complexes with two carboxylate bridges can be obtained using simpler N-donating ligands (with fewer number of functional groups or less sterically hindered). Thus the complex $[\text{Mn}_2(\mu\text{-OAc})_2\text{L}]$ (**10**) was obtained by the condensation of 2,6-diformyl-4-methylphenol with 1,4-diaminobutane in the presence

of magnesium acetate. In this complex, two metal atoms are located inside the macrocycle formed and are additionally linked by two bridging acetate groups.²¹

The binuclear complexes $[\text{Mn}_2(\mu\text{-OAc})_2(\text{L})](\text{ClO}_4)$ (**11**, **12**), $[\text{Mn}_2(\mu\text{-OAc})_2(\text{L})(\text{SCN})](\text{MeOH})$ (**13**), $[\text{Mn}_2(\mu\text{-OOCPh})_2(\text{L})(\text{SCN})](\text{MeOH})$ (**14**), $[\text{Mn}_2(\mu\text{-OAc})_2(\text{L})(\text{MeOH})](\text{ClO}_4)$ (**15**), $[\text{Mn}_2(\mu\text{-OPh})_2(\text{L})](\text{BPh}_4)$ (**16**), HL is 2,6-bis[bis(2-pyridylmethyl)aminomethyl]phenol (**11**), 4-methyl-2,6-bis[bis(2-pyridylmethyl)aminomethyl]phenol (**12**), 2,6-bis[2-(dialkylamino)ethyliminomethyl]-4-methylphenol (Alk = Me, Et) (**13**), 2,6-bis[*N*-(2-dimethylaminoethyl)-*N*-methylaminomethyl]-4-methylphenol (**14**), 4-methyl-2-[bis(2-pyridylmethyl)aminomethyl]-6-[(2-pyridylmethyl)benzylaminomethyl]phenol (**15**) and 4-methyl-2,6-bis[bis(2-methoxyethyl)aminomethyl]phenol (**16**), with two carboxylate bridges^{35–40} were obtained by direct reaction of manganese carboxylates (or of a solution of an inorganic manganese salt and a carboxylic acid salt) with the ligand HL in the presence of a base (for example, triethylamine). NaSCN can be used to precipitate the reaction products, as has been done for complexes **13** and **14**.

Aza-crown ethers containing three tertiary amino groups [for example, *N,N',N''*-trimethyl-1,4,7-triazacyclononane (Me_3tacn)] form binuclear complexes in reactions with manganese, iron, cobalt and nickel salts. The metal atoms in these complexes are linked by bridging oxygen atom of the hydroxyl anion and by two bridging carboxylate anions.^{41–47} The complexes containing the labile bridging OH-fragment constitute active sites of a number of enzymes and therefore can be of interest for bioinorganic chemistry as potential catalysts.

Binuclear manganese(II) and iron(II) complex cations $[\text{M}_2(\mu\text{-OOCR})_2(\mu\text{-OH})(\text{Me}_3\text{tacn})_2]^+ \text{X}^-$ (**17–20**)

M = Fe (**17**, **20**), Mn (**18**, **19**); R = Me (**17**, **18**), Bu^t (**19**), CPh₃ (**20**);
X = ClO₄ (**17**, **19**), PF₆ (**18**), BPh₄ (**20**)

can be obtained both by direct reaction of inorganic metal salts with RCOONa (or RCOOH) and Me_3tacn (syntheses of compounds **17–19**) and by reaction of mononuclear complex $[\text{Fe}(\text{Me}_3\text{tacn})(\text{MeCN})_3](\text{CF}_3\text{SO}_3)_2$ with triphenylacetic acid and triethylamine in acetonitrile (synthesis of complex **20**). Since three out of six coordination sites of each metal atom are blocked by tridentate aza-crown, all dimers of this type are cations. The metal atom and three donating nitrogen atoms of *N,N',N''*-trimethyl-1,4,7-triazacyclononane in dimers **17–20** form a triangular pyramid with nitrogen atoms at the base. The mean values of the N–M–N bond angles are equal to 76.8° (M = Mn) and 79.5° (M = Fe) (in an ideal octahedral environment, these angles are equal to 90°). Thus, the tridentate aza-crown ligand proves to be relatively compact and leaves enough space for dimerisation of metal fragments through various bridges.

Binuclear complexes with a bridging water molecule can be formed even if trace amounts of water are present in solvents or in the starting materials. Thus the complexes $[\text{Mn}_2(\mu\text{-OH}_2)(\mu\text{-OAc})_2(\text{L})_4(\text{OAc})_2]$ [L is imidazole (**21**) and benzoimidazole (**22**)] are obtained by reactions of manganese acetate with imidazole or benzoimidazole in dry ethanol,²⁴ the bridging water molecule in complexes **21** and **22** originates from the starting acetate.

Complex anions $[\text{M}_2(\mu\text{-OH}_2)(\mu\text{-OAc})_2(\text{py})_4(\text{OAc})_3]^-$ (**23**, **24**) are formed in the reaction of the corresponding acetates with Et₄NOAc·H₂O in pyridine.²⁵

M = Mn (**23**), Fe (**24**).

The complexes containing two metal atoms linked by two carboxylate groups are the functional precursors of triply bridged hydroxo-carboxylate (oxo- or aqua-carboxylate) binuclear complexes of the type **17–24**. In contrast to the previously discussed compounds, the carboxylate groups in these complexes can be both bridging and chelating. Such complexes are usually formed when the reaction is carried out in anhydrous solvents. For example, the reaction of iron(II) bromide with thallium 2,6-di(*p*-tolyl)benzoate in THF yields the complex $[\text{Fe}_2(\mu\text{-OOCR})_2(\eta^2\text{-OOCR})_2(\text{THF})_2]$ (**25**).

R = 2,6-(4-MeC₆H₄)₂C₆H₃.

It was shown that the reaction of complex **25** with N-donating ligands, such as pyridine and 1-methylimidazole (Meim), results in the substitution of these ligands for THF molecules to give the corresponding complexes **26** and **27** of similar structures.^{26, 27} Doubly bridged manganese complex $[\text{Mn}_2(\mu\text{-OOCCH}_2\text{Cl})_2(\text{bipy})_4](\text{ClO}_4)_2$ was obtained in the reaction of $\text{Mn}(\text{OOCCH}_2\text{Cl})_2 \cdot \text{H}_2\text{O}$ with 2,2'-bipyridyl in dry ethanol in the presence of NaClO₄.⁴⁸

Polynuclear carboxylate systems can also be prepared in aqueous solutions. Thus the reaction of an aqueous solution of sodium salicylate (NaHsal) with manganese chloride yields binuclear complex $[\text{Mn}_2(\text{Hsal})_4(\text{H}_2\text{O})_4]$ (**28**) in which the carboxylate groups are chelating-bridging.⁴⁹

Complexes containing two carboxylate bridges together with other labile donating ligands are convenient starting compounds for the synthesis of triply bridged dimers. For instance, the reaction of complex **25** with 2-diphenylphosphinopyridine or 2-phenylthiopyridine results in the substitution of two THF molecules and transformation of one chelating carboxylate group into a bridging one (Scheme 1).

However, in the reaction of complex **25** with 3-diphenylphosphinopyridine only the replacement of THF molecules occurs with retention of the original metallo-carboxylate core. The reaction of **25** with 4-phenylphosphinopyridine results in rearrangement of two chelating carboxylate groups into the bridging ones and in formation of a quadruply bridged binuclear complex in which the metal atoms have a pseudo-octahedral coordination formed by four oxygen atoms of four symmetrical bridging carboxylate groups and one donating atom of the axial ligand $\text{NC}_5\text{H}_4\text{PPh}_2$ -4. The second metal atom formally occupies the sixth position in the coordination sphere of each Fe atom. This rearrangement is accompanied by shortening of the $\text{Fe}\cdots\text{Fe}$ distance upon the transition from doubly bridged complexes **25** and **31** [4.283 Å (in **25**) and 4.035 Å (in **31**)] to triply bridged complexes **29** and **30** [3.310 Å (in **29**) and 3.272 Å (in **30**)] and to quadruply bridged complex **32** (2.813 Å).⁵⁰ It was suggested that the type of the resulting binuclear system is mostly determined by the geometrical parameters of the pyridine ligand, particularly by the position of a bulky PPh_2 -substituent in the ring.

Binuclear manganese(II) and iron(II) tetracarboxylates $[\text{LM}(\mu\text{-OOCR})_4\text{ML}]$ are known to a lesser extent than similar cobalt, nickel and copper derivatives. In spite of relatively short distances $\text{M}\cdots\text{M}$ [~ 3.1 Å ($\text{M} = \text{Mn}$) and ~ 2.8 Å ($\text{M} = \text{Fe}$)],

such dimers are paramagnetic, which suggests the presence of high spin metal atoms in these complexes.

Binuclear antiferromagnetic dimanganese tetracarboxylates $[\text{M}_2(\mu\text{-OOCR})_4\text{L}_2]$ containing quinoline as a labile N-donating ligand are formed in the reaction of quinoline with the reaction product of diphenylacetic acid with manganese acetate.⁵¹ The pivalate binuclear complex $[\text{Mn}_2(\mu\text{-OOCBu}^t)_4(\text{Bu}^t\text{COO}\cdot\text{HNEt}_3)_2]$ (**33**) has been obtained by reaction of manganese acetate with pivalic acid and triethylamine in hexane at room temperature. The structure of compound **33** is similar to that of complex **32**, but the axial positions of both metal atoms are occupied by oxygen atoms of the salt $\text{Bu}^t\text{COO}\cdot\text{HNEt}_3$.⁵²

Binuclear quadruply bridged iron(II) carboxylates **34–36** were obtained by reactions of complex **25** with 4-(*tert*-butyl)pyridine, benzylamine or 4-methoxybenzylamine, respectively, under the conditions similar to those shown in Scheme 1 for complex **32**.^{53, 54} The change in the nature of the axial ligand results in distortion of the dimer structure. The fragment $\text{N}-\text{Fe}\cdots\text{Fe}-\text{N}$ in complex **34** is almost linear (the $\text{Fe}-\text{Fe}-\text{N}$ bond angles are equal to 177.5 and 179.5°), these angles in complexes **35** and **36** are significantly smaller [157.1 and 160.7° (in **35**) and 161.1 and 176.2° (in **36**)]. The $\text{Fe}\cdots\text{Fe}$ distances in complexes **35** and **36** are ~ 0.03 – 0.06 Å shorter than that in compound **34**. It should be noted that in contrast to other paramagnetic quadruply bridged dimers of 3d-elements where antiferromagnetic exchange interactions occur, structural distortions in complexes **35** and **36** bring about ferromagnetic intramolecular exchange interactions. Presumably, this effect is due to the difference in electronic and geometrical characteristics of the apical ligands.

Earlier studies aimed at the synthesis of manganese, iron, cobalt and nickel quadruply bridged pivalate complexes have revealed that α -substituted pyridines as apical ligands favour the formation of such complexes,^{55–57} while with unsubstituted pyridine or γ -picoline monomeric or polymeric complexes $[\text{L}_2\text{M}(\text{OOCBu}^t)_2]$ are formed. Undoubtedly, the chemical properties of α -substituents in the pyridine rings are extremely important in subsequent transformations of the complex. However, it has recently been shown that the reaction of polymers $[\text{Fe}(\mu\text{-OOCBu}^t)_2]_n$ and $[(\text{EtOH})\text{M}(\mu\text{-OOCBu}^t)_2]_n$ ($\text{M} = \text{Fe}, \text{Mn}$) or the tetranuclear complex $[\text{Fe}_4(\mu_3\text{-OH})_2(\mu\text{-OOCBu}^t)_4(\eta^2\text{-OOC}\cdot\text{Bu}^t)_2(\text{EtOH})_6]$ with 2,3-lutidine or 2,6-diaminopyridine results

Scheme 1

$\text{R} = 2,6\text{-(4-MeC}_6\text{H}_4)_2\text{C}_6\text{H}_3$, $\text{R}' = \text{PPh}_2$ (**29**), SPh (**30**).

in the formation of dimers $[(\text{Me}_2\text{C}_5\text{H}_3\text{N})_2\text{Fe}_2(\mu\text{-OOCBu}^t)_4]$ (**37**) and $[(\eta^1\text{-(NH}_2)_2\text{C}_5\text{H}_3\text{N})_2\text{M}_2(\mu\text{-OOCBu}^t)_4]$ [$\text{M} = \text{Mn}$ (**38**), Fe (**39**)], respectively,^{58–60} with virtually the same structures regardless of the chemical properties of the α -substituent in the pyridine ring. The only difference is that α -amino groups of pyridine ligands in complexes **38** and **39** form strong hydrogen bonds with the solvent molecules (MeCN) yielding the solvates $[\{2\text{ MeCN} \cdot (\text{NH}_2)_2\text{C}_5\text{H}_3\text{N}\}_2\text{M}_2(\mu\text{-OOCBu}^t)_4]$ (compounds **40**, **41**).

$\text{M} = \text{Mn}$ (**40**), Fe (**41**).

Strong antiferromagnetic[†] exchange interactions have been observed in binuclear compounds **40** and **41**. The structural phase transitions that occur in complexes **40** and **41** at 173 and 184 K, respectively,^{59,64} do not affect the character of these spin–spin interactions. Presumably, such indifference of the magnetic behaviour of the dimers with respect to the change in molecular packing due to phase transition suggests a predominantly intra-molecular nature of spin exchange in these compounds.

III. Mn(II) and Fe(II) carboxylate complexes with three and more metal sites

Trinuclear manganese(II) and iron(II) high spin complexes are represented by a small group of compounds with triangular or linear arrangement of metal sites. Isostructural complexes $[\text{M}_3(\mu_3\text{-OH})(\mu\text{-OAc})_3\text{L}(\text{py})_5]$ [$\text{M} = \text{Mn}$ (**42**), Fe (**43**), Co (**44**), Ni (**45**), $\text{L} = \text{C}_6\text{H}_4\text{O}_2^-$] are trinuclear complexes of divalent metals with a triangular metal core of the $\text{M}_3^{\text{II}}(\mu_3\text{-OH})$ type.⁶⁵

$\text{M} = \text{Mn}$ (**42**), Fe (**43**), Co (**44**), Ni (**45**).

This is a rare example of a series of structurally studied, similar polynuclear carboxylate complexes of divalent metals. All these complexes were obtained by reactions of stoichiometric amounts of $\text{M}(\text{OAc})_2 \cdot 4\text{H}_2\text{O}$ with catechol in pyridine in the presence of 0.2 M ethanolic triethylammonium hydroxide.

A triangular iron(II) complex containing only the molecules of a carboxylic acid and carboxylate anions as the organic ligands, viz., a hydroxo-pivalate ionic antiferromagnetic complex $\text{K}[\text{Fe}_3(\mu_3\text{-OH})(\mu\text{-OOCBu}^t)_6(\text{HOOCBu}^t)_3]$ (**46**), is known.⁶⁶

Complex **46** is formed in the reaction of $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ with KOOCBu^t and HOOCBu^t in acetonitrile under argon.

Yet another triangular antiferromagnetic manganese(II) complex $[\text{Mn}_3(\text{OOCBu}^t)_6(\text{HOOCBu}^t)_3] \cdot 2\text{HOOCBu}^t$ (**47**) was obtained in the reaction of manganese carbonate with pivalic acid.¹⁶

This compound is unique, because the triangular fragment is composed only of bridging carboxylate ligands, while in the majority of known trinuclear systems the metal atoms are linked by μ_3 -bridging oxygen atoms of oxo or hydroxo groups.

Linear trinuclear manganese(II) and iron(II) complexes of $[\text{M}_3(\text{OOCRR})_6\text{L}_2]$ are formed in the reactions of the corresponding metal carboxylates with N,O- and N,N-donating chelating ligands. Thus the complexes $[\text{Mn}_3(\mu, \eta^2\text{-OOCR})_2(\mu\text{-OOCR})_4(2,2'\text{-bipy})_2]$ [$\text{R} = \text{Me}$ (**48**), CH_2Cl (**49**)] were isolated from the reaction of manganese acetate or chloroacetate with the stoichiometric amount of 2,2'-bipyridyl. The Mn(II) atoms in these complexes form a linear structure and are linked by bridging and chelating-bridging carboxylate groups, the peripheral metal sites are additionally chelated by 2,2'-bipyridyl molecules.^{67–69}

$\curvearrowright = 2,2'\text{-bipy}$ (**48**, **49**), 1,10-phen (**50**), 2-bepy (**51**);

$\text{R} = \text{Me}$ (**48**, **50**), CH_2Cl (**49**), Ph (**51**).

It was shown^{70–73} that the chelating properties of a carboxylate group depend upon steric features of the terminal ligand that can hinder the chelating process. For instance, the reaction with 2-benzoylpyridine (2-bepy) or 1,10-phenanthroline instead of

[†]Such interactions are also typical of binuclear nickel and cobalt carboxylates.^{57,61–63}

2,2'-bipyridyl results in the formation of complexes **50** and **51** similar to **48** and **49**. At the same time, bis(1-methylimidazol-2-yl)(methoxy)phenylmethane (biphme) blocks chelation of the carboxylate group due to increase in the N–Mn–N(O) bond angle from $\sim 72.3^\circ$ in complexes **48–51** [72.2° (in **48**), 73.2° (in **49**), 73.4° (in **50**), 70.5° (in **51**)] up to 81.9° in complex **52**.

M = Mn (**52**), Fe (**53**); $\curvearrowright$ = biphme.

The change in the conditions of synthesis affects the structures of the final products. Thus the above-described binuclear complex **33** with four bridging carboxylate groups was obtained in hexane at room temperature. However, heating of the starting reaction mixture in heptane to the solvent boiling point affords the trinuclear complex $[\text{Mn}_3(\mu, \eta^2\text{-OOCBu}^t)_4(\mu\text{-OOCBu}^t)_2(\text{Bu}^t\text{COO} \cdot \text{HNEt}_3)_2]$ (**54**). In this complex, two carboxylate groups are bridging and four others are chelating-bidging groups.⁵²

The change in the conditions of synthesis of complex **46**, namely, the use of EtOH instead of acetonitrile and the removal of pivalic acid from the reaction mixture results in the tetranuclear hydroxopivalate complex $[\text{Fe}_4(\mu_3\text{-OH})_2(\mu\text{-OOCBu}^t)_4(\eta^2\text{-OOC} \cdot \text{Bu}^t)_2(\text{EtOH})_6]$ (**55**).⁶⁰

The metal core of this complex consists of two $\{\text{Fe}_2(\mu\text{-OOCBu}^t)_2(\eta^2\text{-OOCBu}^t)(\text{EtOH})_3\}$ fragments linked by two $\mu_3\text{-OH}$ -groups. All metal atoms of complex **55** lie in the same plane. Cobalt and nickel isostructural analogues of complex **55** are also known.^{74, 75}

The magnetic properties of these isostructural complexes are different. Thus the antiferromagnetic exchange interactions exist between paramagnetic sites in iron and cobalt complexes, while in the nickel derivative, these interactions are ferromagnetic.

The tetranuclear manganese complex $[\text{Mn}_4(\text{O}_2\text{CPh})_6 \cdot 2(\text{OOCCH}_2\text{CH}_2\text{N})_2 \cdot 2(\text{HON}=\text{C})\text{C}_3\text{H}_4\text{N} \cdot 0.6 \text{CHCl}_3]$ (**56**) was obtained by reaction of manganese benzoate with 2-pyridinaldoxime in MeCN.⁷⁶

The metal core of complex **56** is planar and the metal atoms form a rhomb. Manganese atoms are linked by six μ_3 -bridging benzoate groups and two chelating-bridging (2-pyridyl)carboxylate groups resulting from hydrolysis of the oxime and oxidation.

Tetranuclear manganese carboxylate complexes with a planar metal core are also formed in reactions of manganese salts with dicarboxylic acids [maleic (H_2male) or phthalic (H_2phth)] and N-donating ligands (2,2'-bipyridyl or 1,10-phenanthroline). The manganese complexes $\{\text{Mn}_4[(\text{OOC})_2\text{R}]_2\text{L}_8\}\text{X}_4$ (**57–60**) were obtained in this way.^{77, 78}

R = CH=CH (**57, 58**), $\text{C}_6\text{H}_4\text{-o}$ (**59, 60**);
 $\curvearrowright$ = 2,2'-bipy (**57, 60**), 1,10-phen (**58, 59**);
 X = ClO_4 (**57, 58, 60**), PF_6 (**59**).

The manganese atoms in these complexes form a parallelogram and are linked by four bridging carboxylate groups of two molecules of doubly deprotonated acids.

Unusual antiferromagnetic pentanuclear systems $[\text{Fe}_5(\mu_3\text{-OH})_2(\text{OOCPh})_6\text{L}_6\text{L}'_2](\text{CF}_3\text{SO}_3)_2$ (**61–63**) were obtained in the reactions of $\text{Fe}(\text{CF}_3\text{SO}_3)_2 \cdot 2 \text{MeCN}$, N-donors [pyridine, butyronitrile or ethylenediamine (en)], benzoic acid and triethylamine in acetonitrile in the presence of small amount of water. The metal cores of these complexes are formed of two triangular fragments sharing a vertex.⁷⁹

L = L' = py (**61**); L = py, L' = PrCN (**62**); L–L' = en (**63**).

Unfortunately, the chemistry of manganese(II) and iron(II) carboxylates is still insufficiently explored. Only hypothetically, the existence of hexa-, hepta- and octa-nuclear molecules, similar to the known cobalt and nickel derivatives, can be imagined. So far, the range of synthesised polynuclear molecular structures of iron derivatives is limited to the nonanuclear (II) complex ‡ $[\text{Fe}_9(\mu_4\text{-N}_3)_2(\mu\text{-OAc})_8(\mu_5\text{-L})_4]$ [$\text{H}_2\text{L} = (2\text{-C}_5\text{H}_4\text{N})_2\text{C}(\text{OH})_2$] (**64**) (Fig. 1 a).⁸⁰ At present, this is the only known representative of polynuclear iron(II) carboxylate complexes with molecular magnets properties (the ground spin state is $S = 14$ at 2 K). It was obtained by the reaction of iron(II) acetate with bis(2-pyridyl) ketone in acetonitrile and treatment of the reaction product with sodium azide. In this process, bis(2-pyridyl) ketone is converted into a *gem*-diol, which binds five metal atoms simultaneously (Fig. 1 b).

Figure 1. The schematic representation of the structure of complex **64** (a) [the non-coordinated atoms of $(2\text{-C}_5\text{H}_4\text{N})_2\text{COO}^{2-}$ moiety are not shown] and coordination of the *gem*-diol form of bis(2-pyridyl) ketone in complex **64** (b).

IV. Polymeric carboxylate complexes

Most of the so-called 'dicarboxylates' of divalent transition metals with the composition $\text{M}(\text{OOCR})_2 \cdot x\text{H}_2\text{O}$ [$\text{M} = \text{Mn}(\text{II}), \text{Fe}(\text{II})$ and others, $x = 3\text{--}8$] are mononuclear aqua-complexes,^{83–88} however some of them are polymeric. Usually, the latter are stable only in a solid state and are easily converted to monomers when dissolved in water. Complexes $[\text{M}(\text{dmba})_2(\text{H}_2\text{O})_3]_n$ ($\text{M} = \text{Mn}, \text{Co}, \text{Ni}, \text{Zn}$), containing 2,6-dimethoxybenzoic acid (Hdmba) anions, represent this type of polymers. Upon action of a hot aqueous solution of 2,6-dimethoxybenzoic acid on aqueous solutions of metal acetates or sulfates (pH 4–5) followed by cooling, crystalline polymeric complexes are formed.⁸⁹ The polymeric chains in these complexes consist of square-planar *trans*- $\{\text{M}(\text{dmba})_2(\text{H}_2\text{O})_2\}$ units linked by axial bridging water molecules.

In addition to the metalopolymers linked in chains by bridging water molecules, metalopolymers with bridging carboxylate anions are known. Thus polymeric products $[\text{Mn}(\text{OOC} \cdot \text{C}_6\text{H}_4\text{OR-}p)_2(\text{H}_2\text{O})_2 \cdot x\text{H}_2\text{O}]_n$ (**65**, **66**) were obtained in the reaction of sodium *para*-hydroxy- or *para*-methoxybenzoate with a Mn(II) salt. In these compounds, octahedral coordination of metal atoms is formed by four oxygen atoms of bridging carboxylate anions and two oxygen atoms of terminal water molecules in *trans*-configuration.^{90, 91}

65: $\text{R} = \text{H}$, $x = 0$; **66:** $\text{R} = \text{Me}$, $x = 1$.

In aqueous medium, it is possible to obtain polynuclear structures devoid of water molecules in the coordination sphere of the metal atoms. For instance, the ionic polymer $[\text{Mn}(\mu\text{-OOCCH}_2\text{NMe}_3)_3]_n \cdot n\text{MnCl}_4$ has been synthesised by the reaction of manganese chloride with betaine $\text{Me}_3\text{N}^+\text{CH}_2\text{COO}^-$ in water.⁹² The metal atoms in this compound are linked by three carboxylate groups. The complex $\{[\text{Mn}_3(\mu\text{-OOC}(\text{CH}_2)_2\text{NH}_3)_8] \cdot 6\text{ClO}_4 \cdot 2\text{H}_2\text{O}\}_n$ is formed upon action of manganese perchlorate on β -alanine. This crystallises as a linear polymer the repeating unit of which consists of three manganese atoms linked by two bridging and one chelating-bridging carboxylate groups.⁹³

Pivalate complexes crystallise most easily as linear polymers since the *tert*-butyl groups provide a high solubility of these compounds. Thus the polymer $[\text{Fe}(\mu\text{-OOCBu}^t)_2]_n$ (**67**) devoid of neutral ligands was obtained by refluxing the tetranuclear complex $[\text{Fe}_4(\mu_3\text{-OH})_2(\mu\text{-OOCBu}^t)_4(\eta^2\text{-OOCBu}^t)_2(\text{EtOH})_6]$ (**55**) in acetonitrile.⁶⁰

Ferromagnetic exchange interactions are observed in this compound. Polymer **67** undergoes phase transition into magnetic-ordered state at $T_c = 3.8\text{ K}$ and becomes a 'soft magnet'. It should be noted that dissolution of polymer **67** in oxygen-free (but not anhydrous) ethanol results in the formation of the original tetranuclear complex **55**.

Antiferromagnetic manganese(II) pivalate polymer $[(\eta^1\text{-HOEt})\text{Mn}(\mu\text{-OOCBu}^t)_2]_n$ (**68**) can be obtained by reaction of $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$ with potassium pivalate in ethanol under argon (Scheme 2).

Polymer **68** consists of $\text{Mn}(\text{HOEt})$ fragments linked by two carboxylate groups.⁵⁹ Surprisingly, an isostructural analogue of compound **68**, *viz.*, the polymer $[(\text{HOEt})\text{Fe}(\mu\text{-OOCBu}^t)_2]_n$ is formed from tetranuclear complex **55** in the presence of *o*-phenylenediamine.⁶⁰

The structure of polymeric chain can be made more complicated by changing the number of metal atoms in the repeating unit. For instance, the polymeric product $[\text{Mn}_4(\text{OOC} \cdot \text{Bu}^t)_8(\text{HOOCBu}^t)_2]_n$ (**69**) is obtained in the reaction of complex **68** with an excess of pivalic acid in acetonitrile.⁹⁴ It can also be obtained by recrystallisation of the trinuclear complex $[\text{Mn}_3(\text{OOCBu}^t)_6(\text{HOOCBu}^t)_3] \cdot 2\text{HOOCBu}^t$ (**47**) from an acetonitrile–acetone mixture.¹⁶ Thus, the substitution of a carboxylic

‡ Analogous cobalt and nickel complexes have been prepared.^{81, 82}

acid in polymeric complex **68** for ethanol resulted in the structural changes of the polymeric chain due to the ability of pivalate anions to coordinate metal in different modes. The pivalate groups easily pass from O,O-bridging to O-bridging ones (see Scheme 2).

The number of metal atoms in a repeating unit can be controlled by selecting conditions of synthesis. For example, the polymeric structures $[\text{Fe}_2(\text{OAc})_4(\text{py})_3]_n$ (**70**) and $[\text{Fe}_3(\text{OAc})_6(\text{DMSO})_2]_n$ (**71**), containing bi- and trinuclear fragments, were obtained from the same starting mononuclear complex $[\text{Fe}(\text{OAc})_2(\text{py})_4]$ (**72**), but under different conditions. Compound **70** is obtained upon dissolution of complex **72** in diethyl ether, while compound **71**, upon dissolution of complex **72** in DMSO.^{17,95}

Further complication of repeating units of a polymeric chain is also possible by combining bi- and mononuclear fragments, which was demonstrated on an example of manganese and iron pivalate derivatives. *o*-Phenylenediamine ligands have been chosen as the components that control the polymer chain formation. Isostruc-

tural polymeric compounds $\{[(\eta^2-(\text{NH}_2)_2\text{C}_6\text{H}_2\text{Me}_2)_2\text{M}(\mu\text{-OOC}\cdot\text{Bu}^t)]_2[\text{M}_2(\mu\text{-OOCBu}^t)_4]\}_n$ [$\text{M} = \text{Mn}$ (**72**), Fe (**73**)] were obtained by reactions of polymers **68** and **67** with 4,5-dimethyl-1,2-phenylenediamine in acetonitrile.⁶⁰

$\text{M} = \text{Mn}$ (**68**, **72**), Fe (**67**, **73**).

Complexes **72** and **73** are magnetically different: intra- and intermolecular exchange interactions in complex **72** are antiferromagnetic, while in the iron complex **73**, ferromagnetic interactions were observed at low temperature.

A carboxylate group can bind three or even four metal atoms; therefore, the existence of two- or three-dimensional polymers is possible. Thus high-temperature (230 °C) treatment of Mn_3O_4 with acetic acid yields the polymeric complex $\{[\text{Mn}_3(\mu\text{-OAc})_6(\text{H}_2\text{O})_4] \cdot 2 \text{H}_2\text{O}\}_n$ (**74**) of a layered structure.⁹⁶ The crystallisation water molecules in crystals of this compound form the interlayer hydrogen bonds.

The commercially available $\text{Mn}(\text{OAc})_2 \cdot 4 \text{H}_2\text{O}$ widely used in carboxylate synthesis is in fact a layered polymer $\{[\text{Mn}_3(\text{OAc})_6(\text{H}_2\text{O})_4] \cdot 8 \text{H}_2\text{O}\}_n$ (**75**) in which the crystallisation water molecules take part in linking the layers by hydrogen bonds.⁹⁷

Dissolution of $\text{Mn}(\text{OAc})_2 \cdot 4 \text{H}_2\text{O}$ in anhydrous methanol leads to the formation of the polymer $[\text{Mn}_4(\text{OAc})_8(\text{MeOH})_2]_n$ (**76**). The repeating unit of this polymer consists of four Mn atoms linked by acetate bridges.⁹⁸

The increase in the number of metal atoms in a repeating unit up to four results in their distorted non-planar Y-shaped arrangement. Non-planarity of the metal core together with the decrease in the number of neutral molecules in the repeating unit results in the formation of three-dimensional structure (in contrast to layered structures of complexes **74** and **75**). Antiferromagnetic exchange interactions between high spin manganese(II) atoms exist in this compound.

Three-dimensional manganese acetate $[\text{Mn}(\text{OAc})_2]_n$ (**77**) devoid of neutral molecules was obtained by dehydration of $\text{Mn}(\text{OAc})_2 \cdot 4\text{H}_2\text{O}$ in acetonitrile under elevated pressure at 150 °C.⁹⁹ A 3D-system of polymer **77** is built of trinuclear fragments in which the coordination number of one of the manganese atoms is as high as 7 (Fig. 2*a*).

A variety of the carboxylate group coordination modes can be exemplified in complex **77** (Fig. 2*b*). Besides, the dependence of the Mn...Mn distances on the bridging group type is observed in this structure. Thus, while the distance between Mn(1) and Mn(2) atoms linked by three monoatomic carboxylate bridges is 3.202 Å, the distance between Mn(1) and Mn(3) linked by two monoatomic and one triatomic carboxylate bridges increases to 3.373 Å. The Mn...Mn distances between the atoms linked by two triatomic

Figure 2. The structure of a fragment of polymer **77** (*a*) and the coordination types of bridging carboxylate groups in it (*b*).

and one monoatomic carboxylate bridges increase to 3.816 and 3.887 Å. At temperatures below 15 K, compound **77** exists in an ordered antiferromagnetic state.

The use of polycarboxylic acids favours the formation of polymeric carboxylate complexes, the arrangement of the carboxy groups in the acid molecule being very important. For instance, the reaction of manganese chloride with isophthalic acid $[m\text{-(HOOC)}_2\text{C}_6\text{H}_4]$ in the presence of pyridine in aqueous methanol yields the linear polymer $[\text{Mn}\{m\text{-(OOC)}_2\text{C}_6\text{H}_4\}(\text{py})_2]_n$ (**78**) with the binuclear fragment as a repeating unit.¹⁰⁰

The presence of other functional groups in the carboxylic acid molecule also induces the formation of polymeric structures that depend on the geometrical parameters of the ligand. Thus the structure of isomers of pyridinecarboxylic acid determines the type of a carboxylate complex formed. For example, the layered polymeric complex $[\text{Mn}(2\text{-OOCCH}_2\text{CH}_2\text{N})_2]_n$ (**79**) containing no water molecules is formed in the reaction of $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$ with α -picolinic acid in aqueous methanol at 145 °C (Ref. 102).⁸

In the case of β -picolinic acid, the three-dimensional polymeric complex $[\text{Mn}(3\text{-OOCCH}_2\text{CH}_2\text{N})_2]_n$ (**80**) is formed.^{100, 103}

Manganese(II) perchlorate reacts with γ -picolinic acid in aqueous ethanol yielding the three-dimensional ionic polymer $[\text{Mn}_6(4\text{-OOCCH}_2\text{CH}_2\text{N})_{10}(\text{H}_2\text{O})_2](\text{ClO}_4)_2$ (**81**),¹⁰⁴ while the reaction of iron(II) perchlorate with γ -picolinic acid results in the formation of 3D-polymer with a different structure $[\text{Fe}(4\text{-C}_5\text{H}_4\text{NCOO})_2]_n$ (**82**).¹⁰⁵

§ At room temperature, the mononuclear complex $[\text{Mn}(\eta^2\text{-2-OOCCH}_2\text{CH}_2\text{N})_2(\text{H}_2\text{O})_2]$ is formed.¹⁰¹

Polyfunctional ligands of various denticity and geometry (for example, linear or angular bidentate, planar or pyramidal tridentate, planar or tetrahedral tetradentate ligands) are used for the targeted synthesis of polymeric carboxylate complexes of different dimensionality.[†] The maintenance of a correct balance between such ligands and metal sites is very important in this case, because an excess of the ligand brings about smooth formation of mono- and binuclear compounds.

The complex $[\text{Mn}(\text{OOCCH}_2\text{Cl})_2(1,10\text{-phen})]_n$ (**83**) is formed in the reaction of $\text{Mn}(\text{OOCCH}_2\text{Cl})_2$ with 1,10-phenanthroline in the ratio 1 : 1. The manganese atoms in this complex are arranged into infinite chains in which two adjacent metal atoms are linked by two carboxylate groups.^{69,107} Similar linear polymer $[\text{Mn}(\text{OOC}_6\text{H}_4\text{Cl-}m)_2(2,2'\text{-bipy})]_n$ (**84**) was obtained by reaction of manganese *m*-chlorobenzoate with bipyridyl.⁴⁸

In the reaction of 1,10-phenanthroline with a salt of a dicarboxylic acid, *e.g.*, manganese phthalate, instead of a salt of a monocarboxylic acid, the linear polymer $\{\text{Mn}[o\text{-(OOC)}_2\text{C}_6\text{H}_4](1,10\text{-phen})(\text{H}_2\text{O})_2\}_n$ (**85**) is also formed, but its manganese atoms are linked by only one bridging carboxylate group.¹⁰⁸

$\curvearrowright = 1,10\text{-phen}$ (**83**, **85**), $2,2'\text{-bipy}$ (**84**);

$\text{R} = \text{CH}_2\text{Cl}$ (**83**), $\text{C}_6\text{H}_4\text{Cl-}m$ (**84**), $\text{C}_6\text{H}_4\text{COO-}o$ (**85**).

[†]The examples of carboxylate complexes of 3d-metals are given in a review.¹⁰⁶

The reactions of complexes $\text{Mn}(2,2'\text{-bipy})_2\text{Cl}_2$ and $\text{Fe}(1,10\text{-phen})_2\text{Cl}_2$ with isophthalic acid salts yield the corresponding helical polymeric structures $\{\text{Mn}[m\text{-(OOC)}_2\text{C}_6\text{H}_4](2,2'\text{-bipy})\}_n$ (**86**) and $[\text{Fe}(m\text{-(OOC)}_2\text{C}_6\text{H}_4)(1,10\text{-phen})]_2$ (**87**) due to coordination of the second carboxylate group of the acid anion and stacking interactions of aromatic rings.^{109,110}

$\text{M} = \text{Mn}$ (**86**), Fe (**87**); $\curvearrowright = 2,2'\text{-bipy}$ (**86**), $1,10\text{-phen}$ (**87**).

The terephthalic acid dianion obtained upon hydrolysis of 1,4-dicyanobenzene reacts with manganese chloride and 1,10-phenanthroline also to yield the polymer $\{\text{Mn}[p\text{-(OOC)}_2\text{C}_6\text{H}_4](1,10\text{-phen})\}_n$ (**88**) in which this dianion links four manganese atoms at once.¹¹¹

Thus, various *n*-dimensional systems can be obtained by modifying the structure (denticity, functionality and geometry) of carboxylate ligands. Usually, the paramagnetic sites in such polymers are in a high spin state and the predominant exchange interactions between them are antiferromagnetic.

V. Mixed-valence complexes containing manganese(II) and iron(II)

Manganese(II) and iron(II) carboxylate complexes are highly liable to oxidation yielding Mn(III) and Fe(III) derivatives. In the case of polynuclear compounds, these processes usually proceed *via* mixed-valence systems, which are often quite stable. Such compounds containing high spin metal sites are definitely of interest, because even if all the metal atoms in the complex are of the same kind, the molecule turns out to be of a hetero-spin type.

Binuclear mixed-valence systems are usually formed as a result of oxidation of M(II) complexes. The controlled oxidation of iron and manganese binuclear complexes, for example, complexes **17** and **19**, results in the oxidation of one out of two metal atoms and affords complexes $[\text{M}_2(\mu\text{-O})(\mu\text{-OOCR})_2(\text{Me}_3\text{tacn})_2]\text{ClO}_4$ [$\text{M} = \text{Fe}$, $\text{R} = \text{Me}$ (**89**); $\text{M} = \text{Mn}$, $\text{R} = \text{Bu}^t$ (**90**)].^{41,43} Oxidation of binuclear complex **20** by atmospheric oxygen also yields green mixed-valence complex $[\text{Fe}_2(\mu\text{-O})(\mu\text{-OOCPh})_2(\text{Me}_3\text{tacn})_2] \cdot \text{BPh}_4$. Further oxidation of this complex by H_2O_2 results in the

formation of stable orange iron(III) complex $[\text{Fe}_2(\mu\text{-O})(\mu\text{-OOCPh}_3)_2(\text{Me}_3\text{tacn})_2](\text{BPh}_4)_2$.⁴⁴

Mixed-valence systems can also be obtained starting from ordinary manganese(II) and iron(II) salts. For example, the reaction of 2,6-bis[bis[(1-methylimidazol-2-yl)methyl]amino-methyl]-4-methylphenol (Hbimp) with sodium acetate and magnesium(II) or iron(II) perchlorate in methanol results in the formation of dimers $[\text{M}^{\text{II}}\text{M}^{\text{III}}(\text{bimp})(\text{OOCR})_2](\text{ClO}_4)_2$ ($\text{M} = \text{Mn, Fe}$).^{112, 113}

Mixed-valence cationic complexes with a 'Chinese lantern' structure $[\text{Fe}_2(\mu\text{-OOCR})_4(\text{py})_2]\text{PF}_6$ (**93**) and $[\text{Fe}_2(\mu\text{-OOCR})_4.(4\text{-Bu}^t\text{C}_5\text{H}_4\text{N})_2]\text{CF}_3\text{SO}_3$ (**94**) were obtained by single-electron oxidation of iron(II) binuclear complexes **26** and **34** with $[\text{FeCp}_2]\text{PF}_6$ and AgCF_3SO_3 , respectively (Scheme 3).^{114, 115} Oxidation of compounds **26** and **34** by atmospheric oxygen yields complexes $[\text{Fe}_2(\mu\text{-OH})_2(\mu\text{-OOCR})_2(\text{OOCR})_2\text{L}_2]$ [$\text{L} = \text{py}$ (**95**), 4-Bu^tC₅H₄N (**96**), Scheme 3]. In these complexes, the iron(III) atoms are in a different ligand environment and their coordination number increases up to 6.

Manganese and iron oxocarboxylate triangular complexes $[\text{M}_3(\mu_3\text{-O})(\mu\text{-OOCR})_6\text{L}_3]^{n+}$ are well studied by magnetic methods.^{116–119} These compounds play an important role in bioinorganic systems because they may be regarded as models of active sites of metalloproteins and as structural models of oxygen-containing centres in the photosystem II.^{120–122} There are very few neutral ($n = 0$) iron and manganese M(II) and M(III) mixed-valence oxocarboxylate trinuclear complexes. These complexes are interesting as hetero-spin systems with potentially highly variable metal sites.^{7, 123}

Iron mixed-valence trinuclear complexes are obtained by either direct reaction of iron powder with an acid {synthesis of $[\text{Fe}_3\text{O}(\text{OOCBu}^t)_6(\text{HOOCBu}^t)_3]$ }¹²⁴ or reactions of inorganic salts with acids {synthesis of $[\text{Fe}_3\text{O}(\text{OOCCH}_2\text{Cl})_6(\text{H}_2\text{O})_3]$ }.¹²⁵ Terminal ligands in such systems can be replaced by various N-donating molecules, *e.g.*, pyridine. The oxocomplex $[\text{Fe}_3\text{O}(\text{OOCBu}^t)_6(\text{py})_3]$ was obtained from $[\text{Fe}_3\text{O}(\text{OOCBu}^t)_6(\text{HOOCBu}^t)_3]$ by this method.¹²⁴

Manganese acetate is typically used as a starting material in the synthesis of neutral manganese mixed-valence trinuclear oxocarboxylates. Oxidation of a solution of $\text{Mn}(\text{OAc})_2 \cdot 4\text{H}_2\text{O}$ by tetrabutylammonium perchlorate in a mixture of glacial acetic acid and pyridine yields the complex $[\text{Mn}_3\text{O}(\text{OAc})_6(\text{py})_3]$,¹¹⁹ while the oxidation in the presence of benzoic acid in a mixture of ethanol and pyridine results in the substitution of acetate groups and formation of mixed-valence complex $[\text{Mn}_3\text{O}(\text{OOCPh})_6]$.

$(\text{py})_2(\text{H}_2\text{O})$.¹¹⁹ Treatment of the latter with a solution of 2,2'-bipyridyl-3,3'-dicarboxylic acid and triethylamine in acetonitrile affords trinuclear complex $[\text{Mn}_3\text{O}(\text{OOCPh})_6(\text{py})_3]$ with similar structure, but with three terminal pyridine molecules.¹²⁶

More complex starting reagents can also be used for the synthesis of trinuclear complexes. Thus the decomposition of the dodecanuclear complex $[\text{Mn}_8^{\text{III}}\text{Mn}_4^{\text{IV}}\text{O}_{12}(\text{OAc})_{16}(\text{H}_2\text{O})_4] \cdot 2\text{HOAc} \cdot 4\text{H}_2\text{O}$ in trichloroacetic or trifluoroacetic acid is accompanied by partial reduction of manganese atoms and the formation of the mixed-valence complex $[\text{Mn}^{\text{II}}\text{Mn}_2^{\text{III}}\text{O}(\text{OOCR})_6(\text{H}_2\text{O})_3]$ ($\text{R} = \text{CCl}_3$ or CF_3).^{127, 128}

Yet another type of trinuclear systems, *viz.*, asymmetric triangular oxocarboxylate $(\text{Et}_4\text{N})[\text{Fe}_3\text{O}(\text{OAc})_7(\text{OH}_2)]$ (**97**), was obtained by reaction of atmospheric oxygen with the complex $(\text{Et}_4\text{N})[\text{Fe}_2(\mu\text{-OH}_2)(\mu\text{-OAc})_2(\text{py})_4(\text{OAc})_3]$ (**24**).¹²⁹ It was noted

Scheme 3

$\text{R} = 2,6\text{-(4-MeC}_6\text{H}_4)_2\text{C}_6\text{H}_3$;

$\text{L} = \text{py}$ (**26**, **93**, **95**), 4-Bu^tC₅H₄N (**34**, **94**, **96**).

that the oxidation of compound **24** with ferrocenyl cation affords the symmetrical mixed-valence complex $[\text{Fe}_3\text{O}(\text{OAc})_6(\text{py})_3]$ (**98**).

Trinuclear linear complexes of general formula $[\text{Mn}^{\text{II}}\text{Mn}^{\text{III}}\text{L}_2(\mu\text{-OAc})_4(\text{MeOH})_2]$ [**99**: H_2L is 1,3-dihydroxy-2-methyl-2-(salicylidenamino)propane, **100**: H_2L is tris(hydroxymethyl)(salicylidenamino)methane] were obtained by reaction of salicylaldehyde with 2-amino-2-methylpropane-1,3-diol [or tris(hydroxymethyl)aminomethane] and manganese acetate in methanol.¹³⁰ Manganese(II) atom in the obtained complexes occupies the central position and the Mn(III)–Mn(II)–Mn(III) bond angle is equal precisely to 180° . Coordinated methanol molecules in complexes **99** and **100** are labile and can be replaced by other donating ligands, e.g., H_2O or 2-pyridone.

99, 100

$\text{R} = \text{Me}$ (**99**), CH_2OH (**100**).

Mixed-valence tetranuclear complexes of the 'butterfly' geometry are known only for manganese. The ratio of two- and three-valence metals in such complexes may be equal to 1 : 1 as in the complex $[\text{Mn}_2^{\text{II}}\text{Mn}_2^{\text{III}}(\mu_3\text{-O})_2(\mu\text{-OAc})_6 \cdot (2,2'\text{-bipy})_2]$ (**101**), or 1 : 3 as in compounds $[\text{Mn}^{\text{II}}\text{Mn}_3^{\text{III}}(\mu_3\text{-O})_2(\mu\text{-OOCCH}_2\text{X})_7(2,2'\text{-bipy})_2]$ [$\text{X} = \text{Cl}$ (**102**), Br (**103**)].^{131, 132} Complex **101** is formed in the reaction of the trinuclear complex $[\text{Mn}^{\text{II}}\text{Mn}_2^{\text{III}}\text{O}(\text{OAc})_6(\text{py})_3]$ with 2,2'-bipyridyl in acetonitrile and compounds **102**, **103** are formed in the reaction of the complexes $[\text{Mn}_3^{\text{II,III}}\text{O}(\mu\text{-OOCCH}_2\text{X})_7(2,2'\text{-bipy})_2]$ [$\text{X} = \text{Cl}$, Br] with 2,2'-bipyridyl in CH_2Cl_2 . The metal atoms in complexes **101**–**103** are 'butterfly'-shaped, the Mn(II) atoms in compound **101** being located in the 'wings' of the 'butterfly', while in complexes **102** and **103** the 'wings' are formed by one Mn(II) and one Mn(III) atom.

Pentanuclear mixed-valence complexes $[\text{M}_5(\text{OOCBu}^t)_2 \cdot (\text{C}_6\text{H}_4\text{O}_2\text{-}o)_4(\text{py})_8]^+$ [$\text{M} = \text{Mn}$ (**104**), Fe (**105**)] are obtained in reactions of metal pivalates and chlorides with tetrabutylammonium catecholate $(\text{Bu}_4\text{N})_2(\text{C}_6\text{H}_4\text{O}_2\text{-}o)$ in pyridine.¹³³ They were isolated as salts with outer-sphere anions Cl^- , Br^- , PF_6^- . The only three-valence metal atom is located in the central position and can be replaced by another metal. Thus the partial replacement of MnCl_2 by FeCl_3 in the starting reagents ($\text{Mn} : \text{Fe} = 4 : 1$) results in the formation of the heterometallic complex $[\text{Mn}_4\text{Fe}(\text{OOC} \cdot \text{Bu}^t)_2(\text{C}_6\text{H}_4\text{O}_2\text{-}o)_4(\text{py})_8]\text{Cl}$ (**106**). The heterometallic complex

104–107

104: $\text{M} = \text{M}' = \text{Mn}$; **105**: $\text{M} = \text{M}' = \text{Fe}$;

106: $\text{M} = \text{Mn}$, $\text{M}' = \text{Fe}$; **107**: $\text{M} = \text{Mn}$, $\text{M}' = \text{Tb}$.

$[\text{Mn}_4\text{Tb}(\text{OOCBu}^t)_2(\text{C}_6\text{H}_4\text{O}_2\text{-}o)_4(\text{py})_8]\text{NO}_3$ (**107**) was obtained by the same method.¹³⁴

Refluxing of $[\text{Fe}_3^{\text{III}}\text{O}(\text{OOCBu}^t)_6](\text{OOCBu}^t)$ and $\text{M}(\text{acac})_2$ in pentadecane yields pentanuclear complexes $[\text{Fe}_3\text{M}_2(\mu_4\text{-O})(\mu_3\text{-OH})(\mu_3\text{-OOCBu}^t)(\mu_2\text{-OOCBu}^t)_6(\mu, \eta^2\text{-acac})_2(\eta^2\text{-acac})][\text{M} = \text{Mn}$ (**108**), Co (**109**), Ni (**110**)].¹³⁵

108–110

$\text{M} = \text{Mn}$ (**108**), Co (**109**), Ni (**110**).

Unlike iron(II) carboxylates, which are easily oxidised by atmospheric oxygen producing iron(III) derivatives, the oxidation of manganese(II) carboxylates affords stable mixed-valence hexanuclear complexes $[\text{Mn}_6(\mu_4\text{-O})_2(\text{OOCR})_{10}\text{L}_4]$ (**111**–**117**). The metal core of these complexes $\text{Mn}_4^{\text{II}}\text{Mn}_2^{\text{III}}\text{O}_2$ is surrounded by six μ_2 -bridging, four μ_3 -bridging carboxylate groups and four N- or O-donating terminal monodentate ligands.^{16, 136–141} Four manganese(II) atoms in these complexes occupy peripheral positions.

111–117

111: $\text{R} = \text{Me}$, $\text{L} = \text{py}$; **112**: $\text{R} = \text{Ph}$, $\text{L} = \text{py}$; **113**: $\text{R} = \text{Ph}$; $\text{L} = 1/2 \text{ py}$, $1/2 \text{ MeCN}$; **114**: $\text{R} = \text{Bu}^t$, $\text{L} = \text{HO}_2\text{CBu}^t$; **115**: $\text{R} = \text{Bu}^t$,

$\text{L} = \text{py}$; **116**: $\text{R} = \text{Bu}^t$, $\text{L} = \text{THF}$; **117**: $\text{R} = \text{Bu}^t$, $\text{L} =$

The methods of synthesis of such complexes are quite diverse. For example, complex **114** is obtained by refluxing $\text{Mn}(\text{NO}_3)_2 \cdot x\text{H}_2\text{O}$ ($x = 4\text{--}6$) with an excess of pivalic acid in dioxane, while complex **115**, by reaction of complex **114** with pyridine in chloroform, whereupon the terminal pivalic acid molecules are replaced by pyridine molecules. Complex **116** can be obtained either by oxidation of a mixture of $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$ and NaOOCBu^t in methanol and recrystallisation of the reaction product from THF or by oxidation of the complex $[\text{Mn}_3(\text{OOC} \cdot \text{Bu}^t)_6(\text{HOOCBu}^t)_3]$ (**47**) in THF.

Among octanuclear complexes, compounds $[\text{Mn}_6^{\text{II}}\text{Mn}_2^{\text{III}}(\mu_4\text{-O})_2(\mu\text{-OOCCH}_2\text{Bu}^t)_{14}(\text{HO}_2\text{CCH}_2\text{Bu}^t)_4]$ (**118**) and $[\text{Mn}_4^{\text{II}}\text{Mn}_4^{\text{III}} \cdot \text{O}_2(\text{OH})_2(\text{OOCPh})_{10}(\text{L})_4]$ (**119**, L is phenyl 2-pyridyl ketone oxime) have to be noted.^{142, 143} Complex **118** was obtained by reduction of the dodecanuclear cluster $[\text{Mn}_8^{\text{III}}\text{Mn}_4^{\text{IV}}\text{O}_{12}(\text{OOCCH}_2 \cdot \text{Bu}^t)_{16}(\text{H}_2\text{O})_4]$ (**120**) with pyridine-2,6-dimethanol. The metal-fragment $[\text{Mn}_2^{\text{III}}\text{Mn}_4^{\text{II}}(\mu_4\text{-O})_2]^{10+}$ in this complex is identical to

those in compounds **111**–**117**. The build-up of the metal core $\text{Mn}_2^{\text{III}}\text{Mn}_4^{\text{II}}(\mu_4\text{-O})_2$ occurs upon linking of two adjacent bridging carboxylate ligands with two Mn(II) atoms.

Complex **119** obtained by oxidation of $\text{Mn}(\text{OOCPh})_2 \cdot 2\text{H}_2\text{O}$ with tetrabutylammonium permanganate in the presence of phenyl 2-pyridyl ketone oxime also contains metallofragment $[\text{Mn}_4^{\text{III}}\text{Mn}_2^{\text{II}}(\mu_4\text{-O})_2]^{12+}$ but with four Mn(III) and two Mn(II) atoms. In this case, the build-up of the metal core proceeds from the opposite sides of the metal moiety.

In contrast to iron derivatives, mixed-valence manganese complexes are known that contain simultaneously bi-, tri- and tetra-valent manganese ions. For example, the reaction of mixed-valence acetate complex $[\text{Mn}_3\text{O}(\text{OAc})_6(\text{py})_3]$ with 1,1,1-tris(hydroxymethyl)ethane (H_3L) results in the formation of nonanuclear complex $[\text{Mn}_2^{\text{II}}\text{Mn}_4^{\text{III}}\text{Mn}_3^{\text{IV}}\text{O}_7(\text{OAc})_{11}\text{L}(\text{py})_3(\text{H}_2\text{O})_2]$ (**121**).¹⁴⁴

However, the reaction of similar triphenylacetate complex $[\text{Mn}^{\text{II}}\text{Mn}_2^{\text{III}}(\mu\text{-O})(\text{OOCPh})_6(\text{py})_2(\text{H}_2\text{O})]$ with 1,1,1-tris(hydroxymethyl)ethane yields the dodecanuclear complex $[\text{Mn}_2^{\text{II}}\text{Mn}_{10}^{\text{III}}\text{O}_4(\text{OH})_2(\text{OOCPh})_{12}(\text{L})_4(\text{py})_2]$ (**122**). The metal core of this complex consists of ten triangular fragments $\{\text{Mn}_3(\mu_3\text{-O})\}$ with nine common sides.¹⁴⁵ The Mn(II) atoms occupy the peripheral positions in this system.

The dodecanuclear complex $[\text{Fe}_8^{\text{II}}\text{Fe}_4^{\text{III}}(\text{O})_2(\text{OMe})_{18}(\text{OAc})_6 \cdot (\text{MeOH})_{4.67}]$ (**123**) is obtained by controlled oxidation of a methanolic solution of iron acetate in the presence of lithium methoxide.¹⁴⁶ In this compound, six Fe(II) and four Fe(III) atoms are linked by two μ_6 -oxo-bridges.

If a $\text{FeCl}_2\text{-ClCH}_2\text{COOH}$ mixture is used instead of iron acetate, the reaction with LiOMe and atmospheric oxygen results in a similar dodecanuclear complex with a part of carboxylate groups replaced by chlorine atom: $[\text{Fe}_8^{\text{II}}\text{Fe}_4^{\text{III}}(\text{O})_2(\text{OMe})_{18} \cdot (\text{OOCCH}_2\text{Cl})_{5.3}\text{Cl}_{0.7}(\text{MeOH})_4]$ (**124**).¹⁴⁷ More profound oxidation yields the Fe(III) cyclic complex $[\text{Fe}(\text{OMe})_2(\text{OOCCH}_2\text{Cl})]_{10}$ known as a molecular ‘iron ring’.¹⁴⁷

The reaction of manganese dodecanuclear complexes with reducing agents not always results in their decomposition. For instance, one-electron reduction of the complex $[\text{Mn}_8^{\text{III}} \cdot \text{Mn}_4^{\text{IV}}\text{O}_{12}(\text{OOCR})_{16}(\text{H}_2\text{O})_4]$ ($\text{R} = \text{Et}, \text{C}_4\text{H}_3\text{S}$) with tetraphenylphosphonium iodide produces the corresponding ionic molecular magnets $[\text{PPh}_4][\text{Mn}^{\text{II}}\text{Mn}_7^{\text{III}}\text{Mn}_4^{\text{IV}}\text{O}_{12}(\text{OOCR})_{16}(\text{H}_2\text{O})_x]$ [$\text{R} = \text{Et}, x = 4$ (**125**), $\text{R} = \text{C}_4\text{H}_3\text{S}, x = 2$ (**126**)], in which just one manganese atom is in the oxidation state +2 (see Refs 9, 148).

As was mentioned above, the use of polyfunctional ligands in the reactions with metal carboxylate increases the possibility of formation of polynuclear complexes. Thus the tetradecanuclear carboxylate complex $[\text{Mn}_{10}^{\text{II}}\text{Mn}_4^{\text{III}}\text{O}_4(\text{OAc})_{20}(\text{HL})_4]$ (**127**, $\text{H}_2\text{L} = (2\text{-C}_5\text{H}_4\text{N})_2\text{C}(\text{OH})_2$) is the reaction product of manganese acetate with bis(2-pyridyl) ketone, which can exist as a *gem*-diol when coordinated by metal ions, in acetonitrile in air.¹⁴³

The reaction of two triangular complexes $[\text{Mn}_3^{\text{III}}\text{O}(\text{OAc})_6 \cdot (\text{py})_3]\text{ClO}_4$ and $[\text{Mn}_3\text{O}(\text{OAc})_6(\text{py})_3]$ with 2-(2-hydroxyethyl)pyridine (HL) in acetonitrile results in the formation of polynuclear ionic complex $[\text{Mn}_2^{\text{II}}\text{Mn}_{16}^{\text{III}}\text{O}_{14}(\text{OAc})_{18}\text{L}_4(\text{HL})_2(\text{H}_2\text{O})_2](\text{ClO}_4)_2$

127

(128) in which the linear fragment $[\text{Mn}_4^{\text{III}}\text{O}_6]$ is linked to two heptanuclear fragments $[\text{Mn}^{\text{II}}\text{Mn}_6^{\text{III}}\text{O}_9]$.¹⁴⁹

128

The complex $[\text{Mn}_3^{\text{II}}\text{Mn}_{18}^{\text{III}}\text{O}_{14}(\text{OH})_2(\text{OAc})_{16}\text{L}_8(\text{pic})_2(\text{py}) \cdot (\text{H}_2\text{O})](\text{ClO}_4)_4$ (129, Hpic is α -picolinic acid) is formed in the reaction of $[\text{Mn}_{10}^{\text{III}}\text{O}_4(\text{OH})_2(\text{OAc})_8\text{L}_8](\text{ClO}_4)_4$ [HL is 2-(hydroxymethyl)pyridine] and $[\text{Mn}_3^{\text{II}}\text{O}(\text{OAc})_6(\text{py})_3]\text{ClO}_4$ in MeCN.¹⁵⁰ It should be noted, that partial reduction of manganese atoms proceeds due to the oxidation of 2-(hydroxymethyl)pyridine anions to anions of α -picolinic acid. Thus, starting from manganese(III) complex, it is possible to obtain a mixed-valence complex with the $[\text{Mn}_{21}(\mu_4\text{-O})_4(\mu_3\text{-O})_{12}(\mu\text{-O})_{16}]$ metal core. In this metal core, the linear fragment $[\text{Mn}_4^{\text{III}}\text{O}_6]$ is surrounded by two octanuclear fragments $[\text{Mn}^{\text{II}}\text{Mn}_7^{\text{III}}\text{O}_{12}]$ and one mononuclear $[\text{Mn}^{\text{II}}\text{O}_3]$ fragment (marked with bold lines).

129

Recrystallisation of the complex $[\text{Mn}_8^{\text{III}}\text{Mn}_4^{\text{IV}}\text{O}_{12}(\text{OOC} \cdot \text{CH}_2\text{Bu}^t)_{16}(\text{H}_2\text{O})_4]$ (120), which can be obtained by oxidation of manganese(II) acetate with potassium permanganate in the presence of $\text{Bu}^t\text{CH}_2\text{COOH}$, from $\text{CH}_2\text{Cl}_2\text{--MeNO}_2$ affords the complex $[\text{Mn}_3^{\text{II}}\text{Mn}_{26}^{\text{III}}\text{Mn}^{\text{IV}}\text{O}_{24}(\text{OH})_8(\text{OOCCH}_2\text{Bu}^t)_{32}(\text{H}_2\text{O})_2 \cdot (\text{MeNO}_2)_4]$.^{151, 152} This compound has a virtually linear

$[\text{Mn}_4\text{O}_6]$ core, which is fixed between two $[\text{Mn}_{13}\text{O}_9(\text{OH})_4]$ fragments. The quantum tunnelling of magnetisation (QTM) was reported for this compound as well as for not numerous polynuclear complexes 64, 121, 122, 125, 126, 128 and 129. The QTM is possible in polynuclear systems with several states of different multiplicity and a hysteresis at low temperature, thus these compounds belong to a unique class of molecular magnets (SMMs, Single Molecular Magnets).^{8, 9, 153} It should be noted, that the complexes containing eight and more metal atoms are exceptional for such carboxylate systems, rather unique and do not have analogues among carboxylate complexes of other transition metals.

VI. Conclusion

In conclusion, an exceptional diversity of structures of Mn(II) and Fe(II) carboxylates discussed — from relatively simple binuclear complexes up to highly complicated 30-nuclear hetero-spin compounds — is worth noting. Undoubtedly, these compounds with unique magnetic properties, which should be a subject of another review, are extremely important blocks for the creation of molecular electronic devices in the nearest future. The first synthetic strategies of the targeted production of high spin bi- and trinuclear systems with required structure and magnetic properties, already exist. However, the approaches to the synthesis of structures more complicated and probably more interesting as molecular magnets are obviously yet to be developed.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project Nos 04-03-32880, 04-03-32883, 05-03-32767), of the Chemistry and Materials Section of the Russian Academy of Sciences (the Target basic research programme 'Chemistry and Physical Chemistry of Supramolecular Systems and Atomic Clusters'), of the Presidium of Russian Academy of Sciences [Project 'Molecular Design of Magnetoactive Compounds and Materials (Molecular Magnets)'] and of the INTAS (Grant 03-51-4532).

The chemistry of 3-cyanopyridine-2(1*H*)-chalcogenones

V P Litvinov

Contents

I. Introduction	577
II. Methods of synthesis	577
III. Reactivity and chemical transformations	588
IV. Applications	595
V. Conclusion	595

Abstract. The data on the methods of synthesis and chemical properties of 3-cyanopyridine-2(1*H*)-chalcogenones published over the last 20 years are systematised and analysed. Special attention is given to the use of these compounds as building blocks in the synthesis of fused *O,N,S*-heterocycles. The bibliography includes 277 references.

I. Introduction

Pyridine derivatives and their fused analogues have been in the centre of attention of researchers over many years due to the high practical value of these compounds, in the first place, the unusually broad spectrum of biological activities. In a paper by Lukevits¹ devoted to the 150th anniversary of pyridine chemistry, it was noted that more than 10% of the 1500 therapeutic agents most popular to that period contain the pyridine ring in their active components. These include vitamins (B₃, B₆, PP), analgetics, analeptics, antiarrhythmic drugs, antiseptics, antidepressants, spasmolytics, neuroleptics, tranquilisers and other medicines manifesting diverse pharmacological activities. This is why the expediency of improving the existing methods and a search for novel methods for the construction of pyridine-containing substrates as 'building blocks' for organic synthesis leaves no doubt. The synthetic potential of such compounds revealed from the analysis of their structures and reactivities will enable the development of convenient, cost-effective and environmentally safe methods for the preparation of novel pyridine derivatives possessing valuable biological properties.

Recently, functionalised pyridinechalcogenones have become the subject of intensive studies in the chemistry of heterocyclic compounds. This particular class of substances presents both theoretical and practical interest. Pyridinechalcogenone derivatives are used, *inter alia*, as substrates in the preparation of a medicine Bupiron, which possesses antidepressant and analgetic activities and prevents narcotic dependence, and some novel types of calcium antagonists and antioxidants. In addition, these compounds can be used as models for the redox coenzymes NAD and

NADP and as substrates for the synthesis of folic acid derivatives, vitamin B₆ and some other biologically active compounds. 3-Cyanopyridine-2(1*H*)-thione derivatives are used in the production of dyes, pigments, additives to fuels and lubricants, stabilisers for polymers and varnishes, acid–base indicators for titrimetric assays and as other important compounds.

The unfading interest in the chemistry of pyridinechalcogenones observed over the past two decades is reflected in numerous patents and papers that are partially systematised in the reviews^{2–14} and numerous theses (see, *e.g.*, those presented over the past two years^{15–19}).

The topicality of this line of research and the lack of comprehensive reviews on the state-of-the-art and future outlooks in heterocyclic chemistry served as a reason for preparing the present review. Here, an attempt is made at systematisation and analysis of modern data (predominantly those obtained in the past two decades) on the chemistry of 3-cyanopyridine-2(1*H*)-ones (thiones, selones).[†] These compounds contain, along with the nitrile group, an amide, a thioamide or a selenoamide group with the endocyclic nitrogen atom in the vicinal position and represent convenient synthons of a vast array of annelated heterocyclic systems (including those hardly obtainable by other methods). The main attention in the review is focused on the methods for the synthesis of 3-cyanopyridine-2(1*H*)-chalcogenones and their applications as building blocks in the synthesis of biologically active compounds. Aromatic, di- and tetrahydro-forms of these compounds, hydrated derivatives as well as enol tautomers are considered. The physicochemical properties and general regularities of the reactivities of this class of compounds have been discussed earlier (see, for example, Ref. 8) and are beyond the scope of the present review.

II. Methods of synthesis

Systematisation of the methods for the synthesis of heterocyclic compounds is based on different principles (*e.g.*, type of reactants, reaction mechanisms, *etc.*). The formally logical retrosynthetic classification based on the topology of the bonds formed is especially popular. The formation of any heterocyclic system is represented as the formation of specific bonds in preformed structural blocks, which enables comparison and estimation of the value of each approach and the development of novel, hitherto

V P Litvinov N D Zelinsky Institute of Organic Chemistry, Russian Academy of Sciences, Leninsky prosp. 47, 119991 Moscow, Russian Federation. Fax (7-495) 135 53 28, tel. (7-495) 135 88 37, e-mail: vpl@ioc.ac.ru

[†] According to the IUPAC Nomenclature, these compounds should be termed as 2-oxo(thioxo,selenoxo)-1,2-dihydropyridine-3-carbonitriles; however, in this work we shall adhere to the historic names.

unexplored trends. In the framework of this approach, all the methods for the synthesis of 3-cyanopyridine-2(1*H*)-chalcogenones are classified into six groups. Examples of methods for the introduction or modification of substituents in the preformed pyridine substrates and for cyclisation of a five-carbon fragment with formation of the N–C bond are few in number. Most of the data available refer to different methods for the synthesis of the pyridine ring from two fragments. Information on the cyclisation of three- and two-carbon fragments (3 + 2) is especially abundant as can be judged from the number of relevant papers. In this case, the formation of the N–C bond is accompanied by the formation of a new carbon–carbon bond, *viz.*, C(5)–C(4) (structures **A** and **B**) or C(3)–C(4) (structures **C** and **D**).

In addition to a small chapter devoted to the synthesis of the pyridine ring from three fragments (1 + 2 + 2) (structure **E**), some examples of the formation of the pyridine system based on ring transformation reactions are considered.

It is of note that the most promising procedures for the synthesis of pyridinechalcogenones based on cyclisation of several fragments are usually performed as one-pot synthesis. A chain of sequential conversions of functional groups, elongation of the carbon chain and its cyclisation without any additional reagent or a catalyst and without any change in the reaction temperature has got the name cascade heterocyclisation. Such a methodology of the synthesis of 3-cyanopyridine-2(1*H*)-chalcogenones has been discussed in detail.²

1. Introduction or modification of a substituent in a preformed pyridine substrate

Introduction or modification of a substituent in a preformed pyridine substrate is the most direct approach to the synthesis of 3-cyanopyridine-2-chalcogenones. Only a few examples of this approach are known, since the starting compounds for such syntheses are difficult to obtain.

Thus substitution of the cyano group for the bromine atom was employed in a facile preparation of a phosphodiesterase inhibitor drug Milrinone (**1**). The reaction of 3-bromopyridin-2(1*H*)-one **2** with potassium cyanide in acetonitrile proceeds smoothly in the presence of 18-crown-6.²⁰

In some cases, the starting compounds contain a nitrile group in the pyridine (quinoline) ring. For example, 3-cyanopyridin-2(1*H*)-ones **3** were prepared from substituted 2-amino-3-cyanopyridines **4** by diazotisation and subsequent hydrolytic elimination of dinitrogen.^{21, 22}

$R^1 = \text{Ar, Het}; R^2 = \text{Alk, OAlk, SAlk, OPh.}$

Methoxylation of 3-cyano-2-haloquinolines **5** was used for an access to a broad series of 2-methoxy derivatives **6**; their acid hydrolysis resulted in 3-cyanoquinolinones **7**.^{23–27}

$R^1 = \text{H, Alk, CN, NO}_2, \text{Hal}; R^2 = \text{H, Alk, Het, Hal, SO}_3\text{H}; R^3 = \text{Het.}$

2. Cyclisation of a five-carbon fragment with formation of the N–C(6) bond

Only one example of a conversion of an acyclic precursor (*viz.*, polyfunctional alkene) into 3-cyanopyridin-2-one is documented. Synthesis of the aforementioned drug Milrinone (**1**) by cyclisation of tricyanohexa-1,4-dienamide **8** with elimination of malononitrile in EtOH in the presence of a base (**B**) (NaOH, Na₂CO₃ or EtONa) has been patented.²⁸ The yield of the target product was not indicated.

3. Synthesis of the pyridine ring from two fragments

a. Cyclisation of four- and single-carbon fragments with formation of the N–C(6) and C(5)–C(6) bonds

The first, within the given classification, variant of the assembly of the 3-cyanopyridine-2-chalcogenone molecule from two fragments includes cyclisation of four- and one-carbon units. Such reactions result in the formation of the C(5)–C(6) and N–C(6) bonds of the pyridine ring. This approach is exemplified by a single type of reactions, *viz.*, condensation of unsaturated cyanoamides with dimethylformamide acetal.

A non-trivial synthesis of tetrahydroisoquinolinone **9** from cyanoamide **10** and dimethylformamide diethyl acetal has been described.²⁹ This was converted into both isoquinolinedione **11** and pyrido[3,4-*c*]carbazole **12**.

A similar reaction of cyanoamides **13** and **14** with dimethylformamide diethyl acetal was employed in the synthesis of pyrano[3,4-*c*]pyridin-3-one **15**³⁰ and pyrido[4,3-*a*]azepin-3-one **16**,³¹ respectively:

b. Cyclisation of three- and two-carbon fragments with formation of the C(5)–C(4) and N–C bonds

The construction of the pyridine molecule from two- and three-carbon fragments with simultaneous (or consecutive) formation of the C(4)–C(5) and N–C(6) bonds is often used in the synthesis of 3-cyanopyridine-2-chalcogenones. Arylmethylidene(cyano)thioacetamides **17** are usually employed as the principal components to which a two-carbon fragment is attached.

Synthesis of tetrahydroquinolinethiones **18** from (thio)cyclohexanone or enamine **19** is the simplest example of such a reaction.³² This is carried out in methanol at room temperature; the yields are 78%–86%.

X = O, S; Ar = RC₆H₄ (R = H, 2-F, 4-F, 4-Cl, 4-Br, 4-MeO), 3-Py.

Diketones and the corresponding enamines react similarly with arylmethylidene(cyano)thioacetamides **17** to yield partially hydrogenated 3-cyanopyridine-2(1*H*)-thiones or their salts (Refs 11, 33–51). The intermediate thiolates **20** can be isolated; their subsequent dehydration results in 3-cyano-1,4-dihydropyridine-2-thiolates **21**. Upon acidification, the salts **20** and **21** are converted into 3-cyano-3,4-dihydropyridine-2-thiolates **22** which

undergo dehydrogenation in solution to afford 3-cyanopyridine-2(1*H*)-thiones **23**. Enamines derived from diketones react with amides **17** in the absence of basic catalysts; the corresponding 1,4-dihydropyridine-2-thiolates are formed in high yields.

R¹ = R² = Alk.

This type of reactions includes also the condensation of (het)arylmethylidene(cyano)thioacetamides **17** with acetoacetanilides.^{52, 53} Amides **17** enter easily into the Michael reaction with anilides **24** due to the presence of an activated double bond; subsequent cyclisation yields 1,4-dihydropyridine-2-thiolates **25**. The latter are converted into thiols by treatment with HCl; in DMSO, thiols exist as a mixture of tautomers **26A** and **26B**.

Cyclic 1,3-dicarbonyl compounds, in particular, dimedone, are also widely and successfully used in the synthesis of 3-cyanopyridine-2-chalcogenones (**27**). The use of dimedone made it possible to elucidate some peculiarities of the mechanism of its reaction with arylmethylidene(cyano)thioacetamides **17** (see, for example, Refs 7, 52, 54 and 55). In some cases, intermediate Michael adducts **28** were isolated as rather stable salts, which enabled studies of their properties. Thus acidification of salts **28** yielded compounds **29**; heating of the latter in the presence of organic bases (or direct heating of salts **28** with subsequent acidification) resulted in dihydropyridine-2-thiones **30A**. It is of note that compounds **29** are converted into substituted tetrahydro-4*H*-benzo[*b*]pyrans **31** in the presence of triethylamine. These represent the products of kinetic control, which are converted into thermodynamically controlled dihydropyridine-2-thiones **30A** existing in a tautomeric equilibrium with the thiol form **30B** in polar solvents (e.g., ethanol).

Dimedone (**27**) was successfully used in the synthesis of spirofused 3-cyanopyridine-2(1H)-thione from cyclohexylidene(cyano)thioacetamide **32**. The reaction in ethanol in the presence of morpholine afforded 3,4,5,6,7,8-hexahydroquinoline-4-spiro-1'-cyclohexane-2(1H)-thione (**33**) in high yield.^{52, 56}

The reaction of arylmethylidene(cyano)thioacetamides **17** with Meldrum's acids **34** is an example of the use of other cyclic 1,3-diketones in the synthesis of pyridinechalcogenones by this method. This is carried out in ethanol in the presence of a base (e.g., piperidine, *N*-methylmorpholine); under these conditions, 4-aryl-3-cyano-6-oxo-1,4,5,6-tetrahydropyridine-2-thiolates **35** are formed in 85% yields. If the reaction is carried out in benzene, the yields of the products drop down to 30%.⁵⁷

$\text{R}^1 = \text{R}^2 = \text{Me}$, $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_5$; Ar = 2- ClC_6H_4 , 4- BrC_6H_4 .

Pyridinium ylides also play the role of two-carbon fragments.^{58–66} Synthesis of *trans*-6-thioxo-1,4,5,6-tetrahydropyridine-2-thiolates **36** by the reaction of pyridinium ylide **37** with

arylmethylidene(cyano)thioacetamides **17** can serve as an example.^{51, 58, 59, 61}

Ar = 4- XC_6H_4 (X = HO, MeO, F, Cl, Br), 3-Py.

In this reaction, the effect of conditions on the nature of the products formed was observed. Thus heating of amides **17** with *N*-phenacylpyridinium salts **38** in the presence of ammonium acetate in acetic acid yielded 4,6-diaryl-3-cyanopyridine-2(1H)-thiones **39**.⁵⁸ However, reactions of pyridinium ylides **40** generated from the salts **38** with the same amides **17** in ethanol in the presence of triethylamine proceeded with high regio- and stereo-selectivity and gave *trans,trans*-1,4,5,6-tetrahydropyridine-2-thiolates **41**.^{62–64} The latter were converted into thiones **39** by heating in acetic acid in the presence of ammonium acetate.

R = Me, Ph, cyclo- C_3H_5 ; Ar = XC_6H_4 (X = H, 4-MeO, 4- NO_2 , 2-F, 4-F, 4-Br), 3-Py.

Isoquinolinium ylides were also used in the synthesis of thiolates **41**.⁶³

It is noteworthy that the three-carbon fragment (unsaturated thioamide) of the target pyridinechalcogenone is often cut out upon ring transformation of six-membered cyclic enaminonitriles, derivatives of 4*H*-pyran, 4*H*-thiopyran, 4*H*-selenopyran and 1,3-dithiacyclohexene.^{7, 8, 32, 35, 54, 67–81} Thus it was found that heating of 4*H*-thiopyran **42** with pyridinium salt **38** results in the breakdown of the thiopyrane ring.¹¹ Subsequent reaction (formally, cross-ring transformation) of thioacetamide **17** and pyridinium ylide **40** formed thereupon yielded stable 1,4,5,6-tetrahydropyridine-2-thiolates **41**.

$\text{R}^1, \text{R}^2 = \text{Alk}, (\text{CH}_2)_n$; Ar = Ph, 3- FC_6H_4 , 4- FC_6H_4 , 4- ClC_6H_4 .

The reaction of 1,3-dithiacyclohex-4-enes **43** with salt **38** proceeds in a similar manner. Upon elimination of a thioketone,¹¹

pyridinium ylides **40** react with *in situ* generated thioamides **17** to yield stereoselectively thiolates **41**.

The use of selenium analogues of thioamides **17** is documented. The reaction of acetylacetone with 2-furfurylidene(cyano)selenoacetamide **44a** affords, *via* the intermediate Michael adduct **45** and stable salt **46**, 5-acetyl-3-cyano-4-(2-furyl)-6-methyl-1,4-dihydropyridine-2-selenol (**47**) (yield 80%).^{52, 82}

Fu is 2-furyl.

A method for the synthesis of *trans*-5-benzoyl-3-cyano-4-(2-thienyl)-6-trifluoromethyl-3,4-dihydropyridine-2(1*H*)-selenone (**48**) was developed, which consists of treatment of benzoyltrifluoroacetone with 2-thienylmethylidene(cyano)selenoacetamide (**44b**) in the presence of *N*-methylmorpholine (yield 78%).⁴⁰

Condensation of hetaryl(methylidene)(cyano)selenoacetamides **44** with acetoacetanilide (**24**, R¹ = Ph) or acetoacetamide (**24**, R¹ = H) also occurs in a regioselective mode and yields 1,4-dihydropyridine-2-selenolates **49**.^{83, 84}

R¹ = H, Ph; R² = Het, B is morpholine.

In addition to the above-mentioned fragment CH–C(O), the role of a two-carbon component can be played by the CH₂CN group. Thus the reaction of anilides of cinnamic and other 3-aryl-2-cyanoacrylic acids **50** with this type of CH-acids was successfully used in the synthesis of 3,4-dihydropyridine-2(1*H*)-ones. These reactions are carried out in boiling ethanol in the presence of piperidine (Pip).⁸⁵

R = NC, EtO₂C, PhHNC(O), 4-ClC₆H₄C(O).

In conclusion, we mention some interesting examples of the use of unsaturated dinitriles as three-carbon and one-nitrogen atom donors for the pyridine ring. Reactions of dinitriles of the

styrene type with 4-(cyanoacetyl)pyrazolinone **51** give substituted 3,4-dihydropyridine-2(1*H*)-thiones **52** in up to 75% yields.⁸⁶

Reactions of substituted furfurylidene malononitriles **53** with alicyclic and aliphatic *gem*-dithiols **54** were also reported.^{68, 70} Contrary to benzylidenemalononitriles, these reactions directly yielded substituted tetrahydroquinolinethiones **55** rather than the corresponding 1,3-dithiacyclohexenes (see Section II.5).

R¹ = H, Me; R² = Me, Et; R¹–R² = (CH₂)_n (n = 3–5); X = H, 2,4-Cl₂C₆H₃, 3,4-Cl₂C₆H₃; B is morpholine,⁶⁸ Et₂NH.⁷⁰

The synthesis of substituted pyridone **56** is the only example of construction of 3-cyanopyridine-2-chalcogenones from two- and three-carbon fragments; this involves the formation of the C(4)–C(5) and N–C(2) bonds. Nucleophilic addition of enamine **57** to unsaturated nitrile **58** yields the final product.⁸⁷

c. Cyclisation of one- and three-carbon fragments with formation of the C(3)–C(4) and N–C bonds

The construction of a pyridine system from two fragments with formation of the C(3)–C(4) and N–C(6) bonds is the most popular approach to the synthesis of 3-cyanopyridine-2(1*H*)-chalcogenones. Such conversions follow the cascade heterocyclisation mechanism and begin with the addition of 1,3-bis-nucleophile, *viz.*, cyanoacetamide, its thio- or selenium derivative, to a three-carbon fragment. The role of the latter can be played by 1,3-bis-electrophiles, *e.g.*, different forms of α,β-unsaturated carbonyl and 1,3-dicarbonyl compounds, such as aldehydes, ketones and their enols as ethers and salts, as well as by enamines and carboxylic acid derivatives (esters, amides, nitriles).

The majority of published data are devoted to the synthesis of 3-cyanopyridine-2(1*H*)-chalcogenones by the reaction of α,β-unsaturated carbonyl compounds **59** with cyano(thio,seleno)acetamides **60a–c**. This reaction occurs in the presence of organic bases as catalysts; the intermediate Michael adducts **61a–c** undergo cyclisation into 3-cyanodihydropyridine-2(1*H*)-chalcogenones **62a–c** in fairly high yields.

$R^1 - R^3 = \text{H, Alk, Ar, Het; X = O (a), S (b), Se (c); B}$ is a base.

For the first time, this method was used for the preparation of 4,6-diaryl- (Refs 88 and 89) and 4-aryl-3-cyanopyridine-2(1H)-thiones.⁹⁰ Either stable intermediates, *viz.*, salts **63** (for $X = \text{S}$), or salt derivatives of compounds **62**, *viz.*, dihydropyridines **64** (for $X = \text{S, Se}$) or dehydrogenation products **65**, can be isolated depending on the reaction conditions and the nature of the reactants. In the course of isolation, compounds **61** (or **63**) are oxidised (dehydrogenated) by atmospheric oxygen into salts **64**.

In the reactions of cyanoacetamide (**60a**) with unsaturated (hetero)aromatic ketones (**59**, $R^1, R^3 = \text{Ar, Het; } R^2 = \text{H}$), the Michael adducts (amides **61a**) can be isolated in a pure state.^{91,92} Heating of the latter in acetic acid in the presence of ammonium acetate brings about their cyclisation into pyridones **62a**, which are further dehydrogenated into pyridones **65a**.

The reaction conditions and the nature of the base (catalyst) were varied in the synthesis of 3-cyanopyridine-2(1H)-thione derivatives (see, for example, Refs 93–98). Thus the use of sodium alkoxides in boiling alcohol afforded pyridinethiones **65b**,^{89,99–101} while the use of an equimolar amount of an organic base (in ethanol at 20 °C) that served as both the catalyst and a stabilising reagent resulted in salts **63b** and **64b**.^{90,93,95–98,102} Acidification of salts **64b** with hydrochloric acid afforded 3,4-dihydropyridine-2(1H)-thiones **62b**, which were oxidised by atmospheric oxygen to thiones **65b**.

The reaction of chalcones **59** ($R^1, R^3 = \text{Ar, } R^2 = \text{H}$) with cyanoselenoacetamide **60c** in the presence of excess *N*-methylmorpholine under similar conditions gave exclusively 1,4-dihydropyridine-2-selenolates **64c** (yield 90%).^{52,103,104} Treatment of the latter with HCl afforded 1,4-dihydropyridine-2-selenols **66c**, which represent tautomers of dihydropyridine-2(1H)-selenones **62c**; the latter are easily oxidised in the air into the corresponding pyridineselones **65c**.

These data suggest that the nature of the substrate and the reagent should be taken into consideration in each particular case.

Examples of the synthesis of different 3-cyanopyridine-2-chalcogenone derivatives are given in Table 1. In all these cases, the role of the two-carbon component is played by cyano(thio, seleno)acetamide **60**, while a broad range of original 1,3-bis-electrophiles demonstrates the prospects of this approach. The versions of this reaction given in Table 1 are discussed below.

Hetero- and carbocycles (including steroids) can be annelated to α,β -unsaturated carbonyl fragments. No intermediate 3,4-dihydropyridines could be isolated in the reaction of cyclic unsaturated ketone **67** with cyanothioacetamide (**60b**) in methanol in the presence of sodium methoxide (see Table 1, entry 1).^{105–108} However, the structurally similar isochroman-4-one **68** and amide **60a** gave 3-cyano-3,4-dihydroisochromano[3,4-*b*]pyridine-2(1H)-ones **69**, which were further dehydrogenated into compounds **70** (entry 2).¹⁰⁹

Naphthyridinethiones **71** were prepared from 2-aryl-methylidenequinclidin-3-ones **72** and (cyano)thioacetamide (**60b**) (Table 1, entry 3).^{110,111} After treatment with hydrochloric acid, the primary reaction products, *viz.*, piperidinium 4-aryl-3-cyano-5,8-ethano-1,4,5,6,7,8-hexahydro-1,5-naphthyridine-2-thiolates **73**, were converted into 4-aryl-3-cyano-5,8-ethano-1,4,5,6,7,8-hexahydro-1,5-naphthyridine-2(1H)-thiones (**74**), which exist in a tautomeric equilibrium with betaines **75**. Heating of salts **73** or betaines **75** in ethanol in the presence of HCl resulted in their dehydrogenation and formation of compounds **71**.

Steroid derivatives **76** and **77** were obtained by similar reactions of ketones **78** and **79** with (cyano)thioacetamide **60b**,^{112,113} in the former case, saponification of the acetoxy group took place (entries 4 and 5).

The three-carbon fragment used in the synthesis of pyridine-chalcogenones according to the (3 + 2)-scheme can represent a component of a more complex conjugated system. In such a case, compounds containing different functional groups are formed. For instance, dimethylaminomethylidenedimedone **80a** was employed in the synthesis of 3-cyano-6-dimethylamino-pyridine-2(1H)-chalcogenones (**81**).¹¹⁴ Its reaction with *N,N*-dimethylacetamide diethyl acetal afforded diaminodienodione **82** in high yield. Reactions of the latter with cyanothio(seleno)-acetamides **60b,c** resulted in a mixture of pyridine **81** (entry 6), dimedone (**83**) and its derivative **84**.

Reactions of cyanoacetamides with cyclic and acyclic pentadien-3-ones also yielded cyanopyridinechalcogenone derivatives (see Table 1, entries 7 and 8). The reaction of dibenzylidenecyclopentanone **85** with thioamide **60b** in the presence of sodium

Table 1. Synthesis of 3-cyanopyridine-2-chalcogenone derivatives using cyanoacetamides NCCH₂C(=X)NH₂ (**60a–c**).

ethoxide at room temperature gave pyridine-2(1*H*)-thione **86** annelated with the cyclopentane ring.^{83, 115} The reaction of acyclic symmetrical pentadienone **87** performed under more drastic conditions (heating of reactants at 170 °C in a sealed tube without a solvent) afforded substituted 3-cyano-3,4-dihydropyridine-2(1*H*)-ones **88**.¹¹⁶

Amides and esters of cycloalkylidenecyano(thio)acetic acid are also used as 1,3-bis-electrophiles in reactions with amides **60**. Thus the reaction of cyclohexylidenecyanothioacetamide **32** with cyanothio(seleno)acetamides **60b,c** in ethanol in the presence of *N*-methylmorpholine gave salts **89**, which were further converted into 6-amino-3,5-dicyano-1,4-dihydropyridine-4-spiro-1'-cyclohexane-2-thione (**90b**) or -selone (**90c**), respectively, upon treatment with HCl (entry 9).^{52, 117–119} Similar spiro-fused 6-aminothiolates **91** were prepared from ethyl cyclopentylidenecyanothioacetamide (**92**);¹²⁰ 6-oxothiolates **93** were obtained from ethyl cyclopentylidenecyanoacetate (**94**) (entry 10).¹²¹

Mention should also be made of α,β-unsaturated nitriles, which, by virtue of their high availability and high reactivity, are widely employed in the synthesis of pyridinechalcogenones, of their spiro-fused derivatives, in particular. Thus compounds **89c** and **90c** were obtained from cyclohexylidenemalononitrile (**95**) and selenoacetamide **60c** (Table 1, entry 11).^{52, 117–119} Refluxing of cyanoacetamide (**60a**) and dicyanomethylidenecoumarin **96** in ethanol in the presence of piperidine gave the adduct **97**, which underwent intramolecular cyclisation *in situ* into spiropyridine-chalcogenone **98** (Table 1, entry 12).⁸⁶

Regioselective syntheses of isomeric 3-cyano-4(6)-methyl-6(4)-phenylpyridine-2(1*H*)-thiones are documented.^{122, 123} The isomer containing a phenyl group at position 4 (compound **99**) is formed in the reaction of (cyano)thioacetamide (**60b**) with acetylenic ketone **100** (entry 13). However, the reaction with enamino ketone **101** derived from alkyne **100** gave 6-phenylpyridinethione **102** (entry 14). Similarly, enamino ketone **103** gave tetrahydroquinolinethione **104** (example 15).³⁵

1,3-Dicarbonyl compounds and their derivatives, *e.g.*, the above-mentioned enamino ketones **101** and **104**, are successfully employed in the synthesis of 3-cyanopyridine-2(1*H*)-chalco-

genones. Reactions of cyanothioacetamide (**60b**) with sodium enolates of 2-formylcycloalkanones are known to yield pyridine-2(1*H*)-thiones **105** and **106** (Table 1, entry 16).¹²⁴ Reactions of 1,3-diketones **107** with cyanothio(seleno)acetamides (**60b,c**) gave high yields of substituted 3-cyanopyridine-2(1*H*)-thiones (**65b**) and -selones (**65c**) (entry 17).^{34, 89, 125–127} In the presence of bases, a similar reaction of cyclic diketones **108** occurs with high regioselectivity and affords 4,5-polymethylene-3-cyanopyridine-2(1*H*)-thiones(selones) **109** (Table 1, entry 18).^{93, 128, 129}

Different approaches to the synthesis of substituted isomeric trifluoromethylpyridine-2(1*H*)-thiones **110** (Table 1, entry 19) and **111** (entry 20) have been developed. These included the reaction of trifluoromethyl derivatives **112** with (cyano)thioacetamide (**60b**) or the reaction of 4-methoxy-1,1,1-trifluoropent-3-enone (**113**) first with EtONa and then with amide **60b**.^{53, 83, 130–134} The yields reach 90% in both cases.

It is of note that the range of substituents in pharmacologically promising 3-cyano-4-trifluoromethylpyridine-2(1*H*)-thiones is limited by the availability of the starting 1,3-dicarbonyl compounds carrying a trifluoromethyl group. To overcome this limitation, it has recently been proposed to synthesise substituted 3-cyano-4-trifluoromethylpyridine-2(1*H*)-thiones **110** from sodium enolates of trifluoromethyl-1,3-diketones **114** (Table 1, entry 21).³⁰ The latter were prepared by coupling of methylene ketones **115** with ethyl trifluoroacetate; the free 1,3-diketone was introduced without isolation into the reaction with (cyano)thioacetamide (**60b**). The role of the starting methylene ketones was played by dialkyl-, alkylaryl-, hetaryl ketones and five–eight-membered cycloalkanones; in some cases, the yields of pyridine-thiones **110** reached 98%.¹⁷

The reaction of (cyano)thioacetamide (**60b**) with 3-benzylidenecoumarin (**116**) was studied.⁴⁵ It was thiol **117** that was the condensation product (Table 1, entry 22), although no such prototropic tautomer is known for other compounds of this series.⁸

The reaction of 3-arylideneacetylacetone **118** with amide **60b** in ethanol in the presence of piperidine yielded thiolates **119**;

treatment of the latter with HCl resulted in their conversion into thiones **120** possessing neurotropic activity (entry 23).⁹⁷

Reactions of 2-dimethylaminomethylidenecyclohexane-1,3-diones **80** with cyanoacetamide (**60a**) in THF in the presence of NaOH yielded a mixture of quinolinecarbonitriles **121** (entry 24) and benzopyrancarboxamides **122**.¹³⁵ Only quinoline-3-carboxamides **123** were obtained in high yields upon change in the solvent (refluxing of the reaction mixture in absolute ethanol).

$R^1 = \text{H, Me}; R^2 = \text{H, Me, Ph.}$

Thus, numerous examples of the use of cyano(thio,seleno)-acetamides in the synthesis of 3-cyanopyridinechalcogenones listed in Table 1 illustrate the versatility of this approach.

In some cases, the same compounds can be prepared by varying the reactants. For example, the reaction products of acetylacetone with 2-furfurylideneacyanoselenoacetamide **44a** considered above (see Section II.3.b) were also synthesised under mild conditions (abs. EtOH, 20 °C) from 2-furfurylideneacetylacetone (**124**) and (cyano)selenoacetamide (**60c**) in the presence of *N*-methylmorpholine.^{52, 82} Ethyl benzylidene- and 2-furfurylideneacetoacetates react similarly with amide **60c**.^{52, 136–138}

3,5-Dicyano-6-oxo-1,4,5,6-tetrahydropyridine-4-spiro-1'-cyclopentane-2-thiolate (**93**) is formed in the reaction of cyclopentylidene(cyano)thioacetamide **92** with amide **69b** (see Table 1) or ethyl cyanoacetate.¹²¹

Reactions of bis-nucleophiles with bis-electrophiles were described in the foregoing sections. However, each of the reactants

undergoing cyclisation to give the pyridine system can simultaneously contain electrophilic and nucleophilic sites. In this case, the role of a two-carbon fragment is played by CH-acids (*e.g.*, malononitrile, ethyl cyanoacetate, acetoacetanilide, *etc.*).

Several examples of the use of malononitrile in the formation of the pyridine ring have been described. Reactions of chalcones **59** with malononitrile yield δ -keto dinitriles **125**, which give selenolates **64c** upon treatment with hydrogen selenide. The latter can further be converted into compounds **65c** and **66c** (see above).

The synthesis of hydrogenated 3-cyanoquinolin-2-ones by the reaction of malononitrile with 2-aminomethylidenecyclohexane-1,3-diones was studied in detail. It is of note that the direction of this reaction strongly depends on the reactant ratio and the nature of the catalyst and the solvent. Thus refluxing of 2-anilinomethylidene-5,5-dimethylcyclohexane-1,3-dione (**126a**) with an equimolar amount of malononitrile in ethanol in the presence of KOH gave 3-cyano-7,7-dimethyl-1,2,5,6,7,8-hexahydroquinoline-2,5-dione (**121a**)^{139, 140} (Scheme 1), while the reaction in the presence of a two-fold excess of malononitrile yielded 4-cyano-3-imino-6,6-dimethyl-2-phenyl-2,3,5,6,7,8-hexahydroisoquinolin-8-one (**127**) under identical conditions.^{139, 141} The reaction with a two-fold excess of malononitrile and piperidine as a catalyst in ethanol afforded 3-carbamoyl-5-dicyanomethylidenequinolin-2-one (**128**),¹³⁹ while the reaction in DMF in the presence of KOH resulted in *N*-phenyl-substituted 3-cyanoquinolin-2-one **129**.¹⁴² With equimolar amounts of the reactants in the presence of an excess of morpholine, compounds **121a**, **130** and **131a** were obtained in yields of 46%, 25% and 17%, respectively.¹¹⁴ In the absence of a catalyst, this reaction yielded exclusively quinolinone **121a**.

Reactions of compounds **126** bearing other substituents with a small excess of malononitrile were carried out by 1-hour refluxing in ethanol in the presence of catalytic amounts of morpholine to yield exclusively isoquinolinones **131**.¹¹⁴

Scheme 1

(a) $\text{CH}_2(\text{CN})_2$ (1 equiv.), KOH, EtOH, Δ ; (b) $\text{CH}_2(\text{CN})_2$ (2 equiv.), KOH, EtOH, Δ ; (c) $\text{CH}_2(\text{CN})_2$ (2 equiv.), Pip, EtOH; (d) $\text{CH}_2(\text{CN})_2$ (2 equiv.), KOH, DMF; (e) $\text{CH}_2(\text{CN})_2$ (excess), morpholine (cat.), EtOH, Δ , 1 h; (f) $\text{CH}_2(\text{CN})_2$ (1 equiv.), morpholine (excess), EtOH, Δ , 1 h.

$\text{R}^1 = \text{Me, Ph; R}^2, \text{R}^3 = \text{H, Me, Ph; B}$ is morpholine.

Let us consider a non-trivial example of a reaction of 5-hetarylsulfonyl-8-hydroxyquinolines **132** with ethyl cyanoacetate in the presence of ammonium acetate, which afforded a new heterocyclic system **133**.¹⁴³

$\text{R} = \text{Alk.}$

A method for the synthesis of 3,4-dihydropyridine-4-spiro-1'-cyclohexane-2(1*H*)-thione by the reaction of amide **32** with acetoacetanilide in ethanol in the presence of *N*-methylmorpholine (yield 87%) has been described.^{52, 144}

Alkylarylidencyanoacetates **134** reacted with cyanoaceto-hydrazide in boiling ethanol in the presence of triethylamine or piperidine to give pyridones **135** in > 80% yields.¹⁴⁵ However, at room temperature this reaction gave, along with pyridones **135**, 3,4-dihydropyridin-2(1*H*)-ones **136**.^{146–148}

$\text{Ar} = 4\text{-XC}_6\text{H}_4$ ($\text{X} = \text{H, Me, Cl, NO}_2$).

The reaction of *N*-furfurylacrylamide **137** with *N*'-phenylcyanoaceto-hydrazide **138** gave functionalised 3-cyanopyridone **139**.¹⁴⁹

In all the above-cited reactions of the pyridine ring closure, the N–C(6) bond was formed along with the C(3)–C(4) bond.

However, there is only one example of the formation of the N–C(2) bond, *viz.*, condensation of 2-amino-3-benzoylpyridine (**140**) with cyanoacetic acid derivatives. Subsequent hydrolysis gives 3-cyano-2-hydroxy-1,8-naphthyridine **141**.¹⁵⁰

$\text{R} = \text{NH}_2, \text{OMe, OEt.}$

Thus, this method for the preparation of 3-cyanopyridine-2-chalcogenones is represented by the largest number of examples. Presumably, it is the most efficient approach to the synthesis of this class of compounds.

4. Synthesis of the pyridine ring from three fragments

Among other approaches to the synthesis of pyridine chalcogenones, multicomponent condensations (cascade heterocyclisation) have recently gained increasing popularity. For example, three-component condensation (1 + 2 + 2), which consists of reactions of aliphatic, aromatic or heteroaromatic aldehydes with 1,3-dicarbonyl compounds and cyano(thio,seleno)acetamides **60a–c**, is often used in the synthesis of substituted 3-cyanopyridine-2(1*H*)-thiones.^{7, 8, 17, 22, 125, 151–154} In this section, aldehydes and isatins are considered as examples of one-carbon fragments, while substituted acetone, malononitrile and pyridinium ylides, as fragments forming the C(5)–C(6) bond in the pyridine ring. In all these cases, cyanoacetamides **60a,b** were used as nitrogen, C(2) and C(3) sources.

Thus condensation of 4-pyridylacetone (**142**) with aldehydes and cyanoacetamide (**60a**) gave a mixture of pyridones **143–145**, which were separated by crystallisation.¹⁵⁵

$\text{R} = \text{Ar, Het.}$

Substituted isatins **146** reacted with malononitrile and (cyano)thioacetamide **60b** in ethanol in the presence of piperidine. This afforded spiro derivatives **147**, which represent the hydrolysis products of the intermediate 6-iminopyridine-2-thiones and which are difficult to prepare by other methods.¹⁵⁶

As is known, pyridinium ylides generated *in situ* from quaternised pyridines are widely and successfully employed in organic

synthesis,^{155–158} particularly for the preparation of substituted 3-cyanopyridine-2(1*H*)-thiones. Simple procedures for their synthesis were developed on the basis of the three-component coupling methodology.^{17, 51, 58–62, 64–66, 159–163} Thus reactions of pyridinium ylides **148** with aromatic aldehydes and cyanothioacetamide (**60b**) in ethanol in the presence of triethylamine proceeded in a regio- and stereoselective manner and afforded hydrogenated *trans*-4-aryl-3-cyano-5-pyridiniumpyridine-2-thiolates **149** in high yields.^{51, 58–61}

X = NH₂, OAlk; Ar = 4-YC₆H₄ (Y = HO, MeO, F, Cl, Br), 3-Py.

The synthesis of the aforementioned thiolates **41** (see Section II.3.b) was also accomplished using three-component condensation of pyridinium ylides **40**, (cyano)thioacetamide (**60b**) and aromatic aldehydes.^{58, 64, 160}

R = Me, Ph, cyclo-C₃H₅; Ar = XC₆H₄ (X = H, 4-MeO, 4-NO₂, 2-F, 4-F, 4-Br), 3-Py.

5. Ring transformation reactions

The formation of the pyridine ring from other heterocycles represents a non-trivial approach to the synthesis of 3-cyanopyridine-2(1*H*)-thiones. Originally, this method was used for the preparation of pyridines annulated with a five- or six-membered ring at positions 5 and 6.^{67, 69} Thus 4-amino-6-aryl-5-cyano-1,3-dithiacyclohex-4-enes **43** spiro-fused with cycloalkanes [R¹–R² = (CH₂)_n, n = 3, 4] were used in the synthesis of the corresponding 5,6-polymethylene-3-cyanopyridine-2(1*H*)-thiones **18**. This transformation occurs upon short-term heating of the reactants in pyridine or DMF (conditions *a*). This reaction follows a complex mechanism⁷¹ and is accompanied by a loss of two hydrogen atoms and H₂S. Later, this reaction was extended⁷² to non-spirocyclic 1,3-dithiacyclohex-4-enes **43** (R¹ = H, Me; R² = Me), which underwent ring transformation into pyridine-thiones **65** upon heating in methanol or DMF in the presence of a base [diethylamine or morpholine (conditions *b*)]. The yields were moderate in all cases.

R² = Me: R¹ = H, Me (**65**); R¹–R² = (CH₂)_n (n = 3, 4) (**18**);
Ar = RC₆H₄ (R = H, 2-F, 4-F, 4-Cl, 4-Br, 4-MeO), 3-Py.

Thus, the above-cited examples of the construction of 3-cyanopyridine-2-chalcogenone derivatives demonstrate the high promise in the development of novel approaches to their synthesis, on the one hand, and enable the prediction of novel trends in this branch of heterocyclic chemistry, on the other hand.

III. Reactivity and chemical transformations

Chemical properties of 3-cyanopyridine-2-chalcogenones have been the subject of intensive studies over the last 15–20 years. Their main fragment [NC–C–C(X)N–] contains four nucleophilic and two electrophilic sites.

Two vicinal reactive functional groups (the nitrile group and the thio(seleno)amide group incorporating an endocyclic nitrogen atom) possess different properties: addition reactions are characteristic of the former, while the latter reacts with electrophilic reagents. The interest in such systems is caused by two main reasons: the possibility of their transformations into functionalised pyridines possessing valuable characteristics and their use as building blocks in the synthesis of fused heterocycles. 3-Cyanopyridine-2-chalcogenones are promising synthons for complex heterocyclic systems containing a pyridine fragment, *e.g.*, furo-(pyrazolo, thieno, selenopheno)pyridines, pyridothienopyridines, pyridothienopyrimidines and other annulated heterocycles manifesting a broad range of biological activities. The chemical transformations of some 3-cyanopyridine-2-chalcogenones are described below. The primary attention is given to reactions of partially hydrogenated derivatives with halogens and alkylating reagents as well as to heterocyclisation reactions. Dehydrogenation reactions were considered in the previous section in relation to discussion of the methods for the synthesis of these compounds.

1. Reactions with halogens

Reactions of some thiolates with elemental iodine have been studied.^{52, 72, 151} It was found that treatment of salts **25** and **150** and the spiro-fused 6-oxothiolate **151** with iodine in ethanol in the presence of alkali afforded the corresponding disulfides **152–154** in high yields together with small amounts of dehydrogenation products. Such disulfides are usually formed upon oxidation of the corresponding thiones by atmospheric oxygen. Similarly, selenolate **155** gave diselenide **156**.

X = S: R¹ = 2-ClC₆H₄, R² = NC, R³ = H₂N (**150, 153**);
R¹ = 2-ClC₆H₄, 2-Fu; R² = PhNHC(O), R³ = Me (**25, 152**);
X = Se, R¹ = 2-ClC₆H₄, R² = EtO₂C, R³ = Me (**155, 156**).

Bromination of trifluoromethyl-substituted 3-cyanopyridine-2(1*H*)-thiones **110** and **111** also proceeded *via* the corresponding disulfides. However, under the reaction conditions the latter were converted into bromides **157**, which cyclised into isothiazoles **158**.¹⁶⁴

$\text{R}^1 = \text{CF}_3$, $\text{R}^2 = \text{Me}$ (**110**); $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{CF}_3$ (**111**).

2. Alkylation

Numerous recent publications on the reactivities of 3-cyanopyridine-2(1*H*)-chalcogenones deal with different aspects of alkylation of sulfur- and selenium-containing derivatives. Reactions with alkylating reagents may involve two nucleophilic sites due to ambident character of the $\text{HN}-\text{C}(\text{X})$ fragment ($\text{X} = \text{S}, \text{Se}$) of these heterocycles. As a rule, reactions with alkyl halides and activated halides (α -halogenocarbonyl compounds) in the presence of bases involve the chalcogen atom.

Numerous studies have shown (see, for example, Refs 7, 15, 43, 48, 50–52, 103–106, 165–176) that the alkylation of 3,4-dihydropyridinechalcogenones **62b,c** or their salts **64b,c** with alkyl

$\text{R}^1, \text{R}^2, \text{R}^3 = \text{H}, \text{Alk}, \text{Ar}, \text{Het}$; $\text{R}^4 = \text{Alk}$; $\text{X} = \text{S}, \text{Se}$;

B is *N*-methylmorpholine.

halides is regioselective and results in 2-alkylthio(seleno)-1,4-dihydropyridines **159**.

Reactions of betaines **41** with alkyl halides in ethanol or DMF (in the absence of bases) gave 6-alkylthiotetrahydropyridine salts **160**.^{47, 51} However, heating of betaines **41** with allyl bromide in ethanol and subsequent prolonged storage of the reaction mixture at room temperature gave a [3,3]-sigmatropic rearrangement product, *viz.*, compound **161** as a mixture of two epimers (Scheme 2).

A [3,3]-sigmatropic rearrangement of 2-allylthio(seleno)-1,4-dihydropyridines **162** into 3-allyl-3,4-dihydropyridinechalcogenones **163** also occurred in the alkylation of salts **64b,c** with allyl bromide.^{7, 52, 57, 120, 136, 177–179} However, in contrast with analogous transformations of aromatic allyloxy(thio)pyridines and -quinolines,^{180–182} this reaction was regioselective: the yields of compounds **163** reached 98%.

$\text{R}^1, \text{R}^2, \text{R}^3 = \text{H}, \text{Alk}, \text{Ar}$; $\text{X} = \text{S}, \text{Se}$.

A convenient method for the synthesis of hitherto unknown spiro-fused heterocyclic systems (6,8-dicyano-5-oxo-2,3,6,7-tetrahydro-5*H*-thiazolo-[2,3-*a*]pyridine-7-spiro-1'-cycloalkanes, **164**) has been developed.^{52, 118, 121, 183} It includes alkylation of thiolates **94** and **151** with 1,2-dibromoethane in DMF at room temperature.

$n = 1$ (**94**), 2 (**151**).

Reaction of sulfide **22a** with epichlorohydrin yielded thione **165**, which underwent cyclisation into pyridothiazine **166** upon treatment with ethanolic KOH or MeONa .¹⁸⁴

$\text{R}^1, \text{R}^2 = \text{Alk}$; $\text{Ar} = \text{Ph}, 2\text{-NO}_2\text{C}_6\text{H}_4$.

Scheme 2

Haloacetic acid derivatives (amides and chlorides) were also studied as alkylating agents. Thus salts **64b** ($R^3 = \text{Me}$) reacted with iodoacetamide in ethanol to give sulfides **167**. The latter underwent intramolecular cyclisation into 3-oxo-2,3-dihydro-7H-thiazolo[3,2-a]pyridines **168** upon refluxing in acetic acid. The yields depended on the nature of the substituent at position 4 of the pyridine ring: for $R^1 = 4\text{-Py}$, the yields were 70%–85%, while its replacement by the aryl substituent ($R^1 = 4\text{-ClC}_6\text{H}_4$) resulted in a significant reduction of the product yield (down to 25%).¹⁸⁵

$R^1 = 4\text{-Py}$, $4\text{-ClC}_6\text{H}_4$; $R^2 = \text{Ar}$, Het.

N-Substituted chloroacetamides **169** are currently successfully employed as alkylating agents in the synthesis of novel 3-cyanopyridine-2(1*H*)-thiones.¹⁶⁴ A broad range of such derivatives were

$R^1, R^2 = \text{Alk}$, Ar, Het; $R^3 = \text{Pr}^i$, cyclo- C_3H_7 , Bn, $\text{X}_n\text{C}_6\text{H}_{5-n}$ (X = 4-F, 3-F₃C, 3,4-(MeO)₂, 3,4-OCH₂O);

obtained by condensation of chloroacetyl chloride with pharmacologically active amines (*e.g.*, α -phenylethylamine, remantadine, *etc.*). Chloroacetamides **169** reacted with pyridinethiones **65b** in DMF or EtOH in the presence of KOH. Both compounds **170** and the respective intramolecular cyclisation products (substituted thienopyridines **171**) were obtained in high yields.

The alkylation reaction was used for the introduction of α -amino acid fragments into 3-cyanopyridine-2(1*H*)-thiones.¹⁶ Thus chloroacetamides **172** prepared by condensation of chloroacetyl chloride with amino acids reacted with pyridinethiones **65b** to give the alkylation products **173**. The latter cyclised under the reaction conditions into thienopyridines **174** analogous to the above-mentioned compounds **171**. However, thienopyridines **174** contained an ω -carboxy group at position 2 rather than the carbamide group, which enabled their intramolecular cyclisation into 4-dihydro-1*H*-pyrido[3',2':4,5]thieno[2,3-*e*][1,4]diazepine-2,5-diones **175** upon heating.

$R^1, R^2 = \text{Alk}$, Ar, Het; $R^3 = \text{H}$; $R^4 = \text{H}$, Me, Pr^i , Bn; $R^3-R^4 = (\text{CH}_2)_3$.

1-Bromomethylcarborane can also be used as an alkylating agent.^{186, 187}

All the reactions of 3-cyanopyridine-2(1*H*)-thiones with the above-considered electrophilic agents involve the chalcogen atom (sulfur or selenium); the alkylation at the nitrogen atom of the pyridine ring was described in only few cases (see Refs 188–190). This can be explained in terms of the hard and soft acids and bases theory. Whereas soft electrophiles react at the sulfur atom, reactions with harder reagents involve the nitrogen atom. In the presence of aqueous KOH, 2,3,4,6-tetra-*O*-acetyl- α -D-glucopyranosyl bromides **176** react with cyanopyridinechalcogenones **65b** to yield *N*-glycosides **177**. The latter can be prepared in one step starting from cyanothioacetamides **178**, glycosyl bromides **176** and ketones.¹⁹⁰

$R^1, R^2 = \text{Me, Et, Ph}; R^3 = \text{H}, R^4 = \text{OAc}; R^3 = \text{OAc}, R^4 = \text{H}.$

For other aspects of alkylation reactions of pyridinechalcogenones, see Refs 3, 5, 7 and 8.

3. Heterocyclisation

In addition to the aforementioned studies of chemical properties of pyridinechalcogenones, heterocyclisation of their functional derivatives is of the greatest interest as one of the most promising approaches to the synthesis of fused heterocyclic systems containing a pyridine fragment (see, for example, Refs 7, 20–22, 52, 83, 105, 108, 167, 173, 176, 178, 191–200).

Thus the Thorpe–Ziegler cyclisation of 2-alkylthio(seleno)-3-cyanopyridines **179** prepared by alkylation of 3-cyanopyridine-2-chalcogenones (**65**) in DMF or ethanol in the presence of a base gives thieno(selenopheno)-[2,3-*b*]pyridines **180**. The reaction mechanism can be presented by the following sequence:^{11, 201}

$R^1, R^2, R^3 = \text{Alk, Ar, Het}; X = \text{S, Se};$
Z is an electron-withdrawing group.

It was found that the equilibrium between the tautomeric forms $\mathbf{180} \rightleftharpoons \mathbf{181}$ is virtually completely shifted towards the amine **180**. The electron-withdrawing effect of the substituent Z, which determines the stability and the concentration of the carbanion **182**, is the rate-limiting factor of this cyclisation. The following order of activities of substituents Z was empirically established:^{8, 11} $\text{NO}_2 > \text{ArC(O)} > \text{CN} > \text{CO}_2\text{Alk} > \text{C(O)NH}_2 > \text{H}.$

The substituent Z that imparts sufficiently high CH-acidity on the SCH_2Z fragment of compound **179** and stabilises anion **182** usually represents a π -acceptor; only one example of a reaction involving a σ -withdrawing group (the carborane fragment) is documented.¹⁸⁷

The cyclisation is usually carried out in the presence of bases; acid catalysis is used less often. Systems KOH–EtOH , $\text{K}_2\text{CO}_3\text{–EtOH}$, EtONa–EtOH , $\text{K}_2\text{CO}_3\text{–DMF}$, less often $\text{Na}_2\text{CO}_3\text{–EtOH}$, MeONa–EtOH , $\text{KOH–EtOH–H}_2\text{O}$, AcONa–EtOH (abs.) , $\text{Et}_3\text{N–EtOH}$, $\text{K}_2\text{CO}_3\text{–Me}_2\text{CO}$, $\text{Et}_3\text{N–dioxane}$, $\text{Et}_3\text{N–DMSO}$, are generally employed. Bases are used in both stoichiometric and catalytic amounts. Spontaneous formation of thienopyridines in the alkylation of thiones **65b** in the presence of equimolar amounts of the base has been observed in some cases; no intermediate products could be isolated. As a rule, the reaction is carried out at room temperature, although in some cases heating can be required. There are some examples of cyclisation in boiling ethanol^{202, 203} or under phase-transfer catalysis conditions with Bu_4NBr used as the catalyst.^{204, 205}

It is of note that the synthesis of thienopyridines is most often based on the cyclisation of 2-alkylthio-3-cyanopyridines that are conventionally prepared from 3-cyano-pyridine-2(1*H*)-thiones **65b** (or the corresponding thiolates) and an alkylating agent containing an electron-withdrawing substituent in the α -position relative to the halogen atom. This can also be achieved by multicomponent cascade heterocyclisation, which allows an access to pyridinechalcogenones from simple and readily available acyclic precursors in a one-pot procedure.² This strategy served as a basis for the synthesis of thienopyridines and related systems, *e.g.*, derivatives of quinoline, isoquinoline, benzo[*b*]quinoline, pyrano- and thiopyranopyridines, benzothiopyranopyridine, pyridopyridines (naphthyridines) and other fused heterocycles; the bibliography on the subject includes over 170 references (see the monograph¹⁹⁹).

Among numerous examples of this synthesis, special mention should be made of a successful solution of the problem of construction of substituted pyridothienopyridines which is based on the cascade conversions of some 3-cyanopyridine-2(1*H*)-thione derivatives.^{206, 207} On the whole, this type of heterocyclisation has a number of advantages over classical Friedlander annelation, since cascade reactions proceed faster and under less drastic conditions and ensure high yields of target products in one step. Thus the alkylation of thiones **65b** is accompanied by the Thorpe ring closure resulting in thienopyridines **183**; prolonged refluxing of the latter in the presence of the excess of malononitrile affords tricyclic Friedlander cyclocondensation products, *viz.*, compounds **184** (route *a*, yields 67%–75%). Compounds **184** can be prepared in 2 min from the same cyanopyridinethiones **65b** and 2-aryl-3-bromo-1,1-dicyanopropenes **185** (route *b*, yields 57%–95%); in the latter case, the intermediate thienopyridine **186** is not usually isolated from the reaction mixture, but is subjected to cyclisation *in situ* (Scheme 3).

Later, the approach based on the use of bromides **185** was used in the synthesis of other dipyrrothiophenes.^{208, 209} For the first time, thiolates **187** were used as starting materials for the synthesis of 6,9-dihydropyrido [3',2':4,5]thieno[3,2-*b*]pyridines **188**. It is of note that in this case the cascade heterocyclisation occurs spontaneously in the absence of a basic catalyst.²⁰⁸

Scheme 3

Ar = Ph, 4-BrC₆H₄; R¹ = H, Me, Ph; R² = H; R³ = Me, Ph; R²–R³ = (CH₂)_n (n = 3, 4).

R¹ = EtO, Me; R² = 4-MeOC₆H₄, 2-NO₂C₆H₄, 2-thienyl;
Ar = 4-BrC₆H₄.

Among other alkylating agents used in heterocyclisation reactions that yield fused thienopyridine derivatives, alkyl γ -chloroacetoacetates **189**^{17, 210–213} and ethyl 4-bromocrotonate are worthy of mention (**190**).^{177, 208} Some aspects of the use of compounds **189** and **190** in the synthesis of heterocycles are detailed in the review.²¹⁴ The cascade heterocyclisation of substituted pyridine-2(1*H*)-thiones **65b** and γ -chloro β -oxo esters **189** in boiling ethanol in the presence of KOH or EtONa is the most efficient procedure for the preparation of dipyridothiophenes **191**. If the reaction is carried out under mild conditions, the intermediates, *i.e.*, pyridine **192** and thieno[2,3-*b*]pyridine **193**, can be isolated; they easily cyclise in the presence of bases into the target products **191**.²¹¹ Thienopyridine **194** prepared by the reaction of thione **65b** (R¹ = R³ = Ph, R² = H) with crotonate **190** was similarly converted into dipyridothiophene **195** (Scheme 4).¹⁷⁷

The reaction of piperidinium 1,4-dihydropyridine-2-thiolate **196** with the ester **189** (Alk = Et) gave the thienopyridine derivative **197**; the latter was converted into the corresponding dipyridothiophene **198** in good yield under more drastic conditions.²¹¹

(a) **189**, KOH, EtOH, 40 °C; (b) (1) KOH, EtOH, Δ , 5 min; (2) 10% HCl.

Scheme 4

(a) $\text{ClCH}_2\text{C(O)CH}_2\text{CO}_2\text{Alk}$ (**189**) (R⁴ = Et, Prⁱ), KOH or EtONa, EtOH, Δ ; (b) 10% HCl; (c) **189**, 10% KOH, DMF; (d) KOH or EtONa, EtOH, Δ ; (e) Et₃N, EtOH, Δ ; (f) $\text{BrCH}_2\text{CH}=\text{CHCO}_2\text{Et}$ (**190**), KOH or EtONa, EtOH; (g) HCl, MeOH, Δ , 8 h;
R¹, R², R³ = H, Alk, Ar, Het.

The cascade synthesis of pyrido[3',2':4,5]thieno[3,2-*c*]isoquinolines **199** and **200** was accomplished using *o*-bromomethylbenzoic acid derivatives **201** as convenient precursors.^{215,216} This reaction is carried out either as a one-pot procedure or with isolation of intermediate benzylthiopyridines **202**.

(a) KOH, DMF, Δ ; (b) Bu^tOK, DMF, Δ ; R¹, R², R³ = Alk, Ar, Het.

Two approaches to the synthesis of tricyclic pyridothienopyrimidine systems were developed. Reactions of 3-cyanopyridine-2(1*H*)-thione derivatives **65b** with *N*-cyano-chloroacetamide (**203**) afforded thienopyridines **204**,^{173, 208, 217, 218} which underwent cyclisation into pyridothienopyrimidines **205** (yields 60%–90%) under the action of basic or acidic catalysts. These compounds can also be synthesised directly from thiones **65b** and chloride **203**.

(a) EtONa, EtOH, Δ , 6 h; (b) 35% HCl, MeOH, 0.5–12 h; (c) Ac₂O, Δ , 6 h; R¹ = 4-MeOC₆H₄, 4-FC₆H₄, 2-NO₂C₆H₄, 2-thienyl; R² = MeCO, EtO₂C; R³ = Me.

The second approach, *viz.*, condensation of pyridinethiones **65b** with *N*-(ethoxycarbonyl)chloroacetamide, was used in the synthesis of pyridothienopyrimidines **206**.^{17, 213}

(a) EtONa, EtOH–DMF (1 : 1), Δ , 2 h; (b) 10% HCl, 20 °C; R¹ = Ph, 4-FC₆H₄, 4-MeOC₆H₄; R² = Ph, 2-thienyl.

A non-trivial procedure for the synthesis of fused thienoazines has been proposed.²¹⁹ It included radical bromination of pyridinethiones **65b** (R¹ = Me, R² = H) affecting the 4-methyl group with formation of bromides **207**. Reaction of the latter with the starting thiones first yielded intermediates **208** and then tetracyclic systems **209** containing annelated thienopyridine and naphthyridine fragments.

R = Me, Ph; NBS is *N*-bromosuccinimide.

Of note is the multicomponent approach to the synthesis of substituted 6,7,8,9-tetrahydropyrido[3',2':4,5]thieno[3,2-*b*]pyridines **210** based on the reaction of pyridinethiolates **211**, with malononitrile and acetone.^{16, 220–223}

R = Ar, Het; B = *N*-methylmorpholine.

The following reaction mechanism has been proposed:^{16, 223, 224} the starting pyridinethiolate **211** is oxidised by atmospheric oxygen to the corresponding bis(2-pyridyl) disulfide **212**, which reacts with an anion derived from isopropylidene-malononitrile **213** generated *in situ* from malononitrile and acetone resulting in the cleavage of the S–S bond and the formation of dicyanoallyl sulfide **214** and thiolate **211**. The latter undergoes reoxidation into the disulfide, while compound **214** cyclises into dipyridothiophene **210**. The feasibility of this reaction mechanism was confirmed by the independent synthesis of compounds **210** from disulfides **212** formed upon mild oxidation of thiolates **211**. In the latter case, the target products were obtained with the highest yields (60%–75%).

B is *N*-methylmorpholine; R = Ar, Het;
(a) O₂, EtOH, (b) I₂, EtOH–H₂O, 24 h (90%–100%).

A similar reaction of thiolates **215** and **64b** with malononitrile and acetone in boiling EtOH afforded partially hydrogenated pyridothienopyridines **216** and **217** or their dehydrogenated derivatives **218**.²²² Under analogous conditions, hexahydroquinoline-2-thiolates **219** yielded hexahydropyridothienoquinolines **220**.

Heterocyclisation of pyridinechalcogenones under the action of 1,2-bis-nucleophiles was carried out. Thus the reaction of spiro-fused 2-(methylthio)tetrahydropyridone **221** with hydrazine hydrate in ethanol gave 3-amino-5-cyano-6-oxo-4,5,6,7-tetrahydro-1*H*-pyrazolo[3,4-*b*]pyridine-4-spiro-1'-cyclopentane (**222**) (Refs 52, 88, 120, 121).

4. Other transformations of 3-cyanopyridine-2(1*H*)-chalcogenones

Other chemical transformations of 3-cyanopyridine-2(1*H*)-chalcogenones *e.g.*, hydrolysis of the nitrile group, reaction with organometallic compounds, *etc.*, have been described earlier and are not considered in this review. Suffice it to mention the recently studied reaction of 3-cyanopyridine-2(1*H*)-thiones **65b** with *n*-butyllithium and methylmagnesium iodide in ether, which occurs *via* intermediates **223** and **224** to yield ketones **225**.^{225, 226}

R¹ = H, Me; R² = Me, Prⁿ, Buⁿ, Buⁱ, *n*-C₅H₁₁; R³ = Me, Buⁿ;
M = Li, MgI.

Recently, the attention of investigators has been focused on the reduction of the nitrile group in 3-cyanopyridine-2(1*H*)-thiones and their 2-methylthio derivatives. This reaction can be used for the preparation of aminomethyl- and formyl-substituted pyridines, the promising building blocks for the synthesis of novel fused heterocycles. Catalytic hydrogenation with Raney nickel and reduction with complex metal hydrides [*e.g.*, lithium aluminium hydride, lithium triethoxyaluminium hydride, sodium bis(2-methoxyethoxy)aluminium hydride] were studied. It was found that either the reduction of the nitrile group or the cleavage of the C–S bond took place depending on the reaction conditions and the nature of the catalyst.^{19, 227–230}

The use of Raney nickel in the synthesis of nicotelline **226**, a minor alkaloid of the tobacco plant, has been described.^{64, 83, 231}

IV. Applications

It is known^{8, 232–238} that 3-cyanopyridine-2(1H)-thiones are used in the commercial production of dyes, pigments, additives to fuels and lubricants, acid-base indicators for titrimetric analysis²³³ and other industrially important substances. Considerably more attention is given to the biological activities of pyridinechalcogenone derivatives. In the first place, this concerns the cardiotonic effect of a vast majority of compounds of this series (Refs 34, 169, 181, 184, 239–260). Some of them were found to possess cardiovascular, coronary and pronounced vasodilatory activities.^{261, 262} Other biological activities of this class of compounds include analgetic and antihypertensive activities,^{117, 170, 247} anti-anaphylactic,^{108, 192, 193} ionotropic,²⁴⁹ antidiabetic,²⁶³ diuretic and sodium-diuretic activities,¹⁵⁰ as well as antioxidant,^{169, 170, 264, 265} antiviral,^{20, 105, 196, 266} antiinflammatory^{109, 167} and antimicrobial activities.^{105–108, 143, 267, 268} Some of these derivatives are potent tranquilisers,^{269–273} antiallergic drugs for treatment of bronchial asthma,²⁶⁹ antihepatitis agents,⁵⁰ etc. Special attention is given to the detection, among pyridones **227**, of inhibitors of reverse transcriptase of human immunodeficiency virus (HIV-1).^{194, 245, 270–277}

Pyridinechalcogenones formed the basis for the development of biodegradable agrochemicals,¹⁷² plant growth regulators, pesticides and herbicides.^{23, 52, 91, 103, 104, 150} Other applications of cyanopyridinechalcogenone derivatives are also known (see Refs 3, 5, 8 and references cited therein).

V. Conclusion

The development of novel chemo-, regio-, stereo- and enantio-selective methods for the synthesis of multifunctional carbo- and heterocycles possessing valuable properties among which pyridine derivatives occupy a special position is one of the major problems of the synthetic organic chemistry of the 21st century. In this context, the development of synthetic procedures and investigations into reactivities of 3-cyanopyridine-2(1H)-chalcogenones as versatile building blocks acquire special importance. Such compounds found wide application in the synthesis of miscellaneous heterocyclic systems containing an annelated pyridine ring.

The analysis of the data on the methods for the synthesis, chemical behaviour and synthetic potentials of 3-cyanopyridine-2(1H)-chalcogenones has made it possible to outline the prospects of this branch of heterocyclic chemistry and to highlight the most promising trends of research in this area. Based on these data, one can expect further successful escalation of studies aimed at the development of novel approaches to the synthesis of fused O,N,S-

heterocycles possessing a broad range of valuable properties on the basis of pyridinechalcogenones.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No 05-03-32031).

Abstract. The results of physicochemical studies of solid-phase transformations under shock compression are analysed. The characteristic time of phase transitions and chemical reactions in shock-compressed solids found experimentally does not exceed one microsecond. Possible reasons for ultrafast atom diffusion are discussed. Hydrodynamic mixing of reactants is believed to be the most feasible mechanism. Prospects for basic and applied research in the field are outlined. The bibliography includes 151 references.

I. Introduction

In synthetic chemistry, the composition and structure of compounds are often varied using high temperature and high pressure techniques. The results obtained are strongly dependent on the level of thermodynamic parameters used. While the range of appropriate high temperatures is limited by the melting or evaporation of a chemical compound, the static pressure is limited by the ultimate strength of the anvil material. Experiments with diamonds made is possible to reach a pressure of up to $\sim 10^6$ atm (~ 100 GPa) paying for an enhanced pressure with progressive diminution of the working volume (to a few micrometres). Such experiments provide new scientific information but not novel materials.

There is also a basically different method of producing high pressures, which is free from this drawback. The technique is called pulse compression of matter using shock waves, or simply shock compression. Physics of pulse pressures rapidly developed during and immediately after the World War II. The shock wave chemistry, as a new avenue of scientific research, emerged in the late 1950s and its development is to a great extent due to achievements in physics and technology of ultrafast methods of investigation. Of particular interest are investigations of the duration and mechanisms of solid-phase transformations induced or assisted by shock waves. This is the subject of the present review, which also concerns the latest advances in shock wave chemistry.

II. Shock waves

1. Introduction to physics of shock waves

A shock wave is a narrow region of compressed matter, which propagates with a supersonic speed. It emerges upon detonation of explosives, collisions between rapidly moving bodies and obstacles, high-power electric discharges and laser ablation of crystals (see references cited in Ref. 1).

If the shock wave is represented as a plane separating the initial and perturbed state of matter, the following equations hold on both sides of the plane in accord with the laws of mass, momentum and energy conservation:

$$\rho_0 D = \rho (D - U), \quad (1)$$

$$P - P_0 = \rho_0 D U, \quad (2)$$

$$\left[(E - E_0) - \frac{U^2}{2} \right] \rho_0 D = P_0 U, \quad (3)$$

where ρ is the density of matter, D is the shock-wave velocity, U is the mass (particle) velocity behind the shock wave front, P is the pressure, E is the internal energy; the subscript 'zero' corresponds to the initial state (the shock wave and particle velocities are also denoted as U_s and U_p , respectively). The state of matter under shock compression is described by the shock adiabat (or Hugoniot adiabat), most often in the P – V or D – U coordinates. If ρ is expressed in g cm^{-3} and the parameters D and U are expressed in km s^{-1} , the pressure P is given in GPa.

It was experimentally established that at pressures below 100 GPa the shock adiabats of many materials obey a linear relation

$$D = c_0 + \lambda U, \quad (4)$$

where c_0 is a parameter similar to the bulk sound velocity and λ is a coefficient, which characterises the slope of the shock adiabat and is of the order of unity

$$\lambda = \frac{D - c_0}{U}. \quad (5)$$

Rodean² proposed a relation between the coefficients c_0 and λ

$$\frac{1}{2} \left(\frac{c_0}{\lambda} \right)^2 = \Delta H_s, \quad (6)$$

where ΔH_s is the heat of sublimation (here, the heat of atomisation) of a solid. It is valid for metals and some crystalline compounds (alkali metal halides and MgO).

Relation (4) can be derived theoretically from the equation of state for internal energy of shock compression. Using the Morse function (known in spectroscopy), the following expressions for the coefficients c_0 and λ were obtained³

$$c_0 = \frac{A}{3B},$$

$$\lambda = \frac{A}{4} - \frac{1}{5},$$

where $A = \alpha r_0$ (α is the thermal expansion coefficient, r_0 is the bond length under normal pressure) and $B = \sqrt{E/2}$ (here E is the bond dissociation energy). Equation (4) with these coefficients quite correctly reproduces the experimental shock adiabats of metals and covalently bonded compounds. In principle, relation (4) can also be derived from other equations of state, e.g., the Birch–Murnaghan and Mie–Grüneisen equations.

Large deviations of the $D = f(U)$ function from linear law are due to physicochemical transformations of compounds under shock compression and, hence, can serve as indicators of such transformations. From Eqn (5) it follows that a change in c_0 will cause antiparallel changes in the λ coefficient, namely, an increase in the sound velocity (at the same parameters D and U) leads to decrease in the slope of the Hugoniot adiabat and *vice versa*. For instance, for three forms of SiO₂ (glass, crystalline quartz and stishovite) the c_0 values are respectively equal to 1.52, 2.20 and 5.07 and $\lambda = 1.74$, 1.60 and 0.18 (see Ref. 4). Analogously, the Hugoniot equations for molybdenum⁵ at room temperature and at 1400 °C, respectively, have the form

$$D = 5.136 + 1.220 U,$$

$$D = 4.78 + 1.42 U.$$

If Eqn (4) fails to correctly describe experimental data, a parabolic equation

$$D = c_0 + \lambda U \pm \mu U^2, \quad (7)$$

with the coefficient $\mu \ll 1$ is used. The generalised shock adiabat equation is as follows⁶

$$D = c_0 + \lambda U + \frac{\mu U^2}{c_0}. \quad (8)$$

For alkali metals, $\lambda = 1.1$ and $\mu = 0.04$; for other metals and inorganic salts, $\lambda = 1.5$ and $\mu = -0.05$ and for organic liquids $\lambda = 2.0$ and $\mu = -0.1$. Methane, solid and liquid CO₂ and water obey the same generalised shock adiabat equation.⁷

$$D = c_0 + 1.9 U - \frac{0.08 U^2}{c_0},$$

where $c_0 = 1.15, 1.8, 1.0$ and 1.95 , respectively.

It should be emphasised that the shock adiabat describes the bulk compression of a body. Initially, the action of dynamic pressure causes elastic compression of a crystal, which is followed by elastoplastic and then bulk compression of the body with an increase in pressure (Fig. 1). Therefore, the shock adiabat begins with a particular non-zero pressure (point 1). At pressures below the pressure corresponding to point 1, the parameters of state are usually obtained by extrapolating experimental data from the bulk compression region to $P = 0$. X-Ray diffraction studies of crystals undergoing shock compression showed that at low shock velocities a single crystal experiences uniaxial compression accompanied by a change in symmetry (e.g., a cubic unit cell is transformed into a tetragonal one) while bulk compression of the body with preservation of initial symmetry occurs at high shock velocities.^{8–12}

Figure 1. Shock compression diagram of a solid (Al₂O₃ single crystal). Point (1) corresponds to HEL pressure of 20 GPa, and point (2), to a phase transition at 80 GPa. Elastic compression region ($0 < P < 20$ GPa) and bulk compression region ($P > 20$ GPa).

In studies of monolithic bodies it is possible to measure their dynamic elastic limit (Hugoniot elastic limit, HEL). Experimental P_{HEL} values for the polycrystalline state of some elements are listed in Table 1. There are several elements with known P_{HEL} values; therefore, elaboration of methods of *a priori* estimation of these characteristics is required.

Based on the assumption of similarity between the plastic and liquid states of the body, the work of plastic deformation (taken with some coefficient) was equated¹³ to the heat of melting, and an equation relating the HEL pressure to the change in the volume of the body upon ‘mechanical melting’ was derived:

$$P_{\text{HEL}} = k \frac{\Delta H_m}{\Delta V_m}, \quad (9)$$

where ΔH_m is the heat of melting, ΔV_m is the decrease in the volume of the body from the initial volume V_0 to the volume upon mechanical melting, V_m . The calculated P_{HEL} values for a number of elements with presently unknown experimental data are also listed in Table 1.

Table 1. HEL pressures (P_{HEL} /GPa) for chemical elements.^{13, 14}

Parameters of Eqn (4) are related to the mechanical characteristics of the body measured under static loading, namely, the isentropic bulk elastic modulus (B_0) and its pressure derivative, by the following equations:¹⁵

$$c_0 = \sqrt{\frac{B_0}{\rho}}, \quad (10)$$

$$\lambda = \frac{B'_0 + 1}{4}.$$

These expressions make it possible to relate the parameter λ to the Grüneisen constant (Γ)

$$\Gamma = \frac{1}{c_V \sigma} \beta V_0 = \frac{1}{c_P} \beta B_0 V_0,$$

where c_V and c_P is the heat capacity at constant volume and pressure, respectively; σ is the isothermal compressibility and β is the bulk thermal expansion coefficient.

The following empirical relationship¹⁶ correctly reproduces the experimental data for metals:

$$\beta = \frac{1}{3} \frac{B'_0 + 1}{B_0 V_0} c_P. \quad (11)$$

From this equation one gets

$$\lambda = \frac{3}{4} \Gamma. \quad (12)$$

A number of equations describing the dependence of λ on Γ are also available. For instance, the coefficient λ is often estimated using the following relation¹⁷

$$\lambda = \frac{1 + \Gamma}{2}. \quad (13)$$

When applied to metals, Eqns (12) and (13) give similar results.

As a rule, Γ is assumed to be inversely proportional to the volume of the body

$$\Gamma V = \Gamma_0 V_0.$$

However, this is not always true. For instance, in the case of NaCl an increase in pressure from 0 to 3 GPa is accompanied by reduction of the volume and a decrease in the Grüneisen constant of the material from 1.52 to 1.40 (see Ref. 18), whereas heating of molybdenum to 1400 °C leaves the Γ value unchanged (1.52).⁵

All experimentally determined coefficients in the Hugoniot equations for elements and inorganic compounds available at the moment (data taken from monograph⁴ or from more recent studies cited in this review), as well as those calculated using expressions (10) are listed in Tables 2–4. All these data refer to low-pressure phases. In most cases the experimental and calcu-

lated values are similar. Differences between them are due to the phase transformations at elevated pressures (as a result, the characteristics determined under shock compression correspond to certain phases that differ from the phases for which the B_0 and B'_0 were measured; this is the case for, e.g., tellurium).

Table 5 presents the coefficients in the Hugoniot equations of low-molecular-mass compounds and polymers obtained from Refs 4, 27–30 or calculated by the least squares method from experimental D and U values reported in the same studies.

^a Coefficient c (km s⁻¹) can be significantly different from c_0 .

Since the bulk and elastic compression of a body differ by

$$\Delta = D - c_0,$$

the coefficient λ depends on the compressibility of the material. For instance, based on the λ values listed in Table 2, metals can be divided into two groups. One group comprises the main-group elements (except for Cr and Group VIII metals) characterised by $\bar{\lambda} = 1.12 \pm 13\%$; while the other group comprises transition metals with $\bar{\lambda} = 1.61 \pm 7\%$. The difference is due to lower compressibility of the d-metals compared to the s,p-elements. Caesium ($\lambda = 1.58$) presents a particular case, which is probably due to physicochemical transformations of this metal (oxidation or phase transitions) in the course of sample preparation or during the shock compression experiments.

The aforesaid concerns monolithic bodies. However chemists most often work with powders. Here, the porosity of the materials should be taken into account. Propagation of a shock wave through a porous material is accompanied by the 'collapse' of pores and compaction of the powder to form a monolithic body, friction of particles during compaction, their grinding due to unloading (expansion) of the hard material to a softer one or to a pore, deformation of crystalline grains and plastic flow, which leads to heat release and possible contact melting of particles. Highly porous materials are heated to so high temperatures that the effect of heating can exceed the effect of the high pressure (anomalous compression) (Fig. 2).³¹ Shock compression of porous materials with very high porosities made it possible to obtain dense high-temperature plasma.^{32–34}

A number of models are available, in which porous materials under shock compression are treated as loose monolithic bodies (a review of such models can be found in Ref. 35). The Hugoniot adiabats of powders are also calculated under assumption of heterogeneous medium ('mixture of monolithic body and air'). The following equation was derived⁶ assuming a seven-fold decrease in the pore volume upon compression

Figure 2. Shock compression diagrams of bodies of different porosity. Monolithic body ($V_0 \rightarrow V$) (1), porous body ($V_{00} \rightarrow V$) (2), anomalous compressibility of highly porous material (starting point is shifted towards V_0) (3); regions filled with horizontal lines and squares correspond to the energies of compression of porous and monolithic bodies, respectively; V is the final volume of compressed body, V_0 is the volume of monolithic body and V_{00} is the powder volume.

$$U_*^2 = U^2 + \frac{6}{7}(m-1)PV_0. \quad (14)$$

Here U_* is the particle velocity in the powder, U is the particle velocity in the monolithic body, and $m = V_{00}/V_0$, where V_{00} is the powder volume and V_0 is the monolithic body volume.

From the U_* value found from Eqn (14) at constant pressure and powder density one can determine the corresponding shock-wave velocity D_* . In a particular range of pressures the calculated U_* and D_* values can be described by an equation similar to Eqn (4)

$$D_* = a + bU_*.$$

The results of calculations using this equation are in agreement with the experimental data for powders with moderate porosities. But as the sample porosity increases, the parameters a in the experimental Hugoniot equations decrease down to zero. Unlike c_0 , the parameter a cannot be treated as the bulk sound velocity in the porous material; its value lies in the range between the sound velocity inside the grain and the speed of slow motion of the grains involved in 'relay'-type sound transmission in the sample. This approach corresponds to the Touvenin model,³⁶ which considers powders as systems of plates that transmit perturbation in a porous medium.

It was experimentally shown that the behaviour of a powder under shock compression differs from that of a monolithic body. For instance, experiments involving throw of aluminium and copper impactors in porous aluminium ($\rho = 63\%$ of the density of monolithic body) showed that the same pressure corresponds to different shock-wave velocities (difference is 300 m s^{-1}) while different pressures are measured at the same shock-wave velocities in the powder, depending on the impactor material.³⁷ This effect is impossible under shock compression of monolithic bodies.

The Hugoniot parameters

$$D_{1,2} = c_{1,2} + \lambda_{1,2} U_{1,2} \quad (15)$$

of a binary mixture (alloy) composed of the solids 1 and 2 can be calculated using the additivity scheme

$$U_{1,2}^2 = xU_1^2 + (1-x)U_2^2, \quad (16)$$

where x is the mass fraction of a component. Relation (16) has the sense of the law of energy conservation, because the energy of a

mass unit of the mixture equals the sum of the energies of the components that experienced shock compression at the same pressure.

If the Hugoniot adiabats of components are unknown, one can use their mechanical characteristics and sum the B/ρ ratios of the components 1 and 2 with allowance for their mass fractions (because these parameters have the dimension of energy) and then determine the coefficients $c_{1,2}$ as follows

$$c_{1,2} = \sqrt{\frac{B_1}{\rho_1}x + \frac{B_2}{\rho_2}(1-x)},$$

where $\lambda_{1,2}$ is the weight-average value of λ_1 and λ_2 owing to a small difference between these parameters.

The dynamic pressure produced by shock waves differs from static pressure by very short duration of the periods of pressure rise ($\sim 10^{-12} \text{ s}$) and stationary action ($\sim 10^{-6} \text{ s}$). Tensile stress (negative pressures) produced in the solid in the unloading wave allows the shock wave to reach the surface of the sample, which is accompanied by spalling phenomena. These features can cause basically new effects under the action of shock waves on substances compared to those observed at high static pressures.

Whereas determination of dynamic pressures presents no severe difficulties, measuring the shock temperatures is a rather complicated task. In this case the most objective thermocouple method is slow, while optical pyrometry data (this technique is characterised by very short time delay) are interpreted under assumptions (blackbody model, uniform emission of radiation from the surface) that require experimental check-up. A recently proposed, new promising technique for measuring the shock temperatures involves the use of NMR spectroscopy. To date, it was only employed in a study of molybdenum.³⁸ Experimental shock Hugoniots of heated substances are necessary for solving a number of physicochemical problems. However, their number is limited. Such adiabats can be obtained by measuring the bulk elastic moduli at different temperatures.

There is a few crystals with known shock compression characteristics at different temperatures. These are NaCl and LiF,¹⁸ Mo⁵ and SiO₂.³⁹ Heating of the first two materials from 25 to 400 °C causes a decrease in c_0 from 3.3 to 2.9 km s⁻¹ (NaCl) and from 5.0 to 4.5 km s⁻¹ (LiF); the parameter λ decreases from 1.7 to 1.5 (NaCl) and from 1.5 to 1.3 (LiF). The same parameters of molybdenum vary in different fashion on heating from room temperature to 1400 °C; namely, c_0 changes from 5.14 to 4.78 km s⁻¹ while λ changes from 1.22 to 1.42. In glassy SiO₂, the bulk sound velocity (~ 0.75 of the longitudinal sound velocity) increases from 4.46 to 4.84 km s⁻¹ in the temperature range 20–1050 °C. In molten SiO₂, it increases from 4.90 to 4.93 km s⁻¹ in the temperature interval from 1530 to 2010 °C.

The bulk elastic modulus of ZrO₂ and its pressure derivative (265 GPa and 4.0, respectively) remain unchanged in the temperature range from 25 to 1400 °C,⁴⁰ but since the density of the body decreases on heating in this case, it follows from Eqns (10) that the coefficient c_0 increases while the parameter λ retains its value. The results of B_0 measurements for a number of metals at -273 (B_1) and 27 °C (B_2) showed⁴¹ a decrease in this parameter on heating.

Element	Al	Cu	Fe	Pb	α -Pu
B_1/B_2	1.075	1.036	1.030	1.104	1.303

A large change in the elastic modulus of α -Pu is due to changes in the 5f-electron shell of plutonium atom.

No general trend in the influence of temperature on the parameters of Eqn (4) has been revealed so far. This effect should be studied in each particular case.

2. Recovery of shock compression products

Ryabinin⁴² pioneered in the recovery and investigation of the products of shock compression of chemical compounds. Despite the lack of interesting chemical results, his study opened a new research avenue in the physics of shock waves, which was called

Figure 3. Schemes of experimental setups with cylindrical recovery ampoule (a), cylindrical recovery ampoule with layered shell (b) and recovery ampoule with large cavity (c). Detonator (1), explosive (2), ampoule (3) and sample to be compressed (4).

'recovery experiments'. Later on, cylindrical ampoules employed by Ryabinin were significantly simplified and modified. Here we will consider the main types of such ampoules.

Figure 3a presents a scheme of typical experimental setup with a steel cylindrical ampoule. The modification of the ampoules consists in the use of layered shells made of different materials (Fig. 3b). The shells provide a stepwise loading of the substance by shock waves owing to difference between the shock-wave velocities in different materials. Yet another modification consists in the use of an attached large container (Fig. 3c) for expansion (scattering) and subsequent quenching of shock compression products in the course of unloading. Prior to explosion, the cylindrical ampoules can be heated⁴³ or cooled (by, e.g., liquid nitrogen) in order to adjust the thermodynamic conditions. To the same end, water or other substances with high heat capacity can be added to the sample to be compressed (they absorb heat and thus provide corresponding cooling).

In the case of uniformly distributed charge of the explosive, cylindrical ampoules provide an axially symmetrical compression of the substance with minimum deformation of the sample. However, if the explosive is concentrated within some sectors of the cross section (Fig. 4), a strong deformation of the ampoules can be achieved. If the empty regions in the charge (see positions 1 in Fig. 4) are filled with materials of different mechanical hardness, it is possible to control the degree of the ampoule deformation.

Owing to very high pressure in the axial (Mach) region, cylindrical ampoules are, as a rule, used for the synthesis and

Figure 4. Sections of cylindrical ampoule with sector arrangement of explosive. (1) Air (or other inert material), (2) explosive.

modification of chemical compounds. If the thermodynamic parameters in this region are to be reduced, cylindrical ampoules with a metallic rod at the centre are employed. This allows repeated reflection of the shock wave from the rod and walls, thus causing the pressure to increase with minimum heating of the substance.

An important modification was the invention of dynamic-static compression ampoules⁴⁴ where the compound is surrounded by the working substance (e.g., KBr) which undergoes a reversible phase transition. Under loading, KBr undergoes a structural transition of the NaCl $\rightarrow$ CsCl type accompanied by a 15% reduction of the volume, while in the unloading stage potassium bromide should return to its initial state. However, the hard recovery ampoule, which is made of strain-hardening steel and therefore becomes even harder during shock compression, makes the expansion of the working substance impossible. As a result, a residual (static) pressure is produced inside it (Fig. 5). The internal static pressure equal to the phase transition pressure (2 GPa) is rather high; this precludes annealing of thermally unstable high-pressure phases, in particular, a Würtzite-type boron nitride (w-BN) polymorph.⁴⁵

Figure 5. Experimental setup for dynamic-static compression (a) and corresponding pressure-time diagram (b).

(a) Detonator (1), explosive (2), ampoule (3), working substance (e.g., KBr) (4) and sample to be compressed, e.g., graphite-like boron nitride (g-BN) (5).

(b) Temporal evolution of dynamic pressure (1), static pressure (2) and phase transition pressure (2 GPa for KBr) (3).

Another group of recovery systems includes plane ampoules in which pressure is produced using a mud cap (Fig. 6a) or by throw of impactor plate (Fig. 6b). By varying the composition of the explosive, the material and the thickness of the impactor plate it is possible to change the magnitude and duration of the dynamic pressure. Additionally, such systems provide a better possibility

Figure 6. Schemes of plane recovery ampoules employed under shock compression using a mud cap (a) and throw of an impactor (b). Detonator (1), plane wave generator (2), explosive (3), sample to be compressed (4) and impactor plate (5).

for heating of the substance under study without contact between the ampoule and explosive before explosion. Uniaxial loading in plane ampoules is convenient for pressure measurements and calculations, but the design of the experimental setup is labour-consuming. Plane ampoules are most often used for explosive compaction or pre-activation of brittle powders, because in this case the thermodynamic parameters in the bulk of the sample are the same and can easily be controlled. Forced high-strain-rate deformation of samples also appeared to be efficient for compaction. To this end, the diameter of the pellet made of the substance under study should be smaller than the diameter of the ampoule. Planar impact is followed by plastic flow of the sample across the inner section of the ampoule, which sometimes results in transparent samples of rather strong materials.

Stepwise loading of samples in plane ampoules is attained using layered shells or impactors. Here, the temperature of the substance compressed is much lower (isentropic compression) than in the case of single-shot loading with the same explosive. In order to increase the pressure in the plane recovery ampoules, schemes with counter-propagating shock waves are used (Fig. 7). Other types of plane recovery ampoules were described in a review⁴⁶ and in a monograph.⁴

Figure 7. Scheme of a device for shock compression experiments using counter-propagating shock waves. Plane wave generator (1), explosive (2), impactor (3) and sample to be compressed (4).

The most industrially important procedure for recovery of explosion products involves placing a mixture of the substance under study and the explosive in a mechanically hard chamber for preservation of the expanding detonation products. For better annealing of detonation products, the charge is surrounded by an ice shell. The advantage of this technique consists in the absence of recovery ampoules, which makes the process much cheaper. Additionally, expansion of products within a large cavity causes annealing of high-pressure phases. The detonation parameters of, e.g., TNT ($P = 18.4$ GPa, $T = 2900$ °C) are sufficient to ensure transformation of graphite to diamond. As a result, the yield of diamond upon detonation of a graphite–explosive mixture or a pure explosive giving carbon as a solid detonation product can be as high as tens per cent. This is an order of magnitude higher than the yield provided by the ampoule technique (although the detonation diamond particles are much smaller than the particles obtained using the ampoule method). In Russian Federation, detonation diamonds are produced on a large-scale basis.

Probabilistically (assuming a homogeneous detonation cloud), the formation of detonation diamonds in the form of clusters comprising about $\sim 10^4$ atoms is impossible. Indeed, detonation of TNT or TNT–RDX alloys gives H_2 , CO, CO_2 , H_2O , NO, NO_2 , carbon clusters C_n ($n = 1-6$), etc. as products. Even if we restrict ourselves to these products, the probability of formation of a diatomic carbon cluster in the detonation cloud equals 1/7, the addition of the third and fourth carbon atom reduces the probability to 1/49 and 1/343, respectively, etc. Therefore, the probability of formation of a cluster comprising ten carbon atoms approaches zero. Nevertheless, the number of

atoms in the actually formed clusters is three orders of magnitude larger!

We believe that this can be explained by heterogeneous (layered) structure of the detonation cloud. The layers mainly include carbon atoms or hydrogen or water molecules, etc. The formation of layers can be understood if we assume that, upon detonation, all fragments of the explosive molecule have the same kinetic energy of $mv^2/2$ (m and v are the mass and velocity of a molecular fragment). Then, the velocities of the detonation products are inversely proportional to $\sqrt{m}$ and the detonation cloud will contain layers of atoms or molecules of different masses. Formation of diamond clusters will occur in the layer that comprises mainly carbon atoms. Similar masses of different molecules in the same layer impose a limitation on the growth of cluster and it is contaminated with impurities, which is observed in the experiments.

Methods of preservation of the shock compression and detonation products are used for chemical purposes, namely, for performing phase transformations and synthesis of novel compounds. Shock-induced syntheses and compaction, pre-sintering and catalytic activation of brittle materials have been documented in a review.⁴⁷

III. Features of phase transitions in shock waves

Iron shock compressibility studies⁴⁸ revealed a break in the Hugoniot curve at 13 GPa, corresponding to the α -Fe $\rightarrow$ ϵ -Fe transition. Analysis of ϵ -Fe fragments found upon disruption of target unambiguously indicated a phase transition with a duration of $\tau \leq 10^{-6}$ s. Optical studies^{49,50} showed that transitions under shock compression occur 10^7 – 10^{14} times faster than in static experiments.

What is the reason for high rate of the phase transitions under dynamic compression?

Variation of the bond lengths in crystals upon polymorphic transformations lie within the range of amplitudes of thermal atomic vibrations ($\sim 10\%$ of the bond length). Therefore, the duration of the phase transition can be estimated from shock-induced thermal atomic jumps. The action of shock waves causes fragmentation of crystalline grains, produces vacancies and dislocations in them and also causes heating of the body to very high temperatures, which favours intensification of atomic vibrations. The frequency of thermal vibrations is given by

$$w = A \sqrt{\frac{kT}{m}}, \quad (17)$$

where A is a constant, k is the Boltzmann constant and m is the atomic mass. At room temperature, for hydrogen atom one has $w = 6 \times 10^{13} \text{ s}^{-1}$ and $\tau \approx 2 \times 10^{-14} \text{ s}$; for $m = 100$ the time changes by an order of magnitude; with allowance for high pressure and activation energies⁵¹ one gets $\tau \approx 10^{-12} \text{ s}$, which is in agreement with experimental data.

Intensive studies of polymorphic transformations of simple bodies (elements) and compounds under shock compression began in the mid-1950s. Experiments showed that the dynamic phase transition pressures are similar, often being somewhat higher than the static transition pressures. This is due to the hydrostatic character of shock compression (see above) and to the fact that the dynamic loading temperature is higher than the temperature at which static experiments are carried out (usually, room temperature).

Analysis of the available experimental data made it possible to solve a number of fundamental problems concerning the kinetics and mechanisms of shock-induced phase transitions. We will consider these problems from the structural point of view, based on the experimental data only.

First of all, mention should be made of the anisotropy of phase transitions in the crystals of alkali metal halides. Namely, if the crystallographic axis (111) is normal to the shock wave front, the NaCl $\rightarrow$ CsCl type transitions occur at lower pressures, which

corresponds to compression of the unit cell along its spatial diagonal.⁵² This mechanism was studied in more detail using KCl samples; the phase transition points at 2.5, 2.2 and 2.1 GPa along the $\langle 100 \rangle$, $\langle 110 \rangle$ and $\langle 111 \rangle$ directions, respectively, were observed.⁵³ The anisotropic phase transition was explained in terms of atomic displacements along the spatial diagonal of the unit cell. However, coherent atomic displacements cannot cause transformation of the graphite lattice into the diamond lattice. Phase transitions require destruction (amorphisation) of the starting crystalline graphite. This conclusion is substantiated by the maximum yield of diamond in the detonation-induced transformation of the most defect carbonaceous material, namely, carbon black.

Analysis of these experimental findings gave an impetus to studies on geometric modelling of phase transitions that served as a basis for a separate avenue of scientific research.⁵⁴

In the graphite–hexagonal diamond (lonsdaleite) and g-BN–w-BN systems both the initial and final modifications have the same symmetry and the phase transition is driven by the puckering of planar hexagonal graphite sheets accompanied by the formation of sp^3 -bonds between the close-lying atoms belonging to neighbouring sheets. A metastable g-BN phase was detected⁵⁵ with an interplanar separation of 3.28 Å, which is smaller than in the single crystal (3.33 Å), and 002 X-ray reflections are broadened owing to structural deformation in this direction. Annealing of the wurtzite-type BN polymorph causes the formation of the g-BN phase by the same mechanism, but in the reverse order.⁵⁶

Shock compression of CdF_2 , CaF_2 and $CuBr$ results in reduction of the unit cell parameters by 0.002, 0.003 and 0.047 Å, respectively (lattice parameters were measured with an accuracy of ± 0.0005 Å) with retention of the unit cell symmetry and valences of the metal atoms.⁴ Isomorphic reduction of unit cell parameters after shock compression was small, but the dielectric constants (ϵ) responsible for the character of chemical bonding changed substantially, namely, they increased from 7.1 to 7.9 for fluorite and from 10.0 to 17.8 for $CuBr$. This is quite clear, since even a small shortening of the distance compared to the equilibrium value causes a dramatic strengthening of electron interaction and an increase in the atomic polarisabilities. Heating of isomorphically compressed crystals is accompanied by exothermic effect and the crystal structures and properties return to the initial state.

Isomorphic transitions also occur under the action of high static pressures. For instance, the unit cell parameters of samarium chalcogenides are dramatically reduced owing to an increase in the valence of the metal [$Sm(II) \rightarrow Sm(III)$]. In dynamic experiments isomorphic reduction of structural parameters is due to quenching of the shocked samples that occurs with retention of the oxidation state of the atoms.

Specific phase transitions were detected under shock compression of Nb_2O_5 and Ta_2O_5 crystals. Shock compression causes minor changes in the composition and results in the formation of TiO_2 -type structures.⁵⁷ Therefore, this transition is followed by the formation of a structure in which 20% of sites in the metal lattice are vacant (*i.e.*, compounds of the $M_{0.8}O_2$ type are formed). Shock compression of Ln_2S_3 ($Ln = Tb, Dy, Ho, Er, Y$) causes a $Ho_2S_3 \rightarrow Th_3P_4$ -type structural transition; here, each ninth site in the metal sublattice is replaced by a vacancy.⁵⁸ A similar transformation was observed under shock compression of CeF_4 , ThF_4 and UF_4 . These fluorides experienced a $ZrF_4 \rightarrow LaF_3$ structural transition accompanied by the formation of 25% vacant sites in the cation sublattice (*i.e.*, $MF_4 \rightarrow M_{0.75}F_3$ transition).⁵⁹ Such transformations were not detected under static compression, because denser structures with ordered system of defects are retained only upon rapid quenching of corresponding phases during the shock-wave unloading.

An interesting phase transition occurred in TiO under shock. The initial phase belongs to the monoclinic system ($a = 5.85$, $b = 9.34$, $c = 4.14$ Å, $\beta = 107^\circ 32'$). After shock compression the

diffraction pattern exhibited no weak lines while the intense lines corresponded to cubic lattice with $a = 4.176$ Å. In this case the phase transition accompanied by an increase in symmetry is also driven by generation of numerous defects that are characteristic of this crystal.⁶⁰

As shown above, the shock wave technique makes it possible to produce negative pressures that can be realised in the rarefaction wave in the form of tensile stress in the samples under study. Phase transformations at negative pressures can result in the formation of loose structures that cannot appear at $P \geq 0$. Such a structure was first found in our study of turbostratic BN under shock compression. We found a very small amount of a new polymorph (E-phase)⁶¹ whose density was lower than that of w-BN. The last-mentioned phase is formed only after annealing of defects and corresponding increase in the degree of crystallinity of the initial graphite-type boron nitride polymorph (w-BN is formed under shock compression of g-BN if the density of the starting phase is at least ≥ 2.2 g cm^{−3}). The Hugoniot adiabats of the BN samples with different densities show a similar trend.⁴ The structural parameters of E-BN are very similar to those of a certain fullerene phase:^{62, 63}

Parameter	$a/\text{\AA}$	$b/\text{\AA}$	$c/\text{\AA}$	$\rho/\text{g cm}^{-3}$
E-BN	11.14	8.06	7.40	2.50
C ₆₀	11.16	8.17	7.58	2.50

It is important that the E-phase is formed under shock compression only in the axial region of cylindrical ampoules if there is a cavity that appeared under the action of tensile stress in the compressed material after irregular collisions of shock waves. More recently, this phase was obtained by researchers from other groups under the action of various physical factors on g-BN.^{64–69}

Now we will consider yet another unusual type of phase transitions, which is atypical of physics of high static pressures. Usually, heating is accompanied by polymorphic transformations with the formation of looser structures, but there exist a number of crystalline compounds (*e.g.*, PbO , MnS , Ln_2S_3 , Ln_2O_3 , TiO_2 , ZrO_2 and LnF_3) that undergo phase transitions accompanied by densification upon heating. Under shock compression these compounds are transformed into phases with lower density (compared to the initial phase) and looser atomic structure (Table 6).

Table 6. Characteristics of anomalous phase transitions.⁷⁰

Composition	Initial phase		After shock compression	
	structural type	$\rho/\text{g cm}^{-3}$	structural type	$\rho/\text{g cm}^{-3}$
Tm_2S_3	Ho_2S_3	6.27	new type	6.06
Nd_2O_3	A-form	7.42	C-form	6.29
SmF_3	LaF_3	6.93	YF_3	6.64
HoF_3	LaF_3	7.83	YF_3	7.64
GeSSe	α -phase	4.0	γ -phase	3.6
GeSTe	α -phase	5.1	γ -phase	4.7
GeSeTe	α -phase	5.6	γ -phase	5.2
ZrO_2	tetragonal	6.03	monoclinic	5.83
PbO	orthorhombic	9.72	tetragonal	9.43

Anomalous phase transitions accompanied by loosening upon dynamic compression were explained by the action of negative pressures, however detailed studies revealed a more complex phenomenon. Under the action of a shock wave the lattice of the solid is disordered, dislocations are produced, and at higher concentration of defects the crystalline compound transforms to amorphous substance with minimum density (for the given composition). Heating of such a material causes its crystallisation in a phase with minimum density. Upon further heating the material crystallises in a denser phase. This mechanism was experimentally proved taking $GeSeTe$ ⁷¹ and Nd_2O_3 ⁷² as exam-

ples. Here, amorphous phases transformed into crystalline modifications with minimum density upon heating. The temperatures of successive transitions can differ insignificantly; besides, it is difficult to reach the desired range of thermodynamic parameters under shock compression. Therefore, these transitions have not long been detected.

Thus, an anomalous phase transition can be described by the following scheme:

Correctness of this scheme is substantiated by occurrence of anomalous transitions under static shear compression and upon intense irradiation.⁴

The structural approach to the description of the features and mechanisms of phase transitions under shock compression (see above) is not unique. For instance, the kinetic and thermodynamic aspects of this problem were also considered.⁷³

IV. Duration of solid-phase chemical reactions

1. Measurements of the duration of solid-phase reactions

The fact that the shock compression time is sufficient for a phase transition to occur was experimentally established in 1956.⁴⁸ As to solid-phase reactions, this was a moot question for long, because either synthesis or decomposition of chemical compounds in the recovery ampoules can occur both under shock and after unloading due to residual heat.

A solid-phase reaction proceeds in several steps. These are fragmentation of grains and cleavage of chemical bonds in the initial components, mixing of different reagents to bring them into contact at the atomic level and, finally, growth of new-phase crystals to a size that ensures their existence. Since diffusion in solids is slow, being even slower at high pressures (its rate is at least six orders of magnitude slower than the rate required for the synthesis on the microsecond time scale), solid-phase reactions seemed to be hardly probable. At the same time, gas–solid and liquid–solid chemical interactions that take a few microseconds have long been known (see, *e.g.*, Refs 74 and 75).

Actual duration of solid-phase reactions under shock compression was determined by measuring the time of the onset of heat release in exothermic reactions, by search for high-pressure phases among the synthesis products, by elucidating mechanical after-effects of shock-induced transformations in the recovery ampoules and, finally, by measuring the shock-wave velocities and pressure in the reacting mixtures.

a. Temperature measurements

Thermocouple measurements of the temperature of the reaction

were carried out in our research group since 1968 for a period of two decades. The duration of the experiments gradually shortened from 10^{-1} to $\leq 10^{-4}$ s due to the use of thinner thermocouples and improvement of experimental procedure (see references cited in Ref. 76). Measurements were carried out in the recovery ampoules rigidly joined to massive metallic slab in order to ensure immobilisation of the ampoules during the explosion. In order to obtain objective information, the dynamic compression was carried out under the same conditions for the reacting mixture Sn + S, individual components (Sn, S) and reaction product (SnS). Experiments showed that the residual temperatures of these individual compounds measured 0.1 s after explosion varied in the order $110 \rightarrow 120 \rightarrow 130$ °C, whereas that of the reacting mixture reached a value of 1110 °C, which corresponds to a 50% chemical conversion.

The results of X-ray diffraction study of the samples of the recovered products taken from different regions of the ampoule

showed that the synthesis occurs mainly in the axial region of the cylinder (in the so-called Mach stem) and the extent of conversion and the product composition (SnS or SnS₂) depend on the dispersion of the initial powder, which indicates a solid-phase character of the reaction.

The results of thermocouple measurements were checked calorimetrically. After an accurately measured time interval (from several tens of seconds to 1–2 min) after explosion, the recovery ampoule containing the reacting mixture and the product was taken out of the explosion chamber and placed in a water calorimeter. After cessation of heat release in the calorimeter, the temperature of the ampoule was calculated. Then, the ampoule was taken out of the calorimeter, heated in a furnace to a certain higher temperature and again placed in the explosion chamber. This was done in order to cool the ampoule under the same conditions as after the explosion. The cooling curve was measured using a thermocouple. Such cooling curves allow an exact extrapolation of the calorimetrically measured temperatures to zero time instant. The results obtained by the two methods differed by a few per cent. In the cylindrical ampoules with the diameter of the orifice in the bottom plug equal to the diameter of the Mach stem, the substance in the axial region was blown away, which made it possible to determine calorimetrically the contribution of the Mach region to the overall enthalpy of the sample.

Further shortening of the duration of the temperature measurements in the reacting systems was attained by using an optical pyrometer. The results of the studies of Al + Fe₂O₃,⁷⁷ Ni + Al,^{78,79} Sn + S,⁸⁰ and Sn + Te mixtures⁸¹ showed that the synthesis is completed after nearly 10^{-7} s. It is significant that for the Sn + S mixture the dependence of the temperature changes on the pressure applied passes through a maximum (Fig. 8). This indicates that the reaction can occur in a limited range of pressures. Raising the pressure favours SnS formation, which is accompanied by compaction, but simultaneously the thermal effect (and, hence, the thermodynamic driving force) of the reaction decreases.⁷⁶

Real-time studies of the temperature dependences of the shock-induced interaction of magnesium, aluminium and titanium with sulfur were reported.^{82–84} The reaction durations were about 50 ns and the extent of conversion varied from 0.2 to 0.5. An optical study of the Al–S system revealed a dependence of the rate of the shock-induced reaction on the dispersity of the reacting particles, which proves the solid-phase character of the process. Under explosive loading using a TNT–RDX alloy the Mg–S system shows that the first temperature rise region is followed by a region of gradual increase in temperature due to the development of the reaction after unloading. This can serve as a model for the situation in the recovery ampoules.

Figure 8. Shock temperature plotted vs. pressure in Sn + S reacting mixture.

b. Kinematic measurements

Kinematic measurements (*i.e.*, measurements of parameters under shock compression) provide objective information on possible chemical transformations in a mixture of solids. Deviation of the shock compression curve of Sn + S mixture⁸⁵ toward a larger volume and/or pressure at $P \geq 15$ GPa was the first direct proof of the fact that the duration of a solid-phase reaction is of the order of a few microseconds. More recently, chemical reactions in shock waves were detected in the compressibility studies of Sn + Te (at $P > 45$ GPa),⁸¹ Ti + C (at $P > 15$ GPa)⁸⁶ and Ti + Ni (at 3.2 GPa) mixtures.⁸⁷ According to unpublished data obtained by G A Adadurov and S V Pershin (N N Semenov Institute of Chemical Physics, Russian Academy of Sciences), the shock compressibility curves of Fe + S and Cu + Al mixtures exhibit kinks at 28 and 32 GPa, respectively, upon increase in volume (Fig. 9).

Figure 9. Kinks in the shock compressibility curves of various smixtures in the region of chemical interaction. Ni + Ti (~7 GPa) (1), Sn + S (~15 GPa) (2), Ti + C (~15 GPa) (3), Fe + S (~28 GPa) (4), Cu + Al (~32 GPa) (5) and Sn + Te (~55 GPa) (6); in all cases I refers to the mixture and II refers to the product.

Generally, the chemical interaction between the components of a mixture can be accompanied by either a decrease or an increase in volume. For the compositions M^zX^{8-z} ($X = \text{Cl, Br, I; S, Se, Te; P, As, Sb}$), the synthesis of compounds of Group 1B, 2B and 3B metals leads to an increase in the volume, whereas the synthesis of compounds of Group 1A, 2A and 3A metals leads to a decrease in the volume (this is partially compensated by an increase in the volume due to thermal expansion). The magnitude of the changes in the volume can be estimated with ease. Indeed, the exothermic effect lies in the range $100\text{--}200\text{ kJ mol}^{-1}$, the heat capacity is of the order of $40\text{--}50\text{ J (mol K)}^{-1}$ and the temperature of the substance increases to $2000\text{--}4000\text{ }^\circ\text{C}$. The thermal expansion coefficients of solids are about 2×10^{-5} ; therefore, these temperature changes cause the volume to increase by $4\%\text{--}8\%$. Physical measurements showed that the degree of conversion in shock waves is at most 0.5; therefore, the actual increase in volume due to thermal expansion is $2\%\text{--}4\%$. It is these numerical values that should be used when comparing the volumetric changes occurring as a result of a chemical reaction.

As typical examples, we will consider changes in the molar volumes of the low-pressure phases in the reactions

where $M = \text{Zn, Ca}$.

Calculations were performed using the expression

$$V = V_0 \left(1 - \frac{U}{D} \right), \quad (18)$$

derived by combining Eqn (1) and Eqn (2). Here V and V_0 are the initial and final volumes of the body, D and U are the shock and particle velocities (see Section II). For ZnS, the U and D values can be determined from the experimental Hugoniot adiabat⁸⁸ and for CaS this can be done using the Hugoniot adiabat reconstructed from Eqns (10) and the results of supersonic measurements of B_0 (64 GPa) and B'_0 (4.2). For Zn + S and Ca + S mixtures, the particle velocities can be calculated using the additivity scheme from the Hugoniot adiabats of the elements (see Table 2) and Eqn (16). Having determined the $U_{1,2}$ values for a number of the pressure values and knowing the density of the mixtures, one can calculate D_1 using expression (15) and then the V values from Eqn (18). The $P = f(V)$ dependences were established using the following characteristics:

for Zn + S

$$D = 2.085 + 1.804 U, \rho = 3.95\text{ g cm}^{-3};$$

for ZnS

$$D = 3.13 + 1.30 U, \rho = 4.085\text{ g cm}^{-3};$$

for Ca + S

$$D = 2.93 + 1.13 U, \rho = 1.73\text{ g cm}^{-3};$$

and for CaS

$$D = 4.95 + 1.30 U, \rho = 2.61\text{ g cm}^{-3}.$$

Since the synthesis of zinc and calcium sulfides is accompanied by heat release (Q), one should take into account the additional 'thermal pressure' ΔP_Q . According to the Mie–Grüneisen model, at $\Gamma V = \text{const}$ it can be calculated using an approximate relation

$$\Delta P_Q = \frac{2\Gamma Q}{V(\Gamma + 2) - \Gamma V_0}. \quad (19)$$

The Q values for ZnS and CaS are 191.8 and 473.2 kJ mol^{-1} , respectively (see Ref. 89). In fact, the conversions in shock waves are at most 50%; therefore, the parameters of Eqn (19) are as follows: $0.5 Q$, $\Gamma = 0.68$ (ZnS)⁸⁸ and $\Gamma = 1.41$ (CaS).⁹⁰

Finally, we must allow for the change in the thermal effect due to the different compressibility of the mixture and the product. The difference in the shock compression work

$$E_c = \frac{P(V_0 - V)}{2}$$

between the mixture and the product in the $M + S \rightarrow MS$ system causes a decrease in Q by

$$\Delta E_c = E_c(M + S) - E_c(MS).$$

Table 7 presents the results of the $V = f(P)$ calculations using the relations listed above and the P^* values for the heated compounds obtained by summation of the P and ΔP_Q values. Analysis of the data in Table 7 and the plots in Fig. 10 shows that the P – V Hugoniot curve deviates towards larger volumes upon the formation of ZnS and towards smaller volumes for the synthesis of CaS. Raising the pressure causes the curves for CaS and Ca + S to approach each other.

This result is important for the understanding of the processes occurring, *e.g.*, under shock compression of a $\text{Mo} + 2\text{Si}$ mixture. A kink in the P – V plot towards smaller volumes in the pressure range $6.5\text{--}7\text{ GPa}$ was interpreted⁹¹ as a result of the melting of silicon and corresponding increase in the compressibility of the mixture. It was assumed⁹¹ that capillary flow of molten silicon limits the deformation of the molybdenum particles and mixing between the reactants. However, in another study by these authors a partial interaction in the same system, detected in the recovery experiments was interpreted as a reaction of solid molybdenum with molten silicon.⁹² According to Vreeland,⁹³ the reactions of titanium, niobium and molybdenum with silicon proceed by

Table 7. Changes in molar volumes during shock-induced syntheses $M + S \rightarrow MS$.

heterogeneous (liquid–solid) mechanism. The kink in the $P-V$ curve⁹¹ can be due to the reaction

which is accompanied by a decrease in the volume by 27.7% (see Ref. 94). The heat of the reaction (132 kJ mol^{-1}) has no effect on the volume ratio, because the volume of the product increases only by a few per cent.

Probably, similar processes also occur under shock compression of Al + SiO_2 mixture. A kink in the Hugoniot adiabat of this mixture with a decrease in the volume was interpreted⁹⁵ as a quartz $\rightarrow$ stishovite transition. The chemical interaction resulting in Al_2O_3 is also accompanied by compaction and release of much higher energy (619 kJ mol^{-1} for stoichiometric composition), which makes this reaction preferred. Additionally, the kink in the shock adiabat of the mixture was detected at 20 GPa, whereas the phase transition in pure quartz occurs at 38 GPa. Voskoboinikov⁹⁶ analysed the shock adiabats of the mixture and compound and showed that in this case the chemical reaction is more probable than a phase transition.

To decide between the phase transition and shock-induced chemical transformation accompanied by compaction, it is sufficient to measure the temperature, because the heat of a chemical reaction is usually an order of magnitude higher than that of polymorphic transformation. For instance, kinks in the Hugoniot adiabats of CS_2 and C_6H_6 at $P > 6 \text{ GPa}$ with a decrease in

volume⁹⁷ can be treated as phase transitions. However, the results of optical measurements⁹⁸ revealed a stepwise increase in the temperature of the medium by more than 250°C at these pressures, which indicates a chemical reaction (in this case, decomposition). If the decrease in the volume upon a shock-induced chemical transformation is small, it can be compensated by thermal expansion and the shock adiabat will exhibit no features. For instance, the volumes of organofluorine compounds are changed insignificantly,⁹⁹ whereas the changes in the temperature are large, namely, a stepwise increase by 500°C at $P > 22 \text{ GPa}$ owing to decomposition.¹⁰⁰ Similarly, a shock compression study¹⁰¹ of teflon at $P > 34 \text{ GPa}$ showed an abrupt increase in the speed of sound behind the shock-wave front and almost smooth shock adiabat curve. A chemical reaction in the Nb + Si mixture substantiated by the recovery experiments was detected from a jumpwise increase in the speed of sound.¹⁰²

Yet another method of detection of physicochemical transformations under dynamic loading is the study of shock wave damping. From general physical considerations it follows that¹⁰³

$$\frac{\partial D}{\partial \tau} = \frac{c}{c + U - D},$$

where c is the speed of sound behind the shock-wave front. A phase transformation accompanied by densification is characterised by an increase in D and a decrease in U ; therefore, the damping rate will increase.

Measurements in shock compressed metal–oxide mixtures revealed dramatic changes in the shape of the $P = f(\tau)$ curves after particular pressures were reached.¹⁰⁴ For instance, a fivefold increase in the shock wave damping in the Mg + SiO_2 mixture (sample thickness 2 mm) in the pressure range 24.0–28.8 GPa, a twofold increase for the Mg + TiO_2 mixture at 29.6–31.2 GPa, a threefold increase for the Mg + Fe_2O_3 mixture at 18.8–23.6 GPa and a fourfold increase for the Al + Fe_2O_3 mixture at 17.1–22.8 GPa were observed compared to monotonic changes in the damping rates beyond these pressure ranges. In all cases the volumes of products were smaller than those of the starting mixtures. Correspondingly, the deviations of the compressibility curves for these reactions should be opposite in sign compared to the deviations of the compressibility curves for the shock-induced reactions characterised by an increase in volume.

A shock-induced solid-phase reaction

was studied using cold and pre-heated mixtures.¹⁰⁵ The shock velocity in the mixture pre-heated to 242°C showed a jumpwise increase by 0.7 km s^{-1} . Since an exothermic reaction begins at this temperature, the shock velocity jump can be explained by energy transfer from the chemical reaction to the shock wave in the zone of high dynamic pressure. An increase in the shock velocity induced by exothermic reaction was also revealed in a study of the reaction in the Zn + S mixture.¹⁰⁶

In 1993, researchers from the USA first reported pressure measurements in the course of chemical transformations using piezoelectric transducers; in particular, a reaction with a micro-second duration was detected in the Ti–Si system. A review of corresponding studies is available.¹⁰⁷

c. Estimation of the reaction duration from mechanical changes in recovery ampoules

The temperature and kinematic measurements are labour-consuming and therefore cannot be used for quick analysis of the duration of chemical transformations under shock compression. Taking into account the fact that shock-induced synthesis occurs mainly in the axial region of cylindrical ampoules (Mach stem whose size is determined by the energy supplied), the reaction can be detected from the change in the Mach stem diameter and from the action of the Mach stem on the bottom of the ampoule (spall plate) behind the shock wave front.¹⁰⁸

Shock compression experiments carried out under the same conditions revealed a larger diameter and deeper spall for the Sn + S mixture compared to SnS, the mass of the spall plate being 0.06 and 0.003 g, respectively. Since the velocity of the motion of the spall element is given by

$$v = 2U,$$

for this system one gets $v = 4.3 \text{ km s}^{-1}$. From here the kinetic energy of the spall plate, E is about 60 kJ mol^{-1} for the mixture and nearly 3.2 kJ mol^{-1} for the compound. The difference, $\sim 57 \text{ kJ mol}^{-1}$, is the increase in energy equal to the contribution of the heat of the chemical reaction to the energy of the Mach wave. This difference corresponds to an extent of conversion of 30%, which is similar to the reaction yield determined from the temperature and kinematic measurements.

Similar spalling features in the Sn + Te system were observed using more energetic explosives ($D_0 = 7.3 \text{ km s}^{-1}$) and, correspondingly, at a higher pressure of the onset of the chemical reaction detected in kinematic measurements.

Studies of spalling phenomena in the recovery ampoules during shock compression of Ti + C and Zn + S mixtures using explosives with a detonation velocity of 6.2 km s^{-1} in the former and 7.2 km s^{-1} in the latter case showed the formation of compounds TiC and ZnS in ~ 7 and $\sim 90\%$ yields, respectively.¹⁰⁹ A regular decrease in the Mach stem diameter with an increase in the stiffness difference (ρc^2) between the shell and the content of the cylindrical ampoule was also established in that study. The stiffnesses of compounds TiC and ZnS are higher than those of the corresponding mixtures; therefore, a decrease in the difference in ρc^2 between the shell and the substance under study causes extension of the Mach region in the shock compressed material.

Endothermic transformations lead to narrowing of the Mach stem. A dark Mach stem appeared in the axial region of the cylindrical ampoule at a distance of about two diameters from the upper end upon shock compression of CuCl. The downward motion of the Mach stem was accompanied by its monotonous extension in a conical fashion. Once a certain intensity was reached, the substance in the Mach zone melted and the Mach stem narrowed; further motion toward the bottom of the ampoule was again accompanied by extension of the Mach stem until the next melting of the powder.

2. Solid-phase reactions

The formation of high-pressure phases as a result of a chemical reaction indicates that the reaction proceeds in the high-pressure zone. To date, a large body of experimental data on the decomposition and synthesis reactions has been accumulated. In the former case the interacting atoms are inside molecules or coordination polyhedra of crystals, *i.e.*, they can be treated as being in contact with one another, the decomposition occurs instantaneously and time is only taken for the separation and nucleation of a new phase. The latter case requires dispersion and mixing of particles, cleavage of chemical bonds and diffusion of reactant atoms followed by the formation of products and nucleation. Clearly, the decomposition processes are faster than syntheses.

Indeed, disproportionation of Al_2SiO_5 into Al_2O_3 and SiO_2 under the action of high-energy shock waves results in the formation of a high-pressure SiO_2 phase with stishovite-type structure.^{110, 111} Similar phases are formed under shock compression of ZnBaGeO_4 ,¹¹² Mg_2SiO_4 ¹¹³ and ZrSiO_4 .¹¹⁴ A high-pressure boron nitride phase (c-BN) was produced by shock-induced disproportionation of $\text{BH}_3 \cdot \text{NH}_3$.¹¹⁵ Explosive decomposition of organic compounds mixed with explosives, resulting in the formation of diamond as detonation product was reported.^{116, 117} Disproportionation of PbO upon shock compression by high-energy shock waves in a cylindrical ampoule occurs behind the front of the incident shock wave. Propagation of the reflected wave through a mixture is accompanied by separation of the mixture components and accumulation of lead in the Mach region.¹¹⁸ Therefore, the chemical reaction occurs in the region

between the incident and reflected waves and has a duration of $10^{-7} - 10^{-6} \text{ s}$.

At high pressure, water possesses the properties of acid. Because of this, metals preceding hydrogen in the electrochemical series should dissolve in this modification of water. Taking into account this fact, we shock compressed a mixture of zinc powder and ice in cylindrical recovery ampoules cooled with liquid nitrogen before explosion using high-power explosives ($D_0 \geq 6.2 \text{ km s}^{-1}$). Analysis of the recovered product revealed the formation of zinc oxide and dihydrogen following the reaction

The reaction products cannot result from pyrolysis of water, because the temperature of the ampoule after explosion was only slightly higher than room temperature. Similar reactions proceed with other metals (B, Al, Ga, Ge, Ti, Zr, Nb, Cr, Mo, W, Mn) that dissolve in acids, *i.e.*, the chemical transformation does occur in the high-pressure zone.¹¹⁹ A similar experiment¹²⁰ using a cylindrical ampoule with a large reservoir for expansion and quenching of reaction products (see Fig. 3c) resulted in cubic zirconia (high-pressure phase). The reaction

was used for the synthesis of hexagonal diamond (lonsdeilite).¹²¹

Consider now yet another aspect, which also indicates a shock-wave character of chemical transformations. Thermodynamics operates with positive pressures. As mentioned above, shock compression technique allows production of negative pressures and formation of loose structures.

A shock compression study¹²² of Nd_2O_3 revealed the formation of a polymorph called E-phase. According to spectral analysis data, the E-phase also contained SiO_2 ($\sim 30\%$). Experiments proved that spall microparticles from the inner surface (mainly from the bottom and to a lesser extent from the walls) of the recovery ampoule served as the source of SiO_2 . The density of the E-phase (1.6 g cm^{-3}) is much lower than those of the starting neodymium oxide (7.42 g cm^{-3}) and quartz (2.65 g cm^{-3}). A very small amount of single crystals of this phase was obtained. The crystals had a monoclinic lattice ($a = 7.5$, $b = 8.7$, $c = 10.3 \text{ \AA}$; $\beta = 104^\circ$) and low refractive index ($n_g = 1.57$, $n_m = 1.56$, $n_p = 1.54$), whereas the refractive index of the starting neodymium oxide is 2.10. The E-phase of neodymium oxide is insoluble in acids or alkalis and exhibits a high thermal stability with a reversible change of colour from white to violet. Attempts to obtain this phase under shock compression of $\text{Nd}_2\text{O}_3 + \text{Si}$, $\text{Nd}_2\text{O}_3 + \text{SiO}$ and $\text{Nd}_2\text{O}_3 + \text{SiO}_2$ mixtures using various explosives failed. Namely, reactions at any reagent ratios resulted in conventional neodymium silicates of different compositions characterised by high densities and refractive indices. Apparently, the reactivity of the spall elements is strongly different from the bulk sample reactivity due to an increase in the concentration of ruptured chemical bonds in such species upon spalling from the monolithic body.

Similar results were obtained in a shock compression study of $\text{Zr} + 2\text{S}$ mixture, which revealed the formation of ZrS_2 with 'shrunk' unit cell parameters.¹²³ In a detailed study the product was identified as a solid solution $\text{Zr}_{1-x}\text{Fe}_x\text{S}_2$. Here, the source of iron was also the recovery ampoule (no solid solution is formed when using ampoules with quartz embeddings) and the product yield was dependent on the smoothness of the inner surface of the ampoule. The last-mentioned feature means that iron microparticles are spalled from scratches on the inner walls. It is important that no solid solution is formed under shock compression of a mixture of ZrS_2 with iron powder, or by thermal method because the product obtained by shock-induced synthesis decomposes to ZrS_2 and FeS on heating.

When using spall microparticles of elements with equal electronegativities (heat of reaction is zero) as reactants, the thermodynamic situation can change. An example is provided by the reaction

which proceeds under shock compression of SiO_2 in tantalum ampoule,¹²⁴ being impossible under normal conditions.

The supply of iron spall microparticles from the walls of a cylindrical ampoule to the material compressed is governed by the density of the material (the higher the density the lower the supply) and by the physicochemical processes occurring under shock compression. In particular, an increase in the yield of the dense phase from 45% to 85% during the phase transformation of BN is accompanied by fivefold more intense contamination of the sample with iron from the cylindrical ampoule. Shock compression of PbO , PbF_2 and ZnS accompanied by phase transformations in the compounds causes a twofold increase in the contamination of samples with iron compared to the shock compression of the high-pressure phases that do not undergo any transformations. The contamination of products of the shock-induced syntheses

with iron is two times (MnTe , TiO) or even two orders of magnitude (SnS) higher compared to inert compounds of the same compositions under the same conditions. Correspondingly, shock-induced decomposition of CdCO_3 to CdO is accompanied by not only a reduction of temperature and densification but also a decrease in the extent of contamination with iron by an order of magnitude.

An additional argument substantiating the conclusion that solids can undergo chemical transformations under shock is provided by the fact that reactions occur mainly in the axial region of the cylindrical ampoule (Mach region).^{91,94} This seemed obvious for long, because the pressure and temperature are maximum in the Mach stem, decrease in the adjacent layer (here, the reaction is only partially completed) and reach minimum values at the walls of the ampoule where no reaction occurs at all. However, it remains unclear why heat released in the shock compressed mixture (extent of chemical conversion is $40 \pm 10\%$ according to experimental data) does not initiate the process in other regions of the sample that contact the hot zone?

The reason for such a behaviour is the high pressure in the Mach zone, which leads to reduction of the temperature of the reacting mixture (see a dome-shaped plot of temperature changes under shock compression of $\text{Sn} + \text{S}$ mixture in Fig. 8).¹²⁵ What processes do occur in the product after unloading if the high pressure underestimates the heat (it can reach zero upon further heating; this is called 'cold synthesis')? Since the compression–expansion cycle is reversible, unloading should be followed by heat release, but why the heat released does not initiate a chemical reaction in the unloaded sample in the region near the axis of the ampoule?

The answer to this question deserves special studies, however to a first approximation one can assume that in the course of unloading at negative pressures the substance arrives at an additional minimum on the potential surface. Probably, this minimum corresponds to an ordered defect or dislocation lattice, because the densities of all substances synthesised by explosion technique were different from the reference values. For instance, heating of shock-synthesised CrTe is accompanied by densification of the material and corresponding exothermic effect at 410°C . However, we failed not only to complete a transition of the compound to the normal state but even to reach the density of the initial mixture after storage of the sample at 700°C for 2 h.¹²⁶ Therefore, shock-induced synthesis results in compounds that possess new properties. Partial completion of exothermic reactions in recovery ampoules under shock compression can be treated as yet another criterion for occurrence (or absence) of the chemical interaction of solids in the high dynamic pressure zone.

V. Mechanism of ultrafast solid-phase reaction

Experimental facts indicating that solid-phase syntheses can proceed under shock (see above) require a non-trivial explanation. Indeed, conventional diffusion in solids is much slower than that providing the microsecond durations of chemical reactions. Ultrafast atom diffusion in shock compressed materials was explained by several factors. These are a very high concentration of defects, plastic deformation,^{127,128} heterogeneous heating of components with different stiffness,¹²⁹ reduction of activation energy due to crystal lattice breakdown upon phase transitions^{130,131} or melting of one or all reactants.¹²⁷ Although all these factors favour a decrease in the activation energy and acceleration of diffusion, they are insufficient to provide an explanation for the mechanism of ultrafast mixing of components in the reacting mixture and separation of reaction products, a threshold-type character of the reaction pressure and other experimental data.

We have hypothesised that ultrafast forced diffusion of mixture components is due to the particle velocity difference between the components under shock compression.⁸⁵ This was experimentally proved in a number of studies^{132,133} (see also Refs 134 and 135). Indeed, if solid reagents 1 and 2 possess the same mechanical properties, namely, the same shock adiabats and, hence, the particle velocities ($U_1 = U_2$), the motion of the material behind the shock wave front resembles the motion of a chessboard with the same pattern of black and white squares. If differently coloured squares move at different velocities, the velocity difference represents the velocity of forced diffusion ($U_d = U_1 - U_2$), which causes deformation and interdiffusion of the squares. It is important that U_d increases as the pressure increases; this contradicts conventional concepts of retardation of diffusion upon densification. Based on this model, it is possible to immediately determine the mixing time; therefore, the reaction duration can be found as follows

$$\tau \approx \frac{d}{U_d},$$

where d is the grain size. For instance, at $U_d = 1 \text{ km s}^{-1}$ and $d = 0.1 \text{ mm}$ one gets $\tau \approx 10^{-7} \text{ s}$.

Strictly speaking, the rate of forced diffusion in a heterogeneous mixture is not equal to $\Delta U_{1,2}$. Here, a fraction of $\Delta U_{1,2}$ should be used with allowance for unloading of the stiff component into the softer body. For most compounds at moderate pressures this fraction is about 0.5 and therefore the characteristic diffusion time (mixing time) should be determined using the relation^{80,136}

$$\tau = \frac{2d}{\Delta U_{1,2}}.$$

Knowing the Hugoniot adiabats for Sn , S and Te , one can find with ease that for the $\text{Sn} + \text{S}$ mixture (particle size $100 \mu\text{m}$) the time $\tau = 0.3 \mu\text{s}$ corresponds to a pressure of 10 GPa and for the $\text{Sn} + \text{Te}$ mixture (the same particle size) the time $\tau = 0.8 \mu\text{s}$ corresponds to a pressure of 50 GPa. This is consistent with experimental data with allowance for the scatter in the particle size and errors in pressure measurements in the reacting mixture.

How does interdiffusion occur? The most probable model for this process is as follows. Propagation of a shock wave through a heterogeneous mixture of powders is accompanied by fragmentation of grains into blocks of size up to $50\text{--}100 \text{ \AA}$ (according to X-ray diffraction data⁴) due to unloading of the stiff material into milder grains. These blocks ('spalled squares') are mixed at a forced diffusion rate. In this case the chemical reaction immediately occurs on the surfaces of the contacting blocks, thus involving from 20% to 40% of the total number of atoms. It is this degree of conversion that is detected by various physical methods (see above). Probably, reactions on the particle surfaces are also favoured by contact melting of grains during shock compression.

The mechanical properties, *e.g.*, U of the reaction product differ from those of the starting components. Due to the particle velocity difference between the reactants and product the particle surfaces are 'cleaned' from the reacting layer, which ensures continuous chemical interaction.

Different stages of solid-phase reactions, namely, grinding before reaction, interdiffusion and, finally, chemical interaction were considered in studies on the microstructure of products of shock compression of powder mixtures $M + 2\text{Si}$ ($M = \text{Al, Ti, V, Nb, Ta, Cr, Mo, W, Fe}$).^{94, 137–140} Since the pressure and temperature in cylindrical ampoules rapidly decrease from the axial region to periphery, a transition from the mixture of components to compounds synthesised can be observed using the same sample by analysing its cross-section. With the known law of pressure changes across the section of the cylindrical ampoule one can determine the threshold reaction pressure.⁹⁴

Yet another feature should be noted. The degree of conversion is 100% in the axial region of the cylindrical ampoule, decreases as the shock wave intensity decreases towards the periphery of the cylinder and is zero (no reaction) on the walls of the ampoule, although the decrease in pressure should cause the heat of the reaction to increase. This can be explained as follows: the characteristic time of unloading of a shock compressed body in the laboratory experiments with charges 40–60 mm in diameter is $\sim 10^{-6}$ s; the decrease in the dynamic pressure from 100 to 1 GPa means that the duration of the action of the high pressure in each step $\Delta P = 1$ GPa is shortened to $\sim 10^{-8}$ s, which is insufficient for interdiffusion of large reactant particles. Thus, shock-initiated solid-phase chemical reactions proceed with different yields at the same pressure depending on the pressure 'prehistory'. In other words, the results depend on whether the optimum pressure was produced by detonation of a corresponding explosive (here, the duration is $\sim 10^{-6}$ s) or was attained during the drop from a higher level and therefore acts in each step for a much shorter time.

An important feature of shock-initiated reactions is a threshold character of the behaviour of their thermodynamic parameters. Several criteria for the explanation for this phenomenon were proposed. Krüger *et al.*¹⁴¹ assume that the threshold of the reaction $\text{Ni} + \text{Si}$ is determined by the critical energy necessary for initiation of the reaction. Iyer *et al.*¹⁴² determined the threshold wave velocity for the reaction $\text{Ni} + \text{Al}$; Meyers¹⁴³ assumes that the threshold of the onset of the reaction $\text{Nb} + \text{Si}$ is due to melting of silicon; and Thadhani *et al.*¹⁰⁷ concluded that the threshold of the solid-phase interaction is the ultimate strength of the crystalline particles, *i.e.*, the shock-initiated reaction is a mechanochemical process. According to our model, the pressure corresponding to the onset of the reaction is determined by the time taken by the forced diffusion front (due to the mass velocity difference between components) to travel a distance equal to the particle size.

The thermodynamic and kinetic aspects of shock-initiated solid-phase reactions were considered and the results of numerical modelling of the mechanisms of these reactions were presented.¹⁹

Theoretical treatment of the possibility of solid-phase detonation as a result of exothermic shock-initiated reaction was reported.^{144, 145} Constant shock-wave velocities in the reacting mixtures of zinc and sulfur powders and aluminium and fluoropolymer were observed.^{106, 146} Investigations of this phenomenon are of fundamental importance.

VI. Conclusion

There are three promising avenues of research on the chemical transformations under the action of shock waves.

One of them involves improvement of the shock-wave loading techniques, which permits separate variation of thermodynamic parameters of the interacting bodies. For instance, if one reactant is placed in a target and the other reactant is the impactor material, it is possible to increase the chemical potential difference between the reactants that have similar or equal electronegativities (*i.e.*, a

low or zero heat of formation) and therefore do not react under normal conditions. An example is provided by $\text{B} + \text{Sb}$ mixture for which no shock-induced interaction of the components was reported so far.

The second avenue of research in the field of shock-induced synthesis, which has no analogues in traditional chemistry, involves the use of spall microparticles as reactants. In this connection the cumulative effect is of considerable interest. It allows one to generate dense microparticle flows from planar or conical hollownesses in various metals and to control the thermodynamic parameters of reactants by varying the angle of the hollowness, the type of the explosive and the distance to the target.

The third promising field of chemical applications of the shock-wave technique is the synthesis at negative pressures, which results in the formation of loose structures. Macroscopic loose structures can be obtained by shock compression of a mixture of the desired material and explosive in a recovery ampoule. Compression of the ampoule and compaction of the powder are followed by internal detonation and formation of pumice.¹⁴⁷ It is possible to control both the pore concentration and pore topography, which seems to be promising for application in catalysis with allowance for improvement of catalytic activity under shock (see references cited in Ref. 47).

Dynamic-static compression of nanocrystalline powders can also find certain applications. Transition from macroscopic particles to nanoparticles is accompanied by an increase in the elastic modulus by tens of per cent.^{148–151} This is due to the surface energy of micropowders. In the bulk crystal the proportion of the surface energy is negligible, but in an array of size 100 Å and a bond length of 2 Å the number of surface atoms is 6×50^2 or 12% of the total number of atoms. The potential energy of the material increase by the same value and, since $E \sim BV$, the elastic modulus will also increase by 12% at the same volume, which is consistent with experimental data. Will attempts to compact diamond nanopowders to monolithic state at the same size be successful, the novel material should be harder than conventional diamond single crystals or polycrystals.

Abstract. The results of experimental and theoretical investigations of phase equilibria in the W–C system and of the crystal and electronic structures of tungsten carbides are generalised. The phase diagram of the W–C system supplemented by new compounds is considered. The sequence of phase transformations associated with ordering of lower hexagonal carbide β -W₂C is analysed. The region of existence of cubic carbide γ -WC_{1–x} is discussed in detail. The generalised information on the phase equilibria in the ternary system W–Co–C, which forms the basis for the synthesis of hard alloys WC–Co, is given. Methods of synthesis of tungsten carbides and hard alloys based on them are considered. Modern methods for the synthesis of nanostructured hard alloys are discussed in detail as well as their structures and properties. The bibliography includes 131 references.

I. Introduction

Carbides of Group IV–VI transition d-metals belong to non-stoichiometric interstitial compounds.^{1–4} Transition metals of Groups IVA and VA (Ti, Zr, Hf, V, Nb, Ta) form cubic carbides MC_y with the B1-type structure (NaCl), while the metals of Groups VA and VIA (V, Nb, Ta, Cr, Mo, W) form in addition lower hexagonal carbides M₂C_y with the L'3-type structure (W₂C).[†]

A characteristic feature of the structures of these compounds is the presence of the face-centred cubic (fcc) or hexagonal [simple or closely-packed (hcp)] metal lattice, in which the carbon atoms are located in the centre of octahedral or trigonal interstitials of the metal lattice. The metal structure changes with the formation of carbides. In carbides, the metal lattice symmetry differs from that of transition metal lattices. Group IV metals (Ti, Zr, Hf), which have the hcp structure, form carbides with the fcc metal sublattices. Metals with the body centred cubic (bcc) structure (V, Nb, Ta, Cr, Mo, W) form carbides with the cubic or hexagonal metal sublattices. The changeover of the crystal structure of

metals upon formation of carbides suggests strong metal–carbon interactions and negligible interactions between carbon atoms.⁵

In carbides, the carbon atoms, that are located in the interstitial voids of the metal sublattice form a non-metal sublattice. Unoccupied interstitials are called structural vacancies and designated as □. Together with carbon atoms, they form a substitutional solution in the non-metal sublattice. The presence of structural vacancies is a characteristic feature of carbides that belong to the group of non-stoichiometric compounds. The concentration of vacancies and their distribution type have a strong effect on the properties of such carbides. The results of experimental and theoretical studies on how the distribution of atoms and vacancies affects the structure and properties of strongly non-stoichiometric compounds are generalised in monographs.^{1–4,6}

Carbides of Group IV–VI transition d-metals have the highest melting points and are the hardest among all the compounds known.^{3,4,7–12} Therefore, these carbides are used in manufacturing structural and tool materials capable of operating at elevated temperatures, in aggressive media and under heavy loads; they make it possible to develop protective and hard coatings, *etc.* Tungsten carbide WC is not the hardest or the most refractory compound, *viz.*, its melting point (~ 3060 K) is low as compared with non-stoichiometric carbides TiC_y, ZrC_y, HfC_y, VC_y, NbC_y and TaC_y and its hardness (18–22 GPa at 300 K) is also low as compared with these carbides.^{3,4} However, the hardness of WC is sufficiently stable and decreases relatively slightly with the increase in temperature from 300 to 1200–1300 K. Moreover, as compared with carbides of other transition metals, tungsten carbide has a higher modulus of elasticity and a lower coefficient of thermal expansion. It is the combination of the aforementioned properties and their temperature stability that determines the use of WC in the production of wear-resistant hard alloys, which form the basis of all tool materials.

Tungsten carbide was first synthesised in 1893.¹³ The synthesis of refractory carbides including WC from oxides, in which calcium carbide is used as the reactant, was described.¹⁴ The industrial production of hard alloys based on WC started 20–25 years after its discovery and goes on at present.¹⁵

[†] Hereinafter, the lattice types of inorganic compounds are shown according to the following book: W B Pearson *The Crystal Chemistry and Physics of Metals and Alloys* (New York, London: Wiley, 1972); in the parentheses, the typical example of a given type is shown.

The practical interest in tungsten carbide determines the active fundamental investigations of its crystal and electronic structure and also of the physicochemical properties of both WC as such and related compounds and systems that contain it. In the past 20 years, the most active studies were associated with the synthesis and application of nanocrystalline tungsten carbide.

II. Phase equilibria and the crystal structures of phases in the W–C system

In addition to tungsten and carbon, the W–C system includes two phases, namely, W_2C and WC, each having several structural modifications, which are stable in certain temperature and concentration ranges (Fig. 1).

Two successive editions of a handbook on a phase diagrams of binary alloys^{16,17} show the generalised phase diagram of the W–C system, which is mainly based on earlier diagrams of this system^{18–21} and takes into account in part the results of another publication.²² A later handbook²³ represents a phase diagram from a paper by Rudy and Hoffman,²¹ while a Russian handbook²⁴ reproduces a phase diagram of the W–C system given in the handbook cited.¹⁶ Relatively few authors dealt with phase equilibria in the W–C system; however, they used different designations for the discovered phases, which led to the confusion in the description of this system. Even in the handbooks,^{16,17} the table that describes the W–C system confuses the designations for the disordered hexagonal and orthorhombic W_2C phases. To

avoid confusion, in this review, the designations for the W–C system are taken from Ref. 17 (corrected for the revealed mistake). As the illustration, in certain cases we also show the designations used in other sources.

Four modifications are described for lower tungsten carbide W_2C . Three of them are low-temperature β'' - W_2C , intermediate β' - W_2C and high-temperature β - W_2C , which were also designated^{12,18,21} as α -, β - and γ - W_2C , respectively. However, the structures of these modifications were proposed based on the limited experimental data. The structure of yet another modification designated as ε - W_2C (Ref. 25) was revealed sufficiently reliably in neutron diffraction studies.^{25–29}

In all W_2C modifications, tungsten atoms form a hcp metal sublattice, in which one-half of octahedral interstitials are occupied by carbon atoms. These atoms are randomly distributed over the interstitials at high temperatures and are ordered at low temperatures. The possibility of the formation of several structural modifications of W_2C is associated with different types of distribution of carbon atoms. Higher carbide WC with the hexagonal structure is designated as δ -WC [α -WC (Ref. 22) or simply WC (Refs 12 and 21)]. Furthermore, the compositions between lower and higher tungsten carbides include the cubic phase γ - WC_{1-x} [designated also as β -WC (Ref. 22) or α - WC_{1-x} (Refs 12 and 21) or simply WC_{1-x}]. For the first time, tungsten carbide with the cubic structure and the unit cell parameter of 0.416 nm was synthesised³⁰ by its deposition from $W(CO)_6$ vapour and described as a cubic modification of W_2C . Later, a cubic carbide with a unit cell parameter of 0.425 nm was synthesised³¹ in a spark discharge between the electrodes made of hexagonal WC, which were placed into a petroleum bath, and characterised also as lower carbide W_2C . Other authors³² who also detected the cubic modification of tungsten carbide identified it as yet another high-temperature modification of W_2C . However, at present, cubic carbide γ - WC_{1-x} is considered as a structural modification of higher tungsten carbide.

Now, we discuss characteristic features of the crystal structure of phases in the W–C system.

Metallic tungsten has the bcc structure [space group $Im\bar{3}m$ (O_h^9)] of its own structural type A2 (type W). Such a structure is also typical of alkali metals, vanadium, niobium, tantalum, chromium and α -Fe. The crystal structure base contains two atoms in positions 2(a) with coordinates (0 0 0) and (1/2 1/2 1/2).

According to studies by Rudy *et al.*^{18–21} and in line with the phase diagram of the W–C system (see Fig. 1), the most high-temperature phase β - W_2C has a hexagonal [space group $P6_3/mmc$ (D_{6h}^4)] structure of the $L'3$ -type (Fig. 2). The existence of lower

Figure 1. Generalised phase diagram of the W–C system (a) (see Refs 16, 17) and a fragment of this diagram in the high temperature region (b) (see Ref. 22).

Figure 2. Hexagonal structure of the $L'3$ -type of lower disordered carbide β - W_2C .^{1,2}

Tungsten atoms (solid circles) form a hcp sublattice the octahedral interstitials (open circles) of which are randomly occupied by carbon atoms with a probability of 1/2.

tungsten carbide W_2C with the $L'3$ -type structure was directly proved in a neutron diffraction study,²⁵ in which the disordered W_2C phase was observed together with the ordered phase of this carbide. For high-temperature totally disordered W_2C , the $L'3$ -type structure is quite reasonable by analogy with other lower carbides and nitrides. Particularly, the $L'3$ -type hexagonal structure is typical of most non-stoichiometric lower carbides and nitrides M_2X_y ($M = V, Nb, Ta$; $X = C, N$) with the exception of V_2N . In the unit cell of β - W_2C , two tungsten atoms occupy the positions $2(c)$ with coordinates $(1/3 \ 2/3 \ 1/4)$ and $(2/3 \ 1/3 \ 3/4)$ and one carbon atom is randomly distributed between positions $2(a)$ with coordinates $(0 \ 0 \ 0)$ and $(0 \ 0 \ 1/2)$. In other words, the hexagonal β - W_2C phase is disordered, and its carbon atoms randomly occupy one-half of all octahedral interstitials in the tungsten sublattice; hence, the probability of the occupation of any octahedral interstitial is equal to $1/2$. In the β - W_2C structure, along the c axis, the A and B layers formed by metal atoms alternate with the X layers formed by the non-metal lattice sites in the ... AXBXAXBX ... sequence. The hexagonal β - W_2C phase has a homogeneity region from $WC_{0.34}$ to $WC_{0.52}$ and is stable in the temperature range from 2670–2720 K to the melting temperature at 3000–3050 K. The unit cell parameters of the β - W_2C phase with the composition $WC_{0.52}$ were recorded⁹ to be $a = 0.2992$, $c = 0.4722$ nm and are somewhat larger, viz., $a = 0.3002$ and $c = 0.475$ – 0.476 nm according to data from Ref. 19.[‡]

In the X-ray diffraction experiments, the modifications of lower tungsten carbide, namely, β - W_2C , β' - W_2C , β'' - W_2C and ε - W_2C , are virtually indistinguishable, because they have the same hexagonal metal sublattice and the scattering power of tungsten atoms is many times higher as compared with carbon atoms. Indeed, according to calculations, the changes in the carbon atom distribution in the W_2C lattice are reflected in the X-ray diffraction spectrum only in the range of small angles (Fig. 3). The intensities of $(110)_{\text{orthorhomb}}$, $(111)_{\text{orthorhomb}}$ reflections typical of orthorhombic carbide β' - W_2C , $(001)_{C6}$ reflections of carbide β'' - W_2C with the $C6$ -type structure and also $(101)_\varepsilon$ reflections typical of ε - W_2C do not exceed 0.5% of the intensity of the strongest reflection $(101)_{L'3}$ [or $(101)_{C6}$, $(121)_{\text{orthorhomb}}$, $(210)_\varepsilon$ of the corresponding structure]. In other words, in a real X-ray diffraction study, these reflections are well at the background level and far below the experimental error of intensity measurements.

Figure 3. X-Ray diffraction patterns (Cu $K\alpha_{1,2}$ radiation) of different modifications of lower carbide W_2C in the small angle 2θ range for the $WC_{0.50}$ composition, calculated without regard for atomic displacements.^{18, 21}

The modification β' - W_2C of lower tungsten carbide has the rhombic symmetry, although its metal sublattice retains a hexagonal closely packed structure similar to the structure of high-temperature carbide β - W_2C . The structure of orthorhombic β' - W_2C is not yet known with certainty, but can be assigned to the PbO_2 type with the space group $Pbcn$ (D_{2h}^{14}). For this structure, the atomic positions can be specified only in general, namely, the carbon atoms occupy positions $4(c)$ with coordinates $(0 \ y \ 1/4)$ and the tungsten atoms are in positions $8(d)$ with coordinates $(x \ y \ z)$. Based on the comparison of experimental and theoretical positions of the reflections in the X-ray diffraction pattern, it was concluded¹⁸ that lower carbide β' - W_2C (β - W_2C) has an orthorhombic structure similar to the ζ - Fe_2N -type structure of ordered carbide Mo_2C and pertains to the same space group $Pbcn$.³³ However, as was noted above, the hexagonal disordered, trigonal and orthorhombic modifications of W_2C with the same unit cell parameters of the disordered phase are indistinguishable as regards the positions of their X-ray reflections at $2\theta > 30^\circ$. In the range of small angles $2\theta < 30^\circ$, in which the X-ray diffraction spectra are slightly different (see Fig. 3), no reflections were observed¹⁸ and no attempts were undertaken to estimate their possible intensities. Thus, the literature contains no experimental structural data which would substantiate the detection of the orthorhombic lower tungsten carbide β' - W_2C . Moreover, the authors of the study¹⁸ incorrectly determined the coordinates of tungsten atoms in the suggested structure of β' - W_2C carbide [the positions $8(d)$ occupied by tungsten atoms were claimed to have the coordinates $(3/8 \sim 3/8 \sim 1/2)$].

The unit cell of orthorhombic carbide β' - W_2C has the parameters $a = 0.4728$, $b = 0.6009$ and $c = 0.5193$ nm.¹⁸ Our analysis of the distribution of atoms in this unit cell, which is a derivative of the hexagonal cell with the $L'3$ -type structure has shown that tungsten atoms occupy $8(d)$ positions with coordinates $(1/4 \sim 1/8 \sim 1/12)$ and carbon atoms are in $4(c)$ positions with coordinates $(0 \sim 3/8 \ 1/4)$. As compared with the high-temperature hexagonal phase β - W_2C (Fig. 4a), the β' - W_2C phase with

Figure 4. Distribution of carbon atoms in lower carbides β - W_2C (a), β' - W_2C (b), β'' - W_2C (c) and ε - W_2C (d), which are ideal as regards both their compositions and structures.

Planes formed by the non-metal sublattice sites are located normally to the c axis of the basic disordered structure of the $L'3$ -type; tungsten atoms are not shown.²

(a) the $L'3$ -type of β - W_2C carbide with the random distribution of carbon atoms and vacancies; (b) β' - W_2C carbide of the Mo_2C (ζ - Fe_2N) type with the ordered distribution of carbon atoms and vacancies in each plane of the non-metal sublattice; (c) β'' - W_2C (α - W_2C) carbide of the $C6$ type with the ordered distribution of carbon atoms and vacancies in the alternating vacant and carbon-atom-occupied planes of the non-metal sublattice; (d) ε - W_2C carbide of the ε - Fe_2N type with alternating planes of the non-metal sublattice, in which each vacancy is surrounded by six carbon atoms or each carbon atom is surrounded by six vacancies; (1) positions of non-metal interstitial atoms, which are randomly occupied by carbon atoms with a probability of $1/2$; (2) carbon atoms; (3) vacancies.

[‡] Unit cell parameters of all phases discussed in this review were obtained for quenched samples at room temperature.

the ζ -Fe₂N-type structure (Fig. 4b) is ordered with respect to the non-metal sublattice. It is assumed that orthorhombic carbide β' -W₂C has the homogeneity region from WC_{0.34} to WC_{0.49} and exists in an intermediate temperature interval from ~2370 K to 2670–2750 K (see Fig. 1). The later studies failed to detect the orthorhombic (space group *Pben*) phase of β' -W₂C.

The low-temperature phase β'' -W₂C (α -W₂C) is ordered, but the temperature range of its existence and its crystal structure are not yet reliably determined. An electron-diffraction study³⁴ dealt with lower tungsten carbide, which was synthesised by carburisation of a thin metal tungsten film in the carbon monoxide atmosphere at ~1400 K for 5 min. The diffraction pattern of this carbide revealed 74 reflections, which pointed to the ordering of carbon atoms. Presumably, the β'' -W₂C phase has the C6 (*anti*-CdI₂)-type structure with the space group No. 164– $P\bar{3}m1$ (D_{3d}^3); other possible ways of ordering were ignored. In the rhombohedral (trigonal) structure of the C6 type, the layers of carbon atoms regularly alternate with the layers of structural vacancies, being oriented normally to the *c* axis. The layers formed solely by carbon atoms are located between the pairs of layers AB formed by tungsten atoms, and the layers of vacant interstitials, *i.e.*, structural vacancies, are located between the pairs of metal layers BA (Fig. 4c). Note that according to data,³⁴ tungsten atoms occupy virtually ideal positions in the lattice (*z* = 0.25), although the spaces along the *c* axis between the metal layers separated by the layers of vacancies should be slightly shorter than the spaces between the metal layers separated by a carbon-atom layer.

Thus, the ideal structure of β'' -W₂C (α -W₂C) contains two tungsten atoms in positions 2(*d*) with coordinates (1/3 2/3 1/4) and (2/3 1/3 3/4), a carbon atom in position 1(*a*) with coordinates (0 0 0) and a vacant site in position 1(*b*) with coordinates (0 0 1/2). A comparison of the considered structure with that of the high-temperature disordered phase β -W₂C (see Fig. 4c) clearly shows that, as a result of ordering, the positions 2(*a*) one-half of which are randomly occupied by carbon atoms are split into positions 1(*a*) and 1(*b*), where the former are occupied by carbon atoms and the latter remain vacant. At ~2300 K, the homogeneity region of β'' -W₂C (α -W₂C) phase extends from WC_{0.34} to WC_{0.48}; a decrease in temperature is accompanied by narrowing of this region and, finally, its disappearance at 1523 K and a composition of WC_{0.48} (see Fig. 1). The compositions WC_{0.41} and WC_{0.50} of the β'' -W₂C phase have the unit cell parameters *a* = 0.2985, *c* = 0.4717 and *a* = 0.3001, *c* = 0.4728 nm, respectively.¹⁹ If the temperature drops below 1523 K, lower carbide β'' -W₂C decomposes to give W and higher carbide δ -WC (WC). Note that later publications provided no information on the rhombohedral (trigonal) [$P\bar{3}m1$ (D_{3d}^3)] modification β'' -W₂C of lower tungsten carbide with the C6-type structure. It cannot be ruled out that the phases β' -W₂C and β'' -W₂C described in the literature are in fact the same phase differing in the structures and the degrees of ordering of carbon atoms and vacancies.

Insofar as the X-ray diffraction technique fails to accurately determine the structure of W₂C modifications, neutron diffraction analysis was applied^{25–29} in the studies of lower tungsten carbide. W₂C was synthesised by sintering of a pressed powder mixture of tungsten and carbon black (W : C = 2 : 1) at high temperature in vacuum for 3 h; then, the samples were quenched from temperatures of 2670, 2570, 2470 and 2370 K by quick immersion into a bath filled with liquid tin.²⁵ According to X-ray diffraction data, at 293 K all the samples synthesised had a hexagonal metal sublattice with the parameters *a* = 0.2992 and *c* = 0.4721 nm. The diffraction spectra of W₂C, which were obtained with the use of a monochromatic neutron beam (λ = 0.1131 nm), revealed, along with structural reflections, weak superstructural reflections which indicated the ordering of carbon atoms and vacancies to form a trigonal ϵ -W₂C phase which pertains to the ϵ -Fe₂N structural type. The unit cell parameters of the ϵ -W₂C phase were found²⁵ to be *a* = *a*_{L/3} $\sqrt{3}$ = 0.5184 and *c* = *c*_{L/3} = 0.4721 nm.

Tungsten carbide samples with the composition ~WC_{0.43–0.45} synthesised by sintering of pressed mixtures of tungsten and carbon black powders at 1920 K for 30–50 h followed by their 10-min cooling to room temperature, were studied.²⁶ Neutron diffraction analysis has shown that carbon atoms are ordered according to the ϵ -Fe₂N structural type (*i.e.*, the same type as that reported in Ref. 25). It was found that the ϵ -W₂C phase has a trigonal structure and pertains to the No. 162– $P\bar{3}1m$ (D_{3d}^1) space group; the unit cell parameters are as follows: *a* = 0.5185 and *c* = 0.4723 nm. In the ideal trigonal structure of this carbide, all tungsten atoms occupy 6(*k*) positions with coordinates (1/3 0 1/4) and carbon atoms occupy 1(*a*) positions with coordinates *c* (0 0 0) and 2(*d*) positions with coordinates (1/3 2/3 1/2), while positions 1(*b*) (0 0 1/2) and 2(*c*) (1/3 2/3 0) remain vacant. Figure 4d illustrates the distribution of carbon atoms and vacancies in the non-metal sublattice of ideal trigonal (space group $P\bar{3}1m$) ϵ -W₂C carbide. However, the best agreement between the experimental and theoretical neutron diffraction patterns was achieved when the population of the positions in the non-metal sublattice by carbon atoms was varied, and a small number of these atoms occupied positions 2(*c*).

Neutron diffraction analysis (λ = 0.1225 nm) was also used²⁷ for studying the structure of WC_{0.45} carbide, which was synthesised by the arc fusion of pellets pressed from a mixture of tungsten and carbon powders followed by their quenching to room temperature at a rate of 150 deg s^{–1}. According to the data shown, the studied carbide had the same trigonal (space group $P\bar{3}1m$) crystal structure as in earlier studies;^{25,26} the unit cell parameters are *a* = 0.5181, *c* = 0.4722 nm. The best agreement with the experimentally found intensities of reflections (as in Ref. 26) was achieved with allowance made for the different population of non-metal-sublattice sites with carbon atoms; with regard to their population, the sample composition was WC_{0.42}. The trigonal structure (space group $P\bar{3}1m$) of the lower carbide ϵ -W₂C with unit cell parameters *a* = 0.5190, *c* = 0.4724 nm was also revealed;^{28,29} a small number of carbon atoms occupied positions 1(*b*) and 2(*c*), which remain completely vacant in an ideal structure of the ϵ -Fe₂N type.

Thus, neutron diffraction studies^{25–29} of lower tungsten carbide samples, which were quenched from the arc fusion temperature²⁷ and the temperatures of 2670–2370 K (see Ref. 25) and 1920 K,²⁶ revealed only a trigonal (space group No. 162– $P\bar{3}1m$) ordered phase with the ϵ -Fe₂N-type structure. In all the cases, the ordering degree did not reach its maximum. The orthorhombic (space group *Pben*) β' -W₂C phase with the Mo₂C-type structure and the rhombohedral (trigonal, space group No. 164– $P\bar{3}m1$) β'' -W₂C phase with the C6-type structure were not found by the neutron diffraction analysis.

The temperatures of consecutive phase transformations

and eutectoid decomposition

namely, ~2750, ~2410 and 1530 K, respectively, were determined¹⁸ using specially designed instruments.³⁵ The high-temperature differential thermal analysis (DTA) involved³⁵ a highly sensitive optical (photodiodes and micropyrometer) system for measuring the temperature and the temperature difference between the working and reference samples ΔT . This system allowed one to perform measurements up to 3900 K. With the use of such instruments, the temperatures of phase transformations in hafnium, zirconium and titanium and also in lower carbides of tantalum, molybdenum, and tungsten, *i.e.*, Ta₂C, Mo₂C and W₂C, were determined.³⁵ Figure 5a shows a DTA curve, which confirms the presence of consecutive transformations of lower tungsten carbide.¹⁸ The authors only noted that all the effects observed at temperature decrease were exothermic. The

Figure 5. DTA curves of $\text{WC}_{0.48-0.49}$ (32.7 at.% of carbon) (a) and a carbide containing 51.0 at.% of carbon (b).^{18, 21}

The measurements were carried out on a specially designed set-up (see Ref. 35) which allowed measuring the absolute difference of temperatures ΔT between the standard sample and the sample under study, which depends on the initial experimental conditions; hence, the heat effect can have the opposite sign as compared with the measurements carried out on a standard DTA set-up (the arrows indicate the direction of temperature change);

(1–5) see text.

small magnitude of thermal effects could be caused by the incomplete transformation due to the too rapid cooling. With allowance made for the results of neutron diffraction studies,^{25–29} it is more likely that the effects at ~ 2750 and 1530 K (positions 1 and 3), which are observed in the DTA curve, correspond to the transformation

and the eutectoid decomposition

The $\gamma\text{-WC}_{1-x}$ phase has a cubic [space group $Fm\bar{3}m$ (O_h^5)] structure of the B1 type (NaCl) (Fig. 6), which is typical of all non-stoichiometric carbides and nitrides MX_y of Group IV and V transition metals. The researchers who discovered^{30–32} this phase considered it an additional high-temperature phase of lower carbide W_2C . However, based on the theoretical possibility that carbon atoms can occupy all octahedral interstitials in the fcc sublattice of tungsten, it seems more reasonable to consider this phase as a structural modification of higher tungsten carbide. Cubic tungsten carbide was also obtained³² as a result of the electrospark treatment of tungsten foil, *i.e.*, by generating electric discharge between the foil and a graphite electrode. The existence of cubic WC was confirmed.²² A phase of $\gamma\text{-WC}_{1-x}$ ($\beta\text{-WC}$) with the B1-type cubic structure was revealed³⁶ in the products of the plasmochemical synthesis of tungsten carbide; the synthesis was carried out in the argon arc plasma from the tungsten and carbon powders or a tungsten powder and methane. The synthesis with methane gave a product containing from 74% to 96% cubic WC_{1-x} with particles measuring 2–16 nm. No data on the

Figure 6. The B1-type (NaCl) structure of cubic carbide $\gamma\text{-WC}_{1-x}$.^{1, 2} Non-metal sublattice sites are numbered. The first coordination sphere of a tungsten atom in the unit cell centre is formed by sites 1–6 of the non-metal sublattice located in the centres of cell faces; the third coordination sphere is formed by sites 7–14 of the same sublattice, which are located in the cube corners. The second coordination sphere of the central tungsten atom is formed by twelve metal atoms located in the middle of edges.

chemical composition of the obtained cubic phase $\gamma\text{-WC}_{1-x}$ were presented.³⁶

Superconducting transition temperature (T_c) for cubic carbides MoC, WC and solid solutions NbC–MoC, NbC–WC, NbC–TaC, TaC–MoC, TaC–WC, MoC–WC with the B1 structure were determined.^{37, 38} Cubic tungsten carbide was synthesised by rapid quenching from the molten state. According to data from Ref. 37, the T_c value is sufficiently high, namely, 10 K for stoichiometric cubic carbide $\text{WC}_{1.0}$ and 9 K for cubic $\text{WC}_{0.85}$. Yet another sample, which, in addition to the cubic phase, contained lower hexagonal tungsten carbide and a large amount of free carbon, was shown to have $T_c = 8.1$ K. Assuming that, in the first approximation, the unit cell parameter of cubic WC_{1-x} and its temperature of the superconducting transition depend linearly on the carbon content, then $T_c = 8.1$ K corresponds to cubic carbide $\text{WC}_{0.71-0.72}$ with the unit cell parameter $a_{B1} = 0.424$ nm. Note that the temperatures of the transition into the superconducting state of hexagonal carbides $\beta\text{-W}_2\text{C}$ and $\delta\text{-WC}$ are 3.6 and 0.3 K, respectively,³⁷ *i.e.*, substantially lower than those of the cubic phase $\gamma\text{-WC}_{1-x}$.

It was noted³⁹ that the electrospark treatment of the molten samples of tungsten carbide and certain WC-based hard alloys produces cubic carbide $\gamma\text{-WC}_{1-x}$. A cumulative explosion of tungsten, graphite and ammonium nitrate powders allowed the synthesis of samples that contained up to 50 vol.%–70 vol.% $\gamma\text{-WC}_{1-x}$;⁴⁰ the explosion conditions were equivalent to those of steady-state sintering at the temperature of 2770–3270 K. Note that in these studies^{39, 40} cubic carbide $\gamma\text{-WC}_{1-x}$ was designated as $\beta\text{-WC}_{1-x}$.

According to the phase diagram of the W–C system (see Fig. 1), the single-phase cubic carbide $\gamma\text{-WC}_{1-x}$ exists in the composition range of $\text{WC}_{0.58}\text{--WC}_{0.65}$ at temperatures above 2790–2810 K. Moreover, $\gamma\text{-WC}_{1-x}$ was found in the two-phase regions ($\beta\text{-W}_2\text{C} + \gamma\text{-WC}_{1-x}$) and ($\gamma\text{-WC}_{1-x} + \delta\text{-WC}$). The position of the lower boundary of the homogeneity region of cubic carbide $\gamma\text{-WC}_{1-x}$ is independent of the temperature and corresponds to the $\text{WC}_{0.59}$ composition;²² the upper boundary shifts to higher carbon contents with the increase in the temperature and can reach the stoichiometric composition $\text{WC}_{1.00}$ (see Fig. 1b). In particular, at 3000–3040 K, cubic carbide $\gamma\text{-WC}_{1-x}$ has a homogeneity region much wider than reported,^{19–21} namely, $\text{WC}_{0.59}\text{--WC}_{0.92}$; at $\sim 2800\text{--}2810$ K, its eutectoid decomposition to $\beta\text{-W}_2\text{C}$ and $\delta\text{-WC}$ (WC) takes place.

Figure 5b shows DTA curves for cubic tungsten carbide containing 51.0 at. % carbon. As is seen, its heating along curves A up to ~ 3033 K without any exposure at the maximum temperature failed to melt the sample; its subsequent cooling from 3033 to 1940 K revealed no heat effects. However, curve B measured

after the sample was cooled upon its brief exposure at ~ 3270 K, *i.e.*, from its melt, demonstrates peaks corresponding to strong exothermic heat effects at ~ 2990 and ~ 2790 – 2810 K (positions 4, 5). From the viewpoint of the authors,²¹ these effects were caused by the following reversible transformations:

the eutectics formation

and the eutectoid decomposition

According to the conditions under which curves *A* and *B* were recorded, cubic carbide $\gamma\text{-WC}_{1-x}$ is formed relatively easily from the melt, but the direct solid-phase transformation

is either hindered (for it to happen, the temperature should change slowly near the transformation temperature T_{trans}) or the temperature range of its existence near the stoichiometric composition WC is very narrow.

The phase equilibria in the W–C system were studied²² in the temperature interval from 2770 to 3100 K (see Fig. 1*b*) with the use of the X-ray diffraction method, chemical and metallographic analyses and also of the DTA method. To determine the phase composition, the samples heated to 2870 K (or higher) were quenched by cooling to 1800 K in 20 s and lower to 1300 K in 40 s. Samples with the composition between W_2C and WC were quenched from $T \geq 2800$ K by their quick immersion into liquid tin with the temperature of 600–650 K. High-temperature DTA was carried out with the use of specially designed (see a patent of Goton⁴¹) instruments. The temperature interval used in study²² was narrower than that used by Rudy;^{18–21} this is why those phase transitions of lower carbide W_2C , which are associated with its ordering, could not be detected at temperatures below 2750 K.

By and large, the results of independent studies^{18–22} on the determination of the temperature and concentration positions of phase boundaries in the W–C system are almost identical. For example, differences between the found phase-transformation temperatures do not exceed 10 K, *i.e.*, they lie within the experimental error range. However, the region of existence of high-temperature cubic monocarbide $\gamma\text{-WC}_{1-x}$ in the phase diagram was studied in more detail.²² Particularly, a thorough metallographic and X-ray study was carried out for samples quenched from the temperatures above and below 2798 K (the DTA method has shown that a reversible phase transformation takes place at 2798 K in samples containing from 35 at.% to 50 at.% of carbon). Figure 7 illustrates the changes in the microstructures of samples containing 40 at.% of carbon and quenched from 2778 and 2808 K. A sample quenched from 2778 K contained two hexagonal phases W_2C and WC (Fig. 7*a*). A sample quenched from 2808 K also contained two phases $\beta\text{-W}_2\text{C}$ and $\delta\text{-WC}$ but had a different pearlite-like microstructure (Fig. 7*b*), which appeared as a result of the eutectoid decomposition of cubic carbide $\gamma\text{-WC}_{1-x}$ formed at $T > 2798$ K. Cubic carbide $\gamma\text{-WC}_{1-x}$ can be directly visualised in the microstructure of samples quenched from higher temperatures (2988–3023 K) in the solid state, and also in the microstructures of samples quenched from the melt from 3043–3063 K (Fig. 8). It was shown²² that at 3030–3055 K $\gamma\text{-WC}_{1-x}$ has a wide homogeneity region, namely, from $\text{WC}_{0.59}$ to $\text{WC}_{0.98-1.00}$ (see Fig. 1*b*).

High temperature of the transition into the superconducting state, namely, 10 K,^{37,38} confirms that the composition that corresponds to the upper boundary of the homogeneity region of $\gamma\text{-WC}_{1-x}$ is stoichiometric, *i.e.*, $\text{WC}_{1.0}$. It is known^{3,4,42} that, among the cubic carbides of Group IV–VI transition metals, stoichiometric carbides $\text{NbC}_{1.0}$ and $\text{TaC}_{1.0}$ have the highest T_c (10–12 K); however, T_c quickly drops to ~ 4 K upon their deviation from stoichiometry to $\text{NbC}_{0.9}$ or $\text{TaC}_{0.9}$ and $T_c \leq 1$ K for $\text{NbC}_{0.8}$ and $\text{TaC}_{0.8}$. According to Willens and Buether,³⁷ a

Figure 7. Microstructures of carbide samples with 60 at.% of W and 40 at.% of C quenched from 2778 (*a*) and 2808 K (*b*).²² (*a*) The sample contains hexagonal phases of $\beta\text{-W}_2\text{C}$ (light grains) and $\delta\text{-WC}$ (dark grains); (*b*) the sample contains additional phases $\beta\text{-W}_2\text{C}$ and $\delta\text{-WC}$, but has a pearlite-type microstructure which has appeared at the eutectoid decomposition of cubic $\gamma\text{-WC}_{1-x}$ formed at $T > 2798$ K (see text).

Figure 8. Microstructures of samples with cubic carbide $\gamma\text{-WC}_{1-x}$ obtained by quenching from the melt.²² (*a*) A sample with 45 at.% of C quenched from 3043 K contains inclusions of hexagonal monocarbide $\delta\text{-WC}$ in the matrix of cubic $\gamma\text{-WC}_{1-x}$; (*b*) eutectic ($\beta\text{-W}_2\text{C} + \gamma\text{-WC}_{1-x}$) microstructure of a sample with 36 at.% of carbon quenched from 3053 K. The sample surface is etched with a 10% NaOH + 30% $\text{K}_3\text{Fe}(\text{CN})_6$ mixture.

decrease in the carbon content in cubic tungsten carbide causes a relatively smaller decrease in T_c .

The unit cell parameter of $\gamma\text{-WC}_{1-x}$ carbide is $a_{B1} \approx 0.427$ nm;³² that for cubic carbide $\text{WC}_{0.82}$ is $a = 0.4215$ nm.²² Cubic tungsten carbide with an unknown composition was found to have the unit cell parameter of 0.4229 nm,³⁶ while almost stoichiometric cubic carbide was shown³⁹ to have $a = 0.4248$ nm. The unit cell parameters of cubic carbides $\text{WC}_{1.0}$, $\text{WC}_{0.85}$ and $\text{WC}_{0.72}$ were shown³⁷ to be 0.4266, 0.4252 and 0.4240 nm, respectively. For cubic carbide $\text{WC}_{0.61}$, $a = 0.4220$ nm was found;^{19,21} the extrapolation of this value to defect-free cubic carbide gave $a = 0.4265$ nm.⁴³ The unit cell parameter of cubic carbide $\gamma\text{-WC}_{1-x}$ of the unknown composition was found to vary from 0.4222 to 0.4263 nm;⁴⁰ such a small unit cell parameter of cubic carbide $\gamma\text{-WC}_{1-x}$ could be caused by oxygen impurity, because the sample was obtained in a cumulative explosion in ammonium nitrate which contains oxygen. The best agreement was observed for the unit cell parameter values found for cubic carbide $\gamma\text{-WC}_{1-x} \equiv \gamma\text{-WC}_y$ ($y \equiv 1-x$)^{19,21,37–39,43} (Fig. 9). These data are adequately described by a quadratic function

$$a_{B1} = 0.4015 + 0.0481y - 0.0236y^2 \text{ (nm)}$$

and unambiguously point to the increase in the unit cell parameter of the $\gamma\text{-WC}_{1-x}$ phase with the increase in the carbon content.⁴⁴

Higher tungsten carbide $\delta\text{-WC}$ (WC) has a negligibly small homogeneity region (or does not have it at all). Its hexagonal [space group $P\bar{6}m2$ (D_{3h}^1)] lattice pertains to its own structural type B_h (the WC type) with the unit cell parameters $a = 0.2906$ and $c = 0.2837$ nm.^{7,9,10,19} In this structure, tungsten atoms occupy positions 1(a) with coordinates (0 0 0) and carbon atoms are located in positions 1(d) with coordinates (1/3 2/3 1/2).⁴⁵ Tungsten and carbon atoms in $\delta\text{-WC}$ (WC) form simple hexagonal sublattices, in which carbon atoms are located in the centres of trigonal prismatic interstitials of the tungsten sublattice (Fig. 10). The results of simulations of the crystal and electronic structures of hexagonal WC, which were performed⁴⁶ by the pseudopotential local-orbital method confirmed the stability of this compound; the estimated unit cell parameters $a = 0.288$ and $c = 0.281$ nm well agree with experimental results.

A positron lifetime study found an experimental confirmation for the stoichiometry of hexagonal monocarbide $\delta\text{-WC}$.^{47,48} Samples of powder and sintered WC and also samples of a hard WC–Co alloy were studied. The positron lifetime spectra of WC revealed the short-lived ($\tau_{\text{free}} = 124 \pm 10$ ps) and more long-lived ($\tau_{\square\text{W}} = 175 \pm 20$ ps) components. The former corresponds to the annihilation of positrons from the free state, the latter corresponds to the capture and annihilation of positrons in the metal vacancies the concentration of which is very low. No components

Figure 9. Changes in the unit cell parameter a_{B1} of cubic carbide $\gamma\text{-WC}_{1-x} \equiv \gamma\text{-WC}_y$ ($y \equiv 1-x$) with the B1-type structure in its homogeneity region.⁴⁴ (1–5) The data are taken from Refs 37, 38; 22; 19, 21; 39; 43, respectively.

Figure 10. Hexagonal structure of higher carbide $\delta\text{-WC}$ (WC).

that would correspond to the positron annihilation in the carbon-sublattice vacancies were found. Upon the irradiation of $\delta\text{-WC}$ with electrons with the energy of 1 MeV, the positron lifetime spectrum contained only one component, namely, with a lifetime of ~ 136 ps. It was shown⁴⁷ that this component corresponds to the capture and annihilation of positrons in the carbon vacancies, which have appeared upon the irradiation. Indeed, the kinetic energy, which is imparted by the 1-MeV electrons to carbon and tungsten atoms in the collisions, is higher than the displacement threshold of the carbon atom from its position but lower than the displacement threshold of the tungsten atom; hence, the vacancies were induced only in the carbon sublattice of the carbide. Due to the higher imparted energy, the irradiation of $\delta\text{-WC}$ with electrons with the energy of 2.5 MeV resulted in the displacement of both carbon and tungsten atoms and the appearance of vacancies in both sublattices.⁴⁸ A comparison of the experimental results^{47,48} with those obtained in the calculations of the positron lifetime by the method of linear muffin-tin orbitals in the atomic sphere approximation (LMTO-ASA)⁴⁹ in a model carbide WC with the cubic B1-type lattice demonstrated good agreement of calculations with experimental data for $\tau_{\square\text{W}}$ in a metal vacancy and a noticeable deviation in the positron lifetime $\tau_{\square\text{C}}$ in a carbon vacancy. On the whole, the results^{47,48} confirmed that, under normal conditions, higher hexagonal carbide $\delta\text{-WC}$ is stoichiometric and has no carbon vacancies in its carbon sublattice.

Thus, among tungsten carbides, only higher hexagonal carbide $\delta\text{-WC}$ (WC) has virtually no homogeneity region, whereas lower carbides W_2C and cubic $\gamma\text{-WC}_{1-x}$ have relatively wide homogeneity regions. Table 1 gives information on the crystal structures of the phases in the W–C system. It should be borne in mind that the conclusions made in those studies in which the structures of non-stoichiometric tungsten carbides were determined only based on the X-ray diffraction data are merely the assumptions. Particularly, this concerns W_2C , the non-metal sublattice of which was assumed ordered with respect to both atoms and vacancies. The structures of non-stoichiometric tungsten carbide compounds found by the neutron diffraction analysis are more confident and reliable.

The main difference between the phase diagrams of the W–C system proposed by Rudy *et al.*,^{19–21} on the one hand, and Sara,²² on the other hand, concerns the position and width of the homogeneity region of cubic carbide $\gamma\text{-WC}_{1-x}$. The authors of the former studies^{19–21} were short of experimental results sufficient to determine the position of this carbide in the phase diagram and had to use the analogy with the Mo–C system studied earlier.^{50,51} Thus, having detected the $\beta\text{-MoC}_{1-x}$ (Mo_3C_2 or $\text{MoC}_{0.67}$) phase with a narrow homogeneity region, they assumed that the WC_{1-x} phase in the W–C system has the same stoichiometric composition W_3C_2 ($\text{WC}_{0.67}$) and the equally narrow homogeneity region.[§]

[§] It is not by accident that the paper by Rudy *et al.*,¹⁹ in which the version of the phase diagram of the W–C system presented in Fig. 1a was published, was entitled ‘W–C System: supplemental information on the Mo–C system’.

Table 1. Crystal structure of phases that can exist (according to different authors) in the W–C system at $T > 1300$ K.

Note. In the study,¹⁷ the phase diagram of the W–C system takes into account the structural data,^{18–22, 34} some of which were not confirmed later; trigonal (space group $P\bar{3}1m$) ϵ -WC phase the existence of which was reliably confirmed^{25–29} is not shown in the phase diagram of the W–C system (see Ref. 17). Here and in Table 2, the γ -WC_{1-x} phase is identical to the γ -WC_y ($y \equiv 1-x$) phase.

^a Refs 18, 21; ^b Ref. 19; ^c Ref. 18; ^d Ref. 19 for WC_{0.41}; ^e Ref. 19 for WC_{0.50}; ^f Ref. 25; ^g Ref. 21; ^h Ref. 43 for WC_{1.0}; Refs 22, 36; ⁱ Ref. 22; ^k Ref. 31 for WC_{0.85}.

At the same time, it follows from the study by Sara²² that the homogeneity region of cubic γ -WC_{1-x} is much wider than that given in Refs. 19–21 and reaches the WC_{1.0} composition, which agrees with the results of later studies (see Refs 32, 36–39). However, for a cubic carbide of the stoichiometric composition WC_{1.0}, the phase diagram (see Fig. 1 b)²² contains no temperature region of its existence, while the region of the existence of the γ -WC_{1-x} has such boundaries at $(1-x) \rightarrow 1$ that the temperature decrease merely from 3058 to 3028 K causes the following consecutive transformations in the WC_{1.0} composition: first, a peritectic transformation and then a peritectoid one. This is highly improbable. Moreover, the line of phase equilibrium 1–2–3 (see Fig. 1 b) is shown incorrectly in the cited study, namely, from a horizontal that corresponds to the non-variant eutectic process

this line gradually transforms into a monovariant curve, which is physically impossible and incorrect from the viewpoint of thermodynamics. The phase equilibrium shown could be possible if point 2 was a singular point, *i.e.*, a kink point. However, this in turn, would have led to the narrowing of the temperature interval of the existence of a two-phase region $L + \gamma\text{-WC}_{1-x}$ and to the shift of its lower boundary to higher temperatures, which contradicts the DTA results.²² If a cubic carbide with the stoichiometric composition WC_{1.0} had at least a narrow temperature range of stability and the two consecutive phase transitions were somewhat shifted in the composition with respect to one another, then the noted inaccuracies and contradictions could be eliminated and the total body of experimental results could be taken into account.

Figure 11 shows the phase diagram of the W–C system, which was constructed⁴⁴ with allowance made for the presence of the temperature interval of existence of cubic carbide WC_{1.0} and also for experimental results^{18–22, 32, 36–39} and the results of new structural and magnetic-susceptibility studies of tungsten carbides synthesised in our studies. It is evident that, in the temperature range of 3058–2993 K, in the vicinity of the WC_{1.0} composition, a decrease in temperature results first in the peritectic formation of cubic tungsten carbide from the melt

and then in the transformation of cubic monocarbide into the hexagonal modification

The temperature of the eutectoid decomposition

Figure 11. Phase diagram of the W–C ($\gamma\text{-WC}_{1-x} \equiv \gamma\text{-WC}_y$) system⁴⁴ with corrected positions of phase boundaries in the region of lower tungsten carbide W₂C. Corrections were introduced according to the neutron diffraction results^{25–29} (see text).

Table 2. Special points in the phase diagram of the W–C system (Fig. 11) at a temperature above 1300 K (according to Ref. 44 with corrections made in the region of the existence of lower tungsten carbide W₂C).

equal to 2993 K (see Fig. 11) was found from the results of DTA²¹ for a sample with 51 at.% carbon. This value was assigned to the temperature of the eutectic²¹

However, even according to the phase diagram version proposed,²¹ such a carbide composition falls beyond a region where this phase equilibrium is permitted. Therefore, this temperature cannot be the temperature of the eutectic. Although the temperature interval of the equilibrium existence of $\gamma\text{-WC}_{1-x}$ (see Fig. 11) is small, the cubic carbide of the stoichiometric composition WC_{1.0} can at least be quenched from the melt, which agrees with the experimental results.^{37, 38}

The phase diagram W–C published in study⁴⁴ contains the following corrections in the positions of phase boundaries in the lower tungsten carbide W₂C region, which were introduced with allowance made for the neutron diffraction results:^{25–29} the $\varepsilon\text{-W}_2\text{C}$ phase is shown in place of phases $\beta'\text{-W}_2\text{C}$ and $\beta''\text{-W}_2\text{C}$, the existence of which is not confirmed experimentally. These corrections are reflected in Fig. 11. The special points in the phase diagram of this system at temperatures above 1300 K are described in Table 2.

III. Phase equilibria in the W–Co–C system

The wide application of high-strength hard alloys formed in the pseudobinary system WC–Co brought about the investigations of the phase equilibria in the ternary system W–Co–C.

Information on the phases in the W–Co–C system which was obtained before 1952 is generalised in a review,⁵² where new diffraction, metallographic and DTA studies of this system were carried out. In addition, the liquidus surface projection, the total isothermal cross-section at 1673 K and the pseudobinary *c* vs. *T* diagrams along the cross-sections C–Co₄₃W₅₇ and WC–Co were constructed, in which the stable and metastable phase equilibria were specified. In the pseudobinary cross-section WC_y–Co (16 mass % of Co), the effect of the carbon content on the phase equilibria and structure of alloys was studied.⁵³ The results of the metallographic and diffraction studies of the M₆C-type cubic η -carbides, which are formed in the W–Co–C system, were discussed.⁵⁴ Particularly, η -carbide Co₂W₄C with a cubic cell parameter, which varied from 1.107 to 1.125 nm depending on the carbon content, was revealed; two total isothermal cross-sections of the W–Co–C system were constructed at temperatures 1273 and 1673 K. The stability of η -carbides of the M₆C type in the W–Co–C system was also considered by other authors⁵⁵ who showed additional isothermal cross-sections in this system at 1373

and 1573 K. The experimental studies of phase equilibria in the W–Co–C system at 1423 K were supplemented by thermodynamic calculations.⁵⁶

According to the results of numerous studies, the system W–Co–C forms several ternary compounds, viz., cubic [space group $Fd\bar{3}m$ (O_h^h)] η -carbides Co₂W₄C (see Ref. 54) and Co₄W₂C (see Ref. 57) of the M₆C type and also two hexagonal [space group $P6_3/mmc$ (D_{6h}^4)] CoW₃C carbides with the Co₃W₉C₄ (see Ref. 58) and Co₆W₂₀C₇ structures.⁵⁹ Note that the Co₃W₉C₄ structure has two types of metal sublattice interstitials, in which carbon atoms are located as follows: in the unit cell, two carbon atoms of eight are located in the centre of trigonal prisms formed by six tungsten atoms, while the remaining six carbon atoms are in the centres of octahedra formed of five tungsten and one cobalt atoms. A comprehensive study of these carbides showed that all of them can exhibit a noticeable carbon deficiency, i.e., they are non-stoichiometric; hence, their compositions should be written with allowance made for the possible non-stoichiometry, namely, Co₂W₄C_{*y*}, Co₄W₂C_{*y*} and CoW₃C_{*y*}. Carbides Co₂W₄C_{*y*} and Co₄W₂C_{*y*} are often united into a single phase Co₃W₉C₄_{*y*}. It is evident that here we have a pseudobinary solid solution between Co₂W₄C_{*y*} and Co₄W₂C_{*y*}. For the case of deficient carbon content, this variable-composition phase corresponds to the ~Co₆W₆C_{*y*} carbide in the phase diagram.

The results of the aforementioned studies are taken into account in a comprehensive survey,⁶⁰ which is devoted to the thermodynamic properties and phase equilibria in the W–Co–C system; moreover, the author of this survey carried out calculations to refine the phase equilibria by means of the CALPHAD method (see Ref. 61) using the approximations and models described elsewhere.⁶² Figure 12 shows a series of isothermal cross-sections of the ternary system W–Co–C at 2073, 1773, 1698, 1673, 1548 and 1443 K, which were constructed based on these calculations and are shown in a handbook.⁶³ All isothermal cross-sections contain carbide of the ~Co₆W₆C composition and a solid solution Co₃W₉C_{*y*} [in the survey cited (Ref. 60), they appear as M₁₂C and M₆C, respectively]. In the isothermal cross-section at 1273 K, the solid solution Co₃W₉C_{*y*} is absent but a η -carbide Co₂W₄C appears.⁶⁰ As is seen, the ternary compounds are formed where the carbon content in an alloy is lower than the tungsten content. Note that the isothermal cross-section of the W–Co–C system at 1273 K ignores the existence of the hexagonal intermetallic phase Co₃W, which stabilises at $T \leq 1350$ K and decomposes *via* the peritectoid reaction at ~1360 K.

Figure 13 shows a section of the ternary system W–Co–C cut along the WC–Co plane. This section contains two- and three-phase regions. In this system, the liquid phase appears at 1560–1593 K. According to the survey cited (Ref. 60), the maximum solubility of WC in solid cobalt does not exceed

Figure 12. Isothermal cross-sections of the ternary W–Co–C system at 2073 (a), 1773 (b), 1698 (c), 1673 (d), 1548 (e) and 1443 K (f).⁶³ The concentrations are shown in at. %, the triple point position corresponds to the results of thermodynamic calculations;⁶⁰ (1) $\text{Co}_6\text{W}_6\text{C}_7$, (2) $\text{Co}_3\text{W}_3\text{C}_3$.

6.7 mol.% (or 19.3 mass %); as the temperature decreases to 1270 K, the solubility does not exceed 3 mol.% (~9 mass %). According to the earlier data (see Ref. 7, vol. 1, p. 262), the maximum solubility of WC in cobalt reaches 22 mass %. A solid solution of WC in cobalt Co(WC) is formed as a result of the diffusion dissolution and appears when the sintering temperature of the WC–Co system reaches 1420–1570 K. A part of cobalt

which does not belong to the solid solution composition passes into the liquid phase that wets the carbide grains.

IV. Electronic structures of tungsten carbides

The band structures of hexagonal and cubic carbides W_2C and WC were calculated.^{46, 64–68} The electronic structure of hexagonal carbide WC was calculated⁶⁴ by a non-self-consistent method of augmented plane waves (APW). A more correct investigation of the band structure in the bulk and on the surface of hexagonal carbide WC was performed by a self-consistent linear method of augmented plane waves (LAPW).⁶⁵

Figure 14a shows the calculated curve of the density of electronic states for hexagonal WC. The Fermi level is located near the curve minimum, and the density of electronic states on this level is relatively low, viz., approximately 0.34 eV^{-1} ($\sim 4.6 \text{ Ry}^{-1}$) per unit cell. The Fermi surface of hexagonal WC has small hole and electron ‘pockets’ in the vicinity of K and L sites of the Brillouin zone.⁶⁵

The electronic structure of hexagonal WC was calculated⁴⁶ by the pseudopotential local-orbital method. Figure 14b shows the resulting curves of the density of electronic states [it is the density of spin states $N_{\text{sp}}(E)$ that was calculated; to make the comparison easier, the figure shows the density of electronic states $N(E) = 2N_{\text{sp}}(E)$ in place of the density of spin states]. It is evident that the calculated^{46, 65} density-of-states curves of hexagonal WC are in adequate agreement with one another, viz., the Fermi level is located in a distinct density-of-states minimum and the quantity $N(E_F)$ is $\sim 0.3 \text{ eV}^{-1}$ per unit cell. Presumably,^{46, 65} it is the small density of electronic states on the Fermi level that determines the high stability of this carbide. The low temperature of the WC

Figure 14. Curves of the total density of electronic states $N(E)$ for hexagonal (space group $P\bar{6}m2$) tungsten monocarbide. (a) LAPW calculations;⁶⁵ (b) calculations by the pseudopotential local-orbital method.⁴⁶

transition into the superconducting state [~ 1.3 K (see Ref. 69)] was also associated⁴⁶ with the low $N(E_F)$.

The linear method of muffin-tin orbitals in the atomic sphere approximation (LMTO-ASA) used for calculation⁶⁶ of the densities of states not only for higher hexagonal tungsten carbide, but also for cubic ($B1$ -type structure) monocarbide WC [as was shown above (see Section II), to date, non-stoichiometric cubic carbide WC_y with $y \leq 0.82$ is experimentally detected, although the upper boundary of the homogeneity region of cubic tungsten carbide approaches $WC_{1.0}$]. Figure 15 shows the calculated curves of the density of states $N(E)$.

Figure 15. Curves of density of electronic states $N(E)$ of tungsten carbides in the LMTO-ASA approximation.⁶⁶ (a) Hexagonal monocarbide WC (space group $P\bar{6}m2$), (b) cubic monocarbide WC (space group $Fm\bar{3}m$, $B1$ -type structure), (c) lower hexagonal carbide W_2C (space group $P6_3/mmc$).

The curves of the density of electronic states $N(E)$ for hexagonal WC, which are shown in Figs 14 and 15a, differ, first of all, in the Fermi level position. According to calculations,⁶⁶ the Fermi level of this carbide is located in a band formed largely by the 5d states of tungsten, and $N(E_F) = 0.78$ eV⁻¹ per unit cell (10.6 Ry⁻¹), i.e., almost twice greater than it follows from other calculations.^{46,65} Note that in their later publication,⁶⁷ the authors of a study⁶⁶ showed a different density-of-states curve of hexagonal WC, which is closer to those calculated in the studies^{46,65} and has the Fermi level in a different position near the $N(E)$ minimum and also a lower $N(E_F)$ value.

The curve of the density of electronic states for cubic WC (Fig. 15b) is on the whole similar to the corresponding curves of cubic carbides of other transition metals MC ($M = Ti, Zr, Nb, Ta$) and contains a low-energy 2s(C) band with small contributions of s, p and d states of tungsten, a ground-state valence-binding band formed due to the hybridisation of 2p(C) and 5d(W) states and a high-energy band largely formed by the 5d(W) states with an admixture of 6s(W) states. As compared with the $N(E)$ curve of TaC carbide (a typical non-stoichiometric carbide, the closest to WC), the 2s(C) and 2p(C)–5d(W) bands of the cubic tungsten carbide are somewhat broadened due to the smaller WC unit cell parameter.

The band structure of W_2C is intermediate between the band structure of bcc metallic tungsten and hexagonal WC. The main difference in the density-of-states curves of hexagonal W_2C (Fig. 15c) and hexagonal and cubic monocarbides (see Fig. 15a,b) is that W_2C has narrower bands; hence, the hybridised valence-binding and metal 5d(W) bands have the density of states much higher as compared with monocarbides WC. The density of electronic states at the Fermi level is also higher for W_2C as compared with higher hexagonal and cubic WC, namely, the $N(E_F)$ values calculated⁶⁶ per unit cells of hexagonal and cubic WC and also for lower hexagonal carbide W_2C are 0.78, 0.86 and 2.17 eV⁻¹ (10.6 , 11.7 and 29.5 Ry⁻¹), respectively.

Based on the results of band structure calculations, the unit cell parameters, the compression bulk modulus B (also conventionally designated as K) and the Debye temperature θ_D were calculated for these carbides. The modulus of elasticity of hexagonal WC is 655 GPa (6.55 Mbar), which substantially exceeds that of lower carbide W_2C (490 GPa).⁶⁶ For hexagonal WC, the same authors showed a different calculated value of modulus of elasticity equal to 699 GPa (Ref. 67). The B values are 60%–70% higher than the value 413 GPa (4.13 Mbar) found for the same carbide.⁴⁶ The lowest bulk compression modulus equal to 375 GPa, was obtained⁶⁶ for cubic WC; the unit cell parameter a_{B1} was calculated to be 7.98 a.u. (0.422 nm). The small modulus of elasticity of this carbide is associated with its metastable state, because the energy of valence electrons in cubic WC is higher than that in hexagonal carbide by ~ 12.2 eV (~ 0.9 Ry).^{5,66,68}

As noted above, the measurements of the positron lifetime allowed the vacancies to be revealed in the carbon and metal sublattices of irradiated hexagonal carbide WC.⁴⁷ Taking into account this experimental result, an attempt was undertaken⁷⁰ to elucidate how the metal and carbon vacancies affect the WC band structure. The calculations were performed using a self-consistent *ab initio* total potential method (LMTO-TP). The simulations of stoichiometric and defective carbides involved the use of a super-cell formed by eight tungsten-sublattice and eight carbon-sublattice sites which are occupied according to the stoichiometries W_8C_8 (WC), W_8C_7 ($WC_{0.875}$) and W_7C_8 ($W_{0.875}C$). Figure 16 shows the calculated⁷⁰ total density of electronic states for tungsten carbides. According to earlier calculations,^{46,65–68} the valence band of the hexagonal stoichiometric monocarbide consists of two subbands separated by a forbidden gap. The lower subband A is largely formed by states 2s(C), while the subband B of a larger energy is formed by states 2p(C)–5d(W), i.e., is hybridised. The Fermi level [$E_F = 25.3$ eV, $N(E_F) = 0.23$ eV⁻¹ per unit cell] is located near the minimum of the density-of-states curve (Fig. 16a). Upon the introduction of a carbon vacancy, a

Figure 16. The effect of vacancies on the total density of electronic states $N(E)$ of hexagonal tungsten carbide according to LMTO-TP calculations.⁷⁰

(a) Stoichiometric carbide WC, (b) carbide $\text{WC}_{0.875}$ (W_8C_7) with carbon vacancies, (c) carbide $\text{W}_{0.875}\text{C}$ (W_7C_8) with vacancies in the tungsten sublattice.

vacancy peak C appears a little higher than the Fermi level, the density of states on the Fermi level $N(E_F)$ increases up to 0.61 eV^{-1} per unit cell and the band B acquires its fine structure (Fig. 16b). The presence of a vacancy in the tungsten sublattice also results in both the appearance in the Fermi level vicinity of a small vacancy peak and the increase in $N(E_F)$ up to 0.69 eV^{-1} per unit cell (Fig. 16c). The introduction of a carbon or a tungsten vacancy reduces E_F to 25.0 and 22.0 eV, respectively. The calculated⁷⁰ distribution of electronic density in the spheres of the tungsten and carbon vacancies and the charges of these vacancies ($q_{\square\text{C}} = 0.67e$, $q_{\square\text{W}} = 0.51e$) are in qualitative agreement with the positron lifetime in these vacancies:⁴⁷ the charge of a carbon vacancy is higher, hence, the positron lifetime in it is shorter as compared with the vacancy in the tungsten sublattice ($\tau_{\square\text{C}} = 136$ and $\tau_{\square\text{W}} = 175$ ps, respectively).

According to the results of calculations,^{46, 64–68, 70} the band structure of studied tungsten carbides is basically the same, *viz.*, it contains three main bands, namely, the low-energy 2s(C) band, the ground-state hybridised valence binding band 2p(C)–5d(W) and the high-energy band formed largely by the 5d states of tungsten.

V. Methods of synthesis of tungsten carbides and WC–Co alloys with different grain sizes

Polycrystalline metal carbides are usually synthesised by the powder metallurgy methods, which are described in detail in monographs.^{3, 4} Different synthetic methods are also described.^{71–73} The most popular methods are those that involve the direct synthesis from a metal and carbon or from the compounds containing the metal (for example, metal oxides or chlorides) and carbon (*e.g.*, a hydrocarbon or CO).

A conventional method of the synthesis of hexagonal carbide WC involves heating of tungstic acid (H_2WO_4) or ammonium tungstate $(\text{NH}_4)_2\text{WO}_4$ in a mixture of hydrogen and methane at 1020–1270 K. When tungstic acid is used, the metal is completely

reduced even before the carburisation. The carbothermal reduction of WO_3 by carbon in the inert or reductive atmosphere proceeds in a similar way. Tungsten carbide synthesised by carbothermal reduction usually contains traces of oxygen and oxycarbides; therefore, synthesis of a pure substance requires that the latter be additionally annealed at a temperature not lower than 1800 K.

The purest hexagonal WC samples are synthesised by the solid-phase vacuum sintering of metallic tungsten and carbon (gas black) at a temperature not lower than 1400 K. Hexagonal carbide W_2C is synthesised by the solid-phase vacuum sintering of tungsten and carbon powders at 850–900 K. However, the solid-state carburisation at this low temperature proceeds only in the presence of hydrogen or a gaseous hydrocarbon; moreover, the final product contains a relatively high amount of free carbon. Synthesis of a single-phase WC powder with the grain size of 5–6 μm from the metallic tungsten powder in a mixture of hydrogen with methane has been described;⁷⁴ at 2300–2500 K and a gas mixture with ≤ 2 vol.% of methane, WC with the free carbon content < 0.1 mass % could be obtained. High temperature (up to ~ 2400 K) is required in those cases where the solid-state sintering is carried out in vacuum, although the carburisation starts at 1400 K.

Tungsten carbides can also be synthesised using the following methods: deposition from the gas phase in the reaction of $\text{W}(\text{CO})_6$ or tungsten chloride with a mixture of a hydrocarbon and hydrogen, thermal decomposition of various precursors,⁷⁵ self-propagating high-temperature synthesis and mechanochemical synthesis.⁷⁶ For example,⁷⁷ a mixture of carbon (black) and tungsten powder with the grain size of up to 10 μm was ground in a cam-type mill; during the grinding, the average load in the ball impact zone was 10^8 – 10^9 Pa and the quantity of mechanical energy absorbed by the powder during the grinding reached 30 kJ g^{-1} . As a result of such treatment, lower hexagonal tungsten carbide was obtained. Mechanochemical synthesis of carbides from elementary tungsten and carbon in a planetary ball mill with the use of an inert copper matrix was described;⁷⁸ according to authors' estimates, the average size of W_2C and WC particles formed did not exceed 0.5 μm .

We have already mentioned that hexagonal carbide WC is not the hardest and most refractory among carbides. Its melting point (~ 3060 K) is lower as compared with TiC, ZrC, HfC, NbC and TaC, and its hardness at 300 K (according to different sources, from 18 to 22 GPa) is lower as compared with non-stoichiometric carbides TiC_y , ZrC_y , HfC_y , VC_y , NbC_y , TaC_y at the same temperature.^{3, 4} However, the hardness of WC is sufficiently stable, *e.g.*, as a result of carbide heating from 300 to 1300 K, the microhardness H_V of hexagonal WC decreased from ~ 18 to ~ 12 GPa,⁷⁹ whereas H_V of carbides of other metals decreased under the same conditions from their maximum values to 3–8 GPa (Fig. 17). The increase in temperature from 300 to 1100 K is accompanied by a more pronounced decrease (approximately three-fold) in the WC hardness; however, the hardness of other carbides undergoes a still sharper decrease (approximately five-fold) in the same temperature range.⁸⁰ The sharp decrease in the WC hardness with the increase in the temperature follows from the experimental results,⁸¹ which, nonetheless, substantially differ from those given by other authors^{79, 80} (the same study⁸¹ also shows the hardness value for vanadium monocarbide at ~ 900 –1500 K, which is lower as compared with that found in other literature sources). Apparently, the value of WC hardness measured in the study cited (Ref. 81) is severely underestimated. Moreover, note that, as compared with other carbides, WC has a modulus of elasticity higher by a factor of 1.5–2 [~ 700 GPa (see Ref. 82)] and a thermal expansion coefficient lower by a factor of $1.5 [(5-6) \times 10^{-6} \text{ K}^{-1}]$ (see Ref. 82)].

The mentioned properties of WC and their temperature stability during the heating up to 900–1000 K determined its application as the basis of wear-resistant hard alloys that are used in metal-working and drilling operations. The direct use of WC for

Figure 17. The effect of temperature on the Vickers hardness of hexagonal WC and carbides of transition metals.⁷⁹ For comparison, the known $H_V(T)$ dependences of monocarbide WC (1)⁸⁰ and (2)⁸¹ are shown (see text).

these purposes is impossible because of its brittleness and sintering only at very high temperatures. Hence, for a given carbide to be applied in practice, it should be imparted certain viscosity without sacrifice in its hardness. This is achieved by using a metal binder together with WC that provides the plasticity of the composite material and, at the same time, has sufficiently high strength, melting point and impact elasticity.

The choice of a metal for the binder is restricted by the following conditions: this should withstand carburisation and in its molten state should adequately wet the carbide to be modified. Moreover, it is necessary that the carbide and the binding metal be soluble in each other. This provides their strong adhesion. For the case of WC, it is cobalt that best satisfies the mentioned requirements; that is why the first hard alloys that have found wide use in the industry were synthesised in the WC–Co system.[¶]

1. Hard alloys WC–Co

According to the phase diagram of the ternary W–Co–C system (see Fig. 12), at the low carbon content, the ternary compounds of the η -carbide type or the solid solution $\text{Co}_3\text{W}_3\text{C}_y$ based on η -carbides $\text{Co}_4\text{W}_2\text{C}$ and $\text{Co}_7\text{W}_4\text{C}$ can be formed. With further decrease in the carbon content, in the $\text{Co}_3\text{W}_3\text{C}_y$ solid solution, the triple phase diagram shows the appearance of a carbide with the approximate composition of $\text{Co}_6\text{W}_6\text{C}_y$. The mentioned ternary compounds and solid solutions exhibit enhanced brittleness; hence, in the synthesis of hard alloys, those compositions are used that lie in the WC–Co cross-section region where no ternary compounds can be formed. In commercial WC–Co alloys, the cobalt content varies from 4 to 18 mass % depending on their application.

The most important traditional operation in the technology of hard alloys is sintering of an item pressed from a powder mixture with an addition of a plasticiser^{83,84} at 1600–1800 K. During the sintering of a WC–Co alloy, a certain amount of liquid phase, namely, molten cobalt, is formed. The wetting angle of WC with cobalt is zero, *i.e.*, molten cobalt completely wets the tungsten carbide grains and partly dissolves them; they crystallise upon

subsequent cooling. In the sintering of a hard alloy, the following temperature intervals are considered:

- at 470–670 K, the plasticiser is removed;
- at 670–970 K, the admixtures of tungsten and cobalt oxides are reduced;
- at 1050–1400 K, individual carbide grains are welded together in their contact points;
- at 1400–1570 K, a solid solution of tungsten carbide in cobalt is formed, the sample shrinks and all cobalt passes to the liquid phase;
- at 1550–1670 K, due to the migration of carbide grains in the liquid phase, the sample acquires its final compact shape;
- the temperature increase up to 1770–1800 K is accompanied by additional dissolution of the WC grains in cobalt, on the one hand, and the growth of carbide grains due to the recrystallisation *via* the liquid phase, on the other hand; simultaneously, complete degassing of the alloy occurs;
- during cooling after the exposure at the maximum sintering temperature, the dissolved tungsten carbide deposits from the liquid phase onto the surface of carbide grains, which results in their growth.

In the ideal case, the sintered WC–Co alloy is two-phase, containing only WC grains and the metal binder between them. At a deficit or an excess of carbon, the alloy becomes three-phase and contains additionally either an η -phase of $\text{Co}_3\text{W}_3\text{C}_y$ (at carbon deficit) or graphite inclusions (at carbon excess). The graphite inclusions as well as the presence of very coarse (several times larger than the average size) WC grains substantially reduce the alloy service life.⁸⁵

The average size of carbide phase grains increases noticeably upon sintering as compared with the grains in the original WC powder. Fine-grain alloys exhibit better performance and the use of fine-grain mixtures for the sintering allows higher quality alloys to be obtained. All other conditions being equal, the grain size in an alloy decreases with the decrease in the cobalt content due to the decrease in the liquid phase content and the deceleration of the grain growth by recrystallisation *via* the liquid phase; the grain size also decreases at a low content of carbon, which, however, results in the appearance of the brittle η -phase. Deceleration of the growth of carbide-phase grains in WC–Co alloys is achieved by their doping with other carbides. The most efficient dopant in this respect is vanadium carbide. Upon introduction of only 0.3 mass % of vanadium carbide, the average grain size of the carbide phase in fine-grain alloys is $\sim 1 \mu\text{m}$. To obtain fine-grain alloys, it is standard practice to include the long-term (up to 48 h) grinding of WC and Co powders in ethanol at the stage of mixture preparation.⁸⁶

Over the past 20 years, the methods of synthesis of various substances and materials in the nanocrystalline state have been actively developed. In this state, the size of particles (grains, crystallites) does not exceed 40 nm.^{87–90} Substances with particles measuring 40–100 nm are called submicrocrystalline.^{89–91} Monographs^{87–90} describe different methods of the synthesis of nanocrystalline powders and compact nanomaterials, the peculiarities of their microstructures, the methods of certification of nanomaterials, the effect of the particle (grain) size on the physical properties of substances. The manifestations of nanoscale effects in the structure and properties of metals, compounds and materials were reviewed.^{92,93}

2. Nanostructured hard alloys

The most promising way to increase the production of nanostructured alloys with the reduced sintering temperature and the enhanced (due to the superfine-grain structure) hardness, strength, fracture toughness (crack-resistance) is to use nano- and submicrocrystalline carbides as the components of these alloys.^{94,95} The decrease in the WC particle size even in the micron scale is accompanied by a noticeable increase in the wear resistance of WC–Co alloys, as well as the increase in their hardness and the compression and bending strength (Table 3, Fig. 18).^{97,98}

[¶] For the brief analysis of the data published from 1918 to 1923 on the development of hard alloys based on tungsten carbide in which such metals as Fe, Ni and Co were used as the binder, see a review.¹⁵ The author of this review, K. Schrüter, in 1925 patented the alloys WC–M (M = Co, Ni, Fe) in the USA with the priority from 1923. Later, similar alloys were developed in Sweden, Austria and other countries. In Russia, hard alloys based on tungsten carbide were manufactured under a trademark ‘pobedit’.

Table 3. The effect of the WC grain size on certain properties of hard alloys WC–Co.⁹⁶

Alloy composition (mass %)	Grain size / μm	Rockwell hardness /HRA	Density / g cm^{-3}	Bending strength /MPa	Compression strength /MPa	Modulus of elasticity /GPa	Relative wear resistance (%)
97WC–3Co	1–2	92.5–93.2	15.3	1590	5860	641	100

**Figure 18.** (1) Bending strength σ_{bend} , (2) wear rate (wear resistance) w and (3) hardness H_V as a function of the grain size D of the carbide phase of hard alloys WC–6 mass % Co.⁹⁸

The only exclusion known is the decrease in the bending strength of WC–6 mass % Co alloys with the decrease in the grain size (see Table 3). The results of other studies demonstrate that the mechanical properties always improve with the transition from coarse-grain to fine-grain WC–Co alloys. For example, upon sintering of WC–15 mass % Co nanopowders with the average particle size of 970, 490 and 30 nm at 1690 K the resulting alloys with the average grain size of 1350, 950 and 620 nm exhibited hardness of 13.8, 14.7 and 17.0 GPa, respectively.⁹⁴ A hard alloy WC–10 mass % of Co with the carbide phase of superfine structure (the WC grain size is smaller than 0.5 μm) exhibits microhardness of 19.3 GPa and a bending strength of 3890 MPa, whereas the same characteristics of a similar alloy with the grain size of 0.5–1.0 μm are 17.8 GPa and 3780 MPa.⁹⁹ Hard alloys WC–6 mass % Co manufactured by ‘Krupp Widia GmbH’, which contain carbide-phase grains measuring 1.4–1.8, 0.8–0.9 and 0.5–0.6 μm , exhibit the bending strength of 2000, 3000 and 3800 MPa, the hardness of 15.8, 18.0 and 20.4 GPa, the abrasive wear resistance of 1.26%, 2.08% and 2.78%, respectively. A similar improvement in the mechanical properties with the decrease in the carbide-phase grain size was observed for hard alloys with larger (up to 15 mass %) cobalt content. The strength characteristics of conventional (with micron-scale grains) hard alloys based on WC are discussed in a monograph.⁸⁵

Plasmochemical synthesis is among the most widely used chemical methods for obtaining fine-grain powders of nitrides and carbides.^{100,101} The main conditions for the production of fine-grain powders by this method are as follows: the reaction should proceed far from its equilibrium and the new-phase nucleation rate should be high as compared with the nuclei growth rate. Under real conditions of the plasmochemical synthesis, nanoparticles are produced upon fast cooling of the plasma flow in which the gas phase is condensed; this reduces the sizes of the particles formed and suppresses their coalescence upon collisions. The plasmochemical synthesis of carbides makes use of the low-temperature (3000–8000 K) hydrocarbon and argon plasma of the arc, glow, high-frequency and microwave discharges; elements and their halides and other compounds are used as the starting

substances.⁸⁷ The characteristics of the powders synthesised depend on the starting materials, the process of synthesis and the reactor type. The particles obtained in plasmochemical reactions represent single crystals, have regular shapes and the sizes from 10 to 100–200 nm (and higher).

The plasmochemical synthesis is characterised by high rates of formation and condensation of substances, its efficiency is sufficiently high. The major disadvantages of this method are as follows: the wide size distribution of particles and, as a consequence, the presence of sufficiently coarse (up to 1–5 μm) particles, which means that the selectivity of the process is low, as well as high content of impurities in the resulting powder. To date, fine-grain powders of titanium, niobium, tantalum and tungsten carbides have been synthesised by the plasmochemical method.^{87,101–104} For instance, the synthesis of a submicrocrystalline WC powder with a specific surface area of 15 $\text{m}^2 \text{g}^{-1}$ and a particle size not exceeding 300 nm,[†] which was conducted in an argon–hydrogen plasma from methane and tungsten hexafluoride, was reported.¹⁰⁴

Synthesis of fine-grain tungsten carbide powders with the use of an arc plasmatron is described.¹⁰⁵ The plasmochemical synthesis produced a substance of the W–C–O system with a definite carbon-to-oxygen ratio, while the synthesis of the single-phase carbide as such was carried out in a tube furnace by the reduction of this product with hydrogen and CO. The specific surface area of synthesised WC varied from 5–6 to 50 $\text{m}^2 \text{g}^{-1}$. To produce the WC–Co furnace mixture, a cobalt powder with a specific surface area of 8–10 $\text{m}^2 \text{g}^{-1}$, which was synthesised by plasmochemical reduction of the oxide, was used. Sintering of the furnace mixture involved its hot pressing at 1370–1670 K and 10–50 MPa. The WC grain size in the samples sintered in the solid phase was ~ 100 nm.

A design of an electro-arc plasmatron for the plasmochemical synthesis (hydrogen plasma with the temperature of 3000–4000 K) of nanocrystalline powders of refractory compounds including tungsten carbide with the particle sizes from 10 to 100 nm was reported.¹⁰⁶

Low-temperature gas-phase synthesis of WC nanopowders is described.^{107,108} A two-step process was originally proposed¹⁰⁷ which included reduction of tungsten (its nanopowder) from tungstic acid salts, *i.e.*, the reductive decomposition of the precursor, followed by carburisation of tungsten in a CO-containing gas mixture. The synthesis produced a WC powder with the average grain size of 8 nm when conducted at 900–950 K and metastable lower carbide W_2C with particle measuring 13–19 nm when conducted at 600–800 K. A more straightforward one-step synthesis of the nanocrystalline WC carbide powder was described:¹⁰⁸ an H_2/CO gas mixture (2:1 or 1:1 molar ratios) was passed through ammonium tungstate or tungsten oxide powder at 800–1000 K; this directly led to the formation of nanocrystalline WC with particles < 10 nm. One important

[†] Note that WC has a density $\rho = 15.6 \text{ g cm}^{-3}$; hence, the average particle size (diameter) in a powder of the total specific surface area $S_{\text{sp}} = 15 \text{ m}^2 \text{g}^{-1}$ should be $D = 6/\rho S_{\text{sp}} \approx 30$ nm, *i.e.*, 10 times smaller than reported.¹⁰⁴

parameter of the single-step synthesis is the heating rate, which should provide the kinetic balance between the reduction and carburisation reactions. The heating rate of 2 deg min^{-1} is close to the optimum; moreover, heating even up to 1000 K resulted merely in a minor coarsening of WC particles as compared with heating to 800 K.

Mechanochemical synthesis in a cam-type mill produced hexagonal W_2C with the average particle size of 10 nm from a powder mixture of tungsten with the average particle size of up to 10 μm and carbon.⁷⁷

To preserve the positive effect achieved due to the use of nanocrystalline powders for the production of hard alloys, the WC particles should retain small sizes during their sintering. In our studies,^{109–111} we used the X-ray diffraction and magnetic susceptibility measurements to follow the changes in the thermal stability of a WC nanopowder that was obtained by the plasmachemical synthesis from WO_3 and propane at $\sim 3300\text{--}3800 \text{ K}$ in hydrogen plasma with the additional annealing in argon atmosphere at $1100\text{--}1300 \text{ K}$. The average particle size in the nanopowder was 50–55 nm. According to our studies, the particles in this powder retained the stable size when annealed in the temperature range from 300 to 1200 K, while the relaxation of microstresses in them began at $\sim 600 \text{ K}$ and ended at $\sim 900 \text{ K}$.

The fine-grain structure of hard WC–Co alloys synthesised from WC powders is determined not only by the small size of the furnace mixture particles, but also by the way their sintering proceeds. Upon formation of the liquid phase, first, the smallest particles and, then, medium size particles pass to the melt, while coarser particles survive. Insofar as most nanoparticles are of the medium size, the number of crystallisation centres in the alloy will be sufficiently high. In the recrystallisation, tungsten carbide deposits on the surface of non-dissolved WC particles. Due to the excessive surface energy of small particles, they acquire a thicker layer of deposited tungsten carbide as compared with coarse particles. As a result, the size of carbide-phase particles levels off. In an ordinary hard alloy, the number of crystallisation centres is substantially smaller than in an alloy synthesised from the WC nanopowder; hence, a nanocrystalline alloy would have a more fine-grain and uniform structure as compared with an ordinary alloy. However, it should be borne in mind that the growth of grains in nanocrystalline compositions WC–Co can occur at $\sim 1070 \text{ K}$,¹¹² *i.e.*, below the eutectic temperature of the W–Co–C system, which is equal to $\sim 1600 \text{ K}$ (nanopowders of WC–15 mass % Co with the average particle size of 30 nm were studied;¹¹² the liquid phase appeared at $\sim 1420 \text{ K}$ during sintering). This means that, during the liquid-phase sintering of WC–Co nanopowders, the initial growth of carbide-phase grains occurs in the range of solid-phase sintering temperatures, whereas the subsequent liquid-phase sintering only leads to the coarsening of WC grains.¹¹³

Also note that the most compact (non-porous) alloys can be obtained provided the furnace mixture is not monodisperse, because obviously the total volume of a sample cannot be filled without voids with unisized particles. More compact packing is achieved due to the presence of different-sized particles in the furnace mixture, where the finer particles occupy the voids between the coarser particles. Analysis of the three-dimensional packing of spherical particles has shown¹¹⁴ that a very high degree of the free space filling (~ 0.9) can be reached for their bimodal size distribution where, along with medium-size particles (D) that have the maximum share, the fraction of particles with a diameter $\sim 0.1D$ is fairly high. In other words, the size-distribution curve of the particles should possess two maxima, the first of which (abundance) corresponds to the particles with the medium size D , while the second corresponds to the particles with the size $\sim 0.1D$.

Analysis of the literature data has shown that nanocrystalline or submicrocrystalline tungsten carbide can be synthesised by different methods. However, for the production of nanostructured hard alloys WC–Co, it is better that not only tungsten

carbide, but the whole composition mixture WC–Co be in the nanocrystalline state. Such a mixture can be obtained by thermolysis of various precursors.⁷⁵ Particularly, heating can induce the following decomposition reactions resulting in the formation of WC and metallic cobalt:

where R and En are alkyl and ethylenediamine, respectively.

Modern technologies of the production of nanocomposite mixtures WC–Co include several consecutive operations, namely, deposition from colloid solutions, cryogenic sputtering and drying, carbothermal reduction. Thus an efficient method for the production of nanocrystalline compositions of tungsten carbide and cobalt for manufacturing hard alloys is based on the co-deposition of WC and Co precursors from colloid solutions.^{115, 116} According to this method, colloid solutions of tungsten and cobalt salts {*e.g.*, $(\text{NH}_4)_6[\text{H}_2\text{W}_{12}\text{O}_{40}] \cdot 4 \text{H}_2\text{O}$, CoCl_2 , $\text{Co}(\text{NO}_3)_2$, $\text{Co}(\text{CH}_3\text{COO})_2$ } are dried by sputtering, then the obtained powder is subjected to the low-temperature carbothermal reduction in the fluidised bed and thus retains its high-dispersion state. This technology was patented¹¹⁷ as the ‘Spray Conversion Process (SCP)’. Insofar as the synthesis starts in the solution, the components (W and Co) are mixed on the molecular level, which favours the formations of an amorphous carburised powder.

The grain growth can be inhibited and the WC solubility in cobalt can be suppressed by adding up to 1 mass % of non-stoichiometric vanadium carbide to the mixture. The alloy obtained from this nanocrystalline composition demonstrates the optimum combination of high hardness and high strength; for example, its Vickers hardness reached 21.5 GPa, whereas the maximum hardness of an alloy with the same composition, which was obtained from a conventional WC powder, did not exceed 19.5 GPa.^{115–118} The increase in the hardness and the decrease in WC grain size correlate with the increase in the vanadium carbide content in the alloy. Figure 19 illustrates the size distribution of grains in a sample of the WC–6 mass % Co alloy obtained from a nanocomposite mixture prepared by the deposition method described above and containing 0.83 mass % of vanadium carbide, and in a sintered sample of a conventional alloy WC–6 mass % Co containing 0.32 mass % of VC. As is seen, the average size of WC grains in the alloy synthesised from the

Figure 19. Size distribution of grains in WC–6 mass % Co alloy samples.¹¹⁹

(1) Alloy sintered from a nanocomposite mixture of WC, Co and 0.83 mass % of VC, which was obtained by the co-deposition from colloid solution followed by drying and carbothermal reduction; the sample contained 1000 grains; (2) conventional fine-grain alloys WC–6 mass % Co with 0.32 mass % of VC; the studied sample contained 948 grains.

amorphous nanocomposite powder is 250 nm, whereas an ordinary alloy has the grains almost twice larger (450 nm).

It was shown^{119, 120} that each nanocomposite WC–Co particle with a size of $\sim 75 \mu\text{m}$ consists of several millions of nanocrystalline WC grains measuring $< 50 \text{ nm}$, which are distributed throughout the cobalt matrix (Fig. 20). Sintering of a nanocomposite tungsten carbide mixture with 6.8 mass % of Co and 1 mass % of vanadium carbide produced the alloys which contained 60% of the WC grains measuring $< 250 \text{ nm}$ and 20% measuring $< 170 \text{ nm}$. A structure with still finer grains was obtained for an alloy which, in addition to tungsten carbide, contained 9.4 mass % of Co, 0.8 mass % of Cr_3C_2 and 0.4 mass % of VC_y . Upon its sintering at 1670 K, 60% of the tungsten carbide grains were $< 140 \text{ nm}$ and 20% were $< 80 \text{ nm}$. A comparison of the nanoalloy with ordinary polycrystalline alloys of equal hardness have shown,¹²⁰ that the crack resistance of the nanoalloy is higher by a factor of 1.2–1.4 as compared with ordinary coarse-grain alloy.

The described nanocrystalline WC–Co composite powder with the carbide grain size of 20–40 nm is manufactured on the commercial scale in the USA as NANOCARBTM. For the deposition of protective coatings by the thermal sputtering method, the nanocomposite multimodal (containing several frac-

tions of carbide grains, viz., from 8 to 50 nm) WC–Co powder NANOMYTETM was used.

Synthesis of a one-phase nanocrystalline WC powder by grinding tungsten and carbon in a ball mill at room temperature for $2.95 \times 10^5 \text{ s}$ is described;¹²¹ the increase in the grinding time to $4.32 \times 10^5 \text{ s}$ afforded a nanopowder with the average grain size $< 5 \text{ nm}$. Then different amounts of cobalt were added to the WC nanopowder, and grinding was continued for $2.6 \times 10^5 \text{ s}$. The resulting nanocomposite mixtures WC–Co contained different amounts of cobalt, and the particles with the average size $< 5 \text{ nm}$ represented WC covered with a cobalt layer. Its pressing and hot sintering produced an alloy, which contained the carbide phase grains with the average size of $\sim 100 \text{ nm}$. The hardness and the elasticity modulus of the alloys, which contained from 5 mass % to 12 mass % of Co varied in the ranges of 20–12 and 740–580 GPa, respectively.

It was already mentioned that the initial and the most active growth of carbide phase grains occurs in the sintering of WC–Co nanopowders in the temperature range of solid-state sintering. To decelerate the growth of grains in this region, it was proposed¹²² to synthesise the nanostructured hard alloys WC–Co in an electric arc discharge. In this case, the stage of compacting of the nanopowder mixture is combined with its fast sintering and subsequent cooling of the sintered sample. The heating and cooling rates in this method are sufficiently high to avoid the sintering in the solid state and prevent the grain growth during the cooling. Thus a hard alloy was obtained¹²² from a nanopowder of tungsten carbide containing 10 mass % of Co prepared by the SCP technology (see Refs 115–117) and had, on average, 50-nm coherent-scattering regions (according to X-ray diffraction data) or the average particle size of 200 nm (according to the data from scanning electron microscopy). The compacting pressure reached 300 MPa. When a current pulse was passed for several microseconds through a sample with the mass of 2.5 g, the energy (3 kJ g^{-1}) was liberated, which led to sintering. As a result, a hard alloy was obtained that had a density equal to 95% of its theoretical value and contained only WC and a fcc solid solution of tungsten carbide in cobalt. The average grain size in the carbide phase of this alloy was 120 nm according to data from electron microscopy; the measured modulus of elasticity was 550 GPa.¹²²

A hard alloy WC–Co synthesised from a tungsten carbide powder with 30–50-nm particles¹²³ had a more uniform fine-grain structure and exhibited higher hardness and strength as compared with common hard alloys of the same composition. It was mentioned that the introduction of 3 mass %–5 mass % of tungsten carbide nanopowder to the standard furnace mixture containing coarse ($1\text{--}4 \mu\text{m}$) WC grains levels off the deviations in the hardness and strength of the resulting WC–Co alloy, i.e., stabilises the hard-alloy properties.

A virtually ideal version of mechanochemical synthesis, which is coupled with the synthesis of a nanocomposite mixture, was described.¹²⁴ A mixture of coarse ($\sim 75 \mu\text{m}$) tungsten, graphite and cobalt powders was ground in an argon-filled ball mill for 100 h; the resulting nanocomposite WC–Co mixture contained cobalt and tungsten-carbide grains with the average diameter of 11–12 nm. In the hard alloy, which was obtained by cold pressing of the mixture followed by its sintering at 1310 K, most WC grain had a size $< 200 \text{ nm}$, i.e., were several times smaller as compared with conventional alloys of the same composition. The sintered hard-alloy samples demonstrated the hardness of $\sim 18 \text{ GPa}$ and the relative density equal to 80% of the theoretical value. The possibility of sintering of a nanocomposite WC–Co powder mixture at lower temperatures as compared with coarse-grain mixtures is determined by the lower melting point of nanocrystalline cobalt as compared with coarse-grain cobalt.

Bearing in mind that even a small amount of non-stoichiometric vanadium carbide inhibits the growth of the carbide phase grains during the sintering, it was proposed¹²⁵ to synthesise $\text{V}_8\text{C}_7 + \text{WC}$ powder mixtures in the first stage of the synthesis of WC–VC–Co alloys. Joint grinding of WC and V_8C_7 powders

Figure 20. Distribution of WC grains in coarse particles of the amorphous nanocomposite mixture WC–6 mass % Co with 0.83 mass % of VC, which was obtained by the deposition from a colloid solution followed by drying and carbothermal reduction.^{119, 120}

with an addition of 0.5 mass % of Co for 48 h followed by their 3-h exposure at 1470 K to form their mixed (V,W)C carbide produced a mixture with the average particle size of 1.4 μm . Joint grinding of vanadium oxide, tungsten carbide and carbon was also carried out, which was followed by the carburisation of the resulting mixture at ~ 1470 K in the H_2/Ar atmosphere. In this case, the obtained powder had the particles with the average size of 1.8 μm .

The synthetic methods, the structure and mechanical properties of fine-grain hard alloys based on tungsten carbides were discussed briefly in a review.¹²⁶ Studies devoted to the microstructure, hardness and fracture toughness of hard WC–Co alloys¹²⁷ have shown that the hardness increases with a decrease in the thickness of the metal binder layer. It was also noted that the hardness measurements carried out at low loads or using a nanoindenter overestimate its value by ~ 2 GPa. The effects of the microstructure and the grain size of alloys WC–6 mass % of Co on their hardness in the temperature range from 80 to 1170 K was studied.¹²⁸ The examined alloys had the microstructure typical of ordinary hard WC–Co alloys (Fig. 21). Figure 22 illustrates the changes in the hardness H_V of alloys with the average grain size of 0.6, 1.4 and 3.6 μm as a function of the temperature. It is evident that the alloys with a fine-grain structure are harder throughout this temperature range.

Figure 21. A typical microstructure of hard alloys WC–6 mass % Co with the average size of carbide phase grains of 0.6 (a), 1.4 (b) and 3.6 μm (c).¹²⁸

Figure 22. The effect of temperature of the Vickers hardness of WC–6 mass % Co alloys with the average size of carbide phase grains of 1.4 (1), 0.6 (2) and 3.6 μm (3).¹²⁸ The measurements were performed under a load of 6 kg.

Recently, nanopowders of the WC–Co system came into use for synthesising nanocomposites that contain a diamond phase.^{129,130} A nanopowder WC–15 mass % of Co with tungsten carbide grains measuring 100 nm on average was pressed into samples of 8-mm diameter under a pressure of 100 and 300 MPa.¹²⁹ The samples were first heated to 1170 K in a hydrogen atmosphere to remove the oxide film and then sintered in vacuum at 1270–1470 K with 30-min exposure at the maximum sintering temperature. By varying the sintering time at the lowest temperature used, one could control the size and the arrangement of pores in the sample. Then, the samples were kept for 3 h at 1170 K in a flow of $\text{H}_2 + \text{CH}_4$ gas mixture to infiltrate the gas into the pores, after which they were simultaneously subjected to impact of high temperatures and pressures in order to reduce methane to carbon and transform carbon (graphite) into the diamond phase. The resulting superhard nanocomposite material contained ~ 45 vol.% of the diamond phase.¹²⁹ The diamond phase content in the synthesised nanocomposite seems to be significantly overrated.

A somewhat different method for the synthesis of WC–Co–diamond nanocomposites was proposed.¹³⁰ The initial mixture represented a powder mixture of WC with 15 mass % of Co; the average size of WC particles was 100 nm. The samples compacted under a pressure of 200 MPa were heated to 870 K in a hydrogen atmosphere to remove the oxide film and then sintered in vacuum at 1370 K for 30 min. The resulting porous samples with the 70% relative density were subjected to electrochemical etching in an aqueous $\text{NaC}_4\text{H}_5\text{O}_6$ solution. After the etching, the samples were washed with water, dried and then saturated with a gas mixture $\text{H}_2 + \text{CH}_4$, which contained 15% of methane. The infiltration of the gas into pores was carried out at 1170 K for 4 h. Then hydrostatic pressure of 8 GPa was applied at 1770 K to decompose methane in a catalytic reaction

deposit carbon on the pore walls and transform it from the graphite state into the diamond state and also to condense the samples. The hardness of samples near their edges reached 32 ± 3 GPa, which was five times higher than in the bulk.

Thus, nowadays, there are different methods for the synthesis of nano- or submicrocrystalline tungsten carbides, WC–Co composite nanopowders and nanostructured hard WC–Co alloys. The available data suggest (see Table 3, Fig. 18) that the decrease in the size of carbide grains in hard WC–Co alloys is accompanied by noticeable increase in the abrasive wear resistance (by a factor of 2–3). Indeed, when drilling the printed circuit boards, the drills made of ultradispersed hard alloys prove to be

2–3 times more stable as compared with those made of standard alloys.¹²⁶ Therefore, it is reasonable to use the hard alloys with untradispersed and nanocrystalline structures, which combine the enhanced wear resistance, strength and fracture toughness, in those operations that require high wear resistance. However, it deserves mentioning that for ordinary alloys the same and even greater effect of the increase in the wear resistance can be achieved by the deposition of a wear-resistant coating.¹³¹ This should be taken into account when assessing the economic profits associated with the use of nanostructured hard alloys.

VI. Conclusion

Hexagonal tungsten carbide is the most extensively used among all carbides of Group IV–VI transition metals. Originally, in the W–C system, only two hexagonal carbides W_2C_y (β - W_2C) and WC (δ -WC) were known, which despite their similar symmetry differ significantly, namely, lower carbide W_2C_y has a noticeable homogeneity region $WC_{0.34}–WC_{0.50}$, while hexagonal monocarbide δ -WC can have only the stoichiometric composition and contains no vacancies in the carbon sublattice. The non-stoichiometry of a disordered lower carbide W_2C_y , which is at equilibrium from 2700 K up to the melting point, is a prerequisite for its ordering with respect to both atoms and vacancies at lower temperatures. According to the neutron diffraction analysis, with decrease in the temperature, the following disorder–order transformation takes place in β - W_2C carbide:

The earlier concepts on the two consecutive transformations, *viz.*, the disorder–order transformation to form the orthorhombic β' - W_2C phase of the PbO_2 type

and the order–disorder transformation to form the trigonal β'' - W_2C phase of the $C6$ type

were not confirmed by the neutron diffraction analysis of the W_2C structure.

One peculiarity of lower tungsten carbide is that at 1523 K it undergoes the eutectoid decomposition to give tungsten and δ -WC and thus does not exist at lower temperatures. In the 1960s, an additional compound highly non-stoichiometric with respect to carbon, namely, cubic carbide γ - WC_{1-x} was discovered in the W–C system. The region of the existence of equilibrium of this carbide is very wide with respect to composition (from $WC_{0.58–0.59}$ to $WC_{1.00}$) and very narrow with respect to temperature (from ~ 3060 to $\sim 2990–3020$ K); however, due to quenching from high temperature, it can be preserved in the metastable state at 300 K. The temperature of the equilibrium transformation

is 3000–3010 K; however, the temperature of the non-equilibrium transformation of the quenched cubic carbide γ - WC_{1-x} to give hexagonal δ -WC, which occurs on heating, is still unknown.

Studies on the W–C system are also important from the practical viewpoint, because tungsten carbide is used in the production of hard alloys applied in the metal working and drilling. The traditional basis for such alloys is hexagonal stoichiometric carbide WC (δ -WC); to date, no attempts were undertaken to use cubic carbide γ - $WC_{1.0}$ of the stoichiometric composition or non-stoichiometric cubic carbide γ - WC_{1-x} for these purposes. The cubic structure of tungsten carbide can apparently be stabilised by the addition of other cubic carbides, for example, VC_y . The use of cubic tungsten carbide with VC_y additives as the basis for hard alloys can also provide the thermal stability of the carbide phase and the fine-grain structure of the alloy.

Yet another direction in the application of tungsten carbide, which was actively developed in the past 20 years, concerns the nanostructured hard alloys. In the systems W–C and W–C–Co, the nanostructured carbides or nanocomposites of the WC–Co and WC–Co–diamond types were obtained. Their synthesis became possible due to the use of new and, as a rule, combined synthetic methods and non-traditional procedures such as co-deposition of tungsten and cobalt from colloid solutions, thermal decomposition of precursors, plasmochemical reduction, mechano-synthesis, *etc.* The particle sizes in nanocomposites can be very low (10–40 nm); however, the problem of the conservation of the small particles during sintering of a hard alloy is not yet solved completely. Nonetheless, the microstructure of newly developed ultradispersed hard alloys contains carbide-phase grains with the average size of 100–250 nm, which provides the noticeable increase in their hardness, wear resistance and other performance characteristics. The introduction of small amounts of vanadium carbide favours the retention of small-sized grains in nanostructured hard alloys.

On the whole, the studies of tungsten carbides and the related phase equilibria in both the W–C system and more complex systems containing tungsten carbides contribute to the development of fundamental concepts on the nature of refractory compounds of transition metals and serve as the basis for their wide application in the future.

I. Introduction	637
II. Critical dimensions of nanoclusters and nanostructures	638
III. Critical characteristics and properties of nanoclusters and nanostructures	652

Abstract. Theoretical models and experimental data related to the formulation of the discreteness concept for nanoclusters and nanostructures are analysed. The discreteness is shown to be due to the existence of critical sizes of nanoclusters determined by the magic numbers of atoms and thermodynamic parameters. Such nanoclusters exhibit the highest stability in the formation of nanostructures and specific properties. The bibliography includes 116 references.

I. Introduction

There are a few types of discreteness of matter, *e.g.*, discreteness on the atomic level, the elementary particle level and the atomic-molecular level. For instance, the atomic-molecular structure is discrete on the atomic level (of the order of 10^{-1} nm). This manifests itself in individual electronic, optical, magnetic properties of matter on this level of discreteness and in, *e.g.*, the form of X-ray diffraction, electron diffraction and in the onset of co-operative mechanical, thermal, optical, electronic and magnetic properties in the formation of condensed state. The structure and properties of matter on various levels of discreteness have been a subject of atomic physics and quantum chemistry, physics and chemistry of condensed state and physical chemistry. Discreteness of matter on a lower, elementary particle level (of the order of 10^{-6} nm) has been studied by nuclear physicists and chemists.

There is yet another level of discreteness of matter. Some features of the supramolecular structures and nanoclusters of size 1–100 nm also indicate the formation of the most stable clusters (nanoparticles) of particular sizes, which can be treated as manifestation of specific discreteness level.

In addition to the spatial discreteness level in heterogeneous nanostructures involving nanopores, nanotemplates, nanoclusters, *etc.*, discreteness governed by the physicochemical properties of matter emerges. On the one hand, this is a consequence of the microscopic approach and the effect of the atomic or electronic structure of matter on the formation and properties of nanoclusters of size 1–10 nm on going from the local energy levels to the band structure. On the other hand, the laws of thermody-

namics and the effect of the surface dictate the formation of stable nanoclusters of the most probable sizes from 1 to 50 nm and thus the appearance of nanostructures with discrete nanocluster size distributions. (Of course, the case in point are the most probable cluster sizes against the background of overall continuous nanocluster size distribution in nanostructures.) Nanostructures built of the critical-size nanoclusters possess novel co-operative properties.^{1–6}

The aim of this review is to elucidate the discreteness and conditions for formation of critical-size nanoclusters and to consider the properties of such nanoclusters as well as nanostructures, nanomaterials and nanodevices based on them. It should be noted that the functions characterising the state of clusters are determined by not only the cluster size, but also the presence of defects, by the electronic, magnetic and other factors which were ignored in our models.

The review consists of two main parts. The first part is devoted to the formation of critical-size nanoclusters and nanostructures based on them in various media. In the second part we will consider the properties of such nanostructures and nanomaterials.

The first part concerns the mechanisms of nanocluster formation in the gas, liquid and solid phases. The formation of critical-size nanoclusters in the gas phase is considered using the thermodynamic (pressure and temperature dependences) and microscopic (with inclusion of triatomic collisions and the effect of the magic number of atoms in filling the electron shells) approaches and the close packing principle. For the liquid phase (solutions and colloidal systems) we consider the formation of molecular clusters, colloidal clusters and critical-size nanoclusters in a nanopore or a reverse micelle based on the thermodynamic approach and the principle of close packing of atoms.

The formation of mesoporous silica and alumina is also associated with the existence of nanoparticles of characteristic discrete sizes. Solid-phase reaction studies revealed not only the formation of critical-size nanoclusters with the primary structure, but also the existence of aggregates of the critical-size clusters, namely, superclusters that form hierarchical secondary or ternary structures. Using the thermodynamic approach, it is possible to determine the critical cluster sizes corresponding to the onset of sintering and the formation of a nanostructure.

The second part is devoted to those properties of nanostructures that are due to discreteness. We will consider the thermal properties related to the existence of critical cluster sizes at which melting begins and transition to the solid–liquid state occurs. Then, we will discuss the mechanical properties. At certain critical value of the defect concentration, nanoclusters can behave as superhard or superplastic materials. These properties can be controlled by varying the cluster surface area. The conducting and optical properties of nanoclusters and nanostructures are due to

Received 13 January 2006

Uspekhi Khimii 75 (8) 715–752 (2006); translated by A M Raevskiy

the existence of the critical cluster size for one-electron transfer and the critical sizes governed by the occurrence of a plasmon (in the case of optical absorption in metals) or a polaron (in the case of semiconductor luminescence). Laser emission is also related to the maximum and minimum sizes of semiconductor clusters. The electromagnetic properties including the giant magnetoresistance are determined by the critical size of superparamagnetic clusters, the magnetic field magnitude and the ratio of the cluster size to the mean free path of an electron (in the case of electron conduction). Tunnelling magnetisation parameters are characterised by the critical values of external magnetic field. Finally, magnetic phase transitions in clusters can be governed by the critical cluster sizes.

With allowance for specific properties of nanoclusters, nanostructures can be considered as a specific form of matter that is discrete on the cluster (or supramolecular) level.

II. Critical dimensions of nanoclusters and nanostructures

1. Critical sizes of nanoclusters in the gas phase

a. Critical cluster size and nucleation

The metal, oxide, carbon, noble gas and small-molecule (*e.g.*, water) clusters are formed by condensation in atomic beams or vapours. Clustering studies are carried out using the dynamic approach with account of triatomic collisions (in particular, the molecular dynamics or Monte Carlo methods) or the thermodynamic approach.

The formation of a cluster can take a time exceeding 10^{-13} s; the process depends mainly on the kinetic energy of the cluster; however, even the times of the order of 10^{-9} s (*i.e.*, characteristic of a single computer operation) are too short to study the whole history of cluster formation.⁷ The finite size of a stable cluster can be estimated using the thermodynamic approach by minimising the changes in the Gibbs free energy depending on the size of the cluster formed upon the gas–liquid phase transition

$$n A(\text{gas}, P) = A_n(\text{liquid cluster}).$$

In this case one has⁸

$$\Delta G = 4\pi r^2 \alpha - \frac{4}{3}\pi r^3 n R T \ln \frac{P_r}{P_\infty}, \quad (1)$$

where r is the radius of the cluster, α is the surface tension of the cluster, R is the gas constant, n is the number of atoms in the cluster, P_r is the gas pressure above the cluster surface and P_∞ is the pressure above the flat surface. Supersaturation in the system is given by the ratio

$$\Phi = \frac{P_r}{P_\infty}.$$

Clustering occurs at

$$\Phi_{\text{cr}} = \frac{P_{\text{cr}}}{P_\infty}.$$

The smallest critical size (a smaller cluster is unstable due to thermal fluctuations) can be determined from the equation

$$r_{\text{cr}} = \frac{2\alpha m}{\rho k T \ln \Phi_{\text{cr}}}, \quad (2)$$

where m is the atomic or molecular mass, ρ is the cluster density and k is the Boltzmann constant.

The critical characteristic size (diameter) of a water cluster d_{cr} equals 1.6 nm at $\Phi = 4$, which corresponds to about 90 molecules.⁸ The thermodynamic approach gives larger sizes of, *e.g.*, stable alkali metal or aluminium clusters comprising the magic numbers of atoms or noble gas clusters. The size of thermodynamically stable alkali metal clusters can be estimated from Eqn (2). With allowance for the molecular mass, density and surface tension (it is ten times higher than the surface tension for water) differences, an alkali metal cluster should be an order of

magnitude larger than the water cluster and comprise thousands of atoms. However, the most stable clusters with the magic-number-determined sizes only comprise about tens of atoms (see below).

b. Critical nanocluster sizes governed by the electronic and atomic structure

Isolated (ligand-free) clusters are studied using atomic beam methods with supersonic sources. Here, atoms are produced by evaporation of substances on raising the temperature of the environment or by laser ablation from the surface of a solid. A cluster is formed due to the pressure drop and sharp cooling of the environment. Clusters are separated by sizes (masses) in, *e.g.*, time-of-flight mass spectrometers.

Alkali metal nanoclusters. The alkali metal clusters have a simple electronic structure, namely, each atom has one s-electron in addition to the filled electron shells. Such s^1 -clusters are formed in atomic and molecular beams in high vacuum. They are ligand-free, being convenient objects for studying the electronic properties of nanoscale structures (size 1–2 nm). As for molecules, here the key measurable and interpretable parameters are the ionisation energy, electron affinity, dissociation energy and optical absorption of clusters. By studying these characteristics it is possible to construct models for description of the cluster properties.

Ionisation of s^1 -clusters. The ionisation energy (or potential), E_i , of a cluster is minimum in the following process

The E_i value is determined by varying the energy of a laser or some other ionisation source. The formation of charged clusters of particular sizes can be detected using mass spectrometers. The ionisation potential decreases with an increase in the cluster size.⁹ This correlation can be explained using the classical model of a metal drop and the metallic shell (quantum) model. The latter model gives the magic numbers of the metal atoms that form clusters characterised by the higher ionisation potentials and stability.

The classical model correctly predicts the trends in the change in the cluster size, but it seems to be inaccurate in the case of small clusters for which the quantum size effects were established. Here, the shell model is more appropriate, which considers the motion of an s^1 -electron in the effective potential produced by other electrons and ions in the cluster.

In the shell model, which is also called the ‘jellium model’, the cluster-forming ions produce an averaged positive background for the motion of an electron. The shell model for a cluster is constructed similarly to the shell model for an atom. Solving the one-electron Schrödinger equation in the potential field gives the energy levels (eigenvalues of the electron energy). As a result, the energy levels of the clusters with one free electron should be characterised by the principal quantum number N , the number of radial wave functions ($N-1$) and the angular momentum l with a degeneration degree of $2(2l+1)$. This model^{10,11} predicts the closed-shell electronic structure for 1s-, 1p-, 1d-, 2s-, 1f-, 2p-, 1g-, *etc.*, clusters comprising $n = 2(2l+1) = 2, 8, 18, 20, 34, 40, 58, \text{etc.}$, atoms (or having the same numbers of free electrons). These numbers are called the magic numbers.

Ionisation energy measurements for clusters of various sizes provide a method of direct investigation of the cluster shell structure; the filled electron shells should correspond to the highest stability and ionisation energy.

The ionisation energies of potassium, sodium and silver clusters of various size are presented in Fig. 1. The E_i show clearly seen oscillations for the even (higher E_i values) and odd (lower E_i values) atom numbers in the clusters and maxima at $n = 8$ and 20, which confirms the shell structure of these clusters. The shell structure is most pronounced for silver clusters due to strong electron coupling and, correspondingly, higher potential for the

Figure 1. Ionisation energies of potassium (1), sodium (2) and silver (3) nanoclusters.⁹

motion of electrons (deeper potential well), which leads to greater separation of the energy levels.

Fragmentation of s^1 -clusters. Once excited by, e.g., laser radiation, clusters can undergo fragmentation into either isolated atoms or smaller clusters by the evaporation or fission mechanisms (similarly to transformations in atomic nucleus); in this case, the drop model is applicable. Additionally, the cluster dissociation can proceed by the monomolecular mechanism or be accompanied by cascade transformations. The stability of a cluster composed of n atoms is governed by the redistribution of the energy absorbed over a total of $(3n-6)$ vibrational degrees of freedom followed by fixation of a particular cluster breakdown channel and the excited-state lifetimes. The results of cluster stability studies using both the metallic drop model and the shell model indicate a common trend, namely, an increase in the binding energy with an increase in the cluster size.

Monomolecular dissociation studies of singly charged clusters also revealed discrete magic numbers of the atoms in the cluster. For instance, the dissociation energy decreases for the Na_n^+ and K_n^+ clusters comprising $n = 9$ and 21 atoms, which corresponds to 8 and 20 electrons in the filled electron shells, respectively. Clusters containing an even number of electrons are highly stable, which is indicative of electron pairing effects. These effects are more characteristic of Na_n^+ rather than K_n^+ , because for sodium the potential well in the electron field is deeper than for potassium and, hence, the energy differences between the sodium energy levels are larger (greater level – level separation).

Monomolecular dissociation of doubly charged cluster ions is a more complex process compared to the dissociation of singly charged nanoclusters, because it includes not only evaporation, but also fission of clusters. Two possible dissociation mechanisms involve retention of two charges on one fragment

or acquisition of one charge on each fragment

If one cluster fragment remains doubly charged, the potential energy surface has no potential barrier. If both fragments become charged, repulsion between them produces a Coulomb barrier. The fragments are separated upon formation of a transition state. This process is often called the Coulomb fission.

Signals of small doubly charged clusters X_n^{++} are often indistinguishable in the mass spectra; signals of the critical-size clusters (n_c) suitable for Coulomb fission are observed.¹² Usually, it is assumed that small doubly charged clusters of size less than n_c are unstable because the repulsive energy of the positively charged fragments exceeds the binding energy in the cluster. Therefore, the critical cluster size is governed by the dynamics of monomolecular dissociation. In the case of large neutral clusters ($n > 30$), evaporation dominates the Coulomb fission. For clusters of intermedi-

ate sizes ($26 < n < 30$), evaporation and fission ‘coexist’. This points that the height of the Coulomb barrier approximately equals the binding energy. For small clusters ($n < 24$) the Coulomb barrier becomes higher than the binding energy and the doubly charged clusters can no longer exist. The critical sizes of the doubly charged clusters of the first-row elements are as follow:⁹

Element	Na	K	Cs	Au	Ag
n_c	24	17	19	3	5

Aluminium clusters. Aluminium clusters are of interest as models with free electron gas that consists of s^2 - and p^1 -electrons and provides a metallic type of conductivity. Aluminium is widely used as structural material; this makes corresponding reactivity studies topical. Similarly to the alkali metal clusters, the state of aluminium clusters is characterised by the ionisation energy, dissociation energy, polarisation and reactivity that is determined in the reactions with other molecules. Answering the question of applicability of the electron shell model (‘jellium model’) to aluminium clusters requires analysis of all these characteristics.

Ionisation energy of aluminium clusters. Figure 2 presents the results of ionisation energy calculations for Al_n (n from 2 to 70) clusters from the following equation

$$E_i(r, z) = E_{i\infty} + \left(z + \frac{3}{8}\right) \frac{e^2}{r}, \quad (5)$$

where $E_i(r, z)$ and $E_{i\infty}$ are the ionisation energies of the cluster of radius r and charge z and the flat metallic surface, respectively, and e is the electron charge. The open circles denote experimental data and the dashed line shows the prediction of the metallic spherical drop model.

Figure 2. Ionisation energies of Al_n clusters obtained after photoionisation.¹³

The clusters with $n = 7, 14, 23, 36$ and 67 are characterised by abrupt changes in E_i . According to the electron shell model, closed shells are formed at the electron numbers equal to 20, 40, 58, 70, 92, 138 and 198. A decrease in E_i should be expected for the clusters with one or two extra electrons (in addition to the filled shell), i.e., at the electron numbers 21, 42, etc. Taking account of the fact that the aluminium atom has s^2p^1 valence electrons leads to agreement between the experimental data and the predictions of the shell model, because the number of free electrons for aluminium clusters is $3n$. However, no agreement is obtained for larger clusters ($n > 30$).

Yet another feature of aluminium clusters compared to the alkali metal clusters consists in considerable deviation of the calculated ionisation energy (work function of an electron in a metallic sphere) from the experimental values for small clusters

(see Fig. 2). This can be explained by different effect of the conduction band in the alkali metal and aluminium clusters with an increase in the cluster size. The ionisation energies of alkali metal clusters with half-filled s-bands decrease as the cluster size increases. For the s^2p^1 -clusters, the p-band top initially decreases with an increase in the cluster size (ionisation energy increases) and then increases similarly to the situation for the alkali metal clusters. Agreement with the predictions of the classical drop model approximately begins with a 25-atom cluster.

Dissociation of aluminium clusters. Aluminium clusters mainly dissociate by evaporation rather than fission, namely, monomolecular dissociation with evaporation of aluminium atoms or ions occurs. In this case one can expect an increase in the binding energy per atom with an increase in the cluster size.

A dissociation study¹⁴ showed that the Al_n clusters with $n = 7$ and 14 are more stable than clusters with neighbouring n values. The mass spectra exhibit clearly seen signals of the stable clusters Al_7^+ and Al_{14}^+ . The magic numbers $n = 7$ and 14 differ from those found for the alkali metal clusters, but agree with the shell model. Indeed, depending on the type of the potential for the motion of electrons, at $n = 8, 18, 20, 34, 40, 58, 68$ and 92 the set of closed shells includes 1p, 1d, 2s, 1f, 2p, 1g, 2d and 3s for the 'rectangular well' potential or $n = 8, 20, 40, 70$ for the harmonic oscillator potential. The aluminium atom has a valence of three and therefore the Al_7^+ cluster has twenty valence electrons, namely, $7 \times 3 - 1$ (with allowance for the cluster charge). This gives the first magic number, 7. Analogously, the closed shell of Al_{14}^+ cluster has forty-one valence electrons. Of course, the aluminium cluster has a more complex configuration compared to alkali metals because the interaction of the s- and p-valence electrons occurs.

The electron shell scheme also describes the oxidised aluminium clusters with $O=O$ or $O=Al$ bonds that reduce the number of valence electrons in the cluster by two. For instance, the cluster $Al_{15}O_2^+$ is more stable than other oxidised aluminium clusters. Here, the number of valence electrons in the closed electron shell is $3 \times 15 - 1$ (with allowance for the cluster charge) $- 4$ (two electrons per oxygen atom) = 40. The dissociation energy increases as the cluster size increases.

Reactivity of aluminium clusters. The interaction of aluminium clusters with hydrogen or oxygen molecules is an important cluster characteristic. Studies of these reactions can be useful in order to relate the shape of a cluster to its reactivity. The majority of experimental data point that the activation barriers to the reactions involving clusters are higher than the corresponding parameters for bulk material.¹⁴

Now we will consider the best studied reactions of aluminium clusters with oxygen as examples. Reactions of neutral clusters result in Al_nO_2 . Aluminium atoms or dimers react rapidly; the reactivity initially decreases with an increase in the cluster size and then increases. Reactions of positively charged clusters comprised of at most seven Al_2O^+ particles with oxygen produce Al_nO^+ cations as the major product. Possible reactions of larger clusters are shown below:

Here, the activation barriers are of the order of a few tenths of an electronvolt at $n = 3-25$.

Bulk aluminium is readily (almost barrierlessly) oxidised, *i.e.*, clusters are less reactive than bulk material. Reactions of negatively charged clusters with an excess of oxygen lead to stable products in the form of 13-, 23- and 37-atom clusters. This indicates that the shell structure of clusters affects their reactivities, namely, Al_{13}^- , Al_{23}^- and Al_{37}^- have 40, 70 and 112 valence electrons respectively that form closed electron shells in the harmonic oscillator potential. The shape of a cluster is also related to its reactivity. For instance, calculations of Al_7^+ cluster predict a distorted octahedral configuration in which all atoms are equidistant from the centre of mass in such a fashion that they

seemingly are on the surface of a sphere. This cluster is characterised by a closed spherical electron shell with 20 valence electrons. The next closed-shell structure is an icosahedral cluster Al_{13} . A feature of this stable structure is a large energy difference between the filled and unfilled orbitals, which ensures a low reactivity of this system.

Mercury clusters. Mercury clusters provide a unique possibility of studying an insulator-conductor transition. The mercury atom has a closed electron shell ($[Xe]4f^{14}5d^{10}6s^2$) and can be considered as a building block for forming the van der Waals bonds. At the same time, bulk mercury is a metal. Transition from the van der Waals to the metal bonds is accompanied by an increase in the cluster size and in the latter case the metal atom has a $[Xe]4f^{14}5d^{10}6s^{1.46}p^{0.6}$ configuration.

Similarly to alkali metals, silver and aluminium, the ionisation energy serves the key indicator of the properties of mercury. In Fig. 3 the results of ionisation energy measurements for Hg_n clusters (n from 1 to 43) are plotted *vs.* $1/r$.

Figure 3. Ionisation energies of clusters Hg_n plotted *vs.* inverse cluster radius.¹⁵

Dashed line corresponds to the relation for bulk material [$E_i(n \rightarrow \infty) \approx \phi + (e^2/r)$].

Mercury clusters with $n \leq 13$ are characterised by a decrease in E_i with increasing the cluster size. But in this case the E_i energies are appreciably different from the values predicted by the spherical metallic drop model. Moreover, extrapolation of the ionisation energy to $n \rightarrow \infty$ gives a value of 6.5 eV, which much exceeds the work function of an electron in bulk material (4.49 eV). At $n > 13$, the E_{in} sharply decreases and the experimental data approach the results obtained by the spherical metallic drop model.

The ionisation energy was determined from the results of Hartree-Fock MO energy calculations,¹⁶

$$E_{in} = E_n(v_t - 1) - E_n(v_t), \quad (8)$$

where $E_n(v_t)$ is the total electronic energy of an n -atom cluster with v_t valence electrons. It was found that

$$E_{in} = -\varepsilon_{HOS}(n) + \frac{e^2}{2r}, \quad (9)$$

where $\varepsilon_{HOS}(n)$ is the energy of the highest occupied shell. The existence of a critical cluster size (n_c) is assumed, *e.g.*, $n_c = 13$; at $n < 13$, the electron is localised on the atom, whereas at $n_c > 13$, it is delocalised. Thus, an increase in the cluster size is accompanied by an abrupt transition from insulator to conductor. The first term in Eqn (9) describes the changes in the ionisation energy due to the changes in the electronic structure for different cluster sizes and the second term describes the electrostatic contribution after shift of the energy levels upon ionisation $v_t \rightarrow (v_t - 1)$. At $n < n_c$, the atom emits electrons (Fig. 4) and thus the energy of the highest occupied level approaches the energy of the atom, whereas at $n > n_c$ electrons are delocalised and the $\varepsilon_{HOS}(n)$ value should be treated as the energy of the highest occupied MO (HOMO).¹⁶

Figure 4. Scheme describing ionisation for localised ($n < n_c$) and delocalised $n > n_c$ electronic states of Hg_n clusters.

Carbon clusters. A distinctive feature of carbon clusters consists in strong atom–atom interactions. Clustering of carbon atoms occurs much easier compared to all other elements, which is substantiated by, *e.g.*, the formation of carbon black in thermolysis of any carbon-containing structures. Carbon is one of the most abundant elements in the Universe (it ranks fourth after hydrogen, helium and oxygen). Additionally, this is the first stable element produced by thermonuclear fusion. Red giant stars emit a huge amount of carbon to interstellar space, and interstellar dust probably consists of carbon clusters. The clusters in question are also of interest as objects for basic research. In laboratories, they are produced by laser vaporisation or arc evaporation of carbon followed by mass separation using mass spectrometers. The mass spectrum obtained has a bimodal character, namely, one mode corresponds to small clusters (number of atoms $n < 24$) and the other mode ($n > 24$) corresponds to fullerenes.

Small carbon clusters. The mass spectra of small carbon clusters show a period of four carbon atoms, which manifests itself in the even–odd oscillations of the line intensities of the clusters synthesised.^{17–20} The magic numbers of the carbon atoms can be readily determined from the spectra (C_n , $n = 7, 15, 19$ and 23). Such mass spectra are obtained after ionisation of the neutral clusters synthesised by the laser vaporisation method by exposure to UV light. Photoinduced fragmentation studies showed that the process mainly results in neutral clusters C_3 . Larger particles can undergo fragmentation into C_5 clusters.

According to quantum-chemical calculations, neutral carbon clusters should have a chain structure up to nine atoms long, which then transforms into a ring. Taking into account the fact that a covalently bonded cluster tends to reduce the number of free bonds, the cluster shape is governed by the following factors: an increase in the number of carbon–carbon bonds in the cluster (although each succeeding bond is weaker than the preceding one), a change in the number of free bonds and production of strain upon formation of the ring-type structure. The C_3 cluster is considered linear.²¹ The formation of a carbon ring structure is accompanied by disappearance of free carbon bonds and production of additional strain in the cluster.

Ring-type structures are characteristic of larger clusters. The chain-to-ring transition should occur at $n = 10$; the even-numbered clusters tend to form rings at low temperatures.²²

The predicted (calculated) stabilities of particular forms of carbon clusters and transitions from chain to ring-type structures were also observed in the experiments involving the photoelectron spectra of negatively charged clusters.²³

Signals of C_3 clusters were detected in the optical spectra of comets. The signals of C_3 and C_5 clusters were observed in the spectra of interstellar space in the vicinity of some stars; vibrational spectroscopy data confirm the chain structure of the clusters.

The shapes of larger carbon clusters are calculated based on a certain quantum-mechanical model, *e.g.*, the Hartree–Fock model or the density of states approximation.²⁴ According to calculations, three isomers of C_{20} cluster can exist, namely, a ring-type, a bowl-shaped and a fullerene-like structure (Fig. 5).

Figure 5. Ring-type (a), bowl-shaped (b) and fullerene-like (c) isomers of C_{20} .

In principle, the smallest fullerene is a dodecahedron comprising twenty carbon atoms that form twelve pentagonal faces. The laser ablation experiments result only in ring-type clusters. Besides, calculations predict the existence of a bowl-shaped cluster with a graphite-like structure and a minimum number of free bonds. Yet another stable structure is a tetrahedral structure C_{28} . According to calculations, the C_{28} cluster behaves as a superatom with an effective valence of four and high reactivity to both encapsulation of metal atoms and *exo*-attachment of other atoms. Experiments with this cluster revealed the possibility of encapsulating an uranium atom; this structure is denoted by $\text{U}@C_{28}$.²⁴ Additionally, the scandium, titanium, zirconium, and hafnium atoms can be encapsulated inside the C_{28} . The existence of exohedral polymers of the $C_{28}\text{H}_4$ type was predicted.²⁵

Fullerenes. The first representatives of large carbon clusters, namely, fullerenes were discovered by Kroto, Smalley and Curl in 1985. Investigations were initiated by Kroto who used laser vaporisation and mass spectroscopy for production and study of small carbon clusters. He paid attention to a single spectral peak, which appeared under particular conditions for production of carbon clusters. This peak corresponded to the C_{60} cluster, which was called fullerene.^{26,27}

In the structure of C_{60} (Fig. 6), pentagons are embedded into hexagonal graphite sheets for which sp^2 -hybridisation is allowed. As a result, a hollow structure is formed, which has no free bonds and is stabilised through π -bonds. Equivalence of all atoms, unstrained character and the possibility of isolating all pentagons make the 5/6-ring structure of the C_{60} cluster unique. The next (in size) stable fullerene is C_{70} .

Figure 6. Structure of C_{60} cluster.

Formation of fullerenes. The first question that should be answered is as to how stable ordered structures are formed under high-temperature laser vaporisation and chaotic plasma conditions? Probably, graphite species removed by laser form hollow structures, but it is also not impossible that the fullerene formation mechanism is similar to the mechanism of carbon black formation. The kinetic models for growth of clusters from carbon atoms and cluster radicals present in plasma were elaborated.²⁸

The most energetically favourable shape of small cluster radicals is a linear chain. Such chains interact with one another, grow in plasma up to 20–30 atoms long and then undergo

spontaneous transformations to polycyclic aromatic rings or graphite sheets. These structures are preferred because the average coordination number of the carbon atom increases, but they also contain numerous free bonds. It is the decrease in the number of free bonds that makes the growth of such structures energetically favourable. If the density of carbon atoms is high, clusters will have reactive termini whose curvature is appropriate the most energetically favourable arrangement of transient states including matching of the edges of rolled sheets and formation of fullerenes of size up to the size of macroscopic carbon black particles. Such a random plasma process also permits formation of larger fullerenes, *e.g.*, C₁₈₀, C₂₄₀ or C₅₄₀, which can theoretically be stable.

Effective studies of the structure and properties of C₆₀ and heavier fullerenes became possible after the elaboration and improvement of the method for production of sufficient amounts of fullerenes by Kratschmer *et al.*²⁹ An arc discharge using graphite electrodes in helium atmosphere produces carbon black, which is then dissolved in benzene or toluene. Crystallisation of the solution gives gramme amounts of C₆₀/C₇₀ mixture in a 3 : 1 ratio and heavier fullerenes (2%).³⁰

Fragmentation of fullerenes. As mentioned above, fragmentation of small carbon clusters involves detachment of C₃ clusters. Fragmentation of fullerenes occurs by detachment of C₂ fragments owing to stability of the even-numbered clusters.^{31,32}

Based on the kinetic energies of products, the following estimates of the binding energy of C₂ with C₅₈⁺, C₆₀⁺ and C₆₂⁺ were obtained: 4.6 eV for C₅₈⁺, C₆₀⁺ and only 3 eV for C₆₂⁺ (see Ref. 33).

The C_n⁺ shell comprising five-membered rings loses a C₂ unit and transforms to the C_{n-2} shell. The fused five-membered rings transform to six-membered ones and two six-membered rings above and below these five-membered rings transform to five-membered rings. As a result, the total number of five-membered rings remains unchanged, as required for a closed shell upon the loss of a six-membered ring. This mechanism implies a fast surface reorganisation in order to join two five-membered rings.

The ionisation energies and the electron affinity energies of fullerenes (starting with C₆₀) do not show large-amplitude oscillations as in the case of metal clusters. This is probably due to rather large sizes of the former (*n* = 60).³⁴

Generally, the experimental data are in agreement with the spherical metal model, that is, an increase in the fullerene size causes a decrease in the ionisation energies and an increase in the electron affinity energies (*E*_A) that approach the calculated value of 5.37 eV. The average electronegativity (*E*_i + *E*_A)/2 = 5.2 ± 0.2 eV obtained from experimental data agrees with the results of calculations. The slopes of the plots of *E*_i and *E*_A vs. cluster size decrease on going to heavier fullerenes. One should expect deviations from the spherical drop model for those fullerenes (especially, heavy ones) whose shape differs from a sphere.

Taking account of symmetrical closed structure of fullerenes, an impression may be formed of these compounds as low-reactive species. However, this is not the case. Fullerenes react with, *e.g.*, metals and fluorine to form a variety of derivatives that can be classified into different structural types. These are endohedral fullerenes containing one or a few metal atoms inside the fullerene cage, exohedral fullerenes with functional groups attached from the outside of the fullerene cage and substitution fullerenes in which one or several carbon atoms of the fullerene cage are replaced by some metal atom(s).⁶

Noble gas clusters. Noble gas atoms have spherically symmetric electron shells. This is the reason for specific properties of the noble gas clusters. Here, clustering is due to the van der Waals forces that are responsible for the formation of molecular crystals at low temperatures (except helium atoms).

The interaction between two noble gas atoms separated by a distance *R* can be described by the Lennard-Jones potential

$$V_{LJ}(R) = \varepsilon \left[\left(\frac{R}{R_0} \right)^{-12} - 2 \left(\frac{R}{R_0} \right)^{-6} \right], \quad (10)$$

where ε is the depth of the potential well in the field in which atoms move, with a minimum at the distance *R*₀. This interaction can be treated as a contact of soft, weakly attracting spheres. The first term in Eqn (10) corresponds to repulsion between the filled orbitals and can be described by the Morse exponential potential. The second term corresponds to attraction of induced dipoles. The first excited electron state lies between 10 (for Xe) and 20 eV (for He); therefore, crystals formed from noble gas atoms are colourless and transparent.

The ground state of neutral noble gas clusters was simulated using the potential of pair interactions.³⁵

Figure 7 presents the most stable configurations of clusters of various size obtained from calculations. The cluster structures correspond to an isosceles triangle (*n* = 3), a tetrahedron (*n* = 4) and a trigonal bipyramid (*n* = 5). At *n* = 7, five-fold (pentagonal) symmetry arises, which is not observed for infinite crystal lattices. The most stable icosahedral structures begin with *n* = 13. Further increase in the cluster size leads to stable structures with *n* = 55, 147, 309, 561, ... The number of the nearest neighbours of an atom in icosahedron is larger than for all other crystal lattice symmetries. This is the reason for enhanced stability of icosahedral structures. Thus, the noble gas clusters obey the principle of close packing of atoms. As a consequence, the most stable clusters are formed and the magic numbers of atoms arise, namely, *n* = 13, 55, 147, 561, ...

Transition metal clusters. In contrast to the clusters considered above, transition metal clusters have a more complex electronic structure because it is formed by d- or f-electrons. The stability and reactivity of such clusters are governed by two series of magic numbers. One of them is related to the electron shell (as for alkali metal clusters) and the other is associated with the geometric factor (close packing), as for the noble gas clusters. Additionally, the ability of atoms to be in different oxidation states is of

Figure 7. Model structures of noble gas clusters of different sizes. Shown are the numbers of atoms in the structures.

particular value for the transition metals clusters. This factor is responsible for large deviations of the cluster structure from the shell model and difficulties in prediction of the critical sizes of stable clusters using the microscopic approach.

2. Critical sizes of liquid-phase clusters

The formation of liquid-phase nanoclusters (from liquid phase, solutions or melts) can be considered using the thermodynamic or microscopic approach. Both approaches give the critical nucleation and stabilisation sizes for clusters with sizes of a few nanometres. Additionally, by applying the microscopic approach in studies of clustering from solutions and cluster stabilisation by ligands, it is possible to find the most stable clusters comprising the magic numbers of atoms that manifest themselves to the greatest extent in the formation of molecular clusters.

a. Thermodynamics of cluster nucleation

Clusters nucleated from the liquid phase (in, *e.g.*, formation of micellar colloids) have a minimum critical size that is determined by the reagent concentrations, presence of stabilising ligands, surfactants, *etc.* In contrast to nucleation in an infinite volume, cluster nucleation in the closed volume of a nanopore or reverse micelle (see, *e.g.*, Ref. 36) leads to formation of clusters of minimum and maximum critical sizes. Such processes proceed faster than in the macroscopic space and the cluster size is controlled by the size of the closed volume. The minimum size of a nanocluster formed in a closed pore as a result of nucleation from solution or melt can be determined from the equation

$$n_{\min} = \frac{32\alpha^3}{3\rho^2\Delta\mu^3}, \quad (11)$$

where α is the density of the surface energy of the cluster, ρ is the density of the cluster and $\Delta\mu$ is the change in the chemical potential in the cluster formation. The maximum size can be determined from the relation

$$n_{\max} \approx \frac{n_0\Delta\mu}{2 + \Delta\mu}, \quad (12)$$

where n_0 is the number of atoms in the nanopore, involved in clustering (*i.e.*, the nanocluster size should increase with an increase in the nanopore size). At the same time the minimum critical size of a nucleus in the pore is governed by the thermodynamics of nucleation and by the initial concentration of the cluster-forming atoms in the pore space. As the pore size increases, a number of smaller clusters are formed. The rate of nucleation in the nanopore increases owing to a decrease in the potential barrier to nucleation (ΔG) caused by the effect of the pore wall (heterogeneity factor $K < 1$)

$$\Delta G = \frac{16\pi\alpha^3 K}{3\rho^2\Delta\mu^2}. \quad (13)$$

Thus, isolated nanoclusters of the critical sizes from one to a few nanometres³⁶ depending on the nanopore size and initial reagent concentration can form in porous materials with pore sizes of up to 10 nm.

b. Colloidal clusters and nanosystems

Colloidal nanosystems comprise metal and metal oxide sols, conventional and reverse micelles, microemulsions, nanoclusters in micelles and colloidal crystals.

Sols and sol formation. Metal sols are prepared in solutions after reduction reactions. In 1857 (see Ref. 37), Faraday obtained a red gold sol with cluster sizes from 2 to 50 nm by the reaction

Later on, Zsigmondy (see Ref. 37) synthesised monodisperse gold sols with variable cluster sizes by reducing gold salts with hydrogen peroxide and formaldehyde

The reduction involves two stages, (i) nucleation and (ii) growth of the new phase. By controlling the second stage it is possible to form a yellow (size 20 nm), red (40 nm) and blue (100 nm) gold sols.

Oxide sols are formed in the condensation reactions. An example is provided by the widely used hydrolysis of inorganic metal salts

Such sols can exist in the liquid phase for long without precipitation or coagulation due to involvement in Brownian motion of molecules in the solution, weak cluster–cluster interactions, charge repulsion and passivation of the surface. The size of sols formed is determined by the reaction conditions, the nature of the solvent and stabiliser, reaction duration and temperature and to a great extent by the supersaturation of solutions.^{37, 38}

The formation of nanoclusters is related to nucleation (homogeneous or heterogeneous) from solution. An increase in the nanocluster sizes to the maximum critical values [see Eqns (11) and (12)] and the prevention of coagulation are controlled by the surface tension that can be varied by passivating the surface. The range of possible passivators includes thiols, triphenylphosphine and its derivatives, phenanthroline, *etc.*, and various surfactants. In particular, the gold nanoclusters in the sol, prepared by reactions (14)–(16) and passivated by alkanethiols represented metal nanoclusters coated with a dense thiol monolayer. The monolayer self-assembles, which is accompanied by a change in the alkyl chain length in alkanethiols and in the thiol/metal ratio and affects the size of the metal nanocluster.

Colloidal gold clusters thus formed are octahedral or icosahedral single crystals with the face-centered cubic lattice.³⁹ This substantiates the fact that the formation and stabilisation of nanoclusters of the critical sizes obey the close packing principle (similarly to noble gases and molecular clusters). Silver, palladium and platinum sols were also obtained.

Drying silicon hydroxide sols and metal hydroxides or alcohols causes the formation of gel structures, *e.g.*, the known silica gel $n\text{SiO}_2 \cdot m\text{H}_2\text{O}$ or alkoxides Zr(OPr)_4 , Ti(OBu)_4 , Al(OPr)_3 . The sol–gel technique is employed for the preparation of nanomaterials and nanoceramics used in optical, electronic and magnetic devices and for the synthesis of catalysts. Gels are then used as matrices for preparation of nanomaterials, *e.g.*, catalysts coated with metal oxide clusters.

Micelles. Micelles are formed using surfactants that can adsorb on the interface thus reducing the interfacial tension. A surfactant molecule consists of a hydrophobic part and a polar group. The hydrophobic part includes hydrocarbon radicals $\text{C}_n\text{H}_{2n+1}$, $\text{C}_n\text{H}_{2n-1}$, $\text{C}_n\text{H}_{2n+1}\text{C}_6\text{H}_4$, *etc.*, containing at least eight carbon atoms. Depending on the nature of the hydrophilic group, surfactants are classified into cationic (containing primary, secondary, tertiary amines and quaternary ammonium bases), anionic (containing carboxyl, sulfoester, sulfonic acid groups, *etc.*) and non-ionic. The action of surfactants in aqueous solutions is based on structuring of the water molecules surrounding the nonpolar hydrocarbon radicals of the surfactants, which should cause a decrease in the entropy of the system. Since any system tends to a maximum entropy, at a certain critical micelle concentration (CMC) the water molecules and surfactant ions form associates that are called micelles (according to McBen's definition³⁷). Thus, micelles are also characterised by a critical size governed by the structuring of water and the surface tension.

Micelle formation causes a portion of structured water to release; this is accompanied by an increase in the entropy and a decrease in the free energy of the system. The presence of micelles in solution can be determined from the dependences of the surface tension, conductivity, density, viscosity, light scattering and other characteristics on the surfactant concentration. The CMC value

Figure 8. Structures organised as a result of the action of surfactants.

Surfactant monomers (1), micelle (2), cylindrical micelle (3), hexagonally packed cylindrical micelles (4), lamellar micelle (5) and hexagonally packed reverse micelles containing water molecules (6).

depends on the nature of the surfactant, the length of the hydrocarbon radical, the electrolyte and the pH value of the solution. The longer the hydrocarbon radical and the lower the polarity of the polar group the lower the CMC.

At the surfactant concentrations close to CMC, micelles represent spherical particles in which the polar groups contact water and the hydrophobic radicals form a nonpolar nucleus inside the micelles. There are various types of micelles, such as spherical, cylindrical, hexagonally packed and lamellar ones (Fig. 8).

Thus, micellar systems can exist in the form of one-, two- and three-dimensional nanostructures comprising tens to hundreds of molecules.

The molecules of the same surfactant can form different types of micelles in polar (*e.g.*, water) and in nonpolar solvents. Here, micelle formation at the surfactant concentrations higher than the CMC is due to the interaction between the polar groups of the surfactant. Hydrophobic (fatty) fragments of the surfactant molecules are directed outside the micelle and the polar groups are inside. As a result, a nanoreservoir is formed within the micelle, which can be filled with, *e.g.*, water. Such micelles are termed reverse micelles (see Fig. 8). Conventional and reverse micelles can be treated as oil nanodroplets in water and water nanodroplets in oil, respectively.

A valuable property of micelles is the ability to solubilise (*i.e.*, considerably enhance the solubility) hydrocarbons in aqueous micellar solutions or in solutions of reverse micelles in polar liquids. Solubilisation causes the formation of stable isotropic systems called microemulsions. The properties of substances significantly change upon solubilisation in micelles; as a consequence, the rates of chemical reactions also change. This phenomenon is called micellar catalysis. It is widely used in chemistry, biology, medicine and various technological processes.

The properties of microemulsions are to a great extent determined by the size and shape of the components of the dispersed phase and by the properties of the interfacial adsorption layers formed by the surfactant molecules. Microemulsions are characterised by high mobility and large interface surface area and can serve a medium for carrying out many chemical syntheses, *e.g.*, the syntheses of metal, oxide and metal chalcogenide nanoclusters.

Clusterisation in microemulsions. In a microemulsion system the dispersed droplets constantly collide, coalesce and split again, which results in the continuous exchange of their contents. The exchange occurring by collisions of nanodroplets or micelles is controlled by diffusion. It is governed by the interaction between the surfactant adsorption layers and by the flexibility of the interface. Reverse micelles and reverse emulsions are widely used for the synthesis of nanoclusters; here, the inner volume of the reverse micelle serves as a nanoreactor. This is achieved by mixing two identical reverse microemulsion systems, aqueous phases containing, *e.g.*, substances A and B that can react to give a

poorly soluble compound C. Coalescence of micelles is accompanied by exchange of A and B and thus formation of the new compound C (Fig. 9).

Figure 9. Scheme of reactions in reverse micelles.

Metal clusters can also be prepared by introducing a reducing agent (hydrogen or hydrazine) into a microemulsion containing a metal salt or by passing CO_2 or H_2S through emulsion. This procedure was used to obtain platinum, palladium, rhodium and iridium nanoclusters with the nanoparticle size 3–5 nm and bimetallic platinum/palladium clusters. Metal and semiconductor nanoclusters (*e.g.*, CdS, CdSe, CdTe, SnO_2 , TiO_2 , Fe_2O_3 , MoS_2 , HgS, InAs, GaP, GaAs, BiI_3 , SiO_2 , high-temperature ceramics, *etc.*) were prepared by the synthesis in reverse micelles.^{36,37}

The course of the nanocluster formation in microemulsions is affected by various factors. First of all, this is the aqueous phase/surfactant ratio in the nanosystem

$$W = \frac{[\text{H}_2\text{O}]}{[\text{Surfactant}]} \quad (18)$$

This is followed by the structure and properties of the solubilised aqueous phase, the microemulsion dynamics, the average reactant concentration in the aqueous phase and the nature of the surfactant. The sizes of the clusters formed in the cavity of a reverse micelle can be controlled by varying the size of the micelle. A linear dependence of the cluster size on W in the formation of CdS clusters was established.⁴⁰ A similar dependence was obtained in a study of the nucleation of metal oxides in nanopores.³⁶

The size of a cluster synthesised in reverse micelle depends on the nature of the surfactant. For instance, the nanosystem stabilised with sodium di(2-ethylhexyl)sulfosuccinate (AOT) was characterised by a smaller cluster size compared to the system stabilised with polyethylene glycol *p*-(*tert*-octyl)phenyl ether with $n = 10$ (Triton X-100).

Synthesis in reverse micelles offers considerable prospects for the preparation of nanoclusters of various chemical composition and shape. In particular, copper clusters of various shape can be obtained using water micelles stabilised with $\text{Cu}(\text{AOT})_2$ and

Na(AOT) in isooctane. They are mixed with a microemulsion of Na(AOT)-stabilised sodium borohydride. Mixing of the microemulsions leads to reduction of copper, the size of the copper cluster being dependent on W .⁴¹

At $W < 4$, the system contains only spherical droplets whose size is proportional to W . In the range from 1 to 12 nm the cluster diameter (d) obeys a linear relation $d \sim aW$. As the water content increases ($4 < W < 5.5$), micelles lose their spherical shape. As a result, spherical nanoclusters ($d = 8, 2$ and 12 nm) and cylindrical clusters 12 and 18.5 nm long are formed in the microemulsion system. Further increase in W ($5.5 < W < 11$) is accompanied by the formation of a continuous phase containing spherical nanoclusters ($d = 6.7\text{--}9.5$ nm) and rod-like nanoclusters of diameter 9.5 nm and length 22.6 nm. At $W > 11$, a lamellar structure built of rods of diameter $10\text{--}30$ nm and length $300\text{--}1500$ nm is formed. The synthesis of asymmetrical (rod-like, disk-shaped and ellipsoidal) clusters is of great scientific and practical interest. Using reverse micelles and emulsions, it is possible to prepare nanocomposites of the core-shell type.⁴²

Formation of micelles based on block copolymers. A block copolymer includes blocks characterised by strongly different solubilities. In particular, a diblock copolymer containing a hydrophilic and a hydrophobic component can form both simple spherical micelles and complex lamellar or two-phase structures in water. However, the block-copolymer-based micelles differ from the micelles prepared using simple surfactants by greater critical radii (from 7 to 15 nm) and higher stability.⁴³ A general scheme of preparation of such micelles is shown in Fig. 10.

Spherical micelles formed in a block-selective solvent consist of a core including an insoluble segment and a shell formed from the soluble block. Structural stabilisation of micelles occurs through polymerisation or cross-linking of the molecular fragments of the core or the shell and formation of the core- or shell-linked micelles, respectively. If the nanosystem is formed in the solid phase, the nature and size of aggregates depends on the relative size of each block and the molecular mass of the block copolymer. If a diblock copolymer has a short soluble block and a long insoluble block, twisted truncated micelles, vesicles, cylindrical elongated or flattened aggregates are formed; otherwise, spherical aggregates called star-like micelles are formed. In lyotropic systems it is possible to vary the solvent. For instance, an increase in the concentration of the block-selective solvent with respect to the concentration of the solvent affecting both blocks causes the formation of vesicles and cylinders.

Thus, the lyotropic system provides additional opportunities for controlling the formation of nanoscale objects.

Figure 10. Scheme of micelle formation involving block copolymers. Dissolution of monomeric block copolymers in block selective sorbent (1), formation of micellar aggregate (2), formation of cross-links in the block copolymer core (3) and formation of cross-links in the block copolymer shell (4).

Organisation and self-organisation of colloidal structures. Self-organisation and evolution of a colloidal nanosystem is due to the presence of a well-developed surface and thermodynamic instability of colloidal clusters. The excess free energy resulting from the existence of an interface between the dispersed phase and the dispersive medium stimulates various processes resulting in a decrease in the Helmholtz free energy (F). Ignoring the chemical potential, one can write

$$dF = -TdS + d(\alpha s), \quad (19)$$

where α is the surface tension and s is the surface area of the phase boundary. The thermodynamic condition $dF < 0$ can be met by reducing the interface surface area $\alpha ds < 0$ or the interface energy $\alpha ds < 0$; this is accompanied by a change in the entropy of the system. As the interface surface area decreases, the average cluster size increases and the colloid can undergo phase separation into two phases, solid and liquid. Coalescence of clusters is precluded by the energy barrier originating from electrostatic repulsion (E_{el}). For instance, if $E_{el} \gg kT$, the system is stable against aggregation and no larger particles are formed. At $E_{el} \ll kT$, each intercluster collision will lead to aggregation with the rate limited by the diffusion rate in the dispersive medium.

As the concentration of the electrolyte decreases, the coagulation rate decreases (slow coagulation). Coagulation of sols produces aggregates the fractal dimension of which depends on the type of coagulation. The fractal dimension of the aggregates obtained under slow coagulation exceeds that of the aggregates obtained under fast coagulation conditions, which indicates a better organisation in the former case. Long-range cluster-cluster interaction causes the formation of macroscopic ensembles that exhibit the phase stability. Such ordered objects were called periodic colloidal structures.⁴⁴

Surfactant solutions are appropriate for not only self-organisation of molecules in micelles, but also organisation of ordered nanostructures built of the metal and metal oxide clusters prepared by micellar technique. In particular, chemical reactions involving conventional and reverse micelles are widely used for the synthesis of colloidal clusters of 1 to 10 nm size. For instance, Ag_2S clusters are prepared using microemulsions containing two types of reverse micelles, with Na_2S and Ag -surfactant. Collisions, coalescence and exchange of the contents of the aqueous phases lead to formation of Ag_2S clusters whose size is controlled by the micelle size. The cluster size increases from 3 to 5.8 nm in the range mentioned above as the size of the reverse micelle increases,⁴⁵ which is consistent with the model of nucleation in a closed pore.

To release the nanoclusters from the micelle, the latter is destroyed by thiols, the resulting clusters are dissolved in appropriate solvents (e.g., benzene), the solution is filtered and then the solvent is evaporated. This procedure allows one to prepare monodisperse nanoclusters of size up to 10 nm passivated by thiols (e.g., dodecanethiol). Then, ordered nanostructures (colloidal crystals) are formed from these clusters immobilised on certain supports. Two- and three-dimensional colloidal crystals were synthesised from metallic gold, cobalt and silver clusters as well as from the metal oxide and metal chalcogenide clusters.³⁶ Alkanethiols, alkylphosphines and dithiols are used as nanocluster surface passivators.

Figure 11 presents photomicrographs of the Ag_2S nanostructure formed from passivated nanoclusters of size 5.8 nm. Like a conventional crystal, it can contain dislocations and defects. Two-dimensional nanostructures are close-packed monolayers and three-dimensional structures have a face-centred cubic lattice. The clusters assemble into crystals under the action of weak van der Waals interactions similarly to crystallisation of molecular clusters or noble gas clusters. Apparently, weak intercluster interactions are necessary for the formation of ordered nanostructures.

Yet another important condition for organisation of ordered cluster crystals is undoubtedly the monodisperse character of

Figure 11. Ag₂S nanostructure micrographs obtained at different magnification.⁴⁵

White arrow points to a defect in the crystal structure of colloidal crystal.

clusters. Colloidal clusters are used as key elements in nanoelectronics and nanooptics, as well as nanomagnets; because of this, requirements for the strength and stability of such structures become more stringent. Here, it would be more appropriate to work with covalent bonds and covalent crystals. However, the latter cannot be obtained by the methods employed in the crystallisation of colloidal nanocrystals (namely, by coating a substrate followed by evaporation). Ordered nanostructures with monodisperse nanopore or nanofibre size are prepared by template methods using micelles (templates) that set the size of the nanosystem. In this connection the formation of mesoporous silica and alumina is a characteristic manifestation of discrete critical sizes.

Mesoporous silica. Mesoporous silica is prepared by polycondensation of silicon compounds, *e.g.*, tetramethoxysilane or tetraethoxysilane (TEOS) in the presence of surfactant molecules that form a micelle and play the role of a template.⁴⁶ In particular, this procedure is used for fabrication of the family of molecular sieves M41S.⁴⁷ Hydrolysis of TEOS causes the formation of silicas on the surface of surfactant micelles. An example of the material for the micelle and template is provided by cetyltrimethylammonium bromide C₁₆H₃₃NMe₃Br. The phase diagram of the water–C₁₆H₃₃NMe₃Br system is shown in Fig. 12.

Bifunctional C₁₆H₃₃NMe₃Br molecules are amphiphilic, *i.e.*, they contain hydrophilic groups and hydrophobic tails that are directed to the centre of the micelle. The shape of micelles and the degree of micelle formation depend on the surfactant concentration. At high concentrations, the surfactant molecules aggregate to form liquid-crystalline (LC) phases with temperature-dependent structures. Removal of organic micelle template results in mesoporous silica with monodisperse pore size. The pore size can be varied by varying the hydrocarbon chain length in the surfactant molecule. For instance, the pore size in the nanosystem synthesised using C_nH_{2n+1}NMe₃Br (where $n = 8, 10, 12, 14, 18$) as template increases by 0.45 nm as the n value changes by 2.

Silica-based nanostructures also include critical-size particles determined by the principles of close (hexagonal or cubic) pack-

Figure 12. Phase diagram for the H₂O–C₁₆H₃₃NMe₃Br system with two critical micelle concentrations (CMC1 and CMC2).

ing. With block copolymers as templates, the pore size increases; using triblock copolymers, one can prepare pores 5–30 nm in diameter and nanostructures with hexagonal packing.

Mesoporous silicon films deposited from the mesophase (prepared similarly) to bulk material are of the greatest interest. In such films, mesopores represent channels aligned with the substrate surface due to minimisation of the film–substrate interaction energy. For instance, the widely used MCM-41 films have the (100) orientation; they can be prepared on the (110)-oriented silicon substrates.

Porous alumina. Anodic oxidation of high-purity alumina foil produces monodisperse alumina that self-assembles into a nanostructure with nanopores of size from 15 to 100 nm depending on the voltage applied (30 to 150 V).⁴⁸ Alumina membranes thus obtained serve as templates for fabricating, *e.g.*, nanowires. The fact that porous alumina is formed in various electrolytes has long been known,⁴⁹ however fabrication of material with controllable monodisperse nanopore size distribution and assembling templates began only recently. Electrolytic anodic oxidation of alumina surface followed by etching leads to the formation of an ordered hexagonal system of nanopores (channels).

Electrolytic anodisation is schematically shown in Fig. 13. The first stage of oxidation proceeds in an acidic medium and results in the formation of Al₂O₃ nanoclusters that form a discrete ordered structure on polished aluminium surface. The ‘bottom’ clusters merge with organised pore network of the same size in metallic aluminium. After etching of the oxide clusters the aluminium surface is covered with a hexagonally patterned network of pores with monodisperse size distribution. In the second stage of electrolytic oxidation the hexagonal pattern of the surface acts as a template for the growth of an oxide nanostructure that includes cylindrical nanopores with walls 10–30 nm thick and nanopores of size ranging from > 10 to 20 nm the surface of which is coated with alumina. The next stage involves removal of aluminium by, *e.g.*, mercury chloride. This results in an Al₂O₃ membrane with a honeycomb structure and closed channels that can be opened chemically or by using an ion beam. SEM images of such a membrane are presented in Fig. 14. The images show a

patterned structure with monodisperse pores (channels). Deviations of geometric parameters from specified values can be due to structural defects.

c. Molecular clusters

Initially, ligand-stabilised molecular clusters have been the subject of studies in the fields of coordination and structural chemistry. At the same time unusual structure and properties of these species, originating from the presence of a core of metal atoms, gave an impetus to the development of a separate field of science, cluster chemistry, possessing its own computational, synthetic and other methods of investigation. Interest in this type of clusters increased in connection with the development of nanochemistry and nanotechnology, which permit preparation of nanomaterials and fabrication of nanodevices based on molecular clusters. In this Section we will consider the structure and properties of molecular clusters of size 1–3 nm. Molecular clusters with metal cores and clusters based on metal oxides will be described separately.

Molecular metal clusters. The core of a molecular cluster is formed in accordance with the packing pattern of metal complexes and the principle of closest packing of atoms.⁵⁰

The largest molecular clusters are synthesised based on noble metals, palladium and platinum. The formation of their cores obeys the principle of closest packing of atoms.^{51,52}

The number of atoms in a nanocluster constructed in the form of regular 12-vertex polyhedron (cuboctahedron, icosahedron or anticuboctahedron) can be calculated from the expression

$$n = \frac{1}{3}(10N^3 + 15N^2 + 11N + 3), \quad (20)$$

where N is the number of layers around the central atom. Thus, the smallest close-packed core contains 13 atoms, that is, one central atom and 12 atoms in the first layer. Relation (20) gives a set of ‘magic’ numbers of atoms $n = 13, 55, 147, 309, 561, 923, 1415,$

2057, 2869, etc. corresponding to the most stable cores of metal clusters (similarly to the noble gas clusters). Indeed, the following clusters are known: 13-atom (single-layer) clusters $[\text{Au}_{13}(\text{diphos})_6](\text{NO}_3)_4$ (diphos is $\text{Ph}_2\text{PCH}_2\text{CH}_2\text{PPh}_2$) and $[\text{Rh}_{13}(\text{CO})_{24}\text{H}_3]^{2-}$ with icosahedral and cuboctahedral cores, respectively (see, e.g., Ref. 36); 55-atom (two-layer) clusters $\text{Au}_{55}(\text{PPh}_3)_{12}\text{Cl}_6$, $\text{Rh}_{55}(\text{PPh}_3)_{12}\text{Cl}_6$, $\text{Pt}_{55}(\text{AsBu}_3)_{12}$, $\text{Ru}_{55}(\text{PBu}_3)_{12}\text{Cl}_{20}$ with cuboctahedral cores; a 309-atom (four-layer) cluster $\text{Pt}_{309}(\text{phen}')\text{O}_{30 \pm 10}$ [phen' is the sodium salt of 4,7-bis(phenylsulfate)-1,10-phenanthroline] with a cuboctahedral core; a 561-atom (five-layer) cluster $\text{Pd}_{561}(\text{phen})_{60}(\text{OAc})_{180}$ (phen is phenanthroline) with an icosahedral core; a 1415-atom (seven-layer) cluster $\text{Pd}_{1415}(\text{phen})_{60}\text{O}_{\sim 1100}$ and a 2057-atom (eight-layer) $\text{Pd}_{2057}(\text{phen})_{84}\text{O}_{\sim 1600}$ cluster. The structure of the $\text{Pd}_{561}(\text{phen})_{60}(\text{OAc})_{180}$ cluster is schematically shown in Fig. 15.⁵³

Figure 15. Structure of giant cluster $\text{Pd}_{561}(\text{phen})_{60}(\text{OAc})_{180}$.⁵³ (1) Surface palladium atoms bonded to bidentate phen ligands; (2) surface palladium atoms nonbonded to phen ligands; (3) phen ligands.

Molecular clusters based on metal oxides. The cores of molecular clusters based on metal oxides are built of $\{\text{MO}_x\}$ polyhedral units, where M stands for the metal in high oxidation state. Polyhedra can interact with one another and thus form clusters comprising tens and hundreds of metal atoms. Large clusters are known for tungsten, vanadium and molybdenum oxides, the last-named being the largest.^{54,55} Most molybdates possess a mixed valence and form basic units, $\{\text{Mo}_8\}$ and $\{\text{Mo}_{17}\}$, which are then used for constructing larger clusters. An important feature of such clusters is the presence of the large fragments $\{\text{Mo}_{17}\}$. By linking them through various electrophilic groups, e.g., $\{\text{MoO}_2\}^{2+}$, one can obtain very large clusters. Using other electrophilic ions, such as Fe^{III} or V^{IV} , it is possible to form giant-size cluster fragments with the $\{\text{Mo}_{57}\text{M}_6\}$ metal core (M is iron or vanadium in different oxidation states), which can act as giant building blocks. In particular, a compound $\{(\text{NH}_4)_{12}[\text{Mo}_{45}^{\text{VI}}\text{Mo}_6^{\text{V}}(\text{MoNO})_6\text{Fe}_6^{\text{III}}\text{Fe}_{1.5}^{\text{II}}(\text{OH})_3(\text{H}_2\text{O})_{30}] \cdot 64\text{H}_2\text{O}\}_n$ was obtained. It contains the cluster fragment $\{\text{Mo}_{57}\text{Fe}_6^{\text{III}}\}$, which is similar to the structures considered above.

Using the basic cluster blocks, one can continue the cluster buildup.⁵⁴ For instance, cluster anions $[\text{Mo}_{154}(\text{NO})_{14}\text{O}_{448} \cdot \text{H}_{14}(\text{H}_2\text{O})_{70}]^{28-}$ were obtained. This giant ring-type anion consists of 140 octahedral bipyramids $\{\text{MoO}_6\}$ and 14 pentagonal

Figure 16. Structure of supramolecular system $\{\text{Mo}_{36}@\text{Mo}_{148}\}$ in polyhedral representation.⁵⁶

Light and dark octahedra denote $\{\text{Mo}_6\}$ and $\{\text{Mo}_8\}$ units, and pairs of $\{\text{Mo}_2\}$ units are given in gray.

bipyramids $\{\text{Mo}(\text{NO})\text{O}_6\}$. The equatorial diameter of the central cavity is ~ 2 nm. This anion can be treated as an assembly composed of 14 subunits. Each subunit is a $\{\text{Mo}_8\}$ fragment with the $\{\text{Mo}(\text{NO})\text{O}_6\}$ pentagonal pyramid at the centre. The $\{\text{Mo}(\text{NO})\text{O}_6\}$ unit shares vertices and edges with seven $\{\text{MoO}_6\}$ octahedra. Chains built of ring-type clusters can serve as ‘hosts’ for smaller ‘guest’ clusters, e.g., a $\{\text{Mo}_{36}\}$ cluster (Fig. 16). In this supramolecular nanocluster system $\{\text{Mo}_{36}@\text{Mo}_{148}\}$ the ‘host’ and the ‘guest’ are linked through 16 hydrogen bonds and four Na^+ cations arranged between the ‘host’ and the ‘guest’.

Giant ring-type clusters based on metal oxides possess some features differing them from the metal clusters. First of all, this is the presence of nanometre-sized cavities and the possibility of varying the nanoscale supramolecular organisation, well-developed hydrophilic surface suitable for sorption of various substances, e.g., activated charcoal, and replacement of the H_2O ligands by other molecules, which is accompanied by changes in the properties of the nanostructure. Finally, such systems are appropriate for modelling many catalytic reactions, because the composition of the surface of the cluster involved in the reaction is known with certainty.

Another group of molecular clusters based on metal oxides includes highly symmetric clusters (keplerates) with one central point⁵⁶ and layered structure. For example, giant spherical molecular clusters are built of 12-vertex icosahedra and pentagonal fragments.

The pentagonal fragments $\{(\text{Mo})\text{Mo}_5\}$ consist of the central pyramid MoO_7 which shares edges with five MoO_6 octahedra. In the presence of binuclear linkers $\{\text{Mo}_2^{\text{V}}\text{O}_4\}^{2+}$, an icosahedral molecular system is formed, which comprises 12 pentagons and 30 linkers. If the $\{\text{Mo}_2^{\text{V}}\text{O}_4\}^{2+}$ groups have acetate ions as bridging ligands, a spherical cluster of composition $[\text{Mo}_{72}^{\text{VI}}\text{Mo}_{60}^{\text{V}}\text{O}_{372} \cdot (\text{AcO})_{30}(\text{H}_2\text{O})_{72}]^{42-}$ is formed. Here, the central molybdenum atoms in the $\{(\text{Mo})\text{Mo}_5\}$ fragments occupy 12 vertices of an icosahedron and the $\{\text{Mo}_2^{\text{V}}\text{O}_4\}^{2+}$ groups form 30 edges of this polyhedron. Such clusters form polymer networks and serve as building blocks for constructing even larger aggregates. These blocks are sufficiently flexible and can change the shape upon minor changes of corresponding boundary conditions during the

synthesis; they can adjust the size and shape to one another. A giant oxomolybdate cluster composed of 386 metal atoms $\{\text{Mo}_{368}\}$ and 1880 non-metal atoms (ignoring hydrogen atoms) was synthesised.⁵⁷ The cluster similar in size to haemoglobin molecule was obtained by linking 64 $\{\text{Mo}_1\}$ fragments, 32 $\{\text{Mo}_2\}$ fragments and 40 $\{\text{Mo}(\text{Mo}_5)\}$ fragments. The formation of this cluster is accompanied by symmetry violation. The cluster structure includes a giant mixed-valence cluster anion (Fig. 17) $[\text{H}_x\{\text{Mo}(\text{Mo}_5)_8\{\text{Mo}(\text{Mo}_5)\}_{32}\{\text{Mo}_2\}_{16}\{\text{Mo}_2\}_8\{\text{Mo}_2\}_{8'}\{\text{Mo}_1\}_{164}\}]^{48-}$, where $\{\text{Mo}(\text{Mo}_5)_8\} \equiv \{\text{Mo}_6\text{O}_{21}(\text{H}_2\text{O})_6\}$, $\{\text{Mo}(\text{Mo}_5)\} \equiv \{\text{Mo}_6 \cdot \text{O}_{21}(\text{H}_2\text{O})_3(\text{SO}_4)\}$, $\{\text{Mo}_2\} \equiv \{\text{Mo}_2\text{O}_3(\text{H}_2\text{O})_2\}$, $\{\text{Mo}_2\}' \equiv \{\text{Mo}_2(\text{O})_2(\text{O}_{\text{br}})_3(\text{SO}_4)\}$, $\{\text{Mo}_2\}'' \equiv \{\text{Mo}_2(\text{O})_4(\text{O}_{\text{br}})(\text{SO}_4)\}$, $\{\text{Mo}_1\} \equiv \{\text{MoO}(\text{H}_2\text{O})\}$, $x \approx 16$.

Compound $\text{Na}_{48}[\text{H}_x\text{Mo}_{368}\text{O}_{1032}(\text{H}_2\text{O})_{240}(\text{SO}_4)_{48}] \cdot \text{ca.}1000 \text{ H}_2\text{O}$ crystallises in the $I4mm$ space group. Its unit cell contains two giant lemon-like cluster anions having an approximate symmetry D_4 with almost spherical central fragment $\{\text{Mo}_{288}\text{O}_{784}(\text{H}_2\text{O})_{192} \cdot (\text{SO}_4)_{32}\}$ (fragment B) and two ‘caps’ $\{\text{Mo}_{40}\text{O}_{124}(\text{H}_2\text{O})_{24}(\text{SO}_4)_8\}$ (fragments C). The B and C fragments have different local symmetry, D_{4d} and C_4 , respectively. The transition between two types of symmetry is shown in Fig. 17a. The anion consists of 6 building blocks mentioned above that form a cavity of size 2.5×4.0 nm, which can contain up to 400 water molecules. The use of giant ring-type and spherical molecular nanoclusters allows one to go to larger clusters possessing different properties on the one hand and to ‘tune’ the chemical reaction to proceed at the specified centres on the other hand. The use of such systems is also quite promising for carrying out the reaction inside the giant cluster cavity.

3. Critical dimensions of clusters formed in solid-phase reactions

Solid-phase nanoclusters are main structural units of any nanostructures. Processes resulting in the formation of solid-phase nanoclusters are not rare to occur. For instance, this can be melt or solution crystallisation, sintering, various martensite transformations, crystallisation from amorphous systems, formation of magnetic and ferroelectric domains and spinodal decomposition. All these processes obey the laws of thermodynamics and are accompanied by the ordering and self-organisation phenomena.^{58,59}

The fashion of assembling a condensed nanosystem from clusters strongly depends on the procedure for cluster formation. A nanostructure can be formed from individual clusters by compaction or nanostructuring of a bulk solid. These techniques are of great importance for the design of nanomaterials based on metals, alloys, oxides, ceramics, etc. In addition to the nanostructure formation studies, an important research aspect involves investigation of the mechanical, thermal, electronic and magnetic properties that are responsible for the quality and field of application of many structural materials.

a. Cluster nucleation in solids

Thermal decomposition of a metal compound at temperatures above certain critical (threshold) temperature is accompanied by the formation of a mobile reactive medium in which metal oxide (e.g., iron oxide) nanoclusters nucleate. The formation of clusters can be treated as nucleation from individual atoms in solution or melt within a confined volume (e.g., in a pore volume). The volume can be controlled by diffusion, which prevents the concentration fluctuation of the bulk medium (due to the change in the cluster size) from travelling a distance longer than $L \sim (Dt)^{1/2}$ (D is the diffusion coefficient) during the nucleation time (t). Here, it is this distance that can be considered as the size of the cell in which the cluster is confined; the components of the bulk medium cannot escape this cell.

For a system of non-contacting clusters the dependence of the Gibbs free energy (ΔG_{fc}) on the cluster radius (r) for one cluster in the course of atomic nucleation is given by

Figure 17. Structure of the $\{\text{Mo}_{368}\}$ anion in crystals in polyhedral (*a, c*) and ball-and-stick (*b, d*) representation.⁵⁷ Shown are different building blocks and regions with different symmetry; the building blocks include $\{\text{Mo}_1\}$, $\{\text{Mo}_2\}$ and $\{\text{Mo}(\text{Mo}_5)\}$.

$$\Delta G_{\text{fc}} = 4\pi r^2 \alpha_c - \frac{4}{3} \pi r^3 \rho_c \Delta \mu_c, \quad (21)$$

where α_c is the density of the free surface energy of the cluster, ρ_c is the density of iron atoms in the cluster and $\Delta \mu_c$ is the change in the chemical potential of iron upon transfer of one atom from the bulk medium to the cluster structure. It should be noted that in this representation the surface energy is independent of the cluster size and fulfilment of relation (21) implies that the laws of thermodynamics are applicable up to a cluster size of 1 nm.

Let the mixture contain N atoms per cluster, let n_0 out of N atoms be the iron atoms and let $n_c = (4/3)\pi r^3 \rho$ iron atoms be in the cluster structure. Then, at $N \gg n_0$ one has

$$\Delta \mu_c = \Delta \mu_c^0 + \ln \frac{n_0 - n}{N}. \quad (22)$$

Here $\Delta \mu_c^0$ is the change in the standard chemical potential of iron upon transition of one iron atom to the cluster structure, measured in units of kT .

Initially, clusters do not contact one another. Denoting the volume and the surface area of the non-contacting cluster by $V_{\text{fc}} = (4/3)\pi r^3$ and $S_{\text{fc}} = 4\pi r^2$, respectively, expression (21) can be rewritten in the form

$$\Delta G_{\text{fc}} = \alpha S_{\text{fc}} - \left(\Delta \mu_c^0 + \ln \frac{n_0 - n}{N} \right) V_{\text{fc}}. \quad (23)$$

The function ΔG_{fc} has a maximum at $r = r_{\text{cr}}$ and a minimum at $r = r_{\text{max}}$ (Fig. 18).

Relation (23) characterises the stages of cluster nucleation and growth in a weakly interacting system of non-contacting

Figure 18. Change in the Gibbs free energy plotted vs. increase in cluster size upon nucleation and subsequent sintering for $r_{\text{f}} = 1.75 r_{\text{cr}}$.

clusters. As the cluster size increases, clusters contact one another, thus initiating the sintering. The onset of sintering indicates a strong interaction between clusters. If the distance, $2r_t$, between the centres of clusters is constant, the surface area S_{sc} and the volume V_{sc} of a cluster contacting k neighbours are quite correctly given by

$$S_{sc} = 4\pi r^2 + k2\pi r(r_t - r), \quad (24)$$

$$V_{sc} = \frac{4}{3}\pi r^3 + k\frac{1}{3}\pi r(-2r^3 + 3r^2r_t - r_t^3).$$

The change in the Gibbs free energy in the sintering stage (at $r > r_t$) is

$$\Delta G_{sc} = \alpha S_{sc} - \left(\Delta\mu^0 + \ln \frac{n_0 - n}{N} \right) \rho V_{sc}. \quad (25)$$

Thus, the profile of the change in the free energy of the system per cluster in the whole range of changes in this parameter is described by relation (23) at $r < r_t$ and by expression (25) at $r > r_t$.

Figure 18 presents the dependence $\Delta G(r/r_{cr})$ for $r_t = 1.75 r_{cr}$ shown as an example. The curve has three minima separated by two maxima. The minimum at $r = 0$ corresponds to the initial state of the bulk medium. After passing the point r_{cr} , the system goes to the first stable state $r = r_{max}$ and corresponds to the equilibrium state of non-contacting clusters (this is possible at $r_{max} < r_t$). The third minimum corresponds to the system where clusters are sintered and each cluster has k contacts. Correspondingly, the first maximum at $r = r_{cr}$ describes the potential barrier to nucleation and the second maximum corresponds to the potential barrier to sintering. The shape of the potential barrier to sintering for $k = 6$ at different r_t values is shown in Fig. 19. At $r_t = 1.7 r_{cr}$, sintering occurs barrierlessly; at $r_t = 1.75 r_{cr}$, i.e., at lower proportion of clusters in the system, transition to sintering involves the overcome of a potential barrier; if the proportion of clusters is even lower ($r_t = 1.8 r_{cr}$), sintering does not occur because it requires an increase in the free energy.

Figure 19. Change in the Gibbs free energy plotted vs. increase in cluster size during sintering at different r_t values. $r_t = 1.7 r_{cr}$ (1); $1.73 r_{cr}$ (2); $1.75 r_{cr}$ (3); $1.77 r_{cr}$ (4); $1.78 r_{cr}$ (5).

Thus, the formation of a nanosystem involves two main stages. The first stage is characterised by weak interaction between clusters (from nucleation to the onset of sintering), while the second stage is characterised by strong interaction between clusters (after the onset of sintering). A change in the character of intercluster interaction causes many properties of the nanosystem to change; in particular, strong intercluster interaction and sintering produce considerable interfacial stresses. They are generated in the formation of an intermediate neck due to the surface tension⁶⁰ and obey the dependence $P = \alpha/x$, where α is the surface tension and x is the neck radius in the sintering of clusters. Assuming that for iron oxide $\alpha \sim 1 \text{ N m}^{-1}$ and $x \sim 1 \text{ nm}$, we get $P \sim 10^9 \text{ Pa}$. The excess pressure is also produced in the presence of defects and dislocations at the interface and reaches

a value of the order of 10^9 Pa for clusters of size $\sim 10 \text{ nm}$. The stress and pressure in the system of strongly interacting nanoclusters are the key parameters responsible for the formation and properties of the nanostructure. Probably, solid-phase metal, oxide and chalcogenide nanoclusters can be prepared by low-temperature solid-phase reactions carried out at particular r_t and r_{max} values.

Atomic nucleation and subsequent sintering can be accompanied by cluster nucleation (aggregation of clusters). Indeed, analysis of the changes in the free energy of individual clusters nucleation (ΔG_{fa}) into an aggregate of radius R performed as above for atoms [see Eqn (21)] gives

$$\Delta G_{fa} = 4\pi R^2 \alpha_a - \frac{4}{3}\pi R^3 \rho_a \Delta\mu_a, \quad (26)$$

where α_a is the surface tension of the aggregate, $\Delta\mu_a$ is the chemical potential of aggregate formation and ρ_a is the density of the aggregate.

Let the mixture contain N atoms per aggregate, let n_0 out of N atoms be iron atoms and let $n_a = (4/3)\pi R^3 \rho_a$ iron atoms be in the aggregate structure. Then, at $N \gg n_0$ one has

$$\Delta\mu_a = \Delta\mu_a^0 + \ln \frac{n_0 - n}{N}. \quad (27)$$

Here $\Delta\mu_a^0$ is the change in the standard chemical potential of iron upon transition of one iron atom to the aggregate structure, measured in units of kT . Assuming that, similarly to individual clusters, the cluster aggregates do not contact one another in the initial stage and denoting the volume and the surface area of the non-contacting aggregate by $V_{fa} = (4/3)R^3$ and $S_{fa} = 4\pi R^2$, respectively, expression (27) can be rewritten in the form

$$\Delta G_{fa} = \alpha_a S_{fa} - \left(\Delta\mu_a^0 + \ln \frac{n_0 - n}{N} \right) V_{fa}. \quad (28)$$

The function ΔG_{fa} has a maximum at $R = R_{cr}$ and a minimum at $R = R_{max}$ like the corresponding function for the atomic nucleation of isolated cluster (see Fig. 18). However, the r_{cr} and R_{cr} values should be significantly different. Indeed, for a solid with strong covalent bond between iron and oxygen atoms the surface tension of the iron oxide cluster should be much higher than the surface tension of cluster aggregates due to weak van der Waals forces. The surface tension for such aggregates is unknown, but we can assume that the surface tension of the iron oxide nanocluster is of the order of 1 N m^{-1} (see Refs 61 and 62) and the surface tension of the cluster aggregate lies between 0.073 N m^{-1} (water) and 0.02 N m^{-1} (see Ref. 63) typical of large saturated hydrocarbon molecules; these boundary values are due to the hydrogen and van der Waals bonds, respectively. Then, comparing Eqns (23) and (28), one can expect an increase in R_{cr} by a factor of 15 to 50 compared to r_{cr} . A similar conclusion can also be drawn from comparing the energy of the bond between iron and oxygen atoms in iron oxide cluster ($\sim 2 \text{ eV}$ for the covalent bond) and the energy of the bond between noble gas atoms ($\sim 0.1 \text{ eV}$ for the van der Waals interaction). The bond between the noble gas atoms can be treated as an approximation to the bond between cluster aggregates. Cluster aggregation can occur not only by nucleation. The existence of superaggregates comprising a few aggregates formed in accordance with Eqn (28) and characterised by even lower surface tension and, correspondingly, larger critical radii seems not to be impossible.

b. Design of nanoclusters and nanostructures based on iron oxide complexes

The AFM images of the nanostructures formed from iron oxide clusters, obtained at the decomposition temperature of iron oxalate ($T_d = 210^\circ \text{C}$) are shown in Fig. 20.

The section profiles of the AFM image of a surface area of $600 \times 600 \text{ nm}$ along the lines 1 and 2 revealed the formation of two types of nanostructures in the course of thermal decomposition. These are large aggregates of size $\sim 300 \text{ nm}$ and smaller

Figure 20. AFM image (a) of a nanostructure comprised of oxide iron nanoclusters, formed at iron oxalate decomposition temperature of 210 °C and profiles of the sections 1 and 2 (b).

aggregates of size 70–80 nm. Only one type of aggregates (of size 70–80 nm) was observed in a study of the region 300 × 300 nm. On both scales (especially, on the 300 × 300 nm scale) the AFM images show modulation of the aggregate profiles (roughness), which manifests itself as peaks (a total of 25–35 peaks) indicating that aggregates are composed of smaller particles, *i.e.*, nanoclusters whose limiting size was estimated at 2–3 nm. However, the AFM technique cannot look inside the cluster aggregate and determine its structure. To this end, ^{57}Fe Mössbauer spectroscopy was employed.

The Mössbauer spectra of the same nanostructure are shown in Fig. 21. At 4.2 K, the spectrum exhibits a magnetic hyperfine structure (HFS) characteristic of $\gamma\text{-Fe}_2\text{O}_3$. This structure was obtained using the simplest model involving two systems of magnetic HFS corresponding to the surface atoms and to the atoms in the cluster interior. Raising the temperature results in the spectrum diffusion, broadening of the lines of the magnetic HFS and a decrease in the magnetic induction at the nuclear site (B_{in}). Similar spectra are characteristic of superparamagnetic nanoclusters. This makes it possible to estimate the nanocluster size, from, *e.g.*, the simplest equation of superparamagnetism

$$\tau = \tau_0 \exp \frac{KV}{kT}, \quad (29)$$

where τ is relaxation time of the magnetic moment of the cluster, K is the magnetic anisotropy constant, V is the cluster volume and $\tau_0 = 10^{-9} - 10^{-10}$ s. The relaxation time τ was estimated using the slow relaxation model from the broadening of the components of the magnetic HFS.^{64,65} The spectra of nanoclusters measured at $T_d = 210$ °C were processed with the parameters $\Gamma = 0.62$ and 5.12 mm s^{-1} (Γ is the linewidth of the Mössbauer spectrum) determined from the spectra taken at $T = 4.2$ and 25 K, respectively. The value $\Delta\Gamma = 4.5 \text{ mm s}^{-1}$ at $T = 25$ K corresponds to

Figure 21. Mössbauer spectra of a nanostructure comprised of oxide iron nanoclusters, formed at iron oxalate decomposition temperature of 210 °C, obtained at 4.2 (a), 25 (b) and 80 K (c).

$\tau \approx 2.2 \times 10^{-9}$ s. Then for $\tau_0 = 10^{-9}$ at $T = 25$ K and $K = (1-2) \times 10^5 \text{ J m}^{-3}$ (see Ref. 66) the average cluster size is 1.4 to 1.7 nm. At 78 K, the τ value decreases and the Mössbauer spectrum exhibits only a quadrupole doublet.

An AFM study of larger clusters obtained at $T_d = 235$ °C revealed no formation of superaggregates including cluster aggregates. The size of the cluster aggregates was found to be nearly the same (~ 80 nm) as that of the nanoclusters obtained at $T_d = 210$ °C. The interior of these aggregates is difficult to see, but according to Mössbauer spectroscopy data, the nanostructure obtained at $T_d = 235$ °C is characterised by a higher superparamagnetic transition temperature (100 K); the nanocluster size was estimated at $\sim 4-7$ nm.

The AFM images become radically different for sintering of nanoclusters. The AFM images and profiles of nanoclusters in the initial stage of sintering ($T_d = 265$ °C) are shown in Fig. 22. The cluster size estimated in a study of a surface area of 500×500 nm in the system of strongly interacting clusters was 30 to 50 nm. A study on a larger scale (150×150 nm) and analysis of the profile of two contacting nanoclusters gave the half-width (14 nm) and height (6.4 nm) of a protrusion of the cluster. The Mössbauer spectra of this nanocluster structure (Fig. 23) are strongly different from similar spectra of two nanostructures considered above. Despite the absence of superparamagnetic relaxation, calculations for these large clusters using expression (29) lead to $\tau \gg 10^{-8}$ s and the spectra show a doublet characteristic of the paramagnetic or superparamagnetic state of the substance up to 100 K. Processing of the Mössbauer spectra obtained at $T = 78$ K revealed two magnetic hyperfine structures corresponding to $\alpha\text{-Fe}_2\text{O}_3$ and

Figure 22. AFM image of a nanostructure comprised of iron oxide nanoclusters. Scan area 500×500 nm (a); scan area 150×150 nm (b) and surface profile along the dashed line shown in Fig. 22 b (c).

γ -Fe₂O₃. At 120 K and higher temperatures (up to room temperature), the Mössbauer spectra can exhibit one system of magnetic HFS and a quadrupole doublet. A characteristic feature of the series of the Mössbauer spectra with the magnetic HFS (see Fig. 23) is transformation of the magnetic HFS to the quadrupole doublet corresponding to the paramagnetic state of the substance at temperatures much below the Curie or Néel points ($T_C = 965$ K, $T_N = 865$ K) of bulk α -Fe₂O₃ and γ -Fe₂O₃, respectively. Interpretation of this result will be given below.

The AFM images of larger nanoclusters obtained at $T_d = 500$ °C showed the formation of a nanostructure comprising strongly interacting nanoclusters of size ~ 300 nm in the sintering

stage. The room-temperature Mössbauer spectra of this system correspond to bulk α -Fe₂O₃.

III. Critical characteristics and properties of nanoclusters and nanostructures

1. Thermal properties

a. Thermodynamics of cluster melting

The state of a cluster can be considered using a simple thermodynamic model, which makes it possible to predict a number of unusual properties.^{36, 67, 68} The free energy difference between the liquid and solid states of the cluster is given by

$$\Delta G = 4\pi r^2 \Delta\alpha + \frac{4}{3}\pi r^3 \rho \Delta\mu, \quad (30)$$

where $\Delta\alpha = \alpha_l - \alpha_s$ is the surface energy difference and $\Delta\mu = \mu_l - \mu_s$ is the chemical potential difference between the liquid and solid state of the cluster. Clearly, at melting $\Delta\alpha < 0$ and $\Delta\mu > 0$. The dependence $\Delta G = f(r)$ is shown in Fig. 24.

The critical cluster size corresponding to the solid–liquid transition ($\Delta G = 0$) is determined using the expression

$$r_{cr} = 3 \frac{\Delta\alpha}{\rho \Delta\mu}. \quad (31)$$

At $r < r_{cr}$, the cluster is in the liquid state. From Eqn (31) it follows that the solid–liquid transition state cannot occur for certain matrix atoms (at $\Delta\alpha = 0$), where the cluster does not yet form. At the same time a free cluster should be characterised by the maximum $\Delta\alpha$ value. Any intercluster interactions will cause a reduction of this value and, hence, the critical cluster size, which determines the region of possible fluctuations of the solid and liquid states.

The stability of a cluster can be characterised by the changes in the pressure $\delta P = P_0 - P$ or temperature $\delta T = T_0 - T$, which

Figure 24. Change in the Gibbs free energy of an ensemble of atoms in a solid (1), isolated cluster (2) and a system of interacting clusters in the solid (3) and liquid (4) state plotted vs. cluster size. Interacting clusters (3) and clusters treated with surfactants (4).

correspond to a given $\Delta\mu = f(p, T)$ value. Due to these changes the phases equilibrate at a specified cluster size (P_0 and T_0 are respectively the pressure in the medium and the melting temperature of bulk material).

Replacing the function $\Delta\mu = f(P, T)$ by its expansion in powers of δp at the point P_0 with allowance for

$$\frac{\partial \mu_l}{\partial P} = V_l,$$

$$\frac{\partial \mu_s}{\partial P} = V_s$$

(V_l and V_s are the molecular volumes of the cluster in the liquid and solid state, respectively), one gets

$$\Delta\mu \approx -(V_l - V_s)\delta P. \quad (32)$$

Using the Clapeyron–Clausius relation

$$\frac{\partial P}{\partial T} = \frac{q}{T_0}(V_l - V_s), \quad (33)$$

where q is the latent heat of phase transition, one can write

$$\Delta\mu \approx -\frac{q\delta T}{T_0}. \quad (34)$$

Substituting Eqn (34) into expression (31), one gets a hyperbolic dependence of the changes in the phase transition temperature on the cluster radius

$$\frac{\delta T}{T_0} \approx -3 \frac{\Delta\alpha}{\rho q r}. \quad (35)$$

The relation (35) shows a decrease in the melting temperature with a decrease in the cluster size. Taking into account the plots presented in Fig. 24, we can suggest that at the specified temperature and pressure in the medium the initially stable cluster structure ($\Delta\mu > 0$) goes to a metastable state at $r < r_{cr}$.

A decrease in the melting temperature (down to room temperature) with a decrease in the cluster size was observed for gold, tin, CdS, etc. nanoclusters.^{69–71} Additionally, an electron microscopy study⁷⁰ of tin films revealed separation of the melting and freezing points of the cluster and the existence of a specific solid–liquid state characterised by enhanced mobility of clusters in the intermediate temperature range.

Specific features of the melting of clusters were studied taking iron oxide nanoclusters as an example. Figure 25 presents the results of a Mössbauer spectroscopy study of iron oxide nanoclusters obtained by solid-phase thermal decomposition of iron oxalate. The temperature dependence of the spectral area obtained for the γ -iron oxide nanocluster system shows a minimum at $T_d \approx 488$ K. The T_d value is related to the average size of the iron oxide cluster, namely, an increase in the cluster size from 1–2 to 6–8 nm causes T_d to increase from 488 to 508 K.

Figure 25. Mössbauer spectral area (A) for a nanosystem comprising iron oxide clusters formed upon decomposition of iron oxalate plotted vs. decomposition temperature T_d .

Open circles denote experimental data obtained in the absence, and closed circles, in the presence of surfactants: ethanol (1), isopropyl alcohol (2), Twin-65 (3), butanol (4) and sodium dodecylsulfate (5).

The right branch of the spectrum shown in Fig. 25 is associated with a decrease in the spectral area (on lowering T_d) and enhancement of atomic mobility in the cluster. It should be noted that the iron oxide spectra show no ‘broad component’ corresponding to the motion of the whole cluster as a result of, e.g., diffusion. The left branch of the $A = f(T_d)$ curve in Fig. 25 is associated with further reduction of T_d and, correspondingly, with a decrease in the cluster size up to breakdown of clusters into individual iron (Fe^{3+}) atoms, dimers and trimers (see Fig. 24, curve 1). Therefore, the minimum in the dependence curve $A = f(T_d)$ at $T_d = 488$ K is probably due to the onset of formation of the iron oxide clusters with reduced melting temperature.

As mentioned above, the state of the cluster surface is governed by the surface energy, and intercluster interactions should cause this parameter to decrease. Intercluster interactions also affect the intercluster atomic dynamics; however, they can weaken under the action of surfactants and the spectral area also considerably decreases upon the action of surfactants. Thus, weakening of intercluster interactions leads to enhancement of the cluster mobility and to a decrease in the melting temperature. Using relation (31), one can estimate the r_{cr} value corresponding to the onset of melting of γ -iron oxide clusters and compare it with the value found from the experimental Mössbauer spectra. With the following values for γ -iron oxide: $\rho = 5.18 \times 10^6 \text{ g m}^{-3}$ (see Ref. 63), $\Delta\alpha \approx 1 \text{ J m}^{-2}$ (see Ref. 62) and $q \approx 10^{-19} \text{ J m}^{-1}$ (see Ref. 63) one gets

$$r = \frac{aT_0}{\delta T}, \quad (36)$$

where $a = 0.1–1.0$ nm. At $T_m = 300$ K, one has $r = 0.1–1.2$ nm, which is in good agreement with the values 1–2 nm determined from the Mössbauer spectra.

Note also that the effect of adsorption-induced decrease in the strength of substances (Rehbinder effect), which manifests itself on the atom-molecular level owing to wetting and deformation of the surface under the action of surfactants, can be explained by the appearance of a specific solid–liquid transition state characterised by enhanced mobility of atoms.

b. Quantum-statistical model for cluster melting

The thermodynamic model for cluster melting is simple, but it provides no information concerning (i) the behaviour of the material the cluster is made of during transition from the solid to the liquid state, (ii) the predicted new solid–liquid state and (iii) the critical cluster size corresponding to the formation of this state.

Now we will consider some characteristics of the solid and liquid states. Unlike a solid, a liquid has a variable shape. The

liquid is inelastic and changes its shape under the action of weak forces. A solid exhibits an elastic response to the action of rather strong forces, but breaks down after an overload. The flow behaviour of the liquid implies the appearance of soft modes of atomic motions; most atomic vibration frequencies are much lower than the characteristic vibration frequencies of the atoms in the crystal lattice of a solid (10^{12} – 10^{13} s $^{-1}$). Applying this concept to clusters, one can expect that for a liquid cluster the density of states corresponds to lower frequencies and to lower frequencies of transitions between the states and shallow potential wells that limit such states. This allows the low-energy modes to execute slow motions that induce rearrangement and isomerisation of the liquid cluster. Yet another group of structural characteristics that differ for solids and liquids includes the angular and radial correlation functions. For solids, these functions show clearly seen peaks corresponding to the nearest and next-nearest neighbours. Liquids are characterised by a diffuse peak corresponding to the nearest neighbours and very weak peaks corresponding to more distant atoms. These criteria are also applicable to clusters when identifying the solid or liquid state. The difference between the solid and liquid states of a cluster can also be characterised by the ease of exchange in an atom or molecule with an identical species at another position of the cluster and, correspondingly, by the time taken for the process. For most materials, clusters are in the solid state at low temperatures and energies or in the liquid state at high temperatures and energies. Clusters can exist in some intermediate state ('slush') that differs from both the solid and liquid states and can be detected and studied in, *e.g.*, computer experiments.

The phase equilibrium in clusters can be studied using the thermodynamic and dynamic approaches, which depends on the characteristic times of computational procedures. In the case of static equilibrium one can employ the thermodynamic approach, namely, consider the change in the Helmholtz free energy (ΔF) of an ensemble of clusters comprising n atoms each,

$$\Delta F = \Delta E - T\Delta S, \quad (37)$$

where ΔE is the change in the internal energy upon the change in the state of the cluster material and the entropy S is calculated as follows:

$$S = kT \ln Z, \quad (38)$$

where

$$Z = \sum g_i \exp \frac{E_i}{kT} \quad (39)$$

is the partial function which sets the distribution over the states of the system and g_i describes the degeneracy of the energy level E_i . Quantum-statistical calculations of the function $Z = f(T)$ have been a subject of numerous studies. Knowing the partial function, one can determine almost all parameters of the equilibrium system with N states at a given temperature T . Since a cluster is characterised by a much smaller number n compared to a bulk solid, it is quite natural to expect that Z is calculable. For instance, knowing the vibrational and rotational energy levels of the cluster and the corresponding degeneracies, one can calculate the free energy of the cluster.

The energy distributions over the states of a solid and a liquid are significantly different. At low temperatures, the density of states for the solid is higher than for the liquid, but the situation reverses at high temperatures. The equilibrium transition from the solid to the liquid state occurs at the temperature T_{eq} . Therefore, at low temperatures the energy change ΔE is governed by the vibrational and rotational energy levels of the solid. As the temperature increases, the entropy factor (disordered motions characteristic of liquids) dominates. The T_{eq} value (or the melting point of the cluster) depends on the model for calculation of the states of the solid and liquid and on the number of states, *i.e.*, on the cluster size. At $T = T_{eq}$, both phases (solid and liquid) coexist

Figure 26. Partial functions (Z) of a solid (1) and liquid (2) cluster plotted vs. temperature.

in the system. The temperature dependence of $\ln Z$ for this model is shown in Fig. 26.

In fact, if we have a model for calculating the energy level and degeneracies, the energy and other thermodynamic parameters can be calculated as certain averaged thermodynamic characteristics that can be more reliable than those determined for individual energy levels and degeneracies.

In addition to the studies of the solid and liquid states of clusters it is of great interest to investigate the transient region and the conditions for stability of these two forms. Here, one should calculate their free energies and find minima corresponding to stable states. The free energy minimum is determined using the non-rigidity parameter of the cluster. The non-rigidity parameter (γ) can be determined, *e.g.*, phenomenologically by comparing two specified spectroscopic frequencies or on the microscopic level by establishing the degree of disorder and the density of defects. Both methods should give correct γ values for the limiting cases of rigid solid ($\gamma = 0$) and non-rigid liquid-like ($\gamma = 1$) states.⁷² After introduction of this new parameter of the energy of state the partial functions and the free energies become some functions of γ .

Calculations for the solid state can be carried out using the Einstein or Debye models or the harmonic oscillator model, which lead to qualitatively correct description of the equilibrium state of the cluster. Liquid state calculations are performed in the framework of the Gartenhaus–Schwartz model,⁷² which was initially proposed for the atomic nucleus. This pair interaction model applied to an n -atom cluster gives equidistant energy levels with a degree of degeneracy of $(3n-3)$. Analysis of the results obtained using this model showed that the density of cluster states changes differently as the temperature and energy increase; namely, the density of the liquid cluster states increases. Changes in the free energy $F(T, \gamma)$ with an increase in temperature should be studied taking into account the following: only low-lying levels of the solid cluster are populated at low temperatures; the free energy should be a monotonically increasing function of γ ; and the free energy of the solid state is lower than that of the liquid state. However, if the temperature increases, the free energy near the non-rigid limit of variation of the parameter γ decreases due to a greater contribution of the $T\Delta S$ term in the expression for the free energy (37) owing to a large number of the available non-rigid cluster forms. In this case near the non-rigid limit the changes in γ at certain temperature are given by

$$\frac{\partial F(T, \gamma)}{\partial \gamma} = 0.$$

This temperature was termed the freezing temperature (T_f). The solid state is stable only at temperatures below T_f . At temperatures above the freezing point, the function $F(T, \gamma)$ has two minima, one near $\gamma = 0$ and the other near $\gamma = 1$. Each minimum corresponds to a locally stable form, which can be compared with, *e.g.*, a stereoisomer. The system will contain two forms in the equilibrium, a solid and a liquid, with a ratio of

$$\frac{[\text{solid form}]}{[\text{liquid form}]} = K_{\text{eq}} = \exp\left(-\frac{\Delta F}{kT}\right), \quad (40)$$

where $\Delta F = F_{\text{liq}} - F_{\text{sol}}$.

These two forms exist in a dynamic equilibrium at which the cluster spends some time in the solid or in the liquid state. At the equilibrium temperature T_{eq} , one has $\Delta F = 0$ and the ratio (40) equals unity. At temperatures between T_f and T_{eq} the solid phase dominates and at temperatures above T_{eq} , the liquid state is preferred. As the temperature increases, the energy of the system decreases until the temperature reaches T_m . Above T_m , there exists only the liquid state of the cluster and the dependence $F(T, \gamma)$ is a monotonic function which decreases as γ increases.

The free energy is plotted vs. γ at different temperatures including T_f and T_m in Fig. 27. With these plots, one can imagine the cases where a cluster has a particular freezing temperature (only solid forms are stable below it) and a particular melting temperature (only liquid forms are stable above it). It should be noted that the melting and freezing temperatures of the cluster are different.

Figure 27. Free energy plotted vs. non-rigidity parameter γ for several temperatures.

In principle, the description given above is suitable for those clusters which can have well-distinguishable solid and liquid forms and spend in both states a considerable time sufficient to detect them. Actually, only a few clusters meet these conditions.⁷³ This was shown to be true for the simplest noble gas clusters Ar_7 , Ar_{13} , Ar_{15} and Ar_{19} . Other clusters, namely, Ar_8 and Ar_{14} are characterised by the potential energy surfaces having the shape of a potential well with large 'clapped-out' stair-steps which preclude the formation of stable solid or liquid states. Yet another type of clusters, Ar_{17} , rapidly fluctuates between the solid and the liquid states. Here, it is impossible to discuss the existence of the solid and liquid phases because only the 'slush' state is observed.

It is also interesting to consider the temporal aspect of the existence of the solid and liquid phases in clusters and transitions between them. How much time does it take to detect a phase? Of course, the question cannot be answered within the framework of the thermodynamic approach; one has to re-consider the dynamics of the process. All characteristics should be determined by the time necessary for equilibration of the process (relaxation time) and the measurement time. If the observation times are longer than the relaxation time, it is possible to obtain a time-averaged picture of individual phases; otherwise, pictures characteristic of a given temperature with variable phase ratio are obtained. Experimental data on the melting of clusters and existence of the

solid-liquid state corresponded to long observation times ($> 10^{-7}$ s). Similar data were obtained by measuring the spectral linewidths in the optical range. The lines of the probe molecules (e.g., carbazole) attached to argon clusters broadened and shifted to lower frequencies, which was interpreted as melting of argon clusters.⁷⁴

2. Defects and stresses in nanostructures

The appearance of numerous dislocations, defects and intercluster stresses in nanostructures is due to the presence of well-developed interfaces. The density of the interface boundaries (and dislocations associated with them) can be rather high, e.g., $\sim 10^{19} \text{ cm}^{-3}$ for a nanostructure comprised of 7 nm-clusters. Intercluster interactions or contacts between the cluster and its neighbours produce stresses and an excess pressure at the cluster boundaries. Additionally, assuming that the concentration of dislocations in a cluster is determined by the ratio of the cluster surface area to the cluster volume, the excess energy density of the cluster (ε_d) is³⁶

$$\varepsilon_d = \frac{Gb^2}{4\pi(1-\nu)} \ln \frac{R}{R_0} \frac{1}{r}, \quad (41)$$

where G is the shear modulus; b is the Burgers vector characterising the magnitude of the shift of the atoms of an edge dislocations ($b = a/\sqrt{2}$, a is the lattice constant); ν is the Poisson coefficient (usually, 0.3); R is the maximum distance at which the influence of dislocations is still retained; R_0 is the minimum dislocation size; and r is the cluster size.

Thus, in this approximation the excess energy density decreases as the cluster size increases and approaches zero for bulk material. It should be noted that the applicability of this approach to small-size nanoclusters is limited by the thickness of the surface layer of the cluster (which is equal to, e.g., the lattice constant a), i.e., Eqn (41) can be used only for calculating the excess energy of clusters at $r > a$.

When studying the influence of defects and dislocations on the properties of nanostructures, it is interesting to consider the relation between the size of the nanosystem and the density of defects in it. Here, it is convenient to use the thermodynamic approach, which takes into account the chemical potential and the excess energy of the cluster surface. The excess energy gives rise to excess pressure, which equals 1 GPa for 1 nm-clusters. The nanocluster is considered as being surrounded by atoms from the atomic structure and defects (impurity atoms, vacancies, dislocations). It is assumed that the key source of defects is the cluster surface and that defects can be redistributed between atoms inside the cluster, at interfaces and in the intercluster medium. The chemical potential of defects confined within the cluster can be written as

$$\mu_v = \mu_v^0(P) + kT \ln c_v, \quad (42)$$

where P and c_v are respectively the pressure and the defect concentration inside the cluster and μ_v^0 is the standard chemical potential. The chemical potential of the intercluster medium is given by

$$\mu_s = \mu_s^0(P_0) + kT \ln c_s, \quad (43)$$

where P_0 , c_s are respectively the pressure and the defect concentration in the intercluster medium and μ_s^0 is the standard chemical potential. At equilibrium

$$\mu_v = \mu_s, \quad (44)$$

it is assumed that the total number of defects in the nanostructure (c_0) is constant; therefore, the concentrations c_s and c_v are related to each other as follows:

$$c_s = c_0 - \frac{1}{q} c_v, \quad (45)$$

where $q(r) = (1 + R/r)^3 - 1$ (R is the thickness of a layer of the intercluster medium).

The pressure drop between the inside and outside of the cluster shifts the equilibrium in the nanosystem and one has

$$\mu_v^0(\delta P) = \mu_v^0(0) + \delta P v, \quad (46)$$

where v is the defect volume, $\delta P = P - P_0 = 2\alpha/r$ (α is the average surface tension); then one gets

$$\frac{c_v}{c_0} = \left\{ \frac{1}{q(r)} + \exp \left[\frac{\Delta\mu^0(P_0) + 2\alpha v/r}{kT} \right] \right\}^{-1}. \quad (47)$$

The dependence of c_v/c_0 on the cluster size in the r/a units (a is the lattice constant) is shown in Fig. 28. Calculations were carried out assuming $a = 2 \times 10^{-10}$ m for the metal and 5×10^{-10} m for the oxide, $\alpha = 1$ N m, the defect volume $v \sim a^3$ and $\Delta\mu^0 = 0$. The maximum defect concentrations were found for the cluster sizes ranging from 10 to 50 nm; therefore, such clusters have the highest excess energy. The model considered can be explained with ease as follows. In ~ 100 nm-clusters, the defect concentration is low due to the small specific surface area of these species. If the cluster size is < 10 nm, the specific surface area is large enough, but the surface pressure displaces defects from cluster volume; therefore, small clusters are defect-free objects, which was confirmed experimentally.

Figure 28. Defect concentration in cluster plotted vs. relative cluster radius for oxide (1) and metal (2) clusters.⁷⁵

The presence of defects in nanostructures and their relation to structural transformations in nanosystems can be determined by both macroscopic methods (by, *e.g.*, measuring the diffusion rate of a tracer through a macrolayer of a chemical substance or the total magnetic susceptibility of the nanosystem) and microscopic techniques (by, *e.g.*, positron annihilation or Mössbauer spectroscopy).^{76, 77}

3. Mechanical properties of nanoclusters and nanostructures

Among the mechanical properties of nanoclusters and nanostructures, high hardness and superplasticity should be pointed out. The hardness of a material characterises the resistance to plastic deformation and is measured by indenting with a harder material. The Vickers hardness (H_V), which is used in the text below for characterisation of nanomaterials, is measured from the depth of an indentation on the surface after unloading, being mainly determined by the yield point of the material σ . The grain size of a material is an important characteristic of the microhardness, which obeys the Hall–Petch law,^{78, 79}

$$\sigma = \sigma_0 + k d^{-1/2}, \quad (48)$$

where σ_0 is the internal stress, which precludes the motion of a dislocation in bulk material and k is a constant. At temperatures much lower than the melting point of the material, the Vickers hardness is proportional to the yield point. Then one has

$$H_V \approx H_0 + k d^{-1/2}, \quad (49)$$

where H_0 and k are constants.

If deformation occurs by diffusive slip, at temperatures that are much lower than the melting temperature the equation for the deformation rate has the form

$$\frac{d\varepsilon}{dt} = \frac{b\sigma v R D}{k_B T d^3}, \quad (50)$$

where b is the coefficient of proportionality, σ is the stress applied, v is the atomic volume, R is the grain boundary thickness and D is the grain boundary diffusion coefficient.⁸⁰

By extending the action range of Eqns (48)–(50) to nanostructures acting as grains, one can assume that the mechanical properties of nanostructures should be strongly different from those of bulk materials. A decrease in the cluster size should first of all affect the hardness of the nanostructure, which should also increase. At the same time of great importance for nanosized systems is the diffusive slip of nanocrystallites; intensification of this type of motion causes a considerable increase in the deformation rate. The stress–strain properties of a nanomaterial are determined by the relation between the yield point and the deformation rate; therefore, there should exist a critical cluster size corresponding to the maximum hardness of the nanomaterial. Yet another factor favouring an increase in the deformation rate is an increase in the diffusion coefficient with a decrease in the cluster size.

A nanostructure can be several times harder than coarse-grain materials. For instance, the hardness of metallic Ag, Cu, Pd, Se, Fe and Ni increased as the cluster size decreased to 4–6 nm according to the Hall–Petch law. However, if the nanocluster size is increased by annealing the same sample, the Hall–Petch law holds only for $d > 12–20$ nm.⁸¹

Superplasticity studies of metal oxides and ceramics are of great interest. Using the property of superplasticity, one can fabricate ceramic items of complex shape (*e.g.*, with internal cavities and variable curvature) with high accuracy. The superplasticity arises upon nanostructuring of materials; additionally, it increases if nanoparticles are dispersed within amorphous phase and the nanocrystalline grain boundaries are disoriented. Ceramics becomes superplastic at a grain size of less than 1 μm , and the grain size being retained with an increase in the temperature.⁸²

High strength and superplasticity can be explained using the ‘extremal’ dependence of the defect concentration and, hence, the excess energy on the cluster size (see Fig. 28). Indeed, nanosystems composed of small clusters (size less than 10 nm, ignoring diffusion mobility) contain a low proportion of defects and dislocations and exhibit record hardness. At the same time, nanosystems built of clusters of intermediate size ($10 < d < 100$ nm) have the maximum defect concentrations, which predetermines the record plasticities. Summing up, superhard materials should be fabricated using nanosystems containing nanoclusters with $d < 10$ nm, whereas superplastic materials should be prepared involving nanosystems comprising nanoclusters with $10 < d < 100$ nm.

4. Electronic-optical properties

a. The conductivity of nanostructures

Transition from a bulk material to a nanomaterial involves separation of electron energy bands into subbands and individual electron energy levels. Transition from individual atoms and molecules to nanoclusters is accompanied by broadening of energy levels and formation of energy band structure. The appearance of discrete electron energy levels is due to limitation of the mean free path of electrons and characterises the quantum confinement effects in nanoclusters. As the cluster size decreases, the quantum confinement effects cause a decrease in the conductivity and the appearance of a Coulomb barrier to one-electron

transitions between the energy levels separated by kT and higher energies. This barrier is determined by the energy of electrostatic interaction of the tip of a tunnelling microscope used for studying the one-electron conductivity of clusters,

$$E = \frac{e^2}{2C}, \quad (51)$$

where $C \sim r$ is capacitance of the cluster–tip system. This technique was employed to obtain stepwise I – V curves for clusters of size of a few nanometres. Here, the number and height of steps increase as the cluster size and temperature decrease. Starting from certain critical size, reduction of the cluster size is accompanied by the loss of metallic properties and transition to dielectric molecular state.

One-electron transitions between clusters can be induced by, *e.g.*, thermal excitation. Using parameters of such transitions, it is possible to estimate the critical cluster size. Namely, assuming that $C = d_{cr}$ in relation (51) and the electronic transition energy $E_e \geq kT$, the critical cluster size equals ~ 2 – 3 nm at 300 K and ~ 200 nm at 4.2 K. The estimate of the critical cluster size at low temperatures (17 nm) is nearly an order of magnitude larger than the size of a colloidal cluster. This is due to the appearance of electron energy bands in these clusters and inapplicability of the one-electron transition model. This estimate also much exceeds the results obtained at high temperatures for mercury.

Weakening of the conducting properties is also due to the scattering of conduction electrons by the cluster surface, which is enhanced with a decrease in the cluster size and thus hampers separation of the contribution of one-electron conductivity and determination of the corresponding critical cluster size. The formation of nanostructures from nanoclusters is accompanied by retention of the factors favouring a decrease in the number of charge carriers and their scattering by the intercluster boundaries. Additionally, new factors appear, which can induce the tunnelling electron transitions between adjacent nanoclusters, appearance of charges, *etc.* Nanomaterials prepared by compaction of metal nanoclusters exhibit a noticeable decrease in conductivity compared to that of bulk materials. However, this method of fabrication of nanostructured conducting materials offers no prospects for the design of nanomaterials with controllable electrophysical properties. This requires the use of solid state chemistry and cluster chemistry methods.

The conductivity of three-, two- and one-dimensional nanostructures. Promising methods of application of nanocluster structures as conducting materials involve the assembly of different-dimension nanostructures with molecularly controlled conductivities.

Organised conducting or semiconducting structures of atomic or molecular crystals are well known. However, it is difficult to force nanoclusters to form nanocrystals under normal conditions. In the text above we have considered the possibility of organisation of (i) silver, silver sulfide, *etc.* nanocrystals obtained by reverse micellar technique or (ii) ordered nanostructures based on semiconductor nano-islands or (iii) nanowires on epitaxial surface. An efficient method of fabrication of organised three-dimensional conducting cluster structures is provided by the crystallisation of ligand-stabilised semiconductor chalcogenide clusters of particular size. An array of clusters separated by the ligand shells can be schematically represented by a sequence of potential wells containing ground-state and excited-state electron energy levels. In the ground state the valence electrons are localised. In the excited state, tunnelling through dielectric medium is possible. This shows that the conductivity can be controlled by varying the intercluster distance using different ligands (such ligands are called spacers).

As an example, we will consider the change in the conductivity (the Coulomb barrier) for Au_{55} -based molecular cluster crystals with spacers of different length (Fig. 29).⁸³ The crystals studied showed a noticeable decrease in the conductivity (increase in the Coulomb barrier) with elongation of the spacer. These data

Figure 29. Correlation between cluster distance and Coulomb gap.⁸³ Open circles correspond to clusters (1, 2) and systems (3, 4):⁸³ $\text{Au}_{55}(\text{PPh}_3)_{12}\text{Cl}_6(\text{Au}_{55})$ (1), $\text{Au}_{55}(\text{Ph}_2\text{PC}_6\text{H}_4\text{SO}_3\text{Na} \cdot \text{H}_2\text{O})_{12}\text{Cl}_6(\text{Au}_{55}^*)$ (2),

confirm the efficiency of the concept of directed change in the conductivity of a molecular cluster crystal by varying the spacer.

One-dimensional cluster nanostructures can play the role of quantum wires; a feasible example is provided by carbon nanotubes. A method of fabrication of quantum wires based on nanoporous anodised alumina (the preparation of the material was considered above) also seems to be quite promising. Technologically, both the pore size and the pore length can be controlled on the nanometre length scale.⁸⁴ Filling pores with clusters provides a nanowire distribution density of 10^9 – 10^{10} per cm^2 and separation by dielectric alumina matrix. The main problem in fabricating such nanowires, that is, breakdown during the growth, can be solved by soaking the membrane with clusters *in vacuo* or using electrophoresis. A drawback of the vacuum technique consists in evaporation of the solution containing clusters, which produces voids in the membrane channels. In the case of electrophoresis one side of the membrane contacts a metal, *e.g.*, gold or aluminium, thus acting as a cathode to which clusters move. This allows the whole channel to be filled, but breaks are also possible due to large membrane thickness. For instance, a membrane 10 μm thick with channels 10 μm long should contain at most ~ 4000 clusters of diameter 2.5 nm per channel, but this is difficult to reach. At the same time a membrane a few micrometres thick is too brittle. Exposure of a thick membrane to ion irradiation makes it thinner (up to 100 nm) and enables fabrication of continuous nanowires.⁸⁵

b. Optical properties

Metallic nanoclusters and nanostructures. The optical properties of metal nanoclusters are due to plasmon vibrations of electrons in metals. The absorption spectra of small clusters exhibit an intense broad band that is absent in the spectra of bulk metals. This band is due to co-operative excitation of conduction electrons. Absorption in the visible region is responsible for, *e.g.*, unique colour grade of dilute colloidal sols of noble, alkali and rare-earth metals.

The nature of the plasmon peak is as follows. The electric field of incident radiation displaces the conduction electrons in the cluster relative to the charged core. The displacement is co-operative in character and all electrons move with the same phase. As a result of electron displacement, a force arises, which tends to return electrons to the equilibrium positions. As for typical oscillator, this force is proportional to the displacement; therefore, one can consider the eigenfrequency of collective electronic vibrations in the cluster. When the eigenfrequency of electrons becomes equal to the frequency of the external field, a resonance effect should be observed. Quantum mechanics treats

the collective motion of electrons in terms of excitation quanta called plasmons characterised by the energy $\hbar\omega$ and the resonance frequency ω_0 corresponding to the eigenfrequency of collective electronic vibrations (usually, 10^{14} s^{-1}).

The optical properties of colloid clusters are correctly described in the framework of the classical Mie theory,^{86,87} which considers the optical properties of spherical metallic particles in a dielectric matrix. Using this theory, one can describe the optical resonance due to collective excitation of electron plasma. If the cluster size is much less than the emission wavelength (λ), the absorption line in the vicinity of resonance has a Lorentzian shape and is characterised by the position of the resonance maximum, $\hbar\omega_0$, the width Γ and the absorption section

$$\sigma = \frac{n e^2}{m c \Gamma \epsilon_0} \left[\frac{\omega^2}{\omega^2 - \omega_0^2} + (\omega \Gamma)^2 \right], \quad (52)$$

where n is the electron distribution density, ϵ_0 is the dielectric constant, m_e is the effective mass of the conduction electron and c is the speed of light.

In case of spherical monovalent metal particles the equation for the resonance frequency has the form

$$\omega_0^2 = \frac{e^2}{4\pi\epsilon_0 r_s^3}, \quad (53)$$

where r_s is the Wigner–Seitz radius.

The corresponding plasmon frequency for bulk metal is given by

$$\omega_p^2 = \frac{e^2}{4\pi\epsilon_0 v}, \quad (54)$$

where $v = (4/3)\pi r_s^3$. Then the resonance frequency of a metallic sphere should be

$$\omega_0^2 = \frac{\omega_p^2}{\sqrt{3}}. \quad (55)$$

The resonance linewidth is

$$\Gamma_{r0} = 2\epsilon_2(\omega) \left[\left(\frac{\partial \epsilon_1}{\partial \omega} \right)^2 + \left(\frac{\partial \epsilon_2}{\partial \omega} \right)^2 \right]^{-1/2}, \quad (56)$$

where $\epsilon_1(\omega)$ and $\epsilon_2(\omega)$ are the real and imaginary parts of the dielectric permittivity of the cluster, respectively.

It should be noted that the Mie theory predicts no size effect. Nevertheless, the results of numerous measurements show that ω_0 and Γ depend on the cluster size. For small clusters, an important role should be played by collisions between electrons and the cluster surface (mean free path of electrons is $\sim 20 \text{ nm}$). In this case one has

$$\Gamma_r = \Gamma_{r0} + \frac{2\omega_0^2}{\omega^3} v_F \left[\left(\frac{\partial \epsilon_1}{\partial \omega} \right)^2 + \left(\frac{\partial \epsilon_2}{\partial \omega} \right)^2 \right]^{-1/2} \frac{A}{r}, \quad (57)$$

where v_F is the velocity of an electron on the Fermi surface and A is a constant. Clearly, this relation is invalid for small cluster sizes, *i.e.*, at $r \rightarrow 0$. Indeed, the metallic state typical of bulk metal and large clusters will disappear upon localisation of electrons on particular atomic levels and upon transition from the conduction and valence bands to individual localised energy levels. In this case the concept of plasmon resonance should be replaced by the resonant electron absorption between certain electron energy levels. Following this (classical) treatment procedure, it is impossible to obtain a critical cluster size, but this parameter can be determined from experimental data.

Good agreement between the calculated and experimental resonance frequencies and spectral linewidths was reported.⁸⁸ A relatively narrow line of silver clusters is due to a simpler structure of the Ag conduction band compared to the Au and Cu conduction bands characterised by a broad interband transition above 2 eV for bulk metal. Narrow plasmon resonance lines of

silver clusters suggest that they can be used in optical materials for characterisation of the interaction between the clusters and the environment and for studying the surface chemistry effects. Note that narrow spectral lines similar to the silver cluster lines were observed for the plasmon resonances of alkali metals, which was associated with the shell-type cluster structure ('jellium model') and with the fact that only s-electrons are involved in resonance (as in case of silver). However, the alkali metal clusters are extremely reactive and seem to be inappropriate for fabricating optical nanomaterials.

Figure 30 illustrates the size effects for silver clusters in argon matrix. Here, it is possible to determine the critical size for the onset of plasmon vibrations.

Figure 30. Absorption spectra of surface plasmons in silver clusters in argon matrix. The cluster size decreases upward.⁸⁸

As the cluster size decreases, the resonance frequency experiences a clearly seen shift towards the short-wavelength region ('blue' shift) up to the appearance of lines corresponding to individual monomers, dimers, trimers, *etc.* and the spectral lines are broadened. The following empirical dependences for the resonance energy and the line half-width were obtained based on the analysis of experimental data:

$$\hbar\omega = 3.21 + 0.58 \frac{1}{d}, \quad (58)$$

$$\Gamma = 0.04 + 0.59 \frac{1}{d}, \quad (59)$$

where d is the average cluster diameter (in nanometres); here $\hbar\omega$ and Γ are given in electronvolts.

Comparison of experimental spectra showed that if the cluster size is about 1 nm and the number of silver atoms in the cluster is at most ten, a number of resonance lines is observed. The critical size of silver clusters for plasmon resonance was estimated from the characteristics of these lines at $\sim 1 \text{ nm}$.

Semiconductor nanostructures and nanodevices. Semiconductor clusters also exhibit noticeable size effects, namely, a shift of the absorption frequency of optical photons and an increase in the oscillator strength, which are already used in various nanomaterials and nanodevices, *e.g.*, light-emitting diodes or tunable lasers. As the cluster size decreases, the electron excitation bands are shifted to the high-energy region and the oscillator strength (absorption intensity) is concentrated on a few transitions. These

changes associated with the change in the character of transitions between the valence band and the conduction band for bulk material give rise to a line spectrum of the cluster. The transition energy is given by

$$E \approx \frac{1}{r^2},$$

where r is the cluster radius. According to this expression, the transition energy increases as the cluster size decreases. This expression can be derived from the uncertainty relation

$$\Delta p \Delta x \geq \hbar$$

(p is the momentum and x is the coordinate) assuming $\Delta x = r_{\text{cr}}$.

For semiconductors, the absorption and emission of energy are related to the excitation of an electron and to the formation and decomposition of an exciton (hydrogen-like bound state of a conduction electron and a positively charged hole). The equation for the energy of exciton excitation has the form

$$E_n = \frac{\hbar^2 n^2}{3r^2 m_{\text{ef}}}, \quad (60)$$

where n is an integer and m_{ef} is the effective mass of the exciton.

The dependence of the absorption coefficient of CdS colloid clusters of size from 6.4 to 48 nm on the wavelength of incident radiation is shown in Fig. 31. The change in the absorption or luminescence wavelength can be due to the change in the inter-cluster interactions,⁸⁹ photochromic and electrochromic effects. The dependence of the emission wavelength on the cluster size can be employed in, *e.g.*, light-emitting diodes or tunable lasers.

Figure 31. Optical absorption coefficients of CdS clusters of different size plotted vs. photon energy.⁸⁹ Cluster size/nm: 6.4 (1), 7.2 (2), 8.0 (3), 9.3 (4), 11.6 (5), 19.4 (6), 28.0 (7) and 48.0 (8).

As an example, we will consider CdSe-based light-emitting diodes with tunable colour of the emission.⁹⁰ The light-emitting cell has the following structure. CdSe nanoclusters were distributed within a thin surface layer of a luminescent polymer (poly-*p*-phenylenevinylene), the polymer was synthesised on ITO substrate (hole conductor). CdSe nanoclusters were coated with a magnesium/aluminium film for injection of electrons into the CdSe nanoclusters. Applying a voltage to this system causes electroluminescence. The wavelength of emission can be varied by changing the cluster size.

Figure 32. Electrochromic effect in nanostructured WO₃ at different voltage applied: 0 (1), -0.2 (2), -0.3 (3), -0.4 (4), -0.5 (5), -0.6 (6), -0.7 (7) and -0.8 V (8).⁹¹

Nanostructured tungsten oxide WO₃ as well as TiO₂/WO₃, WO₃/V₂O₅ and WO₃/MoO₃ compositions also possess electrochromic properties.⁹¹ The light absorption in tungsten oxide films at different voltages is shown in Fig. 32. At positive potentials (0 V or higher), no absorption occurs, but an increase in the negative potential causes an increase in the IR absorption. At positive potentials, the films are blue, whereas at negative potentials (starting with -1.2 V) they turn brown.⁹¹

Yet another example is as follows. Using nanoclusters (quantum dots), it is possible to fabricate tunable lasers in which the wavelength of emission is varied by changing the nanocluster size. This requires fabrication of ordered nanostructures from clusters with narrow size distribution, dispersed in semiconductor solid solutions. Semiconductors can initiate population of higher electron energy states by injecting electrons and holes into nanoclusters. Transition of nanoclusters to the lowest energy state as a result of relaxation should cause emission of photons with the same wavelength, which can be focussed to produce a coherent laser beam. A scheme of a laser based on this principle is shown in Fig. 33.

The use of nanoclusters in optical devices requires meeting certain conditions related to the cluster size. The minimum critical size of a nanocluster is determined by the condition for the presence of at least one electron energy level and is characterised

Figure 33. Scheme of laser based on InAs nanoclusters.

Change in photon wavelength with a change in the nanocluster size (a) and scheme of a device including InAs nanoclusters (triangles), a medium consisting of an electron injector n-AlGaAs/n-GaAs (-), hole injector p-AlGaAs/p-GaAs (+) and electrodes (b); an arrow shows the output of light emission.

by an energy difference ΔE_c in the conduction band, corresponding to emission in the visible region. For a rectangular potential well, the electron level exists if ΔE_c exceeds the following value

$$\Delta E_c^0 = \frac{\hbar^2}{2m_c^*} \left(\frac{\pi}{D_{\min}} \right)^2 \equiv \Delta E_1, \quad (61)$$

where m_c^* is the effective mass of electron and ΔE_1 is the energy of the first level in the rectangular potential well of width D . Assuming $\Delta E_c = 0.3$ eV for related semiconductors, the nanocluster diameter should be at least 4 nm.

The maximum critical size of a nanocluster is determined taking into account the fact that the energy difference between the cluster levels becomes comparable with the thermal energy, which causes an increase in the population of higher levels

$$kT \leq E_2 - E_1, \quad (62)$$

where E_2 and E_1 are the energies of the first and second energy levels related to the size quantisation of the nanocluster. In practice, it is sufficient that

$$kT \leq E_1. \quad (63)$$

The maximum cluster sizes determined from this condition for various GaAs and InAs compositions lie between 12 and 20 nm.

Porous silicon. The properties of porous silicon differ from those of crystalline silicon. These are, *e.g.*, unusual chemical properties of the surface, biocompatibility and optical properties related to the quantum confinement effects.⁹²

Porous silicon is obtained by etching the surface of crystalline silicon. The material consists of bent silicon wires of nanometre sizes. Formally, radiative transitions between the valence band and the conduction band of crystalline silicon are symmetry forbidden. Nevertheless, transitions do occur, but they are photon assisted and therefore the rate of radiative transitions is low. Because of this, silicon is not used for generation of optical signals. Porous silicon exhibits intense photoluminescence, which was initially associated with possible violation of selection rules in the nanosystem without translational symmetry. The quantum confinement effects do play the key role in the mechanism of onset of photoluminescence upon a change in the intensity ratio of radiative and nonradiative transitions. The intensity of radiative transitions somewhat increases, but the intensity of nonradiative transitions mainly decreases; in particular, the probability of three-body Auger processes associated with electron emission after absorption of light dramatically decreases compared to crystalline silicon.

Specific optical properties of porous silicon can be used for fabrication of optical sensors for, *e.g.*, detecting changes in the reflection coefficients upon adsorption of various molecules. For instance, by measuring the changes in the wavelength with a Fabry–Perot interferometer it is possible to detect small amounts of substances in air at the porous silicon–bulk silicon interface after diffusion of gas through a membrane (Fig. 34). The radiation reflected from the surface of porous silicon and the porous silicon–bulk silicon interface forms an interference spectrum. Adsorption of various molecules on the silicon membrane causes the interference fringes to shift. The magnitude of the shift can be measured in some way. The results of a sorption study of air containing 1.7% of ethanol at different thickness of porous silicon layer are shown in Fig. 35.⁹³

The lowest ethanol concentration that can be determined by this sensor was 250 ppm. It is important that such devices demonstrate good reproducibility of results and can be efficiently reused and that the parameters of porous silicon can be varied over a broad range by etching, thus allowing various gas components to be detected and studied. Additionally, the interference sensor permits temporal separation of binary mixtures (*e.g.*, ethanol and acetone) in air, because the mixture components have different reflection coefficients, which depend on the diffusion and adsorption rates. This is to some extent similar to gas

Figure 34. Scheme of a sensor involving an interferometer based porous silicon.⁹³

Incident radiation (1), detector (2) and porous silicon (2).

Figure 35. Reflectance spectra of porous silicon samples of different thickness before (solid line) and after (dashed line) sorption of ethanol (1.7%)–air mixture.⁹³

chromatography, however the interference sensor offers the advantage consisting in combining separation and detection.

Yet another original field of application of porous silicon consists in initiation of a local explosion in a pore.⁹⁴ The effect is probably due to the hydrogenated surface of porous silicon and to the fact that the reaction was carried out in a nanoreactor, which accelerates the process. For instance, detonation of freshly prepared porous silicon soaked with aqueous $Gd(NO_3)_3$ solution can be achieved by using a mechanical or chemical ignition system. The colour temperature of the microexplosion was estimated at 2000 K, which makes it possible to carry out a microscopic analysis of metals based on their emission spectra. It is possible to initiate microexplosions of porous silicon after condensation of oxygen in a pore. This is achieved by exposure to UV light or by simply scratching.⁹⁵ The power of a microexplosion is 12 kJ g^{-1} and the energy released is 4.2 kJ g^{-1} . In addition to atomic emission spectroscopy and elemental analysis the microexplosions can be used in microelectromechanical systems, as energy sources for electronic systems and in self-destroying computer security networks.

Photonic crystals. Photonic crystals are formed from dielectric or semiconductor particles of size comparable with the wavelength of a photon (hundreds of nanometres for the visible region). Therefore, in this case one deals with the diffraction processes and conditions similar to those for scattering of X-rays by the atomic crystal lattice. This in turn causes manifestation of coherent effects in the scattering and absorption of emitted radiation. These effects are rather sensitive to the energy and direction of propagation of photons. For instance, photonic crystals have a periodically varied reflection coefficient, which makes it possible to change the optical properties of materials. One-dimensional structures are used as interference filters; how-

ever, two- and three-dimensional crystals are of greater interest. The dispersion curves obtained for photon scattering by two-dimensional phononic crystals assembled from nanocylinders are similar to the electron dispersion curves. By analogy with such notions as electron valence, forbidden and band conductivity, the dielectric band, photonic gap and air gap were introduced.⁹⁶ Removal of a row of cylinders in the photon crystal causes the appearance of an energy level in the photonic gap similar to a p- or n-level in the electron energy gap. By removing a cylinder and thus creating a void or by changing the cylinder size one can vary the photon frequency *via* a change in the nanocluster size (Fig. 36).

Figure 36. Frequency dependence of localised states within the photonic band gap.

Air band (1), photonic band gap (2) and dielectric band (3).

The energy and dispersion spectra of three-dimensional photonic crystals are also characterised by the presence of photonic gaps similar to the forbidden bands in the electron energy and dispersion spectra in atomic crystals. Taking into account this fact, one can suggest the existence of a photonic gap with the frequencies at which the propagation of a photon inside the crystal is impossible and the photon experiences elastic reflection from the nanocrystalline layer. This offers prospects for the synthesis of nanomaterials with variable optical properties for the use in light guides and tunable lasers and for the design of devices for integrated electronic networks based on optical integrated systems. Photons propagate in dielectrics at higher frequencies compared to electrons moving in conductors and can be much more informative. Fibre optical systems operate at THz frequencies (*cf.*, GHz frequency range for conventional electric current systems).

Photonic crystals with the photonic gap are fabricated by various methods. One of them involves self-organisation of spherical particles of a critical submicron size (hundreds of nanometres) in a colloid solution to give a face-centred lattice obeying the closest packing principle, which limits further growth of particles. This procedure was used to obtain an artificial opal with inclusions of monodisperse silica spheres. However, this crystal is characterised by unstable photonic gap, which is easily destroyed in the presence of various defects and imperfections. The artificial opal is used as a template for the preparation of semiconductor material. Namely, infiltration of the nanocrystalline opal with silicon followed by removal of the template results in nanocrystalline inverted opal (*cf.* nanosized reverse micelle structure) with an ordered void structure (Fig. 37).

According to calculations, a semiconductor with rather high reflection coefficient (> 2.85) should have a photonic gap. This was experimentally found in a silicon photonic crystal.⁹⁸ In this connection it is of great interest to fabricate GaS-, InS- or GaP-

Figure 37. Cross-sectional view through an incompletely infiltrated opal nanocrystal. After etching out the SiO₂ spheres, the incomplete infiltration of silicon (shown in gray) results in additional triangular (or diamond-shaped) pores.⁹⁷

based photonic crystals capable of emitting intense light or to create ordered voids in a diamond structure that, according to calculations, can have a wider photonic gap and be less dependent on the defects and disorder.

5. Magnetoelectric and magnetic properties

a. Giant magnetoresistance effect

The giant magnetoresistance (GMR) effect represents a great decrease (to 1000%) in the resistance of the nanocluster material in a magnetic field. For comparison, the magnetoresistance of bulk samples changes only slightly under identical conditions (*e.g.*, the resistance of permalloy, 80% Ni–20% Fe, increases only by 3%). The GMR effects were observed in studies of the magnetic properties of various metallic and oxide nanosystems. The mechanisms of GMR origination for nanocrystalline metals and metal oxides are different.

Nanocluster metallic materials exhibiting the GMR effect (magnetic clusters) are prepared by dissolving nanoclusters of one metal (*e.g.*, iron or cobalt) in the matrix of another metal possessing high conductivity (*e.g.*, copper or silver); the two components should be poorly soluble in each other. In a nano-system comprising a conducting metallic matrix and magnetic clusters, the conduction electrons of the matrix are scattered by the magnetic moments of the clusters. The clusters are sufficiently small and can possess superparamagnetic properties. However, for the conduction electrons moving at the Fermi velocity, the magnetic moments of the clusters are blocked, because the magnetisation measuring times (~ 100 s) are much longer than the characteristic time taken by an electron to pass through the sample ($\sim 10^{-9}$ s). The electronic structure of the metallic matrix has marked effect on the magnetic properties of clusters.⁹⁹

If electrons in metals are scattered prior to changing the directions of the spins, the relative orientation of the magnetic moments of the clusters affects the rate of scattering and conductivity. Once a magnetic field is applied to the sample, the direction of the magnetic moments changes, this causes their interaction with the conduction electron and, hence, a change in the conductivity. The magnitude of the GMR effect (and the GMR effect itself) is determined by the ratio of the electron free path to the distance between the neighbouring magnetic clusters, which depends on the concentration of the metal nanoclusters in the matrix. When the concentration is low and, correspondingly, the free path is long, an electron experiences numerous scattering events before it enters into interaction with the magnetic cluster. In this case the direction of the magnetic moment of the cluster has no effect on the electron scattering and no GMR effect is observed. At high concentration of the metal clusters, the mag-

Figure 38. Change in magnetoresistance $[\rho(H_s) - \rho(0)]/\rho(0)$ of Co–Ag nanosystems with different cobalt concentrations at 5 (1) and 300 K (2).⁹⁹

netic clusters interact with one another and are involved in the percolation processes, which eliminates the GMR effect.

An optimum situation is observed for the Co–Ag nanosystem.⁹⁹ As the cobalt concentration changes from 15% to 40%, the GMR effect is observed. The change in the relative GMR effect vs. the cobalt concentration in the sample at different temperatures are shown in Fig. 38. The maximum GMR effect was observed at a cobalt concentration of about 20%, which was associated with the critical size of cobalt clusters in the silver matrix.

The GMR effect increases as the temperature decreases. The mechanism of the effect can be explained using the two-current model, according to which electron scattering on the cluster magnetic moment in a disordered nanosystem is possible in two directions, (e.g., up or down). In a nanosystem ordered by an external magnetic field, one direction, namely, that along the field, has a lower resistance than the other direction; this results in an overall decrease in the resistance by a value of $\Delta\rho$. The $\Delta\rho$ value correlates with the cluster size: $\Delta\rho \sim 1/d$. This indicates that the GMR effect is determined by the ratio of the surface area of the magnetic clusters to the volume of the clusters and that it is the cluster–matrix interface where the spin-dependent electron scattering occurs.

Small cobalt clusters possess the properties of superparamagnetic materials and the direction of the magnetic moment of a cluster can easily be changed in an external magnetic field or by the interaction with conduction electrons. However, this interaction can occur if the time of magnetic moment fluctuations exceeds the travel time of the conduction electrons. The minimum cluster size corresponding to the onset of the GMR effect can be evaluated from Eqn (29) for the superparamagnetic relaxation time. The cluster size estimates obtained assuming $\tau_{cr} \geq \tau_0$ and substituting $K = 10^6 \text{ J mol}^{-3}$ for cobalt are $\sim 4\text{--}8 \text{ nm}$ at room temperature and $\sim 1 \text{ nm}$ at 4.2 K.

In ceramic materials, the GMR effect is observed in a narrower temperature range.¹⁰⁰ The temperature dependences of changes in the magnetoresistance $[\rho(H_s) - \rho(0)]/\rho(0)$ (%), resistance (ρ) and magnetisation (M) for $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_x$ are shown in Fig. 39.

The maximum value of the GMR effect is $\sim 1300\%$ at $T = 200 \text{ K}$. In the region 100–200 K, a metal–semiconductor transition occurs and the magnetisation increases. The appearance of the GMR effect can also be explained by the influence of superparamagnetism in this temperature range. In the temperature interval where the GMR is observed, the Mössbauer spectra exhibit a superparamagnetic doublet which is due to the appearance of nanosized regions of iron-doping induced fluctuations of the magnetic moment of ceramics.¹⁰¹ The characteristic time of thermal fluctuations of the magnetic moment is also determined using expression (29); the estimate of the critical nanocluster size corresponding to the onset of the GMR effect in ceramics is

Figure 39. Parameters $[\rho(H_s) - \rho(0)]/\rho(0)$ (1), ρ (2) and M (3) of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_x$ ceramics plotted vs. temperature.¹⁰⁰

$\sim 2\text{--}4 \text{ nm}$ at $K = 10^5 \text{ J m}^{-3}$. A decrease in temperature leads to reduction of the GMR effect, extension of the fluctuation regions and disappearance of superparamagnetism. This effect can be treated as the percolation effect for metallic matrix. The existence of superparamagnetic fluctuations of the ceramic matrix was also confirmed by inelastic neutron scattering data.¹⁰²

Based on this, one can assume that the GMR effect in the region of the semiconductor–metal transition of the ceramic material is due to the appearance of fluctuating magnetically ordered nanodomains. The nanodomain size increases as the temperature decreases; this is accompanied by an increase in the superparamagnetic relaxation time and in the time taken to attain the magnetically ordered ferromagnetic state. The temperature interval of the magnetic transition spans tens of degrees; the GMR effect observed in the same temperature range is due to the change in the scattering of conduction electrons caused by the change in the relaxation time of the magnetic moment, in the distance between fluctuating clusters and in the cluster size (no ferromagnetic nanoblocks at temperatures below the phase transition temperature and no metallic conductivity at high temperatures).

b. Quantum magnetic tunnelling

Quantum tunnelling transitions in cluster molecular crystals are accompanied by discrete changes in the magnetisation of nanoclusters and of the whole nanocrystal. This was observed for a cluster single crystal $[\text{Mn}_{12}(\text{AcO})_{16}(\text{H}_2\text{O})_4\text{O}_{12}] \cdot \text{AcOH} \cdot 4\text{H}_2\text{O}$ built of identical Mn_{12} clusters with acetate ligands.¹⁰³ This nanostructure is characterised by a stepwise character of the magnetisation curve (Fig. 40).

The hysteresis loop consists mainly of vertical and horizontal portions. In horizontal portions, the relaxation time of the magnetic moment exceeds the measurement time ($t_m \sim 600 \text{ s}$); in the slope portions, the relaxation time is similar to the measurement time. This leads to a number of minima in the plot of the superparamagnetic relaxation time τ on external magnetic field, which are associated with the steps in the hysteresis loop. Experimentally found critical H_0 values corresponding to the steps in the hysteresis loop change from 0 to 2.64 T with an increment of

$$\Delta H = H_{n+1} - H_n = 0.44 \text{ T}.$$

Here, the relaxation time of the magnetic moment of the cluster changes in a stepwise manner. These effects can be explained with allowance for the electronic structure and tunnelling transitions between the electron energy levels of molecular cluster Mn_{12} . The cluster core has a tetragonal two-layer structure in which the

Figure 40. Magnetisation curves of Mn_{12} acetate cluster single crystal at different temperatures.¹⁰³ Temperature /K: 1.77 (1), 2.10 (2), 2.64 (3).

Mn^{4+} atoms form the inner cubane cage Mn_4O_4 with the spin $S = 3/2$, and eight external Mn^{3+} atoms with the spin $S = 2$ form the outer layer. The ground ferrimagnetic state of the cluster with the collective spin $S = 10$ is stabilised by internal exchange interactions. The energy of axially symmetric crystallographic anisotropy

$$\Delta E = DS^2$$

causes the ground spin state to split into two levels with $S_z = \pm 10$ and a crystal field constant $D = 0.61$ T. For a thermally activated process at $kT \gg \Delta E$, off-resonance spin transitions occur with the probability and transition times characteristic of larger clusters. At low temperatures, quantum tunnelling of the projection of the magnetic moment is possible if the energy levels of the clusters with $M = S_n$ and $M = -S_n$ in an external magnetic field coincide. Calculations using the relation

$$\Delta H = \frac{D}{g\mu_B} = 0.44 \text{ T},$$

where g is the gyromagnetic ratio and μ_B is Bohr magneton give $D = 0.6$ T.

Thus, the relaxation of the magnetic moment of the cluster accelerates when tuning by the magnetic field results in coincidence of the energy levels of all clusters in the nanostructure. This effect corresponds to quantum tunneling in the whole nanostructure. Such clusters are treated as molecular magnets with a colossal writing density, which can be used for information storage and retrieval. Owing to multilevel tunneling, such nanodevices can be used in quantum computers in order to achieve a considerable increase in the storage capacity and performance.

c. Magnetic phase transitions

The magnetic phase transitions are classified depending on the type of changes in the magnetisation or in the character of magnetic ordering near the critical temperatures (Curie point for ferromagnetics or the Néel points for anti- and ferrimagnetics). Sharp (stepwise) and gradual changes in these characteristics correspond to the first- and second-order transitions, respectively. Changes in the unit cell volume or the thermal effect in the case of a first-order phase transition can be either significant or not. Most bulk magnets undergo second-order phase transitions, but a number of substances undergo a first-order phase transition on going from the magnetically ordered to the paramagnetic state and upon change in the type of magnetic ordering. Examples are provided by MnAs (ferromagnet $\rightarrow$ paramagnet), MnO , UO_2 , Eu (antiferromagnet $\rightarrow$ paramagnet) and $\alpha\text{-Fe}_2\text{O}_3$ (antiferromagnet $\rightarrow$ weak ferromagnet).¹⁰⁴

When studying nanoclusters and nanostructures, the magnetic phase transitions become of particular importance due to manifestation of versatile new (compared to the case of bulk materials) factors affecting the character and mechanism of transitions (size effects, surface effect, intercluster and nanoclusters–matrix interactions, effect of magnetic fields, *etc.*). Specific features of magnetisation transitions can be used as a new tool of studying the structure of nanosystems and design of novel nanomaterials and nanodevices.

Nanoclusters and nanomaterials also undergo the first- and second-order magnetic phase transitions. Similarly to most bulk magnets, the second-order magnetic phase transitions of metal and metal oxide clusters are characterised by the Langevin dependences of the magnetisation and by gradual disappearance of the magnetic order and spontaneous magnetisation near T_C or T_N . Nanoclusters of size less than 10 nm possess the properties of superparamagnets, which leads to efficient reduction of T_C or T_N .

Unlike bulk metal oxides characterised by second-order magnetic phase transitions, the corresponding oxide nanoclusters undergo the first-order transitions accompanied by abrupt loss of spontaneous magnetisation at a particular temperature or by transition to the paramagnetic rather than superparamagnetic state as the cluster size becomes less than a critical size.³⁶

When observing and studying the first-order magnetic phase transitions of nanoclusters, the problem is first of all to distinguish them from the superparamagnetic behaviour. In most cases, a scatter of cluster size occurs. Additionally, nanosystems that do not form cluster crystals are characterised by scatter of intercluster interactions. These factors hamper the detection of the first-order magnetic phase transitions of nanoclusters and nanostructures by the magnetisation measurements that provide some averaged magnetic characteristics. In this connection, one should expect a high efficiency of spectroscopic methods (in particular, Mössbauer spectroscopy with characteristic times of $10^{-7} - 10^{-10}$ s) that permit separate characterisation of the magnetic and non-magnetic fractions in the same sample.

Magnetic phase transitions manifest themselves differently in systems including isolated clusters (or clusters with weak intercluster interactions) and in nanostructures comprising clusters of size at most 100 nm with strong intercluster interactions. The reasons and mechanisms of the magnetic phase transitions in these cases are different. In this connection, it is appropriate to consider the first-order magnetic phase transitions in (i) nanosystems including isolated small nanoclusters of size less than 10 nm and (ii) nanostructures composed of larger clusters (up to 100 nm in size) characterised by strong intercluster interactions, in which magnetic transitions associated with co-operative change in the nanostructure can occur.

Nanosystems with isolated clusters. The magnetic ordering of a cluster is a co-operative phenomenon. For instance, iron atoms have a magnetic moment and possess paramagnetic properties at all temperatures. This holds for low concentrations of iron atoms present in non-magnetic (*e.g.*, polymer) matrices. A cluster comprising a few (at most ten) iron atoms is characterised by exchange interaction; however, no spontaneous magnetisation appears in this case owing to thermal fluctuations and fast spin–spin relaxation. The number of magnetic moments and, correspondingly, the cluster size should be large enough that the total exchange energy be higher than the energy of thermal fluctuations, which is of the order of kT . Using quantum-statistical methods, one can specify the energy level scheme for a cluster, calculate the total exchange energy and compare it with the energy of thermal fluctuations. This makes it possible to determine the critical cluster size corresponding to the onset of spontaneous magnetisation and magnetic ordering.

However, the character of exchange interactions and, hence, the critical cluster size will be affected by various factors, *e.g.*, the state of the cluster surface, intercluster interactions, cluster shape, *etc.* Therefore, carrying out accurate critical-size calculations is a rather complicated task. Meanwhile, the estimates of the quantum

confinement effects made in considering the electrical, optical, thermal and other properties can also be applied for the determination of the critical size of a magnetic cluster. Indeed, assuming that

$$\Delta p \Delta x = \Delta p d_{cr} \approx \hbar,$$

where p is the momentum, x is the coordinate and d_{cr} is the critical size (diameter) of the cluster, one has

$$\Delta p = \frac{\hbar}{d_{cr}},$$

and the uncertainty of the electron energy, exchange interaction or magnon due to quantum confinement effects is given by

$$\Delta \varepsilon \approx \frac{(\Delta p)^2}{2m} \approx \frac{\hbar}{2m} (d_{cr})^{-2}.$$

Assume now that this value equals the energy of exchange interaction, which is mainly responsible for the onset of magnetic ordering, *i.e.*, $\Delta \varepsilon \approx kT_C$, where T_C is the Curie temperature of bulk material. Then, the critical size (in metres) can be determined from a simple relation

$$d_{cr} \sim 2 \times 10^{-8} T_C^{-1/2}. \quad (64)$$

For $T_C \sim 500 - 1000$ K, one gets $d_{cr} \approx 1$ nm. This is the critical size of a magnetic cluster. Smaller clusters lose the magnetic ordering and undergo a transition to a magnetically disordered (*e.g.*, paramagnetic) state at any temperature. This is also the minimum size of a superparamagnetic cluster (the upper bound is ~ 10 nm and depends on many parameters, *e.g.*, the energy of magnetic anisotropy, temperature, measurement time, *etc.*). Thus, all clusters of size $d < d_{cr}$ should be in the magnetically disordered state.

The critical cluster size can also be determined using the thermodynamic theory of magnetic phase transitions in nanoclusters.^{105, 106} This theory predicts the first-order magnetic phase transitions of nanoclusters and the change in the character of the phase transition depending on the cluster size.

The first-order magnetic phase transitions can occur in bulk samples characterised by a change in the unit cell volume on transition from the magnetically ordered to a non-magnetic state, *i.e.*, in the materials, possessing magnetostriction and exhibiting hysteresis-type temperature dependences of the specific volume and magnetisation.¹⁰⁷

The Curie (Néel) temperature depends on the change in the volume as follows:

$$T_C = T_0 \left(1 + \beta \frac{V - V_0}{V_0} \right). \quad (65)$$

Here T_0 is the Curie temperature of the substance with uncompressed crystal lattice, β is the magnetostriction constant of the substance, V and V_0 are the molar volumes of the substance in the magnetically ordered (compressed) and in the non-magnetic (paramagnetic) states, respectively.

The first-order magnetic transitions of nanoclusters are realised using a dependence similar to expression (65).

The equation for the change in the Gibbs free energy density upon transition of the cluster from the magnetically ordered to the non-magnetic state is written with allowance for the change in the cluster volume as a result of magnetostriction, compressibility under pressure

$$P = \frac{2\alpha}{r}$$

due to the surface tension of the cluster of radius r

$$\Delta G = -\frac{1}{2} NkTm^2 + \frac{1}{2} \eta \left(\frac{V - V_0}{V_0} \right)^2 + \frac{2\alpha}{r} \frac{V - V_0}{V_0} + \frac{1}{2} NkT \left[\ln \left(1 - \frac{m^2}{4} \right) + m \ln \frac{1+m}{1-m} \right]. \quad (66)$$

Here N is the number of atoms with the spin $1/2$, $m = M/M_S$ is the relative magnetisation, η is volume compressibility and α is the surface tension. The equation includes four terms. The first term corresponds to the exchange energy density, the second term reflects the energy of cluster deformation, the third term corresponds to the surface energy and the fourth one is the entropy term responsible for the Langevin type of the temperature dependence of magnetisation.

To obtain the parameters of a stable magnetic state of the cluster, one should minimise the Gibbs free energy with respect to the change in the volume and magnetisation on the magnetic phase transition. Having solved the system of equations

$$\begin{aligned} \frac{\partial \Delta G}{\partial V} &= 0, \\ \frac{\partial \Delta G}{\partial m} &= 0, \end{aligned} \quad (67)$$

which determine the equilibrium state of the system, one gets

$$\frac{T}{T_{C0}} = m \left(\frac{1}{3} \gamma m^2 + 1 \right) \left(\frac{1}{2} \ln \frac{1+m}{1-m} \right)^{-1} \quad (68)$$

where $\gamma = (3/2) NkT_0 \eta \beta^2 / (1 - \eta \beta P)$ and the Curie temperature, *viz.*, $T_{C0} = T_0(1 - \eta \beta P)$, is lower than T_0 due to the pressure produced by the surface tension of the cluster.

The calculated changes in the relative magnetisation at different γ values are plotted *vs.* temperature in Fig. 41. The parameter γ determines the character of the magnetic phase transition. The case $\gamma < 1$ corresponds to the second-order magnetic phase transitions, whereas the case $\gamma \geq 1$ corresponds to the first-order magnetic phase transitions of clusters accompanied by abrupt loss of magnetic ordering. The Z-shaped portion of the magnetisation curve corresponds to an increase in the Gibbs free energy, *i.e.*, to unstable magnetic structures. The abrupt change in the magnetisation for an actually observed first-order magnetic phase transition is shown by dashed line.

Figure 41. Relative cluster magnetisation plotted *vs.* temperature at different γ values. $\gamma < 1$ (1), $\gamma = 1$ (2) and $\gamma > 1$ (3).

The critical cluster size corresponding to stepwise transition from the magnetically ordered to paramagnetic state can also be estimated from the γ value. For convenience, we will re-write the expression for γ as follows:

$$\gamma = \frac{T_{Cc}}{T_{C0}}, \quad (69)$$

where

$$T_{Cc} = \frac{3}{2} NkT_0^2 \eta \beta^2.$$

At $\gamma \geq 1$, clusters pass to the paramagnetic state upon a first-order magnetic phase transition if

$$r \leq r_{cr} = \frac{2\alpha\beta\eta}{1 - T_{Cc}/T_0}. \quad (70)$$

Large clusters ($r > r_{cr}$) will lose their magnetisation with an increase in temperature upon the second-order magnetic phase transitions.

To realise the first-order magnetic phase transitions, one should obtain clusters of substances that have a sufficiently high compressibility η . (Clusters with zero compressibility correspond to $r_{cr} = 0$ and second-order magnetic phase transitions.) The surface tension α is the key parameter that governs the occurrence or lack of the first-order magnetic phase transitions and variation of the critical cluster size [see Eqn (66)]. This model for phase transitions treats an isolated cluster characterised by the surface tension α at the cluster–vacuum interface. Any interaction between the cluster and the stabilising matrix or the neighbouring clusters leads to a decrease in α and r_{cr} and to disappearance of the first-order magnetic phase transitions. Therefore, studies of this type of phase transitions can serve as a tool for characterisation of intercluster and cluster–interface interactions.

In order to observe the first-order magnetic phase transitions, a nanosystem comprising ferrihydrite $\text{Fe}_3\text{HO}_8 \cdot 4\text{H}_2\text{O}$ nanoclusters formed in polysorb pores 13 to 75 nm in diameter was synthesised.^{36,105} This matrix-type nanosystem permits formation of isolated metal oxide clusters or accumulation of several clusters in the same pore. Polysorbs used were styrene and divinylbenzene copolymers without surface functional groups. The pore walls in such polysorbs have hydrophobic properties, which significantly weakens the interaction of ferrihydrite clusters with the matrix and leads to an increase in r_{cr} . Intercluster interactions and the number of clusters in the pore were changed by varying the concentration of iron atoms. To increase the sensitivity of Mössbauer spectrometers, experiments were carried out using ^{57}Fe -enriched iron-containing clusters synthesised in pores by soaking polysorbs with alcoholic solutions of $^{57}\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ with the iron concentrations of 1.2×10^{-2} and 1.2×10^{-3} mol litre $^{-1}$ and subsequent treatment with air/gaseous ammonia mixture. An increase in the polysorb pore size from 13 to 75 nm was followed by an increase in the size of the clusters formed in the pores.

The Mössbauer spectra of ferrihydrite clusters in polysorb pores ($c = 1.2 \times 10^{-3}$ mol litre $^{-1}$) at different temperatures are shown in Fig. 42. At all temperatures, the spectra consist of a narrow-line magnetic HFS and a central doublet. As the temperature increases, the HFS is partially converted to the paramagnetic doublet without passing through the forms corresponding to superparamagnetic broadening and to line shift leading to a considerable decrease in the magnetic field at the core. The results obtained suggest that the first-order magnetic phase transitions occur in ferrihydrite clusters in the temperature range 4.2–6 K.

Analysis of the Mössbauer spectra¹⁰⁵ allows one to reveal the effects of the interactions between clusters and the pore wall and the intercluster interactions on the character of magnetic phase transitions. First of all it should be noted that the Mössbauer spectra of (i) synthetic and natural ferrihydrites of cluster size 2–5 nm (this corresponds to magnetically ordered structures) and (ii) ferrihydrite clusters formed in polysorb pores are different. The former group of spectra exhibits a magnetic HFS at 4.2 K and broad HFS components (~ 1.5 – 2 mm s $^{-1}$, see Ref. 108), while the latter group of spectra is characterised by much narrower lines

Figure 42. Mössbauer spectra of ferrihydrite clusters in polysorbs with pore sizes of 13 (a, b) and 20 nm (c).¹⁰⁵ $c = 1.2 \times 10^{-3}$ mol litre $^{-1}$ at 4.2 (a, c) and 10 K (b).

(~ 0.6 mm s $^{-1}$). This difference is due to isolation of ferrihydrite clusters in copolymer pores and indicates weak intercluster and cluster–pore walls interactions compared to similar interactions in polycrystalline ferrihydrite. Indeed, the iron concentration of 1.2×10^{-3} mol litre $^{-1}$ corresponds to nearly one 1–2-nm ferrihydrite cluster per pore of volume 10^{-22} – 10^{-23} m ^{3} and here the magnetic properties of the cluster depend on the interaction between the cluster and the matrix surface. Thus, a first-order magnetic phase transition occurs at 4.2–6.0 K; clusters that are smaller than the critical cluster abruptly lose spontaneous magnetisation and go to the paramagnetic state.

As the temperature increases to 10 K, the relative proportion of the HFS in the Mössbauer spectrum decreases due to superparamagnetic relaxation. At a constant concentration of iron atoms ($c = 1.2 \times 10^{-2}$ mol litre $^{-1}$), an increase in the pore size to 20 nm is accompanied by an increase in the cluster size, which causes an increase in the proportion of the HFS (see Fig. 42 c), a decrease in the probability of the first-order magnetic phase transitions and strengthening of the interaction between clusters and the pore surface. A tenfold increase in the ^{57}Fe concentration at the same pore size is followed by nucleation of several clusters in the same pore (up to 5–8 clusters of size ~ 2 nm), strengthening of intercluster interactions and, as a consequence, by the overall decrease in r_{cr} values corresponding to the first-order magnetic phase transitions.¹⁰⁵ Here, this makes it possible to estimate the size of ferrihydrite clusters involved in superparamagnetic relaxation. Using relation (29) and $\tau_0 = 1 \times 10^{-9}$ s, $\tau_{cr} \sim 189 \times 10^{-9}$ s, $T = 10$ K and $K = 1.7 \times 10^5$ J m $^{-3}$, the upper limit for clusters with iron concentration of 1.2×10^{-2} mol litre $^{-1}$ was estimated at ~ 2.2 nm.

Thus, these nanosystems permit observation of the first- and second-order (superparamagnetism) magnetic phase transitions

for clusters of size ~ 2 nm. The magnetic phase transitions were detected in the temperature range 4.2–6 K.

An increase in the pore size to 75 nm at an iron concentration of 1.2×10^{-2} mol litre $^{-1}$ causes fundamental changes in the spectral pattern. This nanosystem shows the second-order magnetic phase transitions and clusters behave as superparamagnets. Calculations of superparamagnetic relaxation give an estimate $r \sim 2.5$ nm for both iron concentrations, because the average cluster size in the pore is determined by the average pore size. An increase in the iron concentration in a pore leads to multiple cluster formation, strengthening of intercluster interactions, a decrease in the critical cluster size and suppression of the first-order magnetic phase transitions.

It is interesting to compare the experimental estimates of r_{cr} obtained using the Mössbauer spectra, concentrations of the iron atoms in pores and relationships (68)–(70). Calculations for small clusters carried out assuming the critical first-order magnetic phase transition temperatures of ~ 4.2 –6 K, the second-order magnetic phase transition temperature of ~ 20 –30 K, the molar volume of 14.4×10^{-29} m ^{3} , the inverse compressibility of $\sim 1.5 \times 10^{11}$ Pa, and the cluster surface tension of ~ 1 J m $^{-2}$ led to $r_{cr} \sim 1$ nm, which is in agreement with the experimental estimates $r_{cr} \sim 1.5$ –2 nm. Indications of the first-order magnetic phase transitions were observed for small clusters of other iron oxides (see, *e.g.*, Ref. 36), but this was not observed for metal clusters (Fe, Co, Ni), probably due to lower compressibility of these particles.

The pressure is an important factor determining the appearance or disappearance of the first-order magnetic phase transitions. According to the thermodynamic model for magnetic phase transitions of nanoclusters [see Eqns (68)–(70)], the critical transition temperature reduces as the external pressure increases:

$$T_{C0} = T_0(1 - \beta\eta P). \quad (71)$$

A simple method of producing an excess pressure in a confined volume is to freeze water. The volume of ice is 8% larger than the volume of water and can produce a pressure of up to a few GPa in pores of nanometre size. Investigations of the effects of hydration, freezing of nanostructures and the action of pressure on clusters upon freezing of water in nanopores involved two series of experiments with the systems including iron oxyhydroxide nanoclusters in pores of an ion-exchange resin (sulfo cation exchange resin) and in iron-accumulating protein (ferritin) in the dry and hydrated states.¹⁰⁹

The major difference in the Mössbauer spectra of iron hydroxide clusters in the hydrated and dry samples manifests itself in the temperature range of 8.5–15 K. Comparison of the spectra of the dry samples of sulfo cation exchange resin containing iron oxyhydroxide clusters at 13 K and the spectra of the hydrated samples at 10 K showed that these spectra are identical, which suggests the temperature shift of the magnetic phase transition upon hydration. The transition is completely reversible. The spectrum of hydrated ferritin containing iron oxide core (similar to sulfo cation exchange resin) exhibits an increase in the proportion of the paramagnetic doublet compared to the spectrum of the dry sample. By comparing the spectra, it is possible to determine the magnitude of the temperature shift of the magnetic phase transition under pressure $\Delta T = 3$ –4 K.

Nanostructures. The first-order magnetic phase transitions induced by intercluster stresses and defects can occur in nanosystems containing nanoclusters of size 20–50 nm. Such nanostructures are formed in solid-phase chemical reactions, *e.g.*, cluster sintering; they are characterised by rather strong intercluster interactions. A nanostructure including α -Fe $_2$ O $_3$ and γ -Fe $_2$ O $_3$ clusters exhibits not only the first- and second-order magnetic phase transitions, but also a weak ferromagnetic–antiferromagnetic phase transition and a novel type of magnetic phase transition, accompanied by the formation of twin nanostructures.¹¹⁰

The first-order magnetic phase transitions similar to the transitions in the 1–3-nm ferrihydrite clusters (see Ref. 105) were observed in the α -Fe $_2$ O $_3$ – γ -Fe $_2$ O $_3$ nanostructure formed in the initial stage of cluster sintering by the solid-phase chemical reaction.¹¹⁰ The AFM images of this nanostructure are shown in Fig. 22.

First-order magnetic phase transitions. As mentioned above, Mössbauer spectroscopy is the most efficient method of investigation of the first-order magnetic phase transitions in clusters. The Mössbauer spectra of the α -Fe $_2$ O $_3$ – γ -Fe $_2$ O $_3$ nanostructure at different temperatures are shown in Fig. 23. As the temperature increases, the magnetic phase transitions from the ordered magnetic state to the paramagnetic (superparamagnetic) state of the nanostructure are observed, the former state being characterised by a magnetic HFS. At 77 K, the spectra exhibit two magnetic HFSs corresponding to α -Fe $_2$ O $_3$ ($\Delta E_Q = -0.29$ mm s $^{-1}$) and γ -Fe $_2$ O $_3$ ($\Delta E_Q = 0$ mm s $^{-1}$). Raising the temperature up to $T = 120$ K causes the appearance of a quadrupole doublet with $\Delta E_Q = 0.78$ mm s $^{-1}$ and the isomer shift $\delta = 0.42$ mm s $^{-1}$ relative to the metallic iron HFS, but the overall spectral pattern remains unchanged. Starting with $T = 120$ K, these spectra are transformed into spectra with one magnetic HFS ($\Delta E_Q = 0$ mm s $^{-1}$).

The Mössbauer spectra in the temperature range 120–300 K are characterised by reversible transformations of the magnetic HFS into a paramagnetic doublet without noticeable shift or broadening of the lines characteristic of the second-order magnetic phase transitions (or superparamagnetism). This is an indication of the first-order magnetic phase transitions (magnetisation of the nanomaterial disappears abruptly). These transitions occur at the critical temperatures $T_{C0} = 120$ –300 K, which are lower than T_0 temperatures for bulk samples of α -Fe $_2$ O $_3$ and γ -Fe $_2$ O $_3$ (856 and 965 K, respectively). The lack of superparamagnetism for such large clusters becomes clear from the estimate using relation (29). Taking the magnetic anisotropy constant to be $K \approx 10^5$ J m $^{-3}$ and $\tau_0 = 10^{-9}$ – 10^{-10} s, the relaxation time τ is several orders of magnitude longer than the measurement time (period of Larmor precession for ^{57}Fe nucleus is $\sim 10^{-8}$ s). Therefore, superparamagnetism has no effect on the magnetic properties of these nanostructures and cannot cause a reduction of T_{C0} .

In the nanostructures of α -Fe $_2$ O $_3$ and γ -Fe $_2$ O $_3$ the magnetisation and magnetic ordering disappear due to the first-order magnetic phase transition (abruptly), namely, the magnetic induction decreases from ~ 50 T to 0. It should be noted that the critical size, r_{cr} , of isolated ferrihydrite clusters is about 1.5 nm; smaller clusters undergo a stepwise transition to the paramagnetic state. There is also a narrow temperature range (4.2–10 K) characteristic of the first-order phase transitions. These effects were associated with the effect of surface tension.

For clusters of size 20–50 nm the pressure due to the surface tension should be an order of magnitude lower; additionally, a strong intercluster interaction causes α to decrease. Therefore, there also should be some other reasons for the first-order magnetic phase transitions and reduction of T_{C0} in this nanostructure (corresponding to $\gamma \geq 1$, see Ref. 105). Clearly, these reasons are associated with the influence of defects on the properties of the nanostructure [see Eqn (28)]. It is assumed that iron oxide clusters of size 20–50 nm provide a maximum defect density. For larger clusters, the effect of the surface as a source of defects is insignificant, whereas for smaller clusters the surface pressure is large enough to displace defects from the cluster. So, small clusters are defect-free.¹¹¹

Following this model, there should exist a maximum defect density at which clusters of critical size (tens of nanometres) are formed in the nanosystem. If the cluster sizes are less than the critical size, first-order magnetic phase transitions occur in the nanosystem; otherwise, the second-order magnetic phase transitions characteristic of bulk materials occur.

The extremal character of the dependence of defect concentration on the cluster size [see Eqn (47)] also affects the temperature dependences of the magnetisation of a nanocluster structure comprising clusters of different size. One can assume a linear dependence of the critical temperature on the defect concentration in the cluster

$$T_C = T_{C0}(1 + \beta c_v), \quad (72)$$

where $\beta < 0$, c_v is the defect concentration in the cluster.

Taking into account the magnetic intercluster interaction, the thermodynamic potential of the nanosystem 'magnetic clusters – medium – defects' can be represented by the sum including the surface energy and the change in the chemical potential upon the change in the cluster size and in the defect density in the cluster,

$$G = \Delta\mu n_v + \alpha s n_v - 0.5 N_v k T_{C0}(1 + \beta c_v) m^2 + N k T \left(\frac{1}{2} \ln \frac{1 - m^2}{4} + m \ln \frac{1 + m}{1 - m} \right), \quad (73)$$

where $\Delta\mu = \mu_0 + kT \ln(N_s n_v / N_v n_s)$ is the chemical potential difference between the defects inside the cluster and on the cluster surface; N_v is number of atoms in the cluster; N_s is number of atoms in the intercluster medium per cluster; n_v is number of defects in the cluster; n_s is number of defects in the intercluster medium per cluster; α is the surface tension of the cluster in the intercluster medium; s is cluster surface area; $m = M/M_0$ is the relative magnetisation of the cluster and N is the number of spins in the cluster. The temperature dependences of the relative magnetisation calculated for iron oxide nanoclusters of different size with energy minimisation are shown in Fig. 43.¹¹¹

Figure 43. Relative magnetisation (m) of iron oxide plotted vs. T/T_{C0} at different r/a : 6 (1), 12 (2), 25 (3), 50 (4), 100 (5), 200 (6), 300 (7), 400 (8) and 500 (9).¹¹¹

The temperature dependence of the magnetisation is consistent with the published data.¹¹¹ For the oxide clusters, it predicts the existence of a critical size of 30–40 nm, which corresponds to the maximum defect density in the cluster. If a cluster size is larger (smaller) than the critical size range indicated, the character of the magnetic phase transitions changes from the first-order to the second-order magnetic transitions.

Collective magnetic phase transitions with the formation of twin nanostructures. Now we will consider Fig. 23 in more detail. At low temperatures ($T < 120$ K), both phases, α -Fe₂O₃ and γ -Fe₂O₃ exist in the nanostructure. At temperatures above 120 K, in addition to a Morin transition (transition from antiferromagnetic to a weakly ferromagnetic structure; in bulk iron oxides occurs at 256 K, see Refs 104, 112) the α -Fe₂O₃ and γ -Fe₂O₃ phases undergo transformation into a common phase similar to the

α -Fe₂O₃ phase in ΔE_Q , the structural symmetry of the α -Fe₂O₃ and γ -Fe₂O₃ phases being retained (according to X-ray analysis data). The temperature dependences of the isomer shift show an abrupt change δ at 120 K. As a result, δ for the α -phase decreases while that for the γ -phase increases jumpwise to an average value of 0.45 mm s⁻¹. These data also indicate collective transformations of the γ - and α -phases into an α -like phase with retention of cubic spinel symmetry. This transition can be explained by the formation of a twin structure. Twinning is known to occur upon crystallisation, mechanical deformation, seed sintering, fast thermal expansion or compression, and heating of deformed crystals.^{113, 114}

Nanostructures formed under shear stress and high pressure. Exposure of bulk materials to shear stress under high pressure leads to nanostructuring and a decrease in the nanocrystallite size to 5–10 nm. Simultaneously, plastic deformation leads to generation of numerous defects that affect the magnetic properties of nanostructures, in particular, the character and critical parameters of magnetic phase transitions. When unloaded, nanocomposites comprising α -Fe₂O₃ and γ -Fe₂O₃ nanoclusters retain the stresses and defects; they are characterised by the first-order magnetic phase transitions and a decrease in T_{C0} due to an increase in the defect density. Nanostructuring of bulk samples should also induce shifts of the critical points and change the character of magnetic phase transitions from the first-order to the second order ones or *vice versa*.

Here we will consider magnetic phase transitions in two nanosystems based on the α -Fe₂O₃ and γ -Fe₂O₃ (I) and metallic europium (II) nanoclusters. The first nanosystem included α -Fe₂O₃ and γ -Fe₂O₃ nanoclusters of size 20–50 nm (I.1) and identical α -Fe₂O₃ and γ -Fe₂O₃ nanoclusters with addition of 50% monomeric acrylamide (I.2). The second nanosystem included metallic europium nanoparticles (II.1), metallic europium with addition of 1% of α -Fe₂O₃ and γ -Fe₂O₃ nanoclusters of size 20–50 nm (II.2) and metallic europium with addition of 10% of adamantane (II.3).^{111, 115}

A high-pressure apparatus of Bridgman anvil type allowed one to produce pressures of up to 5 GPa with the simultaneous accumulation of the total shear stress with an increment of 10° during 5 s. A pressure of 2 GPa was applied and the turn angles of the anvil varied from 120 to 240°.

Exposure of system (I.2) to shear stress under a pressure of up to 2 GPa causes polymerisation of acrylamide. The shear deformations in the unloaded polymer remain unchanged, which precludes recrystallisation of α -Fe₂O₃ and γ -Fe₂O₃ and recovery of the initial phase equilibrium. The action of shear stress under high pressure led to an increase in the proportion of the non-magnetic component in this system, but the most remarkable result was obtained for the nanosystem (II.2). The ⁵⁷Fe Mössbauer spectrum of nanostructure (II.2) at 300 K after shear stress under pressure (Fig. 44) exhibits almost complete loss of magnetic ordering in the α -Fe₂O₃ and γ -Fe₂O₃ clusters, which indicates a decrease in the average nanocrystallite size and reduction of the Curie or Néel temperatures below room temperature.

Mössbauer spectroscopy data for the nanosystems based on metallic europium show the reverse, namely, an increase in the transition temperature for europium.

The ¹⁵¹Eu Mössbauer spectra of nanostructures (II.1), (II.2) and (II.3) at 90 K measured after exposure to shear stress under high pressure are shown in Fig. 45.

The spectrum of nanostructure (II.1) includes not only the metallic component corresponding to four lines in the HFS, but also the europium dioxide and europium oxide lines (Fig. 45a). The spectrum of nanostructure (II.2) consists of three components, a broad line of metallic europium and the EuO and Eu₂O₃ lines (Fig. 45b). The spectrum of nanostructure (II.3) exhibits three components corresponding to lines of the magnetic HFS of metallic europium in the magnetically ordered state, a very broad line of metallic europium and a line of EuO (Fig. 45c).

Analysis of the experimental results suggests the following.

Figure 44. ^{57}Fe Mössbauer spectrum of nanostructure II.2 at room temperature upon a pressure with the turn of anvils.

Figure 45. ^{151}Eu Mössbauer spectra of nanostructures II.1 (a), II.2 (b), and II.3 (c) at 90 K upon a pressure of 2 GPa with the turn angle of anvils of 120° .

1. The first-order magnetic phase transitions (jumpwise disappearance of the magnetisation of the nanostructure at certain critical temperature) are observed in nanostructures (I.1), (I.2), (II.2) subjected to shear stress under high pressure. As the measurement temperature increases from 77 to 300 K, the spectra of the nanosystems studied show a transition of iron oxide nanoclusters from the magnetic state characterised by a magnetic HFS to the paramagnetic state without line broadening and shift due to the existence of the critical cluster size.

2. The critical temperatures of magnetic phase transitions (T_C or T_N) in nanostructures (I.1), (I.2) and (II.2) are much lower than the magnetic phase transition temperatures of bulk samples. The critical temperatures decrease even more appreciably upon adding acrylamide or metallic europium.

3. In contrast to nanosystem (I.1), a characteristic feature of nanosystem (II.1) is the second-order magnetic phase transition. This follows from the fact that above the critical transition temperature (~ 80 K, see Ref. 116) the Mössbauer spectrum exhibits a superposition of the narrow line of non-magnetic europium and the broad line with unresolved magnetic HFS of

the magnetically ordered europium. Thus, the magnetic phase transition temperature T_N of nanostructured europium is about 100 K higher than T_N of bulk metal.

4. Adding 1% of $\alpha\text{-Fe}_2\text{O}_3$ and $\gamma\text{-Fe}_2\text{O}_3$ nanoclusters [nanosystem (II.2)] or 10% of adamantane [nanosystem (II.3)] to metallic europium causes further increase in T_N , especially pronounced for nanosystem (II.3).

These features are characteristic of the nanostructures comprised of relatively large nanoclusters in which the high density of defects formed upon exposure to shear stress under high pressure should retain. The results obtained make it possible to employ the defect density distribution in the nanostructure, which passes through a maximum at cluster sizes of 30–50 nm, for characterisation of the magnetic properties of these nanostructures. The critical defect densities should correspond to the critical cluster sizes upon the change in the character of the magnetic phase transition from the first-order to the second-order transition and *vice versa*.

A model for magnetic phase transitions in defect nanostructured systems¹¹⁵ provides an explanation for all the effects considered above for the oxide and metallic nanosystems.

First-order magnetic phase transitions (Z-shaped curves) should be observed for iron oxide clusters of size 20–50 nm. At temperatures above T_C , the magnetisation of such clusters disappears jumpwise. The T_C value also depends on the size of the clusters present in the system. If the cluster size exceeds the maximum critical value ($> r_{cr}^{max}$), the second-order magnetic phase transition characteristic of bulk samples occurs and T_C increases. Reduction of the cluster size ($< r_{cr}^{min}$) also causes the second-order magnetic phase transitions to occur due to the decrease in the defect concentration.

The character of magnetic phase transitions and the T_C value are affected by the intercluster magnetic interactions. However, the changes in the intercluster distance affect the temperature dependence of magnetisation to a lesser extent compared to the changes in the cluster size. For instance, a maximum increase in T_C with a decrease in the intercluster distance from R to the lattice constant a is $\sim 6\%$.¹¹⁵ This is accompanied by the change in the character of the magnetic phase transition from the first-order to the second-order one.

Nanostructuring of nanosystems (I.1) and (I.2) by exposure to shear stress under pressure leads to reduction of the average cluster size and the average intercluster distance. For nanosystem (I.1), the effect of the decrease in the cluster size on T_C is counterbalanced by the effect of compaction, which causes strengthening of the magnetic intercluster interaction. Nanosystems (I.2) or (II.2) are characterised by reduction of T_C and an increase in the contribution of the first-order magnetic phase transition. This is particularly pronounced for nanostructure (II.2) in which the magnetic ordering in all iron oxide nanoclusters is destroyed at room temperature. Therefore, an increase in the intercluster distances leads to weakening of magnetic interactions, extension of the jumpwise magnetic phase transitions and an increase in the probability of the first-order magnetic phase transitions.

Exposure of nanosystem (II.1) to shear stress under pressure leads to nanostructuring of the material. At temperatures below T_N , the starting metal has a domain structure with a domain size of up to tens of nanometres.¹⁰⁴ Above T_N (~ 80 K), bulk metallic europium undergoes a first-order magnetic phase transition accompanied by sharp loss of magnetic ordering. The structure of metallic europium in the magnetically ordered state can be considered as consisting of nanocluster ‘domains’ packed in the crystal lattice of metallic europium. The size of these magnetic nanocluster ‘domains’ close to 20–30 nm provides the maximum defect density and, hence, the maximum density of strain, which induces the first-order magnetic phase transitions in metallic europium.

The aforesaid can be substantiated by high magnetostriction coefficients of rare-earth metals. The shear stress under pressure

causes a decrease in the size of the cluster 'domains' and they become smaller than the critical value. This leads to a decrease in the defect concentration and elimination of strain in the nano-system. As a result, the first-order magnetic phase transition is destroyed and, as a consequence, the magnetically ordered state is extended to the region of higher temperatures. This leads to an increase in T_N of metallic europium. The addition of 1% of iron oxide clusters makes this effect more pronounced due to higher strain in the iron oxides (compared to metallic europium) responsible for the decrease in the size of the nanoclusters composing the nanostructure. The effect is more pronounced upon filling the europium matrix with adamantane molecular clusters, which retain the strain in the nanostructure after the pressure is removed. Additionally, it seems likely that the introduction of iron oxide clusters and adamantane molecules as additives favours uniform nanostructuring on exposure to shear stress under pressure. Thus, nanostructuring of substances can either decrease or increase the T_C (T_N) temperatures of nanomaterials.

* * *

Summing up, nanoclusters and nanostructures exhibit specific features related to their stability and structure, which can be treated as the onset of discreteness of matter on the nanolevel. This manifests itself in the formation of nanoclusters and nanostructures and in consideration of the mechanical, thermal, electrical, optical and magnetic properties. The discreteness is characterised by the 'magic' numbers of atoms and the critical sizes of nanoclusters, which are related to the stability and preferred formation of nanoparticles of particular sizes and to manifestation of certain specific properties of nanomaterials, e.g., changes in the melting temperature, heat capacity, one-electron conductivity, onset of laser emission, appearance of the first-order magnetic phase transitions, etc.

Methods of synthesis of Group 4–9 transition metal imido complexes

D N Zarubin, N A Ustynyuk

Contents

I. Introduction	671
II. Intermolecular imidation methods	672
III. Intramolecular imidation methods	696
IV. Conclusion	701

Abstract. The synthetic routes to Group 4–9 transition metal imido complexes are considered. Both common and less common approaches are analysed. The classification of the methods for the synthesis of imido complexes is based on the way of formation of the imido ligand, the change in the metal oxidation state during imidation and the type of imidation reagent. The bibliography includes 415 references.

I. Introduction

The chemistry of transition metal imido complexes is currently a priority avenue of research in coordination chemistry which arouses an ever increasing interest. The intensive development of this field is caused by a number of reasons, first of all, successful use of imido complexes in organic synthesis and in metal complex catalysis and also as promising materials for various purposes.

It is expedient to distinguish two groups of stoichiometric and catalytic reactions involving imido complexes. The first group includes various nitrogen group transfer reactions (redox reactions and metathesis) with direct participation of the imido ligand of the complex. Examples are amination of alkenes to give *vic*-amino alcohols and *vic*-diamines,^{1–3} allylamines⁴ and aziridines;^{4–6} hydroamination of carbodiimides,⁷ alkenes,⁸ alkynes and allenes;^{9–12} transfer of the imido groups onto tertiary phosphines and isocyanides yielding iminophosphoranes^{13–21} and carbodiimides, respectively;^{22, 23} condensation of organic isocyanates to give carbodiimides;²⁴ and metathesis of carbodiimides^{25, 26} and imines.^{27–31}

The second group comprises reactions involving transition metal imido complexes in which the imido ligand does not undergo chemical transformation but acts as a 'spectator ligand' stabilising the complex. These reactions are exemplified by alkene dimerisation³² and polymerisation;^{33–43} C–H bond activation;^{44–47} and alkene cyclopropanation.⁴⁸ Special mention should be made of the metathesis of unsaturated hydrocarbons catalysed by Schrock imidocarbene complexes.^{49, 50} These reactions include ring-opening metathesis polymerisation (ROMP) of cyclic

alkenes;^{51–58} ring-closing metathesis (RCM) of dienes^{59–69} and diynes;⁷⁰ asymmetric ring-opening metathesis/cross metathesis (AROM/CM) of acyclic and cyclic alkenes;^{64, 69–73} and a tandem of asymmetric ring-opening and ring-closing metathesis reactions (AROM/RCM).^{64, 69, 74–76} R Schrock was awarded the Nobel Prize in 2005 for the invaluable contribution to the development of organic synthesis.

In recent years, the use of imido complexes of some metals as promising starting compounds for the chemical vapour deposition (MOCVD) of nitrides has been reported.^{77–82}

The chemistry, spectroscopic characteristics and structures of transition metal imido complexes have been considered comprehensively in reviews.^{83–86} The present review is devoted to comparative analysis of the methods of synthesis of Group 4–9[†] transition metal complexes with terminal imido RN groups containing alkyl, aryl and trialkylsilyl organic groups. Due to the limited size of the publication, we leave aside the complexes containing bridging imido ligands; they are mentioned only in the cases where a complex contains both bridging and terminal imido ligands. The review is focused on the imido derivatives of d elements; examples of imido compounds formed by f elements reported in the literature are few in number and represented in the review by only uranium complexes.[‡] This review covers publications up to the end of 2004.

Imidation methods are usually classified according to the types of imidating agents.^{83–86} The classification used in this review takes into account consecutively the way of formation of the imido ligand, the change in the metal oxidation state during imidation, the type of the imidating agents and the nature of the starting compounds. All the methods of synthesis of imido complexes known to date can be divided into two large groups. The first one includes intermolecular imidation methods in which the imido complex is formed using an external imidating agent. In the case of intermolecular imidation, the formal oxidation state of the metal in the complex can either change or remain unchanged depending on the nature of the agent and the starting metal-containing compound.

The second group comprises intramolecular imidation methods in which the imido group is formed from another nitrogen-containing ligand present in the metal complex. Nitride and amide complexes are used most often as the starting compounds; examples of the transformation of other nitrogen-containing

[†] Group 10 and 11 transition metals are beyond the scope of the review, as they form complexes with bridging imido ligands.^{87, 88}

[‡] Data on the imido derivatives of p elements can be found in recent reviews.^{89, 90}

Scheme 1

ligands are scarce. In the intramolecular imidation, the formal oxidation state of the metal usually remains unchanged.

Scheme 1 shows the classification of the methods of synthesis of transition metal imido complexes used in this review.

II. Intermolecular imidation methods

1. Imidation of metal complexes with no change in the metal oxidation state

a. Imidation with primary amines

Primary amines were historically the first compounds proposed as external imidation agents. Nevertheless, methods using these reagents have still not lost their practical value, which is determined first of all by wide choice, ready availability and relatively low cost of aliphatic and aromatic amines. Amines are suitable for imidation of metal-containing compounds of various types, among which metal oxides and halides are used most often.

The imidation of oxides (imido-deoxygenation) with primary amines is accompanied by elimination of water and can be carried out for transition metals of Groups 7 and 8, such as Tc, Re, and Os. For example, the first known imido complex, $\text{Bu}^t\text{N}=\text{OsO}_3$, was prepared by treatment of osmium tetroxide with *tert*-butyl-

amine.^{2, 91} Subsequently, this approach has been used to prepare other osmium monoimido complexes.^{2, 3, 92}

R = Bu^t , CMe_2Et , $\text{CMe}_2\text{CH}_2\text{Bu}^t$, Ad.

Table 1 presents examples of rhenium and technetium imido complexes obtained by imido-deoxygenation with amines. For this type of complexes, this is the main method of synthesis, which is usually more convenient than imido-deoxygenation using isocyanates, *N*-sulfinylamines, iminophosphoranes, hydrazines, formamides and hydrazides.

In bi- and polynuclear oxo complexes [for example, $\text{Re}_2\text{O}_3(\text{S}_2\text{CNEt}_2)_4$]¹⁰⁶ containing both bridging and terminal oxo groups, only the latter undergo the oxo–imido exchange.

Table 1. Synthesis of rhenium and technetium imido complexes by imido-deoxygenation with primary amines.
