1070-4272/01/7407-1098$25.00

prepared from palladium(II) chloride and hexachloroplatinic acid hexahydrate, respectively. The working concentrations of the platinum metals and the extractant were varied within the range 0.002–0.2 M and 0.01–0.1 M, respectively. The concentration of palladium(II) and platinum(IV) in both the initial solutions and raffinates was determined on a Hitachi 508 atomic-absorption spectrophotometer equipped with lamps with a hollow cathode made from the metal to be determined. The samples were sprayed into an acetylene–air flame.

The extraction was performed in temperature-controlled separatory funnels at 25±1°C. The constant volume ratio of the aqueous and organic phases was 1 : 1. After the stirring was stopped, the phases was separated within several seconds, and a sharp stable phase boundary was formed. In the course of the extraction no second organic phase was formed. The extracted complexes were precipitated from the extract by addition of hexane.

The extractable complexes of palladium(II) and platinum(IV) were prepared also by the direct reaction between the corresponding reagents. Potassium tetrachloropalladate(II) and potassium hexachloroplatinate(IV) were used as the initial platinum metal compounds. The calculated weighed portions of the disulfide and the platinum metal salts were fully dissolved in acetone and water, respectively. These solutions were combined and kept with stirring with a magnetic stirrer at room temperature until the complexation was completed, as judged from the solution decolorization and precipitation of poorly soluble compounds. These compounds were filtered off, successively washed with water and hexane, and dried. The ^{1}H and ^{13}C NMR spectra of DTD and its complexes with the platinum metals in deuterochloroform were registered on a Bruker AM300 NMR spectrometer (300 MHz, stabilization by the residual signals of chloroform). The IR spectra were recorded on an Specord 80 spectrophotometer (mull in Vaseline oil, KRS-5 windows).

In preliminary experiments we found that the time of contacting the aqueous and organic phases required for attainment of the extraction equilibrium was 15 min for palladium(II) and 2 h for platinum(IV). The real contacting time was 20 min and 2 h, respectively. The distribution of palladium(II) and platinum(IV) between the aqueous solution and the extractant was also studied in relation to acidity. Figure 1 shows that the platinum metals are most efficiently extracted from low acidic solutions (C_{HCl} < 0.5 M). It is known [6] that in the 0.1–0.5 M hydrogen chloride solutions Pd(II) and Pt(IV) predominantly exist in the form of anionic complexes $[PdCl_4]^{2-}$ and $[PtCl_6]^{2-}$, respectively. Therefore, we studied the extraction of palladium(II) and platinum(IV) from 0.5 and 0.1 M HCl solutions, respectively. Comparison of the isotherms of palladium(II) and platinum(IV) extraction with dioxo sufide (Fig. 2) shows that this reagent more efficiently extracts palladium(II) than platinum(IV). At the phase contact time τ = 20 min palladium and platinum are separated with a factor of ~10^4. In extraction of palladium(II) and platinum(IV) with DTD from hydrogen chloride solution containing Cu(II), Ni(II), Co(II), Mn(II), and Fe(III), these metals

do not noticeably pass to the organic phase. Using the techniques of saturation and shift of the extraction equilibrium, we determined that the solvation number *q* in the extractable complexes of platinum metals in question is two. Elemental analysis of the extractable complexes (Table 1) showed that palladium(II) and platinum(IV) are extracted with DTD in the form of compounds with the M : Cl : DTD ratio of 1 : 2 : 2 and 1 : 4 : 2, respectively.

To elucidate the mechanism of extraction of palladium(II) and platinum(IV) with DTD, their complexes with DTD were prepared in neutral aqueous acetone. The results of elemental analysis and several physicochemical characteristics of the prepared complexes are listed in Table 1. These data show that palladium(II) and platinum(IV) react with DTD to form the complexes $PdCl_2(DTD)_2$ and $PtCl_4(DTD)_2$, irrespective of both the ratio between the metals and reagent and the experimental conditions.

In Tables 2 and 3 are given the parameters of the ^1H and ^{13}C NMR spectra of DTD and its complexes with the platinum metals. These data show that in passing from DTD to the complexes the maximal additional downfield shift occurs for the protons (δ = 0.3–0.6 ppm) and the carbon atoms (δ ~4 ppm) of the methylene groups (d) in the α-position to the sulfur atom. The signal of the carbon atoms of the oxo groups (b) is shifted upfield by 1.5–1.7 ppm. At the same time, the position of the proton and carbon atom signals of the methyl groups (a) closest to the oxo groups remains virtually unchanged. These results show that complexation of DTD with palladium(II) and platinum(IV) involves coordination of the platinum metals to the sulfur atom. This conclusion was confirmed by the results of IR spectroscopic studies.

In passing from DTD to its complexes with Pd(II) and Pt(IV) the strong absorption bands in the IR spectra at 1710 and 1358 cm^{-1} due to ν(C=O) and δ_s(CH) vibrations in the –C(=O)–CH_3 group of DTD molecule are slightly shifted toward higher frequencies. This spectroscopic effect shows that the oxygen atoms do not participate in complex formation. At the same time, as a result of complexation, the weak absorption band at 720 cm^{-1} due to ν(C–S) vibrations is shifted toward low frequencies by 20–50 cm^{-1}. The position and intensity of the other absorption bands remain virtually unchanged. A series of the absoption bands in the long-wave region of IR spectrum of the Pd(II) complexes, observed irrespective of their preparation technique, includes a strong absorption band ν(PdCl) at 358 cm^{-1} and a medium-intensity band ν(Pd–S) at 292 cm^{-1}, indicating the

trans configuration of the coordination center [7]. A strong absorption band at 345 cm^{-1} and a weak absorption band at 320 cm^{-1} in the spectrum of $PtCl_4(DTD)_2$ prepared by the direct synthesis can be assigned to ν(Pt–Cl) and ν(Pt–S) vibrations, respectively, in the complex with the *trans* configuration [8]. At the same time, in the spectrum of the identical complex prepared by the extractive technique a broad absorption band of the medium intensity with a maximum near 311 cm^{-1} is observed. It is possible that this band is due to superposition of the close-lying absorption bands corresponding to the stretching vibrations Pt–Cl and Pt–S in *cis*-$PtCl_4(DTD)_2$ [8]. Thus, as opposed to palladium(II) complex, the structure of the $PtCl_4(DTD)_2$ coordination sphere depends on the synthesis technique.

Thus, extraction of palladium(II) and platinum(IV) from hydrogen chloride aqueous solutions with DTD involves formation of *trans*-$PdCl_2(DTD)_2$ and *cis*-$PtCl_4(DTD)$:

$$[PdCl_4]^{2-} + 2DTD \rightleftarrows PdCl_2(DTD)_2 + 2Cl^-,$$

$$[PtCl_6]^{2-} + 2DTD \rightleftarrows PtCl_4(DTD)_2 + 2Cl^-.$$

The apparent concentration extraction constants $\tilde{K}_{Pd}$ and $\tilde{K}_{Pt}$ were calculated by the equations

$$\tilde{K}_{Pd} = \frac{[PdCl_2(DTD)_2][Cl^-]^2}{[PdCl_4^{2-}][DTD]^2} \frac{y(2y + C_H)^2}{x(S_0 - 2y)^2},$$

$$\tilde{K}_{Pt} = \frac{[PtCl_4(DTD)_2][Cl^-]^2}{[PtCl_6^{2-}][DTD]^2} \frac{y(2y + C_H)^2}{x(S_0 - 2y)^2},$$

where x and y are the equilibrium metal concentrations in the aqueous and organic phases, respectively (M), S_0 is the initial extractant concentration (M), and C_H is the hydrogen chloride concentration equal to 0.5 M.

The apparent concentration constants of palladium(II) and platinum(IV) extraction with DTD solution in chloroform are $18\,400 \pm 400$ and 3.55 ± 0.30, respectively. From these values we calculated the equilibrium concentrations of palladium(II) and platinum(IV) in the aqueous and organic phases. Figure 2 shows that the calculated and experimental values are in good agreement.

It is known that effect of diluent on the efficiency of metal extraction is determined by the difference in its solvating power with respect to the extractable complex and extractant. Figure 1 shows that the use of toluene as the diluent ensures the more efficient recovery of platinum(IV). At the same time, palladium(II) is more efficiently extracted with solution of DTD in chloroform. This fact is consistent with the

order in which the extractive recovery of Pd(II) from hydrogen chloride solution with solution of octylthiomethylacetophenone in organic solvents decreases: chloroform > dichloroethane > benzene > carbon tetrachloride, this order correlates with the decrease in the negative nonideality in the extractant–diluent systems [1]. Deviation from this order in the case of extraction of platinum(IV) with DTD is apparently due to the difference in the chemical features of platinum metals concerned and their extractable complexes.

The thermodynamic functions of extraction of palladium(II) and platinum(IV) with DTD were evaluated from the temperature dependence of the distribution factors (Fig. 3). The extraction enthalpy was determined graphically [9]. The calculated values of the thermodynamic functions of the extraction are listed in Table 4. Figure 3 (curves *2*, *3*) shows that with increasing temperature the recovery of palladium(II) and platinum(IV) with DTD solution in toluene increases. The mutual arrangement of curves *2* and *3* is indicative of the larger heat absorption in extraction of platinum(IV), as compared to palladium(II), with solution of DTD in toluene. The heat absorption in extraction of platinum(IV) with DTD solution in chloroform is considerably lower than that in extraction with DTD solution in toluene. In contrast to the other extraction systems concerned, recovery of palladium(II) with DTD solution in chloroform is accompanied by heat liberation. Thus, the enthalpy characteristics of extraction of palladium(II) and platinum(IV) with DTD solutions in organic diluents are consistent with the correlation between the diluent nature and the extraction efficiency.

CONCLUSIONS

(1) The optimal conditions were found for extraction of palladium(II) from hydrogen chloride solutions with 3,7-dimethyl-5-thianonane-2,8-dione (DTD), and thermodynamic parameters of extraction and the apparent concentration constants were determined. DTD can be used as a highly efficient selective extractant for recovery of palladium(II) from aqueous solutions containing along with platinum(IV) several nonferrous metals and iron.

(2) Palladium(II) is more efficiently extracted from hydrogen chloride aqueous solutions with 3,7-dimethyl-5-thianonane-2,8-dione solution in chloroform, whereas in extraction of platinum(IV) the better diluent is toluene.

(3) Palladium(II) and platinum(IV) are bound to the sulfur atom of DTD to form *trans*-$PdCl_2(DTD)_2$ (irrespective of preparation technique), *cis*-$PtCl_4(DTD)_2$ (extraction technique), and *trans*-$PtCl_4(DTD)_2$ (direct synthesis).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Removal of Sulfur from the Active Mass of Lead Battery Scrap

A. G. Morachevskii, Z. I. Vaisgant, A. I. Rusin, and M. N. Khabachev

St. Petersburg State Technical University, St. Petersburg, Russia

Received March 13, 2001

Abstract—Process parameters of sulfur removal from the active mass of lead battery scrap, the main type of lead-containing secondary raw materials, were discussed.

Modern technology of processing lead battery scrap involves sulfur removal from the active mass (desulfurization), which is the most important from the environmental viewpoint [1–4]. The process consists in the conversion of lead(II) sulfate from the active mass to lead(II) carbonate, hydroxocarbonate, or hydroxide, i.e., to compounds which are readily reduced by carbon reagents at relatively low temperature without evolution of noxious gaseous products. At the same time, sulfur passes to the aqueous phase and is thus totally utilized. Aqueous solutions of sodium hydroxide and sodium carbonate are the most appropriate reagents for the sulfur removal [2, 3]. The reaction is based on significantly lower solubility products of lead hydroxide or carbonate compared to $PbSO_4$. For example, in the case of lead(II) sulfate pL_{PbSO_4} is 7.80, and it changes slightly as temperature increases, whereas $pL_{Pb(OH)_2}$ and pL_{PbCO_3} are 15.3 (20°C) and 13.1 (25°C), respectively.

Certain preliminary conclusions on the desulfurization with both sodium hydroxide and carbonate can be made on the basis of our previous studies [5–8] and published data [9–13]. In the case of desulfurization with sodium hydroxide, the preferable concentration range is 20–40 g l^{-1}, and the preferable temperature is 50°C. For the stoichiometric ratio $[OH^-] : [SO_4^{2-}]$ of 2 : 1 the desulfurization degree is 94–96%. A 10–20% excess of alkali with respect to the stoichiometry of the reaction

$$PbSO_4(s) + 2NaOH(aq) = Pb(OH)_2(s) + Na_2SO_4(aq) \quad (1)$$

is required to increase the conversion of lead(II) sulfate. However, at excess of alkali a minor amount of Pb(II) ions pass into solution, and addition of sulfuric acid is required to precipitate them. After solution evaporation, sodium sulfate meeting the standards with respect to the content of heavy metals and other impurities can be obtained [8].

Antimony, which enters the active material of positive and negative plates owing to corrosion electrochemical processes during battery operation, does not pass to the aqueous phase upon desulfurization with sodium hydroxide [7, 14].

Desulfurization of the active mass by sodium carbonate, which was studied in a greater detail, has received wider acceptance [2, 3]. In this case, an excess of the reagents relative to reaction (2) is also required.

$$PbSO_4(s) + Na_2CO_3(aq) = PbCO_3(s) + Na_2SO_4(s). \quad (2)$$

In contrast to desulfurization with sodium hydroxide, lead(II) ions are not detected in solution in excess of Na_2CO_3, but in this case up to 6% of the total antimony content in the active material passes into the aqueous phase [7, 14]. According to [15], the solid phase consists mainly of lead carbonate, but in other publications [9, 10] it was found that, depending on solution pH, Na_2SO_4 concentration, and other process conditions, hydrocerussite $Pb_3(CO_3)_2(OH)_2$ or the double salt $NaPb_2(CO_3)_2OH$ can form by the following reactions:

$$3PbSO_4(s) + 4Na_2CO_3 + 2H_2O = Pb_3(CO_3)_2(OH)_2(s) + 3Na_2SO_4 + 2NaHCO_3(aq), \quad (3)$$

$$2PbSO_4(s) + 3Na_2CO_3 + H_2O = NaPb_2(CO_3)_2OH(s) + 2Na_2SO_4 + NaHCO_3(aq). \quad (4)$$

The occurrence, to certain extent, of reactions (3) and (4) affects the actual consumption of sodium carbonate, which can be determined by reaction (2). The rate of $PbSO_4$ conversion is controlled, irrespective of

1070-4272/01/7407-1103$25.00

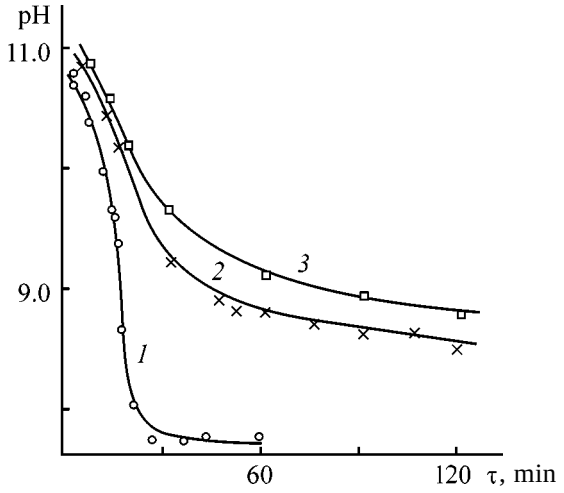

Fig. 2. Variation of pH in the course of desulfurization (for explanations, see text). (τ) Time.

the process mechanism, by the diffusion of CO_3^{2-} ions through the bed of reaction products. Changes in the composition and porosity of the solid phase caused by changes in the composition and temperature of the solution are factors primarily controlling the process rate. For the most part the reaction between pure lead sulfate and Na_2CO_3 solution is complete within 30 min at 20°C and 15 min at 50°C [3]. The experiments [3, 6, 7] show that a 10–20% excess of sodium carbonate over its amount required for reaction (2) is necessary for complete desulfurization of the active mass. The concentration of solution must provide the weight ratio of the solid and liquid phases (s : l) in the range from 1 : 5 to 1 : 3. According to the experimental data, the optimal temperature range is 40–60°C; however, there are indications that the process can be performed at a lower temperature but for a longer time. For example, Lyakov *et al*. [12] carried out the desulfurization at 23°C for 5 h.

At 40–60°C, with sufficient agitation, the recovery of SO_4^{2-} ions into solution reaches 80–85% in the first minutes and 90% within 30 min. Subsequent accumulation of Na_2SO_4 in the solution retards the process. It was of interest to obtain additional data on the permissible content of accumulated SO_4^{2-} ions and on their effect on the solution pH.

The main components of the active mass of lead batteries are $PbSO_4$ and PbO_2. Among other possible components are Pb_2OSO_4, Pb_2O_3, metallic lead, and small amounts of certain impurities. According to [16], more complex compounds like $3PbO \cdot 3PbSO_4 \cdot H_2O$, $4PbO \cdot PbSO_4$ can also be present in the active mass. In [11] the following average chemical composition of the dried active mass was reported (wt %): Pb 73.5, Sb 0.3, As ≤0.04, Ca 0.1, Fe 0.05, and SO_4^{2-} 16.7.

In our experiments the dried active mass containing 47 wt % $PbSO_4$ was subjected to desulfurization. The X-ray diffraction patterns of the active mass before and after desulfurization are shown in Fig. 1. The data were obtained using CrK_α radiation on a BGO diffractometer equipped with an HZG-4 goniometer. There are two major phases, PbO_2 and $PbSO_4$, in the starting sample. After desulfurization the content of $PbSO_4$ abruptly decreases, and the $PbCO_3$ and $Pb_3(CO_3)_2(OH)_2$ phases are present. Several intense peaks are also observed in the diffraction pattern of the sample after desulfurization, but, unfortunately, we failed to identify them with the use of the available database.

Desulfurization experiments were carried out at 50°C under continuous stirring. Crushed active mass (80 g) was added in small portions to the solution (240 ml) which contained Na_2CO_3 in the amount calculated for the complete desulfurization of the active material. The solution pH was controlled during the experiments. After the experiments the desulfurized active mass was washed, dried at 90–100°C for 5–6 h, crushed, and analyzed for the $PbSO_4$ content. The concentrations of Na_2CO_3 and $NaHCO_3$ were determined in the mother liquor. The fact that

the starting solution in addition to Na_2CO_3 contained sodium sulfate with a concentration of 150 g l^{-1} was a specific feature of the experiments. In addition to the active mass of various grain size, a synthetic mixture of finely divided crystalline powders of $PbSO_4$ and PbO_2 with the same content of lead sulfate as in the active mass was subjected to desulfurization. The time dependence of pH for these experiments is shown in Fig. 2. In the case of the synthetic mixture (curve *1*) even within 30 min a constant value of pH is attained, and the $PbSO_4$ content in the solid phase is reduced to 1 wt %. In the case of the active mass with the particle size less than 0.15 mm (curve *2*) desulfurization is slower, and after 2 h the $PbSO_4$ content is 2 wt %. In the case of the active mass with the particle size less than 0.50 mm (curve *3*) even after 2 h the $PbSO_4$ content decreases only to 7 wt %. The experiments also showed that $NaHCO_3$ is accumulated in the solution owing to possible reactions (3) and (4). For example, after a single desulfurization experiment the solution contains 7 g l^{-1} of $NaHCO_3$ and 67 g l^{-1} of Na_2SO_4 (solution density 1.07 g cm^{-3}), and after repeated use, 19 and 138 g l^{-1}, respectively (density 1.13 g cm^{-3}). After the third cycle the $NaHCO_3$ content in the solution attains 35, and that of Na_2SO_4, 208 g l^{-1} (1.19 g cm^{-3}). The time of complete desulfurization (to obtain the residual content of $PbSO_4$ in the active mass less than 3 wt %) increases from 60 to 120 min, and for the third cycle, to 150 min.

It was shown in special experiments that the use of $NaHCO_3$ as a reagent for desulfurization instead of Na_2CO_3 accelerates the process. Thus, the accumulation of Na_2CO_3 is the factor which retards the desulfurization at repeated use of the mother liquor.

Our experiments and earlier studies [5–14] allow the following conclusions. The most important factor affecting the extent of desulfurization is crushing of the active mass. At appropriate particle size and temperature, the accumulation of sodium sulfate strongly affects the desulfurization rate and the possibility of reusing the mother liquor. At the same time, the accumulation of HCO_3^- ions does not inhibit the process. Monitoring of the desulfurization completeness by pH variation is appropriate only in the case of a single-pass desulfurization without recirculation of the mother liquor.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Kinetics of Bulk Crystallization of Salts from Aqueous Solutions of Ethanol

O. D. Linnikov

Institute of Solid-State Chemistry, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia

Received July 6, 1998; in final form, November 2000

Abstract—The kinetics of crystallization of a number of salts from aqueous solutions of ethanol was studied under isothermal conditions on a setup enabling simultaneous automated recording of the electrical conductivity, optical transmission, and light scattering (at an angle of 90° to the incident light beam) of a supersaturated solution in salt crystallization. The rate coefficients of crystal growth were determined.

Control over processes of industrial bulk crystallization requires a knowledge of their mechanism. However, despite the great number of studies carried out in this direction, the question is far from being clear. Recent investigations have shown that crystallization is frequently accompanied by aggregation of crystals [1–5]. Coarse crystals can be formed not only through growth, but also as a result of aggregation of fine, submicroscopic crystals [1–4]. The existing theoretical concepts and methods for processing of experimental data on crystallization do not always take this factor into account. It is unclear whether bulk crystallization is invariably accompanied by aggregation of the forming crystals. In [1, 2], crystal aggregation was observed at solution supersaturation of 5 and more. Crystal aggregation was also observed in studying the spontaneous crystallization of potassium and sodium chlorides from aqueous and aqueous-alcoholic solutions, but at much lower supersaturations [6, 7].

The aim of the present work was to study further the kinetics and mechanism of salt crystallization from aqueous-alcoholic solutions. Since the supersaturation in a solution was created by introducing into it ethanol, it was of interest to reveal the possible influence of ethanol on the kinetic parameters of crystal growth.

The advantage of the method chosen for creating supersaturation consists in the ease of control over crystallization processes and in the possibility of obtaining in some cases compounds that cannot be isolated in the conventional way from aqueous solutions [8, 9]. Therefore, the given method of crystallization has found increasing industrial application recently.

EXPERIMENTAL

Salts with different solubilities and properties were taken for study. The experiments were carried out on a setup that enabled simultaneous automated recording of the electrical conductivity, optical transmission, and light scattering (at an angle of 90° to the incident light beam) of a supersaturated solution in salt crystallization. The salt concentration was determined from the electrical conductivity of a solution with the use of calibration curves. The supersaturation was created by introducing diluted ethanol into an unsaturated solution of a salt. To prevent formation of local supersaturations, ethanol was poured-in in the form of a thin jet, with vigorous agitation of the solution with a magnetic stirrer. Spontaneous crystallization started in a supersaturated aqueous-alcoholic solution of a salt after a certain time (induction period). After the crystallization was complete, the stirrer was switched off and the variation of the optical transmission of the solution in sedimentation of the formed crystals was recorded. The obtained curve was used to calculate the granulometric composition of the crystalline product and the optical absorption constant K_s of the salt [10].

In the process of supersaturation lifting, the solutions in the crystallization cell were thermostated with water flow from a UT-15 thermostat to within ±0.05°C. The error in measuring the light scattering intensity and optical transmission of solutions constituted ±1.5%, the rms deviation of the measured electrical conductivities was 0.2%. The crystalline product formed in each run was subjected to X-ray phase analysis, which demonstrated that the phase composition of the product remained unchanged and corresponded to the composition of the starting salts.

1070-4272/01/7407-1106$25.00

Further processing of the experimental data was done using the formulas

$$W = a + bC, \quad (1)$$

$$-\frac{dC}{d\tau} = \frac{KS}{V}(C - C_{sat})^n, \quad (2)$$

$$D = \log(I_0/I) = K_s S, \quad (3)$$

$$N = (D/4.84K_s)^3\left[\frac{\rho_s}{(C_{in} - C)MV}\right]^2, \quad (4)$$

$$\bar{d} = \left[\frac{6(C_{in} - C)MV}{\pi N\rho_s}\right]^{1/3}, \quad (5)$$

where W is the electrical conductivity of a salt solution (S); a, b are regression coefficients; C_{sat}, C_{in}, and C are the concentrations of a saturated salt solution, initial supersaturated salt solution, and that at instant of time τ, respectively (M); K is the rate coefficient of crystal growth (m s^{-1}); S is the total surface area of the crystals formed in a solution (m^2); $V = 25 \times 10^{-6}$ m^3 is the solution volume in the crystallization cell; D is the optical density of the salt solution in the course of its crystallization; I_0, I is the optical transmission of the salt solution at the initial instant of time and at instant of time τ (%): M is the molar weight of the salt (g mol^{-1}); N is the total number of salt crystals formed in the solution; $\bar{d}$ is the average crystal diameter (m); and ρ_s is the density of salt crystals (kg m^{-3}).

Equation (1) describes the electrical conductivity of salt solutions in the concentration range studied, Eq. (2) gives the rate of supersaturation lifting in a solution in the course of crystallization, and formula (3) represents Wagner's law [10], according to which the optical density of a suspension with a minor amount of the solid phase is directly proportional to the total surface area of solid particles contained in solution. The range of supersaturations of the salts under study was chosen in such a way that Wagner's law was always observed in their crystallization, i.e., the optical density of the forming suspensions was directly proportional to the total surface area of the precipitating crystals. This was verified in special experiments. Formulas (4) and (5) make it possible to calculate the number and average diameter of the crystals formed in crystallization.

If the average volume of salt crystals is v, then, under the assumption that the shape of the crystals is nearly spherical, their average diameter is given by

$$\bar{d} = (6v/\pi)^{1/3}, \quad (6)$$

and the average surface area of a crystal, by

$$\bar{S}_c = \pi d = \pi(6v/\pi)^{2/3} \approx 4.84v^{2/3}. \quad (7)$$

Expressing v in terms of a change in the solution concentration in crystallization and the total number N of formed salt crystals, we obtain formula (5). In a similar manner, with account of the fact that $S = NS_c$, we derive Eq. (4) from (3), (6), and (7). It can be shown that the calculation of the number of crystals formed in solution by means of formula (4) is sufficiently correct if the crystals have nearly spherical shape.

The order n of Eq. (2) describing the rate of salt crystallization is commonly equal to 1 or 2 [11, 12]. Joint solution of Eqs. (1)–(3) gives the rate coefficient of crystal growth and the order n of the crystallization equation. In the simplest case of $n = 1$ this solution has the form

$$K = -\frac{K_s V}{D(\tau - \tau_0)}\ln\frac{W - W_{sat}}{W_{in} - W_{sat}}, \quad (8)$$

where W_{sat} is the electrical conductivity of a saturated salt solution (S); W_{in} is the electrical conductivity of a supersaturated salt solution at the initial instant of time (S); and τ_0 is the duration of the induction period of crystallization, found from measurements of the electrical conductivity of solutions (s).

Basic data on crystallization of the salts under study are listed in Table 1. Figure 1 presents the experimental curves describing the variation of light scattering intensity I_s, optical transmission I, and electrical conductivity W of a solution in the course of KNO_3 crystallization (recording of I, I_s, and W was started immediately after ethanol was introduced into the salt solution). At the initial instant of crystallization, the electrical conductivity of the solution starts to change somewhat, whereas the intensity of light scattering and the optical transmission remain unchanged for a certain time. This corresponds to the induction period of salt crystallization, with the duration of the induction period for I, I_s, and W being not the same, which reflects the different sensitivities of the employed measurement techniques. For example, in KNO_3 crystallization, the induction period duration is zero judging from electrical conductivity measure-

* C_{alc} is the volume fraction of alcohol in solution; n_s, the rotation frequency of the stirrer; S_n, n_n, the standard deviation and number of K measurements; K_2, the rate coefficient of crystal aggregation; S_k, n_k, the standard deviation and number of K_2 measurements; d_{in}, d_f, the average diameter of the forming crystals immediately after the end of the induction period of crystallization and at the end of experiment, respectively; N_0, N_∞, the total number of salt crystals in solution immediately after the end of the induction period of crystallization and at the end of experiment, respectively; and T, the solution temperature.

ments, 28 s for I_s, and 24 s for I (Fig. 1). With the salt precipitating from the solution, I_s, I, and W first change and then level off, indicating the completion of crystallization. Similar dependences were observed in crystallization of other salts.

Experimental data processing demonstrated that the kinetics of crystallization of the salts studied is described by Eq. (2) with $n = 1$. Typical kinetic curves in the coordinates of the integral form of this equation are presented in Fig. 2, whence follows that at the end of the crystallization period, when the total surface area of the formed crystals is virtually constant, the dependence becomes linear. A calculation of the rate coefficients of crystal growth by formula (8) demonstrated that the K value remains constant during the entire period of salt crystallization. This also indicates that $n = 1$. Examples of experimental data processing by means of formulas (1)–(5) and (8) are given in Table 2.

For some of the salts, higher K values were observed in the initial stage of crystallization (e.g., KNO_3; Table 2), which was due to the high transparence of the crystals and the influence of light diffraction (owing to the small size of salt crystals at the beginning of crystallization). This gave underestimated optical densities of the solutions during this

period [10], which is confirmed by calculation of the diameters of formed crystals by means of formula (5). As seen from the data in Table 2, the diameter of KNO_3 crystals formed in solution, calculated using formula (5), is larger at the beginning of crystallization, compared with the diameter at its end. The crystal size varies nonmonotonically with time: first decreases and then starts to increase. This contradicts the available published data. Therefore, "true" values of D, $\bar{d}$, and N were calculated for the initial stage of crystallization with the use of average rate coefficients of crystal growth (Table 1). The calculated true values of D, $\bar{d}$, and N are given in parentheses under the experimental values (Table 2).

It can be seen from Table 2 that no phenomena of this kind are observed in $NaNO_3$ crystallization. The optical density of the solution from the very beginning corresponded to its true value, the rate coefficient of crystal growth remained approximately constant during the entire crystallization period, and the diameter of the formed crystals steadily increased.

The rate coefficients K (average values) of crystal growth for other salts are listed in Table 1. The obtained values indicate the kinetic mode of crystal growth under the experimental conditions. For example, in the diffusion mode of the process

$$K \approx D_1/\delta, \quad (9)$$

where D_1 is the diffusion coefficient of the salt in solution ($m^2\ s^{-1}$) and δ is the thickness of the diffusion layer around a crystal (m).

If account is taken of the fact that, for aqueous salt solutions, $D_1 \approx 10^{-9}\ m^2\ s^{-1}$, $\delta \approx 10^{-6}$–10^{-5} m [6, 7], then the rate coefficients of crystal growth can be evaluated in the diffusion mode of the process as $K \approx 10^{-4}$–$10^{-3}\ m\ s^{-1}$. This value much exceeds the determined values (Table 1).

The obtained results are in agreement with the data of [6, 7, 13] and indicate that the rate coefficients of salt crystal growth decrease with increasing volume fraction of alcohol. This can be attributed to a decrease in the solvent permittivity, resulting in a stronger interaction between the salt molecules and ions in solution with their hydrate shells, and also to a change in the solution structure upon introduction of alcohol.

It should be noted that the crystal diameter is 3.63–87.1 μm after the completion of the induction period of crystallization and increases 3–10-fold by the end of the process (Table 1).

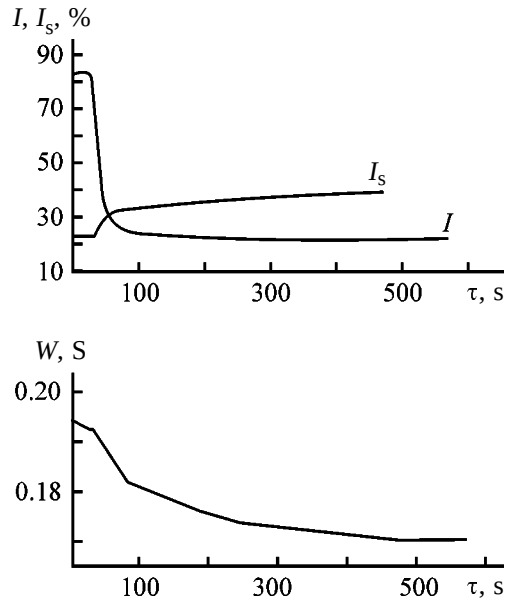

Fig. 1. Light scattering intensity I_s, optical transmission I, and electrical conductivity W of solution in KNO_3 crystallization (run no. 3) vs. time τ.

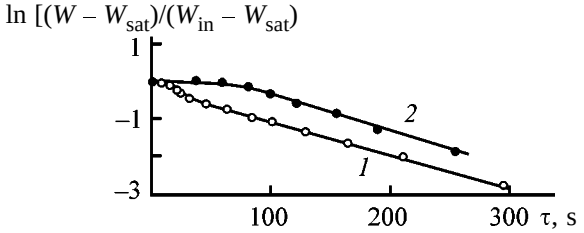

Fig. 2. Kinetic curves of crystallization, plotted in the coordinates of the integral form of Eq. (2) (n = 1). (τ) Time; the same for Fig. 3. (*1*) KNO_3, run no. 2; (*2*) $NaNO_3$, run no. 4.

Calculations by means of formula (4) demonstrated (Table 2) that in the course of crystallization the total number N of salt crystals formed in solution decreases, i.e., there occurs aggregation of the crystals. This phenomenon accompanies crystallization of any of the salts studied, irrespective of its nature, properties, and initial supersaturation of a solution. N is the largest at the initial instant of crystallization (immediately after the completion of the induction period).

Assuming [6, 7] that the kinetics of aggregation of crystals obeys the same laws as the coagulation of colloid particles, we transform the known Smoluchowski formula [14] describing the coagulation of colloid particles

$$\nu = \nu_0(1 + K_1\nu_0\tau)^{-1} \quad (10)$$

to a form convenient for our calculations

$$N = N_0[1 + K_2N_0(\tau - \tau_0)]^{-1}, \quad (11)$$

where ν, ν_0 are the concentrations of colloid particles at the initial instant of time and at a time τ; *N*, N_0 is the total number of salt crystals in solution at the initial instant of crystallization (immediately after the completion of the induction period) and at instant of time τ.

The coagulation constant of colloid particles, K_1, in Eq. (10) is related to the aggregation rate coefficient K_2 by the expression $K_2 = K_1 V^{-1}$. An example of experimental data processing by means of formula (11) is given in Fig. 3. It can be seen that during the initial period of crystallization the dependences are linear. This confirms the validity of formula (11). However, as the equilibrium state is approached, a certain departure from linearity is observed, presumably due to the fact that the aggregation rate coefficient K_2 decreases as the supersaturation in solution is lifted, this making lower the probability of crystal coalescence [15, 16]. Nevertheless, Eq. (11) can be used to describe approximately the kinetics of aggregation of crystals (correlation coefficient 0.60–0.99).

The results obtained in calculations by formula (11) are presented in Table 1. It can be seen that the N_0 and K_2 values may differ by several orders of magnitude in crystallization of different salts. For example, in crystallization of $NaNO_3$, $N_0 = 1820.1 \times 10^5$, $K = 3.28 \times 10^{-10}$ s^{-1}, whereas in the case of KNO_3 crystallization (run no. 3), $N_0 = 0.84 \times 10^5$, $K_2 = 1807.4 \times 10^{-10}$ s^{-1}. With increasing alcohol concentration in

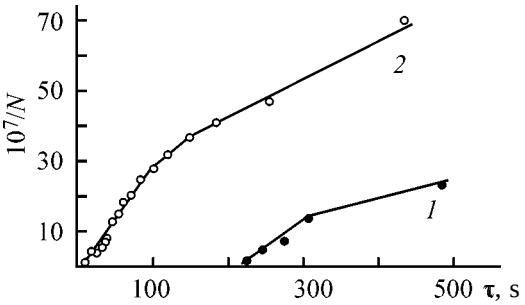

Fig. 3. Kinetic curves of crystal aggregation, plotted in the coordinates of Eq. (11). (N) Total number of crystals in solution by instant of time τ. (*1*) $NaNO_2$, run no. 7; (*2*) $Ba(NO_3)_2$, run no. 3.

solution, K_2 decreases and N_0 grows. This is observed in crystallization of nearly all of the salts studied, being presumably associated with the increasing viscosity of the solution and its growing supersaturation. The latter is supported by data on $CaSO_4 \cdot 2H_2O$ crystallization, according to which the N_0 value grows with increasing supersaturation at the same alcohol concentration in solution. The K_2 value is largely determined by the hydrodynamic state of a solution and, therefore, must decrease with its viscosity increasing upon introduction of alcohol. As known, the number of originally formed crystals, N_0, depends on the initial solution supersaturation and must increase with growing supersaturation, which does occur in crystallization of $CaSO_4 \cdot 2H_2O$. Unfortunately, it was impossible to analyze, as before [6, 7], the granulometric composition of crystals upon crystallization, the relevant data being lost.

CONCLUSION

A study of bulk crystallization of a number of salts from aqueous solutions of ethanol revealed that, irrespective of the nature of a salt and the initial supersaturation in solution, spontaneous crystallization is always accompanied by aggregation of the forming crystals. The greatest number of crystals is formed at the initial instant of crystallization (immediately after the completion of the induction period). Their further aggregation is approximately described by Smoluchowski's coagulation equation. With increasing alcohol concentration in solution, the rate coefficients of salt crystal growth and aggregation decrease. The growth of the forming crystals of the salts studied is described by a reaction equation of first order with respect to supersaturation.

SORPTION AND ION-EXCHANGE PROCESSES

Composite Sorbents Based on Inorganic Adsorbents and Binders

Abstract—The routes of fabricating and the main properties of composite sorbents based on mineral adsorbents as fillers and inorganic binders are considered.

The possibilities and methods of fabricating and the properties of composite sorbents (CSs) based on mineral adsorbents as fillers and organic polymers as binders were considered in [1–5]. In many cases, such CSs were unsuitable for repeated exploitation, because the temperatures for regeneration of sorbents incorporated into CSs exceed the range of stability of organic polymeric matrices.

Synthesis of such CSs and their possible structure have been reported previously [4]. The polymeric nature of some inorganic compounds of silicon and aluminum [6, 7] suggests that interaction of the initial sorbent with the inorganic polymer should occur similarly as with organic binder.

In this work we prepared and stuided CSs based on inorganic sorbents and polymeric binders of various origins and structures.

EXPERIMENTAL

Inorganic sorbents were silica gel (KSMG grade), NaX zeolite, AOA-1 grade active aluminum oxide (AAO), and coarse-pore water-resistant silica gel (OSG grade) impregnated with lithium and calcium chlorides.

Silicic acid sol (SAS), aqueous sodium silicate solution (water glass, WG), and potassium tetrasilicate (PTS) based cement were inorganic binders. They are readily available and have the enhanced thermal stability as compared to organic materials, which is essential in view of necessity of recovering inorganic sorbents at high temperatures (from 180–200°C for silica gel to 350–400°C for zeolite). Moreover, the different structure of these polymeric systems allows the mechanism of the formation of CSs based on inorganic polymers to be analyzed in more detail.

The CS as consolidated mixture was prepared in the shell of the adsorber, which is the main part of its body.

The filler used with a WG binder was NaX zeolite mixed with active aluminum oxide (AOA-1 grade) in the 1 : 1 ratio. The mixture of this composition is optimal for synthesizing, for example, mineral filters intended for complex purification of freons to remove moisture and degradation products of freon oils. After vibration packing of granules, the aqueous binder solution was poured through the mixture and then the fabricated CS was dried for 4–6 h at 200–350°C depending on the initial sorbent. The WG had the ratio $m = 2.2$ of the number of SiO_2 and R_2O groups in sodium silicate and contained 40 wt % sodium silicate. The coagulants (aqueous solutions containing 5–25 wt % H_3PO_4, NH_4OH, or $CaCl_2$) were added to it preliminarily. The coagulant fraction was varied within 10–65 wt % of WG, the latter amounting to 20 wt % of CS.

CS as consolidated mixture with SAS binder was prepared similarly. SAS with a density of 2.5 g cm^{-3}, containing 20 wt % substance, with micelle size of 25 nm and pH 10.5, was used in the experiments. The initial SAS was diluted by a factor of 2 or 3, if necessary. The SAS aqueous solution in an amount of 50% of the volume of the initial sorbent was poured through the mixture.

CS with PTS binder in the form of consolidated mixture was also prepared in the shell of the adsorber. The binder used in this work was the calcination product of the K_2O–SiO_2 (30 mol % K_2O) system ensuring the best strength characteristics of cement stone upon tempering and solidification [8]. According to X-ray phase analysis, PTS is a mixture of potassium tetrasilicate (monoclinic crystal system, density

2.335 g cm^{-3}, mp 765°C) and potassium disilicate (PDS) (rhombic crystal system, density 1.538 g cm^{-3}, mp 1045°C) [8]. The PTS : PDS molar ratio is 60 : 40, as determined by the initial stock composition of the K_2O–SiO_2 system. The grain size of the PTS powder (about 1 μm) was calculated from its specific surface area [9]. The initial sorbent was mixed with PTS, formed as layer in the shell of the adsorber, kept for 6 days at room temperature, and heat-treated for 3–4 h at 350–400°C. The PTS amount was varied from 1 to 30 wt % CS.

The sorption properties and pore structure of CSs were studied using the methods described in [10, 11]. Dynamic study was performed at a 60–65% relative humidity of the initial water vapor–air flow, its temperature of 20°C, and the flow velocity of 0.5 l min^{-1} cm^{-2}, with a 20-mm CS bed. The specific surface area of samples was determined from low-temperature desorption of argon [12]. The hydraulic resistance R was measured as in [13] and the crushing strength, as in [14].

CSs prepared by different procedures were a blown-through mixture consolidated in the shell of the adsorber. The hydraulic resistance of the sorbing bed to humid air flow upon formation of the consolidated mixture increased from 50 in the starting stock to 250–300 Pa in the CSs synthesized with sodium silicate solution. The crushing strength of the article formed outside the shell of the adsorber was (1–2) × 10^5 Pa.

The main sorptive properties and the degree of blocking of sorbent pores with binder were studied on both composite and initial sorbents. The properties with respect to water vapor under static and dynamic experimental conditions for CSs with WG are given in Table 1.

Table 1 shows that the sorption capacity of CSs with WG is somewhat lower (by 7–20%) than that of the initial sorbents. Also, the apparent diffusion coefficient D_a calculated from the kinetic sorption curves obtained on single grains decreases considerably (3–5-fold) compared to the initial stock. The similar phenomenon is observed for both values (0.13 and 0.85) of the relative water vapor pressure P/P_s. However, the deterioration of CS sorption properties compared to the properties of the initial stock was more pronounced for P/P_s = 0.13 than for P/P_s = 0.85.

Most likely, this is due to the fact that the silicon–oxygen xerogel matrix formed at alkaline pH values has coarse-grain structure and, consequently, considerable sorption capacity only at high relative water vapor pressures. The formed matrix partially blocks fine pores of the sorbents, thus decreasing the sorption capacity at low pressures (P/P_s = 0.13). At higher pressures the coarse-pore structure of the forming matrix makes certain positive contribution to the CS sorption capacity. Along with this, the dynamic capacity a_d of CSs decreases by 20–28% in comparison with the initial sorbent (Table 1). The utilization factor of the equilibrium dynamic capacity $k = a_d/a_{eq}$ decreases by 15%, i.e., the kinetic characteristics of the water vapor absorption by the consolidated mixture are satisfactory (a_d is the dynamic capacity of the sorbent corresponding to 10% breakthrough of the water vapor and a_{eq} is its equilibrium capacity corresponding to the moment when the water vapor concentration behind the stock becomes equal to the initial concentration).

Hence, the study performed shows that the use of WG with a coagulant allows preparation of sufficiently active CSs. When WG is used without coagulant, the absorption capacity of the initial stock sharply decreases because of the blocking of the sorbent pores with sodium silicate impermeable film formed on the surface of the initial sorbent. The formation of a permeable silicate film appeared to be possible only with coagulants (Table 1), which, affecting the

sodium silicate solution, cause gelation of silicic acid in its volume. The latter forms xerogels with open porosity. However, some decrease in the sorption capacity and a more considerable decrease in the equilibrium capacity D_{eq} of CS for water vapor shows that the initial sorbent pores are partially blocked with the matrix.

From this standpoint, it is more reasonable to use SAS binder, which is a coarser disperson system than sodium silicate solution. The fact that the molecules in SAS are initially rolled up favors formation of a permeable system upon drying. The lower viscosity of SAS as compared to WG solution is also the positive factor facilitating its penetration into pores of the initial stock and ensuring efficiency of the CS fabrication. Comparatively coarse sol macromolecules may block pores of the initial sorbent if it contains even coarser pores (as in coarse-pore silica gel and AAO). For zeolite sorbent this process is improbable. It should be noted that successful approbation of SAS for preparation of granulated sorbents from silica gel powders and AAO has been described in the literature [3, 5], and we can expect the positive result when using SAS for the fabrication of CSs from granulated commercial sorbents. Therefore, in the next stage we studied the feasible routes of fabrication and the main properties of CSs based on various inorganic granulated sorbents and SAS, as well as the behavior of SAS upon CS synthesis.

The process parameters and properties of CSs are given in Table 2. The presented data show that CSs synthesized with SAS binder have the sorption characteristics virtually identical to those of the initial sorbent. The main characteristics (W_s and S_{sp}) of the initial sorbent surpass by no more than 5% the analogous characteristics of CSs fabricated with sol binder. The D_e and k values of CSs differ from those of the initial sorbents by less than 10%. The R values of CSs exceed those of the initial sorbent only slightly (by no more than 10%), with the exception of those with OSG. For CS with the latter sorbent R increases 13-fold, which may be due to some other mechanisms of the process and to the formation of a voluminous loose film of silicic acid xerogel upon interaction of SAS with calcium and lithium chlorides.

In this work, along with the analysis of the changes in the sorption and hydraulic characteristics of the materials, the variation of pH of the initial sol on the surface of the initial sorbent was also estimated from measurements of the pH value with test paper. For example, for AAO and zeolite pH of the sol decreases insignificantly (Table 2) as compared to silica gel and OSG (silica gel impregnated with potassium and lithium chlorides). Compared to the initial sorbent, the S_{sp} value of CSs slightly decreases in the first case, whereas in the second case it slightly increases.

This difference is presumably due to different mechanisms of the film formation on the surface of granules of the initial sorbent depending on its origin. As known [15], the sorption surface of silica gels exhibits acid properties arising from partially polarized hydroxy groups, whereas that of AAO and zeolite exhibits amphoteric and base properties, respectively, owing to specific chemical nature of alumogels and aluminosilicates [16]. The experimental pH values of the silica gel aqueous extracts and SAS lie within 5–6. At the same time, for AAO and zeolite, they are 7 and 8, respectively. The necessary amount of SAS was added by pouring it through the initial sorbent. Owing to its low viscosity, the process is fast and practically no excess sol requiring removal is formed. A thin SAS film formed on the surface of AAO and zeolite granules undergoes no significant chemical transformations, which is confirmed by a small decrease in the SAS pH (Table 2). At the same time, S_{sp} of CSs obtained by interaction of SAS with AAO decreases by 10% as compared with the initial AAO, which shows that some macromolecules of the initial sol penetrate into the sorbent pores, blocking the active surface. Then, on the surface of sorbent granules a strong porous SAS film is formed upon drying.

When the silica gel sorbent (with and without impregnation) is used for CS fabrication, pH of the initial sol in contact with the initial sorbent decreases from 10.5 to 6–7 (Table 2) and S_{sp} increases by 6–7%. Most likely, this effect may be due to another mechanism of the film formation on the silica surface. Silica gels, including impregnated ones, initiate recondensation of SAS followed by its gelation when coming in contact with the sorbent. At the same time, AAOs and zeolites with the base properties of the surface do not behave as pronounced SAS destabilizers. The effect of sol destabilization is the most pronounced under the action of impregnating additives (Table 2, OSG + SAS) yielding hydroxides and silicates, which are not sufficiently soluble under the conditions considered. As a result, a voluminous film is formed, which, along with amorphous silica, contains potassium silicates and hydroxides. This film blocks CS pores and considerably enhances the hydraulic resistance of the article.

The PTS cement is another representative of silicate binders considered in this work. The character-

* Weight ratio.

istics of the CSs obtained with this binder are given in Table 3.

Study of the fabricated articles show that, as the binder amount increases, the properties of the resulting CSs change regularly. The equilibrium adsorption of water vapor at its relative pressure of 0.13 decreases. In this case, the limiting volume of the sorption space W_s of CSs with respect to benzene, as determined at a relative pressure of benzene vapor P/P_s = 1, and its total pore volume V_Σ, as calculated from the difference in the reciprocal values of the apparent and pycnometric densities of the sorbents, decrease relative to the initial zeolite [10]. Most probably, owing to formation of polymeric crystal hydrates [17], the binder forms a dense film, impeding sorbate diffusion into zeolite pores upon formation of the cement matrix. Nevertheless, the D_e values suggest that the PTS film covering granules of the initial sorbent is sufficiently permeable, which is in line with the published data. At the high relative water vapor pressure (P/P_s = 0.85) the sorption capacity of CSs grows with increasing PTS concentration, which is due to the formation of crystal hydrates of the polymeric matrix under these conditions. The same was not observed at P/P_s = 0.13.

The study of the routes of high-temperature regeneration show that multiple regeneration of the articles obtained with the inorganic polymeric binder of the PTS type does not deteriorate the CS sorption (Table 4). The dynamic sorption capacity a_d and the utilization factor of the dynamic sorption capacity k remain virtually unchanged.

The analysis of the CS characteristics obtained with the use of various polymeric inorganic systems shows that articles with PTS considerably surpass in strength (P_{cr} = 2.5–3.0 MPa) those with sodium silicate and sol binders (P_{cr} = 0.1–0.2 MPa, Tables 1 and 2, respectively). However, their hydraulic resistance R to the air flow is considerably higher (5–6-fold) than that of CS with SAS and is virtually the same as that of SC with WG.

Also, Tables 1–3 evidently show that for articles fabricated with the binder in various dispersion states

Table 4. Sorptive characteristics of NaX + PTS articles after regeneration

the D_e value (as determined at P/P_s = 0.85 for the close values of the binder concentration in CSs) differs from the analogous characteristic of the initial sorbent. With molecular solution (WG) D_e decreases by a factor of 2.7–3.7, whereas with sol binder (SAS), by 6–9%, and with coarsely dispersed binder (PTS), by 5–8%. This indicates that the binder forms films of different structure on the sorbent surface. Thus, the articles fabricated from CSs with sols and coarsely dispersed silicate systems as binders have enhanced kinetic parameters as compared to those fabricated from CSs with solutions, even in the case when coagulants favoring formation of porous and more permeable film are added into the system.

Table 5 shows how the state of the polymeric silicate system correlates with the CS structure and properties. The binders used for preparing CSs were polymeric systems differing in the degree of dispersity. Sodium silicate solution was a molecular solution of the polymer, silicic acid sol was an inorganic colloid, and PTS was a coarsely dispersed system.

The set of the obtained data allows a conclusion that, with binder used as molecular solution, dense weakly permeable film of sodium silicate is formed on the sorbent surface. The materials obtained have considerable strength and equilibrium sorption capacity. At the same time, they have poor kinetic characteristics and considerable hydraulic resistance. This is due to the fact that the binder film formed upon interaction of sorbent with viscous WG solution has considerable thickness. It is appropriate to fabricate articles based on molecular solutions of inorganic polymers in the form of structural elements intended for operation under static conditions.

The film formed on the surface of sorbent granules upon interaction with sol is nonuniform, ensuring free access of adsorbate molecules inside the article. Owing to permeability of the binder film, the capacity and kinetic characteristics of the articles are retained at a level of those of the initial sorbent. The low viscosity of the sol ensures the low residual amount of the binder in the article at the hydraulic resistance close to that of the initial sorbent. At the same time, this produces the negative effect on the strength of sol-bound CSs. It is preferable to prepare the latter CSs in the form of consolidated mixture in the shell of the adsorber and to use them under conditions of a flow-type reactor.

The combination of the initial sorbent with coarsely dispersed binders allows fabrication of articles in the form of both consolidated mixture and single structural element. The strength of a CS is determined by the number of sorbent and binder particles in contact per unit volume of the article, and its sorptive properties, by the binder amount in the article. When

Table 5. Correlation between the state of the polymeric silicate system and the CS structure and properties

State of polymeric structure	Molecular solution (WG)	Colloid (SAS)	Coarsely dispersed system (PTS)

* (CM) Consolidated mixture and (SE) structural element.

the binder amount is 20% of the article weight, strong materials are formed, characterized by high hydraulic resistance and low kinetic parameters. It is appropriate to use such materials under static conditions and at high mechanical loads. The CSs with less than 10% binder content allow fabrication of articles as a mixture consolidated in the absorber. Such articles have low hydraulic resistance, high kinetic factors, and are suitable for operating in the dynamic mode.

By analogy with the classification of organic polymeric systems [4], the correlation between the state of the polymeric system used for CS fabrication and the structure and properties of the fabricated articles and areas of their application is demonstrated in Table 5. The preferable modes of application of CSs fabricated by different methods are printed italic. The structural elements formed with solution are the most suitable for operation under static conditions. For a flow-type reactor we can recommend a consolidated mixture prepared by interaction of the initial sorbent with sol. Coarsely dispersed systems allow fabrication of both types of CSs, i.e., for static and dynamic conditions.

CONCLUSIONS

(1) Strong composite sorbents in the form of block articles or a mixture consolidated in the absorber can be fabricated on the basis of inorganic granulated sorbents and silica matrices. The optimal process parameters are determined, providing high strength and considerable sorption capacity of the articles. The materials of this type exhibit high sorption characteristics inferior to those of the initial sorbent by no more than 5–20%. They have sufficiently high strength and low hydraulic resistance to water vapor–air flow when operating under dynamic conditions.

(2) Use of silicic acid sol and coarsely dispersed binder like potassium silicate cement allows the pore structure of the initial granulated sorbents to be preserved in the course of formation of block articles. At the same time, with sodium silicate solutions the active sorbents can be fabricated only with coagulants.

Abstract—Published data on the interaction of lithium with aqueous solutions of alkali metal hydroxides are discussed. The behavior of lithium in aqueous solutions of LiOH and KOH was studied experimentally.

One of promising chemical power cells is that based on the lithium–water system [1, 2]. Use of lithium in water-activated chemical power cells is enabled by the formation of a passivating film of complex structure on the lithium surface brought in contact with an electrolyte. Presumably, this film consists of an outer porous layer of hydrated lithium hydroxide impregnated with electrolyte and an inner porous layer of lithium oxides of indeterminate composition, adjacent to the metal [3]. This film is stable in an electrolyte with the LiOH concentration exceeding 1.5 m, where m is molality unit (mol/1000 g H_2O) [4]. The film has pores $1–10^3$ nm in size [5]. The total surface area of the pores constitutes approximately 5–25% of the total surface area of the film at a lithium hydroxide concentration in the electrolyte of 5.0–3.5 m [6, 7].

The rate of interaction between the alkali metal and the electrolyte (rate of lithium corrosion) depends on the solution composition and temperature. For example, the rate of lithium corrosion in solutions of the system LiOH–H_2O ($3.1 < m < 4.8$) decreases from 9.8×10^{-4} to 3.9×10^{-4} kg m^{-2} s^{-1} with the lithium hydroxide concentration in solution increasing from 3.1 to 4.0 m [8]. Raising the content of LiOH in solution further has little effect on the amount of corrosion losses. At the same concentration of an alkali metal hydroxide in the electrolyte, the rate of corrosion increases in going from LiOH solutions to solutions of NaOH, KOH, and CsOH (Fig. 1) [8, 9], although the activity of water decreases in this series of electrolytes [10, 11]. Such a discrepancy is possibly due to occurrence of reactions between lithium and alkali metal ions in solution:

$$Li + Na^+ = Li^+ + Na, \quad (1)$$

$$Li + K^+ = Li^+ + K, \quad (2)$$

$$Li + Cs^+ = Li^+ + Cs. \quad (3)$$

The changes in the Gibbs energy for reactions (1)–(3) at 298 K are, respectively, –30, –10, and –0.8 kJ. Since the intensity of interaction between alkali metals and water increases in going from lithium to sodium, potassium, and cesium, the occurrence of reactions (1)–(3) may lead to lithium corrosion rate increasing in the following order of electrolyte solutions: LiOH < NaOH < KOH < CsOH.

The temperature dependence of the rate of lithium corrosion in aqueous solutions of alkali metal hydroxides is well described by the Arrhenius equation [3, 9, 12, 13]. As seen from the table, the activation energies of lithium interaction with water decrease in going from the system LiOH–H_2O to KOH–H_2O.

Lithium corrosion in aqueous electrolyte solutions is a spontaneous electrochemical process which can be represented, in the case of solutions of the system LiOH–H_2O, as conjugated electrochemical reactions

$$Li = Li^+ + e, \quad (4)$$

$$H_2O + e = OH^- + 1/2H_2, \quad (5)$$

$$Li + H_2O = LiOH + H_2. \quad (6)$$

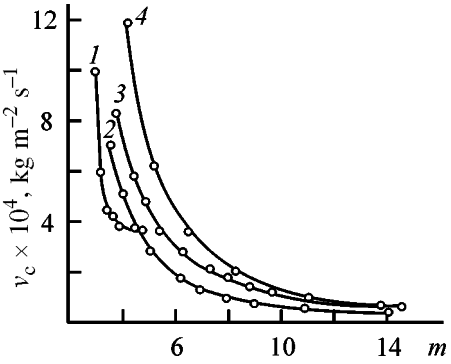

Fig. 1. Lithium corrosion rate v_c vs. molal concentration m of alkali metal hydroxide in solutions: (*1*) LiOH, (*2*) NaOH, (*3*) KOH, and (*4*) CsOH.

1070-4272/01/7407-1118$25.00

The state of the system lithium–aqueous solution of lithium hydroxide can be characterized by the stationary potential of the lithium electrode in this solution. The stationary potential E of the lithium electrode in solutions of the system LiOH–H_2O ($3.1 < m < 4.8$) is virtually independent of the solution concentration, being equal to -2.76 ± 0.01 V relative to the standard hydrogen electrode (s.h.e.) [8]. In solutions of the systems NaOH–H_2O, KOH–H_2O, and CsOH–H_2O, the stationary potential of the lithium electrode $-2.84 < E < -2.79$ V is affected by the occurrence of not only reaction (6), but also reactions (1)–(3). Since hydrogen reduction on lithium by reaction (5) is characterized by a higher overvoltage of about 2 V [3, 14, 15], then, as believed by Littauer and Tsai [3], it is the rate of this electrochemical reaction that determines the overall rate of corrosion.

Anodic dissolution of lithium in aqueous solutions of alkali metal hydroxides

$$Li + OH^- = LiOH + e \qquad (7)$$

proceeds at pore bases through the inner protective layer with thickness of, in all probability, only several molecular layers [3].

Presently, there exists no unified standpoint on what stage is rate-determining in anodic dissolution of lithium in aqueous solutions of alkali metal hydroxides. Cooper *et al*. [16] believe that the anodic dissolution of lithium is controlled by dissolution of the forming lithium hydroxide in the aqueous solution. According to [17], the anodic dissolution of lithium is limited by water diffusion in the film formed on the metal. In [13], it was assumed that the rate-determining stages of the electrochemical process are both water transfer from the solution bulk to the electrode surface and removal of the products formed in the electrochemical reaction. According to our previous study [18], the rate-determining stage of the anodic dissolution of lithium in aqueous solutions of alkali metal hydroxides is LiOH diffusion from the anode surface into the solution bulk.

In anodic polarization of the lithium electrode in aqueous solutions of alkali metal hydroxides from the stationary potential to values $-2.5 < E < -2.3$ V relative to s.h.e., the rate of metal corrosion decreases and the current of anodic dissolution of lithium increases, approaching its limiting value (Fig. 2) [15]. The limiting current decreases with increasing concentration of alkali metal hydroxide in solution [18–22]. In Fig. 2, the rate of lithium corrosion is expressed in electrical units in the form of the current density for the equivalent process of hydrogen reduction, j_{H_2}. With the electrode potential shifted to positive values, the rate of electrochemical lithium oxidation [reaction (4)] increases and that of electrochemical hydrogen reduction [reaction (5)] decreases, which leads to lower corrosion loss and, consequently, to higher efficiency of utilization of the active paste of the anode. As seen from Fig. 2, the highest values of the lithium utilization efficiency in the alkali metal hydroxide solutions studied at 298 K are $81 < \eta < 88\%$. According to [23], the efficiency of lithium utilization in a 4.5 m LiOH solution at $291 < T < 328$ K may be as high as $98 < \eta < 99\%$. At $T > 328$ K, the efficiency of utilization of the active paste of the anode decreases substantially because of the dramatic increase in the rate of lithium corrosion.

Activation energies E_a of lithium reaction with water in electrolytes of various compositions

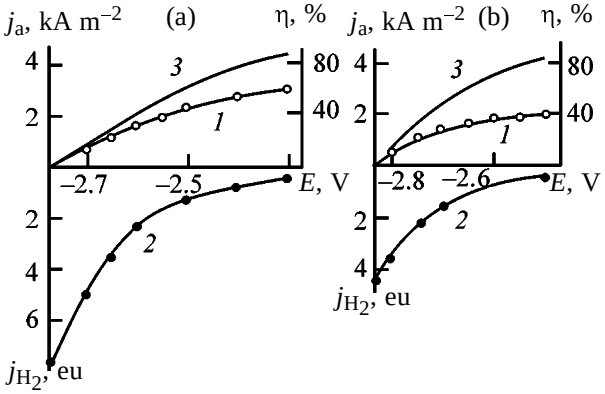

Fig. 2. (*1*) Discharge current density j_a, (*2*) corrosion rate j_{H_2}, and (*3*) lithium utilization efficiency η vs. potential E in solutions of systems MOH–H_2O. (a) 3.2 m LiOH and (b) 6.2 m KOH1.

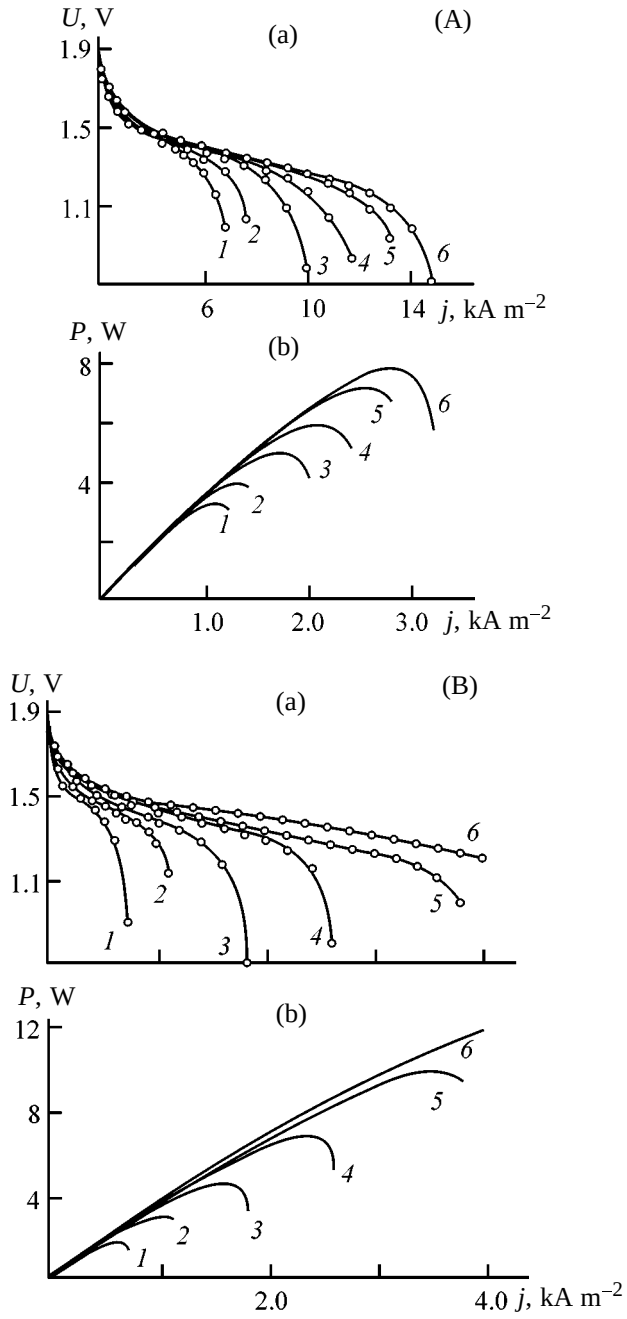

Fig. 3. (a) Discharge voltage U and (b) power P vs. discharge current density j for chemical power cells with (A) $LiOH–H_2O$ and (B) $KOH–H_2O$ electrolytes with varied molal concentration. m: (A) (*1*) 4.5, (*2*) 4.3, (*3*) 4.1, (*4*) 3.9, (*5*) 3.7, and (*6*) 3.5; (B) (*1*) 11.4, (*2*) 10.0, (*3*) 9.0, (*4*) 8.0, (*5*) 7.0, and (*6*) 6.0.

It should be noted that the efficiency of lithium utilization largely depends on the chemical power cell design, and, therefore, the results obtained in an electrochemical cell can only serve as guidelines in choosing the power cell operation mode.

Current–voltage characteristics of chemical power cells with pressure electrodes and electrolytes based on aqueous solutions of the systems $LiOH–H_2O$ and $KOH–H_2O$ were measured at 291 ± 1 K and power values at certain current densities were calculated. As seen from Figs. 3A and 3B, the power of a chemical power cell decreases with increasing content of alkali metal hydroxide in solution. With aqueous solutions of potassium hydroxide used as electrolyte, higher power of chemical power cells can be achieved, compared with the case of the conventional electrolytes of the system $LiOH–H_2O$. In discharge of chemical power cells with 3.5 m LiOH and 6 m KOH as electrolytes in constant-current mode (discharge current density 0.2 and 0.3 A cm^{-2}), lithium utilization efficiencies η = 51 and 50%, respectively, were obtained.

Thus, the obtained results indicate the advisability of using solutions of the system $KOH–H_2O$ in chemical power cells with lithium anode and aqueous electrolyte.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Development of Ways To Diminish Corrosion of Zinc Electrode

T. I. Devyatkina, Yu. L. Gun'ko, and M. G. Mikhalenko

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received November 13, 2000; in final form, March 2001

Abstract—The influence exerted by addition of α-hydroxynaphthoic acid and combined additive Hg + Pb + α-hydroxynaphthoic acid on the corrosion and self-discharge of a porous zinc electrode in alkali solution was studied.

One of disadvantages of nickel–zinc (NZ) power cells is the poor corrosion resistance of the zinc electrode in alkaline solution. As is known, the corrosion rate of the zinc anode depends on the hydrogen overvoltage on zinc in a given electrolyte. To diminish the corrosion of the zinc electrode, it is recommended that metals with high hydrogen evolution overvoltage (Hg, Pb, Cd) should be introduced into the active paste of the electrode [1]. However, all these additives are rather toxic.

An important task is a search for zinc corrosion inhibitors that can simultaneously serve to make lower the content of toxic compounds of mercury, lead, and cadmium. One of ways to lower the corrosion activity of zinc in an alkali solution is to select surfactants that can adsorb onto the zinc electrode and make higher the hydrogen evolution overvoltage. However, the selection of such additives is limited because of the weak adsorption of surfactants on the electrode as a result of competing adsorption of OH^- ions.

In [2], mention was made of the inhibiting action of polyoxyethylene ether on the corrosion of the Zn–In alloy. It was found that this additive has no effect on the rate of zinc corrosion and inhibits the corrosion of the alloy. The inhibition efficiency grows with increasing inhibitor concentration.

Wei Jie *et al.* [3] studied the effect of suppression of zinc corrosion by introduction of oleic and linoleic acids into a 40% KOH solution. Both the acids hinder the corrosion of zinc by forming on the metal a film of chemisorbed molecules of a fatty acid. However, the authors did not demonstrate the effect of these acids on the anodic dissolution of zinc and capacity characteristics of the zinc electrode.

Introduction into electrolyte of potassium salts of perfluorinated aliphatic carboxylic acids makes higher the hydrogen evolution overvoltage in alkaline solutions [4]. Shi Lian-zhen *et al.* [4] found that introduction of both Pb and surfactant lowers the discharge rate of H_2O molecules. Particularly effective is combining the given additives. However, even though the proposed surfactant additive is effective, it is difficultly available for manufacture of power cells with zinc anode. Therefore, it was necessary to search for a surfactant exerting the same effect, but simultaneously readily available and nontoxic. α-Hydroxynaphthoic acid (α-HONA) was chosen as an additive of this kind.

With account of the fact that mercury and lead are introduced into the active paste of the zinc electrode, an attempt was made to introduce into the electrolyte, to diminish corrosion, an α-HONA additive used in manufacture of acid batteries for hindering the corrosion of lead [1].

EXPERIMENTAL

Since α-HONA has been recommended for diminishing lead corrosion proceeding with hydrogen depolarization in acid medium, it was of interest to study its influence on hydrogen evolution on zinc in alkali. Investigations were carried out in concentrated alkali (10 M). This is due to the fact that, with increasing concentration of the working electrolyte, the self-discharge of the positive electrode becomes much weaker [5], which is exceedingly important for designing cells and lowering the corrosion of zinc through a shift of the potential of the hydrogen electrode to more negative values.

The potentiodynamic method was applied to study the effect of α-HONA and deposited Pb (Pb_d) on hydrogen evolution on the zinc electrode from an alkali electrolyte.

1070-4272/01/7407-1122$25.00

It was found that introduction of α-HONA additive into alkali solution has virtually no effect on the hydrogen evolution on zinc. A strong inhibited influence on the corrosion process with hydrogen depolarization on zinc is exerted by a combined additive composed of lead and α-HONA. In this case, a stronger, compared with that in the presence of only lead, decrease in the hydrogen evolution rate was observed (Fig. 1a).

The hindrance to hydrogen evolution on the zinc electrode may be due to adsorption of α-HONA onto lead.

The ability of α-HONA to adsorb on zinc was studied by the Rebinder method. It was found that deposition of lead onto zinc shifts the zero-charge potential to negative values by approximately 20 mV. In the presence of α-HONA in solution, the peak in the curve is shifted to the positive side, which is due to the formation of chelate complexes between lead and α-HONA [6]. No α-HONA adsorption was observed in the absence of lead.

It was also found that these additives hinder somewhat the anodic dissolution of zinc (Fig. 1b). The lowered anodic activity of zinc is presumably due to blocking of active centers of zinc dissolution by chelate complexes formed between Pb and α-HONA.

The decrease in the rate of zinc corrosion in the galvanic couple Zn–Pb (Fig. 2) in the presence of α-HONA in alkali solution is confirmed by the polarization diagram.

In the presence of the α-HONA additive, the corrosion current I_{cor} decreases from 9.7 to 6.7 mA, and the rate of zinc dissolution, from 4.9 to 3.39 g m^{-2} h^{-1}. The efficiency of α-HONA action (%) can be calculated by the formula

$$Z = \frac{K_1 - K_0}{K_1} \times 100, \qquad (1)$$

where K_1, K_2 are the rates of zinc dissolution when in contact with lead without and with α-HONA, respectively.

The protective effect Z of the additional introduction of α-HONA is 30.8%.

As already noted, mercury is one of the most effective corrosion inhibitors. An active paste is known of a porous zinc electrode of a power cell, containing 13% mercury and 0.1–2.0% lead. However, when electrodes with so high mercury content are used, the amount of active paste per unit capacity of a power cell also increases. In addition, since the mercury content exceeds its solubility in zinc (2.5 wt %), it may aggregate into drops short-circuiting the power cell. With account also taken of the high toxicity of mercury, its use in so high amounts is undesirable [7].

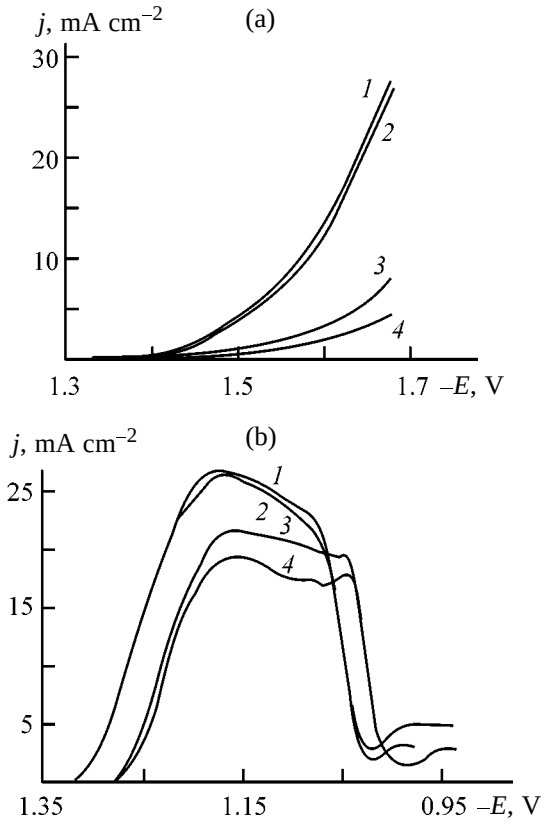

Fig. 1. (a) Cathodic and (b) anodic polarization curves measured on zinc with additives. Sweep rate 4 mV s^{-1}, alkali concentration 10 M. (*j*) Current density and (*E*) potential (vs. s.h.e.). Sample: (*1*) control, (*2*) with addition of α-HONA (in solution), (*3*) Pb_d, and (*4*) Pb_d + α-HONA (in solution).

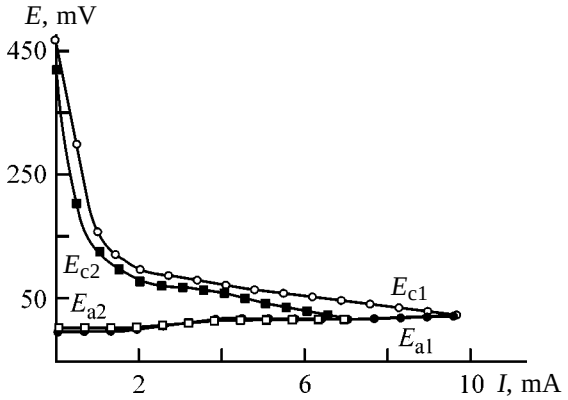

Fig. 2. Corrosion diagram for the galvanic couple Zn–Pb. (*E*) Potential vs. zinc reference electrode and (*I*) current. Cathode, lead; anode, zinc. Alkali concentration 10 M; (*1*) no additive and (*2*) with α-HONA additive.

Effect of α-HONA on the capacity and self-discharge of zinc electrode containing 3% Pb and varied amount of mercury Storage time 300 h at 50°C; electrolyte: 10 M KOH + 15 g l^{-1} $LiOH \cdot H_2O$; j_d = 4 mA cm^{-2}

Additive content		Capacity, A h g^{-1}		Self-discharge, %
in electrode, %	α-HONA in electrolyte, g l^{-1}	before storage	after storage	
6	–	0.629	0.535	14.9
3	–	0.634	0.496	22
3	0.7–1.2	0.629	0.514	18.3
1	–	0.596	0.522	12.4
1	0.7–1.2	0.757	0.707	6.6
0	0.7–1.2	0.447	0.368	17.6

In accordance with the existing technology [5], zinc electrodes are amalgamated to diminish corrosion by introducing 2–10% metallic mercury relative to zinc mass. The authors of [8] recommend introducing mercury in amounts of 1.65–4.5%, noting that making the content of mercury even higher virtually fails to further decrease the hydrogen evolution rate.

To decrease the content of mercury in the active paste of the zinc electrode to improve the environmental safety of manufacture, it is of particular practical interest to search for ways to make lower the content of toxic additives in the negative electrode without impairing the corrosion resistance of zinc. Introduction of α-HONA into the active paste of the zinc electrode or into the electrolyte makes it possible to lower the content of mercury in the electrode from 3–6 to 1% and simultaneously diminish its self-discharge (see table).

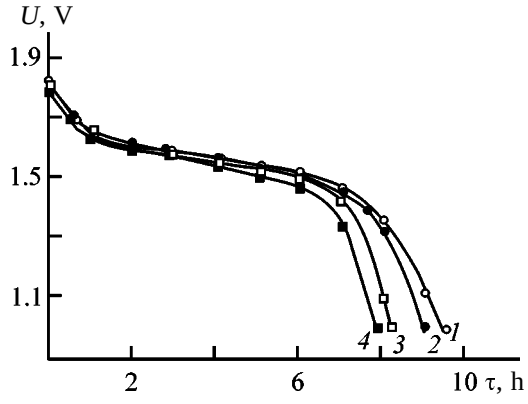

Fig. 3. Effect of additive on the discharge voltage *U* and discharge time τ of a nickel–zinc cell. J_d = 4 mA cm^{-2}, alkali concentration 10 M. Sample: (*1, 3*) control, (*2, 4*) with α-HONA additive in electrolyte, and (*3, 4*) after storage (300 h at 50 ± 1°C).

It can be seen from the obtained data that lowering the content of mercury from 6 to 3% enhances the self-discharge of the zinc electrode. With the content of mercury decreased further (to 1%), the amount of self-discharge decreases substantially, presumably as a result of increased electrochemical activity of zinc. If no mercury is contained in the active paste of the zinc electrode, it is impossible to achieve the required decrease in its self-discharge.

As revealed in the study, the presence of α-HONA exerts a positive influence on the preservation of the zinc electrode. However, one of conditions for possible use of this additive in an NZ cell is the absence of a negative influence on the counterelectrode. It was found in the study that the additive has no effect on the discharge voltage and time of an NZ cell and, consequently, does not impair the working capacity of the nickel oxide electrode (NOE) both before and after its storage at 50°C (Fig. 3). Therefore, it can be recommended for use in NZ cells.

Thus, introduction of α-HONA into the electrolyte of primary alkali–zinc power cells makes it possible to substantially reduce the content of mercury in the active paste of the zinc electrode and to diminish its self-discharge.

CONCLUSIONS

(1) A study of the influence exerted by α-HONA additive, Pb, and combined additive Pb + α-HONA on the rate of hydrogen evolution on the zinc electrode revealed that introduction of the combined additive markedly hinders hydrogen evolution on zinc in alkaline electrolyte.

(2) The α-HONA additive is only adsorbed onto the zinc surface in the presence of lead, which is presumably due to formation of chelate complexes between lead and the acid. The anodic activity of zinc decreases in the presence of this additive.

(3) Introduction of α-HONA additive into the active paste of the zinc electrode or into the electrolyte of alkali–zinc power cells allows a 3–6-fold decrease in the content of mercury in the negative electrode containing mercury and lead additives, with its self-discharge diminished simultaneously.

(4) The recommended additive exerts no negative influence on the counterelectrode (nickel oxide electrode) in the nickel–zinc cell, which demonstrates the possibility of its use in primary power cells of the given system.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Purification of Rhodium-Plating Electrolytes To Remove Nonferrous Metal Impurities

L. B. Khar'kova, S. V. Volkov, and V. I. Pekhn'o

Vernadsky Institute of General and Inorganic Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received February 28, 2001

Abstract—Optimal conditions were determined for purification of sulfate rhodium-plating electrolyte to remove ions of iron(III) and nonferrous metals. Electrochemical and chemical purification techniques were developed.

The sulfate rhodium-plating electrolyte used to deposit anticorrosive coatings in radio engineering and instrument-making is commonly prepared from rhodium trichloride $RhCl_3 \cdot 4H_2O$ of pure grade [1]. This salt contains minor impurities of nonprecious metals, in the first place iron(II) etc. Therefore, a freshly prepared rhodium-plating electrolyte with an Rh content of about 5–10 g l^{-1} commonly contains nonferrous metal ions in the following concentration (mg l^{-1}): Fe^{3+} < 10; Cu^{2+}, Zn^{2+}, Sn^{2+} ≤ 2. Such an impurity content exerts no significant influence on the kinetics of rhodium reduction.

In the course of rhodium plating, ions of nonferrous metals (copper, zinc, and tin) are gradually accumulated in the sulfate electrolyte used for this purpose. The reduction potentials of these impurities being close to the reduction potential of rhodium (Rh^{3+}/Rh +0.27, Cu^{2+}/Cu +0.34, Sn^{2+}/Sn –0.14 V), they can strongly affect the cathodic process at concentrations C_M > 0.20 mg l^{-1}, impairing the quality of the plated coatings.

The method presently used in industry to purify rhodium-plating electrolytes is based on extraction with CCl_4 of diethyldithiocarbamates of nonprecious metals, formed in the electrolyte upon addition of sodium diethyldithiocarbamate [1]. A shortcoming of this method consists in the low limiting concentration of extracted complexes in CCl_4, requiring use of large solvent volumes and additional purification of the electrolyte to remove organic impurities.

The aim of this study was to determine the optimal conditions for recovery of iron and nonferrous metals from sulfate rhodium-plating electrolytes.

EXPERIMENTAL

As objects of study were chosen two rhodium-plating electrolytes: (I) prepared from $RhCl_3 \cdot 4H_2O$ and contaminated in use with Fe^{3+}, Cu^{2+}, Zn^{2+}, and Sn^{2+} ions and (II) prepared from rhodium-containing industrial waste.

Electrolysis was carried out in a 0.5-l glass electrolyzer. Platinum foil served as anode, and preliminarily rhodium-plated (h_{Rh} = 2 μm) copper foil of area 2 cm^2, as cathode. Table 1 presents the composition of the electrolytes under study.

Two purification techniques were studied: electrochemical and chemical.

The optimal electrolysis conditions ensuring deposition of nonferrous metals at the cathode were determined on the basis of the fact that the current density of rhodium reduction is directly proportional to the concentration of rhodium in the electrolyte. At rhodium concentrations of 4–10 g l^{-1}, the optimal current density was in the range 0.4–1.0 A dm^{-2}. Voltammetric studies of sulfate rhodium-plating electrolytes have shown that at cathode current densities i_c <

Table 1. Concentrations of rhodium C_{Rh} and impurity metals C_M in electrolytes under study ($C_{H_2SO_4}$ = 0.1 M)

Electrolyte	C_{Rh}, g l^{-1}	C_M, mg l^{-1}			
		Fe	Cu	Zn	Sn
(I)	6.37	293.5	384.0	118.5	36.5
(II)	5.85	80.0	108.0	32.0	10.0

1070-4272/01/7407-1126$25.00

0.2 A dm^{-2} ($C_{Rh} \geq 4$ g l^{-1}) the current efficiency by metal was less than or equal to 10% [2]. Therefore, for purifying the rhodium-plating electrolyte to remove nonferrous metal impurities, electrolysis was carried out at i_c = 0.1–0.2 A dm^{-2}.

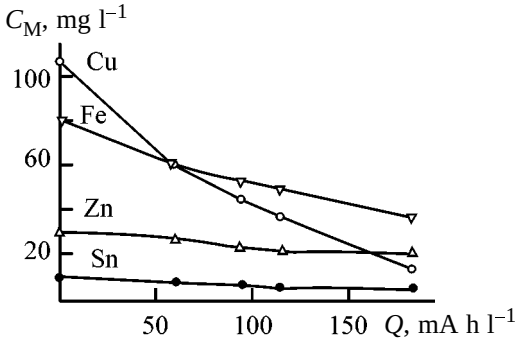
Table 2 and the figure present the concentrations of rhodium and impurity metals in relation to the amount of electricity passed through electrolytes (I) and (II). In both cases, i_c = 0.2 A dm^{-2}. It can be seen from Table 2 that, on passing 0.105 A h l^{-1} of electricity through the electrolyte, the concentration of copper in solution decreases by a factor of 7.3, reaching a value acceptable for the rhodium-plating electrolyte. The concentrations of zinc and tin remain virtually the same and that of iron decreases only slightly. Despite this fact, the electrochemical purification technique can find application in plating since rhodium-plating electrolytes are mainly contaminated with copper ions when in use.

The chemical method for purification of rhodium-plating electrolyte to remove impurity metals is based on the ability of rhodium hydroxide $Rh(OH)_3 \cdot 2H_2O$ to lose crystallization water at 200°C. On further heating it decomposes with oxidation of Rh(III) to Rh(IV) and formation of rhodium dioxide RhO_2 (200–450°C), which is, in turn, reduced to α-Rh_2O_3 at 750°C [3]. Rhodium oxides are insoluble in any of the known acids or mixtures of these.

Hydroxide compounds of rhodium and nonferrous metals were precipitated from the rhodium-plating electrolyte with a 40% KOH solution. After filtration and washing with distilled water, metal hydroxides were calcined at 500°C for 5 h. Iron and nonferrous metals were separated from the obtained mixture of oxides by boiling in HCl (1 : 1). To synthesize rhodium-plating electrolyte, rhodium in the form of filtered-off and washed mixture of oxides was converted into a water-soluble form by fusion with $Na_2S_2O_7$. Metal hydroxide was precipitated from a rhodium sulfate solution and dissolved in a calculated amount of concentrated H_2SO_4 to obtain the rhodium-plating electrolyte.

Table 3 presents the composition of the initial electrolyte (I) and that after purification by the chemical method (Ia). It can be seen that the concentration of impurity metals decreases 2.5–22-fold, reaching values acceptable for rhodium-plating electrolytes.

The loss of rhodium is 2.5–2.8 and 3.5–3.7% in, respectively, electrochemical and chemical purification.



Concentration of impurity metals in rhodium-plating electrolyte C_M vs. amount of electricity Q passed through electrolyte.

CONCLUSIONS

(1) The optimal conditions for purification of sulfate rhodium-plating electrolyte to remove impurities of iron and nonferrous metals were determined.

(2) An electrochemical purification technique based on electrolysis at i_c = 0.1–0.2 A dm^{-2} was developed, lowering the concentration of copper in the electrolyte approximately sevenfold.

(3) A chemical purification technique based on

CATALYSIS

Determining the Activity of Supported Vanadium Catalyst for Sulfur Dioxide Oxidation from Data Furnished by Flow-Through Method

E. I. Dobkina, S. M. Kuznetsova, L. A. Nefedova, and S. A. Lavrishcheva

St. Petersburg State Technological Institute, St. Petersburg, Russia

Abstract—The rate of sulfur dioxide oxidation on a supported vanadium catalyst and the influence exerted by the chemical composition of the catalyst on its activity were studied.

The main service characteristic of any catalyst is its activity. As characteristics of activity can serve both the conversion and the rate constant at an appropriate temperature. The most effective procedure for determining the rate constant and directly the reaction rate is the differential flow-through-circulation conversion of sulfur dioxide [1]. However, implementing this technique requires rather complex kinetic installations, which are frequently difficult to assemble, particularly under industrial conditions of catalyst manufacture and at plants where catalysts are used. Also, reliable data on the activity of the manufactured catalysts are, as a rule, necessary together with monitoring for assessment of the stability of catalyst operation in industrial reactors. In this case, it is advisable to use flow-through installations [1, 2] which make it possible to determine the conversion in a wide temperature range and then to calculate, by means of a chosen kinetic equation, the reaction rate constant.

As is known, sulfur dioxide is oxidized using vanadium catalysts of various kinds. All of these contain vanadium(V) oxide as the main active component, alkaline promoters, and support. The composition of the active component of the catalyst can be expressed as $V_2O_5 \cdot mK_2O \cdot nSO_3$ [1–3]. As a catalyst works, the ratio of the oxides in it changes, depending on temperature, initial concentrations of gas phase components, and the extent of SO_2 oxidation into SO_3. The m value is determined by synthesis conditions, whereas n varies, depending on reaction conditions, between $2m$ and $4m$.

EXPERIMENTAL

A spherical supported vanadium catalyst was chosen for the study. In chemical composition the catalyst is close to the industrial SVD catalyst [1]. The catalyst grain size was 1.5 or 0.75 mm. The dependence of the degree of sulfur dioxide oxidation, x, on temperature and space velocity V is shown for the chosen samples in Figs. 1a and 1b. The experiments were done on a flow-through kinetic setup under the standard conditions specified by Boreskov [1–3]. The virtually complete coincidence of the results for particles 1.5 and 0.75 mm in size guarantees the kinetic control of the process. The curves in Fig. 1 exhibit a characteristic peak determined by the relative rates of the forward and reverse reactions, with the optimal temperature mode corresponding to the maximum x value. With increasing space velocity, the maximum conversions decrease and the optimal temperatures, correspondingly, increase.

The obtained experimental relationships can be used to calculate the reaction rate constant using various kinetic equations [1, 4], e.g.,

$$dx/d\tau = k/a(x_{eq} - x)^{0.8}/x^{0.8}(b - ax/2) \times 273/T\beta, \quad (1)$$

where a is the initial sulfur dioxide concentration; b is the initial concentration of oxygen; τ is the time of contact under normal conditions; x is the conversion; x_{eq} is the equilibrium conversion under given conditions; and β is the correction factor defining the increase in concentration, caused by a decrease in the total volume of the gas mixture as a result of the reaction; in the experiments it was close to unity and, therefore, is not taken into account in what follows.

Equation (1) was used in calculations, with conversions taken from Fig. 1b, and $dx/d\tau$ values, from Fig. 2. The equilibrium conversions (for a gas phase

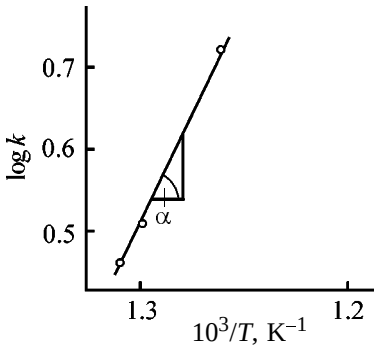

Fig. 3. Reaction rate constant k vs. temperature T.

composition 7% SO_2 + air) were taken from the literature.

The rate constants calculated by means of Eq. (1) were 5.45, 3.25, and 2.86 at, respectively, 520, 500, and 485°C.

The rate constants obtained in calculations by Eq. (1) for a crushed industrial vanadium catalyst SVD virtually coincide with the above values. The closeness of the activities of the catalysts in question is also indicated by their close activation energies.

Vanadium catalysts have different activities at low and high temperatures [1, 2, 4]. The activity changes in the temperature range 400–470°C, which is due to chemical transformations of the active component of the catalyst. The authors were primarily interested in the working range of high temperatures, for which the activation energy was calculated. According to the Arrhenius equation, the dependence of the reaction rate constant k on temperature is as follows:

$$\ln k = -E/RT + \ln k_0,$$

where E is the apparent activation energy, k is the reaction rate constant, and k_0 is the pre-exponential factor in the Arrhenius equation.

The slope of the straight line in the coordinates $\log(k - 1)/T$ is $-E/R$, which makes it possible to determine E. The slope $\tan\alpha$ is found from Fig. 3 and then the activation energy is determined:

$$E = 2.303R\tan\alpha, \quad (2)$$

where $R = 8.31$ J mol^{-1} deg^{-1}, $\tan\alpha = 5 \times 10^3$.

Consequently, $E = 2.303 \times 8.31 \times 5 \times 10^3 = 95.5 \times 10^3$ J mol^{-1}.

Calculation of the activation energy for the SVD catalyst by Eq. (2) gives virtually the same value [1, 4].

CONCLUSION

Analysis of the presented data on rate constants and activation energies confirms once again the Boreskov's concept that the chemical composition, and in the first place the content of the main active component and promoter, rather than the preparation method, determine the primary service characteristic of a catalyst, its activity (the first catalyst of those

studied is supported and the second is of mixed type). It is highly important that the samples should have similar pore structures ensuring a sufficient reaction surface area and "free" mass transfer.

CATALYSIS

Effect of Pore Structure of Al–Co–Mo Catalyst on the Rate of Various Pathways of Hydrofining of Oil Residues

Abstract—Evolution in the activity and texture of the Al–Co–Mo catalyst in hydrofining of black oil is studied. The catalyst efficiency in desulfurization, deasphalting, and demineralization of black oil is estimated as dependent on the catalyst pore structure and process conditions.

The steadily growing demands for the quality of petroleum products, on the one hand, and production of motor fuels by thorough-going processes, on the other hand, make the development of processes of hydrofining of heavy oil cuts particularly important. Furthermore, the growing shear of sulfur-bearing and sour oils in petroleum production [1] makes this problem even more pressing. A thorough-going method for production of low-sulfur fuel oil and raw materials for manufacture of pollution-free motor fuel is hydrofining of petroleum residues, primarily, black oil. However, such processes find no wide applications in industry yet, because their implementation is a rather difficult problem, first of all due to the nature of heavy oil cuts, which represent a complex colloid system in which asphaltenes are dispersed in mutually soluble oil resins and polycyclic hydrocarbons. In other words, the petroleum residues represent a multicomponent heterogeneous system whose constituents are characterized by variable elemental composition, structures, and physicochemical characteristics.

About 60–80% of the total sulfur remains in residues after oil distillation at atmospheric pressure [2], and about 20% is contained in resins and asphaltenes [3]. The fraction of asphaltenes (the most complex and difficultly decomposable component of oil) includes a part of metals contained in oil.

Asphaltenes have a strong decelerating effect on hydrodesulfurization of petroleum residues [4]. This is probably due to the fact that, owing to the low diffusion rate in the liquid phase and catalyst pores, they hinder the access of hydrogen and sulfurous compounds to the inner surface of the catalyst, thus decreasing the desulfurizing activity. Another possible reason is irreversible sorption of asphaltenes on the catalyst surface with formation of condensation products (CPs) of them. It should be pointed out also that sulfur contained in asphaltenes is the most difficultly removable. All these facts require giving particular attention to the catalyst activity in the course of decomposition of the asphaltic-resinous components of the raw material.

The specific features of hydrofining of heavy oil cuts place a series of constraints on the catalyst, among them the presence of a zone of coarse pores, which reduce the diffusion hindrance and increase the coverage of the catalyst surface. The available relevant information is rather contradictory, which may be due to a wide variety of the compositions of the raw materials studied. Thus, the problem of optimization of the catalyst texture should be solved individually for each particular raw material and required product quality [5].

Previously we demonstrated [6] how the pore structure of the Al–Co–Mo catalyst controls its activity in hydrodesulfurization of black oil produced from West-Siberian oil. The goal of this work is to clarify the nature of evolutions in the activity and size of particular zones of the pore structure of the Al–Co–Mo catalyst in hydrofining of black oil, and also the effect of the size of macropores (more than 100 nm in diameter) on the catalyst performance in various process pathways.

EXPERIMENTAL

In the work we studied test samples of varied pore structure, having various concentrations of active sites. The γ-Al_2O_3 support was synthesized by the nitrate technique, and its pore structure was controlled

1070-4272/01/7407-1132$25.00

by introducing varied amounts of a 25% $NH_3 \cdot H_2O$ solution into the aluminum hydroxide paste being formed. The catalysts were prepared by successive impregnation with solutions of ammonium paramolybdate and cobalt nitrate of the support calcined at 550°C. The resulting catalyst mass was allowed to stand in air for 24 h and dried at 60–70°C for 2–3 h under an IR lamp with intermittent stirring and then in an oven at 120°C for 4 h. The dried samples were calcined in air at 450–550°C for 6 h. The specific surface area of the oxide catalyst S_{sp} thus obtained was determined from nitrogen thermal desorption data obtained by the dynamic method. The pore structure was studied by mercury porosimetry.

The catalyst activity was tested in a high-pressure flow-through (no recycling) setup. Prior to testing the samples were sulfidized at 400°C. The testing time was 24–110 h, temperature 380–420°C, pressure 5–10 MPa, and hydrogen consumption at normal conditions 1000 nl l^{-1}. The catalyst grain size was 0.4–3 mm. The space velocity of black oil across the catalyst bed was 1–30 h^{-1}.

In special-purpose experiments we demonstrated that there is no external-diffusion hindrance of the process under the experimental conditions.

The initial black oil contained sulfur, asphaltenes, resins, and the fraction distilled below 360°C in amounts of 1.7, 2.0, 25, and 9 wt %, respectively. The V and Ni contents were 27 and 18 ppm, respectively. As a raw material we used also such model compounds as benzene and cyclohexane. In addition to the desulfurizing activity we also assessed the catalyst activity with respect to deasphalting, demineralization, cracking, hydrogenation, and isomerization. To characterize all the indicated types of the catalyst activity and their evolution during the tests, hydrogenizate samples were periodically taken and analyzed. Sulfur in the initial black oil and hydrogenizates was determined by the burning method [7], asphaltenes, by precipitation with *n*-heptane, and V and Ni, by the atomic absorption method on Saturn and AAS-1N spectrometers using white spirit as a solvent [8]. To determine the fraction distilled below 360°C in the initial black oil and hydrogenizates, they were distilled. The composition of benzene and cyclohexane hydrogenizates was determined chromatographically. As the measures of the catalyst activity we used the conversion α and the average apparent rate of the process *W*.

After the raw material feed was terminated, the reactor was cooled under hydrogen, the pressure was relieved, and the spent catalyst was washed with

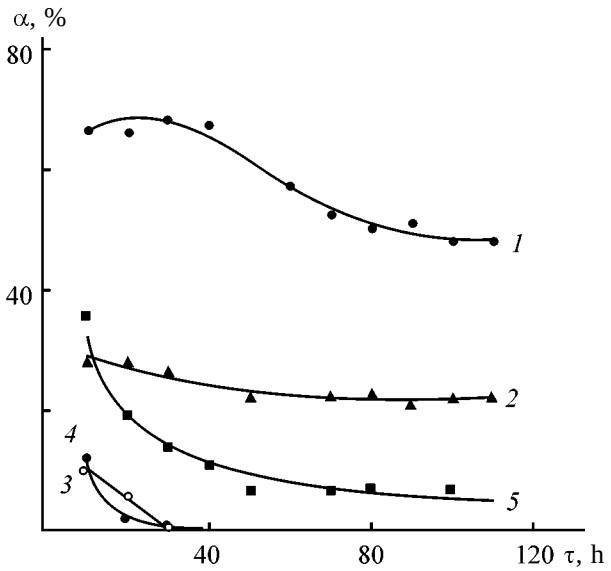

Fig. 1. Activity α of the catalyst as a function of time τ in hydrofining of black oil. Reaction: (*1*) desulfurization, (*2*) deasphalting, (*3*) cracking of the fraction boiling above 360°C, (*4*) conversion of cyclohexane to methylcyclopentane, and (*5*) hydrogenation of benzene.

diesel fraction. Prior to study of the pore structure and determination of S_{sp} and the degree of coking, the catalyst was vacuum-treated at 100°C and 2–3 mm Hg. The amount of condensation products deposited on the catalyst surface was determined by burning.

Figure 1 demonstrates evolution in the activity of the catalyst sample (Mo 9 and Co 3.6 wt %) in a 100-h experiment on hydrofining of black oil. The experiment was carried out in the cyclic mode at 420°C and 10 MPa. Every 10 h throughout the experiment benzene and cyclohexane were passed in turn (for 2 h each) instead of black oil, to characterize the hydrogenizing and isomerizing activity of the catalyst. The hydrogenizates were sampled for analysis in each cycle. The samples were collected in the last 4 and 0.25 h of passing black oil and the model hydrocarbons, respectively.

In the first 40 h of catalyst operation the desulfurization level was practically unchanged, and then the catalyst activity gradually decreased (Fig. 1, curve *1*). The deasphalting level (Fig. 1, curve *2*) remained practically unchanged throughout the experiment (only in the first hours it slightly declined). Similar trends were observed for demineralization. The benzene hydrogenation level drastically decreases in the first hours from 37 to 7%, and then the activity stabilizes (Fig. 1, curve *5*). The cracking and isomerizing

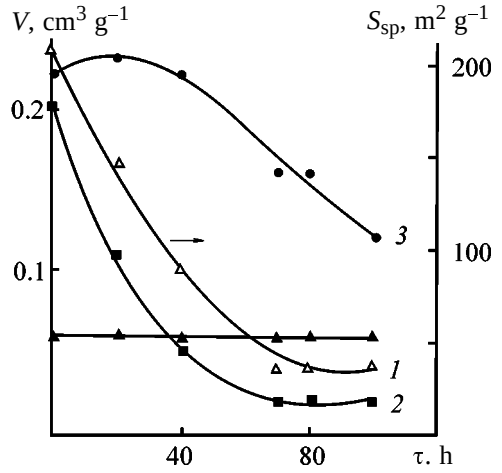

Fig. 2. Evolution of (*1*) S_{sp} and (*2–4*) pore volume V of the catalyst in black oil hydrofining. (τ) Time. Pore radius (nm): (*2*) 4–10, (*3*) 10–100, and (*4*) >100.

activities totally decay in the first 30 h of the catalyst operation (Fig. 1, curves *3, 4*), which is probably due to rapid poisoning of the acidic sites on the catalyst surface. Such a strong difference in the nature of evolution of the two latter types of activity and the desulfurization activity in time indirectly suggests the lack of a close correlation between the desulfurization activity and acidity of the catalyst.

The observed dissimilarity in the dynamics of the catalyst activity with respect to desulfurization, hydrogenation, and cracking (Fig. 1, curves *1, 5, 3*) is consistent with the existing views of the hydrocracking mechanism of sulfur-containing compounds [9], according to which cleavage of the C–S bond of a thiophene ring and hydrogenation of the hydrocarbon fragment proceed by the concerted mechanism on specific active sites of layered MoS_2-like structures.

Refining of such a heavy raw material as black oil is accompanied by vigorous coking of the catalyst surface. In this work we demonstrated that the amount of condensation products in the sample operated for 110 h as a catalyst in black oil refining was about 21 wt %. Concentration of such amounts of CPs should initiate considerable transformation of the catalyst texture and decrease in the catalyst effective area, which can be one of the most significant causes of deterioration of the efficiency and selectivity of hydrofining. Let us consider how the pore structure and S_{sp} of the test sample change in the course of black oil hydrofining (Fig. 2).

Even in the initial stage of hydrofining S_{sp} starts to decrease. It continues to decrease for about 70 h, then remaining practically unchanged. In the initial 50 h we also observed an abrupt reduction in the volume of fine pores (radius 4–10 nm), suggesting that these pores contribute significantly to S_{sp}. The volume of pores with a radius of 10–100 nm starts to gradually decrease even only 40 h of the catalyst operation. We observed no noticeable blocking of macropores (>100 nm) throughout the experiment.

The results show a clear correlation between evolution of the degree of desulfurization and the volume of pores with a volume of 10–100 nm (Figs. 1, 2). Evidently, hydrogenolysis of sulfur-containing compounds contained in black oil occurs primarily on the surface of pores of this size, while fine pores (4–10 nm) do not contribute significantly to desulfurization, as being blocked because of coking of the catalyst. In this process the macropores (>100 nm) fulfil only the transport function.

On the contrary, the observed direct correlation between the volume of fine pores (4–10 nm) and the degree of hydrogenation of benzene suggests that the process occurs essentially on the surface of these pores, which is consistent with small size of benzene molecules and also with considerable contribution of the fine pores to S_{sp}.

The invariability of the volume of macropores (>100 nm) in the course of the process as well as of the catalyst activity with respect to deasphalting suggest that only these pores are accessible for bulky asphaltene macromolecules. Analogous conclusion may be expanded to metal-containing structures either.

Figures 1 and 2 demonstrate that it is the pores over 10 nm in radius that mainly provide the transport and catalytic functions in hydrogenolysis of sulfur-containing compounds and in cracking of the highest-molecular-weight components of black oil. In this case the macropores (>100 nm) are, evidently, of primary importance in transportation of the raw material to the inner surface of the catalyst.

To study in more detail the role of the macropores (>100 nm) in hydrofining, let us consider how their volume influences the coverage of the catalyst surface (catalyst efficiency index) in various hydrofining processes. Therefore, we tested a series of Al–Co–Mo catalysts with variable volume of macropores, Mo concentration (4.8–9.0 wt %), Co/Mo weight ratio (0.3–0.5), and S_{sp} (120–180 $m^2\ g^{-1}$). In the series the volume of pores 10–100 nm in radius was 0.3–0.05 $cm^3\ g^{-1}$. The test time was 24 h. The desulfurization level was maintained to be rather low (25–35%), which was realized by varying the raw material feed rate, depending on the sample activity. The tests

were performed with catalyst samples with coarse (3 mm) and fine (0.4 mm) grains at 380°C and 10 MPa. Grinding to 0.4 mm ensures the reaction to proceed practically in the kinetic control mode, as was demonstrated in a series of experiments with the catalysts with various grain sizes.

The catalyst efficiency index was estimated relating the average apparent reaction rate on coarse grains to that on the fine grains. The results are given in Fig. 3. The observed data scattering can be attributed to the spread in values of the Mo and Co concentrations and, therefore, of the catalyst activity and the diffusion to reaction rate ratios. Despite this fact the results clearly demonstrate that the pore structure of the catalyst has different effects on various hydrofining pathways. The coverage of the catalyst surface in cracking of asphaltenes drastically increases with increasing volume of the macropores. Under conditions of thermal motion in hydrocarbon medium, the asphaltene micelles have a sufficiently long free path. Estimated from the molecular kinetic data on motion of colloid particles in solution (asphaltene concentration 2 wt %; molecular size 5–10 nm), the free path (up to 60 nm [10]) exceeds the size of certain fraction of the pores in the catalyst structure. With increasing fraction of macropores the contribution of molecular diffusion should increase relative to the Knudsen component, facilitating the transport of asphaltenes to the inner surface of the catalyst and increasing its coverage. Previously we observed such a drastic increase in the catalyst efficiency factor with increasing volume of macropores in demineralization of black oil [11].

In the case of hydrodesulfurization (Fig. 3, curve *1*) the effect of the amount of macropores is considerably lower. However, the trend to increasing effective surface area of the catalyst with increasing volume of macropores is observed in this case also. Evidently, in transportation and conversion of sulfur-containing compounds fine pores (10–100 nm) play a crucial role.

Let us consider next how the pore structure of the catalyst influences the desulfurization and deasphalting of black oil at various process conditions.

Figure 4 demonstrates the effect of the volume of macropores on the amounts of sulfur removed and condensation products (V + Ni) in 100 h of the catalyst operation at 380°C and various hydrogen pressures (Mo and Co concentrations in the catalyst 7–8 and 2.5 wt %, respectively). The initial process level was 35–70%. Increase in one of the varied parameters (P, V_{mp}) results in decreasing sensitivity of the process to variation of the other parameter. The higher V_{mp}, the weaker the effect of the hydrogen pressure on the catalyst performance, and vice versa, the effect of macropores decreases with increasing pressure. Evidently, with increasing P and, therefore, decreasing free path and diffusion coefficient [12, 13], the contribution of macropores decreases. The pressure has a considerable effect only at sufficiently strong diffusion hindrances, i.e., at a small fraction of macropores.

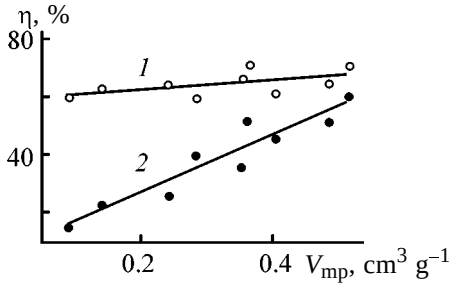

Fig. 3. Effect of the volume of macropores V_{mp} on the coverage of the catalyst surface η (grain size 3 mm) in (*1*) desulfurization and (*2*) cracking of asphaltenes at 380°C and 10 MPa.

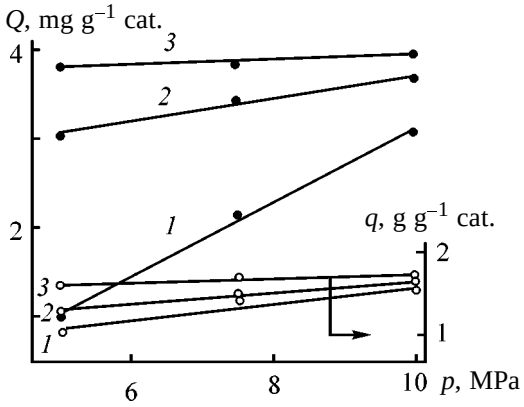

Fig. 4. Effect of the hydrogen pressure p on the amount of sulfur removed q and the total amount Q of V + Ni deposited in 100 h at 380°C. Catalyst grain size 3 mm. Volume of macropores (cm^3 g^{-1}): (*1*) 0.1, (*2*) 0.2, and (*3*) 0.3.

Note that deposition of V and Ni considered separately is described by similar dependence as deposition of their sum (V + Ni, Fig. 4). The degree of removal of V from black oil is higher by a factor of 1.5–2.0 than that of Ni.

Cracking of asphaltenes is sensitive to P and V_{mp} to similar extent as demineralization.

With respect to desulfurization the indicated trends are less pronounced (Fig. 4), additionally confirming the lower contribution of the diffusion factor to this

process. Furthermore, it is worth noting that the desulfurization efficiency only slightly depends on the hydrogen pressure. According to the existing views of the hydrogenolysis mechanism of thiophene as a model compound [9], desulfurization proceeds via concerted electron and hydrogen transfer across the system of chemical bonds of the sulfide bimetallic catalyst, and the first step (adsorption of the sulfur-containing electron-donor molecule) occurs on a Co cation (it acquires acidic properties as a result of oxidative addition of hydrogen with formation of a strongly bound occluded form in the catalyst matrix). The amount of this form of hydrogen is controlled by the number of atoms of the active component of the catalyst; therefore, apparently, the effect of the total hydrogen concentration in the system on the desulfurization efficiency is insignificant.

CONCLUSION

The cracking and isomerizing functions of the Al–Co–Mo catalyst totally decay in the first hours of operation in hydrofining of black oil under the experimental conditions. The reduction in the efficiency of desulfurization, deasphalting, and demineralization of black oil is caused to a considerable extent by changing texture of the catalyst. The relative decrease in the volume of particular fractions of pores in the catalyst structure in the course of the process was found to be 90, 45, and 0% for pores 4–10, 10–100, and >100 nm in radius, respectively, i.e., this parameter decreased with increasing pore size. Desulfurization of black oil proceeds essentially on the surface of pores 10–100 nm in radius. The catalyst efficiency in deasphalting and demineralization as well as the coverage of the catalyst surface in these processes are controlled by the volume of coarse pores (>100 nm).

CATALYSIS

Effect of Composition of Al–Co–Mo Catalyst on Its Desulfurizing, Deasphalting, and Demineralizing Activity in Hydrofining of Oil Residues

Abstract—Effect of the composition of Al–Co–Mo catalysts on their desulfurizing, deasphalting, and demineralizing activities in hydrofining of black oil and interrelation of these activities with coking and deactivation of the catalyst are studied.

Study of physicochemical and catalytic characteristics of catalysts for hydrofining of heavy oil cuts is important in view of growing spread of this process. Thus, in the United States the annual output capacity of heavy cut hydrofining installations in refineries increased by 33 million tons in the period from 1980 to 1996 [1, 2]. This tendency is initiated primarily by steadily increasing atmospheric pollution with SO_2 (about 160 million tons of SO_2 is annually released all over the world to the atmosphere as a result of black oil and coal combustion), so that the steadily growing demand for environmentally clean motor fuels should be satisfied by hydrofining of heavy cuts.

In this connection optimization of the composition of catalysts is one of the most important problem.

Here we report on the effect of the concentration of the active component of the Al–Co–Mo catalyst on its desulfurizing, deasphalting, and demineralizing activities and formation of condensation products (CPs) on the catalyst surface in hydrofining of black oil produced from West-Siberian crude oil.

EXPERIMENTAL

In experiments we used samples with various concentrations of the active components and phase compositions. The γ-Al_2O_3 support for the catalysts was prepared by the nitrate method. The catalysts of fixed composition were prepared by impregnation of the support calcined at 550°C with solutions of ammonium paramolybdate and cobalt nitrate. The resulting catalyst mass was air-dried for 24 h, dried at 60–70°C under an IR lamp with intermittent stirring, and in an oven at 120°C for 4 h. The dried samples were then calcined in air for 6 h at a fixed temperature from the range 450–550°C.

The samples thus obtained varied not only in the Mo and Co concentrations, but also in the relative content of crystallized Co and Al molybdates and the degree of their crystallinity. The phase composition was varied as in [3, 4] using data on the effects of the sequence of application of Mo and Co to Al_2O_3 and the mode of oxidative thermal treatment of the catalyst mass. The Co/Mo atomic ratio in the samples was 0.40 ± 0.03. The phase composition of the catalysts was studied by X-ray diffraction analysis on a DRON-1.5 diffractometer (CuK_α radiation, graphite monochromator for reflected beam). In data processing we used the external reference method. As reference mixtures we used γ-Al_2O_3 + MoO_3, γ-Al_2O_3 + $Al_2(MoO_4)_3$, and γ-Al_2O_3 + $CoMoO_4$.

The catalyst activity was tested in a high-pressure flow-through (no recycling) setup. Prior to testing the samples were sulfidized at 400°C. The testing time was 24–110 h, temperature 380–420°C, pressure 10 MPa, and hydrogen consumption at normal conditions 1000 nl l^{-1}. The experimental space velocity of black oil across the catalyst bed provided the desulfurization level of 25–35%.

In special-purpose experiments we demonstrated that there is no external-diffusion hindrance of the process under the experimental conditions. Furthermore, at a grain size of 0.4 mm internal-diffusion hindrance is not manifested also, which allows an adequate estimation of the effect of the chemical composition of the catalyst on its activity.

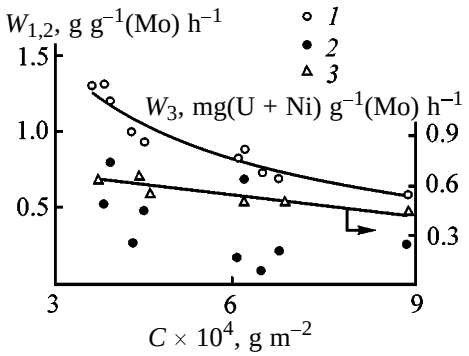

Fig. 1. Average apparent rates of (*1*) desulfurization, (*2*) deasphalting, and (*3*) demineralization as functions of the Mo concentration *C* in the catalyst. Temperature 380°C, hydrogen pressure 10 MPa, catalyst grain size 3 mm; the same for Figs. 2 and 3. ($W_{1,2}$) Desulfurization and deasphalting rates and (W_3) demineralization rate.

The initial black oil contained sulfur, asphaltenes, tars, and the fraction boiling point of below 360°C in amounts of 1.7, 2.0, 25, and 9 wt %, respectively. The V and Ni contents were 27 and 18 ppm, respectively. To characterize the catalyst activity with respect to desulfurization, deasphalting, and demineralization, hydrogenizate samples were periodically taken and analyzed. Sulfur in the initial black oil and hydrogenizates was determined by burning [5], asphaltenes, by precipitation with *n*-heptane, and V and Ni, by the atomic absorption method on Saturn and AAS-1N spectrometers using white spirit as a solvent [6]. As the measures of the catalyst activity we used the average apparent rate of the process *W* at the indicated process level.

After the raw material feed was terminated, the reactor was cooled under hydrogen, the pressure was relieved, and the spent catalyst was washed with diesel fraction. Prior to determination of the degree of coking, the catalyst was vacuum-treated at 100°C and 2–3 mm Hg. The amount of condensation products deposited on the catalyst surface was determined by burning.

The Mo concentration differently influences the rates of desulfurization, deasphalting, and demineralization (Fig. 1). The catalyst activity (estimated per Mo unit mass) in hydrogenolysis of sulfur-containing compounds decreases with increasing Mo content; in demineralization the effect is only slightly pronounced; and as for deasphalting, no clear correlation is observed, suggesting that the indicated processes demonstrate different sensitivity to the composition and structure of the effective catalyst layer.

The observed decrease in the specific desulfurizing activity with increasing Mo concentration irrespective of the phase composition of the catalyst can be attributed to increasing aggregation of Mo species and, hence, decreasing fraction of Mo accessible for sulfur-containing components of black oil.

In deasphalting the highest activity is demonstrated by the catalysts whose oxide precursors contain more cobalt molybdate as compared to aluminum molybdate. In this case the specific activity (per Mo unit mass) increases with increasing crystallinity of the former. The possible reason is that catalytic cracking of an asphaltene micelle requires simultaneous breakdown of a large amount of bonds. Therefore, in this case an active catalytic center should be much greater in size than in hydrogenolysis of ordinary sulfur-containing molecules.

The fact that the activity of the sulfide form of the catalyst depends on the dispersity of Mo in the oxide precursor is consistent with data of [7, 8] demonstrating that this dependence is maintained on passing of the Al–Co–Mo system from the oxide to the sulfide form.

Demineralization of black oil is practically insensitive to variations in the chemical and phase compositions of the catalyst (Fig. 1).

Hydrofining of heavy oil cuts is accompanied by a considerable coking of the catalyst surface, which is the major factor responsible for decreasing catalyst activity. Since the raw material has a complex composition, questions arise as to what components of the reaction mixture are the principal monomers in formation of the condensation products and how the latter process is associated with the other reactions occurring in hydrofining. In [9, 10] it was suggested that asphaltenes having high adsorption capacity and tending to coking are, most likely, precursors of the condensation products. However, it was demonstrated that decreasing asphaltene content in oil residues by a factor of 9 reduces the amount of CPs by a factor of 1.4 only [11], and that introduction of asphaltenes in the cracked distillate even somewhat decelerates formation of CPs [12], which has cast some doubt on the determining role of asphaltenes in coking of the catalysts.

Figure 2 demonstrates the dependence of the amount of CPs deposited on the catalyst surface on the Mo concentration. Figures 1 and 2 show that decreases in the desulfurization activity and amount of deposited CPs with increasing Mo concentration are correlated processes, which is consistent with results obtained in [13] for a series of catalysts with vari-

ous chemical compositions and desulfurizing activities, demonstrating a direct correlation between the amounts of sulfur removed and CPs deposited in 24-h runs. Thus, one may suggest occurrence of a rather close relation between hydrogenolysis of sulfur-containing compounds and formation of CPs. For cracking of asphaltenes such a relation is not found (Figs. 1, 2).

As for metal-containing components of black oil, their concentration is too low to contribute significantly to formation of CPs.

Evidently, CPs are formed primarily from strongly coke-forming unsaturated products of hydrogenolysis of sulfur-containing compounds. This conclusion is confirmed by data on contributions of model organic compounds (with benzene and thiophene) to coking of the Al–Co–Mo catalyst using a radioactive tracer [13]. The contribution of thiophene was demonstrated to be higher by more than two orders of magnitude as compared to benzene. Such a close relation between hydrogenolysis of sulfur-containing compounds and coking of the catalyst suggests that the degree of catalyst deactivation directly depends on the desulfurization level.

It was demonstrated with an example of the simplest model reaction [14] that the deactivation of catalysts can decrease when internal-diffusion hindrance occurs. It is advisable to check this result for consistency in the case of hydrofining of oil residues. Note that comparison of the degree of reduction of the desulfurizing activity of the catalysts should be made taking into account the presence in the raw material of a broad spectrum of sulfur-containing compounds differing in the molecular weight, reactivity, structure, and coke-forming capacity of hydrogenolysis products as precursors of CPs. Changing desulfurization level is not an extensive phenomenon. It results in different qualitative composition of the major monomers of CPs, i.e., it changes the coke-forming capacity of the reaction mixture. Therefore, comparison of deactivation of any catalysts of hydrodesulfurization (including the kinetically and diffusion-controlled zones of the reaction) can provide adequate results only at close desulfurization levels. In this work the experiments were carried out at a desulfurization level of $30 \pm 5\%$, i.e., the above condition was met. We tested the catalysts with fine (0.4 mm) and coarse (3 mm) grains. The results showed that in the former case the initial desulfurization rate was higher by a factor of 1.1–1.2, and the amount of CPs was higher by a factor of 1.3–1.5. In estimating the degree of deactivation it should be taken into account that in the case of the fine-grain catalyst, in order to obtain the desulfurization level close to that for the coarse-grain catalyst, we were forced to use a higher space velocity. Therefore, the catalyst efficiency (amount of sulfur removed) is higher with fine grain also. To take this factor into account in comparison of the deactivation of the catalysts, the difference between the initial and final (after a 24-h run) desulfurization rates was related to the amount of sulfur removed in this time per unit weight of the catalyst. The results show (Fig. 3) that the differential change in the activity of the catalytic system is practically independent of the conditions of mass transfer, but is controlled by the amount of sulfur removed. Thus, we experimentally confirmed that deactivation of the catalysts for hydrofining of oil residues is caused essentially by coking with products of hydrogenolysis of sulfur-containing components of the raw material.

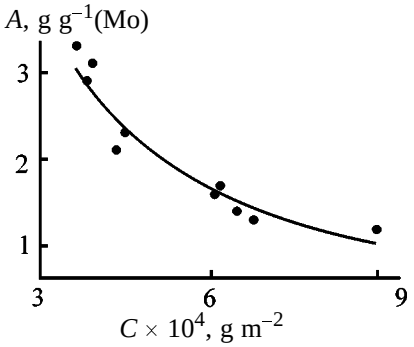

Fig. 2. Amount of CPs A as a function of the Mo concentration in the catalyst C.

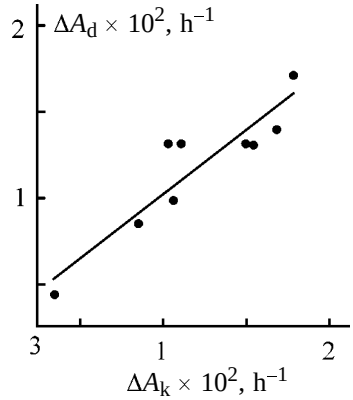

Fig. 3. Correlation between the differential changes in the desulfurization rate on coarse (ΔA_d) and fine (ΔA_k) grains.

CONCLUSION

The rates of desulfurization, deasphalting, and demineralization differently depend on the composition of the Al–Co–Mo catalyst. The specific (per unit

weight of Mo) desulfurizing activity decreases with decreasing Mo content. The deasphalting activity is controlled by the amount of crystallized cobalt molybdate. Demineralization is practically insensitive to changing phase composition of the catalyst as well as the Mo content over the experimental range of its variation. The degree of coking of the catalyst and its deactivation increase with increasing extent of desulfurization.

Received September 12, 2000; in final form, March 2001

Abstract—The effect of organoaluminum compound nature on the kinetic nonuniformity of the active centers of neodymium-containing catalytic systems at butadiene polymerization was studied. The concentrations of each type of active centers were calculated.

Previously [1, 2] we used the Tikhonov's regularization method [3, 4] to characterize the activity of the lanthanide-containing systems in diene polymerization and found that, irrespective of the diene nature and polymerization conditions, macromolecules are synthesized on lanthanide catalysts with participation of four types of active centers (AC). In this work, we studied the effect of the nature of organoaluminum compound (OAC) on the kinetic nonuniformity and structure of the active centers of neodymium catalytic systems in butadiene polymerization.

Using the Tikhonov's regularization method and experimental curves of molecular-weight distribution (MWD) of 1,4-*cis*-polybutadiene (PB) [3–6] (Figs. 1, 2), we characterized the activity of the $NdCl_3 \cdot 3TBP$–OAC catalytic systems in butadiene polymerization as a function of the molecular weight of the polymer formed. Here TBP is tributyl phosphate and OACs are $Al(i\text{-}C_4H_9)_3$ (TIBA), $Al(C_2H_5)_3$ (TEA), $Al(C_6H_{13})_3$ (THA), and $Al(C_8H_{17})_3$ (TOA).

Irrespective of the nature of OAC used, all the curves of the kinetic activity are characterized by a polymodal form and have four maxima. Each point on the curve characterizes the fraction of ACs generating macromolecules with the molecular weight M_i with the probability of the chain termination equal to ψ_i. The function $\pi(\ln\beta)$ shows the kinetic nonuniformity of the catalytic systems, and four maxima of this function indicate the existence of at least four AC types differing in their structure.

As seen, the multimodality of the $\psi(\ln\beta)$ curves is observed even at the lowest butadiene conversions (Fig. 1). This shows that ACs of all the four types arise in the initial stage of the process. Thus, the catalytic system is initially nonuniform.

The curve of the kinetic activity of the $NdCl_3 \cdot 3TBP$–TEA catalytic system differs from the $\psi(\ln\beta)$ curves for the systems with TIBA, THA, and TOA (Fig. 2). For the system with TEA, two pronounced maxima corresponding to ACs forming the lowest-molecular-weight (M_w 10^3–10^4) and highest-molecular-weight ($M_w \sim 10^6$) polymer fractions are typical. ACs of these two types generate the major fraction of the polymer, while the part of ACs giving macro-

molecules with intermediate weights is small. Probably, specifically due to such a feature of the $NdCl_3 \cdot 3TBP$–TEA catalytic system the resulting PB has bimodal MWD [7].

Assuming random character of activity deviations from the maxima, we presented the experimental curves as a sum of Gaussian functions. The area under each Gaussian component corresponds to the fraction of the polymer generated on AC of the given type. Such a consideration allows estimation of the contribution of each AC type and its variation.

Figure 3a shows the position of such Gaussian peaks for the $NdCl_3 \cdot 3TBP$–TIBA catalytic system as a function of the degree of the monomer conversion. The changes in the position are small, i.e., each AC synthesizes macromolecules of the definite length.

The active centers of the neodymium catalytic systems with TIBA, THA, and TOA produce polymer fractions with the same molecular weight. For the system with TEA, the position of the first (low-molecular-weight) peak somewhat differs, and the corresponding AC produces polymer with slightly lower molecular weight as compared to the systems with TIBA, THA, and TOA.

The activity of each AC presented as the corresponding peak area changes during polymerization. Figure 3b illustrates this for the $NdCl_3 \cdot 3TBP$–TIBA catalytic system. As seen, ACs corresponding to the first maximum on the distribution curve (generation of low-molecular-weight polymers) are characterized by low activity, which slightly increases during polymerization. For the second AC type, the activity decreases. For the third type, the increase with saturation, and for the fourth, the steady increase are observed during polymerization. Certain scattering in data is explained by the random nature of the polymerization. Nevertheless, the trend in the activity of various ACs can be estimated.

In Fig. 4A, curves of the activity of the $NdCl_3 \cdot 3TBP$–OAC catalytic systems are grouped together for each type of ACs. The figure reveals the trend in the kinetic nonuniformity of the catalytic systems with various OACs. As seen, with TIBA, THA, and TOA the activities of all four types of ACs vary similarly with increasing monomer conversion (though to a different extent). ACs generating low-molecular-weight fraction increase their activity during polymerization (for the catalytic system with TEA the activity of this center decreases). The activities of the centers corresponding to the second and third peaks decrease for all the catalytic systems studied. For the fourth AC type, the activity steadily grows with all OACs.

For all the four AC types, we measured their activities at various Al/Nd ratios. As in the case of conversion curves, with TIBA, THA, and TOA the dependences of the kinetic activity on the Al/Nd ratio are similar. For the $NdCl_3 \cdot 3TBP$–TEA catalytic system, the first maximum, in contrast to the other catalysts, is high. It slightly decreases with increasing Al/Nd ratio. The behavior of the fourth maximum also differs from that for the other catalytic systems: with increasing the TEA content its intensity increases.

We found that the kinetic activity of ACs of the $NdCl_3 \cdot 3TBP$–OAC catalytic systems is practically independent of the catalyst concentration at the constant OAC content.

Figure 4B shows the effect of the polymerization temperature on the activity of the catalytic systems studied. As seen, the intensities of the first and the

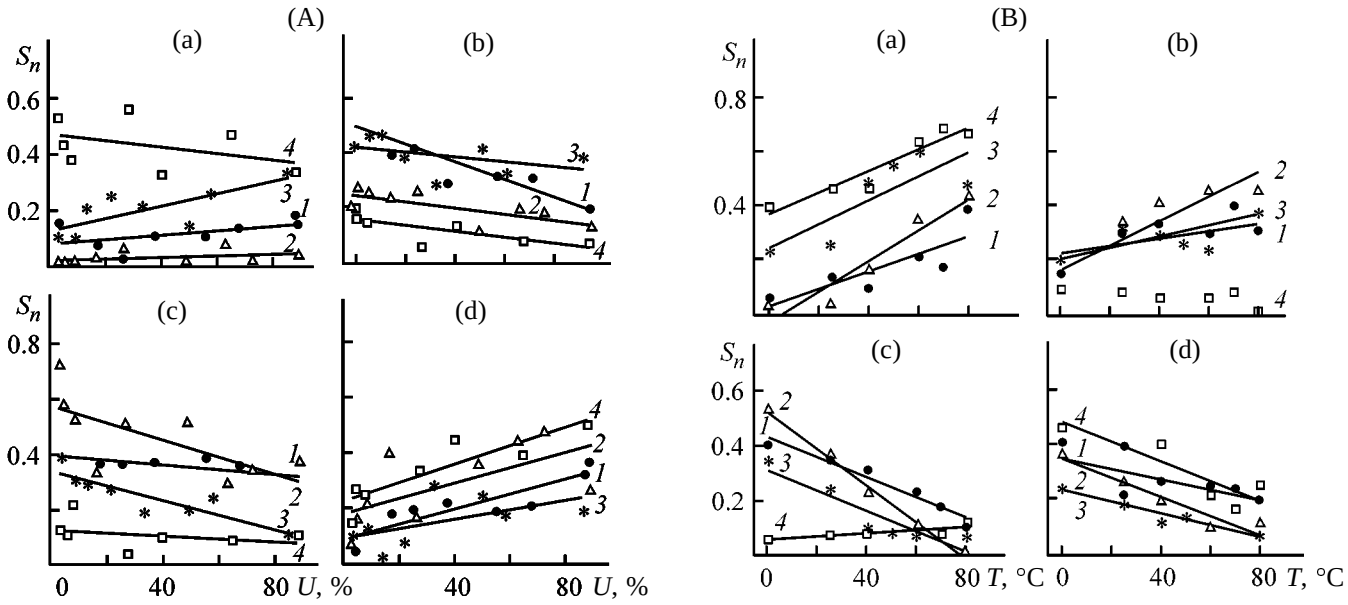

Fig. 4. Kinetic activity S_n of the centers of butadiene polymerization as a function of the (A) monomer conversion U and (B) temperature T. Catalytic systems $NdCl_3 \cdot 3TBP$–OAC. OAC: (*1*) TIBA, (*2*) THA, (*3*) TOA, and (*4*) TEA. Peak: (a) no. 1, (b) no. 2, (c) no. 3, and (d) no. 4.

second peaks corresponding to ACs forming low-molecular-weight polymers increase with temperature. On the other hand, the third and fourth peaks (generation of high-molecular-weight polymers) decrease. This shows that the ACs forming high-molecular-weight fractions are less stable as compared to the ACs forming low-molecular-weight polymers. Similarly to conversion dependences, the activities of ACs corresponding to the second and third peaks are very low for the catalytic system with TEA.

Sharp difference between the system with TEA, on the one hand, and systems with TIBA, THA, and TOA, on the other hand, can be explained by the difference in the association degree of free OAC molecules in the polymerization system. Association sharply increases with decreasing length of the hydrocarbon radical (TIBA is not capable of association because of branching of its hydrocarbon radicals) [8]. Probably, it is the greater tendency of TEA molecules to association in comparison with TIBA, THA, and TOA that is responsible for the observed differences in the activity of ACs.

As mentioned above, the peak area of the separate Gaussian components of the activity curve S_i characterizes the fraction of the chains formed on *i*th AC and is equal to the ratio of the number of these chains Q_{0i} to the total chain number Q_0:

$$S_i = Q_{0i} / Q_0. \qquad (1)$$

Let us assume that

$$\mu = C_{m0} C_{ai} x / \Sigma C_{ai} \qquad (2)$$

is the fraction of the monomer consumed on the *i*th AC by the time corresponding to conversion x, where C_{ai} is the concentration of the *i*th center and C_{m0} is the initial concentration of the monomer.

Then, the quantity

$$\frac{k_{mi} C_m + k_{Ali} C_{Al}}{k_{pi} C_m} \mu \qquad (3)$$

determines the amount of the "dead" chains formed on the *i*th center by transfer to the monomer and OAC by the time corresponding to conversion x, where k_{mi} and k_{Ali} are the rate constants of transfer to the monomer and OAC, respectively, and k_{pi} is the rate constant of the chain propagation on *i*th AC.

The total number of macromolecules formed on the *i*th center is

$$Q_{0i} = C_{ai} + \frac{k_{mi} C_m + k_{Ali} C_{Al}}{k_{pi} C_m} \frac{C_{m0} C_{ai}}{\Sigma C_{ai}} x, \qquad (4)$$

where the first term C_{ai} characterizes the number of "living" chains.

The total number of chains Q_0 is the ratio of the

Concentrations of various types of ACs of the $NdCl_3 \cdot 3TBP$–OAC catalytic systems in butadiene polymerization

OAC	$C_{ai} \times 10^5$, M				$\Sigma C_{ai} \times 10^5$	$\langle C_a \rangle \times 10^5$
	C_{a1}	C_{a2}	C_{a3}	C_{a4}	M	
TIBA	3.9	21.7	7.5	5.7	38.8	40.1
THA	0.05	0.9	1.5	0.8	3.3	3.0
TOA	23.9	6.2	6.9	28.7	65.6	65.0
TEA	6.8	3.9	3.0	6.8	20.5	25.0

amount of the converted monomer to the number-average degree of polymerization P_n:

$$Q_0 = C_{m0} x / P_n. \quad (5)$$

Taking into account Eqs. (8) and (9), Eq. (5) can be transformed after simple operations into

$$\frac{S_i C_{m0} x}{P_n} = C_{ai}\left(1 + \frac{C_{m0} k_{mi}}{k_{p\,i} \Sigma C_{ai}} x + \frac{C_{Al} k_{Ali} C_{m0}}{C_m k_{p\,i} \Sigma C_{ai}} x\right). \quad (6)$$

Let us assume that

$$S_i C_{m0} x / P_n \equiv A_i.$$

The position of the maximum on the kinetic activity curve characterizes the degree of polymerization P_{ni} of the polymer fraction formed on the corresponding ACs, which, in turn, is defined as the ratio of the amount of the monomer μ converted on the *i*th center to the number of chains Q_{0i} formed on it. Using (6), we obtain

$$P_{ni} = \frac{C_{m0} C_{ai}}{Q_{0i} \Sigma C_{ai}} x. \quad (7)$$

For the initial instant of polymerization ($\tau \to 0$), taking into account that the conversion is determined as $x = 1 - e^{-\tau \Sigma k_{pi} C_{ai}}$, we can assume

$$x \approx \tau \Sigma k_{pi} C_{ai} = \tau \langle k_p \rangle \Sigma C_{ai}, \quad (8)$$

where $\langle k_p \rangle$ is the overall rate constant of the chain propagation. Then, taking into account (8), we can write Eq. (7) as

$$P_{ni} = C_{m0} \langle k_p \rangle \tau. \quad (9)$$

It is follows from Eq. (9) that the slope of the $P_{ni}(\tau)$ curves at $\tau \to 0$ is constant for all the ACs and characterizes the given catalytic system. Thus, the shift of the maxima in Fig. 3a in the initial stage of polymerization is the regular phenomenon.

By substitution of Eq. (4) into (7) we obtain the following equation for analysis of P_{ni}:

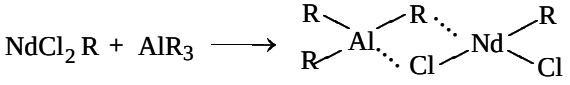
$$B_i \equiv \frac{C_{m0} C_{ai} x}{P_{n\,i} \Sigma C_{ai}}$$

$$= C_{ai} + \frac{k_{m\,i} C_m + k_{Ali} C_{Al}}{k_{p\,i} C_m} \frac{C_{m0} C_{ai}}{\Sigma C_{ai}} x. \quad (10)$$

Extrapolation of the dependence of A_i or B_i on the monomer conversion x to zero conversion in accordance with Eqs. (6) and (10) allows determination of C_{ai}, which is the concentration of each type of AC, and of the total concentration of all ACs ΣC_{ai}.

The concentrations of the separate ACs in butadiene polymerization on the catalytic systems studied are listed in the table. $\langle C_a \rangle$ is also the total AC concentration, but it is determined from the analysis of the polymerization kinetics by the equation $W_p = k_p C_m / \langle C_a \rangle$. As seen, a good agreement is observed for results calculated by both methods. This confirms the adequacy of the model used.

Introduction of OAC into the polymerization system initiates processes yielding ACs. The soluble complex of neodymium chloride with TBP reacts with OAC molecules, which initially abstract TBP molecule, and desolvated neodymium chloride starts to precipitate as the coordination polymer $(NdCl_3)_n$ with chloride bridges. Simultaneously $NdCl_3$ is alkylated with formation of $NdCl_2R$. As shown in [9], TBP is practically removed from the catalytic complex. The excess AlR_3 (Al/Nd ~ 30) can give complexes

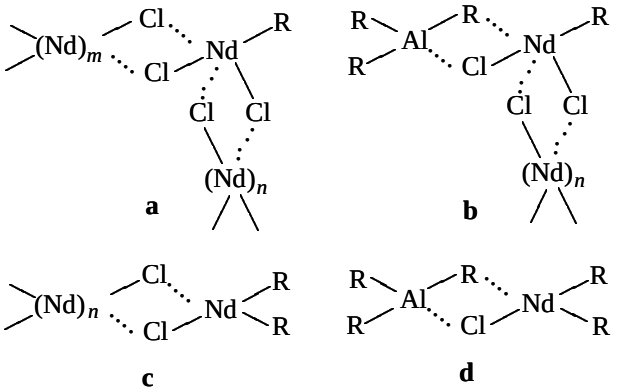


It should be noted that the above processes can occur simultaneously, affecting each other.

The catalytic systems containing no organoaluminum compound are known [10, 11]. Hence, OAC is not the necessary component of the catalytic complex controlling *cis* stereoregulation, although the presence of OAC makes the catalyst substantially more active. This means that ACs do not necessarily contain OAC fragments.

It was shown in [10, 11] that centers forming *cis* units are the compounds with the formula LnX_2R (X is electronegative group), when individual lanthanide organic compounds are used as catalysts of diene polymerization; triorganolanthanides LnR_3 are the catalysts of *trans* polymerization, and the compounds $LnXR_2$ are inactive in polymerization.

Taking into account these facts, we can assume the existence of ACs differing in the degree of alkylation of neodymium chloride and in the content of the organoalunimum component. Structure *a* is formed by alkylation of one Nd–Cl bond (see scheme). Structure **b** arises when, in addition to alkylation, complexation with OAC molecule occurs. When two Nd–Cl bonds are alkylated, active centers **c** and **d** are formed.



EXPERIMENTAL

Butadiene polymerization was performed at 25°C in the presence of the $NdCl_3 \cdot 3TBP$–OAC catalytic systems (OAC = TIBA, TEA, THA, and TOA). The $NdCl_3 \cdot 3TBP$ complex was synthesized according to [9]. The catalyst was prepared *in situ*, i.e., in the solution of the monomer in toluene (C_m = 1.5 M) initially OAC ($C_{Al} = 3 \times 10^{-2}$ M) and then $NdCl_3 \cdot 3TBP$ were introduced. The Al/Nd ratio was 30.

The content of 1,4-*cis* units in polybutadiene was 90–95% and that of 1,2 units was less than 1%, the remainder being 1,4-*trans* units.

The molecular weights and MWD of polybutadiene were determined on a KhZh-1302 gel chromatograph; four columns packed by Waters styrogel with a pore size of 3×10^2–5×10^6 A were used. The separation temperature was 25°C. Chloroform was used as an eluent. The column system was calibrated against polystyrene references with narrow MWD ($M_w/M_n \leq 1.2$) using the universal Benoit dependence [12] and the equation correlating the polybutadiene molecular weight with the intrinsic viscosity [13].

The chromatograms and molecular weights were corrected with regard to device broadening by the special method [14]. The approximation method of solving the Tung equation [15, 16] was taken as a "testing" method.

The distribution with respect to the kinetic nonuniformity of the $NdCl_3 \cdot 3TBP$–OAC catalytic system was calculated by the Tikhonov's regularization method [3, 4]. The minimum of the Tikhonov's functional was attained at the regularization parameter α equal to 9.4×10^{-5} with the root-mean-square error δ^2 0.0001. The unbalance was 1.07×10^{-4}. The method used and the IUPR procedure allow variation of the error in the choice of the integral equation core. However, because the core, which is the Schultz–Flory function, was selected as a model, the error was taken to be $h \to 0$.

CONCLUSIONS

(1) Irrespective of the nature of organoaluminum compound used in the neodymium catalytic system and conditions of the process, butadiene polymerization proceeds on four types of active centers formed at the start of polymerization and generating polymers with different molecular weight.

(2) The method was developed for determination of the concentrations of each type of active centers in the neodymium catalytic systems, and these concentrations were calculated.

(3) The possible structures of the active centers in the neodymium catalytic systems differing by the content of organoaluminum compound in the catalytic complex were proposed.

CATALYSIS

Cobalt(III)–*d*-Metal Triethanolamine Complexes as Catalysts of Electrochemical Reduction of Oxygen

V. S. Kublanovskii and Yu. K. Pirskii

Vernadsky Institute of General and Inorganic Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received September 12, 2000; in final form, April 2001

Abstract—Carbon-supported oxide catalysts of oxygen electroreduction were prepared from Co(III)–M(II) ethanolamine complexes. The electrochemical properties of these catalysts were studied. The apparent activation energies of the reduction were measured.

Development of new electrocatalysts free from noble metals and electrodes on their base for chemical current sources is an urgent problem [1]. One of the most promising catalysts for oxygen electroreduction in metal–air chemical current sources and electrochemical generators are *d*-metal N_4 complexes [2–5]. Catalysts with required properties can be prepared by variation of the ligands and the central metal. Thermal treatment of carbon materials modified with organometallic N_4 complexes enhances their catalytic activity in electrochemical reduction of oxygen and increases the discharge voltage and capacity of voltaic cells. The structure of catalytically active centers depends on the ligand nature and on the temperature and atmosphere of pyrolysis. For example, the active centers of the catalysts prepared by thermolysis of cobalt(II) and iron(II) polyacrylonitrile complexes at 800–900°C are anchored to the carbon support via nitrogen atoms [2]. When a carbon material modified with products of condensation of ethylenediamine and formaldehyde with *d*-metals are used as the precursors, the most active catalysts are formed at 500–600°C [3]. Effective catalysts of oxygen electrochemical reduction were prepared by heat treatment of polymeric cobalt(III) complexes with *p*-phenylenediamine and 2,6-diaminopyridine at 923–1123°C in a vacuum, with the catalytic activity increasing with the temperature of the heat treatment. Tarasevich and Radyushkina [5] showed that effective catalysts based on cobalt(II) and iron(II) porphyrin and phthalocyanine complexes can be prepared by calcination at 800–900°C. Among the best catalysts are 3*d*-metal oxides with the spinel structure [6]. However, the electrical conductivity of these oxides is low, and preparation of catalysts with high surface conductivity by application of these oxides to carbon support is rather complex problem. The electrocatalytic activity of oxides is known [1, 7] to depend mainly on the nature of surface cations and structural defects. The aim of this work was to prepare catalysts of electrochemical oxygen reduction by pyrolysis of cobalt(III)–*d*-metal(II) triethanolamine complexes on carbon support to form metal oxides with the spinel structure.

EXPERIMENTAL

Catalysts of electrochemical reduction of oxygen were prepared by treatment of AG-3 activated carbon with methanolic or aqueous-methanolic solutions of $[Co(HTEA)H_2TEA]_2 \cdot M(OOCCH_3)_2$ (where H_3TEA is triethanolamine and M is Mn^{2+}, Ni^{2+}, Cu^{2+}, or Zn^{2+}).

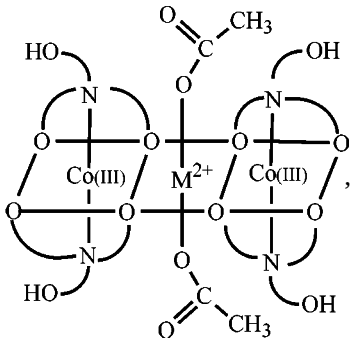
The initial complexes were prepared by addition of a 0.2 M methanolic or aqueous methanolic solution (10 ml) of appropriate *d*-metal (Mn^{2+}, Ni^{2+}, Cu^{2+}, or Zn^{2+}) acetates to 0.004 M methanolic solution (5 ml) of cobalt aminoalcoholate $[Co(HTEA)H_2TEA]_2$ prepared by the procedure in [8]. Methanol was used as the solvent of nickel acetate and zinc acetate and water–methanol mixture (1 : 1), as the solvent for manganese acetate and copper acetate. Manganese(II) acetate was prepared by dissolving metallic manganese in glacial acetic acid, followed by recrystallization from water. The other acetates were of analytically pure grade. AG-3 activated carbon (1 g) with particles smaller than 50 μm and the BET specific surface area of 850 $m^2 g^{-1}$ was added to a solution of appropriate metal acetate. The mixture was allowed to stand for 12 h. Then 80% of the solvent was distilled off. The impregnated carbon was filtered off, washed with a small amount of isopropanol and then with

1070-4272/01/7407-1147$25.00

ether, and dried at 120°C to constant weight. The weight gain of the activated carbon after sorption of $[Co(HTEA)H_2TEA]_2 \cdot Mn(OOCCH_3)_2$, $[Co(HTEA)H_2 \cdot TEA]_2 \cdot Cu(OOCCH_3)_2$, $[Co(HTEA)H_2TEA]_2 \cdot Zn \cdot (OOCCH_3)_2$, and $[Co(HTEA)H_2TEA]_2 \cdot Ni(OOCCH_3)_2$ was 51, 55, 20, and 64%, respectively.

The currents passed through the catalysts were adjusted depending on the weight of the complex applied to the carbon.

The triethanolamine complexes have the following structure:



where curve segments denote the $–C_2H_4–$ fragments.

As seen from this figure, the double-charged metal located in the equatorial plane is bound via oxygen bridges to the triple-charged cobalt ions. There are reasons to believe that this fragment in the form of spinel or substoichiometric mixed oxides can be retained on the carbon surface after pyrolysis of the complexes at definite temperatures. Thermal degradation of the complexes of this type in a carbon matrix is known [5] to start from elimination of the terminal groups. The products are incorporated into the structure of the carbon matrix.

A weighed portion of carbon-supported metal complexes (200 mg) was placed in a quartz tube furnace. The sample was gradually heated in an argon counterflow to the required temperature, kept at this temperature for 1 h, and cooled to room temperature. The heat treatment was performed at temperatures from 200 to 800°C with a 100°C increment. The catalytic activity of the resulting samples in electrochemical reduction of oxygen was studied.

The electroreduction of oxygen was performed at room temperature in 1 M KOH on a floating gas-diffusion electrode [11] in an electrochemical cell with separated cathodic and anodic compartments. The electrochemical measurements were performed in a PI-50-1.1 potentiostat using an Ag/AgCl reference electrode. The partial pressure of oxygen before and after bubbling of oxygen through the electrolyte was measured by an OP-210/3 microanalyzer [12].

The working floating gas-diffusion electrode was prepared by the following procedure. A nickel wire was pressed at a pressure of 50–70 kg cm^{-2} in acetylene black (400 mg) hydrophobized with 30% polytetrafluoroethylene. A thin layer of finely divided catalyst (<20 μm) was applied to the surface of the resulting single-layer porous electrode (d = 10.15 mm, density 0.95 g cm^{-3}, thickness ~1 mm). The composite was pressed at 50–60 kg cm^{-2}. The amount of applied catalysts was determined by weighing the electrode before and after pressing of the catalyst powder. To determine the state of the catalyst surface before and after the electrochemical reduction, polarization curves were recorded in an argon atmosphere with a sweeping rate of 2 mV s^{-1}. The potentiostatic polarization curves were constructed from the current densities measured at constant potentials adjusted with a 10 mV increment by a PI-50-1.1 potentiostat. The current was registered with an M-104 milliammeter with extrapolation to $t \to \infty$.

Since the thermal treatment was performed in an inert atmosphere, we suggest that centers active in the oxygen reduction are metal atoms or their oxides dispersed in AG-3 activated carbon. As seen from the kinetic parameters of oxygen electroreduction on the tested catalysts (see table), the active catalysts are formed after calcination of the cobalt triethanolamine complexes on the carbon support at 300–500°C.

The influence of the calcination temperature on the properties of catalysts based on Co(III)–M(II) triethanolamine complexes is seen from the results presented in the table. The maximal exchange currents are observed for the catalysts prepared at 400°C, which is probably due to formation of active centers. With increasing calcination temperature to 800°C, the currents decrease owing to degradation of these centers to form inactive species. The slopes of the stationary polarization curves lie in the following ranges (mV): b_1 = 44–64 and b_2 = 100–127. The dependence of oxygen electroreduction at a constant potential E = –0.125 V (vs. silver chloride electrode) on the calcination temperature is shown in Fig. 1. The maximal current was observed with the catalysts calcined at 400°C. This is the best temperature for preparing active catalysts from cobalt(III)–*d*-metal triethanolamine complexes. The activity of the tested catalysts decreases in the following order: Co–Mn > Co–Zn > Co–Cu > Co–Ni.

The most active catalysts were prepared from Co–Mn triethanolamine complexes. We suggested that

* j_0 is the exchange current density; b_1 and b_2 are the slopes of stationary polarization curves.

the Co–Ni catalysts would be the next in the sequence of the catalytic activity. However, this was not the case. The X-ray diffraction study showed the absence of the crystalline phase. Since the complexes contain oxygen and metal atoms, we suggest that in this case double metal oxides with spinel or nonstoichiometric oxide structure are formed. The catalytically active centers of this catalyst are formed on structural defects [1, 7] containing excess oxygen. The defects promote formation of cationic vacancies and increase the electrical conductivity. As a result, the electrochemical properties of the catalysts are improved.

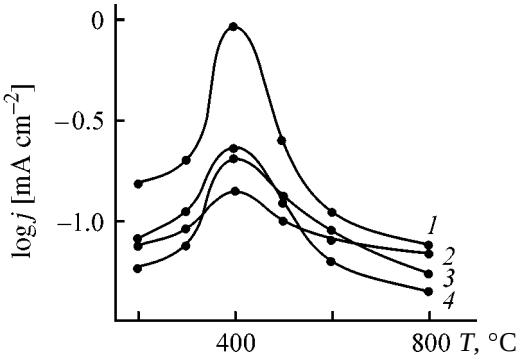

Fig. 1. Rate of oxygen electroreduction in 1 M KOH at 20°C on catalysts prepared by pyrolysis of Co(III)–M(II) triethanolamine complexes on AG-3 activated carbon as a function of the pyrolysis temperature T. Potential E = –0.125 V vs. silver chloride electrode. (j) Current density. Catalyst: (*1*) Co–Mn, (*2*) Co–Ni, (*3*) Co–Cu, and (*4*) Co–Zn.

These data agree with the results of [13] where spinel and nonstoichiometric oxides prepared also at 300–400°C were used as catalysts.

The ponetiostatic polarization curves of oxygen electroreduction on the catalyst prepared from Co–Mn triethanolamine complexes supported on AG-3 activated carbon, AG-3 activated carbon without supported metal, and hydrophobized carbon black substrate are shown in Fig. 2. As seen from Fig. 2, the activity of the catalysts is higher than that of AG-3 carbon. The stationary polarization curve of the catalysts is shifted by 50 mV to the positive potentials. We also calculated the apparent activation energy of oxygen electroreduction on the catalysts prepared from Co(III)–M(II) triethanolamine complexes supported by AG-3 activated carbon. For this purpose the potentiostatic polarization curves of Co(III)–M(II) electrocatalysts were measured in an oxygen at-

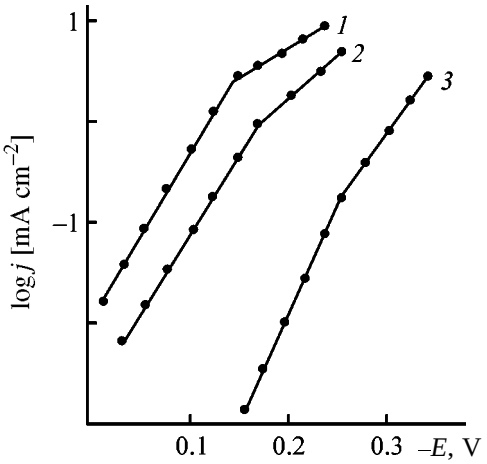

Fig. 2. Potentiostatic polarization curves of oxygen electroreduction measured in 1 M KOH at 20°C on a hydrofibized carbon black substrate. (*j*) Current density and (*E*) electrode poetical. (*1*) Co–Mn triethanolamine complex on AG-3 (400°C, Ar), (*2*) AG-3, and (*3*) hydrophibized carbon black.

mosphere at 20, 30, 40, and 50°C to determine the exchange currents. Then the dependences of the exchange currents of oxygen electroreduction on the reciprocal temperature were plotted. The apparent activation energy was calculated by the following equation [14]:

$$W_{app} = -2.303R\frac{\partial \ln j_0}{\partial(T^{-1})},$$

where W_{app} is the apparent activation energy of oxygen electroreduction, j_0 is the exchange current density, and T is the temperature.

The calculated apparent activation energies of oxygen electroreduction agree with those for the catalysts supported by carbon materials and spinels. The activation energy for the Co–Mn catalysts and AG-3 activated carbon is 54.0 and 60.1 kJ mol^{-1}, respectively. Our results show that the apparent activation energy of oxygen electroreduction decreases with an increase in the catalytic activity. The values of the apparent activation energies and the kinetic data show that the electrochemical reduction is kinetically controlled.

CONCLUSIONS

(1) The best pyrolysis temperature of cobalt–*d*-metal triethanolamine complexes in an inert atmosphere is 300–400°C. Under these conditions the catalysts of oxygen electroreduction were prepared. The spinel and nonstoichiometric oxide structure of the catalysts was suggested.

(2) The most active catalyst was prepared by calcination of Co(III)–Mn(II) triethanolamine complex on AG-3 carbon support at 400°C in an inert atmosphere.

Abstract—Scientific basis for industrial gas-phase fluorination of fluoroethanes with elemental fluorine allowing production of higher-fluorinated fluoroethanes from lower-fluorinated compounds is developed.

Fluorine is extremely reactive and its reactions are highly exothermic. Therefore, at present preparation of fluorinated organic compounds using fluorine has almost no industrial application.

Fluorine is commercially available, and its utilization for production of valuable fluorinated products is rather urgent. These products include a series of fluoroethanes, e.g., 1,1-difluoroethane (DFE, R152a), 1,1,2-trifluoroethane (R143a), 1,1,1,2-tetrafluoroethane (TFE, R134a), pentafluoroethane (PFE, R125), and hexafluoroethane (HFE, R116), which are widely used as refrigerants, propellants, fire extinguishers, reagents for plasmochemical production of superlarge integrated circuits, gas dielectrics, etc. [1]. The world's consumption of these compounds reaches tens thousands tons per year.

The modern industrial process for production of fluoroethanes is based on catalytic fluorination of fluorochloroethanes and ethylenes with hydrogen fluoride. The initial chlorinated materials used in this case are ozone-dangerous, and, in accordance with the Montreal Protocol, their production should be terminated. Moreover, this process yields significant amounts of hydrogen chloride (by-product) and requires periodical replacement and utilization of the spent chromium–manganese fluoride catalyst. Thus, development of alternative procedures for synthesis of fluoroethanes is urgent. One of such procedures can be synthesis of higher-fluorinated ethanes by gas-phase fluorination of lower-fluorinated compounds with elemental fluorine.

The first data on the gas-phase fluorination are given in [2–5]. In particular, the gas-phase fluorination of ethane with fluorine was studied and the possibility of preparing HFE was confirmed. However, the corresponding industrial procedures still are not developed.

The kinetics of 1,1,1,2-TFE fluorination was studied in [6]; it was found that industrial synthesis in the steady-state thermal mode is unsuitable. As shown in [7], industrial fluorination of fluoroethanes should be carried out in the nonstationary thermal mode (wave or combustion modes). In this case fluoromethanes are not formed in noticeable amounts at the initial concentration of fluorine lower than 30 vol %.

Development of the industrial process for fluorination of fluoroethanes requires understanding of the principles of scaling the reactor for gas-phase fluorination operating in the wave mode.

One of the features of combustion is that the reaction profile in a laminar torch comprises tenth fractions of millimeter. In tunnel jets conversion of compounds in the turbulent torch reaches 80% within the length of five diameters of the crater [8]. Such a structure of the turbulent torch suggests that, if the thermal radiation of the gas is negligible, the main conversion of compounds proceeds at temperature fairly close to adiabatic. In this case the composition of the products of 1,1,1,2-TFE gas-phase fluorination in the mode of a steady-state self-propagating wave should be independent of the diameter of the reaction unit and of the gas flow mode (without taking into account thermal decomposition of fluoroethanes outside the fluorination zone). To verify this assumption, we performed a series of tests with reactors of various diameters.

The tests we carried out using changeable tubes with an internal diameter of 10, 4, 3, and 2 mm at flow rates of the cold reaction mixture providing constant velocities of the gas flow. To eliminate the

* FM is total content of fluoromethanes in the reaction products.

breakthrough of the reaction front up with a gas flow into a mixer, the internal diameter of the latter was 0.8 mm. The parameters of these tests (reactor diameter d, gas velocity u_m, Re number, and convection coefficient of the heat exchange from the reaction zone to the reactor wall α) and the composition of the reaction products are listed in Table 1; the fluorine concentration was 30 vol %.

The composition of products formed in the wave process is independent of the convection coefficient of the heat exchange α in the 25–130 W m^{-2} K^{-1} range, which confirms our assumption that there is no heat exchange in the reaction zone of fluorine and 1,1,1,2-TFE and allows extrapolation of these results to larger reactors at a constant initial concentration of fluorine.

Thus, the fluorine concentration is a unique parameter affecting the composition of the products of the wave synthesis, which simplifies design and operation of the reactor.

The kinetic study of the gas-phase fluorination of 1,1,1,2-TFE revealed the autocatalytic character of this process. To explain this feature, we studied the effect of the formed hydrogen fluoride on the reaction rate [6].

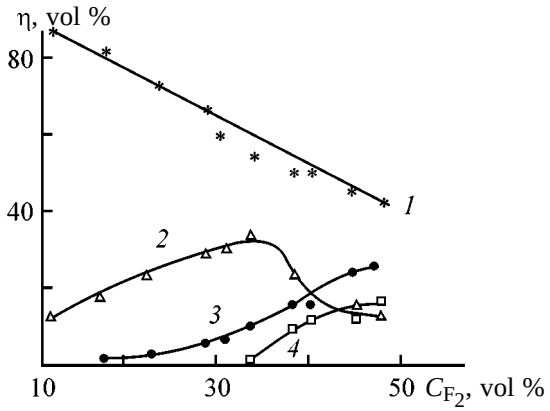

Fig. 1. Composition η of the products of 1,1,1,2-TFE fluorination in the wave mode as influenced by fluorine concentration C_{F_2} in the presence of 5–10 vol % of hydrogen fluoride: (*1*) 1,1,1,2-TFE, (*2*) PFE, (*3*) HFE, and (*4*) total content of fluoromethanes; the same for Fig. 2.

As-produced fluorine always contains hydrogen fluoride [1]. Special treatment is required to remove HF, which increases the cost of its production. Thus, investigation of the effect of small amounts of hydrogen fluoride in the initial mixture on the composition of the reaction products in the mode of self-propagating thermal wave is urgent.

The procedure and experimental setup used were described previously in [7]. Fluorine was mixed with 5–10% of hydrogen fluoride, the fluorine concentration was 11–47 vol %, and the flow rate of the cold reaction mixture was 50–75 cm^3 s^{-1}.

As in the case of pure fluorine [7], we observed the dependences typical for the wave modes. The composition of the reaction products as influenced by the fluorine concentration is shown in Fig. 1. Comparison of these results with those determined for pure fluorine [7] shows that the composition of the reaction products obtained in the wave mode of PFE synthesis is almost independent of the concentration of hydrogen fluoride (5–10 vol %) in the reaction mixture in the entire range of fluorine concentrations.

This fact allows utilization in the wave synthesis mode of the electrolysis gas of fluorine production without additional treatment.

The disadvantage of the wave mode is the requirement to perform the reaction at the substoichiometric concentration of one of the components. In the gas-phase fluorination of fluoroethanes the maximum permissible concentration of fluorine is about 30 vol %. At higher concentrations and thus at higher adiabatic temperature of the wave process the degradation of fluoroethanes becomes pronounced, and significant amounts of fluoromethanes appear in the reaction products.

Tetrafluoromethane (TFM) boils at –128°C, which causes the loss of the desired product during distillation. According to the calculations of the distillation column, the content of TFM should not exceed 0.5 vol %.

At fluorine concentrations lower than 30 vol % distillation of the reaction products becomes simpler, but the conversion of the initial material is relatively low. The following ways to increase conversion are used. (1) A certain fraction of the material to be fluorinated can be replaced by HFE, which does not participate in the reaction at a fluorine concentration <30 vol %, or by another inert compound. (2) Fluorination can be performed using several series-connected wave reactors with intermediate cooling of the reaction mixture. (3) The reaction mixture can be recycled, with recovery of the unchanged material from the products of the wave process and its addition to the initial reaction mixture.

To illustrate the first way, we studied the wave fluorination of 1,1-DFE to prepare trifluoroethanes (Table 2); HFE was used as inert diluent, which increases the conversion of the initial material. The initial 1,1-DFE (14 vol % concentration) contained 0.35% CHF_3 and 0.49% CF_3CH_3. The conversion of 1,1-DFE reached 80%, and the selectivity with respect to trifluoroethanes was 50%. However, at the concentration of fluorine >20 vol % the content of TFM became significant. This is probably due to the fact that at such fluorine concentrations HFE is not absolutely inert to fluorine under the wave synthesis conditions.

We studied preparation of HFE from 1,1,1,2-TFE using dilution with argon. The process parameters and the reaction product composition are given in Table 3. With excess fluorine, the dilution with argon provides almost complete conversion of the initial material, and the selectivity with respect to HFE reaches 97%. The degradation of fluoroethanes under such conditions is insignificant. It should be noted that the reaction was carried out at a temperature of the reaction wall of 200–250°C. At a temperature of the reaction wall of 10°C the gas flow blew off the thermal wave from the reactor.

A series of tests with a mixture containing 32 vol % PFE and 68 vol % 1,1,1,2-TFE was carried out to

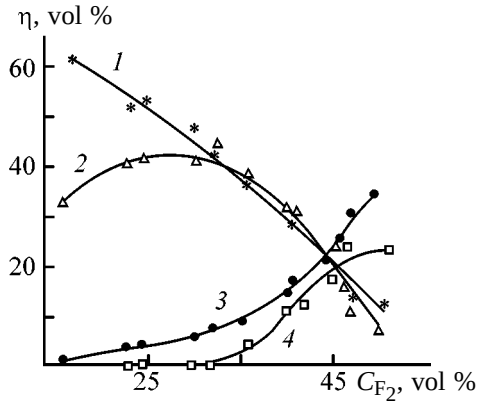

Fig. 2. Composition η of the fluorination products of the mixture of PFE (32 vol %) and 1,1,1,2-TFE (68 vol %) in the wave mode as influenced by the fluorine concentration C_{F_2}.

simulate two-step conversion of 1,1,1,2-TFE into pentafluoroethane. The results are shown in Fig. 2.

In the course of fluorination the content of PFE in the reaction products passes a maximum (43 vol %) corresponding to the fluorine concentration of 27 vol %. In this case the content of HFE is 6 vol %, and fluoromethanes are almost absent. The results given in Fig. 2 allow estimation of the ratio of the fluorination rate constants of 1,1,1,2-TFE and PFE. Assuming that fluorination of 1,1,1,2-TFE and PFE yields only PFE and HFE, respectively, we obtained that at a fluorine concentration of 25 vol % (1000 K adiabatic temperature in the reaction zone) the rate constant of 1,1,1,2-TFE fluorination is 1.5 times greater.

The activation energy of PFE fluorination of 53 kJ mol^{-1} was evaluated from the data given in Fig. 2; the activation energy of 1,1,1,2-TFE fluorination was taken as 50 kJ mol^{-1} [6].

The activation energy of high-temperature fluorination of 1,1-DFE of 44 kJ mol^{-1} was calculated from experimental data (Table 2 in [7]), also assuming that the activation energy of 1,1,1,2-TFE fluorination E = 50 kJ mol^{-1}. In the course of calculations we assumed that fluorination of 1,1-DFE yields 1,1,1-TFE, 1,1,2-TFE, 1,1,1,2-TFE, and 1,1,2,2-TFE, whereas in the case of 1,1,1,2-TFE only PFE and HFE are obtained.

Table 4. Simulated data on the composition of the inlet, outlet, and recycling gas flows in conversion of 1,1,1,2-TFE into HFE on a single-stage wave reactor with recycling of incompletely fluorinated products

Flow	Composition of the gas mixture, kg h^{-1}				
	$C_2H_2F_4$	C_2HF_5	C_2F_6	CF_4	HF
Inlet	11.91	3.59	31.88	0.14	0.40
Outlet	0.83	3.59	46.84	0.21	4.43
Recycling	0.83	3.59	31.88	0.14	0.36

Based on the experimental data on fluorination of 1,1,1,2-TFE, PFE, and their mixtures in the wave mode, the kinetic model of the process was constructed, which involves two main fluorination reactions: hydrogen substitution and cleavage of the C–C bond with formation of fluoromethanes. Based on published data on the bond energies in the corresponding molecules [9, 10], we determined the ratio of the activation energies of these reactions. The ratio of the rate constants was refined using experimental data. The composition of the reaction mixture at the inlet and outlet of the single-stage wave reactor with recycling of incompletely fluorinated products and HFE was simulated by the PC treatment of the system of the corresponding equations. The data on the composition of the inlet, outlet, and recycling reaction mixtures at fluorine concentration in the inlet flow of 25 vol % are listed in Table 4 for the reactor with a capacity of 100 tons per year.

This PC program was improved using the experimental data on fluorination of 1,1-DFE, and fluorination of 1,1-DFE to prepare PFE and HFE using two- and three-stage wave reactors at fluorine concentration of 23 vol % was simulated. The results are shown in Table 5. The intermediate incompletely fluorinated products are recycled. The flow compositions are given for the capacities with respect to PFE and HFE of 954 and 250 tons per year, respectively.

As seen from Table 5, in the case of three-stage wave reactor and recycling of incompletely fluorinated products the 1,1-DFE conversion reaches 90%.

CONCLUSIONS

(1) The gas-phase fluorination of fluoroethanes with fluorine in the mode of self-propagating thermal wave was studied.

(2) The principles for scaling of the wave gas-phase reactor were developed.

(3) In the wave mode the composition of the fluorination products of fluoroethanes is not noticeably influenced by the presence of hydrogen fluoride.

(4) Based on experimental and theoretical data, the ways to improve conversion of the initial raw material

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Alkylation of 5-Aminotetrazole with Dihalo-Substituted Compounds in Dimethylformamide

M. I. Barmin, S. A. Gromova, and V. V. Mel'nikov

St. Petersburg State University of Technology and Design, St. Petersburg, Russia

Received June 19, 2000; in final form, April 2001

Abstract—Possible pathways of alkylation of 5-aminotetrazole with dihalo-substituted compounds and the alkylation products were studied.

Tetrazoles are widely used in organic and coordination chemistry, medicine, biology, and agriculture [1–5]. At the same time, because of the lack of systematic data on alkylation of 5-aminotetrazole (5-AT) with dihalo derivatives, the pattern of its reactivity was incomplete. The enthalpy of formation, the thermal and chemical stability, the solubility in water and alkaline solutions, and the nitrogen content are higher in bis derivatives of 5-AT described previously [6]. In this context, we prepared bis(5-aminotetrazolyl) derivatives, studied their structure and properties, and examined the feasibility of using them as fungicides.

The selectivity of alkylation of 5-substituted tetrazoles is largely determined by the electronic structure of the substituent at the cyclic carbon atom. Electron-donor substituents at the 5-position of the tetrazolate ion favor alkylation at the N^1 atom, and electron-acceptor substituents, at the N^2 atom [2, 7]. The ratio of the alkylation products in an alkaline solution depends on the nature of the alkylating agent insignificantly [8]. However, with diazomethane (in ether) as alkylating agent, the N^2-alkylated product is formed irrespective of the nature of the 5-substituent [8]. The selective alkylation at N^2 in the reaction with diazomethane and the insensitivity to the electronic effect of 5-substituents may be due to the nonpolar transition state in this reaction. Alkylation of 5-substituted tetrazoles with *tert*-butyl, isopropyl, or cyclohexyl alcohol in a strongly acidic medium ensuring virtually total protonation of the tetrazole ring and excluding existence of tetrazoles in the anionic and neutral forms yields exclusively N^2-substituted tetrazoles [9], irrespective of the nature of the 5-substituent. Thus, the substituent effect is the most significant in reactions involving the tetrazolate anion.

Study of the influence of cation on the ratio of the reaction products in alkylation of 5-phenyltetrazole salts with dimethyl sulfate in acetonitrile showed [10] that at substrate concentrations of 10^{-5}–10^{-4} M, at which its dissociation is practically complete irrespective of the cation, the reactive species is the 5-phenyltetrazolate anion. The cation in these reactions, however, affects the ratio of the resulting isomeric tetrazoles. With decreasing cationic radius, the degree of cation coordination in the intermediate increases, and the fraction of the N^1-substituted isomer decreases. The high selectivity of alkylation of triethylammonium 5-aryltetrazolates with vinyl methyl ketone in aprotic dipolar solvents (only the N^2-substituted products are formed) is due to steric shielding of the N^1 atom of the tetrazole ring with the bulky triethylammonium cation [8, 10], which forms a hydrogen bond with the ring. The individual products were isolated from isomer mixtures by fractional crystallization [11–13], chromatography [14], and selective extraction [9, 15]. The reactions of 1,1'-bis(chloromethyl)-ferrocene with sodium tetrazolate, 5-methyltetrazolate, and 5-nitrotetrazolate in acetone or dimethylformamide (DMF) yielded the corresponding alkylation products, heteroannular bis(heterylmethyl) ferrocene derivatives [16]. Analysis of the isomeric composition of the products by ^{1}H NMR spectroscopy showed that with 5-methyltetrazole alkylation occurs at the N^1 positions of both rings, and with 5-nitrotetrazole, at the N^2 position. Alkylation of sodium tetrazolate gave two reaction products identified as 1,2'- and 2,2'-alkylated derivatives. The third possible isomer, 1,1'-alkylated product, was not isolated, probably because of its low yield. The melting point of the 1,2' isomer (101–103°C) is lower than that of the 2,2' isomer (107–108°C) [16].

Reaction of potassium 5-phenyltetrazolate with 1,2-dibromoethane gave 1-(5-phenyltetrazol-1-yl)-2-

1070-4272/01/7407-1156$25.00

(5-phenyltetrazol-2-yl)- and 1,2-bis(5-phenyltetrazol-2-yl)ethanes. Their structure was proved by ^{1}H NMR spectroscopy. The yields of the 1,2' and 2,2' isomers are 8 and 29%, respectively. 5-Aryl(heteryl)tetrazoles in the presence of excess K_2CO_3 at 130°C in DMF give the 1,2' and 2,2' bistetrazole derivatives [18], with the 2,2' isomer prevailing; the content of the 1,2' isomer increases in the presence of electron-donor substituents and decreases in the presence of electron-acceptor substituents at the 5-position of the tetrazole ring. The melting points of the 1,2' isomers are lower than those of the 2,2' isomers.

Different reactivity of the exocyclic amino group and hydrogen atom at N^1 in 5-AT is obvious. This fact, and also the occurrence of 5-AT in solution in the imino form [19–21] imparted abnormal properties to the monomeric units and ultimately led to chain termination in polycondensation and to formation of oligomers [22]. Therefore, our next task was preparation of monomers based on 5-AT in which two amino groups would exhibit similar reactivity. To this end, we performed alkylation of potassium 5-aminotetrazolate (K-5-AT) with dihalo-substituted compounds in DMF.

The choice of the potassium cation was governed by conclusions made in [23]. For comparison, we performed experiments also with sodium 5-aminotetrazolate. Under equal other conditions, the yield of the target product was lower than with K-5-AT by 25–30%. As reaction medium we also tested acetone. However, attempted synthesis of 1,1'-bis(5-aminotetrazolyl)methane in acetone failed. No target product was isolated after heating the reaction mixture for 32–36 h at 55–56°C. As alkylating agents we used dibromomethane, 1,2-dibromoethane, 1,3-dibromopropane, and 1,4-dibromobutane.

Let us consider the reactivity of these agents in nucleophilic substitutions. It is known that in S_N1 reactions 1,2-dibromoethane is more reactive than dibromomethane, whereas in S_N2 reactions dibromomethane is more reactive. Since in dialkylation the limiting stage is S_N2, dibromomethane will be more active. When considering the effect of methylene groups on the reactivity of the compounds, it should be taken into account that these groups exhibit a $+\gamma$ effect and will favor displacement of halogen from the molecule. In the series $F^- < Cl^- < Br^- < I^-$, the stability of the anion increases, and hence the R–Hlg bond will be cleaved more readily in the reaction with dibromomethane. When comparing the reactivities of such compounds as β,β'-dichlorodiethyl ether (Chlorex) and γ,γ'-dichlorodipropyl ether, it should be taken into account that the electronic effect of the ether group in the latter compound is weaker. Thus, all the alkylating agents can be ranked with respect to decreasing reactivity in the order indicated above. Thus, we predicted the conditions of 5-aminotetrazole alkylation.

According to the ^{1}H NMR spectra of reaction mixtures, alkylation of 5-AT with dibromoalkanes yields three isomers, irrespective of the nature of the solvent and counterion. The characteristics of the isolated alkylation products, previously unknown bis(aminotetrazolyl)alkane **I**–**IX**, are listed in Table 1. In alkylation of 5-AT salts with bis(chloroalkyl) ethers, two isomers were detected by ^{1}H NMR in the reaction mixtures, identified as 1,1' and 1,2' isomers. Pure isomeric bis(aminotetrazolyl)alkanes were isolated and characterized [3]. The influence of solvents and cations on the reaction selectivity was studied with alkylation of 5-AT by 1,2-dibromoethane as example. In the range δ 4.5–4.9 ppm in which the ^{1}H NMR signals of the NCH_2 protons are detected, neither the initial compounds nor the reaction by-products have signals, and all the three isomers give well-resolved signals with the difference in the chemical shifts of about 0.15 ppm. Thus, the isomer ration can be determined from the ratio of the integral intensities of these signals.

Monoalkylation of tetrazoles via tetrazolate anions usually involves two stages: deprotonation of the substrate and nucleophilic substitution [24, 25]. However, not always the solvent suitable for the first stage is appropriate for the second one, and vice versa. The following conditions should be met [24]: The base should deprotonate the substrate; the base and/or substrate should be sufficiently soluble in the solvent to ensure deprotonation; the substrate anion and/or electrophile should be sufficiently soluble in the solvent to ensure the reaction; the base should not decompose the substrate or solvent; the solvent should increase the nucleophilicity of the substrate anion.

It was shown [3] that, irrespective of the solvent and counterion, 5-AT anion in the reaction with 1,2-dibromoethane gives all the three isomeric products: 1,2-bis(5-aminotetrazol-1-yl)ethane (**I**), 1-(5-aminotetrazol-1-yl)-2-(5-aminotetrazol-2-yl)ethane (**II**), and 1,2-bis(5-aminotetrazol-2-yl)ethane (**III**). The isomer ratio depends on the reaction conditions. Ethanes **I**–**III** were isolated by selective extraction followed by fractional recrystallization (Table 1). In all cases the major product was the 1,2' isomer.

contain three groups of signals: a singlet at 4.51 ppm, two triplets centered at 4.60 and 4.79 ppm, and a singlet at 4.90 ppm, belonging to the NCH_2 protons in **I**–**III**. The signals were assigned taking into account the trend observed with alkylated tetrazole derivatives: The methylene signals of the N^2 isomers are shifted downfield relative to the N^1 isomers [16, 26–28]. Furthermore, the molecular structure can be judged from the signal shape: The unsymmetrical 1,2' isomer gives a multiplet of NCH_2 protons [17] which at a high resolution is resolved into two triplets, whereas the signals of the symmetrical 1,1' and 2,2' isomers are singlets [28, 29]. In reaction of K-5-AT with 1,2-dibromoethane, the ratio of the isomers 1,1', 1,2', and 2,2' is 1.5 : 2.5 : 1, and with the triethylammonium salt of 5-AT, 1 : 3 : 1. An additional factor in favor of the given assignment is the trend observed with the melting points (Table 1): It is known that the melting point of the 1,1' isomer is the highest, and that of the 1,2' isomer, the lowest [17].

To identify compounds **I**–**III**, we compared their dipole moments. In the series of monoalkylated 5-R-tetrazoles, 1,5-disubstituted products have higher dipole moments than the corresponding 2,5 derivatives [22, 24]. For tetrazoles **I**–**III**, no data on dipole moments is available. For comparison with the monosubstituted derivatives, we calculated by the MNDO method the dipole moments of **I**–**III** (Table 1). The dipole moments decrease in the order 1,1' > 1,2' > 2,2'. Our conclusions are indirectly confirmed by the R_f values (Table 1). The 2,2' isomer **III** has the highest R_f value in the system benzene–acetone (1 : 1), as it is the least polar and is most readily eluted with benzene, whereas R_f of the most polar 1,1' isomer **I** is the lowest. Reactions of the triethylammonium salt of 5-AT with 1,3-dibromopropane and 1,4-dibromobutane yield three isomers each, **IV**–**VI** and **VII**–**IX**, respectively; however, accurate determination of the isomer ratio was impossible because of the overlap of the proton signals of the isomers. Nevertheless, experiments on isolation of the products showed that in both cases, similar to the reaction with 1,2-dibromoethane, the 1,2' isomers [1-(5-aminotetrazol-1-yl)-3-(5-aminotetrazol-2-yl)propane (**V**) and [1-(5-aminotetrazol-1-yl)-4-(5-aminotetrazol-2-yl)butane (**VIII**), respectively] are the major products (Table 1).

The structures of the products were proved by IR and ^{1}H NMR spectroscopy, and also by correlation of the calculated dipole moments with the TLC data and by comparison of the melting points. Previous calculations of the normal vibrational modes and frequencies in tetrazole and its derivatives [30], and also recent data [4] allowed assignment of the vibrational frequencies of the tetrazole ring in the IR spectra of our compounds. To the stretching vibrations of the tetrazole ring in 5-AT belong the bands at 1605, 1460, 1445, and 1298 cm^{-1} [30]. As in the spectra of monosubstituted tetrazoles, in the IR spectra of **IV**–**IX** we can distinguish three groups of the ring stretching vibrations at 1600, 1470 and 1450, and 1265 cm^{-1}. An interesting feature is the low-frequency shift of the latter band, originating mainly from the C–N and N–N vibrations of the ring, as compared to 5-AT (1298 cm^{-1}), 1-methyltetrazole (1279 cm^{-1}), and 2-methyltetrazole (1352 cm^{-1}). Apparently, this band is the most sensitive to substituents in the ring. The stretching–bending vibrations of the ring lie at 1160–995 cm^{-1} (in the case of **IV**–**IX**, at 1000–1140 cm^{-1}). The out-of-plane bending vibrations of the ring lie below 700 cm^{-1}. In the range 3400–3200 cm^{-1}, there are two well-resolved medium-intensity and strong bands, assigned to the stretching vibrations of the amino group. In the ^{1}H NMR spectra of bistetrazoles **IV**–**IX**, the proton signals of similar groups (NCH_2, CH_2, NH_2) in the isomers differ by 0.05–0.1 ppm. Alkylation of K-5-AT with bis(chloromethyl) and β,β'-dichlorodiethyl ethers yielded 1,1' and 1,2' isomers **X**–**XIII**. From the reaction mixture we were able to isolate only the 1,1' isomer, 1,5-bis(5-aminotetrazol-1-yl)-3-oxapentane (**XII**) (Table 1). In the reaction with dichlorodimethyl ether, formation of two isomers was proved only by ^{1}H NMR spectroscopy and chromatography, as the reaction products undergo tarring in air at attempted isolation. In reactions of 5-AT with the dihalo derivatives, the major reaction products are the 1,2' isomers.

It is known that the thermodynamic stability of isomers can be evaluated by semiempirical quantum-chemical calculations. Since in these cases the structurally related molecules are compared, the errors inherent in calculation procedures are mutually compensated. The enthalpies of formation ΔH_f of **I**–**XIII** were calculated by the PM3 method (Table 2).

In the gas phase, for all the compounds, the 1,1' isomer is the most favorable, and the 2,2' isomer, the least stable. However, the products isolated from the reaction mixture show a different trend: In the reaction with dibromoalkanes the major product is the 1,2' isomer. Only in the reactions with dichloro ethers the isomer ratio is consistent with the ΔH_f values. In S_N2 reactions, of major importance are steric factors, namely, hindrance of formation of the transition state at increasing size of the nucleophile and substrate. Hence, along with thermodynamics there are

Table 2. Enthalpies of formation of bis(aminotetrazolyl) derivatives **I**–**XIII**

Compound	ΔH_f, kJ mol^{-1}, for indicated isomer

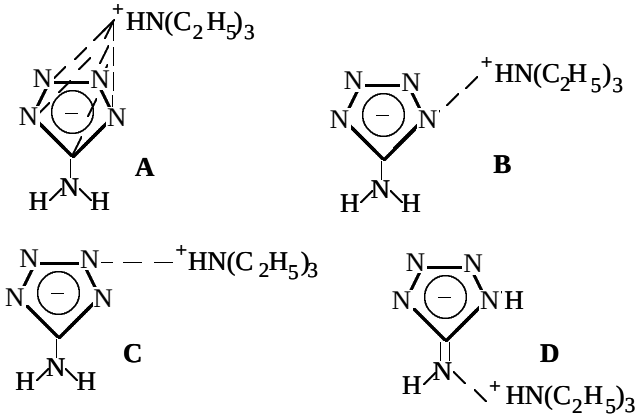
Bistetrazolyl-2-oxapropanes **X**, **XI**	574.0	578.6	590.2
Bistetrazolyl-3-oxapentanes **XII**, **XIII**	553.2	560.1	567.9

some other factors affecting the isomer ratio. Since the reaction was performed in solution at initial reactant concentrations of about 1 M, and dissociation of tetrazole salts is complete at concentrations of about 10^{-3} M [8], actually the reacting species were ion pairs, and hence the alkylation site should depend on the counterion. It is known [29] that the MNDO method is unsuitable for systems with hydrogen bonds, and hence it cannot be used for calculating triethylammonium salt of 5-AT. Therefore, we used the AM1 semiempirical method [29]. To reduce the calculation time and improve the convergence of the molecular geometry of the triethylammonium salts, we preliminarily characterized by molecular mechanics [30] the 5-AT anion and structures **A**–**D**:



In such solvents as acetone or DMF, ammonium or triethylammonium ions form with organic anions H-bonded complexes [31]. For tetrazolate anions, various structures are possible. X-ray diffraction study of 5-AT monohydrate [32], 5-AT hydrazinate [33], and guanidinium salt of 5-AT [34] showed that hydrogen bonds can be formed not only through the ring hydrogen atom but also through those of the amino group. For triethylammonium tetrazolate, Bryden [34] concluded that the most energetically favorable is the planar structure with the hydrogen bond with the N^1 atom of the ring. For triethylammonium salt of 5-aminotetrazole were calculated the structures in which the cation was located over the ring plane and was hydrogen-bnded with the ring. In the first stage the steric hindrance in formation of the transition state is less important than the electron density distribution in the ring, and the reaction mainly goes at the N^1 position, which is characteristic of monoalkylation of 5-AT salts. In this case, with K-5-AT, the yield of the N^1 isomer should be higher than in alklylation of the triethylammonium salt in which, despite large difference in the charge densities between the N^1, N^4 and N^2, N^3 atoms (Table 3), the bulky triethylammonium cation prevents approach to the N^1 atom.

In going to the second stage, the steric hindrance in formation of the transition state of 5-AT salts with bromoalkanes containing a bulky heteryl substituent become decisive, and the reaction mainly occurs at the N^2 atom. The change in the attack direction in going from the first to the second stage explains predominant formation of the 1,2' isomer in alkylation with dibromoalkanes. In alkylation of K-5-AT with dichloro ethers, the isomer ratio is different, which is probably due to the fact that increase in the length of the alkyl chain (reaction with Chlorex) and introduction into the alkyl chain of the ether oxygen atom, which is less bulky than the CH_2 group, decrease the steric hindrance in the transition state, so that the 1,1' isomer becomes the major product. Based on these data, we can predict the behavior of 5-substituted tetrazoles in alkylations with dihaloalkanes. When the 5-position is occupied by an electron-withdrawing group, the 2,2' isomer is the major product, since the steric and electronic effects act in the same direction, favoring alkylation at N^2. When the 5-substituent is an electron donor, a mixture of all the three isomers (1,1', 2,2', and 3,3') can be obtained, with the isomer ratio varying depending on the reaction conditions. In alkylation with dibromoalkanes, the thermodynamically favorable 1,2' isomer is the major product.

The ^{1}H NMR spectra were taken on a Bruker WP-80 spectrometer (80 MHz) in DMSO-d_6, internal reference TMS. The IR spectra were taken on an IKS-29 spectrometer (KBr pellets). The reaction progress was monitored and the isomeric purity checked by TLC on Silufol UV-254 plates with UV development.

Bis(5-aminotetrazolyl)alkanes I–VI. (a) To a solution of 7.38 g (0.06 mol) of K-5-AT in 20 ml of DMF we added dropwise 4.7 g (0.025 mol) of 1,2-di-

bromoethane. The mixture was stirred at 118–120°C for 16 h. The reaction completion was determined by the Beilstein's test for bromine. Th KBr precipitate was filtered off, and the solvent was distilled off. Total yield of the crude reaction products 4.16 g (85%). The dry residue was treated with dioxane. From the dioxane solution, 0.38 g (9% of total yield) of 1,2-bis(5-aminotetrazol-2-yl)ethane (**III**) was isolated, mp 163–164°C (from benzene). After treatment of the residue with ethanol, 2.26 g (54% of total yield) of 1-(5-aminotetrazol-1-yl)-2-(5-aminotetrazol-2-yl)ethane (**II**) was isolated from the ethanol solution, mp 135–136°C. By crystallizatiuon of the residue from distilled water, 1.08 g (26% of total yield) of 1,2-bis(5-aminotetrazol-1-yl)ethane (**I**) was isolated, mp 226–227°C. IR spectrum, ν, cm^{-1}: 3410, 3340, 1630, 825 (NH_2), 1585, 1565, 1530, 1515, 1460, 1425, 1300, 1110, 1095, 1025, 1080, 1065, 1040 (ring), 2920, 1390, 1360 (CH_2).

(b) A solution of 4.7 g (0.025 mol) of 1,2-dibromoethane in 25 ml of acetone was added to a mixture of 6.18 g (0.06 mol) of 5-AT monohydrate and 6.06 g (0.06 mol) of triethylamine in 25 ml of acetone. On stirring with reflux for 1 h, the mixture became homogeneous. The stirring and refluxing were continued for an additional 2 h. After cooling, the mixture of **I**–**III** was filtered to remove triethylammonium bromide, and the solvent was evaporated. Total yield of the crude products 4.27 g (87%). The isomers were separated and purified similarly. Yields, g (% of total): **I**, 0.76 (18); **II**, 2.43 (57); **III**, 0.70 (16).

A solution of 5.05 g (0.025 mol) of 1,3-dibromopropane in 25 ml of acetone was added to a mixture of 6.18 g (0.06 mol) of 5-AT monohydrate and 6.06 g (0.06 mol) of triethylamine in 25 ml of acetone. On stirring with reflux for 1 h, the mixture became homogeneous. The stirring and refluxing were continued for an additional 2.5 h. After cooling, the mixture of **IV**–**VI** was filtered to remove triethylammonium bromide, and the solvent was evaporated. Total yield of the crude products 4.41 g (84%). The dry residue was treated with dioxane. From the dioxane solution, 0.71 g (16% of total yield) of 1,3-bis(5-aminotetrazol-2-yl)propane (**VI**) was isolated, mp 152–153°C (from benzene). After treatment of the residue with ethanol, 2.07 g (47% of total yield) of 1-(5-aminotetrazol-1-yl)-3-(5-aminotetrazol-2-yl)propane (**V**) was isolated from the ethanol solution, mp 117–118°C (from acetone). By crystallization of the residue from distilled water, 0.93 g (21% of total yield) of 1,3-bis(5-aminotetrazol-1-yl)propane (**IV**) was obtained, mp 220–221°C (from water). IR spectrum, ν, cm^{-1}: 3420, 3350, 1640, 835 (NH_2), 1595, 1575, 1540, 1525, 1450, 1415, 1290, 1100, 1085, 1015, 1070, 1055, 1030 (ring), 2910, 2870, 1380, 1350 (CH_2).

Bis(5-aminotetrazolyl)alkanes VII–IX. A solution of 5.4 g (0.035 ml) of 1,4-dibromobutane in 25 ml of acetone was added to a mixture of 6.18 g (0.06 mol) of 5-AT monohydrate and 6.06 g (0.06 mol) of triethylamine in 25 ml of acetone. On stirring with reflux for 2 h, the mixture became homogeneous. The stirring and refluxing were continued for an additional 3 h. After cooling, the mixture of **VII**–**IX** was filtered to remove triethylammonium bromide, and the solvent was evaporated. Total yield of the crude products 4.87 g (87%). The dry residue was treated with dioxane. From the dioxane solution, 0.73 g (15% of the total yield) of butane **IX** was isolated, mp 147–148°C (from benzene). After treatment of the residue with ethanol, 2.05 g (42% of the total yield) of butane **VIII** was isolated from the ethanol solution, mp 108–109°C (from acetone). By crystallization of the residue from distilled water, 1.31 g (27% of the total yield) of 1,4-bis(5-aminotetrazol-1-yl)butane (**VII**) was isolated, mp 195–196°C (from water). IR spectrum, ν, cm^{-1}: 3415, 3370, 1650, 810 (NH_2), 1600, 1580, 1555, 1540, 1485, 1470, 1460, 1280, 1110, 1090, 1070, 995 (ring), 2940, 2910, 1355 (CH_2).

Bis(5-aminotetrazolyl)alkanes X and XI. To a solution of 7.38 g (0.06 mol) of K-5-AT in 20 ml of

DMF we added dropwise 5.4 g of dichlorodimethyl ether (0.025 mol). The mixture was stirred at 110°C for 30 h. The reaction completion was determined from the Beilstein's test for bromine. The KCl precipitate was filtered off, the solvent was distilled off, and the residue was analyzed. Total yield of crude reaction products **X** and **XI** 2.3 g (44%). IR spectrum, ν, cm^{-1}: 3450, 3340, 1660 (NH_2), 1620, 1440, 1260, 1130 (ring), 1100 (C–O–C).

Bis(5-aminotetrazolyl)oxapentanes XII and XIII. Total yield of crude products 3.66 g (61%). After twofold crystallization from acetone, 3.18 g (87% of the total yield) of oxapentane **XII** was obtained, mp 210–212°C. IR spectrum, ν, cm^{-1}: 3420, 3330 (NH_2), 1605, 1500, 1545, 1470, 1440, 1290, 1160, 1120, 1045, 1005 (C–O–C), 995 (ring), 1270, 1380, 1360 (CH_2).

CONCLUSIONS

(1) The pathway of alkylation of 5-aminotetrazole with dihaloalkanes changes from the first to the second stage. The first stage predominantly yields the N^1 isomers, whereas in the second stage the steric hindrance to formation of the transition complex between the 5-aminotetrazole salt and bromoalkane becomes decisive, and the reaction occurs at the N^2 atom. As a result, the 1,2' isomer becomes the major alkylation product.

(2) The number of isomers increases with increasing electrophilicity of the radical in bis(aminotetrazolyl) derivatives. In alkylation, the number of isomers increases with increasing polarity of the aminoazole molecule.

(3) Alkylated 5-aminotetrazoles exhibit a high-frequency shift of the absorption bands of the tetrazole ring in the IR spectra; in the ^1H NMR spectra, the signals of the 1,1' isomer are shifted upfield relative to the 1,2' and 2,2' isomers.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Identification and Quantitative Determination of 5-(Hydroxymethyl)furfural in Sugar Color

I. G. Zenkevich, A. I. Pimenov, L. I. Sokolova, and V. G. Makarov

Adaptogen Interregional Center, Private Company, St. Petersburg, Russia

Received March 1, 2001

Abstract—The possibility was examined for quantitative determination of 5-(hydroxymethyl)furfural without reference samples by chromatographic analysis with several internal references whose molar extinction coefficients are known.

Sugar color (SC, E150a) is a concentrated aqueous solution of saccharose caramelized at 160–180°C. It is widely used in food industry as coloring agent for confectioneries and numerous drinks. Therefore, it is necessary to develop efficient procedures for both standardization of sugar color and its determination in various samples [1–3]. Among substances formed by caramelization of carbohydrates, the volatile components have been studied most comprehensively; they can be identified by gas chromatography and GC–MS. The volatile components include numerous compounds belonging to the main "sequence" of hexose dehydration, $C_6H_{12}O_6 \rightarrow C_6H_{10}O_5 \rightarrow C_6H_8O_4 \rightarrow C_6H_6O_3$, and also partially reduced compounds such as $C_6H_8O_3$, $C_6H_8O_2$, and some other products, in particular, and derivatives of furan [furfural, 5-(hydroxymethyl)furfural, 2-acetylfuran, 2-acetyl-3-hydroxyfuran (isomaltol), substituted 3-hydroxy-2-(5*H*)- and 4-hydroxy-3(2*H*)-furanones], 4-pyrone (maltol), etc. Among diverse carbohydrate oligocondensation products, SC presumably contains caramelan ($C_{24}H_{36}O_{18}$), caramelene ($C_{36}H_{50}O_{25}$), and still more complex compounds (caramelin). Maltol exhibits a bactericidal effect and is used as a special additive (E636) to enhance the taste and odor of foodstuffs [2]. Also, aldehydes of the furan series present in SC impart to it certain antioxidant effect.

The diversity of components of different chemical nature and the variability of SC composition complicate its standardization and determination in various objects. One of ways to solve the problem is to choose a specific compound among the main products of thermal degradation of hexoses [4] whose chromatographic parameters would be sufficiently specific for its separation from concomitant components by gas and reversed-phase high-performance liquid (HPLC) chromatography. In the latter case, the presence of a chromophore for UV detection is necessary. As such component in HPLC analysis we can suggest 5-(hydroxymethyl)furfural. This work is devoted to identification of this compound by HPLC and to evaluation of its content in commercial SC samples without using reference samples of this product.

EXPERIMENTAL

Commercial SC samples (Meligen Private Company, Leningrad oblast) were prepared by thermal treatment of saccharose at 160–180°C for 4 h, followed by addition of 50 wt % water.

Analysis by reversed-phase HPLC was performed with a Beckman System Gold chromatograph [UV detector, Gold V-402 software, Luna C_{18} column (150 × 4.6 mm, sorbent particle size 5 μm), 20 × 4.6-mm precolumn packed with the same sorbent]. Elution was performed in a step mode with a mixture of acetonitrile (Kriokhrom Scientific and Production Complex, St. Petersburg) with 0.05% aqueous trifluoroacetic acid (pH ~2.0). Isocratic elution (5% acetonitrile, 5 min) was followed by gradient elution with the acetonitrile content varied from 5 to 100% over a period of 95 or 40 min. Detection was performed at 220, 229, 254, 284, and 320 nm. Prior to analysis, SC samples were dissolved in water (1 : 100 ratio); the dosage was 10 μl. To determine the retention indices (RIs), we measured in parallel the retention times of reference alkyl phenyl ketones $C_6H_5COC_nH_{2n+1}$ (n = 1–3). The RIs of the compounds eluted before the first reference component (acetophenone) were determined by extrapolation in the scale of the retention times squared [5].

1070-4272/01/7407-1164$25.00

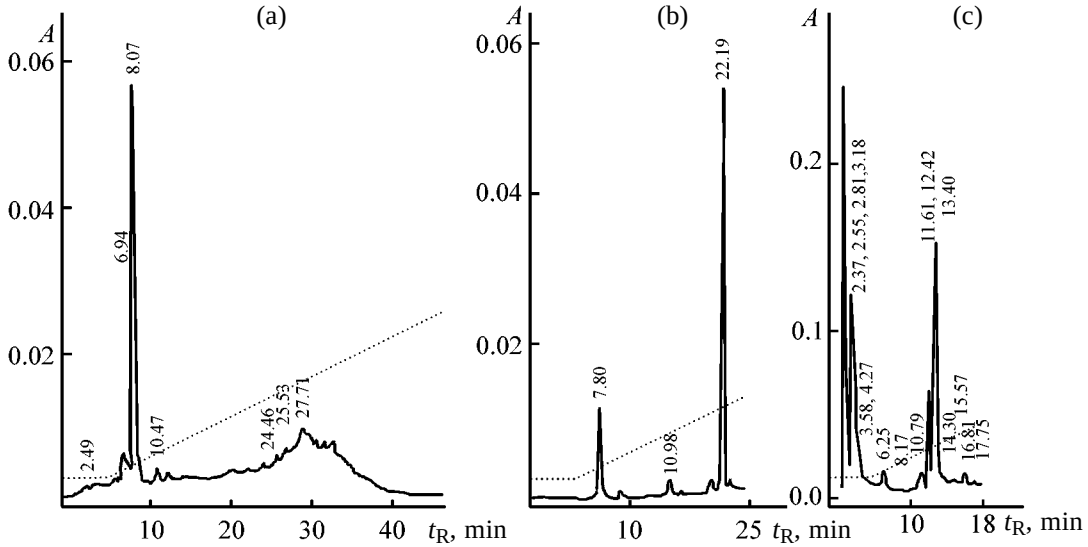

Fig. 1. Chromatograms of sugar color: (a) initial aqueous solution, (b) after acetylation, and (c) after treatment with hydroxylamine. HPLC analysis UV detection at 254 nm. (*A*) Optical density and (t_R) retention time.

To prepare acetyl derivatives, 0.5 ml of SC was treated with 0.5 ml of acetic anhydride containing catalytic amounts of sulfuric acid, and an additional 0.5 ml of the anhydride was added 1 min after the mixture warmed up. To prepare oximes, to a solution of 0.5 ml of SC in 2 ml of 50% ethanol we added 0.5 g of hydroxylamine hydrochloride and 0.3 g of NaOH and stirred the mixture for 3 min. Both samples before chromatographing were dissolved in 50% ethanol (1 : 100 ratio). For quantitative determinations, samples of SC and internal references (10–25 mg) were dissolved in 50 ml of water or 80% ethanol, depending on their hydrophobicity.

Statistical treatment of the data was performed using the software for a CASIO PB 10 programmable calculator; the hydrophobicity parameters of organic compounds ($\log P$) were estimated with ACD software.

A typical total chromatogram of SC (HPLC, detection wavelength 254 nm) is shown in Fig. 1. Under the chosen conditions of gradient elution, only a single predominant signal of an individual component (retention time 8.0 ± 0.2 min, RI 619 ± 3) is detected. The remaining compounds absorbing in the near-UV range are eluted as a broad band of unresolved peaks with the retention times in the range 20–35 min; the available columns do not ensure their separation. Specifically this group of peaks is mainly responsible for the interfering effect of SC in analysis of SC-containing samples. The only detected individual chromatographic peak is thus the most characteristic manifestation of SC. Therefore, we can formulate the goal of this work as identification and quantitative determination of the corresponding component. As already noted, both problems can be solved without using reference samples.

Identification of substances by HPLC is based on the use of chromatographic retention parameters, UV data, and derivatization reactions. The principal element of the logical scheme is transforming the problem from exploring analysis (identification of an unknown compound without any additional available data) to confirming determinations (the nature of the analytes is assumed *a priori*). In our case, the hypothesis to be verified is the structure of 5-(hydroxymethyl)furfural, the expected main product of thermal degradation of hexoses [4]. To confirm this assumption unambiguously, it is necessary to prove the presence of two functional groups (CH_2OH and CHO) and to determine the chromophore type.

One of the simplest ways of derivatization of compounds containing active hydrogen, including that in aliphatic hydroxy groups, is preparation of their acyl (in particular, acetyl) derivatives [6, 7]:

$$X\text{–}OH + Ac_2O \rightarrow X\text{–}OAc + AcOH.$$

The general chromatographic (including HPLC) feature of monoacetyl derivatives is the difference between the RIs of the reaction products and initial substances, amounting to 126 ± 16 according to [7] (provided that the molecule contains no intramolecular hydrogen bonds). Treatment of an SC sample with excess acetic anhydride yields a single reaction product

with the retention time of about 22 min and RI 717 ± 3 (Fig. 1b); the RI difference, $(717 \pm 3) - (619 \pm 3) = 98 \pm 5$, is close to the above-indicated range. This unambiguous result makes it unnecessary to use more complex derivatization procedures (e.g., treatment with a mixture of two reagents to determine the number of functional groups [8]).

The structure of the detected reaction product can be additionally confirmed by independent evaluation of the RI of the acetyl derivative of 5-(hydroxymethyl)furfural using a well-known correlation between the retention indices of organic compounds in HPLC and their hydrophobicity parameters, namely, logarithms of the distribution factors in the system 1-octanol–water $\log P$ [9]. To the retention index of 5-(hydroxymethyl)furfural (RI 619 ± 3) corresponds the calculated value of $\log P$ of -0.45 ± 0.35; as a second component we can choose acetophenone [$\log P$ 1.73 (experimental value); RI 800 (by definition)]. For the acetate, the calculated value of $\log P$ is 0.44 ± 0.36; linear interpolation gives the expected value of RI of 693 ± 31, which agrees with the experimental value of 717 ± 3.

To confirm the presence of the formyl group, we can use oximation:

$$\text{Y–CHO} + \text{NH}_2\text{OH}\cdot\text{HCl} + \text{NaOH} \rightarrow \text{Y–CH=NOH} + 2\text{H}_2\text{O} + \text{NaCl}.$$

The chromatogram of the reaction mixture after treatment of an SC sample with hydroxylamine contains two product peaks with the intensity ratio of 1 : 2.2 (irrespective of the detection wavelength), belonging to the *syn* and *anti* isomers of 5-(hydroxymethyl)furfural oxime (Fig. 1c); their retention times are 11.6 and 12.4 min, and retention indices, 648 ± 2 and 653 ± 2, respectively. Thus, the qualitative reactions with HPLC monitoring of the reaction mixtures confirm the presence of the expected functional groups.

The simplest way to confirm the type of the chromophore in a molecule under conditions of HPLC analysis is comparison of the experimental relative optical densities $A_{rel} = A(\lambda_1)/A(\lambda_2)$ with reference data [10]. However, total tabulated UV spectra [11] are not available for 5-(hydroxymethyl)furfural, and the molar extinction coefficients are only given for the peak maxima ($\lambda_1 = 229 \pm 1$ nm, $\log \varepsilon_1 = 3.46 \pm 0.12$; $\lambda_2 = 284 \pm 1$ nm, $\log \varepsilon_2 = 4.22 \pm 0.01$). This means that for identification of the chromophore it is necessary to compare the areas of the chromatographic peaks, measured specifically at these detection wavelengths, since $A_{rel} = S_1/S_2$. The experimental value of $A_{rel}(284/229)$ for different SC samples is 5.9 ± 1.9, which is consistent with the ratio of the molar extinction coefficients, $10^{4.22-3.46} = 5.6 \pm 0.5$. This ratio is also close to the relative optical density for unsubstituted furfural [$\lambda_1 = 229 \pm 1$ nm, $\log \varepsilon_1 = 3.51 \pm 0.11$; $\lambda_2 = 277 \pm 1$ nm, $\log \varepsilon_2 = 4.14 \pm 0.05$; $A_{rel}(227/229) = 4.3 \pm 0.3$], which also proves the nature of the chromophore in the molecule. In addition to the quantity $A_{rel}(284/229)$, we determined for 5-(hydroxymethyl)-furfural two similar quantities, $A_{rel}(254/220) = 0.43$ and $A_{rel}(320/254) = 2.2$, which, if necessary, can also be used for identification of this compound.

The main methods for quantitative chromatographic analysis (absolute calibration, external and internal references, standard addition) imply the availability of reference samples of a compound to be determined. However, if such samples are lacking, this does not mean that quantitative determination is impossible. Furthermore, development of new analytical procedures without using reference samples is one of the most urgent problems of modern organic analytical chemistry [13, 14].

The problems with quantitative determinations in such a case are the greatest specifically in HPLC analysis, since the relative sensitivity coefficients of UV detectors to different compounds, depending on the chromophore type, can vary within several orders of magnitude. However, in this case it is possible to use as internal references any available compounds with known quantitative characteristics of the UV spectra [13, 14]. The weight m or concentration a of an analyte in the sample is given by

$$m_X(c_X) = m_{ref}(c_{ref})[(M_X/M_{ref})(\varepsilon_{ref}/\varepsilon_X)](S_X/S_{ref}), \quad (1)$$

where the subscripts X and ref refer to parameters of the compound to be determined and chosen reference, M is the molecular weight, ε is the molar extinction coefficient, and S is the chromatographic peak area; the absolute values of ε and S depend on the chosen detection wavelength.

The expression in brackets is the coefficient of relative sensitivity of a UV detector to the compound being determined relative to the chosen internal reference:

$$f(\text{X/ref}) = (M_X/M_{ref})(\varepsilon_{ref}/\varepsilon_X). \quad (2)$$

In our case, among the simplest available substances we chose four compounds with the known molar extinction coefficients at 229 and 284 nm [11].

Initial analytical data and results of evaluating the content of 5-(hydroxymethyl)furfural (**I**) (M = 126) in an SC sample without a reference sample of the compound to be determined

Internal reference	c_{SC}, mg ml^{-1}	λ, nm	M_{ref}	c_{ref}, mg ml^{-1}	$\varepsilon_{ref} \times 10^{-3}$	$\varepsilon_X \times 10^{-3}$	f(X/ref)	S_X (arb. units)	S_{ref} (arb. units)	c_X, mg ml^{-1}	Concentration of **I** in SC sample, wt %*
Nitrobenzene	10.04	284	123	0.46	5.43	16.6	0.34	50.8	157.3	0.050	0.50
Acetol	10.04	229	148	0.35	7.69	2.88	2.3	13.8	59.6	0.051	0.51
Benzoic acid	10.98	284	122	0.28	0.479	16.6	0.030	132.7	32.1	0.034	0.31
	5.27	284	122	0.24	0.479	16.6	0.030	70.7	23.2	0.022	0.42
Coumarin	5.27	284	146	0.20	8.02	16.6	0.42	70.7	209.7	0.028	0.53

* Average 0.45 ± 0.09.

According to [14], the set of such internal references can be arbitrary:

Compound (in the order of chromatographic elution)	$\varepsilon(229) \times 10^{-3}$	$\varepsilon(284) \times 10^{-3}$
5-(Hydroxymethyl)furfural (compound to be determined)	2.88	16.6
Benzoic acid	14.6	0.479
Coumarin	32.0	8.02
Nitrobenzene	2.26	5.43
Acetol	7.69	6.38

In the table are given the initial experimental data and the results of quantitative determination of 5-(hydroxymethyl)furfural in one of typical commercial SC samples, using all the four above-named substances as internal references. The mean weight fraction of 5-(hydroxymethyl)furfural is 0.45 ± 0.9 (variation coefficient 20%). Since the published values of ε used as reference data were measured under conditions differing from those of HPLC analysis (for solutions in ethanol; for nitrobenzene, in aqueous solution), the reproducibility of the results may be different depending on the particular reference and detection wavelength. Indeed, the scatter of the c_X values determined at 229 nm (0.44 ± 0.28) considerably exceeds the scatter at 284 nm (0.45 ± 0.09). However, the mean concentrations themselves coincide, which confirms the reliability of our approach. Along with difference between the conditions of UV measurements in reference literature and UV detection in HPLC, another significant source of the random error, as noted in [14], is the error of peak integration. Nevertheless, the content of 5-(hydroxymethyl)furfural (see table) was determined with the relative standard deviation as low as 20%, which does not exceed variations in its concentration in different SC samples due to specific features of the production process.

In SC prepared by the other (not used in Russia) procedures, including sulfite (E150b), ammonia (E150c), and ammonia–sulfite (E150d) procedures [2], the content of 5-(hydroxymethyl)furfural should be lower owing both to a different major pathway of carbohydrate degradation in basic media [4] and to reaction of aldehydes with sulfites [15]:

$$Y\text{–}CHO + HSO_3^- \rightarrow YCH(OH)SO_2O^-.$$

The resulting hydrosulfite derivatives are considerably more hydrophilic and exhibit different UV characteristics.

CONCLUSIONS

(1) 5-(Hydroxymethyl)furfural is one of the most characteristic components of sugar color (E150a food additive) in analysis of samples containing sugar color by reversed-phase HPLC.

(2) A combination of chemical derivatization procedures with UV examination was suggested for identification of this compound, and a version of the internal reference method using several reference compounds with known molar extinction coefficients at different wavelengths was suggested for its quantitative determination for the case when the reference sample is not available.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Thermal Transformations of Polymetallosiloxanes Prepared by the Sol–Gel Procedure

Received October 30, 2000; in final form, April 2001

Abstract—Thermal stability and crystal structure transformations of polyalkoxymetallosiloxanes (metallosilicas) prepared by the sol–gel procedure involving hydrolytic polycondensation of tetraethoxysilane with salts and oxides of Group I, II, and IV metals (Cu, Zn, Hg, Sn, and Pb) were studied.

Incorporation of metal atoms (M) into polysiloxane structure to form Si–O–M–O–Si groups strongly affects thermal and hydrolytic stability, adhesion, and cohesion of the initial silicon polymers and imparts to them biological activity and some other important properties [1–3]. This is due to changes in the steric and stereoelectronic structure of their crystal lattice and changes in the nature of the intramolecular interactions. The strength of the Si–O–M fragments appreciably depends on the nature of the heteroatom M and its ability to form M ← O coordination bonds [1].

Although the structure and properties of heterosiloxanes are extensively studied, precise prediction of their thermal and chemical transformations is difficult and requires special investigation. This is, in particular, due to the fact that the structure and properties of polymetallosiloxanes depend on the preparation procedure and can strongly differ even at almost identical composition [1, 4].

Taking into account theoretical and practical importance of this problem, we studied thermal transformations of polymetallosiloxanes prepared previously by the sol–gel procedure [5].

EXPERIMENTAL

Heterosiloxanes (polyalkoxymetallosiloxanes or metallosilicas) were prepared by hydrolytic polycondensation of partially hydrolyzed tetraethoxysilane (Etilsilikat-40) with Group I, II, and IV metal compounds in the presence of NH_4OH as a catalyst. The products were dried at 120 ± 0.5°C to the xerogel state.

The initial metal compounds were CuO, $CuSO_4 \cdot 5H_2O$, $CuCl_2 \cdot 2H_2O$, $Cu(OH)_2$, $Cu(NO_3)_2 \cdot 3H_2O$, $Hg_2(NO_3)_2 \cdot 2H_2O$, $Hg(NO_3)_2 \cdot 0.5H_2O$, Pb_3O_4, $Pb(OCOCH_3)_2 \cdot 3H_2O$, $SnCl_2 \cdot 2H_2O$, $Zn(NO_3)_2 \cdot 6H_2O$, and finely dispersed zinc powder.

We studied thermal transformations of the metallosiloxanes during programmed heating in air with a 10 deg min^{-1} rate (MOM derivatograph, Hungary). The structural transformations were studied by powder X-ray diffraction (DRON-3 diffractometer).

Incorporation of metal atoms into the siloxane lattice appreciably enhances the thermal stability of silica xerogels. The DTA curves of ethoxylated xerogel contain a weak exothermic peak at 265°C, whereas several exothermic effects are observed at higher temperatures in the DTA curves of the tested metallosiloxanes (Table 1). This is likely due to shielding of the residual ethoxy groups by the Si–O–M–O–Si fragments and indicates higher thermooxidative stability of the heterosiloxanes.

The exothermic peaks in the DTA curves of the metallosilica xerogels containing copper, zinc, and mercury(II) heteroatoms are usually broad (diffuse) with the main maxima at 700°C. These peaks are probably due to several parallel and consecutive processes.

(1) Thermal degradation of residual ethoxy groups shielded by the Si–O–Si and Si–O–M bonds. This is confirmed by the weight loss at 200 – 600°C (Table 2).

(2) Formation of additional Si–O–M–O–Si groups in this temperature range by the following condensation:

$$\equiv SiOEt + XM- \rightarrow \equiv Si-O-M + EtX,$$

$$\equiv SiOH + XM- \rightarrow \equiv Si-O-M + HX,$$

where M is the bivalent metal; X is the acid anion or OH^-.

(3) Crystallization of the resulting metallosilicas, confirmed by X-ray diffraction (Figs. 1a–1j).

(4) Structural transformations at elevated temperatures [6] of amorphous silica prepared by the sol–gel procedure, increasing the porosity of the metallosilica structure (swelling); this, in turn, affects the heat capacity of the samples.

The exothermic effects in the DTA curves of metallosilica xerogels prepared from $CuSO_4$, $Hg_2(NO_3)_2$, $PbOCOCH_3$, and $SnCl_2$ are observed at lower temperatures as compared to the silica xerogel. This can be due to catalysis of thermal degradation of ethoxy groups by the heteroatoms. It is also possible that the resulting highly dispersed polymetallosiloxanes are compositions of macromolecular structures with various condensation degree (exothermic peaks at 300°C and higher temperatures) and low-molecular-weight powders with weak intermolecular interactions (exothermic peaks at temperatures lower than 300°C).

The metals are incorporated into the siloxane structure not only by hydrolytic polycondensation to form endo- and exoskeleton heterosiloxane structures but also by parallel sorption of the initial metal compounds on the resulting highly porous silica and metallosilica matrices. This is confirmed by the fact that the X-ray patterns of the majority of thoroughly washed metallosilica xerogels dried at 120 ± 0.5°C contain sharp and strong reflections superimposing on the diffuse "halo" and coinciding with those of the initial metal compounds.

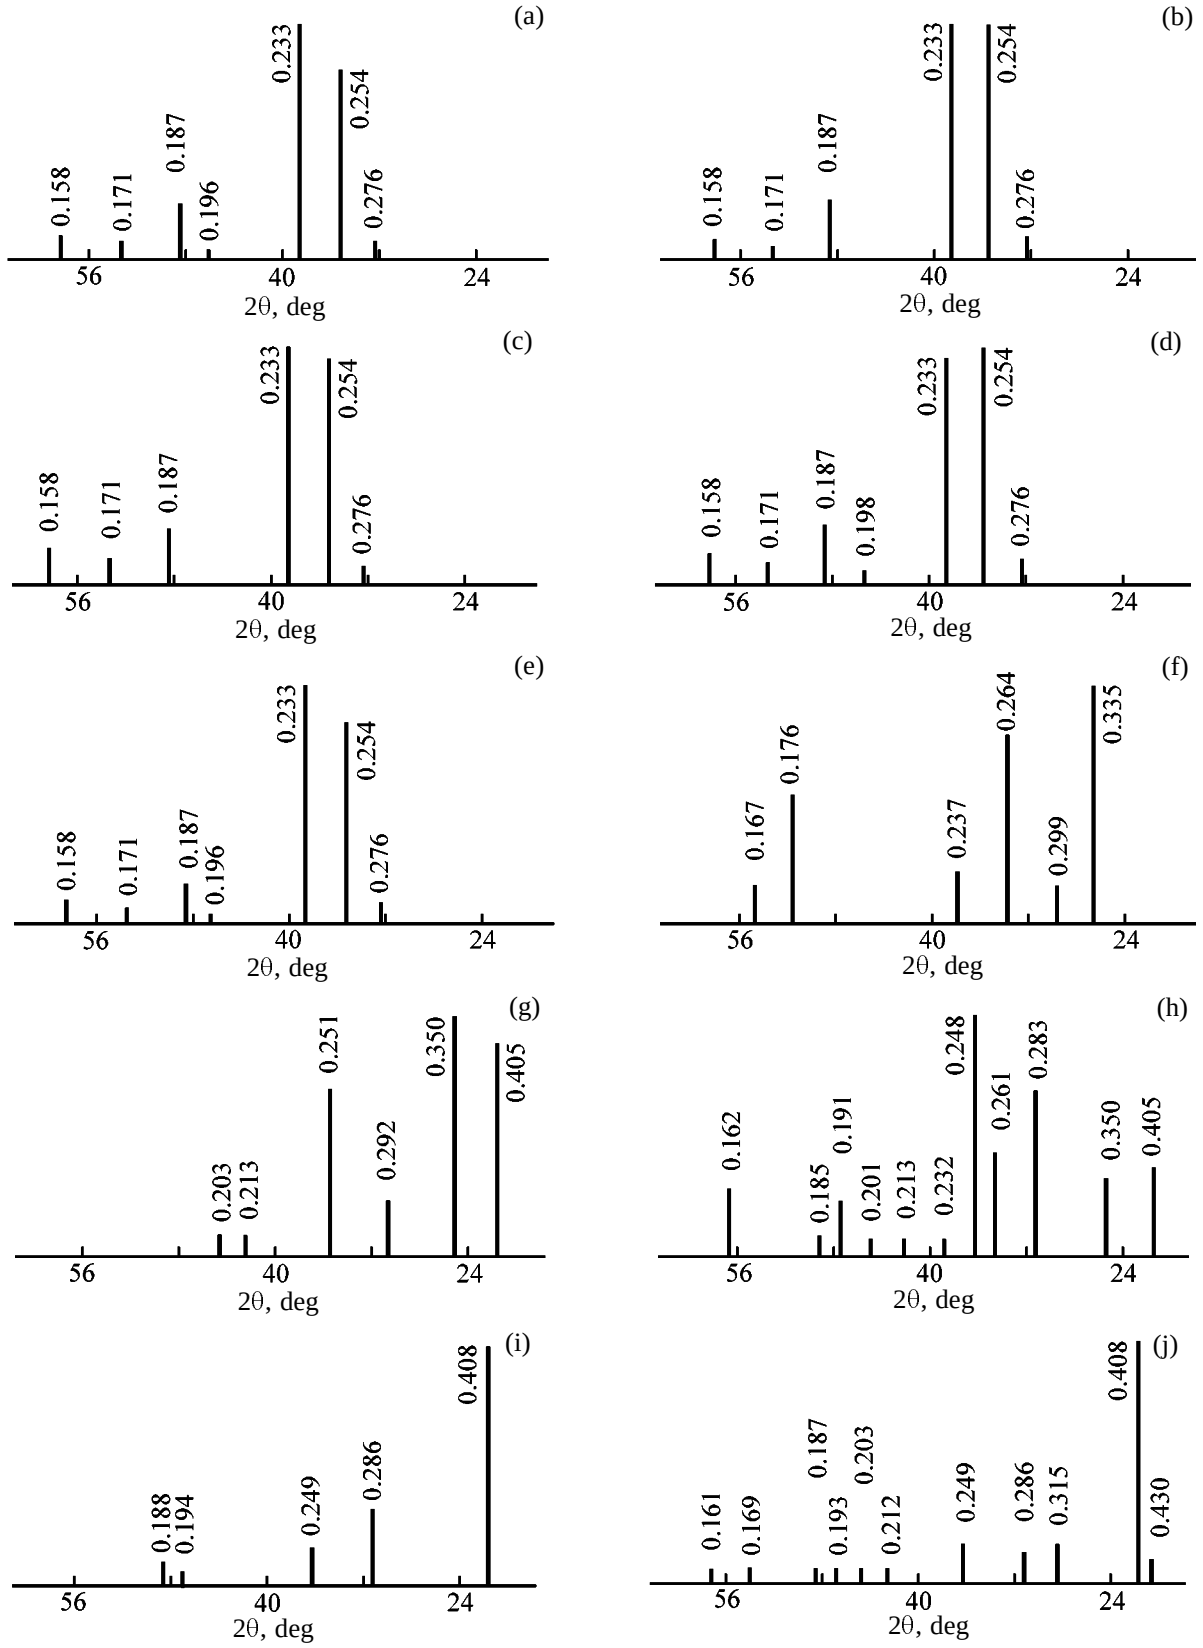
The presence of these reflections indicates sorption of the initial compounds on the surface of silica and metallosilica matrices. The sorption layer should be thicker than 10 nm, since reflections from thinner layers are blurred and cannot be observed against the background. This is the case, for example, for the metallosilicas prepared from $Cu(NO_3)_2$, $CuCl_2$, $CuSO_4$, $Zn(NO_3)_2$, and $Pb(OCOCH_3)_2$.

As seen from Fig. 1, the X-ray diffraction patterns of the majority of the metallosilicas heated to 900°C with a rate of 10 deg min^{-1} contains sharp and strong refections assigned to metal oxides formed probably by the following reaction:

$$\equiv Si–O–M–O–Si\equiv \rightarrow \equiv Si–O–Si\equiv + MO.$$

The X-ray diffraction patterns of the metallosilicas contain reflections of CuO (*d* 0.254, 0.233, 0.187, 0.171, and 0.158 nm). Along with copper oxide, traces of unidentified phase were also detected (*d* 0.276, 0.198, 0.196 nm). The X-ray diffraction patterns of metallosilicas prepared form zinc powder and zinc nitrate contain sharp strong reflections of β-cristobalite [7] (*d* 0.405, 0.283, 0.251, 0.248, 0.213, 0.203, and 0.191 nm) formed by crystallization of amorphous silica. Zinc oxide (*d* 0.247, 0.191, and 0.162 nm) and appreciable amounts of willemite Zn_2SiO_4 (*d* 0.350, 0.263, 0.261, 0.232, 0.203 nm) formed by reaction of ZnO with SiO_2 were also detected.

The weight gain of polymetallosiloxanes prepared



X-ray diffraction patterns of metallosilicas prepared from (a) CuO, (b) $Cu(NO_3)_2$, (c) $CuCl_2$, (d) $CuSO_4$, (e) $Cu(OH)_2$, (f) $SnCl_2$, (g) $Zn(NO_3)_2$, (h) Zn powder, (i) Pb_3O_4, and (j) $Pb(OCOCH_3)_2$ and heated at 900°C.

from CuO and ZnO (up to 1.67 and 2.05 wt %, respectively) at temperatures from 600 to 1000°C is due to high-temperature genesis of metal oxides. For example, copper formed at lower temperature by reduction of CuO with eliminated ethanol is oxidized with atmospheric oxygen to CuO even at 400–500°C:

$$CuO + CH_3CH_2OH \rightarrow Cu + CH_3CHO + H_2O,$$

$$Cu + 0.5O_2 \rightarrow CuO.$$

The X-ray patterns of metallosilicas prepared from $SnCl_2$ and heated at 900°C contain reflections of SnO_2 and SnO.

As determined by X-ray diffraction, two crystalline phases, β-cristobalite and PbO, are present in the lead-containing silicas. Lead oxide is formed only in the metallosilica prepared from $Pb(OCOCH_3)_2$. Weaker and broader reflections in the X-ray pattern of the metallosilica prepared from Pb_3O_4 indicate smaller amount and lower degree of crystallizaton of β-cristoballite in this material.

The X-ray diffraction patterns of mercurosilicas heated at 900°C contain no reflections of crystalline phases. This indicates degradation of the mercurosilica matrix with mercury liberation:

$$\equiv Si–O–Hg–O–Si\equiv \xrightarrow{T_1} \equiv Si–O–Si\equiv + HgO,$$

$$2HgO \xrightarrow{T_2\ (>T_1)} 2Hg + O_2.$$

The silica xerogel heated at 120 or 900°C is also X-ray amorphous.

We suggest that Zn and Pb atoms present in the siloxane structure as ≡Si–O–M–O–Si≡ fragments and salts and oxides of these metals sorbed on the metallosilica matrix catalyze β-cristobalite formation from amorphous SiO_2 even at temperatures lower than 900°C. This is primarily due to both the nature of the metal atom M and high molecular uniformity of the polyheterosiloxane systems. The catalytically active species are mainly ZnO and PbO formed from xerogel thermolysis (except for the system with Pb_3O_4). The catalytic action of these oxides can be also explained by the Headwall's effect, i.e., increased reactivity of highly dispersed substances with disordered crystal lattice, formed in the course of phase transformations.

Amorphous SiO_2 prepared by the sol–gel procedure from tetraethoxysilane was previously shown to crystallize into β-cristobalite at 1300°C. This process can be controlled by the synthesis conditions [6, 8].

Thus, zinc and lead atoms incorporated into the polysiloxane structure effectively catalyze silica crystallization.

CONCLUSION

Incorporation of copper, zinc, tin, and lead atoms into the siloxane skeleton of silica strongly enhances the thermal stability of the initial xerogel. The lead and zinc atoms catalyze crystallization of amorphous silica in the corresponding metallosiloxanes.

Abstract—Film formation from binary mixtures of latexes of thermodynamically incompatible polymers was studied. Partial segregation of the polymers in the course of latex film formation, causing asymmetry of the resulting films, was proved by IR Fourier spectroscopy. The influence of various factors on the segregation of polymers was examined.

Film preparation from a mixture of two latexes of thermodynamically incompatible polymers can result in formation of various structures. The extreme cases of such structures are (1) uniform distribution of particles of one polymer in the matrix of the other polymer and (2) total segregation of the two polymers. It is clear that both these cases are idealized. Nevertheless, even a tendency to predominant formation of one or another structure creates prerequisites for solution of many applied problems.

Of particular interest are latex films in which the polymeric components undergo segregation in the course of film formation from a mixture of two latexes. Such films, often termed asymmetric films, owing to different chemical composition of the surfaces can find diverse applications: films with an adhesive layer, films with increased surface hardness and high adhesion to the substrate, films with increased surface electrical conductivity, films with increased hydrophobicity or hydrophilicity, etc. Usually latex films of such kind are prepared by successive immersion of a substrate in two different latexes, with intermediate drying of the film after each immersion [1]. Preparation of an asymmetric film from a mixture of latexes by a single immersion cycle is a more promising process.

Numerous studies [2–5] showed that the polymers are distributed nonuniformly across the film prepared from a mixture of latexes. Okubo *et al.* [2, 3] suggest that formation of asymmetric films may be due to different sedimentation rate of particles of different size.

Sedimentation stability of latexes is only one of the factors affecting preparation of asymmetric films. In this study we attempted to reveal the role of other factors, such as, e.g., aggregative stability of latexes and the capability of polymers for specific interactions with a substrate on which the film is formed.

EXPERIMENTAL

Two types of latexes, poly-*n*-butyl acrylate and styrene–*n*-butyl acrylate (ST–BA) copolymer, were prepared with the aim to examine the influence of various factors on the film formation from latex mixtures. Usually synthesis was performed in two stages. In stage 1 we prepared a seeding latex by charging to the reactor a small amount of the monomers and (co)polymerizing them to complete conversion. In stage 2 the monomers were added gradually, and the process was performed in the semicontinuous mode.

Emulsion copolymerization was performed in 250- or 500-ml flasks equipped with a reflux condenser, a stirrer, a dropping funnel for adding monomers, and a nipple for feeding nitrogen. The following chemicals were used.

Monomers, styrene (ST) and *n*-butyl acrylate (BA), were vacuum-distilled; their characteristics agreed with the reference data.

Initiators [potassium persulfate (PP), azobis(isobutyronitrile (AIBN), and 2,2'-azobis(2-amidinopropane) dichloride (AAPDC)] were used without additional purification.

* (*T*) Polymerization temperature, (*d*) particle diameter, (σ) surface tension of the latex, and (ρ) polymer density.

** Concentrations of the initiators and surfactants are given relative to the weight of the monomers.

*** Designations of the latexes include the chemical composition of the polymer or copolymer, type of surfactant [(A) anionic, (C) cationic, (N) nonionic, and (0) no surfactant], and particle charge [(+) positive and (–) negative; no sign means no charge]; into (BA)-A$^-$ and (ST–BA)-A$^-$ latexes after synthesis completion we introduced an additional portion of SAS (4% relative to the polymer weight.

Surfactants [sodium alkylsulfonate C_{14}–C_{16} (SAS), cationic surfactant trimethyldodecylammonium chloride (TMDAC), and nonionic surfactant OS-20, a mixture of oxyethylated aliphatic alcohols $C_{14-16}H_{29-31}\cdot(OCH_2CH_2)_{20}OH$] were used without additional purification. To prepare thermosensitive latexes, we used modified oxyethylated alkylphenols $C_{8-10}H_{17-21}C_6\cdot H_4O(CH_2CH_2O)_{8-10}CH_2N^+(CH_3)(C_2H_5)_2\ C_6H_5SO_3^-$ (leveling agent A) and $C_{8-10}H_{17-21}C_6H_4O(CH_2CH_2\cdot O)_{10-12}SO_3^-\,Na^+$ (S-10). Latexes were prepared in distilled water. The synthesis conditions and characteristics of latexes, and also, for comparison, the characteristics of SKF-32 fluororubber latex (copolymer of trifluorochloroethylene and vinylidene fluoride) are listed in Table 1.

The latex dry residue was determined by drying the latex samples under an IR lamp to constant weight. The size of the latex particles was determined from the turbidity spectra, namely, from the dependences of the optical density of the diluted latex on the incident light wavelength [6]. The surface tension of latexes, measured by the du Nouy (ring detachment) method, qualitatively characterizes their adsorption saturation. Lower surface tension and hence higher adsorption saturation are characteristic of latexes prepared in the presence of surfactants of any type.

Several mixtures containing various types of latexes were prepared to study the effect of various factors on formation of films from latex mixtures. It should be noted that in each system at least two factors act simultaneously, which makes it difficult to distinguish the effects of particular factors. However, we chose the compositions of latex mixtures so as to make the effect of one of the factors predominant.

Films from latex mixtures were cast on different supports: those from glass, Teflon, and siliconized paper (SP). In experiments on ionic deposition of latexes, we used as support an ion-exchange membrane of the Nafion type (copolymer of tetrafluoroethylene with a fluoromonomer containing a sulfonyl fluoride group which was converted to the sulfonic acid form by hydrolysis in an NaOH solution followed by treatment with boiling nitric acid). For studying thermal coagulation, we used a heavy glass support heated to 100°C. For experiments we prepared 100-μm-thick films, unless otherwise stated. The films were used 24 h after preparation.

The extent of polymer segregation in latex films was evaluated from the composition of the polymer compound on the polymer–air (P–A) and polymer–support (P–S) boundaries. The composition was determined by IR Fourier ATIR spectroscopy using an HTR-25 attachment to a Perkin–Elmer (model 1750) Fourier spectrometer. With a KRS-5 prism (45°), the effective penetration depth of the light wave was 2.0 ± 0.8 μm depending on the position of the analytical wavelength and refractive index of the compound. The wavelength dependence of the penetration depth was corrected with a special program.

The ST : BA weight ratio was determined from the

intensity ratio of the bands at 700 (phenyl group of styrene) and 1729 cm^{-1} (carbonyl group of *n*-butyl acrylate). Coatings prepared from ST–BA/SKF-32 latex mixtures were characterized by the intensity ratio of the bands at 700 and 509 cm^{-1} belonging, respectively, to the styrene unit and SKF-32 polymer.

As an example, the figure shows the spectra of two surfaces of a film prepared on a heated support from a mixture of (ST–BA)-A^- and (BA)-0^+ + S-10 latexes. Comparison of the intensity of the band at 700 cm^{-1} for these two phase boundaries shows that the P–A surface is strongly enriched in the ST–BA copolymer.

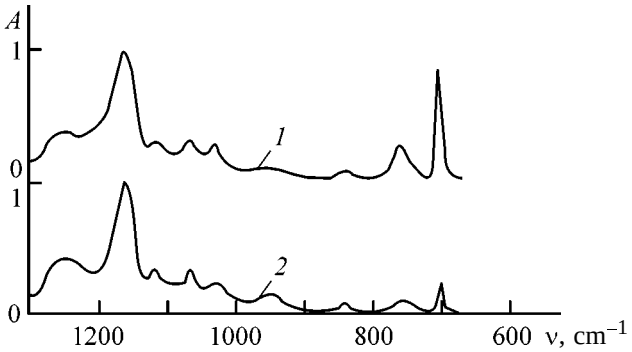
The role of the sedimentation stability of latexes was studied with a mixture of (ST–BA)-0^- and (SKF-32)-A^- latexes strongly differing in the particle density (Table 1). Films were prepared on different supports and at different temperatures. As seen from Table 2, in this system the factor of the polymer density remains decisive. Despite smaller size of SKF-32 particles and low aggregative stability of particles of the ST–BA copolymer prepared in the absence of surfactants, in all cases the P–S surface is enriched in SKF-32. The effect is more pronounced with the Teflon support exhibiting a higher affinity for the fluoropolymer.

With decreasing temperature, i.e., with increasing time of film formation, the effect of polymer segregation, as expected, is enhanced irrespective of the type of support. The polymer composition on the P–A surface fully corresponds to the polymer ratio in the latex mixture. The lack of balance between the polymer ratios on the P–A and P–S surfaces may be due to complex distribution of polymers in the inner layers of the film.

The influence of the aggregative stability of the latexes, as opposed to the sedimentation stability, was examined with mixtures of latexes of chemically similar polymers, namely, with two pairs of latexes: (ST–BA)-A^-–(BA)-0^- and (ST–BA)-0^-–(BA)-A^-. This factor was studied with SP in order to eliminate possible specific interaction of polymers with the support.

Table 3 shows that in both systems the P–A surface is depleted of, and the P–S surface, enriched in the polymers synthesized in the absence of surfactants, i.e., polymers with lower aggregative stability of the particles.

The effect of specific interactions of polymers with the support was studied with a mixture of latexes (ST–BA)-N and (ST–BA)-C^+, with a Nafion ion-exchange membrane in the acid form as support. The process is essentially similar to coagulative immersion of the substrate in the latex, with the polymeric electrolyte used as coagulant. In the process, we used a mixture of latexes one of which was stabilized with a cationic surfactant, and the other, with a nonionic surfactant. In this case we analyzed only the P–A surface, because it was difficult to separate the formed film from the support.



IR Fourier ATIR spectra of the (*1*) P–A and (*2*) P–S surfaces of the latex film prepared from the latex mixture (ST–BA)-A^-–[(BA)-0^+ + S-10] on a glass support at 100°C. (*A*) Normalized absorption and (ν) wave number.

Table 4 shows that the P–A surface is enriched in the ST–BA copolymer whose particles are stabilized with the nonionic surfactant. The difference between the polymer ratios in the latex mixture and on the P–A boundary is maximal in the film formed immediately after preparing the latex mixture. If the latex mixture was used 24 h after its preparation, the difference between the polymer ratios was minimal. Probably, this is due to redistribution in time of the cationic and nonionic surfactants between particles of different latexes.

When a film is formed on a hot support from a mixture of latexes one of which is thermosensitive,

Table 2. Polymer ratios on the P–A and P–S boundaries in films prepared from the latex mixtures (SKF-32)-A^-–(ST–BA)-0^-*

Support	Film formation temperature, °C	Weight ratio SKF-32/(ST–BA)	
		P–A	P–S
Teflon	12	1.0	2.70
	65	1.0	2.20
Glass	12	1.0	1.77
	65	1.0	1.26

* The weight ratio of the polymers in the latex mixture was 1.0 : 1.0.

Table 3. Polymer ratios on the P–A and P–S boundaries of films formed from mixtures of latexes with different aggregative stability*

Latex mixture	Weight ratio of the polymers (ST–BA)BA		
	latex mixture	P–A	P–S
(ST–BA)-A^-	1.82	5.60	1.18
(ST–BA)-A^-	0.50	0.44	1.03
(BA)-A^-	1.00	0.64	1.72

* Temperature of film formation 20°C; SP support.

Table 4. Polymer ratios in the film prepared on an ion-exchange membrane from the latex mixture (ST–BA)-N–(BA)-C^+*

Polymer weight ratio (ST–BA) : BA on P–A	Film formation conditions
1.32	Support (ion-exchange membrane) is kept for 1 min in latex mixture immediately after mixture preparation
1.26	Support is kept for 15 min in latex mixture 30 min after mixture preparation
1.09	Support is kept for 15 min in latex mixture 24 h after mixture preparation

* (ST–BA)/BA ratio in the latex mixture 0.97, film formation temperature 18°C.

segregation of the polymers can be expected. The capability of latexes for thermal coagulation was realized by introducing thermosensitive additives: leveling agent A and S-10. The effect of such additives is based on complete neutralization of the electric charge of latex particles with the corresponding ionic groups of the surfactant. The steric stabilization of particles due to the presence in the surfactant molecules of ethylene oxide units under ambient conditions prevents coagulation of the latexes. However, it is known that at elevated temperatures nonionic surfactants at certain values of the hydrophilic-hydrophobic balance can become water-insoluble owing to dehydration [7]. Thus, latexes for which the steric factor is the only stabilizing factor can coagulate on heating.

When preparing a thermosensitive latex, it is important to properly choose the sensitizing additive. At very low concentrations neutralization of the electric charge of the latex particles is incomplete. On the contrary, high concentrations can cause particle recharging. In both cases the thermal sensitivity of the latex will be insufficient or lacking at all.

To find the optimal concentration of the additive, we determined the coagulation temperature T_c of the latex depending on the additive concentration. We used latexes prepared in the absence of surfactants, because we expected that the thermal sensitivity could be imparted to such latexes at relatively low concentrations of the additives. We tested the following combinations latex–additive: (BA)-0^- + leveling agent A and (BA)-0^+ + S-10. The influence of the concentration of the thermosensitizing additive on the latex coagulation temperature is illustrated below:

[Leveling agent A], % of polymer weight	0.20	0.33	1.00	1.66	2.33	3.00	3.66
T_c, °C	*	*	*	55	60	*	*
[S-10], % of polymer weight	1.80	2.23	2.43	2.66	2.90	3.33	
T_c, °C	82–84	70	71	75	75.5	95–96	

* No coagulation at 100°C.

Our results show that in the first system coagulation occurs only in a narrow range of concentrations of the additive (1.66–2.33 wt %). At other concentrations, no coagulation is observed even on heating the latex to 100°C. In the second system, coagulation occurs in the entire range of S-10 concentrations. However, the coagulation temperature is the lowest at the S-10 content within 2.33–2.90 wt %.

In agreement with our results, thermosensitive latexes were obtained at concentrations of leveling agent A of 1.66 and of S-10 of 2.43 wt %, ensuring the lowest coagulation temperature. The additives were introduced as 5% aqueous solutions. The resulting thermosensitive latexes were mixed with the anionic latex at room temperature. Thus, we studied the thermal coagulation of the following latex mixtures: (ST–BA)-A^-–[(BA)-0^- + leveling agent A] and (ST–BA)-A^-–[(BA)-0^+ + S-10].

The films were prepared on glass supports at 100°C and also, for comparison, at 20°C. Table 5 shows that in all cases the P–A surface is depleted of the thermosensitive polymer even when the films are formed at 20°C. This result could be expected, since the latexes prepared in the absence of surfactants, owing to large particle size, have decreased sedimentation stability. Preparation of films on heated supports appreciably

Table 5. Influence of thermal coagulation on film formation from latex mixtures

Latex mixture	Film formation temperature, °C	Weight ratio (ST–BA) : BA		
		latex mixture	P–A	P–S
(ST–BA)-A^-–[(BA)-0^- + leveling agent A]	20	3.12	4.59	3.22
	100	3.12	5.56	3.03
(ST–BA)-A^-–[(BA)-0^+ + S-10]	20	1.00	2.80	1.04
	100	1.00	9.23	0.51

enhances the effect of polymer segregation, especially in the system (ST–BA)-A^-–[(BA)-0^- + S-10], which may be due to simultaneous action of several factors, i.e., to the difference between the latexes not only in thermal sensitivity but also in sedimentation and aggregative stability.

The influence of the film thickness on the segregation of polymers was studied with the system (ST–BA)-A^-–[(BA)-0^+ + S-10]. The films were formed on SP at 21°C. The results listed in Table 6 show that the polymer segregation is enhanced with increasing film thickness. Presumably, this effect is due to longer time of formation of thicker films. Similar trends related to slower film formation at lower temperatures were discussed above (Table 2). These results seem to be quite obvious, since the differences in the sedimentation stability of latexes and in their capability for specific interaction with the support should be manifested to a greater extent at longer process times.

CONCLUSIONS

(1) Study of films prepared from mixtures of latexes of thermodynamically incompatible polymers demonstrated the principal possibility of polymer segregation in the course of film formation. The result of the segregation is formation of asymmetric films in which the film–air and film–support surfaces differ in the chemical composition.

(2) The main factors affecting the polymer segregation were considered: sedimentation and aggregative stability of latexes, capability of one of the latexes for specific interactions with the support substance or for thermal coagulation, and film formation time. The polymer segregation in the course of film formation occurs to the greatest extent when several factors act simultaneously.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Chemical Structure of Diarylpenta-1,4-dien-3-one Chromophores on the Nonlinear Optical Properties of Their Polymeric Complexes with Poly-1,10-decamethyleneacetamidine

Abstract—A study was made of the ability of the ionic complexes formed by diarylalkadienone chromophores with poly-1,10-decamethyleneacetamidine to exhibit third-order nonlinear-optical effects. The chemical structure of the chromophores was correlated with the third harmonic generation efficiency.

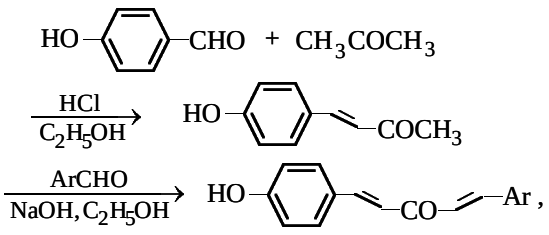
In recent decades, materials exhibiting nonlinear optical (NLO) properties have attracted ever growing researchers' attention [1]. This is due above all to the promise offered by materials able of second and third harmonic generation (SHG and THG, respectively) in creation of the next generation of computers, so-called "optical computers" with photons instead of electrons as working element. At present, NLO-active devices utilize primarily inorganic materials such as potassium niobate [2], barium β-borate [2], etc. It is generally recognized, however, that the most promising for this purpose are organic, especially polymeric NLO-active substances. In contrast to inorganic materials, the chemical structures of organic and polymeric compounds and, correspondingly, the NLO properties can be widely varied. Also, the film-forming ability of polymeric NLOs significantly facilitates fabrication of optical devices thereof.

Within a large class of materials exhibiting pronounced NLO response, of greatest importance become those characterized by a refractive index widely varying with the light intensity, i.e., those able of THG. As known, practically suitable susceptibilities $\chi^{(3)}$ are exhibited by compounds containing a fairly long π-conjugation system, e.g., β-carotene, polyacetylene, polythiophene, etc. [3]. Despite significant success achieved in this sphere, preparation of this type of macromolecular compounds able of film formation or of the guest–host type composite materials is a complex problem. The reason is the low solubility and difficulties posed by synthesis of polyconjugated polymers in the former case and thermodynamic incompatibility of the polymer and the low-molecular-weight substance in the latter.

In [4], we proposed an alternative procedure of preparing polymeric systems able of THG. It consists in preparation of ionic complexes between low-molecular-weight NLO chromophores and polymer carriers [4], in particular, complexes of di(4-hydroxyaryl)alkadienones and poly-1,10-decamethyleneacetamidine. It was shown that the polymeric complexes with the quinoid structures yielded by ionization of chromophores by highly basic poly-1,10-decamethyleneacetamidine are heat-resistant and stable for more than a year, are capable of film formation, and are able of efficiently generating third harmonic.

In this work, we study the THG efficiency of the ionic complexes of 1-(4-hydroxyphenyl)-5-(aryl)penta-1,4-dien-3-one chromophores with poly-1,10-decamethyleneacetamidine as influenced by the chemical structure of the chromophores.

Synthesis of 1-(4-hydroxyphenyl)-5(aryl)penta-1,4-dien-3-ones followed the scheme



1070-4272/01/7407-1178$25.00

where Ar = C_6H_5 (**I**), 4-FC_6H_4 (**II**), 4-CH_3O–C_6H_4 (**III**), 4-$NO_2C_6H_4$ (**IV**), 4-$N(CH_3)_2C_6H_4$ (**V**), 1-naphthyl (**IV**), 9-anthryl (**VII**), $CH{=}CHC_6H_5$ (**VIII**), $CH{=}CH{-}C_6H_4$-4-NO_2 (**IX**), and CH_3CONH (**X**).

4-(4-Hydroxyphenyl)but-3-en-2-one was prepared by condensing 4-hydroxybenzaldehyde with acetone as described in [5]. Attempts to condense 4-(4-hydroxyphenyl)but-3-en-2-one with substituted aromatic aldehydes under the same conditions failed. However, the desired products were obtained in a 40–50% yield by acid-catalyzed crotonic condensation.

Poly-1,10-decamethyleneacetamidine was synthesized by the method described previously in [6], according to the scheme

$$NH_2(CH_2)_{10}NH_2 + CH_3C(OC_2H_5)_3$$

$$\xrightarrow[150^\circ C]{CH_3COOH} -(CH_2)_{10}N{=}\underset{CH_3}{\overset{}{C}}{-}\overset{H}{N}- .$$

A gel-permeation chromatographic (GPC) study showed that the sample of poly-1,10-methyleneacetamidine used in this work had the molecular weight of 5000 amd the polydispersity coefficient of 2.6.

Complexes of poly-1,10-methyleneacetamidine with chromophores were prepared by mixing saturated ethanol solutions of the polymer and chromophore, followed by removing the solvent.

The thermal-analytical data suggest that the resulting complexes are individual polymeric species rather than mechanical mixtures of the polymer with the low-molecular-weight compound. Whereas the DSC curves for poly-1,10-decamethyleneacetamidine exhibit a transition only at 5°C (T_g), those for all the complexes exhibit only a glass transition in the range 25–75°C, depending on the polymer–chromophore ratio (Fig. 1).

The thermogravimetric curves evidence the onset of thermal degradation (1% mass loss) of the resulting complexes at 195–200°C. This suggests the lack of thermal degradation of the samples during measuring the NLO characteristics. The $\chi^{(3)}$ values obtained refer specifically to the complexes of interest, rather than to the products of thermal degradation under irradiation during measurements (the samples warm up to 150°C).

It should be noted that the films of the complexes under study do not change their physical and spectral characteristics for a long time (no less than a year) under normal conditions; they are resistant to most solvents (toluene, ethanol, acetone, ethyl acetate) and exhibit good adhesion to glass, quartz, and mica.

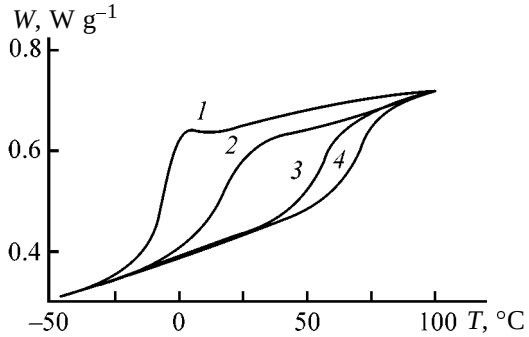


Fig. 1. DCS curves of complexes of **III** with poly-1,10-decamethyleneacetamidine at different content of the chromophore in the complex. (*W*) Heat flux and (*T*) temperature. Polymer : chromophore molar ratio: (*1*) 1 : 0.2; (*2*) 1 : 0.25, (*3*) 1 : 0.5, and (*4*) 1 : 0.75.

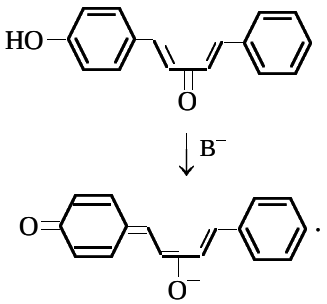
High basicity of poly-1,10-decamethyleneacetamidine (pK_a 10.9) is responsible for deprotonation of the chromophore and, thereby, affects their spectral characteristics. As seen from the table, formation of the complexes is accompanied by a bathochromic shift of the long-wave absorption band by more than 100 nm. These changes are evidently due to extension of the π-conjugation system owing to formation of the quinoid species



We showed earlier [4] that such a change in the conjugation type, namely, a transition from cross-conjugated to linear π system, is necessary for arising of the third-order NLO effect in the systems under study. It should be noted that this idea was exploited in development of guest–host-type NLO-active systems from derivatives of squaric acid and polymethyl methacrylate [7]. Figure 2 presents the UV absorption spectra of the complexes of poly-1,10-decamethyleneacetamidine with 1-(4-hydroxyphenyl)-5-(4-methoxyphenyl)penta-1,4-dien-3-one at different molar ratios between the monomer unit of the polymer and the chromophore. It is seen that with decreasing content of the chromophore the peak corresponding to the quinoid species grows in intensity (λ_{max} = 456 nm), and at a ratio close to 1 : 0.25 the peak corresponding to the nondeprotonated chromophore (λ_{max} = 377 nm)

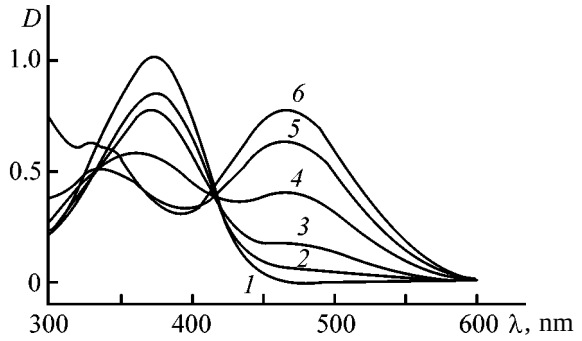


Fig. 2. Absorption spectra of the complexes of **III** with poly-1,10-decamethyleneacetamidine at different content of the chromophore in the complex. (*D*) Optical density and (λ) wavelength. Polymer : chromophore molar ratio: (*1*) 0 : 1, (*2*) 0.5 : 1, (*3*) 1 : 1, (*4*) 1 : 0.75, (*5*) 1 : 0.5, and (*6*) 1 : 0.25.

virtually disappears. For this reason, specifically this ratio was chosen for studying the NLO properties of the complexes.

In this work we studied the NLO properties of the synthesized materials by the GTH method. In view of the difficulties involved in determining the absolute values of the exciting radiation intensity for a sample, the NLO succeptibilities of the materials under study were determined by the relative procedure, by comparison with a reference sample under the same conditions. The reference sample was a 0.5-mm thick melted quartz plate adjusted to the first maximum of the third Maker's beat harmonic intensity [8].

In this case, $\chi^{(3)}$ can be determined by a simple expression, by comparing the intensities of the signals of the third harmonic from the sample and reference:

$$\chi^{(3)} = \chi_s^{(3)}[I^{1/2}(3\varphi)/I_c]/[I_s^{1/2}(3\varphi)/l_{c,s}],$$

Here, $I(3\omega)$ and $I_s(3\omega)$ are the THG intensities for the sample and reference, respectively; I_c and $I_{c,s}$ are the respective coherence lengths; $\chi_s^{(3)} = 3.11 \times 10^{-14}$ cgs units for SiO_2 at $\lambda = 1063$ nm.

Long-wave absorption maxima and THG efficiencies of the complexes

Chromophore	λ_{max}, nm	$\chi^{(3)}$, cgs units
I	451	4.9
II	463	3.8
III	456	7.1
IV	487	3.5
V	471	6.5
VI	465	4.7
VII	464	0.7
VIII	467	7.7
IX	483	2.3
X	455	5.6

The $\chi^{(3)}$ values obtained are presented in the table. It is seen that the majority of the complexes have $\chi^{(3)}$ of the order of 10^{-12} cgs units. This is close to the corresponding values for polyphenylvinylenes [9] and polythiophenes [10] which are considered by the majority of investigators as the class of polymers most suitable as NLO-active media.

The above-said suggests the following. The two-dimensional growing of the π-conjugation system, namely, the change from the phenyl to 1-naphthyl moiety in the chromophore, does not significantly affect the THG efficiency. This is most probably due to steric hindrance and increase in the dihedral angle formed by the naphthyl group and the double bond, which decreases the degree of conjugation. This assumption is substantiated by the fact that with 9-anthryl instead of 1-naphthyl moiety $\chi^{(3)}$ decreases by almost an order of magnitude. This is undoubtedly due to the sterically hindered rotation about the C–C bond between the 9-anthryl and ethylene moieties. One-dimensional growing of the π-conjugation system, namely, the change from the phenyl to styrene moiety, affects $\chi^{(3)}$ only insignificantly. It can be assumed that this minor increase is due to steric factors. Whereas 1,5-diphenylpenta-1,4-dien-3-ones exist as planar conformers, introduction of an additional double bond, evidently, disturbs the coplanar π system and causes the degree of conjugation to increase out of proportion. This follows from the fact that the dihedral angle φ of the C–C bond in butadiene moieties is known to be equal to 40°–50° on the average and the degree of conjugation, to change proportionally to $\cos^2\varphi$.

The tabulated data show that auxochromic substituents introduced in the *para* position of the phenyl ring significantly affect the NLO activity of the complexes. One of the most convenient methods of semiquantitative assessment of the influence exerted by substituents on the conjugated system is that based on the Hammett correlation approach [12]. Figure 3 shows the NLO response of a series of complexes as dependent on the σ constants of the substituents. The parameter $\chi^{(3)}$ correlates well with the electronic effect of the substituent. As known, $\chi^{(3)}$ depends on the polarizability of the electron cloud of the chromophore and on the difference in the dipole moments of the chromophore in the ground and excited states [2]. As a rule, the molecule in the ground state should have a sufficiently large dipole moment. In our case,

the effect of increase in the polarizability prevails, as indicated by increase in $\chi^{(3)}$ with enhancing donor effect of the substituent. The same is indicated by the lack of correlation between $\chi^{(3)}$ and Hammett constants σ_1 which, unlike σ constants, take into account only the inductive effect of the substituent.

EXPERIMENTAL

1-(4-Hydroxyphenyl)-5-(4-methoxyphenyl)penta-1,4-dien-3-one (III). To a stirred solution of 1.6 g (0.01 mol) of 4-(4-hydroxyphenyl)but-3-en-2-one and 1.45 (0.011 mol) of 4-methoxybenzaldehyde in 15 ml of ethanol, a solution of 0.8 g (0.02 mol) of NaOH was added in the form of 40% aqueous solution. The resulting mixture was heated at 50°C for 1 h and left overnight at room temperature. Then the mixture was diluted with a tenfold volume of water, filtered, and neutralized with 5 ml of dilute acetic acid. The resulting precipitate was separated and recrystallized from ethanol. Yield 1.7 g (65%), mp 169°C. Elemental analysis:

Found, %: C 76.89, H 5.70.
Calculated, %: C 77.12, H 5.75.

^{1}H NMR (Bruker DRX 500; CD_3OD; 25°C; δ, ppm): 3.85 (s, 3H, OCH_3), 6.84 (d, 2H, H_{ar}), 6.98 (d, 2H, H_{ar}), 7.06 (d, 1H, –CH=), 7.10 (d, 1H, –CH=), 7.58 (d, 2H, H_{ar}), 7.66 (d, 2H, H_{ar}), 7.71 (d, 1H, –CH=), 7.72 (d, 1H, –CH=).

The other chromophores **I**–**X** were prepared similarly. The elemental analysis data and the spectral characteristics corresponded to the expected structures.

Solutions of the complexes were prepared by mixing at room temperature solutions of the chromophore and poly-1,10-decamethyleneacetamidine in ethanol at the polymer : chromophore ratio of 1 : 0.25 (molar ratio between the polymer units and the low-molecular-weight compound). The samples for optical studies were prepared by casting the ethanol solutions of the complexes onto a rotating glass substrate followed by evaporating the solvent at room temperature and atmospheric pressure. The resulting films were dried in a vacuum (0.1 torr) to a constant weight before measurements.

The calorimetric measurements were carried out on a DSC 7 Perkin–Elmer calorimeter in the range from –50 to 250°C at a rate of 10 deg min^{-1}. The UV spectra were recorded on a Varian Cary 100 spectrophotometer from ethanol solutions and thin films for measuring the NLO characteristics. Thermogravimetric measurements were carried out on a Perkin–Elmer TGA-7 instrument, in the 30–700°C temperature range, at the heating rate of 10 deg min^{-1}.

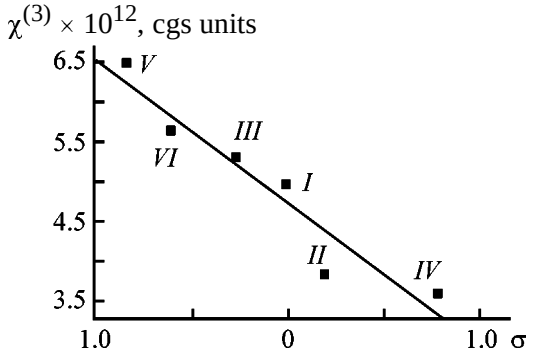

Fig. 3. Correlation of the efficiency $\chi^{(3)}$ of THG genetation by the complexes under investigation with the Hammett constants σ of substituents in chromophores: (*I*) H, (*II*) F, (*III*) OCH_3, (*IV*) NO_2, (*V*) $N(CH_3)_2$, and (*VI*) CH_3CONH.

The samples were excited by a pulse neodymium–garnet laser; the radiation wavelength was 1063 nm. The laser operated in the modulated *Q*-factor regime; pusle duration was 15 ns. The energy of radiation in the pulse was varied within 1–30 MJ.

CONCLUSION

The influence of the chemical structure of the chromophores on the nonlinear-optical properties of polymeric complexes between diarylpenta-1,4-dien-3-ones and poly-1,10-decamethyleneacetamidine was elucidated. The influence exerted by the substituents on the efficiency of generation by the complexes of the third-order nonlinear-optical effects can be described semiquantitatively using Hammett σ constants.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Features of the Crystal Structure of the Polyimide Derived from 3,3'-Diaminobenzophenone and 3,3',4,4'-Benzophenonetetracarboxylic Dianhydride

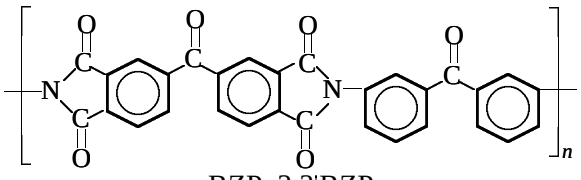
Abstract—Changes occurring in the structural organization of the thermoplastic polyimide derived from 3,3'-diaminobenzophenone and 3,3',4,4'-benzophenonetetracarboxylic dianhydride on heat treatment at temperatures in the range 250–350°C were studied, and the influence of these changes on the rheological behavior of the polymer was examined.

Polyimides (PIs) show considerable promise as polymeric binders for preparing fibrous composites with high heat resistance, high softening point, and enhanced crack resistance. It is well known that these polymers, on the one hand, withstand heating up to 500°C and, on the other hand, preserve elastic properties down to the liquid nitrogen temperature [1]. However, the factors making PIs the most heat-resistant among the known polymers (rigidity of the polymer chain and high level of intermolecular interactions) also make them difficultly processable, which significantly limits their use as a matrix in composites.

At present, active efforts are made to solve this problem by developing crystallizing fusible PIs combining the positive properties of thermoplastics (namely, increased viscosity of the matrix failure) with enhanced heat resistance due to crystallization [2, 3].

Such PIs are particularly attractive owing to their excellent resistance to heat and to thermal oxidative degradation, high mechanical and adhesion characteristics, and resistance to solvents, especially to water and alkalis:



BZP–3,3'BZP

As shown in [4], the structure of this PI in its native state is largely determined by the conditions of its chemical synthesis. In particular, the BZP–3,3'BZP polyimide prepared under conditions of low-temperature chemical imidization in amide solvents is a partially crystalline substance with a low melting point (270–290°C). The same polyimide prepared by thermal imidization, depending on the reaction conditions, can be either amorphous or partially crystalline, with an appreciably higher melting point (340–350°C).

In this work we studied the features of the crystal structure of the BZP–3,3'BZP polyimide and the influence of changes in its structural organization on its rheological behavior. These data are useful for improving the procedures for PI processing to obtain a matrix of a composite.

EXPERIMENTAL

The initial prepolymer (polyamido acid, PAA) was prepared as a 25 wt % solution in *N*,*N*-dimethylacetamide (DMA) from BZP dianhydride (mp 225–226°C) recrystallized from dry acetic anhydride and diamine 3,3'BZP (for preparation procedure, see [4]), taken in a stoichiometric ratio. To prepare the oligoimide (OI), the amount of the dianhydride was decreased to 0.75 mol per mole diamine, and the reactive terminal amine groups were converted at the end of the syn-

1070-4272/01/7407-1183$25.00

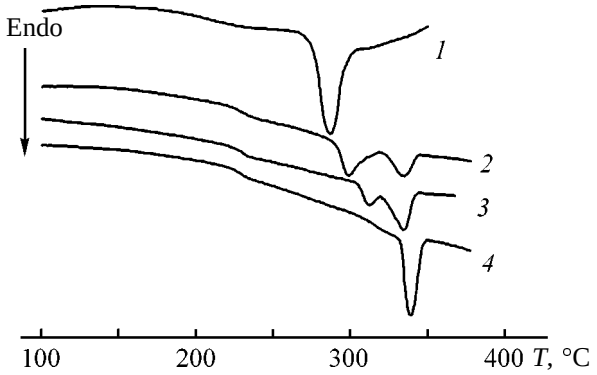


Fig. 1. DSC thermograms of BZP–3,3'BZP CPI samples: (*1*) initial and (*2*–*4*) additionally heated (*2*) at 250°C for 40 min, (*3*) at 300°C for 10 min, and (*4*) at 300°C for 60 min. (*T*) Temperature; the same for Figs. 3 and 4.

thesis by reaction with 0.5 mol of phthalic dianhydride.

Powdered PI and OI samples were prepared by chemical imidization in DMA solution [4]. To exhaustively remove residual solvents and agents of the imidizing mixture, the resulting samples were treated with diethyl ether in a Soxhlet apparatus for 5 h and dried under reduced pressure (50 mm Hg) at 140–150°C.

To prepare carbon-reinforced plastics, an ELUR-P-01 carbon tape was impregnated with a solution of BZP–3,3'BZP PAA, dried at 150°C to remove the solvent, and heated for 15 min at 230°C for thermal imidization of PAA. From the carbon fabric with the supported polymer, we prepared a 24-layer prepreg and pressed at 0.2 MPa under the following conditions: 300°C, 30 min; 350°C, 30 min. When powdered BZP–3,3'BZP PI (OI) was used as binder, it was added to the initial PAA solution in a 1 : 1 ratio, and the carbon tape was impregnated with the resulting suspension. Subsequent preparation and pressing of prepregs were performed similarly.

The IR spectra of PI (or OI) powder (KBr pellets) were taken on a Specord M-80 spectrophotometer. The degree of imidization was determined from the intensity of the imide absorption band at 1780 cm^{-1} [1].

The viscosity of melts of oligoimide powders was measured with a PIRSP rheogoniometer (Russia) with a cone–plane working unit (cone angle 1°, diameter 40 mm) at a constant shear rate of 1×10^{-2} s^{-1} at a given temperature.

The DSC curves of PIs were recorded on a Mettler microcalorimeter at a scanning rate of 10 deg min^{-1}.

The TGA curves were taken with a modified C derivatograph (MOM, Hungary) in air at a heating rate of 10 deg min^{-1}.

X-ray diffraction studies were performed on a DRON-5 diffractometer and an ARS-5 installation with a KRON-1 camera. The Ni-filtered CuK_α radiation was used. For measurements, polyimide powder was pelletized at room temperature and a pressure of 2 atm.

The mass-spectrometric thermal analysis (MTA) was performed with a device based on a magnetic sector mass spectrometer of the MKh-1320 type. The field ionization unit of a standard MKh-1320 device was modified with the aim to provide heating of thin polymer layers on a metallic support-heater with the welded thermocouple (support: oxidized 200-μm-thick Ta foil; thermocouple: Chromel–Alumel, 100 μm in diameter) in the vacuum chamber in the vicinity of the ion source. A thin layer of the polyimide powder was applied directly to the support surface with a putty knife. The sample weight was 10 mg. The area of the sample layer was about 20 mm^2. The heating rate was 10 deg s^{-1}. The rate of release of volatiles from the sample was judged from the intensity of the corresponding molecular peaks (e.g., 87 for DMA and 18 for water). For each PI sample five runs were performed to measure the rate of release of each volatile product.

The bending strength of carbon-reinforced plastics was determined by three-point bending with a 1958U-10-1 breaking machine at a loading rate of 5 mm min^{-1}. The shear moduli of elasticity G'_c and loss G''_c of carbon-reinforced plastics were determined with a torsion pendulum [5] in the range 20–400°C. The glass transition point of the composite T_{gc}, close to T_g of the matrix resin, was determined as the temperature at which G''_c reaches a maximum.

The interlaminar failure viscosity G_{IC} (start of the cleavage crack) of ~3-mm-thick carbon-reinforced plastics was determined by the double cantilever method [6, 7] using the calculation procedure from [7].

BZP–3,3'BZP polyimide prepared by chemical imidization (CPI) in DMA solution is partially crystalline and has a low melting point, T_{m1} = 295°C (Fig. 1, curve *1*). As CPI is additionally heated to 300°C, the melting peak T_{m1} gradually disappears from the DSC curves (Fig. 1, curves *2*–*4*), and a new melting peak, T_{m2}, appears at about 340°C. This fact suggests transition from one crystalline modification, CM1, of the CPI polymer to another, CM2, in the course of heating in the range 250–300°C. In the process, T_{m1} somewhat increases: from 295 to approximately

Table 1. Interplanar spacings *d* of PZB–3,3'BZP CPI samples prepared under various conditions of heat treatment

Sample no.	Treatment	*d*, A									Modification
1	Initial sample	10.5				4.73	4.43		3.90	3.23	CM1
2	250°C/40 min	10.3			5.30	4.70	4.40	4.08	3.94	3.30	CM1 + CM2
3	300°C/60 min		10.3	6.52	5.66	5.21	5.03	4.65	4.03		CM2
4	>350°C	Halo ~4.8									Isotropic

310°C. Heating of CPI above 350°C makes it amorphous (isotropic). The amorphous polymer is characterized only by the glass transition point T_g = 245°C, which becomes clearly detectable in the DSC curves only after heating of the initial CPI to 250°C and higher (Fig. 1, curves *2–4*).

Indeed, according to X-ray diffraction analysis, heating of CPI at 250 and 300°C is accompanied by transition from the structural modification CM1 characteristic of the initial CPI to the modification CM2 (Fig. 2, Table 1). Note that in the polymer heated at 250°C the CM1 and CM2 modifications apparently coexist (Table 1, sample no. 2).

The IR spectra show that the degree of imidization of the initial native CPI does not exceed 85%, and on heating to 300°C it increases to practically 100%. The weight loss (≤2%) of CPI samples on heating in the range 200–300°C, detected by TGA, may be due specifically to imidization of the residual amido acid units in the initial CPI on additional heating (so-called afterimidization) with release of water.

To examine in more detail the changes occurring in CPI in this temperature range, we studied by MTA [9] the kinetics of release of low-molecular-weight substances from the polymer. According to the mass spectra (Fig. 3), water release has a maximum at 293°C (Table 2). At the same time, approximately in the same temperature range the residual solvent DMA in which CPI was prepared is released also (Fig. 3, Table 2). Both water and the solvent, according to the mass spectra, are released in a narrow temperature range close to the melting point T_{m1} of the sample (Table 2). Presumably, afterimidization occurs after melting of CPI accompanied by release of DMA. A striking feature is that DMA is released at a very high temperature, exceeding by almost 140°C its boiling point.

It is known [10] that the amido acid units of PAA form with molecules of an amide solvent like DMA stable complexes decomposing in the course of PAA heating in the range 100–200°C. In our case the solvent molecules, probably involved in complexation with the residual amido acid units of CPI, are retained up to nearly 300°C (Table 2). Presumably, these solvent molecules are incorporated into the ordered CPI structure and are therefore released from the polymer only on melting. Apparently, melting of native CPI at T_{m1} "defrosts" the mobility of the polymer macromolecules and thus facilitates its afterimidization. The water release observed in this temperature range directly confirms this assumption (Fig. 3, Table 2).

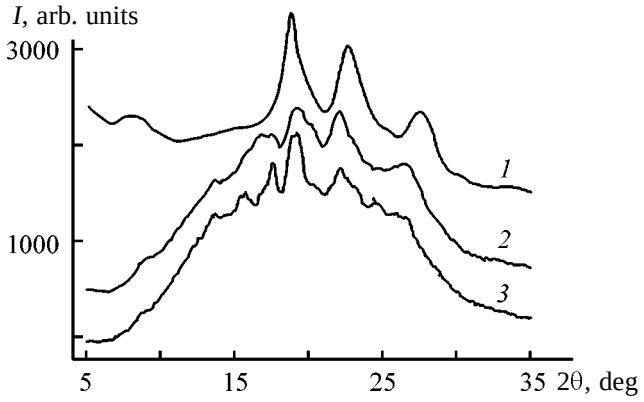

Fig. 2. X-ray diffraction patterns of BZP–3,3'BZP CPI samples: (*1*) initial and (*2*, *3*) heated at 250°C for 40 min and at 300°C for 60 min, respectively. (*I*) Intensity and (2θ) Bragg angle.

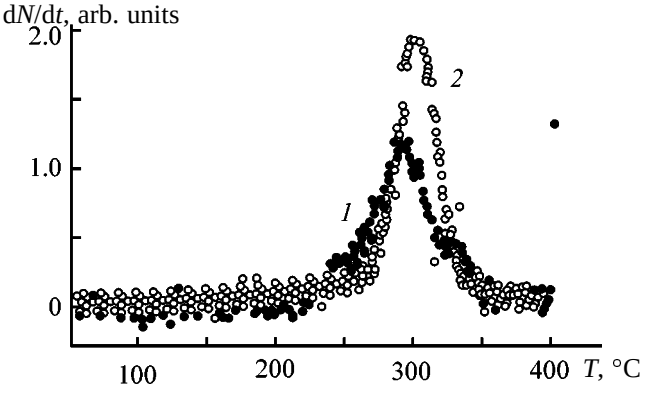

Fig. 3. Temperature dependences of the release rate d*N*/d*t* of (*1*) water and (*2*) solvent (DMA) from CPI samples, monitored by the corresponding peaks in the mass spectra.

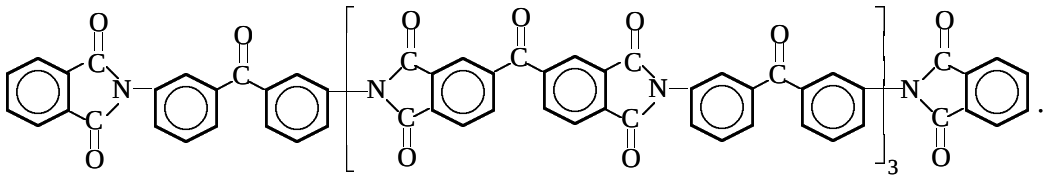
Table 2. Melting points T_{m1} and mean values of T_{max} of the release of the solvent and water from BZP–3,3'BZP PI and OI samples

Sample	T_{max} of DMA	T_{max} of H_2O	T_{m1}
	°C		
CPI	303	293	295
OI	252	268	275

Thus, the initial native CPI is characterized by the presence of the crystalline modification CM1 whose melting point T_{m1} (290–310°C) is abnormally close to the glass transition point of the polymer (245°C). The ratio of these temperatures (converted to the Kelvin scale) is considerably lower than the ratios commonly observed for PI: T_m/T_g = 1.25 [3] or 1.3 [1]. Strictly speaking, the initial CPI is not a 100% imide, as indicated by the IR data. The MTA data show that the peaks of release of the solvent and water, accompanying afterimidization of CPI, are observed specifically in the range of CM1 melting. This fact suggests that the CM1 modification is characteristic of the incompletely imidized CPI sample only. In the course of heating and afterimidization, CM1 transforms into the high-melting modification CM2 typical of the completely imidized CPI sample. At the same time, Wang *et al.* show that native partially crystalline CPI that was rendered amorphous by heat treatment at 310°C and then kept in *N*-methyl-2-pyrrolidone at 160°C shows a melting peak in the DSC curve at abnormally low T_m = 300°C [11]. However, X-ray diffraction data that could prove the CM1 modification of the sample with T_m = 300°C are lacking in [11]. Therefore, the possibility of formation of the CM1 modification in the sample completely imidized at 310°C is still the matter of discussion and requires further studies.

Nevertheless, the existence of the CM1 modification in the initial BZP–3,3'BZP CPI is extremely important from the processing viewpoint, because this thermoplastic at moderate temperatures (300–350°C) can pass to the viscous-flow state required for its processing to a matrix of a composite. For more detailed study of the rheological behavior of CPI as influenced by structural rearrangements in the polymer, we studied OI of the following structure:



The oligoimide was also prepared by chemical imidization in the DMA solution.

Figure 4 shows the DSC curves of the initial native OI (curve *1*) and of that additionally heated at 250°C for 40 min (curve *2*). Two melting points are detected for OI: T_{m1} = 272–276°C with ΔH = 35–36 J g^{-1} and T_{m2} = 324°C with a low ΔH = 2–8 J g^{-1}, i.e., for OI, similar to CPI, the low-melting (about 275°C) crystalline modification exists also. According to the X-ray diffraction data (Table 3), this low-melting crystalline modification of OI is practically identical to the crystalline modification of CM1 detected in CPI (Table 1).

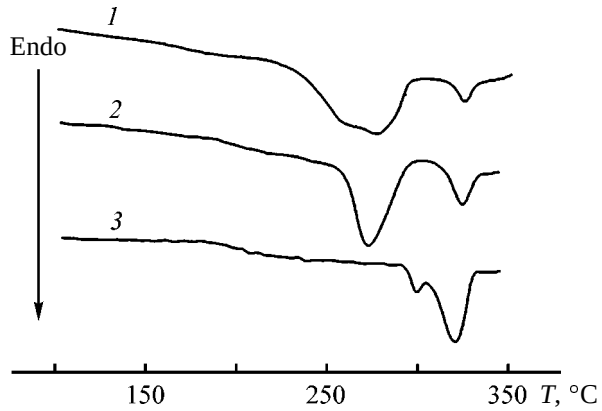


Fig. 4. DSC thermograms of BZP–3,3'BZP OI samples: (*1*) initial and (*2*, *3*) additionally heated at 250°C for 40 min and at 320°C for 60 min, respectively.

According to IR spectroscopic analysis, the degree of imidization of OI is no less than 90%. The TGA data show that the main weight loss, which does not exceed 1.5%, occurs in the range 200–270°C and is probably due to afterimidization of the OI samples. The MTA data (Table 2) show that, similar to CPI, the solvent and water are released from the OI sample in essentially the same temperature range close to the melting point of OI T_{m1}. The whole set of our data shows that, similar to CPI, the melting of OI at T_{m1} is followed by cyclization of the residual amido acid

Table 3. Interplanar spacings *d* of BZP–3,3'BZP OI samples after various heat treatments

units and, strictly speaking, the low melting point T_{m1} is characteristic of the incompletely imidized sample.

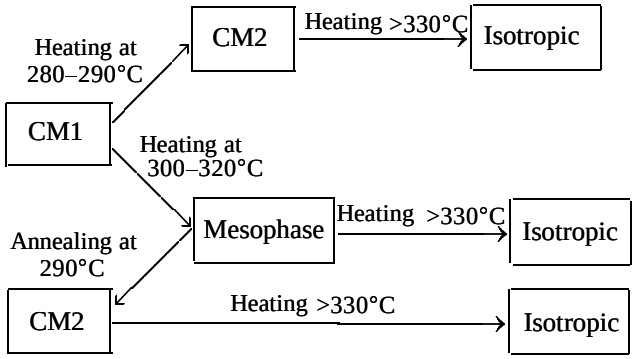
It seemed interesting to compare how the viscosity of the melt of the initial OI varies in time under isothermal conditions at temperatures between T_{m1} and T_{m2} and above T_{m2}, since carbon-reinforced plastics are pressed specifically at these temperatures. The rheological behavior of OI at 330°C (Fig. 5, curve *4*), i.e., above T_{m2}, is typical of thermoplastic PI melts and suggests the possibility of obtaining stable flow of the OI melt for at least 1.5 h. Certain increase in the viscosity in the first minutes of the experiment is apparently due to increase in the oligomer rigidity owing to afterimidization. The DSC and X-ray diffraction data show that in this temperature range (above 330°C) OI passes to the fully amorphous state which is preserved on cooling the melt to room temperature at a rate of 10 deg min^{-1}.

At 280 (Fig. 5, curve *1*) and 290°C (curve *2*), the viscosity of OI fairly rapidly (within 10–20 min) increases to 10^6 Pa s. As follows from the DSC (Fig. 4, curve *3*) and X-ray diffraction (Table 3, sample no. 3) data, at 290°C OI undergoes the transition from the crystalline modification CM1 to CM2 (T_{m2} = 322°C), i.e., the increase in the viscosity at 280–290°C is primarily due to the structural transition of OI from CM1 to CM2.

At 300°C, the OI viscosity gradually (over a period of 20–40 min) increases from 10^3 to almost 10^5 Pa s (Fig. 5, curve *3*). Examination with a polarization microscope shows that the OI melt passes from the fully isotropic state to a mesophase. X-ray diffraction data (Table 3, sample no. 4) confirm that upon annealing for 1 h at 300°C the first crystalline modification CM1 transforms into a mesophase characterized by the presence of two clear reflections against the background of a halo. Subsequent cooling to 290°C and annealing at this temperature for 120 min convert this oligomer from the mesomorphic to fully crystalline (CM2 modification) state (Table 3, sample no. 6).

The whole set of X-ray diffraction and DSC data suggest the following scheme of the structural behavior of OI on melting above T_{m1} = 272°C.

Scheme of structural transitions in BZP–3,3'BZP at various heat treatments



At 280–290°C, OI passes from the first (CM1) to the second (CM2) crystalline modification within a relatively short time (10–20 min). At 300–320°C, the crystalline modification CM1 transforms into a

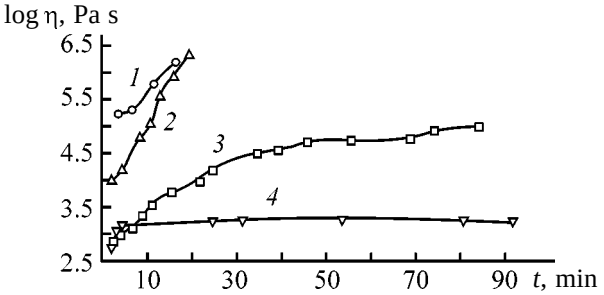


Fig. 5. Viscosity η of BZP–3,3'BZP OI melt as a function of time *t*. Temperature, °C: (*1*) 280, (*2*) 290, (*3*) 300, and (*4*) 330.

Table 4. Thermomechanical properties of carbon-reinforced plastics based on BZP–3,3'BZP PI

Sample no.	Polymer	V_f, %	σ_b, 20°C	σ_b, 200°C	G'_c, 20°C	T_{gc}, °C	G_{1C}, J m^{-2}
			GPa				
1	PI	48	0.9	0.84	3.7	250	470
2	PI + 50 wt % OI	55	1.0	0.94	4.2	231	620
3	PI + 50 wt % CPI	50	0.96	0.90	3.7	250	–

mesophase, which can be converted to the crystalline modification CM2 by annealing at 290°C for 2 h (Table 3, sample no. 6). Above 330°C, OI transforms into the fully isotropic state.

From BZP–3,3'BZP we prepared carbon-reinforced plastics and determined some of their thermomechanical characteristics: the volume fraction of fiber V_f, bending strength σ_b (at 20 and 200°C), shear modulus of elasticity G'_c, and glass transition point T_{gc} of the polymeric matrix of the composite. In Table 4 these characteristics are given for carbon-reinforced plastics based on the pure thermally imidized binder BZP–3,3'BZP PI and on the same binder with addition of 50 wt % OI (sample no. 2) or CPI (sample no. 3).

Addition of CPI and especially OI to the matrix of the carbon-reinforced plastic somewhat increases the volume fraction of fiber in the composite, probably owing to a decrease in the melt viscosity on pressing, which, in turn, increases σ_b and G'_c at room temperature. The bending strength of the carbon-reinforced plastics decreases insignificantly as the temperature is increased from 20 to 200°C, which is due to their sufficiently high glass transition points. However, a noticeable decrease in the glass transition point of the polymeric matrix of the composite prepared with OI (Table 4, sample no. 2) suggests lower softening point of the carbon-reinforced plastic in this case.

Table 4 also contains data on the interlaminar failure viscosity G_{IC} characterizing the crack resistance of the carbon-reinforced plastics. It is seen that addition of partially crystalline powdered OI to the binder noticeably increases G_{IC}.

Also, we prepared carbon-reinforced plastics using as prepregs the layers of carbon fabric with the CPI powder applied by electrostatic spraying. Such a procedure allowed us to abandon the use of a polyamido acid solution for impregnation of the carbon fabric and to prepare the composite on the basis of powdered partially crystalline CPI only. Samples of thus prepared carbon-reinforced plastic are characterized by high G_{IC}, at a level of 730–750 J cm^{-2}.

As noted above, native partially crystalline OI and CPI are rendered amorphous by heat treatment at temperatures above T_{m2}. Therefore, according to DSC, the polymeric matrix is amorphous in all the carbon-reinforced plastics under consideration (the final pressing temperature was 350°C).

Optimization of the pressing temperature and composition of the initial matrix, with the aim to attain simultaneously high values of strength, softening point, and failure viscosity of the resulting material, requires further study of fine structural rearrangements in the crystallizing fusible polyimide binder under conditions of temperature and force fields.

CONCLUSIONS

(1) BZP–3,3'BZP polyimide can exist in two crystalline modifications: CM1 with T_{m1} = 275–290 and CM2 with T_{m2} = 330–350°C. Appearance of the crystalline modification CM1 in the initial native polyimide prepared by chemical imidization in an amide solvent impedes complete imidization of the polymer, which is complete only on melting of the crystallites. Above 350°C the polymer passes into a fully isotropic state, and restoration of its crystalline state on cooling is practically impossible.

(2) It was shown by the example of the corresponding oligoimide that at temperature close to T_{m1} an increase in the viscosity of the oligoimide melt is due to structural transition from the low-melting crystalline modification CM1 to the high-melting modification CM2. The partially crystalline BZP–3,3'BZP polyimide in CM1 modification undergoes a similar structural transition in this temperature range. In the range between T_{m1} and T_{m2}, the oligoimide melt can pass to the mesomorphic state, with increase in the melt viscosity to 10^5 Pa s. Annealing of the mesophase at 290°C results in crystallization of the oligoimide in the CM2 modification.

(3) The partially crystalline BZP–3,3'BZP polyimide is a thermoplastic with a unique property:

Thanks to formation in the chemically imidized polymer of the low-melting crystalline modification CM1, it can be processed into a matrix of a carbon-reinforced composite at temperatures of 300–350°C close to T_g. The resulting carbon-reinforced plastics exhibit fairly high softening points (T_{gc} = 250°C), with high levels of strength (1 GPa) and failure viscosity (G_{IC} = 750 J m^{-2}).

Received October 8, 2000; in final form, April 2001

Abstract—Photoinduced recombination chemiluminescence was applied for monitoring of the network structure formation under UV exposure of films prepared by esterification with acrylic acid of oligomers such as UP-612, ED-16, and Oksilin commercial epoxy resins. The chemiluminescence decay was described in terms of the fractal kinetics model. The spectral dimension parameter, apparent luminescence activation energies, and glass transition temperatures of the polymers were calculated.

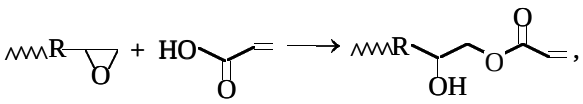
Epoxy–acrylate resins polymerizing under UV irradiation find application as protective coatings for quartz fibers intended for fiber-optics systems and printed-circuit boards in radioelectronics [1]. Such protective coatings must satisfy a number of requirements which for the most part determine the properties of the articles, in particular, resistance to temperature and mechanical changes and the environment, tensile strength, etc. [2]. The properties of such polymers are mainly determined by the degree of cross-linking. There is a number of classic methods for estimating the latter parameter, of which we will mentioned that based on determining the degree of swelling of polymer in appropriate solvent [3]. In recent years, methods based on the use of luminophores [4], measurement of the post-polymerization reaction heats, UV spectroscopy, etc. have received development [5]. However, studies of cross-linked polymers still lack a uniform experimental approach. This makes urgent the search for new methods of determining, e.g., the degree of cross-linking of polymers, the active chain length, and the radical curing kinetics for such systems.

One of the methods for studying polymer properties that recently have found wide application is recombination luminescence [6]. Recombination luminescence is recorded as a weak light emission arising on UV exposure of organic glasses, resins, and other materials; it depends on the physical properties of the material, radiation energy, and the polarity of the medium. Irradiation can initiate ionization of molecular groups characterized by low electron affinity and photooxidation [7–9]. In the latter case, the luminescence is due to recombination of the leading radical oxidation chain and is treated as recombination chemiluminescence (CL).

In this work we applied recombination CL to monitoring of the network structure formation under UV exposure of films obtained from oligomers such as acrylated UP-612, ED-16, and Oksilin commercial epoxy resins.

EXPERIMENTAL

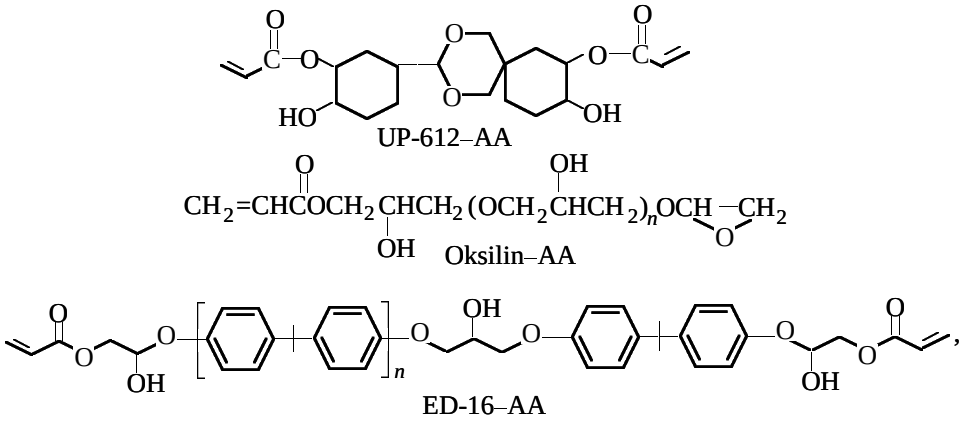
Epoxy–acrylate resins were synthesized by esterification with acrylic acid (AA) of equimolar amounts of epoxy oligomers in the presence of polymerization inhibitors at 120°C according to the scheme



where R is the oligomeric block of epoxy oligomer.

The reaction was monitored by variation of the refractive index. As epoxy oligomers served UP-612, Oksilin, and ERD-16. Acrylic acid was purified by distillation. The resulting oligomer contians (according to epoxy numbers) both acrylates (<75%) and epoxy–acrylates. The assumed structural formulas of these oligomers can be presented as

1070-4272/01/7407-1190$25.00



The CL kinetics after photoirradiation were studied using UP-612–AA, Oksilin–AA, and ED-16–AA films prepared from acetone solutions of the initial oligomers with $M_w \times 10^{-3}$ of 3.5, 3.6, and 3.7, respectively, containing 5% of benzophenone (BP) as photoinitiator. Films were ~10 μm thick; they were cut into 0.5 cm^2 squares and exposed to light with the wavelength of 313 nm cut by ZhS-3 and UFS-2 light filters from the spectra of two SVD-120 lamps (VIO-2 illuminator). The patterns of variation of the CL characteristics with the wavelength of the irradiating light were obtained using DKSSh-1000 xenon lamp and MZD-2M wide-aperture monochromator. The irradiating light intensity was determined with a ferrioxalate actinometer [10]. Chemiluminescence was recorded on a photometric setup equipped with a low-inertia temperature-control unit.

Upon exposure to the light with a wavelength of 313 nm, the preliminarily cured epoxyacrylate films that were kept for several days exhibit CL whose typical intensity decay curve is presented in Fig. 1.

The CL decay was described in terms of the fractal kinetics model proposed by Postnikov *et al.* [8, 11, 12]. According to this model, the observed rate constant k_1 of radical recombination varies with time as

$$k_t = k_0 t^{d_s/2 - 1},$$

Here, k_0 is a constant; $t > 1$ (or $t \approx 1$); and d is the "spectral dimension" parameter which is physically related to the diffusion-controlled aggregate [8].

The CL decay is described by the equation [8]

$$I_{cl} = I_1(1 + t/t_1)^{d_s/2 - 1} \alpha^{-2},$$

where I_{cl} is the CL intensity, rel. units; I_1 is the CL intensity at the moment t_1 of taking the first reading; and α is the parameter describing the part of the CL decay due to radical concentration decrease proper. The contribution from the parameter α is significant only at fairly long times.

Figure 2 presents, as an example, a set of curves characterizing the CL decay kinetics for ED-16–AA films cured at different irradiation doses, with the measurement delay time taken into account. The data obtained by processing these curves are presented in the table.

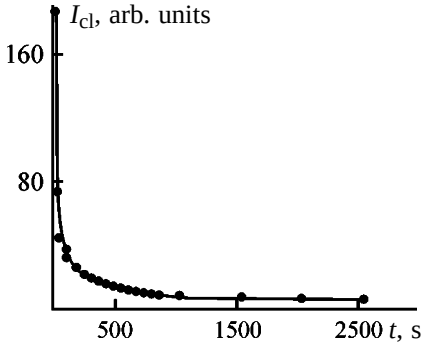


Fig. 1. CL decay curve of cured ED-16–AA film at the dose of 1.1×10^{19} photon cm^{-2}. (I_{cl}) CL intensity and (t) luminescence time; the same for Fig. 2.

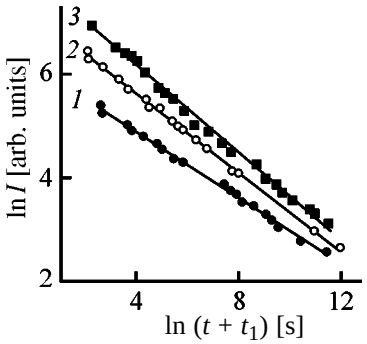

Fig. 2. Kinetic curves of CL decay for ED-16–AA samples cured by irradiation at λ = 313 nm. Irradiation dose $Q \times 10^{-19}$, photon cm^{-2}: (*1*) 1.1, (*2*) 6.4, and (*3*) 24.

Influence of the irradiation dose Q for polymer films on the spectral dimension parameter d_s

Oligomer	$Q \times 10^{-19}$, photon cm^{-2}	d_s
ED-16–AA	1.1	1.36
	6.4	1.26
	24.0	1.16
Oxilin–AA	1.2	1.37
	5.8	1.22
	26.0	1.14
UP-612–AA	0.9	1.32
	6.6	1.20
	24.3	1.18

Note: Spectral dimension is calculated accurately to within 15%.

The spectral dimension d_s determined by the type of inhomogeneous distribution of the reacting particles tends to decrease with increasing irradiation dose. This trend can be interpreted with taking into account formation of interpolymer bonds and three-dimensional structure under irradiation. The parameter d_s determines the space for random motion of peroxy radicals.

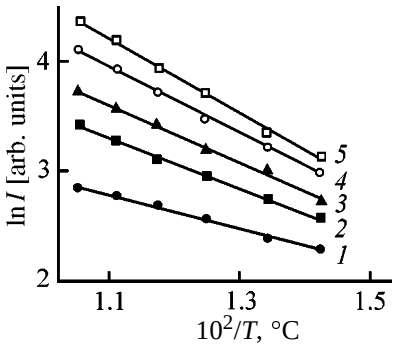

Fig. 3. Steady-state CL intensity I of the ED-16–AA film as a function of the temperature T in the Arrhenius equation coordinates. Irradiation dose Q, photon cm^{-2}: (*1*) 1.4×10^{16}, (*2*) 8.3×10^{16}, (*3*) 2.4×10^{17}, (*4*) 7.9×10^{17}, and (*5*) 1.2×10^{18}.

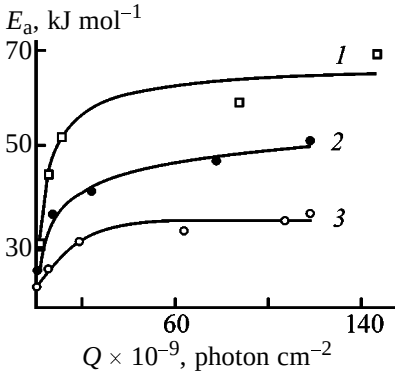

Fig. 4. Apparent activation energy E_a of steady-state CL as a function of the irradiation dose D of polymers (*1*) UP-612–AA, (*2*) ED-16–AA, and (*3*) Oksilin–AA.

Within fairly long time (2–3 h after recording the first point) the CL kinetics become virtually steady-state, with the CL intensity decreasing by less than 1% per hour even at 70°C. The steady-state character of the CL is, evidently, due to major diffusion-related restrictions posed on the reacting particles.

Temperature changes take the system out of the steady state, but under isothermal conditions the system comes to a new steady state. Evidently, under such conditions the response of the system to the temperature change is due to the structural changes in the matrix. Thus, the activation energy calculated from the temperature dependence of the steady-state CL intensity can be considered as a characteristic of the polymer matrix and its evolution during irradiation. The Arrhenius plots, similar to those shown in Fig. 3 for ED-16–AA, allowed calculation of E_a. Figure 4 shows how E_a varies with the irradiation dose. It is seen that under actual conditions formation of the polymer and its network structure is complete at irradiation doses of $(50–70) \times 10^{19}$ photon cm^{-2}. For example, for UPK-612–AA, ED-16–AA, and Oksilin–AA systems E_{max} is equal to 60.7, 48.1, and 34.8 kJ mol^{-1}, respectively. This parameter is, evidently, a function of the rigidity of the polymer network and, probably, reflects in an implicit way the degree of development of the polymer network. Also, account should be taken of the reactivity of the oligomers with triplet BP. The role of the latter as photoinitiator is confined to initiating the reaction of homolytic hydrogen detachment from the OH group of the secondary and tertiary C–H bonds and generating alkoxy- and carbon-centered radicals.

However, under conditions of long-term stationary irradiation, on the one hand, and relatively high rate of hydrogen detachment ($k = 10^5–10^6$ l mol^{-1} s^{-1} [13]), on the other, the reactivity of oligomers with BP in these systems is insignificant. At the same time, at low irradiation doses the reactivity of the oligomers is significant and essentially determines the network formation rate.

Under linear heating at a rate of about 10 deg min^{-1}, the plot of the CL intensity for the films prepared from ED-16–AA passes through a maximum in the temperature range 100–140°C. This suggests a glass–gel transition characterized by the glass transition temperature T_g in the temperature range indicated (Fig. 5). Plots for sample cured and kept for several

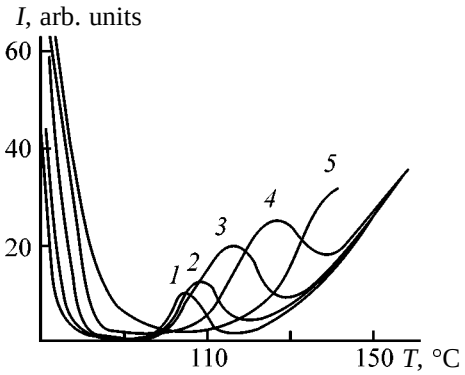

Fig. 5. Temperature dependence of the CL intensity for the polymer based on ED-16–AA. Film thickness 10 μm, λ = 313 nm. (*I*) Irradiation intensity. Irradiation dose *Q*, photon cm^{-2}: (*1*) 1.4×10^{16}, (*2*) 8.3×10^{16}, (*3*) 2.4×10^{17}, (*4*) 7.9×10^{17}, and (*5*) 3.3×10^{18}.

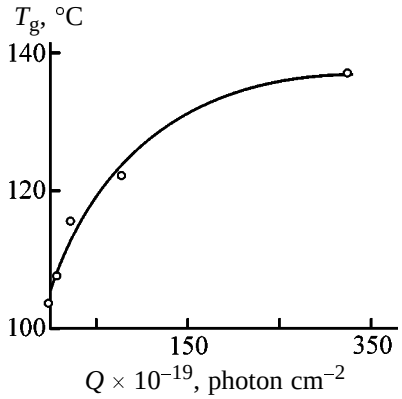

Fig. 6. Dependence of the glass transition temperature T_g, for ED-16–AA epoxy–acrylate polymer on the UV irradiation dose *Q*.

days but not subjected to subsequent photooxidation do not exhibit maximum in this temperature range under linear heating conditions. With increasing irradiation dose in the course of curing, the maxima of the luminescence curves shift to higher temperatures. Figure 6 shows how the parameter T_g varies with irradiation dose. Evidently, T_g, similar to E_a, describes the network formation during UV curing of epoxy–acrylate oligomers.

The data in Figs. 4 and 6 show that the irradiation doses at which the plots flatten out are of the same order of magnitude. The fact that the plots of the glass transition temperatures T_g and the activation energies E_a vs. irradiation dose attain saturation, i.e., that these parameters become independent of the amount of the photons taken up during further irradiation, evidences the maximal possible cross-linking of the polymers under the actual conditions.

CONCLUSION

Activation energy and glass transition temperature determined by the recombination luminescence method characterize the degree of cross-linking of UV-cured polymers. The spectral dimension decreases with increasing irradiation dose, while the apparent luminescence activation energies and glass transition temperatures for the polymers studied tend to increase.

Abstract—The Tikhonov regularization method was proposed for correction of gel chromatograms for instrumental broadening. The results obtained in solving the Tung equation by approximation and regularization methods and also in using the Gauss and Pearson distributions as a function of instrumental broadening were compared.

At present the gel-permeation chromatography (GPC) is a well-developed method of analysis of molecular characteristics and molecular-weight distribution (MWD) of polymers.

However, owing to nonideality and irregularity of chromatographic separation the chromatograms are smeared and, as a result, the MWD diagrams are broadened. The necessity of considering the smearing effect in processing of the experimental chromatograms causes significant complications in passing from gel chromatogram to MWD. A correction of chromatograms is essential when the MWD characteristics serve as the initial data for further calculations, e.g., for identification of the kinetic models of polymerization on the basis of the total MWD of a polymer [1–4].

In the general case the procedure of correction of chromatograms is reduced to solving the Tung equation [5, 6]

$$F(\nu) = \int_{\nu_2}^{\nu_2} W(y)\, G(\nu - y)\mathrm{d}y, \qquad (1)$$

where $F(\nu)$ is the experimental chromatogram; $W(y)$ is the required MWD; and $G(\nu - y)$ is the nucleus of the integral equation which describes the diffusion, concentration, and other effects resulting in a deviation of $F(\nu)$ from $W(y)$.

In the limiting case, when the diffusion is absent, $G(\nu - y) = 1$ and the function $W(y)$ becomes indentical to $F(\nu)$.

Numerous procedures for correction of chromatograms with the use of the Tung equation (1) were suggested [6–11]. All these procedures are generally based on various methods of numerical solution of the Fredholm integral equation of the first kind [1, 6, 12] and are associated with the incorrectly formulated problem. The latter is caused by the fact that, first, in numeral solution of Eq. (1) "oscillations" appear at the ends of the function $W(y)$, and, second, small variations in the slope of $F(\nu)$ result in significant variations in the shape of the resulting function $W(y)$.

When $F(\nu)$ is determined from an experiment with the highest accuracy and the function $G(\nu - y)$ is chosen correctly, the solution for $W(y)$ can be obtained by any procedures proposed in [6–11]. However, actually none of these two conditions can be realized: the analytical form of integral equation (1), which describes the smearing of the bands of polymer homologs in the chromatographic system, is unknown *a priori*, and a certain error δ occurs in all experimental results.

As a rule, this uncertainity of the functions $F(\nu)$ and $G(\nu - y)$ transforms into oscillations of $W(y)$, which is clearly pronounced at the ends of chromatograms, where the function $F(\nu)$ is determined with the lowest accuracy. The problem becomes still more complicated in the case of a large smearing or when the sample contains very narrow peaks.

To avoid these difficulties, the experimental chromatograms are usually presmoothed. In the procedures used in practice this smoothing was carried out in an explicit or implicit form, and the choice of the correction procedure was governed by the success of this operation rather than by the mathematical approach used [1, 6]. In this case, it should be noted that, when

1070-4272/01/7407-1194$25.00

the smoothing is rough, a part of characteristics of the chromatographic curve reflecting the true MWD of polymer can be lost, and when the smoothing has not been performed to completion, the oscillations inevitably appear in the solution of Eq. (1).

Thus, the practical experience of using the above methods shows that at present there is no procedure eliminating the effect of instrumental broadening in evaluation of MWD from the results of gel-chromatographic analysis with fair efficiency and minimum expenditure of time.

The Tung equation is a Fredholm equation of the first kind. Solving Eq. (1) gives the reverse problem of $W(y)$ reduction from the approximate values of $F_\delta(\nu)$, which is a feature of incorrectly formulated problem [13]. The Tikhonov regularization method is the most developed and efficient method of solving of the Fredholm integral equation of the first kind (1) [13, 14]. Therefore, in this work we attempt to use the Tikhonov regularization method for correction of chromatograms for instrumental broadening.

The regularizated solution $W_\alpha = R[\alpha, F_\delta(\nu)]$, i.e., the function $W_\alpha(y)$ at which the minimum of smoothing Tikhonov functional is reached, was selected as an approximated solution

$$M_\alpha(W) = \int_{-\infty}^{\infty} \left[\int_{-\infty}^{\infty} G(\nu - y)\, W(y)\mathrm{d}y - F_\delta(\nu) \right] + \alpha \int_{-\infty}^{\infty} \left[W^2 + (\mathrm{d}W/\mathrm{d}y)^2 \right] \mathrm{d}y, \quad (2)$$

where α is the numerical parameter of regularization, $\alpha > 0$.

We used the standard software IUPR for solving Fredholm single-dimension operator equation. The software realizes the Tikhonov regularizing algorithm [15–17] with selection of the regularization parameter by the generalized discrepancy principle [14, 18].

The regularization procedure gives the approximated solution $W(y)$ on the basis of *a priori* data, e.g., on the errors in the initial data and nucleus $G(\nu - y)$. Therefore, the proximity of the found solution to the true solution is governed by the choice of the nucleus $G(\nu - y)$, which is the function of the instrumental broadening. The selection of the function $G(\nu - y)$ depends on the model in hand, and for various levels of approximation to the instrumental broadening determined experimentally this function has its own form.

In solving Eq. (1) some researchers [5, 8, 9, 12] assume that the diffusion obeys the Gauss law; in this case, $G(\nu, y)$ is approximated by the Gaussian

$$G(\nu, y) = \frac{1}{\sigma(2\pi)^{1/2}} \exp[-(\nu - y)^2/2\sigma^2]. \quad (3)$$

However, in this case the "slopeness" of the instrumental broadening curves is not considered. The method of moments, considering the curve asymmetry [19], requires a great deal of preliminary experiments; in so doing, these experiments should be repeated with variation of the chromatographic conditions. Hence it follows that the choice of the instrumental broadening function should be not random but should follow from the features of chromatographic analysis.

We used the approximation of experimental data on the narrow-dispersion polymeric reference by the system of the Pearson density functions [20]:

$$G(x) = A^2 \frac{2m^{1/2}\Gamma(2^{1/m} - 1)}{\pi\Gamma(m - 1/2)w} \left[1 + 4\frac{2^{1/m} - 1}{w^2}(x - x_c)^2 \right]^{-m}, \quad (4)$$

where $x = (\nu - y)$; the parameters of Eq. (4) were determined from the correlation of the experimental chromatogram of the polystyrene reference sample and the calculated curve by the least-squares technique to be $A = 1.610$, $w = 1.474$, $m = 4.695$, and $x_c = 11.265$; $\Gamma(z)$ is the gamma function

$$\Gamma(z) = \int_{-\infty}^{\infty} t^{z-1} \exp(-t)\mathrm{d}t. \quad (5)$$

Previously [1, 19] it was shown that distributions of this type well approximate both the solution of the system of differential equations describing GPC process and the shape of the chromatogram of individual components.

Figure 1 presents the results of approximation of the experimental chromatogram (curve *1*) of narrow-disperse polystyrene reference sample by the Gaussian (curve *3*) and Pearson (curve *2*) distribution. As seen, the smearing in the chromatographic system in hand is asymmetric and is "sloped" to the range of high eluent volumes. The use of the Pearson distribution gives a higher approximation for description of the smearing of polymer homologs.

As a testing procedure we used the approximation method of solving the Tung equation [12], in which

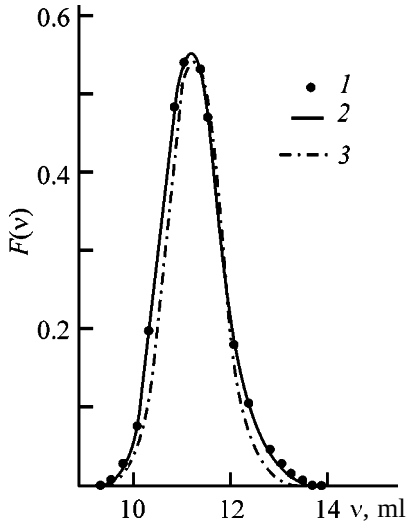

Fig. 1. Approximation of the experimental chromatogram of narrow-disperse polystyrene reference sample. (ν) Eluent volume; the same for Fig. 2. (*1*) Experimental curve, (*2*) Pearson distribution, and (*3*) Gauss distribution.

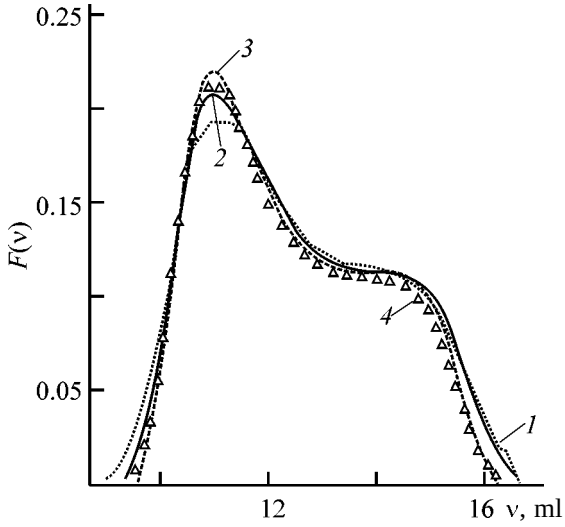

Fig. 2. Results of processing of (*1*) experimental chromatogram of polyisoprene sample by (*2, 3*) regularization technique with the use of the (*2*) Gauss and (*3*) Pearson distributions and (*4*) by the approximation method.

the nucleus of the integral equation and the sought-for solution are approximated by the following function:

$$Q(x) = \begin{cases} C_1 \exp(C_2 x), & x < x_1, \\ P_n(x), & x_1 \le x \le x_2, \\ C_3 \exp(C_4 x), & x < x_2, \end{cases} \qquad (6)$$

where $x = y - \nu$; $P_n(x)$ is a polynomial of the degree n; coefficients C_1–C_4 and also the polynomial coefficients and change-over points x_1 and x_2 are determined by least-squares fitting.

The function $Q(x)$ is butted end-to-end at the interval boundaries. The required solution of $W(y)$ is selected by the least-squares method with optimization of the functional

$$\Phi(z) = \sum_{i=1}^{N} [F(\nu_i) - \int_{y_2}^{y_1} W(y)\, G(y - \nu_i)\mathrm{d}y]^2, \qquad (7)$$

where the elements of vector z are the variables given in Eq. (6): C_1–C_4, change-over points x_1 and x_2, and the polynomial coefficients.

This method has some drawbacks. First, the search for the solution in the form of function (6) can result in some cases in the loss of information at the tails of the chromatograms. In other words, the exponential form of the function $W(y)$ at the ends of the curve, on the one hand, allows elimination of oscillations and, on the other hand, smoothes all data in these portions which can contain additional information. Second, the use of this method for calculation of the true MWD is time-consuming. In correction of multimodal distributions there is a need to increase the polynomial dimension in Eq. (6), which abruptly decreases the rate of processing even with the use of modern computers.

Nevertheless, in spite of these drawbacks, as shown in [12], this method gives data adequate to the true distribution. In so doing, there are no excessive maxima common under these conditions, since the oscillations appearing at the ends of the interval are suppressed by the form of the chosen function. Therefore, this procedure of processing of chromatograms was used for testing the calculations performed by the method proposed in this work.

The results of correction of chromatograms by the regularization technique are presented in Fig. 2. For comparison, we performed evaluations in which both the Pearson and Gauss distributions were used as a nucleus of Eq. (1).

Despite the fact that smearing of the sample in the chromatographic system in hand is insignificant, there are some differences between the experimental and corrected chromatograms. The maxima in the "corrected" distributions are more clearly pronounced, and these distrubutions become somewhat narrower. This fact has no dramatic effect on studying the molecular characteristics of a polymer but affects the determination of the kinetic parameters and also the shape of distributions of polymerization centers with respect to the kinetic activity [2, 3].

Curve *3* in Fig. 2, obtained with the use of the Pearson distribution as a nucleus of the integral equation, is closer to the solution obtained by the approximation method (curve *4*), especially in the range of large eluent volumes, in comparison with the symmetrical Gaussian (curve *2*). This is one more argument in favor of the chosen instrumental broadening function.

This procedure also takes into account the possible errors in choice of the nucleus of the integral equation $G(v - y)$. A quick-operating software allows the use of this procedure in automated processing of chromatographic experiments.

EXPERIMENTAL

The chromatograms of polymers were measured on a KhZh-1302 gel chromatograph. Four columns packed with styrogel (Waters) with the pore size of 3×10^2–5×10^6 Å were used. Chloroform was used as an eluent; the flow rate of the eluent was 2 ml min^{-1}. The system of columns was calibrated from polystyrene references with narrow MWD ($M_w/M_n \cong 1.2$) using the Benoit universal dependence [21] and the relation between the molecular weight of polydiene and the intrinsic viscosity [22]. All calculations were carried out using a specially developed software in the Turbo Pascal environment.

CONCLUSION

A procedure of correction of gel chromatograms was developed, based on the Tikhonov regularization method and approximation of the nucleus of the integral equation by the Pearson distribution. The proposed procedure allows correction of chromatograms without presmoothing and with consideration of asymmetry of the instrumental broadening function.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Phase Distribution of Filler on the Viscosity of Heterogeneous Polymer Blends

A. E. Zaikin and V. V. Molokin

Kazan State Technological Institute, Kazan, Tatarstan, Russia

Received December 14, 2000; in final form, May 2001

Abstract—The influence of the distribution of carbon black between phases of binary heterogeneous blends of polyethylene with elastomers on the viscosity of their melts was studied.

Materials based on polymer blends containing disperse fillers find increasing use [1–3]. However, the rheological properties of such materials are studied poorly. Furthermore, it is known that particles of finely dispersed fillers are usually distributed nonuniformly between the phases of heterogeneous polymer blends and that changes in their distribution can significantly affect the properties of the blends [1, 4–6]. However, in most cases the influence of this distribution on the rheological properties of polymer blends was not taken into account. Only a few works consider this problem [7–10]. However, no general trend was revealed in the influence of the phase distribution of filler particles on the rheological properties of polymer blends [4]. Revealing such trends is of scientific and practical interest and is particularly urgent for blends used in industry.

EXPERIMENTAL

In this work we studied blends of polyethylene with various elastomers, filled with carbon black (CB). We used low-density polyethylene (LDPE) of 15 803-020 brand with the viscosity-average molecular weight M_η = 37 000 and the melt flow index (MFI) of 2.4 g/10 min (at 190°C and a load of 2.16 kg) and high-density polyethylene (HDPE) of 273 brand with $M_w = 2.6 \times 10^5$ and MFI 0.55 g/10 min (190°C, 5 kg). Polyurethane thermoelastoplastic (PU) of Urelan brand, prepared from polyfurite, diphenylmethane-4,4'-diyl diisocyanate, and 1,4-butanediol in the molar ratio 1 : 2 : 1, had the molecular weight of 3.5×10^4 and MFI 60 g/10 min (190°C, 5 kg). Isoprene–styrene block copolymer of the styrene–isoprene–styrene type of IST-30 brand, containing 30 wt % styrene, had $M_w = 7.3 \times 10^4$ and MFI 4.5 g/10 min (190°C, 5 kg). Butadiene–acrylonitrile rubber of SKN-40m brand, containing 39.5 wt % acrylonitrile, had $M_\eta = 2.2 \times 10^5$ and the Mooney viscosity of 54. As disperse filler we used N 254 carbon black with the mean size of primary aggregates of 28 nm and specific adsorption surface area of 225 $m^2 g^{-1}$.

The components were blended on rollers at 130–140°C for the materials containing LDPE and at 145–155°C for those containing HDPE. To control the CB distribution between the phases of polymer blends, the sequence of mixing was varied [1, 5]. According to one procedure, CB was preliminarily dispersed in a melt of one of the polymers, after which the second polymer was added. According to another procedure, CB was added to a melt of the polymer blend prepared in advance. The mixing time was 5 min in each stage. Hereinafter, the sequence of mixing is indicated by placing in parentheses the components mixed in advance. All polymers contained 0.2 wt % Irganox 1010 stabilizer to prevent thermal oxidative degradation.

In all the HDPE + SKN blends the SKN phase was subjected to "dynamic" vulcanization directly on rollers in the course of mixing. To do this, we added to the ready mixture on the tenth minute of mixing 4 wt % of the standard sulfur vulcanizing mixture of the composition (wt %) ZnO 50, stearic acid 15, 2-mercaptobenzothiazole 15, and sulfur 20 [11], after which the mixing was continued for an additional 10 min.

The viscosities of the melts of the polymers and their blends were measured with an IIRT capillary viscometer at a constant pressure by a known procedure [12]. To take into account the pressure loss at the inlet of the melt into the capillary, we used two capillaries of different length [12].

Measurement conditions: (*1*, *2*) 130°C, shear stress $\tau = 1.25 \times 10^5$ Pa; (*3*, *4*) 190°C, $\tau = 39 \times 10^4$ Pa.

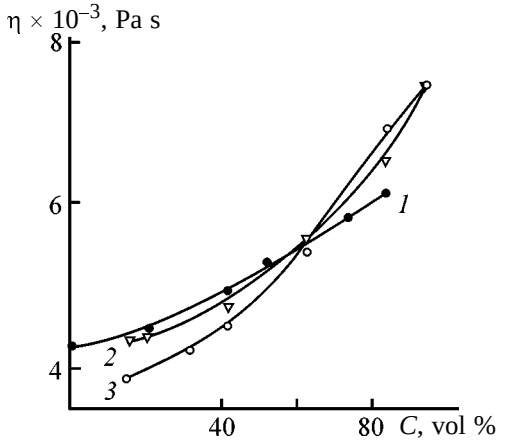

Fig. 3. Apparent viscosity η of the LDPE + IST + CB blend at 190°C at 190°C and $\tau = 3.9 \times 10^4$ Pa as influenced by the IST content *C*. CB content 5.3 vol %. Sequence of component mixing: (*1*) (PE + CB) + IST, (*2*) (PE + IST) + CB, and (*3*) (IST + CB) + PE.

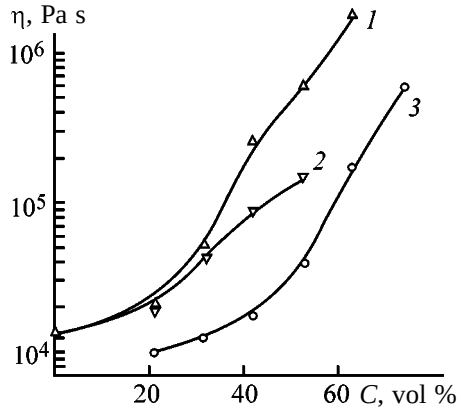

Fig. 2. Apparent viscosity η of HDPE + SKN + CB blends at 190°C and $\tau = 1.8 \times 10^5$ Pa as a function of the SKN content *C*. CB content 8.4 wt %. Sequence of component mixing: (*1*) (PE + CB) + SKN, (*2*) (PE + SKN) + CB, and (*3*) (SKN + CB) + PE.

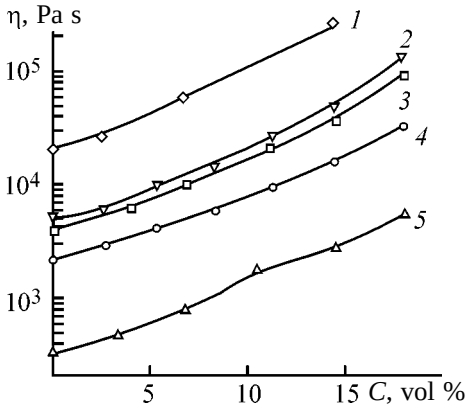

Fig. 4. Apparent viscosity η of polymers at $\tau = 3.9 \times 10^4$ Pa as a function of the CB content *C*. (*1*, *5*) PU, (*2*, *4*) LDPE, and (*3*) IST. Measurement temperature, °C: (*1*, *2*) 130 and (*3*–*5*) 190.

It is known that the mutual solubility of the components of sufficiently high molecular weight in the systems PE + PU, PE + SKN-40, and PE + IST-30 in a wide temperature range does not exceed 1% [13–15].

Finely dispersed filler practically fully remains in that phase of the heterogeneous polymer blend into which it was preliminarily introduced [1, 4, 5]. This fact was used to control the filler distribution between the phases of polymer blends.

Studies showed that the viscosity η of the melt of the filled polymer blend depends on the phase distribution of the filler. This dependence is the more pronounced, the larger the difference between the polymer components in viscosity (Figs. 1–3). For example, the viscosities of LDPE and IST-30 at 190°C are close (Fig. 4); therefore, the viscosity η of their blend only slightly depends on the phase distribution of CB (Fig. 3). In the system LDPE–PU, the difference in η (Fig. 4) is larger, and hence the effect of the sequence of mixing is stronger (Fig. 1). The strongest effect of the sequence of mixing on η is observed with HDPE + SKN blends (Fig. 2) in which SKN shows no flowability because its phase is vulcanized under dynamic conditions on mixing [2, 3].

The experimental data (Figs. 1–3) allow us to reveal the following regular trends in variation of the viscosity of the polymer blends as influenced by the phase distribution of the filler. All the systems in a wide range of the component ratios have the lowest η in the case of localization of CB in the more viscous

component and the highest η in the opposite case. This relationship is observed when the relative contents of the polymers are comparable or when the low-viscous polymer prevails. However, at high concentrations of the more viscous component the influence of the phase distribution of CB on the flowability of the blend is quite opposite (Figs. 1–3). Hence, as the polymer ratio is changed, the influence of the sequence of component mixing on the viscosity of the blend changes. This trend is observed with PE + PU and PE + IST blends. The stronger the difference between the polymer components in viscosity, the narrower the range of relative concentrations in which the highest viscosity is observed when CB is localized in the phase of the low-viscosity polymer. No such trend is observed with HDPE + SKN blends in which the elastomer phase shows no flowability (Fig. 2).

The compositions prepared by adding CB to the polymer blend prepared in advance have intermediate viscosity in the entire composition range (Figs. 2, 3).

It is important that the revealed trends in the influence of the mixing sequence on the viscosity of the blends are related neither to features of polymer–CB interactions nor to different degree of degradation of the polymer components in the course of filling; these trends are governed exclusively by the ratio of the polymer viscosities. This follows from variation of the viscosity of the same composition LDPE + PU + CB at different temperatures (Fig. 1). At 190°C the blends prepared by the scheme (PE + CB) + PU show the highest flowability, whereas at 130°C the system (PU + CB) + PE is the least viscous (Fig. 1). This difference is due to the fact that at 190 and 130°C the less viscous components are PU and LDPE, respectively (Fig. 4). Hence, at both temperatures the viscosity of the blend in a wide composition range is lower if CB is localized in the phase of the more viscous polymer.

The simplest explanation of the observed influence of the phase distribution of CB on the viscosity of polymer blends involves an assumption that the viscosity of blends at filling varies in accordance with variation of the viscosities of the phases. Such explanation was already made in [9, 10]. According to this assumption, the blend viscosity will be the highest if all CB is localized in the phase of the polymer whose viscosity increases on filling to a greater extent.

To reveal the effect of filler on the polymer viscosity, it is appropriate to use well-known expressions fairly adequately describing the experimental dependences $\eta = f(\varphi)$ [16], e.g., the Mooney equation $\ln(\eta/\eta_0) = K_E\varphi(1 - \varphi/\varphi_m)$ or the equation $\eta/\eta_0 = (1 - \varphi/\varphi_m)^{-2.5}$, where η is the viscosity of the composition, η_0 is the viscosity of the initial polymer, φ is the volume fraction of the filler in the polymer, φ_m is the volume fraction of the filler at its maximally close packing, and k_E is the Einstein's coefficient.

These equations and experimental data (Fig. 4) show that, the higher the polymer viscosity, the larger its absolute increase on filling. Then, according to the above assumption, the viscosity of the blend will be the highest when the filler is localized in the phase of the more viscous polymer. However, in the major part of the range of polymer ratios the trend is opposite (Figs. 1–3). Hence, this assumption is incorrect.

The revealed trends can be explained by considering the structure and behavior of polymer blends in a flow. It is known that the rheological properties of heterogeneous polymer blends are not additive. The viscosity of a two-phase polymer blend is mainly determined by the viscosity of the dispersion medium [1, 17, 18]. Under conditions of flow, in the major part of the range of the component ratios, the low-viscous polymer forms the continuous phase, and it is this polymer that determines the viscosity of the blend. When both phases are continuous, the low-viscosity phase will experience larger shear strains. Hence, in this composition range also the rheology of the blend will be mostly determined by the rheology of the low-viscosity polymer. Therefore, in a wide range of polymer ratios filling of the low-viscosity phase increases the viscosity of the blend to a greater extent than filling of the high-viscosity phase (Figs. 1–3).

However, at a low content of the low-viscosity component the pattern changes. In this case, even under the flow conditions, the dispersion medium is formed by a high-viscosity polymer which mainly determines the viscosity of the system. Therefore, in this composition range introduction of the filler into the more viscous dispersion medium decreases the melt flowability to a greater extent than filling of the less viscous dispersed phase. Hence, the change in the influence of the phase distribution of CB on the blend viscosity at variation of the polymer ratio is due to the fact that the low-viscosity polymer, which initially was the dispersion medium, becomes the dispersed phase. It is known that, the larger the difference between the polymeric components in viscosity, the narrower the composition range in which the high-viscosity polymer can form a continuous phase [1, 17–19] and hence the narrower the range in which the highest viscosity is observed with the blend in which

CB is localized in the more viscous polymer. In the PE + SKN blend prepared under conditions of dynamic vulcanization, the continuous phase is always PE. With this blend, the above-discussed change in the influence of the sequence of the component mixing on the viscosity is not observed (Fig. 2).

The feature of the PE + SKN blend is that at a low content of the elastomer (up to 30 vol %) the flowability of the system PE + CB is lower than that of the system (SKN + CB) + PE (Fig. 2) at equal CB content. From the viewpoint of composition, this relationship seems abnormal. Indeed, addition to the system PE + CB of the nonflowing vulcanized elastomer decreases its viscosity. However, when taking into account the CB distribution, the pattern becomes quite logical. Actually we compare the viscosity of PE containing finely dispersed CB with that of PE containing relatively coarsely dispersed rubber particles incorporating the same CB. It is known that the viscosity of any fluid increases as the degree of dispersion and specific surface area of the filler increase [20]. It is quite reasonable that relatively coarsely dispersed (5–20 μm) rubber particles present in PE in an amount of up to 20–30 vol % do not increase the PE viscosity to the same extent as finely dispersed (specific surface area 225 $m^2 g^{-1}$) CB in an amount of 5–8 vol %. Indeed, CB in the PE phase binds by its very developed surface a large number of PE macromolecules [20], considerably increasing the melt viscosity. When CB is localized in the coarse particles of the added elastomer phase, it does not exert such an effect on PE, and the viscosity of the system becomes lower.

When CB is added to a polymer blend prepared in advance, it is mainly localized in the less viscous polymer [1, 5]. Therefore, the flowability of the blend is relatively low and close to that of the system prepared by adding CB in advance to the less viscous polymeric component (Figs. 1–3). If the fraction of the low-viscosity polymer is low, a significant fraction of CB is localized in the continuous high-viscosity phase. As a result, the viscosity of such a blend is intermediate between the two extreme cases of the phase distribution of CB.

CONCLUSIONS

(1) Distribution of filler particles between the phases of heterogeneous polymer blends considerably affects their viscosity, because the contribution of the polymeric phases to the rheological properties of the blend is out of proportion.

(2) The lowest viscosity is observed when all the filler is localized in the dispersed phase; in the range in which both polymeric phases are continuous, the viscosity is the lowest when the filler is localized in the more viscous polymeric component.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Behavior of Tetrazole-containing Acrylic Hydrogels in Electrolyte Solutions

A. V. Igrunova, N. V. Sirotinkin, and M. V. Uspenskaya

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received March 16, 2001

Abstract—The influence of temperature, pH, and chemical composition of the medium on the equilibrium swelling of polymeric polyelectrolytic tetrazole-containing acrylic hydrogels was examined.

Interaction of hydrogels with electrolyte solutions, resulting in limited swelling, is actively studied for a long time. Polyelectrolytic hydrogels are of interest from the viewpoint of both modeling of bioinformation systems and various practical applications: agricultural gels, gels for sanitation purposes used for water treatment, etc. Wide prospects are opened by the possibility of varying the phase state of polymeric gels, i.e., of performing transitions between the swollen and collapsed states, under the action of minor changes in the medium. In the past decade major attention has been given to hydrogel systems sensitive to fluctuations of temperature, pH, and ionic strength of solution [1, 2].

Complexation of polymers with metal ions can both increase and decrease the degree of swelling [3]. Modification of the chemical structure of acrylic hydrogel with various comonomers can also affect the degree of swelling in salt solutions.

In this work we studied the features of behavior of polymeric hydrogels of acrylic acid (AA), 2-methyl-5-vinyltetrazole (MVT), and methylenebisacrylamide in various electrolyte solutions and the influence of temperature on the water absorption of the polymers.

EXPERIMENTAL

Hydrogels based on AA and MVT or methylenebisacrylamide (MBAA) as a cross-linking agent were prepared by polymerization in aqueous solution at 60°C in the presence of the initiating system ammonium persulfate (AP)–tetramethylethylenediamine (TMED). The content of the components was as follows (wt %): monomers 30, cross-linking agent 0.1–0.9, and MVT 15–70. The features of synthesis and gelation are described elsewhere [4].

The degree of equilibrium swelling was measured by the standard gravimetric procedure and calculated by the equation

$$Q = (m_s - m_d)/m_d,$$

where m_s is the weight of the swollen sample and m_d is that of the dried sample (g).

In calculations, we averaged the results for five similar samples. The solution pH was monitored with a pH-150 digital pH meter.

The influence of the swelling–drying cycles on the absorption capacity of the hydrogels was studied as follows. Samples of dry hydrogels were placed in an excess of distilled water and kept at 50°C to attain the equilibrium swelling. After separation from the nonabsorbed water, the gel was dried at 50°C to constant weight. The cycles were repeated until the gel either dissolved or lost the absorbing power because of the collapse.

The behavior of acrylic hydrogels modified with MVT in electrolyte solutions has certain specific features. The major advantage of new hydrogels is the high degree of equilibrium swelling in $<10^{-2}$ M solutions of polyvalent metal salts. Under these conditions, the degree of equilibrium swelling of hydrogels in solutions of cobalt, nickel, and copper salts was more than 200 g g^{-1}. In some cases at a low salt concentration (10^{-5}–10^{-4} M) the degree of equilibrium swelling of the gel was higher than in distilled water [5]. Figure 1 shows how the degree of equilibrium swelling of the gel containing 43.5 wt % MVT and 0.1 wt % MBAA (in the monomeric mixture) depends on the concentrations of NaCl and $CoCl_2$ and on the solution pH. The degree of swelling of tetrazole-

containing gels is due to the capability of tetrazole for complexation and its structure-making effect on water [6]. Within the first day, the degree of swelling can exceed the equilibrium value by a factor of 1.5–2.

0.2	130	171
0.5	124	142

Swelling of the gels containing 33.3–43.5 wt % MVT is characterized by two successive stages: sharp increase in the degree of swelling and subsequent decrease in the rate of water binding.

At the electrolyte concentration $C_s = 10^{-3}$ M and initial concentration ratio (mol : mol) of the salt and polymer (C_p) C_s/C_p = 1.5–3, the swelling of the gels passes through a maximum in time. The swelling kinetics in a 10^{-3} M solution of $CoCl_2$ is shown in Fig. 2. In the first 2 h the gel absorbs pure water, then absorption of metal ions starts, with $C_s \cong C_p$. Then the degree of equilibrium swelling increases over the course of 6–8 h irrespective of the gel composition, after which it gradually decreases to the equilibrium value, which is as high as 200–500 g g^{-1}. The salt solution is concentrated inside the gel, as indirectly indicated by the intensity of the gel color, as compared to the color of the initial solution.

The pattern of the variation of the swelling degree in time (Fig. 2) shows that before attainment of the equilibrium the curves are adequately described by the equation of a straight line $dQ/dt = k$, or $Q_i = kt_i$, where Q_i is the degree of swelling in time t_i; k is the coefficient determined by the nature of the salt and polymer. As seen from Fig. 2, as the content of MVT in the copolymer is increased, the swelling rate increases; this is due to the complexing power of the tetrazole ring.

The swelling rate of the tetrazole-containing gels is described by the equation $k = \alpha$[MVT], where [MVT] is the weight fraction of MVT in the monomer mixture. The equation describes the swelling rate in the range 13.5–43.5 wt % MVT, and α is determined by the nature of the salt and experimental conditions. In our case $\alpha \cong 1$. The dependence of the swelling rate on the content of the cross-linking agent in the polymer is given in Table 1.

Table 1 shows that, as the cross-linking density is increased, the swelling rate in solutions of metal salts increases, which is due to the high osmotic pressure of swelling. Statistical treatment of the kinetic data on swelling of gels in solutions of different salts, with the same content of MVT in the monomer mixture, gives the correlation $k = \beta$[MBAA], where β is the coefficient depending on the nature of the salt and on swelling conditions. This relationship holds for the range of MBAA concentrations in the monomer mixture 0.05–0.2 wt %; however, it is not valid for MBAA concentrations higher than 0.5 wt % or for the samples containing 70 wt % MVT. This is probably due to the defective structure of the network,

presence of interweavings, engagements, free loops, and strong intermolecular interactions [4]. These factors are responsible for the decrease in the degree of equilibrium swelling in the range of MVT concentrations 40–70 wt % (Fig. 3).

Our studies show that below 11°C or at $C_s/C_p > 5$ the metal ions in the course of swelling are taken up faster than water, which results in gradual contraction of the initially swollen gel to 70–150 g g^{-1} and its subsequent collapse. High degrees of equilibrium swelling of the tetrazole-containing acrylic hydrogels are due to complexation of both tetrazole rings and acrylate groups with metal ions, with presumable formation of chelates [7]. The arising additional bonds act as "intermolecular cross-links" in weakly cross-linked gels and increase the effective density of the network. Coordination of water molecules increases the effective volume and degree of equilibrium swelling.

The effect of complexation at swelling in solutions of polyvalent metal salts is indicated, along with the step course of swelling at $C_s = 10^{-3}$ M, also by a change in the gel color (in some cases, at swelling in a 10^{-2} M $CoCl_2$ solution). Initially the gel becomes blue, which indirectly suggests a change in the number of coordinated water molecules in the inner sphere of the cobalt aqua complex [7].

The hydrogels under consideration, at a content of the cross-linking agent in the monomer mixture of 0.1–0.2 wt %, show a high degree of equilibrium swelling in physiological solution (as compared to copolymeric hydrogels of AA and acrylamide prepared at cross-linking agent concentrations less than 0.06% [2]). The degrees of equilibrium swelling in physiological solution and water at 16°C of the gels prepared at the concentrations of MBAA and MVT in the monomer mixture of 0.1–0.5 and 0–70 wt %, respectively, are listed in Table 2.

Table 2 shows that, as the MVT content is increased, the degree of equilibrium swelling increases. As the content of the cross-linking agent is increased, this quantity decreases. At the MVT concentration less than 40 and that of MBAA in the range 0.05–0.5 wt %, the gels preserve their shape in the swollen state, i.e., exhibit sufficient elasticity.

The gels under consideration show high values of equilibrium swelling in the practically important range pH 3–7. At pH 1.7–2.5 the tetrazole-containing gels collapse, and at pH 2.25 the swelling passes through a maximum. This is probably due to the fact that the ion exchange H^+/Na^+ in the carboxylate groups of the gel is preceded by the phase transition coil–globule of the polymer chains.

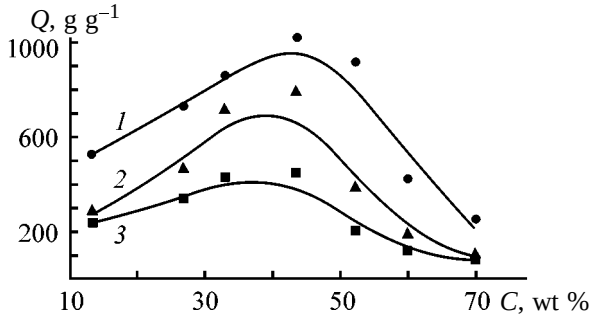

Fig. 3. Degree of equilibrium swelling Q of hydrogels in 0.001 M electrolyte solutions as a function of MVT concentration C. Electrolyte: (*1*) NaCl, (*2*) HCl (pH 3.24), and (*3*) $CuCl_2$.

In various electrolytic media, the influence of the incorporated MVT units on the degree of equilibrium swelling of the hydrogel is characterized by a curve with a maximum at MVT concentrations in the range 27.0–43.5 wt %. Such a shape is characteristic of solutions of both mono- and polyvalent metal salts and acids. At a salt concentration of 10^{-4} M the equilibrium degree of swelling in solutions of polyvalent metal salts is higher than in solution of NaCl, which is due to complexation (Figs. 1, 3).

The hydrogels containing MVT exhibit a high heat resistance. The activation energy of thermal oxidative degradation of the tetrazole-containing copolymers, according to DTA, is E_a = 420 kJ mol^{-1}. The influ-

ence of the content of MVT and MBAA in the gels on their thermal sensitivity is illustrated in Table 3.

The hydrogels studied exhibit a high degree of equilibrium swelling below 60°C [8], whereas above 60°C the degree of swelling decreases. At high temperatures the compaction of the gel structure can occur along with dissolution. Compaction is characteristic of gels prepared at a high content of tetrazole (up to 70 wt %) or MBAA (up to 0.9 wt %) in the monomer mixture.

Results of experiments on cyclic swelling–drying of the tetrazole-containing gels at 50°C allow them to be recommended for use in recirculation processes at elevated temperatures, e.g., for agricultural purposes. The highest performance is shown by hydrogels containing 27.0 wt % MVT and 0.1–0.5 wt % MBAA; these hydrogels withstand more than eight cycles without appreciable changes in the absorption power. The gels containing 0.05 wt % cross-linking agent show poor thermal stability at cycling and withstand up to three cycles. When the content of the cross-linking agent exceeds 0.9 wt %, after five cycles the structure undergoes compaction, and the degree of equilibrium swelling noticeably decreases. In the gels with the MBAA concentration higher than 0.1 wt %, the degree of swelling increases after the sixth cycle, suggesting the onset of degradation, but the swollen samples preserve elasticity.

CONCLUSIONS

(1) Tetrazole-containing acrylic hydrogels exhibit a high degree of equilibrium swelling in electrolyte solution in the practically significant concentration range (10^{-3}–10^{-5} M for polyvalent metal salts, 10^{-2}–10^{-5} M for univalent metal salts; pH 3–7).

(2) The water-absorbing power of the hydrogels in salt solutions of concentrations less than 10^{-2} M is 500–1800 g g^{-1}, which is due to chelate formation. The tetrazole-containing gels exhibit a high degree of equilibrium swelling at pH 3–7 and high thermal stability in the swollen state.

(3) The thermal sensitivity of the gels allows their use for treating water and concentrating aqueous solutions of polyvalent metals.

(4) The stability of gels in cyclic swelling–drying processes at elevated temperatures (up to 50°C) allows them to be recommended for agricultural use.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

IR Spectroscopic Study of the Chemical Structure of Ethylene–Vinyl Acetate Compolymers Modified with Saturated Alkoxysilane

O. V. Stoyanov, S. N. Rusanova, O. G. Petukhova, and A. B. Remizov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received March 30, 2000; in final form, March 2001

Abstract—The transformations of chemical structure of ethylene–vinyl acetate copolymer after modification with ethyl silicate were studied by IR spectroscopy.

One of effective procedures for modifying polyolefines is introduction of organosilicon compounds into their structure. For this purpose unsaturated silanes are grafted to macromolecules in the presence of radical initiators. Then cross-linked polymers are formed by catalytic hydrolysis and polycondensation of silane functional groups.

However, these are other methods of chemical modification of polyolefins with silanes. Kreshkov *et al*. [1, 2] showed that alkoxysilanes enter ester interchange with carboxylic acid esters to form the corresponding orthosilicates. We suggest that modification of ethylene–vinyl acetate copolymers with saturated alkoxysilanes will change their properties owing to formation of cross-linked polymers with grafted siloxane chains.

Previously we found [3] that physicomechanical properties of polyolefines can be improved by modification with saturated orthosilicates. The resulting material retain the flowability of the initial polymer and can be prossessed by conventional procedures.

In this work the transformation of the chemical structure of some polyolefins modified with saturated alkoxysilanes was studied in detail by IR spectroscopy.

EXPERIMENTAL

We studied industrial ethylene–vinyl acetate copolymer (EVC) [TU (Technical Specifications) 6-05-1636–78, 301-05-56–90] of grades 11104-030, 11306-075, 12508-150, 11708-1250, 11808-240 with different content of ester groups (EVC-7, EVC-14, EVC-30) and low-density polyethylene (PE) of grade 15803-020 [GOST (State Standard) 16337–77). The properties of these materials are presented in the table.

ETS-32 ethyl orthosilicate (tetraethoxysilane, TES) [TU (Technical Specifications) 6-02-895–78], light yellow low-viscous low-freezing transparent liquid, was used as modifier. The silicon content recalculated to silica and tetraethoxysilane content are 30–34 and 50–65%, respectively; the density is 1062 kg m^{-3}; the viscosity is 1.6×10^{-3} Pa s.

The initial EVC-30, EVC-14 and EVC-7 copolymers were modified by mixing with ethyl silicate on laboratory microrollers for 10 min at 80, 120, and 140°C, respectively. Polymer films were prepared by pressing or casting a 2% toluene solution on a KBr support. The IR spectra in the 400–4000 cm^{-1} range were recorded on Specord 75-IR and M-80 spectrophotometers.

The band at 610 cm^{-1} assigned to the bending vibrations of the C–O bond of the ester group of EVC and the band at 1306 cm^{-1} assigned to $\gamma(-CH_2-)$ bending vibrations in PE were used as the references. To separate overlapping bands, the spectra recorded in *D* (optical density)–ν (wave number) coordinates were treated by appropriate computer program.

Alkoxysilanes are known to enter ester interchange with carboxylic acid esters to form the corresponding orthosilicates:

$$4R^1OOC^2 + Si(OR^3)_4 \rightarrow Si(OR^1)_4 + 4R^3OOC^2,$$

$$4R^1CH(OR^2)(CH_2)COOR^2 + Si(OR^3)_4$$

$$\rightarrow [R^2OOC(CH_2)CHR^1O]_4Si + 4R^2OR^3.$$

1070-4272/01/7407-1207$25.00

Properties of tested polymers

Property	EVC-7	EVC-14	EVC-30	LDPE
Vinyl acetate content, %:				
saponification	7.1	14.0	30.1	–
IR spectroscopy	6.8	13.8	29.7	–
Density, kg m^{-3}	929	935	955	920
Degree of crystallinity, %	25.5	16.6	5.3	35.6
Maximal melting point, °C	103	97	74	113

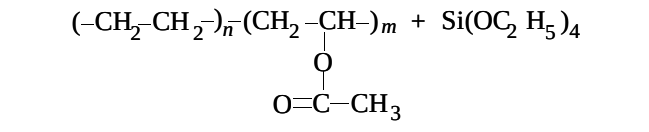
Relative elongation at break, %	670	670	650	550

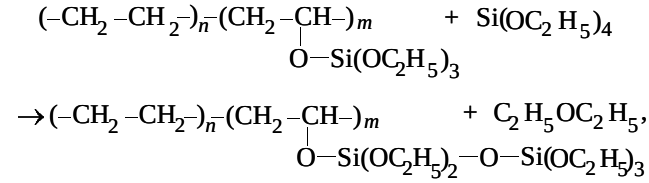
We suggest that similar reaction is possible between alkoxysilanes and polymers containing ester groups.

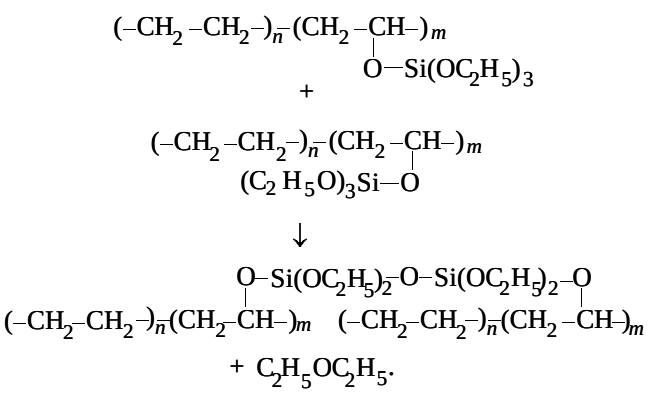
Polyolefins containing ester groups, in particular, polyvinyl acetate and vinyl acetate copolymers, relatively readily undergo saponification with alkalis. Determination of the ester number and preparation of polyvinyl alcohol and its copolymers are based on this reaction. Copolymers of esters can react under appropriate conditions with alcohols, acids, and salts of organic acids [5]. Alkoxysilanes and products of their partial hydrolysis with H_2SO_4 were used as cross-linkers for hydroxylated polymers [partially saponified vinyl chloride–vinyl acetate copolymers containing up to 50% of polyvinyl alcohol and copolymers of hydroxyalkyl (meth)acrylate and polyetherpolyols] [6].

Based on the above consideration, we suggested that EVCs can be modified with saturated orthosilicates. In addition, since the Si–OR bond is highly reactive, silanol chain branches and cross-links can be formed during thermochemical modification.

Reaction of EVC with tetraethoxysilane as well as reaction of silane with low-molecular-weight esters occur probably by the ester interchange mechanism:







Acetic acid formed by degradation of ester groups during thermomechnaical treatment catalyzes silanol condensation, i.e., is "internal catalyst."

Ethylene–vinyl acetate copolymer reacts with ethyl silicate to form new functional groups in the polymer. The bands in the regions 1110–1180, 1020–1090, and 780–830 cm^{-1}, assigned to stretching vibrations of the Si–O, Si–O–Si, and Si–O–C bonds, appear in the IR spectra of modified EVCs. The optical density of the bands at 1050–1100 and 760–830 cm^{-1} increases and the bands typical for Si–O and Si–O–Si bonds in the open siloxane chains and three-dimensionally cross-linked structures appear with increasing content of the organosilicon additive.

During ester interchange the acetyl fragment of vinyl acetate is substituted by the residue of the organosilicon modifier, which is confirmed by splitting of the C–O stretching band of the ester groups at 1240 cm^{-1} in the IR spectra of modified EVC (Fig. 1). A simultaneous decrease in the intensity of the characteristic band of the CH_3 bending vibrations of vinyl acetate at 1462 cm^{-1} (Fig. 2) also indicates that the acetyl fragment of the copolymer is involved in the reaction.

Since EVC is modified in a melt, reaction of ester

groups of the polymer with ethoxy groups of ethyl silicate is sterically hindered. Our data show that introduction of alkoxysilane in the amount of up to 1% sharply increases (to 30%) the fraction of vinyl acetate groups involved in the ester interchange. On further increase in the modifier concentration the fraction of these groups increases to 35% (Fig. 3). This is probably due to the fact that alkoxysilane reacts mainly with the grafted organosilicon fragment, increasing the length of the siloxane chain owing to higher reactivity of the Si–OR bond as compared to the C–OR bond. An increase in the intensity of the absorption bands of the Si–O–Si bonds in siloxane chains (830 cm^{-1}) and three-dimensionally cross-linked structures (450 cm^{-1}) confirms formation of these fragments in modified EVCs (Fig. 4a, 4b).

We found that the change in the optical density of these characteristic absorption bands during EVC modification strongly depends on the content of ester groups in the copolymer. This is probably due to the fact that the amount of the modifier directly reacting with acetyl fragments of EVC increases with an increase in the content of vinyl acetate groups in the copolymer. In this connection, the increase in the reduced optical densities characterizing the mole fraction of vinyl acetate groups in the copolymer ($D_i^{red} = D_i^{rel}/C_{va}$, where $D_i^{red} = D_i/D_{610}$ and C_{va} is the molar content of vinyl acetate), is faster for EVC-7 having the lower content of ester groups (Fig. 4a, 4b). The differences in the shape of the optical density–modifier concentration dependences confirm the assumption that the amounts of the grafted siloxane chains and three-dimensionally cross-linked organosilicon fragments are different owing to steric hindrance and competition of branching and cross-linking reactions.

The absence of chemical reaction between ethylene fragments of EVC and ETS-32 is confirmed by the fact that the characteristic bands at 720 and 731 cm^{-1} assigned to the bending vibrations of the CH_2 groups do not change. Similar results were obtained for PE modified with hydroxylated methyldiethoxychlorosilane [7]. No broadening or coalescence (as in the case of amorphization) of this split narrow doublet typical for crystalline polyolefins was observed [7].

The IR bands assigned to vibrations of the Si–O, Si–O–C, and Si–O–Si groups also appear in the IR spectra of modified polyolefins free from ester groups (PE) (Fig. 5). The fact that the intensity of the bands of vinyl and vinylidene groups at 909 and 888 cm^{-1} remains the same after modification of PE indicates that the double bonds in the polyolefins are not in-

volved in the reaction. However, the optical density of the characteristic band at 1740 cm^{-1} assigned to stretching vibrations of the C=O bond sharply decreases after modification of PE with ETS-32 (Fig. 6). This is probably due to reaction of tetraethoxysilane with oxygen-containing free radicals formed by thermomechanical degradation of polyolefins. The data agree with the results of the study of thermochemical modification of polyolefins with polyorganosiloxanes.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Composite Fibers Based on Chitin

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received January 30, 2001

Abstract—Composite fibers containing chitin and cellulose ethers (methyl, hydroxyethyl, and hydroxypropyl cellulose) and also chitin and polyvinylpyrrolidone were prepared. The effect of the ratio of system components and also the molecular weight of polyvinylpyrrolidone on the deformation-strength characteristics of the composite fibers and their supramolecular organization was studied.

Chitin is nitrogen-containing derivative of cellulose in which one hydroxy group of the pyranose ring is substituted by the acetamide group. Similar to cellulose, chitin is capable of forming fibers. However, high friability of chitin fibers restricts their use; therefore, chitin fibers are not produced commercially throughout the world. Chitin is well crystallized, and brittle failure of chitin fibers is caused by precisely this feature [1]. Partial heterogeneous deacetylation of chitin results in an increase in its structural nonuniformity and complicates crystallization of macromolecules in production of fibers, which increases their elasticity [2]. At the degree of deacetylation of chitin equal to or lower than 0.30 the fiber is tied and retains up to 40% of the initial strength. However, the use of additional heterogeneous base deacetylation in the production of chitin fiber, decreasing its fiber-forming ability, is not appropriate.

It is well known that the structural nonuniformity of the systems used for production of polysaccharide fibers hampers crystallization of macromolecules. This results in an increase in the elasticity of the fibers. The structural nonuniformity of oriented chitin can be reached by both its chemical modification and incorporation of modifying additives into the fiber.

The method of improvement of physicomechanical characteristics of fibers by their production from a polymer blend has attracted considerable attention [3, 4]. For example, on addition of only 0.1–1.0% of copolymer of acrylonitrile with methyl acrylate (95 : 5) to polyamidobenzimidazole the strength of the fiber increases by 5–13% [5].

Polymers can be blended by mixing their melts or solutions. Since the temperature of degradation of polysaccharides (180–200°C) is lower than their melting point (450–500°C), blends of polysaccharides with various polymers can be obtained only by mixing their solutions. In choosing polymer additives to chitin solutions it is important that these additives should be compatible with chitin in the solution. These additives can be cellulose ethers: methyl, hydroxyethyl, and hydroxypropyl cellulose, having the similar structure and different side substituents, and also polyvinylpyrrolidone (PVP).

Polyvinylpyrrolidone is a unique polymer widely used in industry and medicine. The main features of this polymer are ability to complex formation and solubility in water and organic solvents. It is well known that grafting of PVP to cellulose fibers improves their elasticity, increases hygroscopicity and dyeing ability, decreases shrinkage, and increases laundering resistance of clothes. Addition of PVP as a modifier to fibers produced from polymers able to form hydrogen bonds also improves their deformation-strength characteristics. For example, in modification of poly-*p*-phenylene terephthalamide fibers by addition of PVP to the spinning solution the fiber elongation at break, strength, aging resistance, fire resistance, etc. significantly increase [6]. In addition, prolonged boiling of the fibers modified with PVP does not result in its removal; the characteristics of fibers remain the same.

Methyl cellulose, converted to gel at 80°C, and hydroxypropyl cellulose, coagulating at 60°C, must remain in fibers and hamper crystallization of chitin in fiber formation.

Therefore, it seemed appropriate to modify chitin fibers by both above cellulose ethers and PVP and also to establish the effect of modifying additives on the structure and characteristics of the composite fibers.

1070-4272/01/7407-1211$25.00

EXPERIMENTAL

We used dimethylacetamide (DMAA) dehydrated by boiling with P_2O_5 and distilled in a vacuum, fraction with bp 42°C (7 mm Hg); *N*-methylpyrrolidone (*N*-MP) dehydrated by storage over NaOH and distilled in vacuum, fraction with bp 81°C (12 mm Hg); lithium chloride crystal hydrate dehydrated at 400°C; chitin produced from North Sea shrimp[1] with an ash content of 0.03%, protein-free, degree of polymerization (DP) 1350, molecular weight *M* 275 000; methyl cellulose (MC) with DP of 980 and degree of substitution 0.94; hydroxyethyl cellulose (HOEC) with DP 1220 and the substitution modulus (SM) 1.98; and hydroxypropyl cellulose[2] (HOPC) with DP 1050 and SM 3.0.

Polyvinylpyrrolidone with M_w 8×10^3, 12×10^3, 35×10^3, 8×10^5, and 15×10^5 was produced by radiation-induced polymerization.

The fiber was formed under the standard conditions on a PIFV-01 setup using a dosing syringe and a spinneret (1/0.4). The precipitation bath was a mixture of ethanol and ethylene glycol at the volume ratio of 50 : 50, T = 20°C. The plasticization bath was a mixture of 2-propanol and water at the volume ratio of 80 : 20, T = 50°C.

The fiber was washed to remove lithium chloride to a total absence of chloride ion in the wash water. The fiber was dried at 105°C.

The mechanical tests were carried out on an Instron-110 universal tearing machine. The stress–strain diagrams were obtained for a 50-mm sample at the loading rate of 5 mm min^{-1}. Before testing the samples were kept in a desiccator for 24 h at a relative humidity of 65%.

Chitin and modifying polymer additive were dissolved separately. The solvent was a mixture of DMAA and *N*-MP at the ratio of 50 : 50, containing 5% of lithium chloride. The polymer concentration in the solution (both chitin and modifier) was 3%. To obtain the required solutions, a calculated amount of the modifier was added to the chitin solution. The mixture was thoroughly mixed, degassed in a vacuum, and used in forming of the fiber.

The X-ray studies were carried out on a DRON-2 diffractometer and in an RKV-86 camera using CuK_α radiation filtered with Ni.

[1] Sevtekhrybprom Research and Production Association.
[2] Polimersintez (Vladimir).

Studying the dependence of the intrinsic viscosity of chitin on the DMAA : *N*-MP ratio and the content of lithium chloride in the solvent showed [2] that at the ratio of 50 : 50 and 5% LiCl the intrinsic viscosity has a minimum, and a 3% solution of chitin in this solvent has the optimum rheological characteristics for forming the fiber. Therefore, in the study we used this composition of the solvent. All types of the modifiers in hand are readily soluble in this solvent, and their solutions form transparent mixtures with equiconcentration solutions of chitin.

The cellulose ethers used in the study are nontoxic, have close DPs, but differ in the structure of substituents. At the degree of substitution of 0.94 methyl cellulose contains, on the average, two unsubstituted hydroxyls in each pyranose ring; therefore, the ether is structurally uniform. At SM 2 hydroxyethyl cellulose contains substituents of various length, since in production of HOEC ethylene oxide forms short side chains with DP 2–3. In this case, the number of hydroxyls in the substituted pyranose unit remains equal to 3, since each hydroxyethyl substituent contains one hydroxyl. Therefore, HOEC is structurally nonuniform and able to form hydrogen bonds with both the atom of the acetamide group of chitin and the hydroxy group of the pyranose fragment. The latter conclusion refers all the more to HOPC since hydroxypropyl group is longer and propylene oxide tends to polymerize to a greater extent in etherification of cellulose. We believed that these features of the structure of cellulose ethers would allow control of the elastic characteristics of the composite fibers.

It should be noted that the fibers produced from nonmodified solutions of chitin are characterized by the tensile strength of 300 MPa and the elongation at break of 1.9%.

Figures 1a and 1b present the dependences of the strength and deformation characteristics of composite fibers produced from chitin and cellulose ethers on their composition. It is seen that the largest modifying effect is observed for MC. For example, addition of MC to chitin solution in the amount of up to 1.0% increases the fiber strength to 834 MPa and its elongation to 4.5%. Throughout the studied range of compositions (from 0.5 to 10% of MC) the strength of the modified fiber and the elongation at break are noticeably higher than those of the initial fiber. It is likely that the presence of methyl group, unable to form hydrogen bonds, in MC considerably hinders packing of macromolecules in the crystals, which increases the elongation at break and also favors orientation strengthening of the fiber.

Substitution of hydroxyethyl group for methyl group in the modifier and an increase in its content somewhat decrease the strength characteristics of the resulting fibers. The structural nonuniformity typical for HOEC results in appearance of defective supramolecular structure. The fibers have lower strength but at a low content of HOEC are characterized by a higher elasticity. The elongation at break of the fiber at a 2.5% content of HOEC exceeds that of the initial fiber by a factor of 2.

Addition of HOPC as a modifier, in which substituents vary in the unit length to a greater extent than in HOEC, increases the fiber strength to 450 MPa and the elongation at break to 4%. With the use of this modifier, variation of its content in the systems does not noticeably affect the strength characteristics of the modified fibers. It seems likely that the presence of substituents of various length hampers ordering of the fiber structure even at the minimum addition of HOPC, which acts as interfibrillar plasticizer at the microlevels of the supramolecular organization of system 2.

The results of testing of composite fibers produced from chitin–PVP blends are presented in Figs. 2a and 2b. It is seen that addition of PVP improves the deformation and strength characteristics of chitin fibers. Small (1–2.5%) additions of PVP provide the greatest effect on the mechanical characteristics of the fiber. On addition of 2.5% of PVP with M = 12 000 to the spinning solution the tensile strength increases by a factor of 2, the modulus of elasticity, by 40%, and the relative elongation, by a factor of 3.5 in comparison with the fiber produced from straight chitin. At the PVP concentration in the spinning solution above 2.5% all mechanical characteristics of the fiber are impaired. This trend is observed for PVP of any studied molecular weight.

Considering the effect of molecular weight of PVP at the same concentration in the spinning solution (Fig. 3), the optimum molecular weight is 12.0×10^3, at which the strength is maximal and the deformation of modified fibers is high. The modulus of elasticity of the fibers in the range of the molecular weights of PVP from 12.0×10^3 to 8.0×10^5 does not noticeably vary and is in the range 3–4 GPa. At the extreme values of M (8.0×10^3 and 1.5×10^6) the modulus of elasticity decreases to 1.5–2.5 GPa. This dependence of the mechanical characteristics of the fiber on the molecular weight of PVP is apparently caused by formation of microheterogeneous supramolecular structures even in the spinning solution of chitin with PVP of low and moderate molecular weights. It does not form an individual phase, is uniformly distributed along the solution bulk, exhibits the plasticizing effect, and hampers crystallization of chitin macromolecules in formation of fiber. It is apparent that macromolecular PVP, having a similar effect, favors to a greater extent amorphization of the fiber structure,

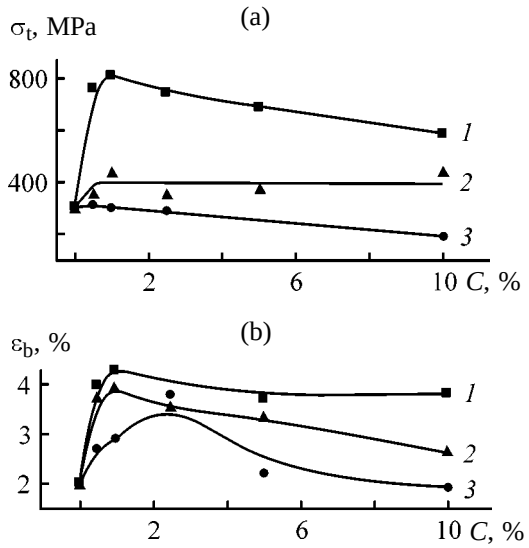

Fig. 1. (a) Tensile strength σ_t and (b) elongation at break ε_b of chitin fibers as functions of modifier concentration C. (*1*) MC, (*2*) HOPC, and (*3*) HOEC.

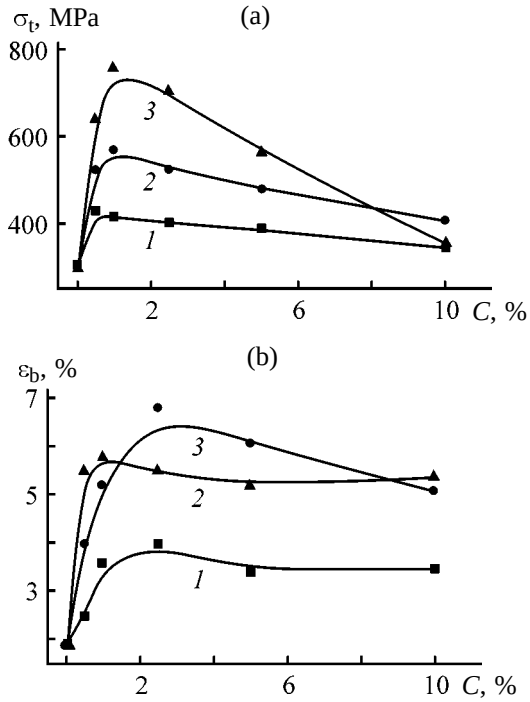

Fig. 2. (a) Tensile strength σ_t and (b) relative elongation at break ε_b of chitin fiber as functions of concentration C of PVP with various molecular weights. Molecular weight: (*1*) 800 000, (*2*) 35 000, and (*3*) 12 000.

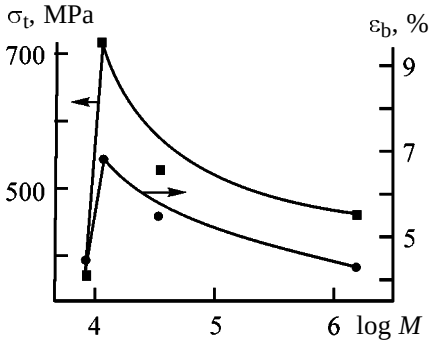

Fig. 3. Tensile strength σ_t and relative elongation at break ε_b of chitin fiber as functions of PVP molecular weight *M*. PVP concentration 2.5%.

which results in deterioration of mechanical characteristics of modified fibers.

The X-ray studies of the fiber produced from straight chitin and composite fibers with addition of cellulose ethers and PVP in the amount of 0.5–2.5% (PVP with molecular weight of 12.0×10^3 and 35.0×10^3) show that the fiber retains its highly ordered structure characteristic for nonmodified chitin fibers. In the diffraction patterns recorded along the fiber axis (meridian) there are reflections at $2\theta = 17°$ and 26° caused by the interplanar spacings of 5.02 and 3.36 Å, respectively. In the diffraction patterns of the fibers containing PVP and MC the reflection at $2\theta = 9°$ is somewhat blurred. In the diffraction patterns recorded across the fiber (equator) there are sharp reflections at $2\theta = 9°$ and $2\theta = 19°36'$ caused by the interplanar spacings of 9.8 and 4.45 Å, characteristic for the initial chitin fiber.

The results of these X-ray studies show that the modifiers do not form individual phases at a concentration of up to 2.5%. It is apparent that addition of this amount of the modifier only weakly affects the crystal packing of chitin in the fiber. The improvement of deformation and strength characteristics of the composite fibers may be due to plasticization of the system on the interfibrillar level.

The electron-microscopic studies of the composite fibers revealed distinctions in the surface morphology. The composite fibers have a smoother and denser surface than the fiber from straight chitin. In shelling of these fibers we found no pores and cavities.

CONCLUSIONS

(1) The composite fibers of chitin with cellulose ethers and polyvinylpyrrolidone were produced. It was shown that the amount of the modifier, molecular weight of polyvinylpyrrolidone, and also the degree of substitution and chemical structure of the substituent in cellulose ethers affect the deformation-strength characteristics of the composite fibers.

(2) The largest positive effect is observed at a 1.0–2.5% content of the modifier.

(3) Methyl cellulose and polyvinylpyrrolidone with $M = 12\,000$ are the best modifiers.

ACKNOWLEDGMENTS

We are grateful to V.N. Ushakova for the samples of polyvinylpyrrolidone and also to O.V. Kudasheva for the electron-microscopic studies.

Received October 25, 2000; in final form, April 2001

Abstract—Copolymerization of alkali metal salts of acrylamido sulfonic acids with acrylamide and acrylonitrile in concentrated aqueous solutions was studied. The influence of the chemical nature, ratio, and physical interactions of monomers on polymerization and on the intrinsic viscosity of the copolymers was examined.

Water-soluble sulfonic acid copolymers show considerable promise for various branches of engineering, in particular, for water treatment, paper production, and other processes involving changes in the viscosity, structure (thixotropy), and stability of water-based colloidal systems. Functional sulfo groups in the copolymers ensure stability of their performance at high temperatures in the presence of cations of various valences, virtually in the entire pH range.

Recently new interesting procedures were developed for preparing various acrylamido sulfonic acids such as 2-acrylamido-2-methylpropanesulfonic acid and 4-acrylamido-4-methylsulfolane-3-sulfonic acid (AMPSA and ASA, respectively) [1, 2]. However, their copolymerization with such water-soluble monomers as acrylonitrile (AN), acrylamide (AA), and others is studied insufficiently. (Co)polymerization is usually studied at low monomer concentrations, whereas from the practical viewpoint it is more interesting to study relatively concentrated systems. Such systems often show deviations from the classical theory, which are due to strong intermolecular interactions, occlusion, and gel effect, often making the process diffusion-controlled even in the early stages of the reaction.

In this work we studied the features of copolymerization of potassium salts of AMPSA and ASA with AA and AN in concentrated aqueous solutions.

EXPERIMENTAL

In synthesis of polyelectrolytes we followed a typical protocol of radical polymerization in aqueous solution, initiated with $K_2S_2O_8$ [TU (Technical Specifications) 38.103270–87] at 60°C. For the synthesis we used a 30% aqueous solution of AA (TU 2433-004-07507802) prepared by biocatalytic hydration of acrylonitrile and containing no impurities of other monomers; AN [GOST (State Standard) 11097–86]), main substance content 99.9%; laboratory samples of AMPSA (Chair of Technology of Polymeric Materials, Yaroslavl State Technical University), main substance content 97.8% (2.2% *tert*-butylacrylamide); ASA (Chair of Technology of Organic Substances, Dzerzhinsk Branch, Nizhni Novgorod State Technical University), main substance content 96.9%, sulfuric acid content 1.8%; as chain-terminating agent we used diisopropylxanthogen disulfide (diproxyd, TU 6-14-21–75); the other chemicals were of analytically pure grade.

Polymerization was performed in an inert gas atmosphere in a temperature-controlled glass reactor equipped with a thermometer, an electric power-driven stirrer, an inlet for feeding nitrogen, and a sampler. The reactor was charged with an aqueous phase containing AA and amido sulfonic acid preliminarily neutralized with KOH to pH 7.0–7.2 (in a neutral medium polymerization of sulfonic acids, which is too fast in acidic solutions [3], occurs with a controllable rate, and a labor- and time-consuming stage of neutralization of the polymerization product is avoided). AN with dissolved diproxyd was fed in a nitrogen flow. After the required temperature was attained, $K_2S_2O_8$ was added, and this moment was considered as the start of the reaction. Samples were taken at regular intervals, transferred into ampules,

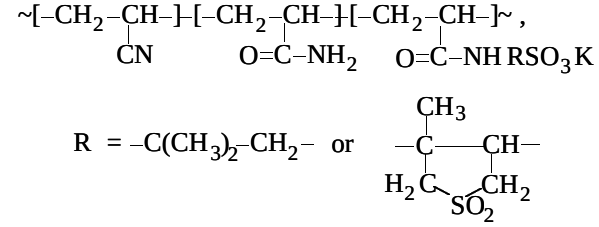
and stabilized with hydroquinone. The total conversion of the monomers was determined by the procedure in [4], based on determination of bromine that added to the double bonds of the unchanged monomers; the content of unchanged monomers was also monitored chromatographically. Polymerization was performed to a ≥98% conversion. (Co)polymers of the general formula



were obtained.

The intrinsic viscosity of the (co)polymers was determined with a Ubbelohde viscometer in a phosphate buffer solution of pH 6.86 (GOST 8.135–74) at 25°C.

Table 1. Apparent rate constants k'_{app} of polymerization, reaction orders with respect to monomers *m*, and reliability of approximation by the logarithmic equation R^2

Initial monomers*	k'_{app}, $l^{m-1}\ mol^{1-m}\ s^{-1}$	*m*	R^2
AMPSA	4.60×10^{-4}	13.1	0.955
AA–AMPSA	2.50×10^{-8}	11.7	0.952
AA–AN–AMPSA	1.19×10^{-7}	9.1	0.759
ASA	8.36×10^{-2}	7.8	0.940
AA–ASA	8.59×10^{-6}	6.8	0.958
AA–AN–ASA	3.52×10^{-5}	5.1	0.960

* Amido sulfonic acids, being strong acids, at pH 7 totally exist in the form of K salts.

To efficiently control the polymer synthesis at high concentrations of the initial mixture, we studied the kinetics of copolymerization of amido sulfonic acids (in the form of K salts) with AA and AN. The kinetic curves are shown in Fig. 1. To estimate the variation of the kinetic parameters, we performed the mathematical treatment of the dependences using the simplified equation for the polymerization rate

$$V_p = k'_{app}[M]^m,$$

where $k'_{app} = k_{app}[I]^n$ at [I] = const.

By taking the logarithms we obtain a linear regression with the slope equal to the reaction order with respect to the monomers; this straight line intercepts the ordinate in the point $\log k'_{app}$. The regression parameters calculated by the least-squares procedure using the MS Excel program are listed in Table 1. It is seen that the values of k'_{app} for all the monomeric mixtures with ASA are higher by a factor of 10^2 than those for the mixtures with AMPSA. This fact is apparently due to the capability of AMPSA for chain transfer to the monomer [5]. With a good, on the whole, approximation of the experimental data (Table 1) by a linear function (Fig. 2 shows an example of regression for the ASA–AA mixture; for the other mixtures the pattern is similar), high reaction orders with respect to the monomers show that the reaction is very sensitive to their concentration and to the nature of the monomer mixture, since polymerization of these monomers in concentrated solutions does not fit in the classical scheme [notably, under these conditions, attempts to choose the required amount of the inhibitor (sodium nitrite, hexachloroquinone, stable iminoxyl radical) to study the reaction kinetics with a scanning calorimeter led either to immediate occurrence of the gel effect or to total inhibition of the reaction]. Apparently, polymerization occurs with the gel effect practically from the very beginning. It is known that under such conditions all the kinetic parameters are variable [6], especially the rate constants of chain termination (and "apparent" values of the reaction orders can be relatively high).

According to published data [7, 8], the reaction order of radical (co)polymerization in dilute systems with respect to AMPSA, AA, and many other acrylic monomers is close to 1.5. This value was used to calculate the apparent rate constants of copolymerization from the experimental data. However, the resulting values did not agree with the real distribution of the

reaction mixtures with respect to the initial reaction rate (Fig. 3).

Figure 3 shows the dependences of the reduced polymerization rate V_r on the monomer conversion for the studied compositions of the monomer mixtures. The growth of V_r and the maxima in the curves at 5–15% conversions suggest occurrence of the gel effect practically from the very beginning of the polymerization. Early occurrence of the gel effect may be due to strong intermolecular interactions of the monomers at their high concentration; most probably, copolymerization involves formation of charge-transfer complexes (CTCs). In homopolymerization, dimerization of sulfonic acids (similar to dimerization of unsaturated carboxylic acids [9]) may play a certain role. Thus, at the chosen concentrations of the monomer and initiator the (co)polymerization of the potassium salts of AMPSA and AA even at low monomer conversions is not described by the classical scheme, and the kinetic parameters (Table 1) merely reflect the strong effect of the concentration and ratio of the monomers. Notably, copolymerization of the potassium salts of AMPSA and ASA with AA and especially AN is fast, with a high intensity of the gel effect. An increase in the reaction rate is due to high cross propagation constants and probably to high constant of AA homopolymerization, not complicated by the electrostatic effects in contrast to polymerization of ionized amido sulfonates. At the same time, copolymerization with AN is still faster, although AN is known to be a less reactive monomer. For example, with AA and AN the copolymerization constants are 1.357 and 1.875, respectively [10]. Increased elementary rate constants of addition of monomers to the "foreign" radical may be due to formation of a CTC between sulfo anions and AA or AN, with stronger intermolecular interactions as compared to sulfonic acid dimers. Amide and nitrile groups can undergo protonation in acidic (and neutral) media to form $-(O)C-NH_3^+$ and $-C\overset{+}{\cdots}NH$ moieties [11] acting as Lewis acids toward RSO_3^- (it is known that carboxylate copolymers of AA and AN form strong bonds via these units with negatively charged particles of mineral dispersions [12]). Such reaction mechanism is supported by the total lack of blocks of amido sulfonate units in the microstructure of the polymers [13], whereas their homopolymerization is not fully hindered by electrostatic factors.

Along with increase in the overall reaction rate in copolymerization of amido sulfonates with protonated monomers, the contribution of the chain termination reactions probably decreases owing to decrease in the

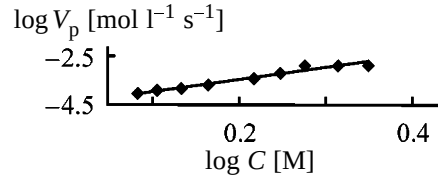


Fig. 2. Polymerization rate V_p as a function of the current concentration of monomers in the reaction mixture C. Molar ratio of monomers: ASA : AA = 11.0 : 89.0.

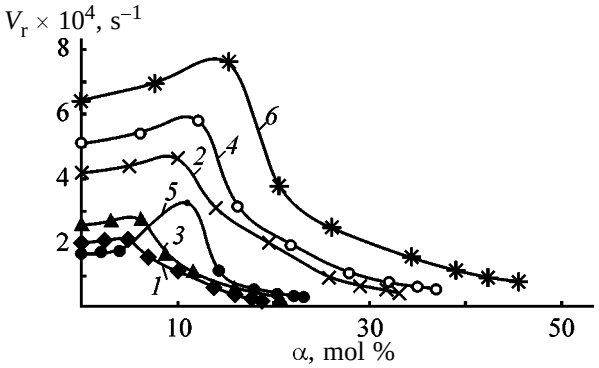

Fig. 3. Reduced rate V_r of (co)polymerization as a function of monomer conversion α.

chain transfer to AMPSA bound in a complex with AA or AN, or to decrease in the AMPSA content. It is known [5] that chain transfer to the monomer plays an important role in radical polymerization of AMPSA, limiting the growth of the molecular weight of the polymer, as clearly seen from the intrinsic viscosities [η] of AMPSA–AN copolymers (Table 2). In the series of AMPSA–AN copolymers, [η] decreases with increasing content of the sulfo monomer in the mixture, despite increase in the content of the ionic groups and decrease in the content of AN units in the copolymer, resulting in compaction of the macromolecular coils in solution. Thus, presumably, the molecular weight of AMPSA copolymers is considerably higher than that of the homopolymers prepared under the same conditions.

The copolymerization rate, k'_{app}, and the intensity of the gel effect in synthesis of ASA (co)polymers are appreciably higher, i.e., with ASA the chain transfer to the monomer does not occur or occurs to a considerably lesser extent than with AMPSA. This conclusion is confirmed by the dependence of the intrinsic viscosity of the synthesized ASA copolymers on the composition of the monomer mixture (at 100% conversion).

For AMPSA–AA–AN terpolymers, at a constant content of AMPSA units, [η] decreases with increasing content of AN. For AMPSA–AA copolymers in a broader composition range [η] passes through a max-

imum, which is due to the simultaneous effect of several factors (decrease in the molecular weight and increase in the polyelectrolytic effect with increasing content of sulfo groups). For binary and ternary ASA copolymers, in the examined composition range, the intrinsic viscosity increases with increasing content of sulfo groups.

CONCLUSIONS

(1) Radical copolymerization of potassium salts of 2-acrylamido-2-methylpropanesulfonic and 4-acrylamido-4-methylsulfolane-3-sulfonic acids with acrylamide and acrylonitrile at initial concentrations of the monomer mixtures exceeding 0.2 M occurs with an intense gel effect, which is confirmed by the copolymerization kinetics and by the intrinsic viscosity of the resulting polymers.

(2) The intensity of the gel effect depends on the concentration and composition of the monomer mixture; for the case of copolymerization of alkali metal salts of amido sulfonic acids with acrylamide and acrylonitrile, it was explained in terms of formation of complexes with strong intermolecular interactions (charge-transfer complexes of sulfonate anions with protonated monomers).

(3) 4-Acrylamido-4-methylsulfolane-3-sulfonic acid is a more active monomer than 2-acrylamido-2-methylpropanesulfonic acid, which may be due to the low constant of chain transfer to the monomer and increased tendency to complexation with protonated monomers (acrylamide and acrylonitrile) due to the presence in the former of the second center of strong intermolecular interactions ($-SO_2-$).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Variation of Functional Composition of SKEPT Rubber in the Course of Ozonolysis

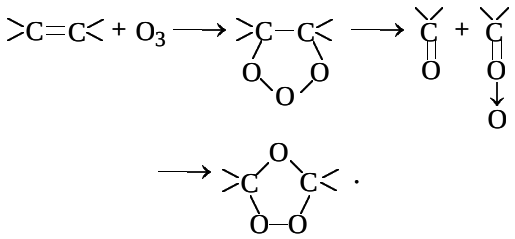
Abstract—Ozonolysis in hexane of ternary ethylene–propylene rubber (SKEPT), accompanied by formation of oxygen-containing groups and intermolecular cross-linking, was studied. These processes become more pronounced when ozonolysis is performed in hexane containing pyridine.

Ternary ethylene–propylene rubbers (SKEPTs), owing to the chemical inertness of their backbone chain, find growing use in production of articles with enhanced resistance to various kinds of degradation. The favorable properties of SKEPT rubbers could be enhanced if their macromolecules contained polar groups. Such groups would enhance the adhesion and cohesion properties of these rubbers and furnish an opportunity for additional modification via these functional groups and hence for significant modification of the properties of the resulting materials.

SKEPT rubbers contain double bonds in pendant chains. Ozonolysis of double bonds and subsequent transformations can principally be regarded as a route of chemical modification of the pendant fragments. The major advantage of such an approach is that ozonolysis does not require catalysts and high temperatures and pressures; furthermore, no waste to be utilized is formed.

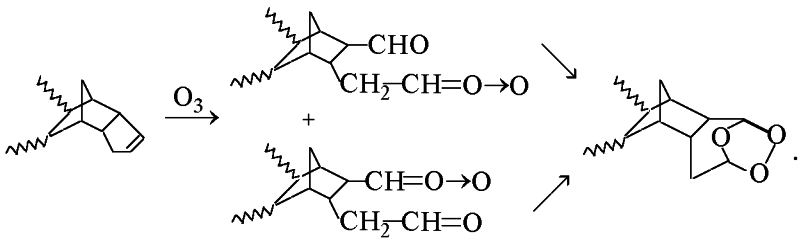
Ozonolysis of double bonds involves a sequence of transformations: 1,3-dipolar addition of ozone to double bonds to form 1,2,3-trioxolanes, their decomposition to carbonyl compounds and carbonyl oxides, and 1,3-dipolar cycloaddition of carbonyl oxides to give 1,2,4-trioxolanes [1–3]:



The synthetic advantage of ozonolysis is that the reaction intermediates, carbonyl oxides and carbonyl compounds, can be scavenged by various chemical agents, which allows direct transformation of a C=C double bond into complex functional groups. These possibilities were demonstrated in [4] for ozonolysis of rubbers containing double bonds in the backbone chain as example.

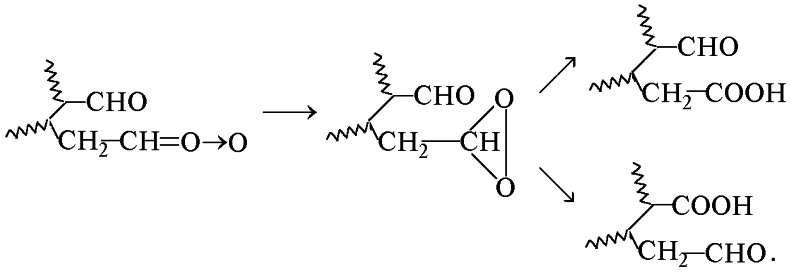
In this work we studied the functional composition of SKEPT rubber prepared with participation of the third monomer, dicyclopentadiene, and subjected to ozonolysis under various conditions.

Initially we performed ozonolysis of SKEPT rubber in a chemically inert solvent, hexane. We expected that ozonolysis in this case would involve no side processes and yield 1,2,4-trioxolanes as final products:



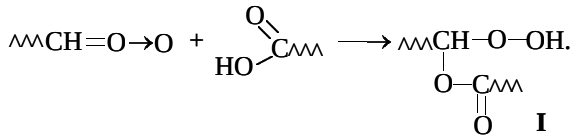
1070-4272/01/7407-1220$25.00 © 2001 MAIK "Nauka/Interperiodica"

However, actually the above transformation was not the sole process. In the course of ozonolysis the solution viscosity increased, suggesting occurrence of intermolecular reactions. Probably, carbonyl oxide (or aldehyde) groups of one macromolecule react with aldehyde (or carbonyl oxide) of another. Such reactions were observed previously in ozonolysis of SKEPT rubber prepared with ethylidenenorbornene as the third monomer [5]. However, in our case changes in the functional composition were more complex. We found that ozonolysis was accompanied by formation of carboxy groups (Fig. 1). This fact suggests that the intermediate carbonyl oxides undergo one more transformation, namely, isomerize into dioxiranes which subsequently either transform into carboxy groups [1, 2] or oxidize the adjacent aldehyde group into carboxy group [6]:

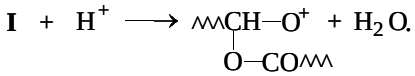


The factor favoring such transformation is that formation of 1,2,4-trioxolane requires a turn of the aldehyde and carbonyl oxide groups formed from decomposition of the primary ozonide by 180° relative to each other, which is impeded by the conformational rigidity of the norbornene moiety. The increased lifetime of carbonyl oxides facilitates side reactions involving them. Isomerization of the dioxirane moiety into the carboxy group and oxidation of the aldehyde group with the dioxirane probably occur by the latent radical mechanism ensuring high product yield [7].

The amount of carboxy groups formed in the course of ozonolysis of SKEPT rubber initially grows and then decreases with time (Fig. 1). It is known [1–3] that carboxylic acids readily react with carbonyl oxide groups to form acyloxy hydroperoxides:

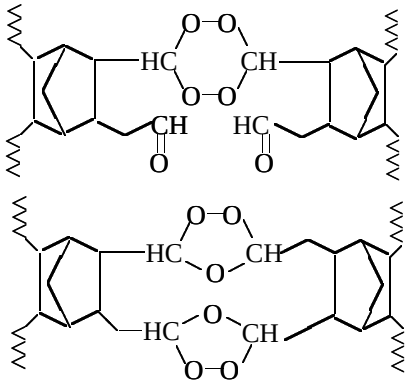


Experimentally we did detect the hydroperoxide groups, but they disappeared already within 15 min after the start of the ozonolysis.The increased basicity of the hydroperoxy group due to α effect [8] results in its relatively facile acid-catalyzed cleavage:



The resulting O-centered electron-deficient intermediates usually undergo deprotonation to form acid anhydrides. Note that ozonolysis of SKD butadiene rubber in the presence of acetic acid allows quantitative preparation of succinic acis [9].

It was already noted that ozonolysis of SKEPT rubber is accompanied by increase in the solution viscosity. The gel remaining after removal of the solvent shows unique properties: It remains unchanged after prolonged storage in chlorinated, aromatic, and saturated hydrocarbons, and also in concentrated nitric and sulfuric acids. The latter fact gives insight into the nature of intermolecular bonds formed in the course of ozonolysis of SKEPT rubber. If these bonds were formed solely by intermolecular reactions of carbonyl oxide and carbonyl groups, i.e., if the structures like



were formed, the ozonolysis product would hardly be resistant to concentrated acids, since acetal derivatives are unstable in acid solutions [10]. The high acid resistance of the ozonolysis products suggests partial

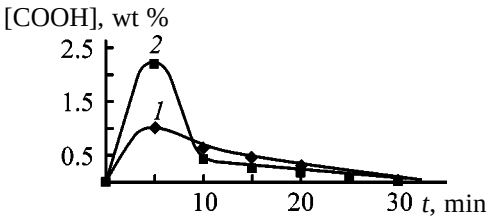


Fig. 1. Content of carboxy groups [COOH] as a function of time *t* in ozonolysis of a 1% solution of SKEPT rubber in (*1*) straight hexane and (*2*) hexane containing an equimolar amount of pyridine relative to the multiple bonds.

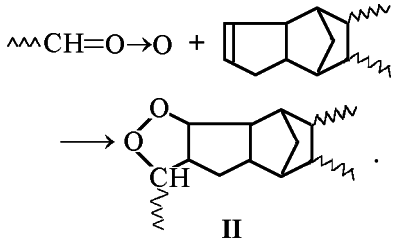
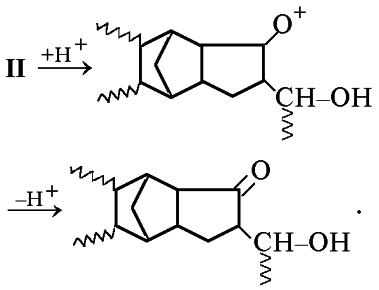
formation of intermolecular bonds by reaction of the carbonyl oxide group of one molecule with the C=C double bond of another, occurring as 1,3-dipolar cycloaddition:



II

The acid-catalyzed transformations of the resulting functional groups should not be accompanied by cleavage of links between separate macromolecules

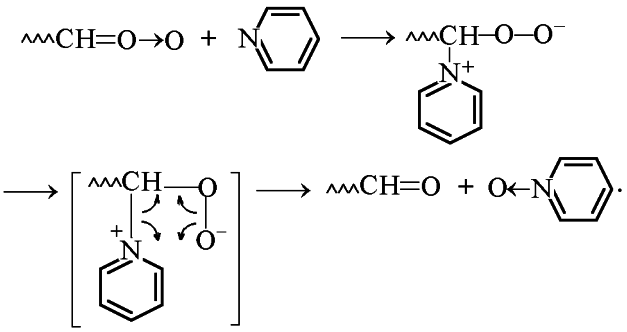


Thus, ozonolysis of SKEPT rubber in an inert solvent, hexane, involves a complex reaction pattern with formation and disappearance of carboxy and hydroperoxy groups; the reaction yields a vulcanization product with a high chemical stability. This fact is of practical interest, since surface treatment with ozone of rubber articles fabricated using SKEPT rubber may enhance their performance. However, ozone vulcanization prevents purposeful use of functional groups generated by ozonolysis in the subsequent modification of SKEPT rubber.

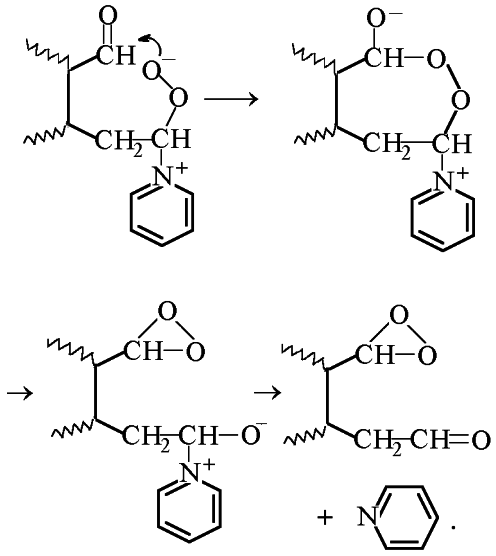
To prevent ozone vulcanization, in subsequent experiments we performed ozonolysis of SKEPT rubber in hexane in the presence of pyridine, since it is known [1–4] that pyridine is an effective agent for transformation of carbonyl oxides into carbonyl compounds. Since in such transformation the carbonyl oxide groups disappear, we could expect that the presence of pyridine would prevent cross-linking of macromolecules.

However, our experiments on ozonolysis of SKEPT rubber in hexane in the presence of pyridine gave a quite opposite result. In the presence of pyridine, carboxy groups are formed at a higher rate (Fig. 1), and their maximal concentration reaches a high level. The rate of formation of hydroperoxy groups in the first stage also increases, and subsequently these groups disappear. Ozonolysis in the presence of pyridine is accompanied by more intense gelation.

Formation of pyridine *N*-oxide in reaction of pyridine with carbonyl oxides can be represented as decomposition of the intermediate bipolar ion via a strained four-membered transition state:



A specific feature of these systems is that the carbon atom of the adjacent carbonyl group becomes accessible for attack by the anionic center of the bipolar ion, which can result in formation of a weakly strained seven-membered ring:



Decomposition of the seven-membered bipolar ion can yield aldehydodioxiranes. The dioxirane group can subsequently transform into the carboxy group. Pyridine in this process is the catalyst. Pyridine *N*-oxide exhibiting strong nucleophilic properties [11–13] can behave similarly.

For the above transformations to occur, the carbonyl and aldehyde groups in the initial molecule should be located close to each other. In cases when in the course of ozonolysis the carbonyl oxide and carbonyl groups are separated in space (e.g., in ozonolysis of SKI and SKD rubbers, and also of SKEPT rubber with ethylidenenorbornene), pyridine practically quantitatively transforms the carbonyl oxide groups into carbonyl groups [4].

Ozonolysis of SKEPT in hexane in the presence of pyridine resulted in formation of the vulcanization product, so that further transformations of the arising functional groups were impossible.

With the aim to obtain soluble ozonolysis products of SKEPT rubber, we attempted ozonolysis in the presence of ethanol. Alcohols are known to scavenge carbonyl oxides [1–4] with formation of alkoxy hydroperoxides:

$$\sim\!\!\sim CH{=}O{\rightarrow}O + HOR \longrightarrow \sim\!\!\sim \underset{\displaystyle OR}{\overset{\displaystyle |}{C}}H{-}OOH.$$

The interest in such ozonolysis conditions was due to the fact that the reaction of carbonyl oxides with alcohols can occur by the molecular mechanism. Figure 2 schematically illustrates interaction of the frontier orbitals of the carbonyl oxide and hydroxy groups. It is seen that the concerted process is allowed by the orbital symmetry rules.

Indeed, ozonolysis of SKEPT rubber in the presence of alcohol occurs with no signs of intermolecular cross-linking. Figure 3 shows how the intrinsic viscosity of SKEPT rubber solutions varies in the course of ozonolysis in the presence of ethanol. The intrinsic viscosity remains constant for a long time. After exhaustion of all the double bonds, the intrinsic viscosity starts to slowly decrease; we believe that this is due to ozone-initiated oxidation of the saturated chain of the rubber. The radical centers arising in saturated fragments should inevitably initiate radical β-decomposition reactions involving carbon–carbon bonds, with the resulting decrease in the molecular weight of the rubber and in the intrinsic viscosity.

Ozonolysis in the presence of alcohol is accompanied by gradual increase in the amount of hydroperoxy and carboxy groups (Fig. 4); their content does not decrease up to complete exhaustion of the C=C double bonds. Oxidative degradation of the rubber is accompanied by active accumulation of carboxy groups. Simultaneously, the content of hydroperoxy groups decreases. The observed trend is consistent with the acid-catalyzed mechanism of their decomposition.

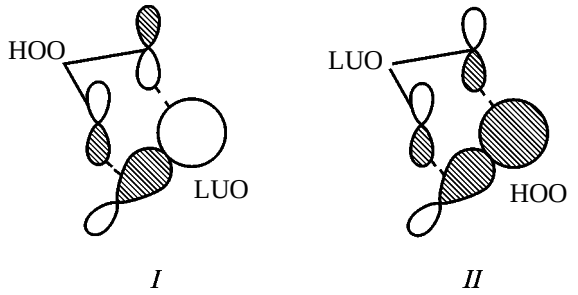


Fig. 2. Scheme of interaction (*I*) of the highest occupied orbital (HOO) of carbonyl oxide with the lowest unoccupied orbital (LUO) of the OH bond and (*II*) of LUO of carbonyl oxide with HOO of OH bond.

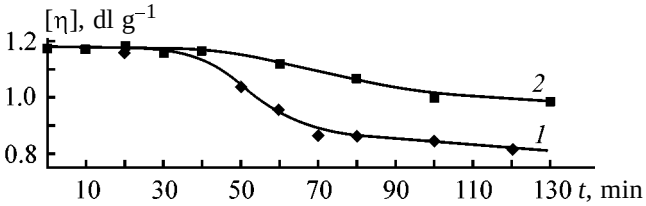

Fig. 3. Intrinsic viscosity [η] as a function of time *t* in the course of ozonation of (*1*) 1% and (*2*) 2% solutions of SKEPT rubber in hexane with addition of ethanol. Molar ratio of double bonds and alcohol 1 : 1; the same for Fig. 4.

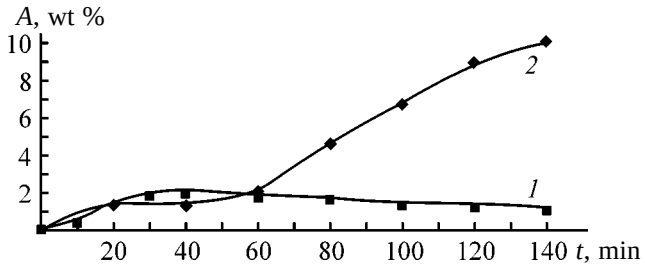

Fig. 4. Accumulation *A* of (*1*) hydroperoxy and (*2*) carboxy groups in ozonolysis of 1% solution of SKEPT rubber in hexane with addition of ethanol. (*t*) Time.

The advantage of the ozonolysis of SKEPT rubber in the presence of alcohol is formation of a large amount of hydroperoxy groups. Hence, a possibility arises of performing radical transformations with their participation (e.g., of preparing block copolymers of SKEPT rubber with various monomers).

The following bands appear in the IR spectra of SKEPT rubber ozonized in the presence of ethanol:

a broad band at 3350–3550 cm^{-1} corresponding to associated OH groups; a band at 1718 cm^{-1} ($\nu_{C=O}$); and bands at 1005, 1040, 1069, and 1100 cm^{-1} assignable to the O–O stretching vibrations. These data confirm the above-discussed reaction patterns.

Thus, it is possible, using ozonolysis, to introduce into the structure of SKEPT rubber alkoxyhydroperoxy, carboxy, and aldehyde groups. We hope that such a substantial change in the functional composition of the rubber will allow development of new routes of its modification.

EXPERIMENTAL

SKEPT rubber (Nizhnekamskneftekhim Joint-Stock Company) contained 35% propylene and 5.8% dicyclopentadiene. Low-molecular-weight impurities and antioxidants were removed by reprecipitation in acetone.

Ozonolysis was performed in a glass bubbler with a porous bottom, charged with a rubber solution in hexane. The process was performed at 15°C. An ozone–air mixture [ozone concentration $(1.5–2.4) \times 10^{-5}$ M] was fed at a rate of 14 $l\,h^{-1}$.

The reaction progress was monitored by variation of the viscosity. Ozonolysis was performed directly in the reservoir of a modified Ubbelohde viscometer with a sealed-in tube for feeding the ozone–air mixture. The intrinsic viscosity $[\eta]$ ($dl\,g^{-1}$) was determined by the Schultz–Blaschke empirical equation [14]

$$[\eta] = (\eta_{sp}/C)/(1 + 0.28\eta_{sp}).$$

In control points, we took samples and calculated $[\eta]$ as $\lim_{C \to 0} \eta_{sp}$. The results of different determinations agreed within 1%.

In the course of ozonolysis we took samples and determined in them the content of carboxy [15] and hydroperoxy [16] groups. The content of available oxygen in the ozonation products was determined by iodometric titration [16].

The IR spectra were taken on a 16 PC FT-IR spectrometer. Samples were prepared as films on KBr.

CONCLUSIONS

(1) Ozonolysis in hexane of SKEPT rubber containing dicyclopentadiene is accompanied by gelation, which is not eliminated by adding pyridine.

(2) Ozonolysis of SKEPT rubber in the presence of alcohol prevents formation of intermolecular bonds. The process is accompanied by formation of ethoxyhydroperoxy, carboxy, and aldehyde groups.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Separation of Styrene–Butadiene Rubbers from Latexes Using Dimethyldiallylammonium Chloride–SO_2 Copolymer

V. N. Verezhnikov, S. S. Nikulin, T. N. Poyarkova, and V. M. Misin

Voronezh State University, Voronezh, Russia

Received March 6, 2001

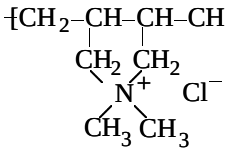
Abstract—The suitability of *N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride–SO_2 copolymer as coagulant for isolating rubber from synthetic latexes was investigated.

Emulsion rubbers are traditionally separated from latexes using inorganic salts under acidification of the system being coagulated with a mineral acid [1]. Though highly efficient, this procedure does not satisfy the environmental requirements because the wastewater generated by emulsion latex production is heavily polluted with mineral salts. They are not degraded at wastewater treatment facilities and are discharged into natural water reservoirs, which results in environmental pollution and salinization of soils and potable water sources. Environmentally promising are salt-free coagulation methods using proteins of different origin [2] and synthetic cationic polyelectrolytes [3] as coagulants. For separation of butadiene–(α-methyl)styrene latexes, a coagulant based on poly-*N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride (PDMDAAC) was proposed [4, 5]. With this cationic polyelectrolyte, coagulant can be used in a small amount of 1.7–5.0 against 180–250 kg t^{-1} of rubber in the case of sodium chloride. This significantly decreases the pollution of production wastewater with mineral salts. Also, PDMDAAC reacts with anionic components of the latex and bounds them chemically, thus decreasing the level of pollution of wastewater with surfactants, as the resulting poorly soluble complexes are deposited onto the rubber crumb being separated from the latex [6].

However, the presence in the rubber of PDMDAAC and/or the products of its reactions with the emulsion system components accelerates vulcanization of rubber stocks [7]. Wide application of PDMDAAC as coagulant on commercial scales will require correction of the rubber stock composition.

Extension of the spectrum of polyelectrolyte-type cationic coagulants and comparative assessment of the efficiency of their coagulation action and the influence on the properties of rubbers separated and vulcanizates thereof are of scientific and practical interest.

In this context, copolymers of *N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride (DMDAAC), in particular, with sulfur(IV) oxide [8, 9]



seem promising. In this work we studied the flocculation effect of the copolymer of DMDAAC with SO_2 (PDMDAAC–SO) in separation of rubber from SKS-30 ARK styrene–butadiene latex and the EPB emulsion polybutadiene latex, as well as the influence of the flocculant on the properties of the rubbers separated and vulcanizates thereof.

We used commercial latex samples. The initial solution of PDMDAAC–SO (44 wt %) was a yellow viscous liquid exhibiting a strongly acid reaction (pH 0.11), evidently, owing to incomplete neutralization of hydrochloric acid formed during synthesis [8, 9].

The intrinsic viscosity [η] (measured in the presence of 2 M sodium chloride suppressing the electrolytic swelling) was equal to 0.056 dl g^{-1}. This small [η] value suggests relatively low average molecular weight of the copolymer.

Separation of rubber was studied as follows. Latex (50 ml) was placed into a coagulation setup and kept at appropriate temperature for 10–15 min, whereupon an aqueous solution of PDMDAAC–SO was introduced under permanent stirring. The resulting crumb was separated from the aqueous fraction (serum), washed with warm (30–40°C) distilled water, and

dried in an oven at 75–80°C. The degree of coagulation was estimated visually, from the transparency of the serum, and gravimetrically, from the amount of the rubber separated from the latex. Complete coagulation in some cases required certain keeping time.

In view of the high acidity of the initial PDMDAAC–SO solution, it was reasonable to elucidate how pH varies with the degree of dilution of the solution so as to decide whether it is necessary to additionally acidify the system to be coagulated, in view of the fact that rubbers are separated in an acid medium [1]. We found (Fig. 1) that pH tends to decrease with decreasing content of PDMDAAC–SO in solutions. The log *C*–pH dependence is linear, which suggests the presence of a free acid in solution. Therefore, the subsequent experiments on separation of rubber were run both with and without additional acidification of the system being coagulated with sulfuric acid.

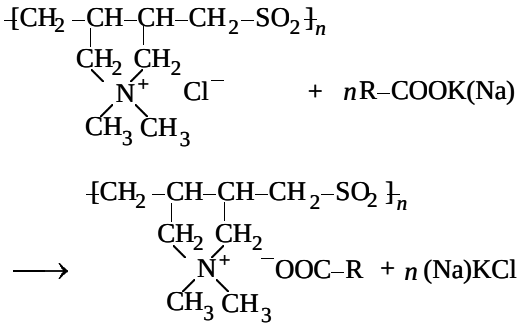
Our experiments showed that the plot of the fraction of the rubber separated from latex vs. the specific amount of the consumed PDMDAAC–SO passed through a maximum (flocculation optimum, Fig. 2). The same pattern of variation was also observed earlier in flocculation of styrene–butadiene latexes by PDMDAAC homopolymer [10]. Complete separation of the rubber from SKS-30 ARK latex is achieved at the amount of PDMDAAC–SO of 18–20, and from EPB latex, of 14–15 kg t^{-1} of rubber.

Addition of sulfuric acid as acidifying agent at the optimal amount of PDMDAAC–SO did not significantly affect the amount of the resulting coagulum. However, at reduced amounts of the flocculant the amount of the added sulfuric acid exerted a major influence. For example, at the amount of PDMDAAC–SO of 9.0 kg t^{-1} of rubber complete separation of the SKS-30 ARK rubber from the latex was achieved at the amount of sulfuric acid of 8.0 kg t^{-1} of rubber. Similar effect was observed for EPB coagulation as well: At the amount of PDMDAAC–SO of 10.8 kg t^{-1} complete coagulation was achieved with sulfuric acid in the amount of 6.0 kg t^{-1} of rubber.

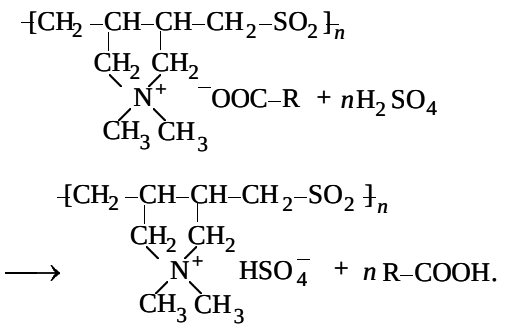
The kinetic relationships in the latex flocculation were studied using the plots of the turbidity τ of dilute ($1 : 10^4$) SKS-30 ARK latex vs. time (Fig. 3). As in the case of the other cationic agents (PDMDAAC [4, 11], 2-methylimidazole [12], and 2,2,4-trimethyl-1,2-dihydroquinoline [13]), the turbidity initially tends to increase and then flattens out, reaching a maximum τ corresponding to formation of large, not degrading in time, floccules. The plots of 1-min turbidity τ_1 characterizing the initial flocculation rate and of the limiting turbidity τ vs. PDMDAAC–SO concentration pass through a maximum (flocculation optimum, Fig. 4). The occurrence of the flocculation optimum established from the kinetic data and the polymer separation curves (Fig. 2) suggest that upon complete

neutralization of particles the subsequent adsorption of the excess polyelectrolyte molecules results in recharging of the particles and restabilization of the dispersion. Similar situation was observed in the case of flocculation of polystyrene [11, 14, 15], styrene–butadiene, and nitrile–butadiene latexes [10] by PDMDAAC–SO, and the recharging was confirmed in all the cases by measurements of the electrokinetic potential of the latex particles.

Chemical analysis of the serum formed after coagulation of SKS-30 ARK latex with PDMDAAC–SO copolymer showed (Table 1) that the dry residues of serum are by a factor of 10–20 smaller than those in the case of separation of rubber with coagulant (sodium chloride). This suggests that the content of soaps of synthetic fatty acids (SFAs), tall oil rosin soap, Leukanol, and other components of the emulsion system in the reference serum significantly exceeds that in the test sample. Reactions of PDMDAAC–SO with emulsifiers can be described by exchange reactions occurring during coagulation of the latex



Under acidification, the resulting product can react with sulfuric acid with elimination of free acids by the following scheme:



The physicomechanical properties of the rubber stocks and vulcanizates based on SKS-30 ARK rubber separated from latex with the use of PDMDAAC–SO and sodium chloride as coagulants are presented in Tables 2 and 3.

The vilcanization kinetic curves (Fig. 5) show that vulcanization of rubber stocks based on SKS-30 ARK rubber separated from latex with PDMDAAC–SO coagulant begins within a shorter period compared to the reference sample separated with sodium chloride. The optimal times of vulcanization for the reference and test samples are close. However, rubber stocks based on rubber separated from latex with PDMDAAC–SO under acidification attain the vulcanization optimum within a shorter period. In the former case, vulcanization can be accelerated either by PDMDAAC–SO cationic coagulant proper or by the products of its reaction with the emulsion system components. Similar relationships were observed for PDMDAAC as coagulant [14]. Physicomechanical tests (Table 3) showed slight improvement of the strength characteristics of vulcanizates based on the

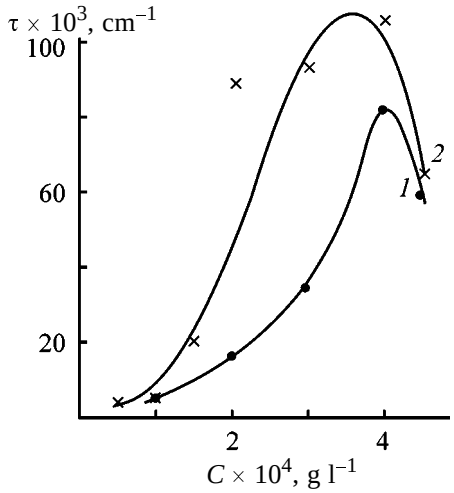


Fig. 4. Variation of (*1*) 1-min and (*2*) limiting turbidity τ with the PDMDAAC–SO concentration *C*.

rubber separated from latex with PDMDAAC–SO compared to the reference sample separated with sodium chloride.

CONCLUSIONS

(1) Rubbers are satisfactorily separated from latexes by the copolymer of poly-*N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride with SO_2 both with and without acidification. Additional acidification of the system being coagulated with aqueous sulfuric acid makes it possible to reduce the coagulant consumption.

(2) The plot of the fraction of the polymer separated, as well as of the kinetic parameters of flocculation, vs. coagulant concentration pass through a maximum (flocculation optimum). Restabilization of the system can be due to recharging of the particle surface after introducing excess flocculant.

(3) Poly-*N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride and the products of its interaction with the emulsion system components accelerate vulcanization.

CHEMISTRY OF FOSSIL FUEL

Analysis of Impurities in Mixtures of West-Siberian Crude Oils

O. Yu. Begak and A. M. Syroezhko

Mendeleev Russian Research Institute of Metrology, St. Petersburg, Russia

Received April 5, 2001

Abstract—The content of B, Mg, Na, Al, P, V, Mn, Cu, Cr, Fe, Ni, Zn, Ag, Br, Sn, I, Ba, W, Pb, and Bi in 24 samples of industrial mixtures of West-Siberian oils was studied using the method of inductively coupled plasma with mass spectrometric registration.

At present the contribution of difficultly extractable oils to the total balance of the oil production of the FSU countries increases significantly, which requires special procedures to improve the oil field efficiency [1]. In most cases such treatment of the oil layer involves the use of corrosion-active compounds, which along with native heteroatomic compounds (S–, O–, N–) and impurities accumulated in the oil cause local and systematic failure of the metallic equipment (tubes, process apparatus, and engines using motor fuels) in the course of the oil production and recovery [2]; therefore, monitoring of such impurities is an urgent problem. In this work we analyzed impurities, including corrosion-active organic and inorganic compounds, in industrial mixtures of the West-Siberian oils processed at the Kirishinefteorgsintez Joint-Stock Company.

EXPERIMENTAL

The initial oil samples (a total of 27) were taken from the Yaroslavl–Kirishi pipeline in July–October 2000. The total content of sulfur in the samples was determined by X-ray fluorescence analysis using a Spectroscan L-F spectrometer with an accuracy of ±0.07–0.09%. The procedure was certified at the Mendeleev Russian Research Institute of Metrology.

The elemental composition of the oils and impurities (metals and nonmetals) was analyzed by mass spectrometry with inductively coupled plasma (ICP-MS) on a VG Plasma Quad PQ mass spectrometer under the standard conditions using imported reference samples.

The content of sulfur in 19 of 27 studied oil samples varies within 1.2–1.67 wt %, whereas in the other eight samples its content is 0.3–1.18 wt %. Such difference in the sulfur content (5.56 times) suggests that the Kirishinefteorgsintez Joint-Stock Company is supplied with crude oil not only by the Surgutneftegaz Joint-Stock Company but also from the other oil fields (with higher and lower content of sulfur as compared with standard oil). Due to technical reasons, the Kirishi Oil-Refining Plant does not process the purchased crude oil separately. As a result, the quality of the light petroleum products, mazut, and asphalt varies in wide ranges, even when the process conditions on the AT and AVT units are strictly followed. This significantly affects operation of the bitumen and reforming units. Moreover, special procedures are necessary to obtain the required quality of the boiler fuel.

The content of 20 impurity elements (ppm) in the oil samples is listed in the table. Only the iodine, chlorine, bismuth, and tungsten ions are detected in all the samples. The other impurities are distributed nonuniformly. Let us analyze the experimental results.

Elements of the main and secondary subgroups of Group I of the periodic system (sodium, copper, and silver). The content of sodium in the oil samples differs significantly from its almost total absence (sample nos. 21, 22, 459) to 450–530 ppm (sample nos. 453 and 463). The highest content of sodium (1200 ppm) was observed for sample no. 17, which is also characterized by abnormal content of the other impurity elements.

As known, significant content of impurity sodium and magnesium ions is typical for the stratal water of the oil fields, and these ions, due to the ion exchange, easily pass into the oil phase forming organic salts. In this case carboxylic acids, phenols, thiophenols, and complex molecules of resins and asphaltenes containing acid groups can act as counterions [3]. These

salts are highly corrosion-active, and their content in the oils supplied to the Oil-Refining Plant should by thoroughly controlled and restricted.

The copper ions were observed only in six samples, and only in sample nos. 1 and 427 its content is significant (12 and 27 ppm, respectively).

Silver was found in nine oil samples, and its content varies from 0.04 (sample nos. 2 and 16) to 11 ppm (sample no. 18).

Elements of the main subgroup of Group II of

the periodic system (magnesium and barium). Only six samples (nos. 1, 20, 419, 459, 463, and 467) contain large amounts of magnesium, and its content varies by an order of magnitude from 12–15 (sample nos. 1 and 467) to 143 ppm (sample no. 459).

Barium was found in 17 samples; its content varies from 0.6–0.9 (sample nos. 463 and 23) to 16 ppm (sample no. 419).

Elements of the main subgroup of Group III of the periodic system (boron and aluminum). Boron compounds were found in sample nos. 1, 2, 16–18, 22, 421, 427, 433, 441, 463, and 467, and its content varies from 33 (sample no. 16) to 706 ppm (sample no. 17).

Significant content of aluminum is typical for sample nos. 1, 17, 18, 427, and 463; the Al(III) content ranges from 12–15 (sample nos. 427 and 463) to 180 ppm (sample no. 17).

Elements of the main subgroup of Group IV of the periodic system (tin and lead). Tin compounds were observed only in sample nos. 2, 19, and 453, and the tin content varies from 2.2 (sample no. 453) to 13 ppm (sample no. 2).

Lead is present in almost all the samples, and its content varies from 0.003 (sample no. 19) to 31 ppm (sample no. 419). The presence of organometallic tin compounds in oils was first found in [4]. It is known that tin and lead form compounds with one or several alkyl or aryl groups [4, 5].

Elements of the main subgroup of Group V of the periodic system (phosphorus and bismuth). Phosphorus compounds were observed in 13 of 24 oil samples. The content of phosphorus varies from 1.1–1.2 (sample nos. 21 and 1) and 0.3 (sample no. 23) to 24–26 ppm (sample nos. 467 and 441). As seen from the published data, in oils phosphorus forms heteroorganic compounds in which it is bound to relatively small hydrocarbon radicals.

It should be noted that phosphorus compounds activate corrosive hydrogenation and failure of steels (increase amount of hydrogen penetrating into the steel), which increases hydrogen corrosion and accelerates failure of the process equipment [6]. Phosphorus ion exhibits the highest activation affect on the hydrogen corrosion of steels: P > S > As > Se > Sb > Te > Bi [7].

Bismuth ions were found in all the samples, and its content varies from 0.11 (sample no. 19) to 5 ppm (sample no. 445).

Elements of the secondary subgroup of Group VI of the periodic system (chromium and tungsten). Chromium compounds were detected only in eight oil samples, its content changes from 0.07 (sample no. 16) to 12 ppm (sample no. 427).

Tungsten was observed in all the samples, its content ranges from 0.12 (sample no. 23) to 23 ppm (sample no. 427).

Elements of the main and secondary subgroups of Group VII of the periodic system (bromine, iodine, and manganese). Bromine ions were found in only eight of 24 oil samples; its content ranges from 1.6–2.0 (sample nos. 421 and 463) to 12–14 ppm (sample nos. 16 and 419).

As known, bromine compounds significantly accelerate the equipment corrosion, and their corrosion activity strongly increases with heating [8]. Bromine can be present in all classes of petroleum compounds, but, as compared with the other halogens, it prefers more complex asphaltene structures [9].

Large amounts of iodine were observed in all the samples studied, which indicates that the crude oils supplied to the Oil-Refining Plant contain significant amounts of corrosion-active iodine compounds. The content of iodide ions in the samples varies from 14 (sample nos. 2 and 19) to 82 ppm (sample no. 17).

Iodine compounds, similarly to bromine and chlorine, strongly accelerate corrosion of petroleum processing equipment, in particular pipelines, especially in the presence of water. It should be noted that iodide ions are the most corrosion-active under other equal conditions. As known [8], aluminum and its alloys even at room temperature react with 0.13% HI (corrosion rate >72 g cm^{-2} day^{-1}), whereas in hydrochloric acid these alloys are considered as materials with decreased stability but suitable for operation (corrosion rate ≤24 g cm^{-2} day^{-1}). Armco iron, cast iron, and carbon steels, which are also the materials with decreased stability but suitable for operation in hydrochloric acid at room temperature, cannot be used in HI because their corrosion rate exceeds 72 g cm^{-2} day^{-1}.

Manganese ions were observed in only 9 of 24 oil samples, and its content varies from 0.4 (sample no. 16) to 2.4 ppm (sample no. 463). It is often considered that the manganese and iron ions, occurring in the oil, substitute the protons in some compounds, especially multifunctional resin molecules.

3*d* transition elements (vanadium, nickel, iron, and zinc). Significant amounts of vanadium compounds were found in sample nos. 1, 2, 16, and 467,

and its content varies within 14–18 ppm. Vanadium compounds are corrosion-active [7, 10]. It was found that about a half of this element in the oil occurs in porphyrin complexes [11].

High content of nickel is typical only for sample nos. 16, 20, and 433. The nickel content varies by a factor of 15: from 2.4 (sample no. 463) to 36 ppm (sample no. 16). Similarly to vanadium, 5–50% of nickel occurs in the oil as porphyrin complexes [12].

Iron was found in seven oil samples, but only in sample nos. 17, 459, and 463 its content is significant and varies from 15 (sample no. 463) to 850 ppm (sample no. 17).

Zinc was determined in only 8 of 24 oil samples, and its content ranges from 1.3 (sample no. 441) to 12–13 ppm (sample nos. 22 and 427).

Significant content of metal and nonmetal impurities in the oil samples can be due to the fact that the stratal water impurity occurring as emulsion in crude oil includes significant amounts of dissolved salts and suspended mineral particles. Moreover, some fraction of metals occurs in the oil proper as complex compounds (chromatography–mass spectrometry data), and certain fraction of impurities appears in the oil with the corrosion products of oil-extraction equipment. Pretreatment of the oil does not ensure complete removal of such impurities, and oil often contains finely dispersed water and colloidal particles. These factors can significantly affect the composition and concentration of impurities in the oil, increasing, in particular, the content of the main rock-forming elements (cations and anions) such as Al, Fe, P, Na, Mg, and Ba and Br and I and thus increasing the corrosion activity of the oil supplied to the Oil-Refining Plant [9].

There are no general trends in the distribution of impurities in the samples studied. At the same time, all the samples studied can be subdivided into three main groups.

The first group (12 oil samples) includes the samples with the highest content of sodium ions (sample nos. 2, 16, 17, 19, 20, 23, 25, 26, 419, 421, 453, and 463). The second most abundant element in the majority (7 of 12) of the samples is iodine, and its content in all the samples is significant. The sodium : iodine ratio in this group does not, as a rule, exceed 10 (in 9 of 12 samples), but in sample no. 463 this ratio is 33, whereas for sample no. 17 with abnormal content of impurities the Na/I ratio reaches 146.

The second group (7 oil samples) includes the samples containing significant amounts of boron (sample nos. 1, 18, 22, 427, 433, 441, and 467), and the next most abundant in this group are sodium or iodine. As a rule, the boron : iodine ratio does not exceed 10, except sample no. 18 (B/I = 14.6).

The third group includes four oil samples (sample nos. 21, 24, 437, and 445); the iodide ions are the main impurity in these samples.

Only sample no. 459 contains magnesium as the main impurity.

The lack of regular trends in the impurity distribution and significant difference in the total content of sulfur in the oil samples studied indicate that the Kirishinefteorgsintez Joint-Stock Company is supplied with crude oil from oil fields of various regions or with mixture of crude oils from different oil fields.

It is obvious that the oil samples with the higher content of sodium, magnesium, iodide, chloride, and bromide ions exhibit a higher corrosion activity as compared with the other samples.

CONCLUSIONS

(1) The total content of sulfur in 27 oil samples supplied for processing varies within 0.3–1.67 wt %.

(2) The content of B, Mg, Na, Al, P, V, Mn, Cu, Cr, Fe, Ni, Zn, Ag, Br, Sn, I, Ba, W, Pb, and Bi in 24 samples of industrial oil mixtures was studied. Their concentration varies within a wide range, and only tungsten, bismuth, and iodine were observed in all the samples studied.

(3) The oil samples for processing can be subdivided into three groups by the content of the main impurities (sodium, boron, and iodine) determined by the method of inductively coupled plasma with mass-spectrometric registration.

(4) Variation in the content of sulfur and 20 impurity elements in the oil samples indicates that in different periods the Kirishinefteorgsintez Joint-Stock Company is supplied with crude oil not only by the Surgutneftegaz Joint-Stock Company but also from the other oil fields.

(5) In the oil samples studied the sulfur compounds and impurities of iodine, bromine, chlorine, sodium, phosphorus, magnesium, and vanadium are highly corrosion-active.

Received March 6, 2001

Abstract—A broad spectrum of softeners for vulcanized rubber and corrosion-resistant materials are obtained by mechanical mixing of kerogen shale (Kerogen-70[1]) with commercial products of petroleum refining and shale chemistry such as oil tar, bitumens BND 90/130 and G, softener A-10, residue of atmospheric distillation of crude shale oil boiling above 350°C, and also by thermal treatment of the indicated mixtures at 360–400°C.

Selection of the type and concentration of plasticizers (softeners) in rubber compounds is made depending on the destination of a product. Softener B (residue of atmospheric distillation of crude shale oil) finds wide application in reclaiming of tire rubber. However, the quality of this softener is not sufficiently high. One of the most important factors controlling the quality of a softener is its polarity. High polarity provides strong interaction of a softener with the polymer and high strength of the reclaimed rubber. The performance of shale softeners of various fraction and chemical compositions in reclaiming of rubber of various types was studied at the Research Institute for Tire Industry (Moscow, Russia). The best performance was demonstrated by the softeners containing phenols in the high-boiling fraction of shale oil and also thermal polycondensation products obtained by thermal treatment at about 400°C of high-boiling fractions from atmospheric distillation of crude producer shale oil. Such softeners are characterized by a softening point of about 80–100°C (determined by the ring-and-ball method). High reclaiming characteristics of these softeners were confirmed by production test results. Rubraxes were demonstrated to be high-quality softeners also. They facilitate dispersion of carbon black in a rubber compound and improve the moisture resistance of the products, their hardness and modulus of rupture, but somewhat decrease the elasticity. Rubraxes have diverse effects on vulcanized rubber, since they tends to oxidation, condensation, interaction with sulfur, and antiscorching.

The purpose of this work was development of modified softeners based on kerogen shale (Kerogen-70) and the product of thermal treatment of high-boiling residue from atmospheric distillation of producer shale oil boiling above 350°C [1, 2], and also of those based on Kerogen-70 and oil tar. Additionally, to obtain the softeners we used mechanical mixing of commercial products from the Ukhta refinery (bitumen G or BND 90/130; softener A-10) with Kerogen-70. The softeners obtained in the work were compared with the ordinary softeners (Rubraxes) [3].

[1] Contains 70% organics.

EXPERIMENTAL

The characteristics of the initial products used in this work were as follows. Kerogen-70. Working moisture content 1.1% and ash content 27.2%. Elemental composition of the organic (kerogen) fraction (%): C 77.4, H 9.65, O 9.75, N 0.6, and S 2.6.

Crude producer shale oil. Density 1010 kg m^{-3}. Fraction composition, °C (%): <200 (8), 200–250 (10), and 300–350 (14). Elemental composition (%): C 83, H 8.8, S 1.1, N 0.3, and O 6.8.

Softener A-10 is produced at the Ukhta refinery from a mixture of asphalt of Yarega oil (25%), heavy cuts from motor oil production (50%), and residue from distillation of Usinsk oil (25%). Softening point 126°C and penetration at 25°C 11×0.1 mm. Elemental composition (%): C 84.31, H 10.68, N 0.49, S 0.71, and O 3.81.

Bitumen G (Ukhta refinery). Softening point 126°C and penetration at 25°C 5×0.1 mm.

Bitumen BND 90/130 (Kirishi refinery). Softening point 46°C and penetration at 25°C 100×0.1 mm, ductility 60 cm (25°C), and brittle point –23°C.

Table 1. Composition of stock blend no. 2711

Material	Consumption per 100 wt parts of rubber	Component content in compound, %
Synthetic rubber SKMS-30 ARK P	100	19.19
Tire thermochemical reclaim	169.75	32.39
Ground natural crude sulfur M 9950	3.021	0.58
2-Mercaptobenzothiazole	3.021	0.58
Zinc white	2.917	0.56
Cleaned natural chalk	68.75	13.19
Kaolin	100	19.1
Crude furnace black P-803	43.75	8.4
Naftoplast oil	10.625	2.04
Rubrax (high-melting oxidized oil asphalt)	20.208	3.88

Rubrax (granulated oil asphalt oxidized in the presence of alkali). Softening point 137°C and penetration at 25°C 32×0.1 mm.

Mixtures of Kerogen-70 with asphalt from AVT-6 plant of the Kirishi refinery and leavings of distillation of producer shale oil were thermally treated in a Fischer converter controlling the treatment temperature and time and the softening temperature of the resulting softener.

The resulting softeners were characterized by the volatile matter and ash contents, determined according to GOSTs (State Standards) 6383–91 and 1102–75, respectively. The softening point of the samples was determined by the ring-and-ball method in accordance with GOST 9950–83 and the penetration (needle penetration depth), with GOST 11508–78. The elastomechanical characteristics in load tension were measured in accordance with GOST 270–75 and the Shore hardness, with GOST 263–75. The vulcanization characteristics were determined with a Mooney viscometer (GOSTs 10722–64, 12536–67) and the rebound elesticity, with a UMR-2 pendulum elastometer (GOST 6950–54). The tear resistance was measured in accordance with GOST 262–73.

As a reference material we selected rubber compound no. 2711 used at the Treugol'nik Joint-Stock Company (St. Petersburg, Russia) for rubber covering of textile materials in footwear manufacture. The compound includes 20 parts of Rubrax (by weight), which makes it a convenient object for comparison with the products prepared using modified plasticizers proposed in this work. Therefore, we prepared rubber compounds with the composition similar to mother batch no. 2711 (Table 1), but containing various amounts of Rubrax and the modified softeners.

Rubber compounds were prepared in two steps with an AG 320 160/160 laboratory roller mixer. Initially a stock blend containing synthetic rubber and all other ingredients (except for a softener) was prepared. In the second step a fixed amount of Rubrax or a modified softener was introduced. The resulting blend was vulcanized at 150°C for 15 min with an electric hydraulic press.

In the initial stage of this work we examined the possibility of changing Rubrax for bitumens modified with Kerogen-70. A fused bitumen (or a softener) was rapidly mixed with Kerogen-70 (25–50 wt %). Introduction of Kerogen-70 (25 wt %) increased the softening point of bitumen G or softener A-10 by 11%, i.e., to that of Rubrax (137°C). Introduction of Kerogen-70 (50 wt %) in bitumen BND 90/130 increased the softening point from 46 to 78°C.

Figures 1a-1h demonstrate the effect of softener on the mechanical properties of vulcanized rubber. The strength, modulus ε, relative elongation, and tear resistance of vulcanized rubber containing 20–40 wt % Rubrax (relative to rubber) are higher than those of vulcanized rubber with the test softeners (A-10, bitumens G and BND 90/130). However, the hardness, elasticity, Mooney viscosity, and moisture content of vulcanized rubber with the test softeners are higher than with Rubrax.

In the second stage of the work a mixture of Kerogen-70 (25%) with leavings of distillation of crude shale oil boiling above 350°C or oil tar was thermally treated at 350°C for 60 min in a Fischer converter.

The products of thermodissolution of Kerogen-70 in crude shale oil and oil tar (Table 2, sample nos. 1 and 2, respectively) provide a lower stickiness of rubber compounds and easier distribution throughout the polymer matrix as compared to Rubrax.

Rubber compounds were vulcanized in the com-

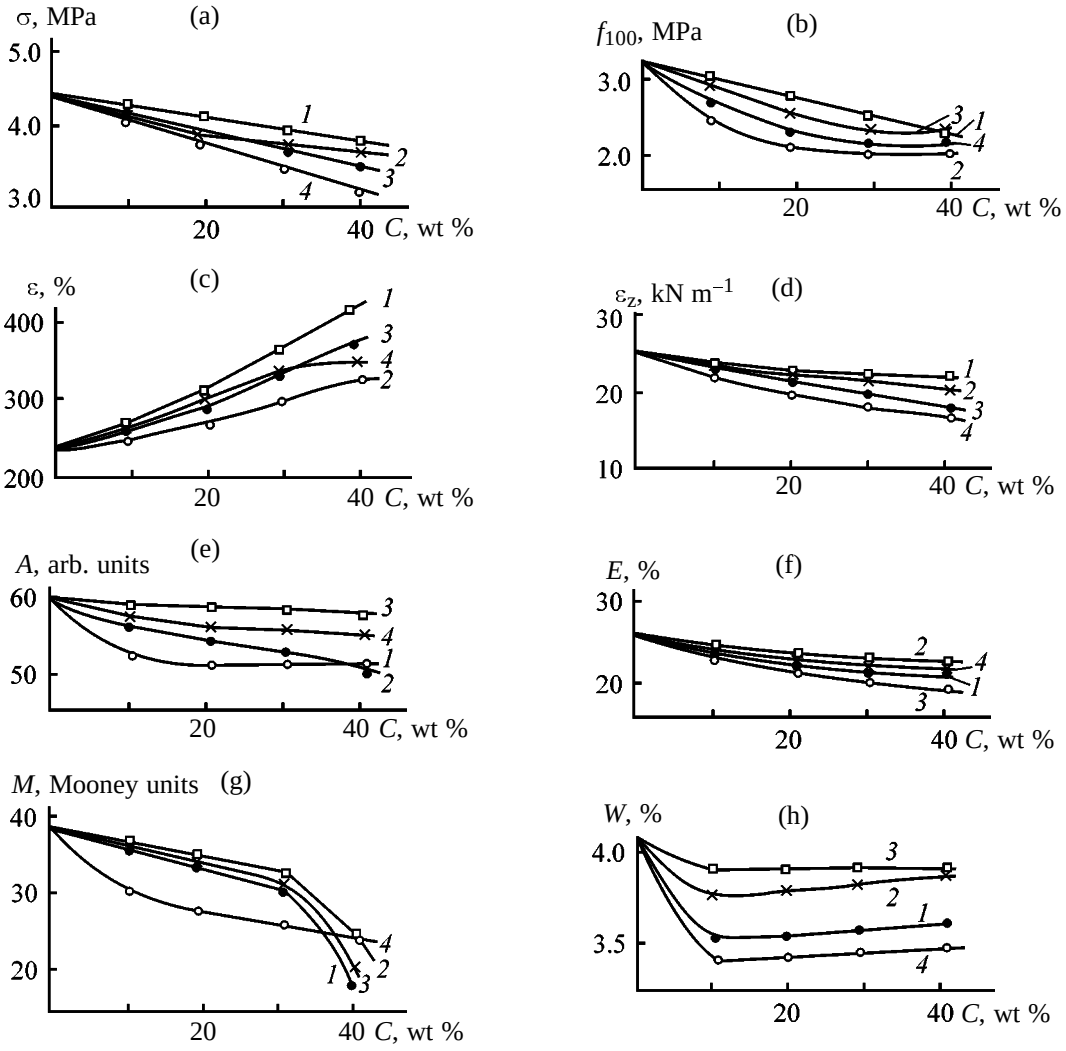

Fig. 1. (a) Strength σ, (b) nominal strength at 100% elongation (modulus *f*100), (c) relative elongation ε, (d) tear resistance ε_Z, (e) hardness *A*, (f) elasticity *E*, (g) Mooney viscosity of the mother blend *M* (Mooney units), and (h) swellability (moisture content) *W* as functions of the softener content *C*. monly accepted mode. The performance characteristics of vulcanized rubbers with the modified shale oil and oil tar softeners are summarized in Table 2. Sample no. 1 was obtained by thermal dissolution of Kerogen-70 (25 wt %) in leavings after distillation of crude producer shale oil at 360°C, and sample no. 2 (softening point 108°C), in oil tar (AVT-6 plant; Kirishinefteorgsintez Production Association, Joint-Stock Company) at 360°C for 90 min.

The results show that the mechanical properties (strength, modulus α, tear resistance, hardness, elasticity, and relative elongation) of vulcanized rubber with these softeners compare well with those containing Rubrax.

In further experiments we tested the method for preparation of corrosion-resistant materials by thermal dissolution of ordinary or enriched shale in a reactor with a mechanical stirrer. Ordinary or enriched shale (70–90% enrichment) was dissolved in commercial shale oil (products of thermal treatment of shale) or in high-boiling oil fractions (black oil, vacuum gas oil, oil tar), or in bitumen at 350–400°C at continuous removal, cooling, and condensation of hot-vapor products, to obtain a homogenous solution. The solvent to shale weight ratio was varied from 0.33–1.0 to 2.0, and the process time, from 0.25 to 3 h.

Characteristics of the solid products thus obtained are given in Table 3. Then they were applied to steel (St. 3) plates and immersed in water containing 3 wt % NaCl and allowed to stand for 6 months. The coatings

110	1	2.36			33.3

Notes: (T_s) Softening point (ring-and-ball method); (P) penetration at 25°C, 0.1 mm; and (W) moisture content.

remained unchanged after the experiment, and we found no indications of corrosion of the metal.

Table 3 demonstrates that we were able to obtain a broad spectrum of solid products of thermal dissolution with the performance characteristics varied in a wide range. Thus, the softening point varies from 26.2 to 130°C, the penetration at 25°C, from 1×0.1 to 230×0.1 mm, and the moisture content, from 0.036 to 4.41%. The samples demonstrate fairly high shear (2–11.7 kg cm^{-2}) and breaking adhesion ($2 \times$ 10.6 kg cm^{-2}). The content of toluene-insoluble fraction, which correlates indirectly with the ash content, varies from 1.4 to 33.3%.

Study of the corrosion resistance of the samples in 5% H_2SO_4 and 5% NaOH revealed that the metal is fairly reliably protected in the alkali solution, but rapidly corrodes in the acid solution, which can be attributed to the presence of carbonate in the mineral fraction.

CONCLUSIONS

(1) Low-temperature modification by mechanical mixing of Kerogen-70 with oil tar, bitumens G and BND 90/130, and softener A-10 only slightly increases (by 10–11°C) the softening point. Therefore, these composites cannot be regarded as a full-value alternative to Rubrax in rubber compounds.

(2) High-temperature (360–370°C) treatment of a mixture of Kerogen-70 (25%) and heavy leavings after distillation of crude producer shale oil boiling above 350°C for 60 min in a Fischer converter produces softeners with the softening point of 100–108°C, whose performance characteristics compare well with Rubrax.

(3) Products of thermal dissolution of ordinary or enriched shale in shale oils (light-middle, overall, and heavy) or in heavy leavings (black oil, vacuum gas oil, oil tar, and bitumens) are effective corrosion-resistant coatings.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

To Centennial Anniversary of Awarding the First Nobel Prize in Chemistry (1901–2001)

International prizes have been awarded annually, beginning in 1901, in accordance with Alfred Nobel's will, for outstanding discoveries in physics, chemistry, physiology, and medicine, and also for creation of the most prominent literary work and valuable contribution to fraternity among nations and promotion of peace. During the last century, Nobel Prizes in chemistry were not awarded, for various reasons, only in 1916, 1917, 1919, 1924, 1933, and 1940–1942 [1, 2].

Vast literature is devoted to A. Nobel's life and activities and his will [2–8]. Nevertheless, there are essentially different opinions on some important issues associated with A. Nobel's scientific and engineering activities. Detailed biographic evidence can be found in E. Bergengren's book [2] and also in memoirs of A. Sohlmann (1870–1948) [5], A. Nobel's close friend and assistant and one of the two executors of his last wishes, named in his will. The memoirs were written in the late 1940s, shortly before the author's death.

Alfred Bernhard Nobel was born on October 21, 1833, into the family of Immanuel Nobel (1801–1872), an architect and inventor engaged in various business activities. In view of severe economic grievances, I. Nobel, having left his family in Sweden, moved to Turku (Finland) in 1837, and thence went to St. Petersburg, where he later managed to found a large, by that time, plant *Liteinye zavody i mekhanicheskie masterskie. Emmanuel' Nobel' i ego synov'ya* (Casting Yard and Machine Shop. Immanuel Nobel & Sons). In the autumn of 1842, when Alfred was 9, the whole family moved to his father to Russia. During the Crimean War (1853–1856), Nobel's plants had particular numerous delivery orders, manufactured underwater mines and other kinds of armament for the Russian Navy.

In 1841–1842, A. Nobel attended school in Stockholm; later he was educated at home and, in addition to Swedish, spoke fluent Russian, German, French, and English, well knew the world history, was deeply interested in literature, and possessed profound knowledge in chemistry. According to some of his biographers, A. Nobel was instructed in chemistry by

A. Nobel.

Professor N.N. Zinin (1802–1880), later an academician of the St. Petersburg Academy of Sciences and one of founders of the Russian Chemical Society and its first President (1868–1877). The founder of the Kazan school of organic chemists, Zinin moved to St. Petersburg in the end of 1847, and was elected there an ordinary professor at the Chair of Chemistry and Physics of the St. Petersburg Medical-Surgical Academy (Military Medical Academy since 1881) [9]. However, there is also some evidence [10, 11] that A. Nobel became acquainted with Zinin and his works on explosives only in 1855.

In 1850, A. Nobel went to the United States to complete his education and then visited France and other European countries. Little is known about his stay in New York, it has only been mentioned that A. Nobel met there J. Ericsson (1803–1889), a Swedish engineer working in the field of steam engines. In 1851–1852, A. Nobel worked in Paris at the laboratory of Professor T.J. Pelouze (1807–1867), a promi-

1070-4272/01/7407-1240$25.00

nent scientist and foreign corresponding member of the St. Petersburg Academy of Sciences (since 1856). There he became acquainted with A. Sobrero (1812–1873), an Italian chemist and the inventor of nitroglycerin, who was a pupil of Pelouze and J. Liebig (1803–1873), an outstanding German chemist.

A. Nobel returned to St. Petersburg and resumed his work at his father's plant only in the autumn of 1854. However, already in 1859, in view of the diminishing military orders and the resulting unfavorable economic situation, Immanuel Nobel went to Sweden together with his wife and younger son. Alfred Nobel and two his elder brothers, Robert (1829–1896) and Ludwig (1831–1888), continued business in Russia.

A. Nobel's attention was increasingly attracted by the manufacture of explosives, which were in steadily high demand for building and mining purposes. In 1863, A. Nobel returned to Sweden, and in 1865, started there manufacture of nitroglycerin and also founded "Alfred Nobel and Co." for production of nitroglycerin in some other countries. Accidents occurring in manufacture, transportation, storage, and use of nitroglycerin forced A. Nobel to work hard in order to develop safer explosives. Dynamite patented by A. Nobel in a number of countries in the end of 1867 proved to be the most successful invention. The manufacture and use of dynamite were started already in the late 1860s.

Also insufficiently clear is the question as to what extent A. Nobel's engineering and scientific activities were affected by his acquaintance with works in the field of explosives, carried out in St. Petersburg by Zinin and military engineer V.F. Petrushevskii (major-general since 1871 and lieutenant-general since 1881; 1829–1891) [10–13]. To keep state secrets, Russian scientists did not patent their designs, although they undoubtedly have priority in the technology of large-scale manufacture of nitroglycerin and its practical use in blasting and defense technology.

In 1879, A. Nobel invested heavily in *Tovarishchestvo neftyanogo proizvodstva brat'ev Nobel'* company (Nobel Brothers' Oil Production Company) [14].

Alfred Nobel died of heart attack on December 10, 1896, at the age of 63, in San Remo (Italy). The last will and testament, signed by him in Paris on November 27, 1895, was made public in early January 1897. The will, in particular, stated that "the whole of my remaining realizable estate shall be dealt with in the following way. The capital shall be invested by my executors in safe securities and shall constitute a fund,

J.H. van't Hoff.

the interest on which shall be annually distributed in the form of prizes to those who, during the preceding year, shall have conferred the greatest benefit on mankind. The said interest shall be divided into five equal parts, which shall be apportioned as follows: one part to the person who shall have made the most important discovery or invention within the field of physics; one part to the person who shall have made the most important chemical discovery or improvements; one part to the person who shall have made the most important discovery within the domain of physiology or medicine; one part to the person who shall have produced in the field of literature the most outstanding work of an idealistic tendency; and one part to the person who shall have done the most or best work for fraternity among nations, for the abolition or reduction of standing armies and for the holding and promotion of peace congresses... It is my express wish that in awarding the prizes no consideration whatever shall be given to the nationality of the candidates, so that the most worthy shall receive the prize..." [2, 5].

By the time of A. Nobel's death, his property was worth more than 31 billion Swedish crowns by that time's rate. The commonly accepted date of foundation of the Nobel Foundation is December 10, 1896, the day of Alfred Nobel's death. This foundation acquired official status after the statute of the Nobel Foundation was approved by a royal decree on June 20, 1900, together with special rules regulating the

activities of Swedish committees awarding the prizes. In accordance with A. Nobel's will, the Prizes in physics and chemistry were to be awarded by the Swedish Royal Academy of Sciences.

The first Nobel Prize in chemistry was awarded to Jacobus Henricus van't Hoff, prominent Dutch scientist of the late XIX–early XX century, a founder of the modern physical chemistry.

He was awarded Nobel Prize on December 10, 1901, for "his pioneering work on chemical dynamics and osmotic pressure in solutions."

A great number of studies, including those performed in Russia, have been concerned with van't Hoff's life and scientific activities. Among active supporters and advocates of van't Hoff's ideas in Russia in the late XIX century were such well-known scientists as I.A. Kablukov (1857–1942), professor of the Moscow University, and V.A. Kistyakovskii (1865–1952), professor of the St. Petersburg Polytechnic Institute. They published voluminous works explaining approaches of van't Hoff and S. Arrhenius (1859–1927) to the understanding of solution properties [15–17]. The most complete biographic evidence was presented by Cohen [18], van't Hoff's pupil and close friend.

In the domestic literature, van't Hoff's life and main directions of his scientific activities were first considered by D. Dobroserdov [19] in connection with scientist's death. In more detail, these issues were discussed by Professor M.A. Blokh, a known historian of chemistry [20, 21]. A biographic essay about van't Hoff, written by Blokh, was also included in the Russian edition of the most important scientific work of the Dutch scientist [22]. Later Russian publications about van't Hoff [23–26] are largely based on Blokh's works. Van't Hoff's contribution to investigation of solutions and to other branches of physical chemistry was considered in ample detail in Yu.I. Solov'ev's monographs [27, 28] and a book concerned with the theory of the chemical process [29]. In 1984, the series *Klassiki nauki* (Classics of Science) published selected van't Hoff's works on chemistry [30] including as supplement a scientific-biographical essay about the scientist's life, compiled by N.A. Figurovskii. An essay about van't Hoff was included in the biographies of great scientists [31].

J.H. van't Hoff was born on August 30, 1852, in Rotterdam (The Netherlands) into a family of an ancient Dutch kin. His father was a known physician and had sufficient means to provide good education and upbringing for his children. Beginning with his early youth, van't Hoff exhibited disposition to natural sciences and figurative thinking. He had his primary education in a splendid private school and, having finished in 1867, passed examinations to enter the fourth form of a five-year municipal school, where he made his first acquaintance with chemistry. In 1869, the scientist-to-be entered the Polytechnic School in Delft, where much attention was given to teaching of chemistry, physics, and mathematics. He completed a three-years' course in two years and obtained a technology diploma in 1871.

Aiming to deepen his knowledge of mathematics, van't Hoff entered Leiden University; however, a year after, he makes final decision to devote himself entirely to studying chemistry. Van't Hoff moved to Bonn (Germany) and, in the autumn of 1872, started his work at the laboratory of Professor F.A. Kekule (1829–1896) at the university of that town. Kekule's interests were mainly centered in the field of theoretical organic chemistry and synthesis of organic compounds. In 1865, Kekule suggested the cyclic structural formula of benzene. A known scientist, he was repeatedly elected president of the German Chemical Society and was a foreign corresponding member of the St. Petersburg Academy of Sciences (since 1887). By Kekule's advice, and having his recommendations, van't Hoff went to Paris already in June 1883 to work at the laboratory of another prominent chemist of that time, Professor A. Wurtz (1817–1884), reiterated president of the French Chemical Society, member of the Paris Academy of Sciences, foreign corresponding member of the St. Petersburg Academy of Sciences. Undoubtedly, the work at the laboratories of such outstanding scientists as Kekule and Wurtz had positive effect on the subsequent van't Hoff's scientific activities. In October 1874, he returned to his homeland and completed his education by backing his doctoral dissertation *Contribution to the Knowledge of Cyanoacetic Acids and Malonic Acid*. Virtually at that same time van't Hoff published in Dutch a small, but meaningful article on the spatial arrangement of atoms in molecules of organic compounds. In 1875, this paper was published in French (*La chimie dans l'espase*), and in 1887, in German (*Lagerung der Atome im Raume*). Nearly simultaneously, and independently of van't Hoff, a similar paper was published by French chemist J.A. Le Bel (1847–1930). According to the concepts developed by these scientists, the affinity units of the carbon atom are directed along axes of a tetrahedron; also, mention was made of the existence of two stereoisomers of compounds containing carbon atoms with four different substituents. The results obtained by

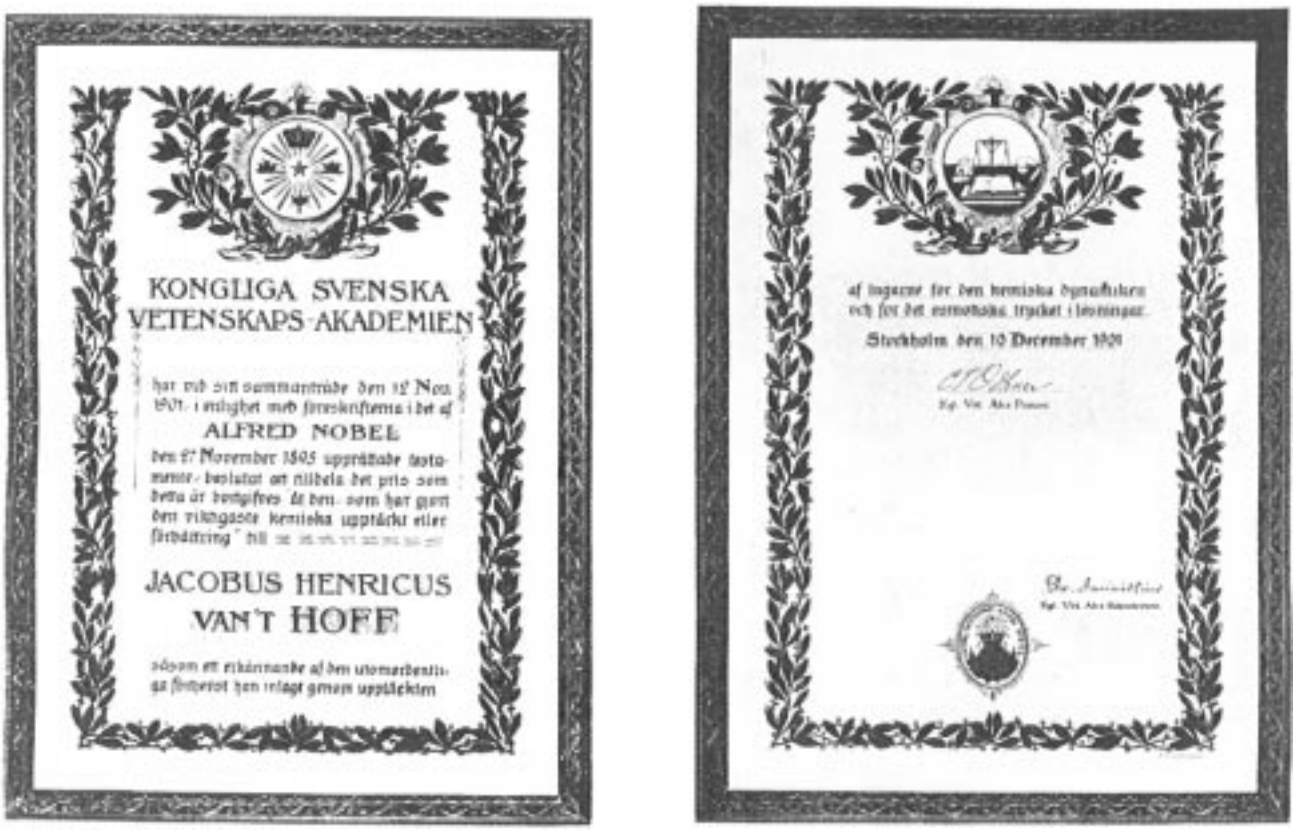
van't Hoff and Le Bel were compared, and these studies were related to earlier concepts of L. Pasteur (1822–1895) concerning the spatial arrangement of atoms, by L.A. Tschugaeff (1873–1922) [32]. Van't Hoff's works laid foundation for a prominent branch of modern science, stereochemistry.

Despite all these investigations, the young scientist could obtain lecturer's position only in March 1876: he was elected a docent of Veterinary College at Utrecht. In 1877, a prominent change occurred in van't Hoff's scientific career: he became professor of chemistry, mineralogy, and geology at the University of Amsterdam. Van't Hoff occupied this position during 18 years despite numerous proposals from higher school institutions of quite a number of countries. Together with delivering lectures, he performed, during this time, fundamental investigations in chemical thermodynamics, kinetics, and theory of solutions. In 1881, van't Hoff published a book *Principles of Organic Chemistry* in which he made an attempt to correlate the molecular structure of substances with their physical and chemical properties. But fame was brought to the author by *Etudes de dynamique chimique* [22, 30] published in 1884, in which he for the first time presented strictly and logically, with the use of the necessary mathematical apparatus, quite a number of problems underlying the understanding of chemical processes. Already in 1885, Arrhenius wrote in a review of these essays that van't Hoff "provided explanation of the mathematical laws of chemical transformations... Although the author has already attained fame owing to his ability to disclose secrets of nature, all his previous works are entirely outshone by this paper..." [33]. A detailed analysis of the essays was made in a study of Blokh [20], in the already mentioned article of Figurovskii, and in other studies of van't Hoff's creative work [18, 26] and history of modern physical chemistry [27, 28].

A further development of van't Hoff's physicochemical investigations was the article *Chemical Equilibrium in Systems of Gases and Dilute Solutions*, published in 1886. The author demonstrated theoretically and experimentally the applicability of the laws of gas state to describing the osmotic pressure in dilute solutions. The value of the universal gas constant, obtained by him from osmotic pressure measurements, was virtually the same as that for ideal gases. However, in the case of mineral acids and salts van't Hoff had to introduce a factor whose physical meaning was unclear. At the same time, this factor could be found by means of a number of independent methods. An explanation of this factor was provided already in 1887 by Arrhenius in his theory of electrolytic dissociation [15, 33]. In 1903, he was awarded Nobel Prize in Chemistry as "acknowledgment of the particular importance of his theory of electrolytic dissociation for the development of chemistry." A prominent Swedish scientist, Arrhenius was elected for his scientific achievements a member of academies and scientific societies of a number of countries. He was a foreign corresponding member of the St. Petersburg Academy of Sciences (since 1903) and honorary member of the Academy of Sciences of the USSR (since 1926). In 1887, van't Hoff took active part in the foundation of the first world's journal devoted to physical chemistry (*Zeitschrift für Physikalische Chemie*). The Editor-in-Chief of the journal was W. Ostwald (1853–1932), a professor of the Leipzig University. In 1909, he was also awarded Nobel Prize in chemistry as "acknowledgment of his works on catalysis and also investigation of the basic principles of control over chemical equilibrium and rates of reactions." Ostwald was a foreign corresponding member of the St. Petersburg Academy of Sciences (since 1896). Van't Hoff's investigations gained universal acceptance by the late 1880s. He was elected an honorary member of the German Chemical Society in 1889; the Royal Society of London awarded him, together with Le Bel, the Davy medal in 1893; he also received a Legion of Honor from the President of France in 1894. In 1895, the Dutch scientist was elected a foreign corresponding member of the St. Petersburg Academy of Sciences and a honorary member of a number of scientific societies in Russia and other countries. On January 30, 1896, van't Hoff was elected a member of the Prussian Academy of Sciences. Simultaneously he occupied a position of a professor of the Berlin University with minimum pedagogical obligations. In accordance with his own wishes, he delivered a course of physical chemistry during four semesters, one hour a week. Van't Hoff's lectures on theoretical and physical chemistry were published in 1898–1900 in three parts. The last of these, concerned with solutions, was translated into Russian under the editorship of Kistyakovskii.[1]

In 1901, van't Hoff was invited to the Chicago University (USA) and delivered eight lectures on physical chemistry. These lectures were also published in Russia in 1903 under the editorship of Academician P.I. Val'den (1863–1957) with his preface. The structure and specific features of the lectures was analyzed in detail by R.B. Dobrotin and Solov'ev

[1] A list of van't Hoff's books published in Russian was given in [26]. A complete bibliographic index of published works of the Dutch scientist in chronological order can be found in the supplement to his Selected Works [30].



J.H. van't Hoff's Nobel diploma.

[26]. The singularity of the lectures consists in the particular attention to the presentation of those problems of physical chemistry which were studied by the author.

In his introductory statement at the Academy of Sciences in Berlin on July 2, 1886, van't Hoff explained in which direction he would continue his investigations: "In the first place I am going to devote my efforts to that branch of physical chemistry which is concerned with transformations and formation of double-decomposition salts... Of particular importance is the idea of its possible application in Stassfurt industry and geology" [20, 26]. Here are meant large deposits of potassium salts in Saxony near Stassfurt.

Already before moving to Berlin, van't Hoff started experimental investigations of heterogeneous equilibria in various condensed systems. However, large-scale studies of salt equilibria began during the Berlin period of the scientist's life. Beginning in 1897, and till 1908, van't Hoff and coworkers published a series of 52 communications under the common title *A Study of the Conditions of Formation of Oceanic Salt Deposits and, in Particular, Salt Deposits at Stassfurt.* Basic data were obtained on the behavior of Na^+, Mg^{2+}, K^+, SO_4^{2-}, and Cl^- in brines, mainly at 25°C. Some systems were studied at higher temperatures.

The principal van't Hoff's co-worker in these large-scale investigations was W. Meierhoffer (1864–1906), his pupil and friend. The investigations were conducted at a small private laboratory created by the scientists. The obtained results were summarized in a book by van't Hoff, Meierhoffer, *et al*., *Zur Bildung der okeanischen Salzablagerungen*, which was published in two parts (part 1, 1905; part 2, 1909). In 1936, the book was translated into Russian. The scientists established that the key factor in salt formation is temperature. In some cases, a major role is played by time. Studies of the conditions of formation of oceanic salt deposits and the obtained results are rather important for geology, halurgy, and chemistry. Among Russian scientists, F.Yu. Levinson-Lessing (1861–1939) [34] and I.A. Kablukov [35] were those who highly appreciated these investigations.

Beginning in 1905, van't Hoff was strongly interested in biochemical problems; it seemed of importance to him to reveal in the first place the action of enzymes in plants, from photosynthesis to formation of glucosides. However, his illness interfered

with these intentions. Van't Hoff died of pulmonary tuberculosis on March 1, 1911, in Berlin.

The outstanding van't Hoff's scientific merits gained the widest recognition. Numerous academies of sciences all over the world, scientific societies, and universities elected him a member and awarded him honorary medals and titles.

In 1936, opening a meeting of the Moscow branch of the Mendeleev All-Union Chemical Society, devoted to 25th anniversary of van't Hoff's death, Academician N.S. Kurnakov named the Dutch scientist "one of the most prominent chemists and thinkers of the present epoch" [36]. The first winner of the Nobel Prize in chemistry went down in history as a founder of stereochemistry, the theory of chemical equilibrium and chemical kinetics, osmotic theory of solutions, and chemical geology.

BOOK REVIEWS

Reznik, I.D., Ermakov, G.P., and Shneerson, Ya.M., *Nikel'* (Nickel),

Moscow: OOO Nauka i Tekhnologiya, 2001, vol. 2, 468 pp.

The first volume of the three-volume monograph by I.D. Reznik and co-authors[1] was devoted to general problems of the development of nickel industry in the Soviet Union in 1945–1991 (part I, chapters 1 and 2), preparation of nickel ores for metallurgical processing (part II, chapters 3–9), and concentration of oxidized nickel ores (part III, chapter 10). The second volume (parts IV–VII, chapters 11–26) presents exclusively evidence concerning oxidized nickel ores: their deposits and processing features, theory and technology of pyro- and hydrometallurgical processing of oxidized ores.

The authors characterize in sufficient detail deposits of oxidized nickel ores, give their mineralogical composition (ch. 11), and present data on the world resources of these ores (ch. 12). It is noted that the world's land stock of nickel ores is estimated to be 135 million tons in terms of nickel, including proven resources of 49 million tones by the beginning of 1998. Of the proven resources, 40 to 66% of nickel is contained in oxidized ores; 33%, in sulfide ores; and 0.7% in others. The reserves of nickel ores proven to industrial extent will last 50 years at the modern level of mining and processing. The largest deposits of oxidized nickel ores are possessed by Cuba, New Caledonia, Indonesia, and some other countries. At present, processing is, as a rule, done with ores containing more than 1.4% nickel, although a tendency have emerged toward use of lower-grade ores. According to the estimates presented in the book, out of 30 nickel-producing plants of the world (as of 1997), 17 plants processed oxidized nickel ores to produce about 300 thousand tons of nickel, i.e., 40% of the world output of this metal. The authors point out specific features of flowsheets used at plants processing oxidized nickel ores (ch. 13).

A separate part of the monograph (part V) is devoted to theoretical foundations of the pyrometallurgical processing of oxidized ores. Fusibility curves of a number of metallic, oxide, and more complex systems, which are important for analysis of pyrometallurgical processes (ch. 14), and physical characteristics of some oxide and oxide–sulfide melts (ch. 15) are discussed. Much attention is given by the authors to the distribution of nickel and cobalt among smelting products (ch. 16). The presentation is mainly descriptive, without any detailed physicochemical or thermodynamic analysis of the occurring processes. Also considered is the influence of various factors on the rate of reduction of iron oxides by solid carbon in melts (ch. 17). Introduction of calcium oxide in silicate-ferriferous slags markedly accelerates the carbothermic reduction of iron oxides to metal, which gives nickel- and cobalt-leaner slags.

The central place in the second volume (part VI) is occupied by a description of pyrometallurgical methods used to process oxidized nickel ores. Production of ferronickel by electrosmelting, presently the most widely accepted technology, is considered in detail (ch. 18). The technology of manufacture of ferronickel at the Russian Pobuzh ferronickel plant and a number of plants in other countries is discussed. Also considered are other techniques for smelting of oxidized nickel ores to give ferronickel (ch. 19). Of interest are the methods for processing of secondary nickel-containing raw materials: spent iron–nickel alkaline batteries, waste alloyed steels from metal-working industry, and other kinds of raw materials, described by the authors. An electrothermic shop for processing of secondary raw materials to produce ferronickel was put into practice at the Rezh nickel plant in 1970 (ch. 20). Joint smelting of oxidized nickel ores and phosphorites is also described (ch. 21).

Much attention was paid by the authors to blast smelting of oxidized nickel ores to produce matte (ch. 22). Designs of shaft furnaces and specific features of the process are considered in detail. It should, however, be kept in mind that the blast smelting to produce matte has been preserved mainly in Russia.

The final part of the second volume is concerned with the present state of hydrometallurgical techniques

[1] For review, see *Zh. Prikl. Khim.*, 2001, vol. 74, no. 4, p. 691.

1070-4272/01/7407-1246$25.00 © 2001 MAIK "Nauka/Interperiodica"

for processing of oxidized nickel ores (part VII). It discusses autoclave sulfuric acid leaching (ch. 24), ammonia-carbonate leaching of ores upon their reduction (ch. 25), and methods for recovery of nonferrous metals from solutions and sludges obtained in ammonia–carbonate leaching (ch. 26). The authors point out that autoclave sulfuric acid leaching is the lowest-cost technology allowing recovery of both nickel and cobalt to give high-quality products.

The information value of the material included in the second volume is rather high, much attention is given to a detailed description of flowsheets used at a number of plants beyond Russia. The second volume gives reference to 383 works, mainly of Soviet and Russian authors. Of much interest is the evidence concerning the history of development of the nickel industry.

BOOK REVIEWS

Fedorov, P.I. and Akchurin, R.Kh., *Indii* (Indium),

Moscow: Nauka–MAIK "Nauka/Interperiodica," 2000, 276 pp.

The monograph by P.I. Fedorov and R.Kh. Akchurin considers a wide variety of problems concerning the chemical properties, manufacturing technology, and some fields of application of indium and some of its most important compounds. The material presented in the book well supplements the previously published monograph by S.P. Yatsenko: *Indii, Svoistva i primeneneie* (Indium, Properties and Use), published in 1987 and mainly concerned with indium alloys.[1]

The book comprises nine chapters and a vast bibliographic list including 574 references to papers by domestic and foreign authors.

A small introductory chapter (pp. 7–11) mentions the most important fields of application of indium and its alloys and compounds and gives brief evidence concerning the scale of manufacture and consumption of indium in a number of countries and indium prices on the world market. The authors present requirements to the purity of various domestic brands of indium.

The second chapter (pp. 12–22) is devoted to the physical and chemical properties of metallic indium. Also discussed are the possible oxidation states and coordination numbers of indium in various compounds.

The third, and the largest, chapter summarizes data on properties of indium compounds: oxides, hydroxides, hydroxoindates, indates, indium salts of oxygen-containing salts, indium halides and oxohalides, indium cyanide and related compounds, chalcogenides, compounds of indium with Group V elements (nitrogen, phosphorus, arsenic, antimony), other nonmetals, and organic compounds. The presentation is rather detailed; particular attention is given to indium halides and systems containing these compounds. A large number of investigations of the properties of indium compounds have been carried out by one of the authors of the monograph, Professor Fedorov, and his co-workers.

The fourth chapter (pp. 134–141) considers the state of indium in aqueous solutions. It mainly presents published evidence concerning the nature of complexation processes involving indium(III) and (I) ions in various media.

The fifth chapter (pp. 142–153) discusses types of indium deposits and industrial sources of indium in relation to its behavior in processing of zinc, lead, and copper concentrates, and tin or iron ores.

The sixth chapter (pp. 154–196) contains evidence concerning the technology of indium recovery from various materials. The authors mention that no specific chemical processes are known for indium, which could allow its separation from large amounts of associated elements. In this connection, flowsheets for indium recovery from one or another raw material are rather complex and include multiple stages. As examples are briefly considered general principles of direct recovery of indium from zinc ores and its recovery from zinc-containing sublimates and material produced in processing of lead ores. Much attention is paid by the authors to describing separate procedures used for concentrating and purifying indium-containing solutions. To procedures of this kind belong hydrolytic precipitation, cementation with pure metals and amalgams, extraction with organic solvents, sorption and ion exchange, ionic flotation. The same chapter considers production of metallic indium from various raw materials and processing of secondary indium-containing materials.

The seventh chapter (pp. 197–215) is devoted to indium refining. It considers both chemical (successive cementation, chloride method) and electrochemical techniques (chloride, chloride–sulfate aqueous electrolytes), amalgam refining, distillation, and crystallization techniques. Examples are given of flowsheets for manufacture of high-purity indium.

The eighth chapter (pp. 216–252) contains data on indium-based semiconductor materials. The basic properties and methods of preparation of III–V compounds (InSb, InAs, InP) and solid solutions on their base are discussed. The solid solutions are commonly

[1] For review, see *Zh. Prikl. Khim.*, 1987, vol. 60, no. 12, pp. 2748–2749.

1070-4272/01/7407-1248$25.00 © 2001 MAIK "Nauka/Interperiodica"

produced through isovalent substitution of elements in the cation or anion sublattices of indium compounds with Group V elements.

The final, ninth chapter (pp. 253–254) points to the toxicity of some indium compounds.

Monitoring of scientific information shows that the second half of the XX century was characterized all over the world by a dramatic rise in the amount of chemical information (on the territory of the Former Soviet Union this process slowed down only in the last decade). Any adequate systematization of this information seems to be rather valuable. The monograph by Fedorov and Akchurin contains in the first place a systematical presentation of chemical properties of widely different classes of indium-containing compounds. Much less attention is given to industrial problems. Unfortunately, the entire information about manufacture of indium in Russia is limited to the following. "Russia occupies one of the leading places in the world in manufacture of indium. Large quantities of indium are exported." This seems to be insufficient. It would be of interest to find in such a summarizing monograph at least historic evidence concerning the development of indium industry in the Soviet Union. The material of the eighth chapter could be enlivened by description of how the semiconducting properties of III–V compounds were discovered.

The utility and high quality of Fedorov and Akchurin's monograph are beyond any doubt. The book is of interest for a wide variety of specialists in chemistry and chemical technology of rare elements, inorganic materials science, and technology of materials for electronics.

INFORMATION

IX Enikolopov Symposium

IX Enikolopov Symposium (March 13, 2001, Moscow) was held at the Enikolopov Institute of Synthetic Polymeric Materials, Russian Academy of Sciences (RAS). The symposium was organized by RAS (Department of General and Technical Chemistry together with Scientific Council on Macromolecular Compounds) with active participation of the Enikolopov Institute of Synthetic Polymeric Materials, RAS; Semenov Institute of Chemical Physics, RAS; Institute of Problems of Chemical Physics, RAS; and Moscow Physicotechnical Institute.

The advisory board of the symposium included such distinguished scientists as S.M. Aldoshin, N.F. Bakeev, A.A. Berlin, A.L. Buchachenko, V.A. Kabanov, N.N. Kudryavtsev, A.G. Merzhanov, A.N. Ozerin, and N.A. Plate. The symposium program included four plenary lectures which were presented by Academician N.S. Enikolopov' disciples.

S.L. Blazhenov in his plenary lecture examined degradation of unidirectional fiber plastics. The macrokinetic problems, as applied to design of turbulent tube reactors, were reported in a lecture given by A.A. Berlin. A.N. Ozerin gave a lecture on the modern status of the problem of the structure of dendritic molecules. The lecture held by B.I. Zapadinskii on photocurable composites for direct forming using laser stereolithography has evoked a considerable interest.

The lectures presented at the symposium revealed a close relation between the modern theoretical concepts and current practical problems. IX Enikolopov Symposium has demonstrated that Enikolopov's ideas stated in the period from 1980 to early 1990s are being successfully developed by his disciples, being, without question, of considerable theoretical and practical interest.

The next X Symposium will be held in March 2002.

INFORMATION

Polymeric Materials 2000

The 1st International Conference "Polymeric Materials 2000" was held from September 25 to 27, 2000 in Halle (Germany). The conference was organized on the basis of the Martin Luther University (Halle–Wittenberg) under scientific coordination of W. Grellmann and J. Kressler. Sixteen German organizations and research centers were sponsors of the conference. The conference participants were more than 400 scientists from 24 countries (Austria, Azerbaijan, Belarus Republic, Brasilia, Bulgaria, China, Czech Republic, Egypt, France, Germany, Greece, Hungary, Italy, Japan, Poland, Portugal, Romania, Russia, Slovak Republic, Spain, Switzerland, Ukraine, the United Kingdom, and the United States). The conference topics covered a broad spectrum of problems of the chemistry and physics of polymers and composite materials, including synthesis, characterization, and applications.

In the opening ceremony professors W. Grellmann and J. Kressler outlined the topicality of the problems to be discussed, and their importance from the theoretical and practical standpoints. Then Prof. W. Grecksch (Rector of the Martin Luther University) and W. Fichler (Culture Minister of the Sachsen-Anhalt Land) told about the contribution of scientists of the Martin Luther University and other research institutions of the Sachsen-Anhalt to the progress of the polymer science.

There were presented 9 plenary lectures on the basic topics of the conference, including colloid systems and new polymeric materials [M. Antonietti (Golm, Germany)], new advancements in Dow polyolefins technology [Che-I Kao (Dow Chemical, Middland, Michigan, the United States)], polymer melts in chemical technology [H.M. Laun (BASF AG, Ludwigshaften, Germany)], innovations in polymer engineering [P. Eyrer, Stuttgart, Germany)], investigation on polymer lasers [F.E. Karasz (University of Massachusetts, Amherst, the United States)], polymers for medical use [E. Wintermantel (Schlieren, Switzerland)], biosynthesis of polyesters and polyamides [A. Steinbuchel (Munster, Germany)], fatigue crack growth in engineering plastics [R.W. Lang, (Leoben, Austria)], and structure in thin polymer blend films [M. Stamm (Mainz)].

Then the Conference was held as nine sections. The main lecture of Section A (New Materials) was devoted to the effect of laser light on polymer films [J. Feldman (Munich)]. The section included 15 oral presentations on applications of polymers in optics, polymers as lubricant additives, development of liquid-crystal systems for use in electrooptical displays, etc. Section B (Biopolymers and Medical Applications). G.E. Zaikov (Institute of Biochemical Physics, Russian Academy of Sciences, Moscow, Russia) in his main lecture told about the kinetic aspects of biodegradation and biocompatibility of polymers. Then various aspects of biodegradation of polymers and of medical applications of polymers (biomimetics, polymer materials for surgery, polymer implants of temporary and continuous action, polymeric forms of drugs, etc., were examined in 15 lectures).

Section C (Functionalized Polymers and Surface Modification). The main lecture [K. Lunkwitz, H.-M. Buchhammer, M. Muller, U. Oertel, G. Petzold, and S. Schwarz (Dresden, Gernany)] was devoted to modification of polyelectrolytes and polyelectrolyte complexes. Section D (Polymer Testing and Diagnostics). The main lecture on the topic was given by G. Busse (Stuttgart, Germany). The section included 15 oral presentations on various aspects of polymer structure and evolution of the polymer morphology in time. A special section (Section E) was devoted to the morphology and characterization of polymers. The main lecture on the topic (Applications of Block Polymers in Polymer Blends) was given by V. Altstadt, H. Ott, A. Mantey, and V. Abetz (Hamburg, Germany). The section included 15 oral presentations on various aspects of the topic.

Section F (Modelling and Simulation) included a main lecture and 5 oral presentations. The main lecture [B. Michel (Berlin, Germany)] was devoted to modeling and prediction of the thermomechanical behavior of polymers of various structures. Section G (Polymer Processing and Innovative Products) included a main lecture and 5 oral presentations. G. Menning (Chemnitz, Germany) in his main lecture told about the advances in processing of thermoplastics.

Section H (Sustainable Development, Recycling, and Ageing) included 9 oral presentations. The main

1070-4272/01/7407-1251$25.00 © 2001 MAIK "Nauka/Interperiodica"

lecture was prepared by B. Bohlmann, P. Eyrer, Th. Hirth, S. Kroner, and K. Worsing (Pfinzthal-Berghausen, Germany). All oral presentations including the main lecture were devoted primarily to practical problems.

Finally, Section I (Elastomers, Networks, and Foams) included 9 oral presentations and a main lecture. In the main lecture G. Heinrich (Hannover, Germany) told about high-performance elestomers (synthesis, characterization, and applications). Also the conference included the corresponding poster sessions (a total of more than 100 poster contributions).

As a censorious remark, a drawback of the conference organization was that the most of the plenary and main lectures were given by German scientists, although many distinguished researchers from other countries were among the conference participants. For instance, among the Russian participants one may say about Yu.K. Godovskii (Karpov Physicochemical Institute, Moscow) and Yu.Ya. Gotlib (Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg), who could give very interesting lectures on such topics as Morphology and Phase Transitions and Elastomers and Networks. This may be related also to V. Privalko (Kiev Institute of Macromolecular Compounds, Ukrainian National Academy of Sciences). Generally, the Conference has demonstrated a high theoretical and experimental research level and a good potentiality of such meetings where lectures are combined with discussions and living contacts of a large number of scientists. The 2nd International Conference "Polymeric Materials 2002" will be held in the same place. Russian scientists are already invited.

REVIEWS

Applied Significance of Polyimides

Yu. N. Sazanov

Institute of Macromolecular Compounds, Russiam Academy of Sciences, St. Petersburg, Russia

Received April 18, 2001

Abstract—The review is devoted to the use of polyimides in various fields of science and technology. Polyimide materials as films, fibers, foams, membranes, plastics, composites, glues, adhesives, and coatings are widely used for fabrication and coating of various structures, units, and parts operating under extreme temperature conditions. The progress of modern science and technology is impossible without polyimide materials.

The history of the search for heat-resistant materials exhibiting, along with thermal stability, also a number of other valuable, often mutually excluding properties reflects the history of the scientific and technological progress in the second half of the XX century as a whole. Since the 1950s, scientists, engineers, technologists, and businessmen throughout the world became involved in the race for new scientific and technical achievements. With the development of space engineering, the speeds increased by several orders of magnitude, and problems arose related to protection of objects operating under extreme conditions. By protection was meant the whole complex of materials and measures related to developing, testing, and bringing into practice various kinds of insulation from extreme thermal, biological, radiation (with broad spectrum), mechanical, and acoustic impacts.

Initially, the problems were not solved comprehensively, and all stringent requirements to insulation were satisfied on the basis of the trial-and-error method. However, one of the major goals of science and technology was significant extension of the operating temperature range of objects. With respect to many parameters, the available heat-resistant materials (mainly inorganic) appeared to be fully unsuitable, primarily because of the poor mechanical properties, high density of inorganic insulators, sophisticated production processes, shortage of required raw materials, etc. Therefore, the search for new heat-resistant insulators was focused on the development of synthetic materials based on macromolecular compounds. Polymeric substances, often in combination with inorganic materials, were already known and used at that time as electrical and thermal insulators. However, they showed stable service characteristics only at temperatures below 100°C. The search for more heat-resistant polymers started with studies of organic compounds resistant to high temperatures. Under the guidance of such prominent organic and polymer chemists as V.V. Korshak, M.M. Koton, and A.N. Pravednikov in the former Soviet Union; J. Marwell in the UK; D. Stille in the US; and N. Iwakura in Japan, works were initiated on preparation of new polymers containing various aromatic and heterocyclic fragments, because, as shown for low-molecular-weight model compounds, just fragments of this kind exhibit the highest thermal stability both in air and in inert atmosphere. The cyclic fragments should be linked in polymer molecules in such sequences that would ensure, along with the high heat resistance, good service characteristics of the material. Polyoxazoles, polyoxadiazoles, polythiadiazoles, polytriazines, and related materials were prepared. Of particular interest were polymers with condensed rings, e.g., those formed by combination of benzene rings with five- and six-membered heterocycles. It was found that a combination of two condensed cyclic structures in such polymers as polybenzimidazoles, polyquinoxalines, etc. extends the range of thermal stability of the macromolecule to 300°C. However, it was difficult to pass from laboratory samples to commercial production, because it was necessary to ensure not only high heat resistance of the new polymers but also their resistance to thermal shocks in the range from –190 to +400°C. Also, these polymers should exhibit sufficient strength, flexibility, and elasticity. Further search for organic structures meeting these requirements revealed structures withstanding brief heating to 600°C without noticeable decomposition; furthermore, when incorporated into a polymer chain, these structures appeared to

1070-4272/01/7408-1253 $25.00 © 2001 MAIK "Nauka/Interperiodica"

appreciably surpass the low-molecular-weight analogs in the heat resistance. The entire history of the search for heat-resistant polymers showed that the best properties are exhibited by a rigid structure consisting of a benzene ring tightly linked to two five-membered nitrogen-containing rings (pyromellitdiimide). Such polymers were termed aromatic polyimides.

For already 40 years the polymers of these class remain the most versatile heat-resistant polymers; their unique characteristics ensure their leading position among polymeric materials used in various branches of science and technology. Polyimides are subjects of numerous monographs and regularly published reviews [1–6]. Various polyimide-based materials such as films, fibers, coatings, varnishes, plastics, composites, binders, and foam and vapor materials can operate under extreme temperature conditions.

During the 1990s, there has been a considerable progress in applications of these materials. Economical problems (competition of polyimides with other polymeric materials) stimulated the solution of some problems that were "bottlenecks" of the first- and second-generation polyimides.

Modification of the chemical structure (preparing fluorinated polyimides and polyimides containing bulky and asymmetric groups in side substituents; making macromolecules more flexible by introducing various "hinge" links; preparing random and block copolymers) made polyimides soluble in common organic solvents [7–12]. The use of polyamido acid esters allowed solvent-free synthesis of polyimides and preparation of a series of fusible polyimides [8, 12–14]. These achievements extended the temperature range of nondestructive processing of polyimides, which simplified and made cheaper forming of ready items from them. It appeared feasible to apply to a wide range of polyimides common procedures for processing plastics such as powder pressing, pressure casting, extrusion, solution processes, etc.

FILMS

Polyimide films were the first commercial material used for production of highly heat-resistant dielectrics [15]. At present, annual production of polyimide films in the world amounts to 1000 t. The first place is occupied by PM films (based on pyromellitic dianhydride and diaminodiphenyl ether) [16]. Recently, there has been a certain functional redistribution in the total production balance of polyimide film materials.

As previously, polyimide films are used as insulators of electrotechnical items: cables, generators, electric motors, and other units and parts operating at elevated temperatures. Polyimide insulation in electrotechnical items is used not only for insulating materials of the highest grade of heat resistance (H and C) but also for items operating at lower temperatures, which considerably extends their service life and ensures reliable protection in the case of emergency overheatings.

In some electrotechnical items used in cable industry, various polyimides combine well with other insulation materials. For example, Du Pont mastered production of multilayer insulation for aviation wire by combining Kapton polyimide with fluoroplastic. The junction of both the materials is tight, and the insulation characteristics are acceptable even with the insulation thickness decreased by a factor of 2–3, which saves 25 and 50% of weight and space, respectively. The service life of such wires exceeds 2000 h at 250°C.

The service life can be considerably prolonged by using, in combination with polyimide, heat-resistant graphitic carbon fillers. A particular attention is given to chemically resistant polyimide coatings which successfully operate in deep-well electric engines used in oil extraction [17]. In some cases Upilex polyimide film is used for these purposes, as well as for enhancing the hydrolytic resistance of insulating electrotechnical materials. This film has an adhesive layer and is prepared from diphenyltetracarboxylic acid and diaminodiphenyl ether or *p*-phenylenediamine [18]. The high stability of the surface layers of polyimide films determines their predominant use in production of resistors. The scatter of the surface resistivity of such films is a factor of 2–3 smaller than that of devitrified glass supports, owing to the different surface roughness [19].

Further improvement of the electrical insulation based on polyimide films resulted in the production of films heat-weldable from two-layer polyimido-fluoroplastic films (PMF) (Plastik Research and Production Association, Joint-Stock Company) which well compare with the imported analog, Kapton HV [20] (Table 1). This film is widely applied as insulation of PPI-U wires for motors used in deep boring units. Subsequently, the PMF film was improved by replacing the fluoroplastic layer by layers of thermoplastic polyimide, which soften at high temperatures and retain high radiation resistance. Single- and double-layer films were developed, weldable by electric-current contact welding at 300–350°C under a pressure of 0.15–1.0 kg cm^{-2}. The adhesion strength of the weld is 200–250 N m^{-1}. The nonshrinking polyimide film produced by Plastik Re-

search and Production Association is used for fabricating cables and flexible and flexible-rigid printed-circuit boards of precision grade IV–V. The properties of this film are compared in Table 1 with those of the analog produced by Du Pont. The film exhibits high dielectric stability at elevated temperatures close to thermal breakdown [21]. Such films of the PMK type with a coating containing industrial carbon are intended for production of heating elements, heat-resistant coatings of printed-circuit boards, wires, and cables. Another modification is a protective film with an adhesive coating, protecting the conducting pattern of flexible printed-circuit boards from corrosion and preventing shorting and accidental contact of conductors with metallic surfaces of the equipment.

Instead of fluoroplastic coatings of the polyimide films, thermoplastic copolyimide layers can be used [22], or fluoirine can be introduced into the polyimide structure [23]. Such modifications simplify the production of compound cables [24] and enhance the flexibility of wire circuits in items that are subject to prolonged sign-variable loads.

The demand for heat-resistant film coatings for microelectronics has considerably increased during the recent decades; with particular attention given to ultrathin films with low dielectric constant ε. Process regulations for production of printed-circuit boards and microcircuits for various devices require combination of high thermal and mechanical characteristics with low coefficients of thermal expansion and minimal shrinkage. In addition to these characteristics, which are presently met by polyimides, some of these materials have ε in the range 2–3, whereas the dielectric constant of silicon oxide widely used in integrated circuits is 4–10, depending on the moisture content. When passing to polymeric materials, particular attention should be given to the stability of this parameter. Numerous studies in this field have shown that the set of characteristics of polyimide film materials make them suitable for production of some parts and units of electronic devices [25, 26], but for high-precision units it is often necessary to strictly ensure the low moisture content, which cannot be provided by common polyimide films like PM or Kapton whose moisture absorption varies within 2.5–3.5%.

A good way to make polyimide films with low ε hydrophobic is synthesis of fluorinated polyimides [7]. According to [7], membranes based on fluorinated polyimides are promising dielectrics; their ε is within 2.3–3.0, and moisture absorption, within 0.5–0.85%. As the temperature is raised to 300°C, ε increases by no more than 1–1.5%. It should be noted that replacement of hydrogen atoms in polyimide by fluorine extends the range of solvents in which these polymers are soluble, which simplifies production of various parts for microelectronics. Also, global computerization brings about many problems related to the cost of computers. One of the ways to decrease the costs or preserve their level with extension of the potential of computers and other microelectronic devices is to

Table 2. Comparative characteristics of some fluorinated polyimide of the general formula [7]

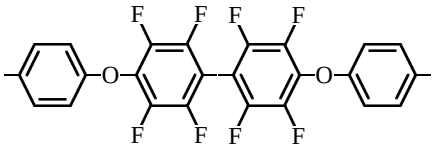
R3 =



decrease the size of the parts used. Although minicomputerization is not a new topic, its urgency stimulates development of suitable polymeric materials. The increased solubility of fluorinated polyimides and their good capability to soften allowed the temperature range of their processing to be extended to 150–200°C. Various combinations of fluorinated segments of the polyimide chain with bulky substituents in the side chains and at the ends of oligomeric constituents, and also blends of fluorinated polyimides and copolyimides (Table 2) considerably expanded the assortment of heat-resistant materials for fabrication of mini- and microparts of electronic devices [7, 8, 27].

Detailed studies of fluorinated polyimides showed that fully fluorinated films based on (diphenyl oxide)-resorcinoltetracarboxylic dianhydride and *m*-phenylenediamine, and on cyclobutanetetracarboxylic dianhydride exhibit high optical transparency in the visible and UV ranges [8]. This allows their use in optical telecommunications technology. Since the mid-1990s, the body of data on the use of these polyimides for microelectronics started to increase. This concerns light guides and microfilters made of fluorinated polyimides [28], thin (0.035 mm) flexible polyimide films for forming components of electronic curcuits [29], planar orientation for optoelectronics [30], polyimide films with fullerene and a dye as laser radiation power limiters [31], and an exclusively transparent polyimide film [32]. From the viewpoint of production automation, it appeared convenient to use the polyimide based on benzophenonetetracarboxylic dianhydride and *p*-phenylenediamine; this polymer is used for ensuring high size precision in automated assembling of integrated circuits on a tape support and in semiconductors and multilayer microchips [16].

A number of polyimide films and film coatings are used in liquid-crystal (LC) systems of various displays. As structural layer, polyimide films are capable of orienting LC molecule in the support plane [33]. These films were also tested for negative compensation of birefringence for white nematic LC displays [34]. A combinatiuon of LC with polyimide films operates in acceleration of reversible recording processes in holographic arrays [35]. Polyimide supports in LC displays show induction reorientation of signals [36]. Noticeable alignment of the LC layer of indicator cells was reported in [37–40].

A prominent place in wireless communication systems and in production of various resistors and capacitors is occupied by metal-coated polyimide films. The field of their application extends beyond conducting structures and includes, in particular, the areas where strong, flexible, and heat-resistant supports are required for mirrors, screens, and reflectors of broad-spectrum energy flows. Polyimide films can be joined, using an adhesive, with a metal foil, or a metal can be sputtered directly on the film surface [1, 15]. To improve the adhesion, the film surface is modified by corona discharge, plasma or laser treatment, chemical etching, or application of a silicone binder [12, 27, 41, 42]. In some cases the metal is introduced into the polyimide film in the prepolymer stage. For example, certain amounts of gold and silver are introduced as a fine dispersion into a polyamido acid solution. Its imidization and surface treatment yield a film with uniform distribution of metal throughout the film bulk [43–46]. As for surface metallization, such polyimide films are used in space engineering, in mirror coatings of solar battery parts and heliotechnical equipment, and in multilayer protective clothes for astronauts, firemen, and emergency

teams of hot shops and nuclear power plants [47–49]. One of the main application fields of polyimide films in electronics is fabrication of heat-resistant photosensitive coatings. Depending on the destination and design features of photoconducting systems, polyimides of various chemical structures are used, from common PM polyimide to fully fluorinated polymers based on aromatic dianhydrides and diamines.

Particular attention is given now to ultrathin Langmuir–Blodgett films (LBFs) whose preparation, properties, and use are described in [50]. It is also emphasized in [50] that polyimide LBFs, thanks to their unique characteristics, have found use in production of various parts for photonics and molecular electronics. Preparation of polyimide LBFs with a monolayer thickness of 4 Å allowed forming of multilayer structures with which many photoelectric processes can be controlled on the electronic and molecular level, e.g., photoinduced molecular direct and reverse current switching in LBF monolayers [50, 51]. Polyimide LBFs are widely used in structures of a three-layer photodiode, in positive resists [52], in photolithography [53], and for stabilization of sign-variable voltages in commutation memory systems [54, 55]. As a rule, soluble polyimides are used as photosensitive components of both negative and positive types [56–61].

It should be noted that in the past 5–7 years there has been considerable interest in carbonization of polyimides from the scientific standpoint and in view of applications of carbonized polyimide materials. It was reported in [6] that high-temperature treatment of polyimides yields cross-linked carbo- and heteroaromatic structures with reasonable yield (up to 50–70%), which exhibit new interesting characteristics making these new materials promising for practice. Subsequent studies [62–66] showed that the properties of carbonized polyimides depend on the chemical structure of the initial polymer, its supramolecular structure, process parameters of heat treatment, and shape and size of the materials and items thereof. The major application field of carbonized polyimides is production of various composite materials [67, 68].

FIBERS

In the period of active search for new heat-resistant fiber-forming polymers, theoretical foundations were laid in Russia for production of polyimide fibers, and these processes were commercially implemented [15]. Arimid T polypyromellitimide fiber still remains the most heat-resistant synthetic fiber with the operation range from –270 to +450°C. This fiber is fire-resistant; Arimid T fabric placed for 2 min in a gas burner flame preserves its structure and is destroyed only after an external action. Polyimide fibers fully preserve the elasticity and strength [breaking elongation 6–10%, strength (70–78) × 10^3 kg cm^{-2}] at the liquid nitrogen temperature. These are the only fibers that withstand without noticeable damage total doses of nuclear and UV radiation of up to 10–30 MGy. Polyimide fibers and fabrics virtually completely restore upon elastic deformations at elevated temperatures. The main thermochemical characteristics of polyimide fibers are compared in Table 3 with those of the other heat-resistant fibers. A combination of unique properties allows the polyimide fibers to be used in equipment operating for a long time at increased levels

of radiation and temperature; for reinforcing rubber items, fiber glass materials, thermoplastics, and multilayer structural materials; for production of work outfits for hot shop and nuclear plant workers; and for production of volume filters for treatment of hot gases and corrosive liquids.

During the past decade, the interest in further search for new polyimide materials for fiber production has decreased somewhat. This is due to a number of factors, one of which is the sophisticated production process as compared with production of other heat-resistant fibers (polyamides, copolyimides, other polyheteroarylenes). Improvement and simplification of the production process, effective stabilizers and modifiers—all these factors allowed such fibers as Fenilon, Nomex, Kevlar, Kermel, etc. to compete well with pure polyimide fibers. Furthermore, analysis of reviews concerning synthetic fibers [69] reveals a world's trend toward a decrease in the share of synthetic fibers and items thereof in production of artificial fibers. For example, in 1998, the rise in the world's production of synthetic fibers and yarns was smaller than that in 1997 by almost a factor of 10. The production of synthetic fibers in South-East Asia slightly increased, whereas in developed countries (the US, ASEAN, Japan, West Europe) it decreased by approximately 5%. The demand for polyimide fibers noticeably decreased, which is confirmed by the lack of surveys of new developments in recent reviews [69–71]. Only in [72, 73] mention is made of the relative heat resistance and other mechanical characteristics of Arimid T, Aramos, SVM, Pogllen, and some other fibers produced beyond Russia (Nomex, Conex, Kermel, PBI, P-84). In the subsequent papers one can find only consideration of the results of the past decade, summary of procedures for manufacturing of Kapton fiber [74], and main principles of construction of aromatic homopolyimides [75] and copolyimides [76]. To conclude, we can mention polyimide fibers prepared by a process that considerably differs from the traditional technology used for forming polyimide-based fibers for fiber optics. Defect-free hollow fibers of asymmetric structure were prepared from polyimides based on hexafluoropropane derivatives. These fibers are suitable for membrane technology [77, 78]. The forming process and particular properties of fluorinated polyimides allowed preparation from them of light guides for fiber optics [28, 79–81].

POLYIMIDE FOAMS

Foamed plastics. Foamed plastics have long been studied as materials for insulation of various apparatus, devices, units, and mechanisms from external impacts [82]. However, every decade (and now even every year) the requirements to such insulation become more and more stringent. In this connection, unique properties of polyimides attracted particular attention of researchers working on development of protective structures for high-speed apparatus, primarily for air- and spacecrafts. The ways to protect the crew and the scientific apparatus in drone air- and spacecrafts were sought for long before flights at speeds of thousands and tens thousand kilometers per hour became real. The main requirements to such protection are enhanced heat and fire resistance, low density of the inner casing of cockpits, flexibility and elasticity of various components of the insulation, and the possibility of using multilayer insulation with jointless junction of parts. In the case of emergencies, the foam insulation should not burn or release toxic degradation products or smoke. Comparison of various properties of foamed polyimides (according to ASTM standards) with those of the well-known and widely used foamed polyurethanes revealed an undoubted advantage of polyimide foams. For example, the weight loss of foamed polyimide and polyurethane in fire tests is 11 and 84%, respectively; the smoking is zero from polyimide and 100% from polyurethane; the release of HCN and CO toxic gases from polyimides is a factor of 10–30 lower than that from polyurethanes. Furthermore, with respect to a number of electrical, acoustic, and deformation-strength properties, foamed polyimides surpass foamed polyurethanes. One of the main tests passed only by foamed polyimide is the test for crew insulation under extreme conditions. Namely, the material should withstand, together with the cockpit material, the fire impact for no less than 5 min without release of toxic products, with increase in the internal temperature to 200°C and strong acoustic overloads. Laboratory tests showed that the polyimide foam withstands for 5 min the action of the gas burner flame (about 1500°C) without losing shape. The most suitable polymers meeting these requirements are polyimides for which a number of procedures have been developed for production of foam materials. These procedures are based on various chemical reactions causing foaming during formation of the polyimide structure [83–86]. All these reactions involve formation of low-molecular-weight volatile products whose release from a viscous melt of the intermediate and final imidization products results in foaming of the reaction mixture, followed by solidification. With account of specific parameters of ready items, foamed polyimide materials can exhibit a wide range of various characteristics (density; heat, fire, and acoustic resistance; deformation-strength characteristics; environmental safety). These proper-

ties can be controlled not only by varying the synthetic procedures but also by using various procedures for preparing foamed materials. For example, with air-circulation furnaces, cells of irregular structure are formed in the bulk of the polymer, with a large scatter of the foam density throughout the bulk of the material. This drawback can be eliminated by using high-frequency (or microwave) heating. This procedure allowed preparation from polyimide prepolymers of the best grades of foamed materials with cells of similar structure and with the minimal content of cavities and other defects, which is especially important in production of insulation materials for casing of cockpits in supersonic aircraft and manned spacecraft [87]. However, in some cases, despite the fact that the principal parameters determining the suitability of foamed polyimides for aerospace engineering are met, additional problems arise requiring further modification of foamed materials. One of such "particular" examples is the development of special hydrolysis-resistant foamed polyimides for seats and arm rests. Despite the flexibility and elasticity of seats made of common foamed polyimides, these materials caused discomfort of the crew and passengers because of the insufficient hydrolysis resistance. This problem was solved by preparing special copolyimides and abandoning surfactants in foaming.

Of particular significance is foamed polyimide insulation in medicobiological tests under conditions of prolonged space flight. The tests revealed the reliability of fixation of various medical glassware at high G-factors, increased vibration, and lack of gravity. In unmanned spacecraft, the application sphere of foamed polyimides is not restricted to biological shielding, and the service range of foamed polyimides with respect to thermal, mechanical, acoustic, and radiation characteristics is considerably extended. For example, the service temperatures on satellites cover the range from –60 to +180°C, the mechanical overloads exceed by a factor of 2–3 those acceptable in manned spacecraft, and the radiation background depends on specific operation conditions of a satellite. Foamed polyimide protection ensures uninterrupted tele- and radiocommunication, reliable preservation of scientific data, and coordinated work of the electrical, electronic, and optical equipment of space laboratories [87].

Depending on design features and functions of specific units and parts of a spacecraft, the density of foamed polyimides varies in a wide range: from 6.5 to 950 $kg\,m^{-3}$. This is achieved by proper choice of the chemical structure of the initial polyimide components and of the foaming process and by the use of additives ensuring the required flexibility, elasticity, or rigidity of foamed materials used for manufacturing walls, floors, seats, ceilings, and other elements of not only air- and spacecraft, but also ships, submarines, high-speed trains and cars, and also certain units of pipelines, compressors, and other parts for transporting corrosive gases and liquids [88, 89]. In some cases, to enhance the rigidity and impact strength, foamed polyimides are formed in combination with reinforcing materials such as fiber glass, fibrous carbon, spherical fillers, honeycomb cells, semirigid segments with addition of boron nitrides, etc. It seems quite realistic to construct in the outer space large structures of high strength and low weight, using reinforced hollow carbon fibers connected with ultrathin semiconducting polyimide hybrid films. This will allow construction of high-power solar batteries for spacecraft.

Analysis of the literature published in the late 1990s shows that the major attention in the field of development and modification of foamed polyimides was given to the development of new polyimide nanostructures [8, 12, 89–92] with simplified and cheap process for production of foamed materials. Major attention was paid to powder technology. For example, Dutruch *et al.* [93] reported a very simple process for production of foamed polyimide by heating a mixture of oligoimide containing nadic and benzhydroxy groups (97%) and a silicone elastomer (3%). The resulting foamed polyimide exhibits high insulating power and preserves its mechanical characteristics up to temperatures as high as 300°C. Also of interest are foamed polyimides with glass sphere fillers; these materials surpass in strength and acoustic resistance the analogous materials based on epoxy resins [94]. Recently, production of foamed polyimides from various mixed formulations was initiated; in these formulations, polyimides are combined with copolyimides and other aromatic polymers and their derivatives. A light and strong material with high softening point (260°C), stable up to 570°C, was prepared from such mixtures (IPO-2) in combination with carbon and synthetic felts fabricated from such fibers as SVM, Arimid, Arimid VM, Oksalon, or Terlon [95–99]. The initial material for the IPO-2 binder is a powder soluble in methanol, ethanol, and acetone. The powder melts at 120–130°C, and the melt viscosity is 0.8–1 Pa s. When IPO-2 is used in combination with a surfactant, an elastic polyimide is obtained with density, mechanical strength, and cell size adjustable in a wide range. It is feasible to add reinforcing components into the same formulation and to obtain materials used as finishing and insulating materials in aviation, automobile construction, and ship building. The density

Table 4. Properties of multilayer foamed composites based on polyimide binders, H complexes of benzophenonetetracarboxylic acid and aromatic diamines [97]

of such materials varies within 0.1–1.2 g cm^{-3}; they are heat-resistant up to approximately 400°C and have an oxygen index of 45–50%. Some characteristics of composites based on these materials are listed in Table 4 [97].

Foamed polyimides are widely used in microelectronics as dielectrics with a very low dielectric constant (ε = 1–1.5) [100], protective sensor coatings, and stress buffers for compensation of vibration loads on integrated curcuit components under extreme conditions [27].

Membranes. The unique properties of polyimides allowed development and putting into practice, within the past 20 years, of a new generation of membranes for separation of gases, vapors, and liquids. Polyimide membranes exhibit exceedingly high resistance to almost all chemical agents. Their heat resistance allows separations to be performed for a long time at elevated temperatures, and the high selectivity is very important for gas separation. The possibility of obtaining membranes that would be highly selective and, at the same time, permeable for water and organic substances is due to specific molecular design of polyimides. This problem can be solved on the macromolecular level if methods are available for preparing structures with reliable articulation of rigid backbone segments providing, in their turn, calibrated interchain packing with very narrow free volume distribution. In polyimides, this possibility is fully implemented owing to the well mastered methods for adjusting the polymer structure by varying the chemical structure of the diamine and dianhydride components of the polyimide. Basic theoretical studies and rich experience in synthesis of polyimides by various polycondensation procedures allowed fabrication of diverse membranes from more than hundred polyimides of various chemical structures [1, 2, 27, 101–107]. A conglomerate of rigid oriented polyimide structures with a definite polarization, the possibility of their interaction with the surrounding substrate via hydrogen bonds and other weak short-range forces give polyimides undisputable advantages over other polymers, and their unique heat resistance and chemical stability considerably extend the possibility of using these polymers for purification, separation, and ultra- and microfiltration of numerous chemical and biological products.

Fifteen years after the synthesis of the first high-molecular-weight polyimide from pyromellitic dianhydride and aromatic diamine, Du Pont developed the first commercial polyimide membrane, Permasep, for treatment and desalination of water. Since that time, there has been enormous progress in commercial production of polyimide membranes. As judged from the patent literature, by the end of the XX century the total number of the developed commercial procedures for preparation and use of polyimide membranes exceeded that in the 1970s by three orders of magnitude. At present, the leading place in the polyimide membrane industry is occupied by the United States and Japan.

Polyimide membranes showed the best performance in treatment and separation of gas mixtures, especially "simple" gases such as hydrogen, helium, carbon dioxide, and some other gases from petrochemical industry. In this field, there is a practically unlimited market for separation devices with polymeric filters exhibiting high heat resistance, resistance to high pressures, low solubility, stability toward corrosive

gases, and high separation factors and permeability. At present, hydrogen, the demand for which grows year by year, is isolated, purified, and concentrated with polyimide membranes. The main sources of hydrogen are gases from refining of hydrocarbon raw materials; synthetic gas mixtures used in various chemical, coal-chemical, and metallurgical processes; gaseous wastes from production of ammonia; and electrolysis by-products. Each of these sources has its specific features related to the technology of the main product. The limiting temperature and pressure, their drops, gas flow rate, chemical composition of the gases to be separated, the corrosiveness under process conditions, catalysts, structural materials of the reactors and communications—all these factors impose requirements, often very stringent, on the material of separators for hydrogen recovery. Practical experience has shown [2, 101, 108] that polyimides are the best materials among other polymers and inorganic products used for hydrogen membranes. For example, polyimide membranes used by Ube (Japan) for separation and purification of hydrogen operate at 150°C and a pressure of 15 MPa; the pressure drop is 14 MPa, and the H_2/CH_4 separation factor, 200–250. The membrane material is resistant under these conditions to ammonia, hydrogen sulfide, carbon dioxide, and vapors of water and some organic substances (Table 5). In a number of parameters, polyimide membranes considerably surpass membranes made of cellulose acetate, polysulfonesilicone elastomer, and polyaramides. Polyimide membranes are also advantageous as compared with glass membranes (Table 6). These examples show that the considerable progress in mastering of polyimides as materials for hydrogen purification membranes leads to significant quantitative results. As the separation factor is raised from 50 to 200, the yield of hydrogen from a hydrocarbon mixture with methane increases from 65 to 98%. The increase in the permeability coefficient allowed the production capacity to be raised to $(7.5–10) \times 10^3$ $m^3 h^{-1}$. High physicomechanical parameters of polyimide membranes eliminate the problem of "utilization" of hydrogen from gas flares, typical of fuel technology. With polyimide membranes, it is now possible to solve the problem of production of ultrapure hydrogen widely used in semiconductor industry, refining of some metals, and chemical reactions involving fine catalytic processes. Ohya *et al.* [2] described installations operating on by-products of ammonia production at a flow rate of 120 $m^3 h^{-1}$, ensuring recovery with polyimide filters of 99.9996% pure hydrogen containing as impurities no more than $(1–2) \times 10^{-6}$% nitrogen, argon, and methane.

Table 5. Chemical resistance of polyimide fibers produced by Ube Industries [2]

H_2/CO permeability ratio	2.3	50
Outer diameter of fiber, mm	2	0.4
Membrane area in a standard unit, m^2	94	470

Another gas equally well purified on polyimide membranes is helium. Helium is recovered both from mixtures of natural gases and from artificial mixtures containing air and industrial gases. A two-step installation for recovery of helium from mixtures with nitrogen, ensuring an increase in the helium concentration in the gas flow from 6 to 93%, have operated for approximately 10 years. Removal from helium of impurities of air and other gases allows production of 99.7% pure helium. One of the most interesting problems solved with polyimide membranes is recovery of helium from spent deep-sea respiration gas mixtures [109]. Combination in a single unit of several membranes and step compressors allowed recovery of 90 to 95% of helium from a ternary gas mixture consisting of oxygen, nitrogen, and helium.

Of no less urgency is the problem of CO_2 recovery from various gas mixtures for its subsequent use in chemical technology or for its removal from gases (as well as the problem of removal of other so-called acidic gases). Thanks to unique properties of polyimide membranes, there has been an impressive suc-

cess in recovery of CO_2 from various gas mixtures in gas and oil-refining industry. For example, it is well known that the output of worked-out wells can be increased by elevating the pressure in depleted oil-bearing strata. This can be achieved, e.g., by pumping gas mixtures containing CO_2 into the strata. When returning to the surface, the spent gases become enriched in methane. Carbon dioxide is separated from methane with various membrane separators. In this field, the advantage of polyimide membranes is also beyond any doubt, since they ensure a CO_2/CH_4 separation factor as high as 40–60, whereas with the other membranes this factor does not exceed 20–25. The high heat resistance of polyimide membranes was used for treatment of gases from electrolysis of carbonate melts; the initial temperature of these gases (H_2 + CO_2) is 650°C.

At present, an important problem is treatment of natural gas. Its composition strongly depends on a particular gas field. As a rule, natural gas is a mixture consisting mainly of methane and CO_2. The content of methane varies from 40 to 60%. For using this mixture as a fuel, it should be enriched in methane, which is mainly provided today by the membrane technology. Comparison of the efficiency of various polymeric membranes shows that polyimide membranes allow production of a concentrate containing up to 94% methane and no more than 1% CO_2. This process allows solution of still more important environmental problems related to utilization of biologically active wastes accumulated in municipal dumps. The experience of using a process line consisting of a cascade of separators with polyimide membranes [2] showed not only the economical efficiency of recovery and concentrating of methane from gaseous decomposition products but also a significant environmental effect due to removal and utilization of such gaseous products as CO, CO_2, H_2S, etc. There also has been a considerable success in Japan in using polyimide membranes for treatment of natural gas to remove CO_2. It was shown that, even at an initial CO_2 content of about 20%, the content of CO_2 in the gas lines was as low as 1.7% in the course of a 2-year service. Certain advantages of the membrane process, compared with liquid treatment with diglycol ammonia, were revealed. These advantages are manifested in the absence of corrosion of compressor units and considerable simplification of maintenance, which now actually consists in measuring weekly the CO_2 concentration and replacing every year the filters [2].

Successful use of polyimide membranes for treatment of low-boiling gases stimulated research works in the field of use of these materials for separation and treatment of gas flows to remove various vapors of organic and inorganic substances, primarily for dehydration of gases. It was found [110, 111] that the permeability of polyimide membranes to water vapor is a factor of 200–500 higher than that to air and that permeation of vapors of organic compounds through these membranes is an exponential function of their normal boiling points. Two types of water vapor separators are produced, using various arrangements of compressors and separators and packing of polyimide materials used as membranes (mainly hollow fibers): membrane driers and filters for conditioners. Their design and operation are described in [112–114]. Along with household purposes, polyimide membranes are used in chemical industry for vapor-phase dehydration of organic solvents. Owing to the high thermal and chemical stability of polyimides, these processes can be performed at temperatures of up to 120°C and the optimal pressure of 0.1–0.2 MPa (economic mode). Installations for dehydration of ethanol, purification of isopropanol, and synthesis of catechol esters, equipped with polyimide membranes, have operated for more than 10 years [110–115]. Effective treatment of gas–air flows containing various solvents (alcohols, ketones, ethers, esters, aromatic and halogenated compounds) can be ensured by proper design of the apparatus and combination of membrane units with different separation factors. Such systems are used for trapping environmentally hazardous hydrocarbon vapors from off-gases of oil refineries, oil tanks, pipes, and terminals for fuel pumping. Furthermore, recovery of fuel from tanks brings a certain economic effect corresponding to thousands tons of naphtha, gasoline, hexane, and other fuel components [116]. During the past decade, a success was acheived in industrial use of polyimide membranes for purification, separation, and concentating of organic liquids. Along with ultrafiltration treatment of some high-boiling organic solvents, polyimide membranes were used [117, 118] for quantitative recovery from paint-and-varnish wastes and machine oil of such solvents as toluene, xylene, methyl ethyl ketone, ethyl acetate, etc. Thanks to the high stability of polyimide membranes and their chemical inertness, first attempts were made to use them in food and medical industry for treatment of vegetable oils and development of artificial organs. For example, membranes from fluorinated polyimides were tested in an artificial lung apparatus. As compared with silicone coatings, this material for vascular oxygenation shows considerably better gas exchange with respect to oxygen (by a factor of 3) and carbon dioxide (by a factor of 4) and good compatibility with blood components [119].

PLASTICS

Syntheses and studies of polyimides of varied chemical and supramolecular structure showed the feasibility of preparing novel materials whose processing to finished items became so simple that the well-known and mastered procedures used in production of common plastics appeared to be quite suitable without significant changes. The solubility, fusibility, and good rheological properties of melts and thermoplastics, characteristics of polyimides of the third and fourth generations, lifted many limitations in polyimide processing. In the mid 1980s polyimide plastics, binders, and press powders were mainly produced from PM-67 and PM-69 materials in the former Soviet Union and from Vespel and Skybond plastics [1] in other countries, whereas at present from 350 to 500 diverse materials and articles containing from 5 to 100% polyimides and their derivatives are patented annually.

Since the formation of stable solvation complexes between polyamido acids and various solvents [120–122] and interpolymeric complexes between polyimides and other polymers [123–127] was proved, polyimides and their prepolymers came into use for preparation of diverse composite materials with wide application fields. To ensure the process efficiency, it is appropriate to use plasticization of polyimide prepolymers or oligoimides in the stage of thermoplastic curing. It is proposed to use SKN-type rubbers for this purpose, and reactive solvents based on furan derivatives [128, 129] for lowering the curing point of API-type oligoimides. These procedures allowed preparation of a series of imido plastics, a base for strong and heat-resistant composite materials with working temperatures of 300–450°C. Such composite imido plastics are used in aerospace parts, such as tips of nose cones and front edges of wings of space shuttles, control surfaces, nozzle linings, and parts of gas pipes of rocket and aviation engines [130]. Some polyimide materials and blends are processed by extrusion [131], pressing [132], and other methods known for thermoplastics [133].

Thermoplastic polyimide Aurum was developed by Mitsui Toatsu (Japan) on the basis of pyromellitic dianhydride and 3,3'-diphenyldioxydiphenylmethane [134]. This polymer belongs to superstructural plastics; its glass transition point is 250°C, and melting point, 388°C; it is stable without weight loss to approximately 500°C, radiation-resistant, and inert to acids, oils, organic solvents, and other chemicals. Aurum is used in various modifications in both crystalline and amorphous forms; it is also used in the form of composites reinforced with fiber glass or carbon fibers (Table 7). These composites surpass in a number of strength parameters such thermoplastic polymers as Torlon, Ultem, LARC-TPI, PES, PEEK, and PEN. The main application fields of Aurum are structural elements and sliding parts. For example, in supporting structures designed for cyclic loads, Aurum with carbon fiber replaced aluminum in parts of new V2500 aircraft engine, which resulted in decreased (by half) weight and increased strength of the parts; no deformation at 300°C was observed. Owing to its thermal plasticity, Aurum is used in friction units for direct molding of precision high-strength and heat-resistant sliding parts of complex shape (detachable cams for duplicators, thrust collars for various machines, gears, disks, supporting cantilevers of electronic equipment, cog wheels, valves, bearings for various mechanisms in automobile construction, hydraulics, oil-and-gas equipment) [135–138]. For antifriction parts, polyimides with Teflon or graphite filler are used [139–142]. Such units operate for a long time at 280°C and for a short time at temperatures of up to 480°C; they show minimal creep and high impact strength. The same materials are used to mold rods, sticks, sheets, tubes, or gaskets [143, 144]. Polyimide materials are suitable in engine construction for carburetors, high-strength motor parts, reducers, and other parts [145–147]. Among plastics in which polyimides are essential components, laminated plastics and especially carbon-reinforced plastics should be mentioned. For structural elements, of particular promise are imido plastics with reinforcing elements from fiber glass in the form of honeycomb materials [125, 140, 148, 149], laminates for electronics [150], and various printed-circuit boards made from polyimides in combination with epoxy resins and aramide nonwoven materials [151]. Recently, the use of polyimides and their prepolymers and derivatives considerably improved the service parameters of carbon-reinforced plastics, especially their heat and fire resistance and strength. Studies of the features of polyimide carbonization [65, 66, 141, 152–158] made it possible to develop, test, and put into practice in Russia a series of polyimide binders based on di- and tetraacetyl derivatives of aromatic diamines and dianhydrides of aromatic tetracarboxylic acids (ITA binders, Table 8) [13, 159–162] and oligoimides based on one or several aromatic diamines and acidic diesters of aromatic tetracarboxylic acids with terminal nadic groups (IPO binders) [12, 163–165]. The processability of carbon-reinforced plastics by melting can be improved by using thermoplastic polyimide binders based on polyesterimides prepared from polynuclear sulfur-containing diamines (PEI binders) [166, 167].

* Characteristics of carbon–carbon composites based on ITS thermolysis products and ELUR fiber.

From the same polymers and their derivatives, binders were prepared whose structure is a semi-interpenetrating polymer network (SIPN). SIPN binders contain oligoimides with maleinimide and nadic groups. To the same group of PEI binders belong thermoplastic partially crystalline polyimides [168–174].

Carbon-reinforced polyimide plastics surpass in crack and heat resistance the carbon composites prepared on another polymer base [175]. These materials are of particular interest for development of reliable spacecraft and hypersonic aircraft (M > 2). Along with aviation, these materials can be successfully used in military and civil ship building in bellow compensators with reinforcing rings fabricated from carbon-reinforced imide plastics, in shock absorbers for ship equipment, in vibration-absorbing coatings, in fireproof shields, in structural elements for air-cushion ships, and in casings for high-power electric motors on ships. As substitutes of aluminum and titanium alloys, imide plastics with carbon fillers are competitive in automobile construction for manufacturing parts and mechanisms operating at high speeds, temperatures, and loads, in power engineering for reactor insulation, and in equipment for chemical industry [176].

VARNISHES, ADHESIVES, AND COATINGS

Polyimide varnishes, adhesives, and coatings are still the major kinds of polyimide materials. The development of soluble and fusible polyimides and new polyimide prepolymers allowed successful use of previously mastered processes of plastics technology, with application of coatings to parts of any shape and subsequent curing under mild conditions.

Polyimide varnishes are successfully used, both as solutions and as adhesive formulations, for preparing enameled copper, aluminum, and steel wires. Russian varnish PAK-1 and its American analog Pyre-ML considerably surpass in service characteristics, especially in heat and crack resistance, varnishes based on other polymers [1, 15] and are still used, along with polyamidoimide varnishes, in electrotechnical industry [177]. The same is true for adhesives such as Skybond, Pyralin, Nodimide NR-150, LARC-15, etc. [1, 168], which are in some cases still indispensable for joining polyimide films with each other and with metallic articles [178, 179]. As for advances of the recent decade, the development of new varnishes is undoubtedly associated with microelectronics. This field requires readily soluble materials forming elastic, flexible, hydrophobic, low-shrinking, and transparent coatings. These requirements are met by partially or fully fluorinated polyimides [7, 8, 27]. In polygraphic fabrication of various semiconductor curcuits, these polyimides are used as photosensitive layers. Many process parameters and characteristics, such as photosensitivity, resolving power, exposure time, and irradiation intensity, depend on the chemical structure of a polyimide, thickness of applied layer, and concentration of sensitizers and photosensitive groups in the polymer [27, 180–183].

Along with fluorinated imides, siloxane-containing polyimides are used as adhesives in electronics [184, 185]. Owing to methylsiloxane substituents in the polyimide, they exhibit very low dielectric constant as compared with other polyimides (0.33–0.35) and low hygroscopicity. Good adhesion and high heat resistance allow their use as adhesive varnishes and films or as special sealants in automated assembling of integrated curcuits on a tape support. Also, these materials are equally useful in flexible and rigid multilayer printed-circuit boards. The assortment of adhesives has been recently supplemented with polyimides and oligoimides with reactive groups in the chain (malimide, hydroxy, cyanurate, epoxy, acrylate). An example of such polyimides is bisallylnadicimide [186] used in various adhesives in combination with epoxy and other resins for plastics, electric insulation coatings, coatings for magnets, etc. Polyamides containing sulfur in the backbone, aliphatic substituents in pendant chains, and also polyhydroxy imides with diazonaphthoquinone in combination with other soluble adhesive polyimides are used for assembling devices in microelectronics and luminescence engineering [187–189].

CONCLUSION

Analysis of publications of the past decade shows that advances in synthesis of new polyimides made it possible to overcome certain bottlenecks in the technology for producing materials based on them. Preparation of soluble, fusible, and readily processable polyimides strengthened their leading role in advanced branches of industry. High heat resistance, combined with other unique characteristics (strength, radiation and chemical resistance), allows use of films, fibers, plastics, composites, foams, membranes, adhesives, and other materials in diverse structures, apparatus, units, and parts operating under extreme conditions of high speeds in any media (surface, underground, air, underwater, space).

Abstract—The phase relationships in the system $CaSiO_3$–$BaGeO_3$ were studied and its phase diagram was constructed.

Proceeding with investigations of phase equilibria and isomorphism in partial sections of a ternary mutual system CaO, BaO || SiO_2, GeO_2 [1–5], we studied the system $CaSiO_3$–$BaGeO_3$, which is a diagonal section of the concentration quadrangle $CaSiO_3$–$CaGeO_3$–$BaGeO_3$–$BaSiO_3$.

The chemical composition of the simplest pyroxenoids is expressed by the general formula $M_n[SiO_3]_n$, where M represents a group of cations with large ionic radius (Ca^{2+}, Sr^{2+}, and Ba^{2+}) in various integral and fractional ratios [6].

Extending the range of chemical compositions of pyroxenoid silicates, studying the phase relationships between them, and establishing the concentration regions of homogeneity in these systems constitute one of necessary stages in the development of new materials.

According to previous studies [4, 7, 8], potassium metasilicate $CaSiO_3$ crystallizes in two polymorphic modifications: low-temperature β-form with chain-like structure of anionic radicals and high-temperature pseudowollastonite α-form with ring-like structure of anionic groups. The temperature of the β→α transition is 1180°C; the given polymorphic transformation is monotropic under atmospheric pressure.

Barium metagermanate $BaGeO_3$ also exists in two polymorphic modifications. Its low-temperature pseudowollastonite α-form transforms at 1225°C into a high-temperature β-form with chain-like structure of anionic radicals. The latter form differs from β-$CaSiO_3$ in the arrangement of tetrahedral chains. In β-$CaSiO_3$, the anionic chains with identity period of three tetrahedrons consist of diortho groups alternating with separate tetrahedrons. In the structure of barium metagermanate (β-form), the anionic chains with identity period of two tetrahedrons are formed solely by diortho groups [8, 9].

In the present study, samples for analyzing phase equilibria in the $CaSiO_3$–$BaGeO_3$ system were prepared by solid-phase synthesis. As starting components of the stock served $CaCO_3$ (special purity), $BaCO_3$ (chemically pure), GeO_2 (special purity), and SiO_2 (99.99% pure). Prior to synthesis, a stock of prescribed composition was thoroughly ground in distilled water, compressed into pellets, and then subjected to high-temperature calcination for a time varied between 3 and 50 h, depending on sample composition. The temperature of the initial calcination was 1180°C. Samples of intermediate compositions were synthesized both from oxide mixtures and from the end members of the section, β-$CaSiO_3$ and α-$BaGeO_3$, synthesized in advance. The system was studied in the temperature range 1000–1450°C, using a set of physicochemical methods, including X-ray phase (XPA, Cu_{K_α}-radiation) differential thermal (DTA, MOM derivatograph, Hungary), and crystal optical (immersion) analyses, and the method of annealing and quenching.

The phase diagram of the $CaSiO_3$–$BaGeO_3$ system was constructed on the basis of the results obtained in the experiment performed (Fig. 1). The phase relationships in the subsolidus region are characterized by a certain complexity and diversity of the crystallizing structural types. Optical and X-ray characterization of the phases existing in the system are presented in Figs. 2 and 3. Five regions of homogeneity are distinguished in the diagram, differing in their dimensions along the concentration and temperature axes. A region with the broadest concentration range is occupied by the $Ca_{1-x}Ba_x(Si_{1-x}Ge_x)O_3$ ($0.18 < x < 0.56$,

1070-4272/01/7408-1270 $25.00 © 2001 MAIK "Nauka/Interperiodica"

at T = 1060°C) solid solution having a walstromite-like structure according to XPA [10]. The given phase is stable over the entire temperature range studied, up to its melting point. The existence of a broad homogeneity region in the central part of the system is confirmed by a steady change in the refractive indices of the crystals and by monotonic change in the interplanar spacings d/n. In all probability, the walstromite-like solid solution $Ca_{1-x}Ba_x(Si_{1-x}Ge_x)O_3$ is formed from a compound similar in nature to double salts with 2 : 1 stoichiometric ratio of the starting components.

To the end members of the system, $CaSiO_3$ and $BaGeO_3$, are adjacent narrow homogeneity fields (2 to 10 mol %) based on their α- and β-polymorphic modifications. The boundary lines in the phase diagram were plotted on the basis of DTA and XPA data and the results obtained using the method of annealing and quenching. The concentration region of homogeneity of the α-$CaSiO_3$ solid solution is narrow, its boundary is plotted conventionally.

As follows from the phase diagram, the conjugate isomorphism $Ca^{2+}Si^{4+} \rightleftarrows Ba^{2+}Ge^{4+}$ affects differently the thermal stability of different structural types of the metasilicates–metagermanates studied. For example, simultaneous substitution of Ba^{2+} for Ca^{2+} and Ge^{4+} for Si^{4+} raises the thermal stability limit of a solid solution based on the low-temperature modification of $CaSiO_3$ from 1180 to 1300°C (i.e., to the temperature of its incongruent melting). With Ba^{2+} and Ge^{4+} in the α-$BaGeO_3$ lattice replaced by, respectively, Ca^{2+} Si^{4+}, the temperature range of stability of this solid solution is markedly narrowed and that of its high-temperature modification (β-form) considerably broadened. For the phase of variable composition, $Ca_{1-x}Ba_x(Si_{1-x}Ge_x)O_3$, the homogeneity region becomes only slightly narrower with increasing temperature for $CaSiO_3$-richer compositions.

The optical characteristics of the phases crystallizing in the system (Fig. 2) differ in the refractive indices n_g, n_p and birefringence $\Delta = n_g - n_p$. The largest birefringence is observed for crystals of the α-$CaSiO_3$ and α-$BaGeO_3$ solid solutions, and the smallest, for the $Ca_{1-x}Ba_x(Si_{1-x}Ge_x)O_3$ solid solution. The X-ray diffraction patterns of the α-forms of the $CaSiO_3$ and $BaGeO_3$ solid solutions are similar (Fig. 3). The only difference is that the diffraction peaks are shifted to smaller angles and the relative intensities of the reflections are redistributed in the case when calcium ion is replaced in this structural type by the larger barium ion. Figure 3 also clearly shows that the X-ray diffraction patterns of two solid solutions, β-$CaSiO_3$

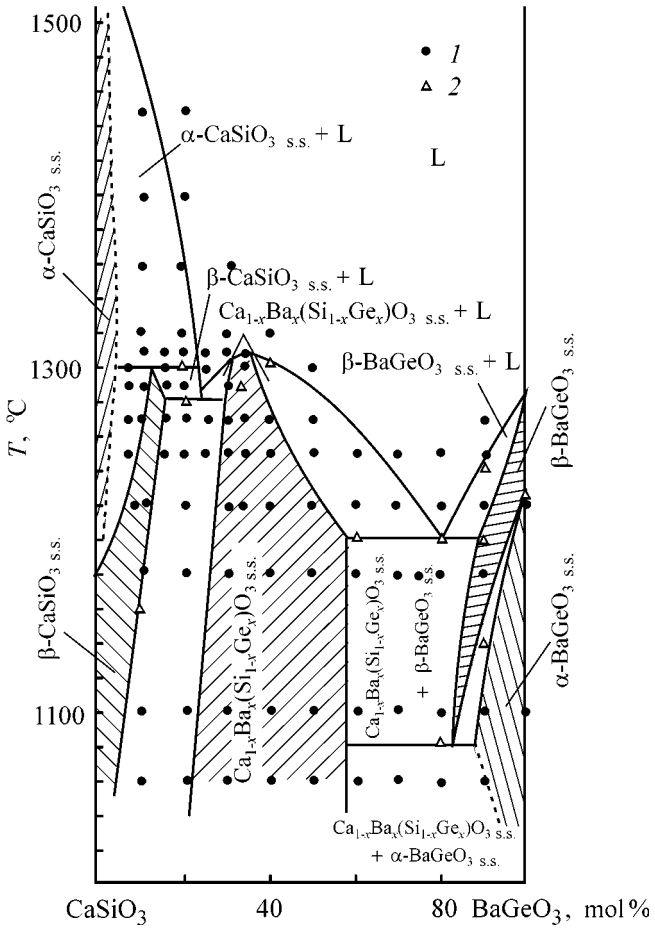

Fig. 1. Phase diagram of the system $CaSiO_3$–$BaGeO_3$. (T) Temperature. Method: (*1*) annealing and quenching and (*2*) DTA.

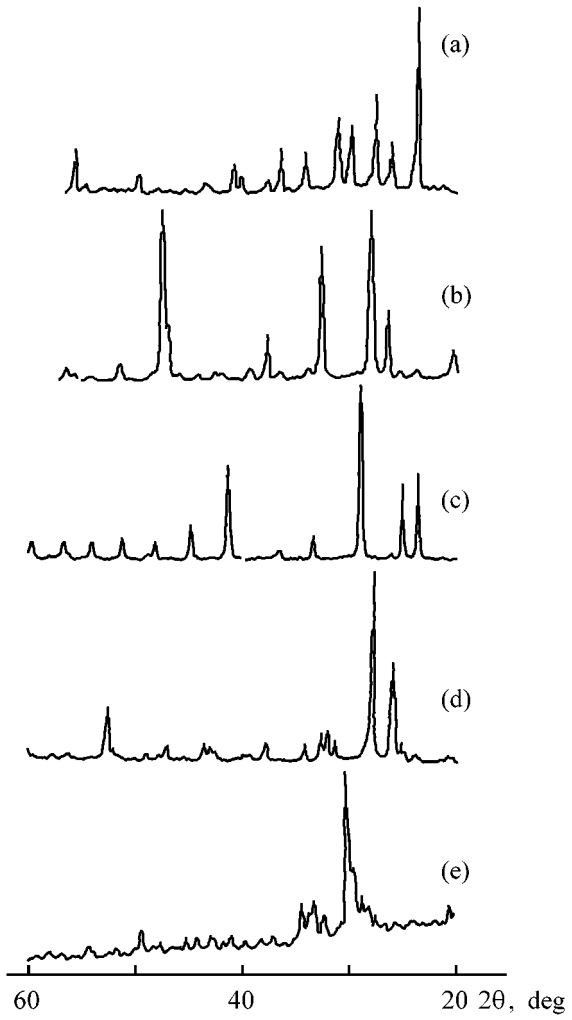

Fig. 3. X-ray diffraction patterns of solid solutions in the system $CaSiO_3$–$BaGeO_3$. (2θ) Bragg angle. (a) β-$CaSiO_3$, (b) α-$CaSiO_3$, (c) α-$BaGeO_3$, (d) β-$BaGeO_3$, and (e) $Ca_{1-x}Ba_x(Si_{1-x}Ge_x)O_3$ ($0.2 < x < 0.56$) (walstromite structural type).

and β-$BaGeO_3$, are markedly different. This is due to the difference in the identity periods of their chains and, correspondingly, in the configurations of the tetrahedral chains in their structure. The X-ray diffraction pattern of the $Ca_{1-x}Ba_x(Si_{1-x}Ge_x)O_3$ solid solution is typical of the structural type of walstromite $Ca_2BaSi_3O_9$.

In the concentration range 56–87 mol % $BaGeO_3$, the system is represented by two-phase fields based on one of the two polymorphic modifications of $BaGeO_3$ (α- or β-form) and by the $Ca_{1-x}Ba_x(Si_{1-x}Ge_x)O_3$ solid solution (Fig. 1). In the given concentration range at 1080°C, eutectoid decomposition of the β-$BaGeO_3$ solid solution into the solid solutions α-$BaGeO_3$ and $Ca_{1-x}Ba_x(Si_{1-x}Ge_x)O_3$ occurs in the system. In all probability, the revealed eutectoid decomposition of β-$BaGeO_3$ into α-$BaGeO_3$ and the limiting composition of the walstromite solid solution ($x = 0.56$) reflects a kinetically nonequilibrium process, which is responsible for the slope of the limiting solubility boundaries untypical of the given case of phase decomposition.

The results of DTA and XPA and a crystal optical study of samples quenched from different temperatures confirm the eutectic nature of the interaction between the β-$BaGeO_3$ solid solution and the walstromite-like phase.

The liquidus and solidus curves of the system were plotted on the basis of data furnished by DTA and the visual-polythermal method, using the results of crystal optical studies of samples quenched from different temperatures.

Establishing the liquidus and solidus relationships in the concentration range from 10 to 40 mol % $BaGeO_3$ was made difficult by the fact that the fields of equilibrium coexistence of the liquid and solid solution phases are narrow. The close phase transition temperatures (1280–1300°C) in the given concentration range required an additional study to elucidate the nature of melting (eutectic or peritectic) of the $Ca_{1-x}Ba_x(Si_{1-x}Ge_x)O_3$ solid solution and to detail its interaction with the β-$CaSiO_3$ solid solution.

In this case, the key factor were the results obtained in studying quenched samples successively annealed within the 1250–1340°C range with a step of 10–20°C. Four samples with compositions differing by 5 mol % were simultaneously annealed in a platinum crucible. The visual-polythermal and crystal optical analyses of these samples showed that the most readily fusible composition in the concentration range studied is $Ca_{0.75}Ba_{0.25}(Si_{0.75}Ge_{0.25})O_3$. Liquid phases appeared in the sample at a calcination temperature of 1280°C. At higher temperatures (1290–1300°C) their phase composition changed. In the samples enriched in calcium metasilicate, compared with the boundary composition $Ca_{0.75}Ba_{0.25}(Si_{0.75}Ge_{0.25})O_3$, only prismatic crystals whose refractive indices n_g and n_p were similar to those of the β-$CaSiO_3$ solid solution were in equilibrium with the liquid. For $BaGeO_3$-enriched samples, only isometric grains with considerably higher values of n_g and n_p were clearly revealed in an immersion preparation along with the liquid phase, which is characteristic of a walstromite-like solid solution (Fig. 2). Analysis of the obtained experimental data confirms unambiguously that the interaction between

the $Ca_{1-x}Ba_x(Si_{1-x}Ge_x)O_3$ and β-$CaSiO_3$ solid solutions is eutectic. The eutectic composition is 75 mol % $CaSiO_3$ + 25 mol % $BaGeO_3$, and T_{eut} = 1280°C. The β-$CaSiO_3$ solid solution melts peritectically at 1300°C to give the α-$CaSiO_3$ solid solution and a liquid.

The performed study of the phase relationships in the system $CaSiO_3$–$BaGeO_3$ (Fig. 1) demonstrated that the given system belongs to those with limited mutual solubility of the solid-state components to give the $Ca_{1-x}Ba_x(Si_{1-x}Ge_x)O_3$ berthollide phase of variable composition. In the concentration region in which this phase exists, the liquidus curve has a clearly resolved irrational peak at 1310°C for the composition corresponding to $CaSiO_3$: $BaGeO_3$ = 2 : 1. However, the refractive index curves show no inflection point for this solid solution composition. This means that there is no pronounced singularity point in the phase diagram owing to the high degree of dissociation of the compound and, correspondingly, confirms that this phase has berthollide physicochemical origin (Fig. 1).

Taking into account that Ca and Ba, and Si and Ge are similar in chemical nature, one would expect that extensive regions of homogeneity exist in the system considered on basis of its end members. However, according to the data obtained, nothing of this kind is actually observed. By contrast, a rather broad region of the $Ca_{1-x}Ba_x(Si_{1-x}Ge_x)O_3$ berthollide-like solid solution isostructural with walstromite is formed in its central part. The given structure is in fact a distorted pseudowollastonite form [10]. When the conjugate isomorphous substitution $Ca^{2+}Si^{4+} \rightleftarrows Ba^{2+}Ge^{4+}$ occurs in the cationic and anionic sublattices of the system, the appearance of a walstromite-like phase seems to be reasonable because of the significantly different types of behavior exhibited by the end members of the system. Probably, the walstromite structural type allows more substantial variation of the size of large cations constituting the distorted pseudowollastonite lattice, compared with the pyroxenoid structure.

CONCLUSIONS

(1) The phase relationships in the $CaSiO_3$–$BaGeO_3$ system were studied and its phase diagram was constructed.

(2) The system in question is polymorphic and belongs to systems characterized by limited solubility of components in solid state and formation of the $Ca_{1-x}Ba_x(Si_{1-x}Ge_x)O_3$ berthollide phase of variable composition ($0.2 < x < 0.56$ at T ~1050°C).

(3) The liquidus–solidus relationships in the system are characterized by the existence of eutectic and peritectic equilibria.

(4) Correlations were established between the temperature and concentration boundaries of isomorphous substitutions in the solid solutions of the given system.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Preparation of Al, Cr, Nb, Mo, and W Monophosphides from a Lithium Metaphosphate Melt

V. V. Lesnyak, D. A. Stratiichuk, V. S. Sudavtsova, and M. S. Slobodyanik

Shevchenko National University, Kiev, Ukraine

Received November 13, 2000; in final form, March 2001

Abstract—Synthesis of a series of phosphides (AlP, CrP, NbP, MoP, and WP) by reactions of powdered metals with a melt of lithium metaphosphate $LiPO_3$ was studied. Thermodynamic parameters (ΔH^0_{298}, ΔS^0_{298}, ΔG^0_{298}, and ΔG^0_{1273}) of the reactions were calculated and their temperature modes were optimized on the basis of the standard thermodynamic characteristics of the initial substances and the reaction products. X-ray patterns of the powders of the obtained compounds are presented.

The main method for synthesizing phosphides of *d* and *p* elements consists in direct reactions of metal powders with red phosphorus [1]. The reactions are carried out in evacuated quartz ampules at 1073–1473 K. Hydrogen or carbon dioxide is often used as carrier gas for phosphorus vapors. Certain phosphides are prepared in industry by immersing white phosphorus in a bath with molten metal. Thermally unstable higher phosphides are obtained by the "Faraday method," which consists in heating metal powders with an excess amount of red phosphorus. In this case, the temperature does not exceed 1373 K, and excess phosphorus is condensed in the coldest part of the apparatus. When the reaction is carried out at temperatures exceeding the boiling point of red phosphorus, its vapor pressure in the system increases considerably. This procedure for synthesizing higher phosphides is called "process under pressure" [2]. The majority of lower phosphides are obtained by sintering higher phosphides with stoichiometric amounts of metals. For example, V_3P was obtained by heating metallic vanadium with vanadium monophosphide VP, which, in its turn, was prepared by thermal decomposition of the diphosphide VP_2 [3].

The high-temperature electrolysis of sodium metaphosphate melts containing oxides or salts of heavy metals (vanadium, titanium, chromium, etc.) is the most promising industrial method of synthesis, which widely uses phosphates of alkaline and alkaline-earth metals as a source of phosphorus. Controlling the melt composition, synthesis temperature, and current density allows directional synthesis of various types of phosphides of a metal. Tungsten phosphide W_4P was obtained in such a way, whereas all other methods were unsuccessful [4].

In chemistry of solids, particularly in the preparative chemistry, the problem of directional synthesis of phosphides of *p* and *d* elements under specified conditions often arises. In most cases, it is possible to obtain mixtures consisting of lower and higher phosphides, the reaction products often containing unreacted starting substances or by-products.

In this work, we made thermodynamic calculations for certain redox reactions and, on this basis, carried out directional syntheses of a number of phosphides of *p* and *d* elements with the use of high-temperature melts of lithium metaphosphate.

EXPERIMENTAL

The following reagents were used in the work: Li_2CO_3, $(NH_4)_2HPO_4$, both of chemically pure grade; powders of Cr, Al, Nb, Mo, and W metals, all of chemically pure grade, with grain size of 4–8 μm; and also a glass based on lithium metaphosphate. The glass was obtained by the following technique. Stoichiometric amounts of lithium carbonate Li_2CO_3 and ammonium hydroorthophosphate $(NH_4)_2HPO_4$ were heated in a platinum ware (973 K) to complete removal of carbon dioxide, water, and ammonia:

$$Li_2CO_3 + 2(NH_4)_2HPO_4 \rightarrow 2LiPO_3 + CO_2\uparrow + 3H_2O\uparrow + 4NH_3\uparrow.$$

1070-4272/01/7408-1274 $25.00 © 2001 MAIK "Nauka/Interperiodica"

As a result, we obtained a transparent metaphosphate glass with fixed ratio $Li_2O : P_2O_5 = 1 : 1$. Phosphides were synthesized in the range 298–1273 K in the setup shown in the figure. Temperature was controlled with accuracy of ±1–2 deg. Phosphides of metals were obtained from a high-temperature melt of lithium metaphosphate by the following reactions:

$$3LiPO_3 + 13/3Al \rightarrow 5/3Al_2O_3 + Li_3PO_4 + 1/4P_4 + AlP, \quad (1)$$

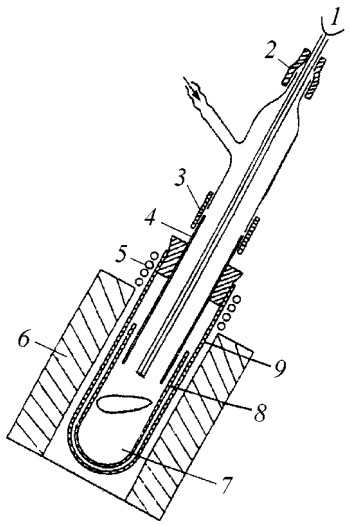
$$3LiPO_3 + 13/3Cr \rightarrow 5/3Cr_2O_3 + Li_3PO_4 + 1/4P_4 + CrP, \quad (2)$$

$$3LiPO_3 + 7/2Nb \rightarrow 5/2NbO_2 + Li_3PO_4 + 1/4P_4 + NbP, \quad (3)$$

$$3LPO_3 + 7/2Mo \rightarrow 5/2Mo_2O_3 + L_3PO_4 + 1/4P_4 + MoP, \quad (4)$$

$$3LiPO_3 + 7/2W \rightarrow 5/2WO_2 + Li_3PO_4 + 1/4P_4 + WP. \quad (5)$$

A mixture of powders of a metal and an excess amount (15–20% wt %) of lithium metaphosphate were thoroughly ground in an agate mortar and placed in a corundum crucible to fill its volume by 15–20%. Then the system was evacuated to residual partial oxygen pressure of 1–10 Pa. The system was heated at a rate of 20–30 deg h^{-1} up to 1253–1273 K, kept under these conditions for 5–6 h, and then cooled at a rate of 10–15 deg h^{-1} to room temperature. We found that metal phosphides were crystallized as needle-like crystallites in the colder part of the reactor (~923–1023 K) as a result of a gas-transport reaction. The transport agent in these reactions is phosphorus vapor formed as a by-product in the reaction between a metal and a melt. The main reactions result in the formation of metal oxides, which enter in the composition of the obtained orthophosphate melt.



Setup for synthesis of metal phosphides: (*1*) thermocouple, (*2*) Teflon sealant, (*3*) sealing titanium foil, (*4*) stainless steel tube, (*5*) cooling jacket, zone of condensation of phosphides (~923–1023 K), (*6*) SShOL-1-2 shaft furnace, working zone (~1253–1273 K), (*7*) starting mixture of metal powder and lithium-metaphosphate glass, (*8*) corundum crucible, (*9*) sintered corundum tube.

The contents of metals and phosphorus in the resulting crystalline phases were determined by X-ray fluorescent analysis on a VRA-20 instrument. According to this analysis, we assigned the following empirical formulas to the obtained crystalline phases: AlP (Al 42.59 and P 56.81 wt %), CrP (Cr 64.96 and P 35.83 wt %), NbP (Nb 75.05 and P 24.5 wt %), MoP (Mo 75.59 and P 23.91 wt %), and WP (W 85.58 and P 13.52 wt %). The X-ray patterns of the powders were recorded on a DRON-3 instrument using Cu_{K_α} radiation (λ = 1.54178 Å) and processed using the LATEX program and the ASTM structural database. The obtained results are given in Table 1.

The calculated crystallographic unit cell parameters a_{exp}, b_{exp}, and c_{exp} for the obtained phosphides agree with the data of the ASTM file (a_{theor}, b_{theor}, and c_{theor}) (Table 2). To optimize the synthesis conditions and to substantiate theoretically the data obtained, we calculated ΔH^0_{298}, ΔS^0_{298}, ΔG^0_{298}, and ΔG^0_{1273} for reactions (1)–(5) on the basis of standard thermodynamic functions [5–7] of the starting substances and reaction products. The calculations proved that these reactions are possible in the temperature range 298–1273 K (Table 3). The thermodynamic functions ΔS^0_{298} for the phosphides were calculated according to the additivity law.

Table 3. Thermodynamic parameters of reactions (1)–(5)

Reaction	ΔS^0_{298}, J mol^{-1} K^{-1}	ΔH^0_{298}	ΔG^0_{298}	ΔG^0_{1273}
		kJ mol^{-1} of phosphide		
(1)	–76.0	–1188.5	–1165.6	–1101.2
(2)	37.4	–1411.9	–1019.5	–1047.6
(3)	14.3	–653.3	–657.6	–671.5
(4)	13.0	–9.1	–13.1	–22.1
(5)	14.3	9.8	5.5	–8.4

In the case of reaction (1), (preparation of aluminum phosphide AlP), despite the negative ΔS^0_{298} value (–76 J mol^{-1} K^{-1}), the value of $\Delta_f H^0_{298}$ for the resulting aluminum oxide (–1676.81 kJ mol^{-1}) strongly affects the ΔG^0 of the reaction, which becomes negative at both 298 and 1273 K.

Theoretically, reaction (2) (synthesis of chromium monophosphide), which yields thermally stable chromium(III) oxide, is possible even at room temperature: ΔG^0_{298} = –1019.5 kJ mol^{-1} of the phosphide. To prepare M_2O_3 oxides by reactions (1) and (2), the values $\Delta_f H^0_{298}$ for their formation must be about –1 MJ mol^{-1}. In the case of formation of MO_2 oxides, the reaction would be intensive only when $\Delta_f H^0_{298}$ is within the limits –0.8…–1 MJ mol^{-1}. Greater negative values of both ΔG^0_{298} and ΔG^0_{1273} K for reaction (4) (synthesis of molybdenum phosphide), compared with reaction (5) (synthesis of tungsten phosphide), are attributable to the negative value of ΔH^0_T for reaction (4). This means that molybdenum has greater affinity to phosphorus than tungsten and also confirms the empirical rule which states that the stability of phosphides in subgroups of *d* metals decreases with increasing atomic weight of metal.

CONCLUSIONS

(1) The conditions of monophosphide syntheses (1)–(5) were optimized in accordance with thermodynamic calculations.

(2) It was shown that niobium, aluminum, chromium, tungsten, and molybdenum monophosphides can be synthesized by gas-transport reactions in M–$LiPO_3$ systems.

Received April 16, 2001

Abstract—The solubility was studied in the systems Na_2SO_3–NaCl–NH_4Cl–$(NH_4)_2SO_3$–H_2O at 20 and 40°C and NH_4HSO_3–$NaHSO_3$–NaCl–NH_4Cl–H_2O at 40°C by the graphic-analytical method. The obtained results were used to choose the most efficient method for obtaining sodium sulfite by conversion and to substantiate the optimal temperature condition of the process. The data obtained in studying stages of conversion of ammonium sulfate solution with sodium chloride and crystallization of a by-product—ammonium chloride, made it possible to find the optimal technology of the closed cyclic process.

The conversion technologies for inorganic salt production are widely used because of their simplicity, high intensity, and efficiency. They are among the main techniques employed to manufacture chlorine-free potassium fertilizers. The conversion technology also underlies methods for obtaining potassium sulfite from ammonium sulfate and sodium chloride. The practical use of this technique obviates the necessity for soda ash, thereby reducing the cost of the target product. There have been reports that sodium chloride can be used to obtain sodium sulfite [1]; however, they cannot serve as a basis for practical implementation of the given method, being scanty. In particular, the optimal pathway of the conversion and the choice of the temperature conditions have not been substantiated to a sufficient extent. The problems associated with water balances and with the possibility of performing a closed cyclic process have not been considered in the literature at all.

The conversion method for obtaining sodium sulfite is based on processes occurring in aqueous mutual salt systems Na_2SO_3–NaCl–NH_4Cl–$(NH_4)_2SO_3$–H_2O (sulfite system) and NH_4HSO_3–$NaHSO_3$–NaCl–NH_4Cl–H_2O (hydrosulfite system) at temperatures ranging from 20 to 85°C. Since there are no published data on solubility in these systems in a sufficiently wide temperature range, prognosticating how the composition of solutions of the sulfite and hydrosulfite systems varies with temperature and optimizing the technological cycle seems to be rather complicated and problematic task.

To solve this problem, the solubility in the sulfite and hydrosulfite systems has been studied and new data have been obtained for the solubility in the sulfite system at 20 and 30°C and in the hydrosulfite system at 40°C [2]. The obtained results were used to plot solubility isotherms and their water projections at 20–85°C for the sulfite system and 25–60°C for the hydrosulfite one. This served as a theoretical basis for optimizing the conversion of sodium chloride to give sodium sulfite.

Three most feasible variants of the given technological process were chosen (see the scheme). These variants were analyzed using the graphic-analytical method for studying solubility diagrams in the sulfite and hydrosulfite systems at various temperatures [3]. The obtained results made it possible to determine the optimal variant and to substantiate some technological parameters of the process.

As the main criterion for choosing the optimal variant of the process served the maximum yield of the target process at the minimum power consumption. In addition to establishing the optimal pathway of the process, the graphic-analytical analysis of solubility diagrams was used to determine the optimal temperature conditions of crystallization stages of the target product and by-product.

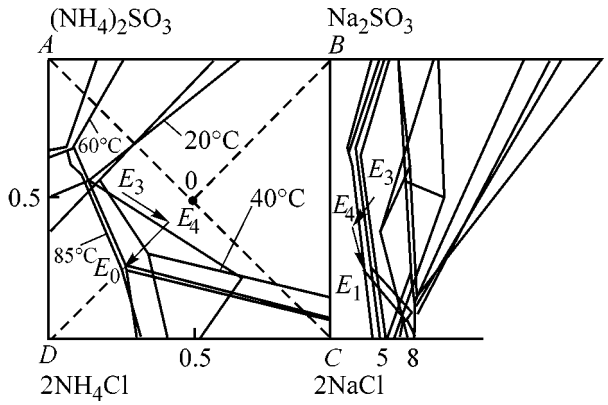

Fig. 1. Solubility diagram for the system Na_2SO_3–NaCl–NH_4Cl–$(NH_4)_2SO_3$–H_2O (sulfite diagram).

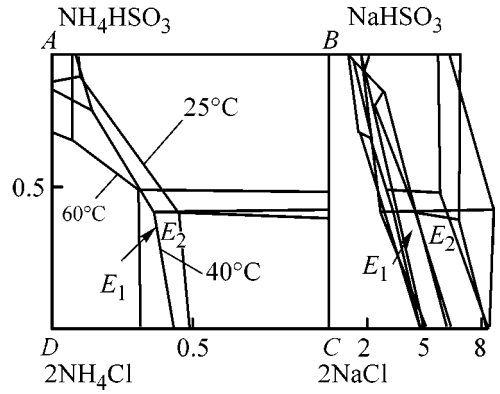

Fig. 2. Solubility diagram for the system NH_4HSO_3–$NaHSO_3$–NaCl–NH_4Cl–H_2O (hydrosulfite diagram).

Variant I, chosen for comparison, was described in [1], but its detailed analysis based on graphic-analytical method for studying the solubility in the corresponding aqueous-salt systems have not been performed so far. In the general form, this is a cyclic process whose initial stage is production of an ammonium sulfite solution via absorption of sulfur dioxide by ammonia solution by the reaction

$$2NH_3 + H_2O + SO_2 = (NH_4)_2SO_3. \quad (1)$$

Further, an equimolar amount of sodium chloride is introduced into the resulting solution

$$(NH_4)_2SO_3 + 2NaCl = Na_2SO_3 + 2NH_4Cl. \quad (2)$$

The figurative point of the salt system formed upon introduction of an equimolar amount of sodium chloride lies at the intersection of diagonals (point 0) of the solubility diagram of the sulfite system (Fig. 1). In the temperature range 20–80°C, point 0 lies within the crystallization field of Na_2SO_3. Therefore, the salt system is a suspension whose solid phase consists of sodium sulfite which crystallizes along ray *B*0 from point 0 to the intersection with the crystallization field of ammonium chloride (point E_0). Further, ammonium chloride (by-product) should be isolated into the solid phase from the mother liquor (point E_0). Otherwise, the finished product will be strongly contaminated with ammonium chloride in the case of a closed, with respect to the liquid phase, process (recycling of the mother liquor). For this purpose, the mother liquor is saturated with sulfur dioxide in the proposed variant to convert sulfite into hydrosulfite by the reaction

$$Na_2SO_3 + SO_2 + H_2O = 2NaHSO_3. \quad (3)$$

The composition of the system formed in this case will be represented by a figurative point E_1 in the solubility diagram of the hydrosulfite system NH_4HSO_3–$NaHSO_3$–NaCl–NH_4Cl–H_2O (Fig. 2). As it can be seen from the diagram, the figurative point E_1 lies within the crystallization field of ammonium chloride at below 60°C. Consequently, a sufficient amount of the by-product can be isolated into the solid phase by cooling the solution of the above-mentioned composition. (point E_1). However, it should be mentioned that intermediate isolation of NH_4Cl can be achieved in both the hydrosulfite and sulfite systems. The main criterion for selecting a system in which intermediate isolation of ammonium chloride is feasible is the parameter "optimal yield of ammonium chloride."

As seen from reaction (2), two moles of NH_4Cl are to be removed from the system per every mole of the forming sodium sulfite in accordance with the stoichiometric equation. That yield of ammonium chloride is to be considered optimal for which a stoichiometric, or a somewhat greater amount of NH_4Cl is isolated into the solid phase. If the actual amount of isolated ammonium chloride much exceeds the optimal value, then the ammonia consumption will be much greater. Otherwise, the excess amount of ammonium chloride will pass into the solid phase in the stage of crystallization of the target product, contaminating it.

Thus, to find the most efficient technological way to isolate ammonium chloride (sulfite or hydrosulfite system), it is necessary to determine the theoretical optimal yield of ammonium chloride and further compare the actual yields for the sulfite and hydrosulfite systems. This can be done in graphical analysis of the crystallization stages of ammonium chloride in the systems under consideration.

After separating ammonium chloride by the given procedure, ammonia is introduced into the solution to obtain ammonium sulfate and convert the hydrosulfite system into the sulfite one

$$2NaHSO_3 + 2NH_3 = Na_2SO_3 + (NH_4)_2SO_3. \quad (4)$$

The composition of the system upon ammoniation is represented in the sulfite diagram by a figurative point E_3 lying within the crystallization field of sodium sulfite. The obtained solution is recycled into the stage of conversion with sodium chloride. Graphically, the course of sodium sulfite formation is represented by a broken line $E_3E_4E_0$ (Fig. 1), where segment E_3E_4 corresponds to dissolution of sodium chloride, and segment E_4E_0 of the crystallization conode B_0E, directly to crystallization of sodium sulfite.

The results obtained in studying the solubility isotherms in the systems Na_2SO_3–NaCl–NH_4Cl–$(NH_4)_2SO_3$–H_2O and NH_4HSO_3–$NaHSO_3$–NaCl–NH_4Cl–H_2O served as a basis for calculating theoretically the optimal pathway of the process and substantiating graphically the temperatures of separate stages. With this aim in view, the compositions of the starting and intermediate solutions at varied temperature were first calculated. Then the optimal temperature conditions of conversion of ammonium sulfate with sodium chloride and isolation of the by-product were determined by means of graphical analysis. For this purpose, the yields of sodium sulfite and ammonium chloride were calculated at varied temperature [4]. The yield of crystalline Na_2SO_3, $W_{Na_2SO_3}$, was calculated with respect to the total content of Na_2SO_3 in the starting solution.

A preliminary calculation based on the solubility diagrams of the sulfite system (water projections) demonstrated that the concentration of the initial ammonia solution should be 14.8 wt % NH_3. Saturation with gaseous sulfur dioxide of an ammonia solution with this concentration yields an ammonia sulfite solution containing 39.4 wt % $(NH_4)_2SO_3$. After mixing this solution with sodium chloride and separating the precipitating sodium sulfite, the composition of the mother liquor is represented by the figurative point E_0 corresponding to a triple eutonics of the sulfite system. According to a calculation based on published data on the solubility at 85°C, the eutonic solution E_0 contains 32.6 wt % NH_4Cl and 13.4 wt % Na_2SO_3 (85°C). The calculated theoretical yields of sodium sulfite into the solid phase are presented below in relation to the conversion temperature of ammonia solution, T_{cn}:

T_{cn}, °C	$W_{Na_2SO_3}$, %
40	52.4
60	62.4
85	65.1

The yield of sodium sulfite was not calculated at temperatures below 40°C since at < 33.4°C the precipitate is only composed of sodium sulfite heptahydrate $Na_2SO_3 \cdot 7H_2O$, which is not the target product in the technology being developed.

The highest yield of crystalline sodium sulfite is observed at the temperature of ammonium sulfite conversion and, correspondingly, at the temperature of crystallization of sodium sulfite, equal to 85°C. Consequently, the optimal temperature of the stage of Na_2SO_3 crystallization is 80–85°C. This is also indicated by the configuration of the diagrams (Fig. 1), according to which the working solutions are 1.7–2 times more dilute at 40°C, compared with similar solutions at 60 and 85°C.

However, the most important problem in obtaining sodium sulfite by a process of this kind is mother liquor utilization. This solution should be either discharged into a slurry pond or processed in a cyclic manufacture of sodium sulfite, envisaging its intermediate discharge as a by-product. Since the solubility of NH_4Cl decreases as temperature is lowered, isolation of the by-product into the solid phase will occur on cooling a saturated ammonium chloride solution.

The yield of the NH_4Cl precipitate into the solid phase was calculated with respect to the total content of ammonium chloride in the starting solution. Calculations of the theoretical yield of ammonium chloride, W_{NH_4Cl}, into the solid phase upon cooling of solutions with composition corresponding to the composition of the system at the eutonic points E_0 and E_1 in the hydrosulfite system at different crystallization temperatures T_{cr} give the following results

T_{cr} NH_4Cl, °C	W_{NH_4Cl}, %
60	23.3
40	40.2
25	58.7

The stoichiometric yield of ammonium chloride, calculated for reaction (2), is 34.9% relative to its content in solution. Consequently, that yield of crystalline ammonium chloride is to be considered optimal, which is the closest to the stoichiometric value, but is no less than 34.9%.

Table 1. Physicomechanical properties of NH_4Cl crystals in relation to crystallization temperature*

T_{cr}, °C	H, wt %	L, μm	$K_f \times 10^5$, cm s^{-1}
40	11.4	24.3	1.1
30	32.75	28.9	0.89
25	43.33	35.6	0.78

* H is humidity, L crystal fragment size, and K_f filtration coefficient.

To verify the theoretical data, experiments were carried out to determine the actual yield of ammonium chloride into the solid phase on cooling to different temperatures a solution corresponding to point E_1 of the hydrosulfite system. The obtained results are presented below.

T_{cr} NH_4Cl, °C	W_{NH_4Cl}, %
50	28.1
40	39.3
30	52.4
25	58.7

As seen from the obtained results, the practical yield of ammonium chloride, equal to 39.3%, is the closest to the theoretical (calculated) value at 40°C. It should be mentioned for comparison that at a temperature of 25°C, recommended in [1], the yield of ammonium chloride into the solid phase is 58.7%, which is nearly 50% higher than the optimal value. Moreover, lowering the crystallization temperature to 20–25°C involves additional consumption of energy for cooling and the subsequent heating of the reaction mixture. Cooling the solution to 40°C leads, in addition to lower consumption of ammonia, to much lower energy expenditure and shorter process duration, and, consequently, to a higher intensity of sodium sulfite manufacture.

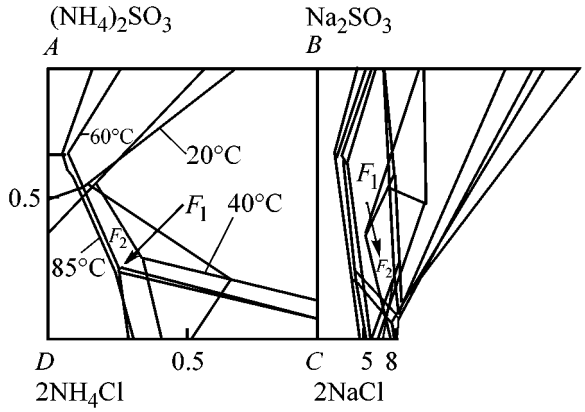

Fig. 3. Solubility diagram for the system Na_2SO_3–NaCl–NH_4Cl–$(NH_4)_2SO_3$–H_2O (variant II).

Also, as shown by additional investigations (Table 1), lowering the crystallization temperature entails a significant deterioration of the physicomechanical properties of ammonium chloride (the humidity of the precipitate becomes much higher and its filterability is impaired). Judging from data furnished by optical microscopy, the present case involves accreted dendrite composed of spherical ammonium chloride fragments, rather than individual crystals.

It is the formation of dendrites that accounts for the lack of correlation between the physicomechanical properties of the NH_4Cl precipitate formed at different temperatures and the size of its fragments.

It should be kept in mind that moisture contained in the humid cake is nothing other than mother liquor saturated at this temperature. In drying of a precipitate, the ingredients of the mother liquor pass into the product, contaminating it. This is confirmed by the results of an X-ray phase analysis of ammonium chloride precipitates for different crystallization temperatures. For example, an X-ray diffraction pattern of a precipitate obtained by cooling the starting solution to 25°C contains additional peaks corresponding to sodium chloride. At the same time, there are no such peaks in the X-ray pattern of the precipitate obtained on cooling the solution to 40°C.

The studies performed suggest that 40°C should be considered the optimal temperature in the stage of by-product isolation—crystallization of ammonium chloride. This conclusion is confirmed by a comparative calculation of material and heat balances of the cyclic process at cooling temperatures in the crystallization stage of 25 and 40°C. Comparison of the results obtained in calculating the heat balance shows that performing the crystallization at 40°C lowers the consumption of circulating water by 18.7% (by 1628.9 m^3 per 1000 kg of Na_2SO_3) as compared with the cooling of the starting solution in this stage to 25°C.

Another possible way to obtain sodium sulfite is conversion of a saturated sodium chloride solution after its preliminary ammoniation, with subsequent neutralization of ammonia with gaseous sulfur dioxide. The course of this variant of the process is described by the functional scheme. At a NaCl : $(NH_4)_2SO_3$ molar ratio of 2 : 1, the figurative point of the system, F_1, lies at intersection of the diagonals of the sulfite diagram (Fig. 3), and crystallization of sodium sulfite will occur at a temperature of 60–85°C in the resulting system Na_2SO_3–NaCl–NH_4Cl–$(NH_4)_2SO_3$–H_2O. It may be assumed that, since diffusion processes at

the phase boundary (dissolution of sodium chloride) are ruled out with the process carried out in this way, high-purity sodium sulfite can be obtained.

A graphical analysis of the given process demonstrated that, to obtain as a result of conversion a eutonic solution of composition corresponding to point E_0 (13.4 wt % Na_2SO_3, 32.6 wt % NH_4Cl; Fig. 4), at which the yield of sodium sulfite is at a maximum, the starting sodium chloride solution must have a concentration of 37.3 wt %. However, such a solution cannot be prepared in principle, since the solubility of sodium chloride at 80°C is 27.6 wt %. With a 27.6% solution of sodium chloride used as a basis, the solution after introduction of an equivalent amount of ammonium sulfite will be described by point F_1 (Fig. 3), corresponding to the intersection of diagonals of the sulfite diagram, with water coordinate I = 5.35 mole H_2O/1 mole of a sum of dry salts. After crystallization and separation of sodium sulfate, the mother liquor contains 14.8 wt % Na_2SO_3 and 23.1 wt % NH_4Cl, has a water coordinate I = 6.28 mole H_2O/1 mole of a sum of dry salts, and is represented in the sulfite diagram by point F_2 (Fig. 3). Consequently, the position of the segment F_1F_2 in the diagram indicates a substantial dilution of the working solution, much impairing the efficiency of the process. The theoretical yield of sodium sulfite into the solid phase does not exceed 45.6% of its total content in the starting solution, which is 20% lower than the value in the case of a process employing sodium chloride in crystalline form. Therefore, the given variant of the process cannot be considered optimal and recommended for practical use.

Variant III of obtaining sodium sulfite by conversion consists in that the process is only performed in the sulfite system. The functional scheme of such a process is presented in Fig. 4. The process is carried out in a closed technological cycle. The base solution is the mother liquor with removed sodium sulfite, containing 13.4 wt % Na_2SO_3 and 32.6 wt % NH_4Cl, which corresponds to the composition of the system at the figurative point E_0. The ammonium chloride byproduct is isolated by cooling the base solution, with the subsequent filtration of the resulting suspension (segment E_0X_2 of the crystallization ray DX_2). Thus, under the optimal conditions, the course of the cyclic process for obtaining sodium sulfite by the given variant is described in the sulfite diagram (Fig. 4) by the broken line $E_0X_2E_3E_4E_0$.

The results obtained in a graphical calculation of the yield of ammonium chloride in cooling a solution

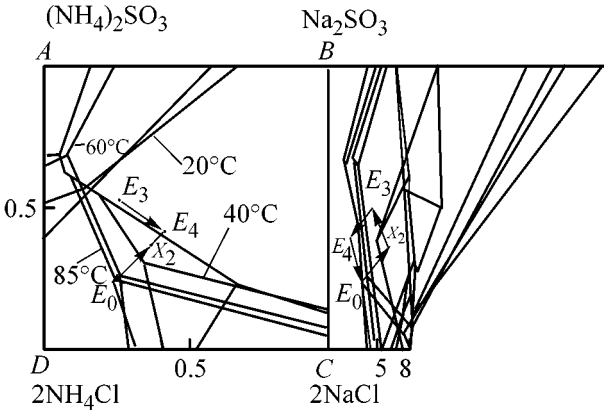

Fig. 4. Solubility diagram for the system Na_2SO_3–NaCl–NH_4Cl–$(NH_4)_2SO_3$–H_2O (variant III).

in the sulfite system to different crystallization temperatures are presented below.

T_{cr} NH_4Cl, °C	W_{NH_4Cl}, %
60	2.7
40	26.7
20	54

Analysis of the obtained data shows that the yield of ammonium chloride in the sulfite system is much lower than that in the hydrosulfite system at about the same temperatures. For example, in cooling a eutonic solution (point E_0) to 60°C in the sulfite system, the yield of crystalline NH_4Cl is 2.7%, and the yield in the hydrosulfite system at the same temperature, 25.2%. To isolate in the crystallization stage the optimal, stoichiometric amount of ammonium chloride (34.9%) when carrying out the given process in the sulfite system, the base solution is to be cooled to below 30°C, whereas in the hydrosulfite system the theoretical yield is 40.2% even at 40°C (actual yield 39.3%). Consequently, performing the stage of ammonium chloride isolation in the sulfite system at 40°C will fail to ensure isolation of the amount of ammonium chloride required by stoichiometric calculations and will lead to its accumulation in the system, with the yield of the target product lowered and the product contaminated. At the same time, crystallizing ammonium chloride at lower temperatures (below 30°C) will lead to much higher energy consumption as compared with carrying the process out in the hydrosulfite system (by variant I).

Thus, the performed graphical analysis of the possible ways to obtain sodium sulfite by conversion, based on the solubility diagrams for the systems Na_2SO_3–NaCl–NH_4Cl–$(NH_4)_2SO_3$–H_2O and NH_4HSO_3–$NaHSO_3$–NaCl–NH_4Cl–H_2O, made it possible to select the optimal variant of such a process and substantiate its optimal temperature conditions.

Table 2. Compositions of solutions used in a cyclic process for production of sodium sulfite*

Solution	Composition, wt %		
	SO_3^{2-}	Cl^-	NH_4^+
Mother liquor after separation of Ns_2SO_3	6.8 / 6.57, 6.7, 6.38	21.63 / 21.7, 19.4, 21.8	10.97 / 9.3, 9.7, 11.3
After absorption of SO_2	12.74 / 12.9, 12.8, 12.4	20.25 / 19.4, 21.9, 20.8	10.27 / 10.0, 9.6, 10.0
Mother liquor after separation of NH_4Cl	14.28 / 12.0, 15.1, 14.0	14.46 / 16.8, 16.4, 15.8	7.48 / 6.6, 7.5, 8.1
Ammoniated	13.74 / 11.1, 11.3, 11.3	14.2 / 15.5, 14.8, 14.5	11.2 / 12.2, 11.4, 11.1

* Numerator: theoretically calculated content of particles; denominator: actual content of particles in solution.

Variant I should be regarded as the optimal since it ensures the highest yield of the target product (65.2%) at the lowest energy expenditure for isolation of the by-product. In this case, crystalline sodium chloride is used as sodium-containing raw material without preliminary dissolution, and the target product (NH_4Cl) is isolated in the hydrosulfite system on cooling the solution to 40°C.

To confirm the validity of the conclusions made in the graphic-analytical study, a set of experiments was carried out in order to obtain sodium sulfite in a closed technological cycle in accordance with the theoretically substantiated optimal technological parameters. Three successive cycles were performed in the experiments. The working solution compositions are presented in Table 2.

The obtained data suggest that the process of sodium sulfite production is stable since the solution compositions in the same stages, but different cycles are identical. The actual solution compositions are close in content of the basic ions to the solution compositions calculated from the theoretically substantiated optimal parameters of the process.

CONCLUSION

As a result of the investigations performed, the most efficient pathway and the optimal technological parameters of sodium sulfite production in conversion with sodium chloride were substantiated theoretically and verified experimentally. The obtained data can serve as a basis for developing a full-scale technological installation and setting-up industrial manufacture of the given product.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

A Study of Liquid–Vapor Phase Equilibrium in Binary Organic Mixtures

N. N. Gorlova, T. M. Gredneva, S. A. Vasil'eva, L. V. Polyakova, and L. F. Komarova

Polzunov Altai State Technical University, Barnaul, Russia

Received July 5, 1999; in final form, September 2000

Abstract—The liquid–vapor equilibrium was studied experimentally in the following binary systems: ethyl cellosolve–toluene, acetone–ethyl cellosolve, butanol–ethyl cellosolve, and butyl acetate–toluene. The obtained experimental data are described mathematically in terms of the Wilson equation, and parameters characterizing the concentration dependence of the component activity coefficients are calculated.

In plants of various branches of industry, where organic solvents are used, spent mixtures form a flow of toxic liquid wastes whose discharge into the environment is unacceptable. This makes necessary the development of technologies for recovering the starting solvents from the wastes and recycling them, and just this is the goal of the present study. Spent mixtures containing alcohols, ethers and esters, ketones, and aromatic hydrocarbons frequently undergo thermal destruction, which accounts for 26 to 35% of the total loss in the technological process [1].

As a mixture for study was chosen a 646 solvent widely used in the national economy. In addition, its three-, four- and five-component constituents are independent commercial products with their own brand names (647, 648, 650, and KR-36 solvents). The mixture under study contains (wt %): acetone (AC) 7, ethanol (E) 15, butanol (B) 10 toluene (T) 50, butyl acetate (BA) 10 and ethyl cellosolve (EC) 8. Spent solvents contain varied amount of water.

The components of the mixture under study belong to different classes of organic compounds and, depending on their functional groups, differ in polarity, density, boiling point, viscosity, vapor pressure, etc. The components of a number of binary and ternary constituents have close boiling points, which suggests possible formation of azeotropes with different numbers of components.

The most common methods for processing of liquid wastes in order to recycle the valuable components are various distillation and rectification techniques [2]. The choice of one of the possible variants is governed by the requirements to the quality of recovered products, by the physicochemical properties of the components being separated, and by a number of other requirements. Since the composition and volume of spent solvents vary widely, the following requirements to the technology were formulated: it must be versatile, the processing technique must uniform, the apparatus employed sufficiently simple, and the cost of mixture processing low. These requirements are met by the batch rectification methods, chosen as the basis in the present study.

The development of a technique for separating a mixture under study assumes that data are available on the vapor–liquid equilibrium in a certain range of temperatures and pressures, corresponding to the industrial conditions. Published data on the vapor–liquid equilibrium could be found for the following systems: acetone with butyl acetate, toluene, butanol, ethanol, or water; butyl acetate with butanol, water or ethyl cellosolve; butanol with water, toluene, ethanol, or butyl acetate; and ethanol with ethyl cellosolve, toluene, or water [3, 4]. Data for the binary constituents toluene–butyl acetate, ethyl cellosolve–acetone, and butanol–toluene could not be found in the literature and were obtained experimentally using the known methods [3] at a pressure of 760 mm Hg.

In the first stage of the study, the starting substances were purified [5]. The achieved purity was evaluated by the boiling point, refractive index, and results of a chromatographic analysis on a commer-

cial LKhM-80 chromatograph, version 1, with heat conductivity detector and programmed temperature control units. Individual substances and aqueous–organic mixtures were analyzed using combined gas-liquid and gas-adsorption chromatography. The content of water was determined using SEPARON porous polymer as adsorbent. Tests with various fixed phases demonstrated satisfactory results in analysis of the organic constituents of the solvent on a XROMATON-N-AW-DMCS phases modified with polyethylene glycol with molecular weight of 1500. The obtained chromatograms were processed using an I-02 integrator. The composition of the mixtures being analyzed was calculated by the method of normalization of peak areas with account of correction coefficients [6].

The liquid–vapor equilibrium was studied by analyzing the dependences of the boiling point and vapor phase composition on the composition of the liquid phase (*X*–*Y*–*T*) under isobaric conditions (*P* = 760 mm Hg) with the use of a Jillespi circulation device [3]. The binary systems under study were prepared by means of gravimetry. The boiling point was measured with a mercury thermometer to within 0.1°C, with account taken of the corrections for pressure and the projecting mercury column [5]. The obtained experimental data on the liquid–vapor equilibrium in the systems studied are presented in Table 1.

The experimental and published data on the liquid–vapor equilibrium in binary systems were described using the Wilson equation [7].

To model the liquid–vapor equilibrium in n-component systems and calculate the rectification process, it is necessary to determine the temperature dependence of the vapor pressures of individual substances, given by the Antoine equation

$$\log P_0 = A - B/(C + T),$$

where P_0 is pressure (mm Hg); T temperature (K); A, B, and C the constants of the Antoine equation.

The constants listed in Table 2 were further used to describe mathematically the liquid–vapor equilibrium in terms of the Wilson equation.

The obtained binary interaction parameters for two-component constituents of a mixture under study, λ_{12} and λ_{21}, are presented in Table 3 together with average and maximum deviations of the boiling point.

As reliability criterion for the obtained parameters may serve modeling of the liquid–vapor equilibrium in ternary systems and comparison of the results of modeling with experiment. Data on the liquid–vapor equilibrium in ternary subsystems, acetone–toluene–ethyl cellosolve, acetone–butanol–ethyl cellosolve, and toluene–butyl acetate ethyl cellosolve could not be found in the literature and were obtained experimentally.

* Systems studied experimentally.

For a limited number of points in the concentration field, the dependences of the boiling points on the liquid phase composition were determined as described above. The results obtained in an experimental study of the liquid–vapor equilibrium are presented in Table 4.

The liquid–vapor equilibrium in ternary systems was modeled using the set of binary interaction parameters of the Wilson equation, presented in Table 3. The average and maximum absolute deviations of the calculated and experimental boiling points are presented for ternary systems in Table 5.

Table 5 shows a satisfactory agreement between the calculated and experimental values, suggesting that the binary interaction parameters are reliable.

With the use of the experimental and available published data [8], the existence of azeotropes in the binary and ternary constituents of the solvent under study were established, which markedly hinders the isolation of individual components.

The modeling of the liquid–vapor equilibrium in the ternary constituents revealed an azeotrope—H_2O–toluene–butanol, whose properties were determined with more precision experimentally. Boiling point (°C): H_2O 100, toluene 110.6, butanol 117.3, azeotrope 84.5; concentration (wt %): water 55.0, toluene 42.1; heterogeneous azeotrope.

CONCLUSIONS

(1) The liquid–vapor equilibrium was studied experimentally in the following binary systems: acetone–ethyl cellosolve, butanol–ethyl cellosolve, toluene–butyl acetate, and toluene–ethyl cellosolve.

(2) The Antoine equation parameters were determined for calculating the temperature dependence of the vapor pressure of pure substances.

(3) The obtained experimental data were described mathematically to give a set of binary interaction parameters for the components of the system under

study. This set can be used to model the liquid–vapor equilibrium in multicomponent systems.

(4) The reliability of the binary interaction parameters was confirmed by comparing the calculated and experimental values characterizing the equilibrium in ternary systems.

(5) The modeling of the liquid–vapor equilibrium in the ternary constituents of the system under study revealed a ternary azeotrope—H_2O–toluene–butanol.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Dissolving and Selective Properties of Morpholine-based Mixed Solvents

V. G. Kozin and A. A. Mukhamadiev

Kazan State Technological University, Kazan, Tatarstan, Russia

Received December 19, 2000; in final form, April 2001

Abstract—Liquid–liquid phase equilibria were studied in the systems morpholine–monoethanolamine–hexane–benzene, morpholine–mono(ethylene glycol)–hexane–benzene, morpholine–monoethanolamine–heptane–toluene, and morpholine–mono(ethylene glycol)–heptane–toluene at 40, 50, and 60°C. A mathematical description of the phase equilibria in the systems studied was obtained.

A number of requirements, the most important among which are selectivity and dissolving ability, are imposed upon extracting agents used to recover individual aromatic hydrocarbons from reforming catalyzates by liquid extraction techniques. Various solvents have acquired industrial importance [1–4]; however, no solvent has been found up to now, satisfying all the requirements. The main extracting agents used in domestic industry still are tri(ethylene glycol) (TEG) and di(ethylene glycol) (DEG) possessing low selectivity and dissolving ability. In this connection, extraction is commonly performed at a temperature of 150°C and high solvent to raw material mass ratio [(8–15) : 1], which leads to high operation costs. The most promising way to solve this problem is to pass to use of extracting agents of mixed type, whose application will improve the performance characteristics in manufacture of monocyclic aromatic hydrocarbons.

This study is concerned with phase equilibria in liquid–liquid systems formed from hexane–benzene and heptane–toluene model mixtures and morpholine-based binary solvents of varied composition.

EXPERIMENTAL

Liquid–liquid phase equilibria were studied in four-component systems morpholine–monoethanolamine (MEA)–benzene–hexane (**I**), morpholine–mono(ethylene glycol) (MEG)–benzene–hexane (**II**), morpholine–MEA–toluene–heptane (**III**), and morpholine–MEG–toluene–heptane (**IV**). The physicochemical properties of the solvents and hydrocarbons—density and refractive index after purification and drying by known techniques [5]—were in agreement with published data. The content of the second component in morpholine was varied within 35–100 wt % for MEG and 40–100 wt % for MEA. Experiments were performed in sealed thermostated 15-ml test-tubes at 40, 50, and 60°C. The thermostating of the systems under study was done with a UT 2/77 laboratory thermostat to within 0.2°C. The composition of equilibrium phases was determined by gas-liquid chromatography on a Tsvet-500M chromatograph. For each binodal curve, 6 or 7 equilibrium compositions were determined at fixed composition of a binary extracting agent. The sampling of coexisting phases after the attainment of equilibrium was done with a 1-μl chromatographic syringe preliminarily heated to the temperature of experiment. Each solution was analyzed three times under the following conditions: flame ionization detector; flow rates (ml min^{-1}): hydrogen 30, air 300, carrier gas (nitrogen) 30; temperature (°C): column thermostat 140, evaporator and detector 160. A 3-m chromatographic column with 3-mm inner diameter was used, as immobile liquid phase served PEG-20M on Chromaton. The component concentrations were calculated by the internal normalization method, the calibration coefficients for the compounds being analyzed were found by the known procedures [6].

The obtained experimental data on the composition of the coexisting phases for systems (**I**) and (**II**) at 40°C are presented in Tables 1 and 2.

Analysis of the experimental data shows that addition of a second component to morpholine makes the heterogeneous region wider, and at MEA and MEG content exceeding, respectively, 60 and 50 wt %, bi-

nodal opening occurs, enabling production of highly concentrated extracts. With increasing content of the second component in a binary extracting agent, the slope of chords steadily grows. At equal contents of MEA and MEG in morpholine, higher heterogeneity is observed for system (**II**). A common property of systems (**I**)–(**IV**) is the rather high solubility of the extracting agents in the raffinate phase, becoming higher with decreasing content of the second component in the solvent, which is due to the pronounced mutual solubility of morpholine and paraffin hydrocarbons [4]. A similar behavior was observed for the rest of the systems studied at 40, 50, and 60°C.

The phase equilibria in the four-component systems studied were described using complete third-order polynomials of the type

$$Y_i = B_0 + B_1X_1 + B_2X_2 + B_{11}X_1^2 + B_{22}X_2^2 + B_{111}X_1^3 + B_{222}X_2^3 + B_{12}X_1X_2 + B_{122}X_1X_2^2 + B_{112}X_1^2X_2, \quad (1)$$

where B_i are the regression equation coefficients; X_1 the mass fraction of the second component (MEA or MEG) in the extracting agent; X_2 the mass fraction of aromatic hydrocarbon in the extract phase; Y_i the mass fractions of hexane or heptane, and MEA or

MEG, in the extract and raffinate phases, and mass fraction of benzene or toluene in the raffinate phase.

The concentration of morpholine in the extract and raffinate phases was found from the condition $\Sigma Y_i = 1$. The coefficients of Eq. (1) were calculated by the least-squares method. These equations make it possible to determine for each system at an appropriate temperature the content of all the components in coexisting phases, i.e. the family of binodal curves within the region studied. The boundaries of this region are defined by the minimum and maximum concentrations of the second component (MEA or MEG) in the mixed solvent. For example, for systems (**I**) and (**II**) at 40°C these intervals are, respectively, 50–100 and 25–100 wt % (Tables 1 and 2).

The significance of the coefficients of Eq. (1) was evaluated using Students criterion at a significance level of 0.95 and a number of degrees of freedom $f = 2$ for three parallel runs for each Y_i. Discarding of the insignificant coefficients and recalculation gave coefficients of Eq. (1). The coefficients for systems (**I**) and (**II**) at 40°C are presented as an example in Table 3, in which S^2_{ad} and S^2_{rep} are, respectively, the adequacy and reproducibility variances calculated by methods described in [7]. Other coefficient tables are not given here because of their vast volume. The

adequacy of the obtained equations was verified using Fisher's test $F = S^2_{ad}/S^2_{rep}$.

As it can be seen from Table 3, all the equations adequately describe phase equilibria in the system studied at the adopted significance level of 0.95. The correctness of the obtained experimental data was verified using Hand's correlation method [8], with the four-component system regarded as a pseudoternary system in which the concentration of the extracting agent was equated to the sum of concentrations of the constituents of the mixed extracting agent. The high correlation coefficient $R > 0.98$ indicates the correctness of the obtained experimental data.

The obtained experimental data on phase equilibria were used to determine, using the method of graphical interpolation after Sherwood [8], the compositions of the coexisting phases under conditions of single-stage extraction of model mixtures hexane–benzene and heptane–toluene. The content of the aromatic hydrocarbon in the raw material was chosen to be 35 wt %, and the mass ratio of the solvent to the raw material, 2 : 1. The obtained data were used to calculate the coefficients of distribution of the aromatic hydrocarbon among the phases, $K_a = X_{ae}/X_{ar}$ and the separation coefficients $\beta = K_a/K_{na}$ characterizing the selectivity of the given process [9], where K_a and K_{na} are the

Table 4. Results obtained in single-stage extraction of model mixtures with different solvents*. Extracting agent to raw material mass ratio 2 : 1, content of aromatic hydrocarbon in raw material 35 wt %

* C is the content of aromatic hydrocarbon in the extract, α the degree of extraction of the aromatic hydrocarbon, and K the distribution coefficient for the aromatic hydrocarbon.

coefficients of distribution of the aromatic and nonaromatic hydrocarbons, respectively, between the extract and raffinate phases; X_{ae} and X_{ar} are the mass concentrations of an aromatic hydrocarbon (benzene or toluene) in the extract and raffinate phases.

The experiments demonstrated that, with increasing content of the second component in a binary solvent, the separation coefficient grows, whereas the distribution coefficient of the aromatic hydrocarbon decreases. For example, making the MEG content higher than 75 wt % for systems (**I**) and (**III**) is inexpedient in view of the substantial decrease in the dissolving ability; the corresponding values for systems (**II**) and (**IV**) are 50 and 60 wt %, respectively. At equal contents of the second component, adding MEG to morpholine leads to lower distribution coefficients and wider stratification region. A similar behavior was observed for all of the systems studied.

The content of the second component in the extracting agent, which ensures the best combination of selectivity and dissolving ability, is about 70 wt % for MEA and 50 wt % for MEG. The results obtained in calculating the basic parameters in the case of a single-stage extraction with binary solvents of composition morpholine + 70% MEA and morpholine + 50% MEG are listed in Table 4, presenting in addition the corresponding parameters for some commercial extracting agents. The basic parameters of single-stage extraction were calculated by means of the conventional formulas [8, 9] with the use of compositions of coexisting phases, found by Sherwood's correlation method. Content of aromatic hydrocarbon in the raw material 35 wt %, solvent to raw material mass ratio 2 : 1. The correlation line was plotted using equilibrium data for binodals corresponding to 70% MEA and 50% MEG in the binary extracting agent (Tables 1 and 2).

As seen from Table 4, the proposed extracting agents surpass DEG and TEG in both selectivity and dissolving ability. Compared with the extracting agent Arosolvan [*N*-methylpyrrolidone (*N*-MP) + 40% MEP], the extracting agents studied have lower dissolving ability, but higher selectivity.

Thus, the analysis of the experimental data obtained with model mixtures suggests that the binary solvents studied, morpholine–MEA and morpholine–MEG, exhibit sufficiently high dissolving and selective properties and can be recommended as extracting agents for recovery of aromatic hydrocarbons from reforming catalyzates. However, final assessment should be made after optimization and calculation of performance parameters.

CONCLUSIONS

(1) Equations adequately describing phase equilibria in the systems morpholine–monoethanolamine–hexane–benzene, morpholine–mono(ethylene glycol)–hexane–benzene, morpholine–monoethanolamine–heptane–toluene, and morpholine–mono(ethylene glycol)–heptane–toluene at 40, 50, and 60°C were obtained.

(2) The extracting properties of binary solvents were studied in relation to their composition. It is shown that morpholine-based binary extracting agents with addition of monoethanolamine or mono(ethylene glycol) show good extracting properties and surpass tri(ethylene glycol) and di(ethylene glycol) in both selectivity and dissolving ability.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption and Desorption of Ni(II) in Quartz–Aqueous Solution Systems at Various pHs

K. P. Tikhomolova, Yu. V. Kufman, and I. N. Urakova

St. Petersburg State University, St. Petersburg, Russia

Received October 25, 2000; in final form, May 2001

Abstract—Adsorption of Ni(II) onto quartz from aqueous solution with pH 3–7 and its subsequent desorption are studied. The desorption was done by three procedures with different extents of action on adsorbed metal ion.

This study is one of a series of works on adsorption of metal cations capable, in principle, of forming chemical bonds with active sites on the adsorbent surface [1–4]. Our selection of the subject matter was determined by the possibility of donor–acceptor bonding, with account of the electronic structure of the ion and the lability of the resulting adsorption complex. In this connection, transition metal cations (as possible acceptors of unshared electron pairs) and oxides whose surface groups are potential donors of such pairs are chosen to constitute an adsorbate–adsorbent pair. The coordination properties of surface groups of an oxide can be judged from the general concepts of the coordination chemistry, including those of the structure of electronic shells and the mutual effect of the constituents of the complexes formed in the solution bulk [5–8]. Therefore, those oxides should be selected in which an adsorbed metal does not enter the crystal lattice, i.e., oxides nonisomorphous with a given metal.

Of course, electrostatic (Coulombic) forces also contribute to the interaction between the cation and negatively charged sites on the adsorbent surface. The range of these forces is much longer than the length of the donor–acceptor bonds. Adsorption controlled by these forces is totally reversible, and the adsorption equilibrium (controlled by cation diffusion) is established rapidly. The role of the Coulombic interaction is restricted to concentration of the cations in the diffusion layer at the interface; the higher the surface potential, the higher the metal concentration.

The adsorption of ionic and molecular species is only one type of possible interactions. At sufficiently high pH values, hydroxide particles (colloids in many cases) form a new phase. In this case, the sorption mechanism changes fundamentally, and adsorption gives way to interaction of species of varied nature and size, which will be further be treated in terms of adhesion.[1]

It is known that in most of actual systems the species are considerably more tightly associated than in the case of a simple coagulation contact, when no chemical interaction between active centers of the species is realized (this case is treated in the classical version of the DLFO theory). Our thought is that the presence of $-O^-$ and –OH groups on the surfaces of the hydroxide adsorbate and oxide adsorbent and the larger size of the colloidal particles as compared to ionic and molecular species may result in that hydrogen bonding plays the determining role in fixation of the adsorbate species on the adsorbent surface [4]. Donor-acceptor bonding can contribute to adhesion also, but, probably, to a lesser extent, as follows from the known strict steric limitations.

In this work we studied Ni(II) as an adsorbate. Being a *d* metal ($3d^8$), Ni can serve as an acceptor of the electron pair in complexation with oxygen-containing ligands. According to coordination chemical views, Ni(II) forms more or less stable, depending on the ligand nature, and relatively inert complexes in the bulk of aqueous solutions. From the practical standpoint the selection of Ni is due to the fact that it is a component of waste of many industries.

[1] In the cases when coagulation in dispersions with species having different nature and size is the subject matter, the term heteroadagulation is sometimes used. We prefer to use the term adhesion for the indicated process, as emphasizing the point of sticking of hydroxide species to the adsorbent surface.

1070-4272/01/7408-1295 $25.00 © 2001 MAIK "Nauka/Interperiodica"

As in the previous studies, we used quartz as adsorbent. In the adsorption–desorption experiments, we employed powdered quartz with equivalent particle diameter of <120 μm (the powder contained a relatively large amount of small particles). In the electrophoretic experiments, we used quartz with particle size of several micrometers.

The selection of quartz is due primarily to the fact that it is nonisomorphous to Ni(II) compounds, and, in contact with aqueous solutions at pH 3–7, its surface is charged negatively (on the average over the surface); the zero-charge point of quartz varies from 1.5 to 2.0. The slope of the pH dependence of the electrokinetic potential of quartz is rather high [2, 3]. The ionic centers of the negatively charged quartz surface are $[\equiv SiO]^-$ and $[\equiv SiOH]^0$, both being potential surface ligands. Note that the siloxane groups [=Si=O] can be surface ligands, too. The indicated fraction of quartz was selected to follow the effect of electroosmosis without applying concentration polarization [9].

Finally, the selection of quartz as adsorbent appears to be relevant, since quartz sand and other Si- and O-containing compounds are among the basic components of the soil. By virtue of its relatively low cost, quartz sand may appear rather efficient adsorbent for *d* metals under certain conditions.

The main goal of this work was to study the kinetics of adsorption (adhesion) of Ni(II) onto quartz and of its desorption. The processes were monitored by the Ni(II) concentration in the solution bulk, *C*, and the amount of metal on the adsorbent surface, *X* (recalculated to 1 g of adsorbent). Nickel(II) was determined in solution spectrophotometrically with a Specol-10 instrument using 0.01% ethanolic solution of PAN [1-(2-pyridylazo)-2-naphthol] as indicator [10].

Adsorption (adhesion) was studied by the static method. Quartz after adsorption (adhesion) is called modified.

Desorption was studied by the static, dynamic, and electroosmotic displacement methods differing in the effect exerted on the adsorption layer. Among these methods, the static method is the mildest, and the electroosmotic method, the most vigorous. In all cases, we used in the desorption stage Ni-free solutions (supporting solutions) having the same composition by the other components as the Ni(II) solution used in the adsorption stage (working solution). In static desorption experiments, modified quartz was placed in weighing bottles, and the supporting solution was refreshed at fixed intervals. In the dynamic and electroosmotic modes, the supporting solution was passed through a membrane of modified quartz, under the action of a pressure gradient and dc field, respectively.

To compare the efficiencies of desorption by the dynamic and electroosmotic methods, experiments were carried out at the same flow rates of the supporting solution. In the electroosmotic experiments, the dc field strength was 10 V cm^{-1}. The pressure gradient in the dynamic desorption experiments was estimated by the formula for the maximal electroosmotic rise [11], derived with the Darcy equation [9] substituted for Poiseuille's equation.

The static and dynamic techniques are widely used in desorption experiments. Hereinafter these methods are called conventional. Studies devoted to the potentialities of the electroosmotic technique for this purpose are scarce. The main concern of these works is mostly soil compaction or consolidation grouting [12].

The working solutions were prepared from a 10^{-4} M $Ni(NO_3)_2$ stock solution (total ionic strength 10^{-3}) at pH 3.0, 5.0, 7.2–7.4, and 9.4 (system nos. 1–4, respectively). The Ni(II) concentration in the working solutions was chosen for studying the adsorption efficiency in view of the fact that the commonly used wastewater treatment processes can reduce the metallic pollutant concentration to 10^{-3}–10^{-4} M, which is much higher than the maximal admissible concentration.

To evaluate the effect of aging of the working solution through Ni(II) hydrolysis, the solutions were potentiometrically titrated 1 and 24 h after preparation.

The results obtained with the freshly prepared solutions are consistent with those reported in [13] for pH < 9.5. At the same time, the results clearly demonstrated that Ni(II) speciation substantially changes with time, especially at pH > 8. For example, at pH 9.4 and short contact time, the amount of the hydroxide was determined to be 80% of the total; such ionic species as $[Ni(H_2O)_5(OH)]^+$, $[Ni(H_2O)_3(OH)_3]^-$, and $[Ni(OH)_4]^{2-}$ were present in nearly equal amounts (6–7%). With longer contact time, the amount of the hydroxide decreased to 48%, and the content of ionic species increased. Therefore, we used in our experiments fresh working solutions (age 1–2 h). In these solutions, about 97% of the total Ni(II) exists at pH 7.2–7.4 as $[Ni(H_2O)_6]^{2+}$. However, it is known that Ni(II) exists essentially in hydroxo forms at pH 8.3. Therefore, the difference between pH 7.2–7.4 of the working solution and pH 8.3 of hydroxide precipitation is too small to eliminate the possibility of occurrence of a minor amount of the hydrolyzed form $[Ni(H_2O)_5(OH)]^+$ in the working solutions. Note also that Farley *et al*. [14] suggested that at pH only

slightly lower than that corresponding to the onset of hydroxide formation in the bulk of the liquid phase, formation of hydroxides and their further association may occur in the surface layer.

The ionic strength and pH of the working solutions were adjusted by adding KNO_3, HNO_3, or KOH. It is known that at the experimental pH values the quartz surface is charged negatively, i.e., Ni(II) aqua cations must be attracted to the surface by electrostatic forces. To characterize the electrostatic interaction and the evolution of the relative amounts of the surface groups $[\equiv SiO]^-$ and $[SiOH]^0$ with increasing pH, we measured in the working systems, and also in the system with pH 10.5, the electrokinetic potential ζ by the microelectrophoretic method. The initial ζ values ($t_{ad} = 0$) of the working systems were –7, –35, –50, –70, and –100 mV. These values and their evolution with increasing pH and t_{ad} suggest that, in all the cases, the quartz surface has active sites $[\equiv SiO]^-$. In the systems with pH 3, the amount of these groups is small; and most of the sites exist in the $[\equiv SiOH]^0$ form. Naturally, the amount of the $[\equiv SiO]^-$ groups increased with growing pH at the expense of the $[\equiv SiOH]^0$ form, and it is most likely that $[\equiv SiO]^-$ is the dominant form in the system with pH 10.5. Thus, in all of the working systems the quartz surface possesses surface sites of both types.

The above working pH values were chosen on the basis of the speciation data for fresh Ni(II) solutions, solubility product of $Ni(OH)_2$, and relative amounts of the indicated two forms of the surface sites.

Both in the case of adsorption (adhesion) and in desorption, the metal concentration in the liquid phase C was monitored. Then we estimated the amount X of Ni(II) on quartz in adsorbed (adhering) state per gram of the adsorbent. The adsorption (adhesion) efficiency was characterized by the amount of adsorbed (adhering) Ni(II) related to its total amount in the system, X_{ad} (%). The desorption efficiency is characterized by the decrease in the amount of adsorbed (adhering) Ni(II) related to its total amount in the system, X_{des} (%), by the same decrease but related to the limiting adsorption in the preceding adsorption stage, X^{∞}_{des} (%), and by the increase in the metal ion concentration related to the limiting adsorption in the preadsorption stage C^{∞}_{des} (%):

$$X^0_{ad} = \frac{C_0 - C_{ad}}{C_0} \times 100,$$

$$X^0_{des} = \frac{(C_0 - C_{ad})V_{ad} - C_{des}V_{des}}{C_0V_{ad}} \times 100,$$

$$X^{\infty}_{des} = \frac{(C_0 - C_{ad})V_{ad} - C_{des}V_{des}}{C^{\infty}_{ad}V_{ad}} \times 100,$$

$$C^{\infty}_{des} = \frac{C_{des}V_{des}}{C^{\infty}_{ad}V_{ad}} \times 100,$$

where the lower indices ad and des refer to the adsorption and desorption, respectively; C_0 is the Ni(II) concentration in the aqueous phase before adsorption; and V is the volume of the liquid phase (time-independent in adsorption and depending on the number of refreshments of the supporting solution in static desorption and the desorption time in dynamic and electroosmotic desorption).

The error of spectrophotometric determination of Ni(II) was within 0.5–3.0%. Within these limits the error increased with increasing pH. The reason is that the Ni(II) concentration in the solutions after adsorption and after desorption by the conventional methods was very low (close to the determination limit by the method used). The error of determination of pH was no more than 0.05 pH units in the acidic region and 0.1 pH units in the alkaline region. The error of determination of the ζ potential ranged from 3 to 15%; in the neutral and alkaline regions the standard deviation was below 3% for seven parallel runs, and in the acidic region it was 8–15%.

The major trends in the adsorption–desorption behavior of Ni(II) in the investigated system are demonstrated in Figs. 1 and 2. The dependences $X_{ad} = f(t_{ad})$, $X_{des} = f(t_{des})$, and $C^{\infty}_{des} = f(t_{des})$ are given in Figs. 1a, 1b–1d, and 2, respectively. Additionally, some X_{des} values are given in the text.

Figure 1a shows that, in all the systems, Ni(II) is intensively adsorbed from the liquid phase but in different amounts. The most clearly pronounced differences are observed with increasing pH in the systems with Ni(II) in the form $[Ni(H_2O)_6]^{2+}$. The limiting adsorption of Ni is 36, 60, and 90% of the total at pH 3, 5, and 7.2, respectively. At pH 9.4, i.e., in the case of hydroxide adhesion, Ni is virtually totally removed from the liquid phase.

The time of attainment of the adsorption equilibrium (limiting adsorption) was found to be about 4 h in the systems in which ionic species of Ni(II) are adsorbed; in the case of adhesion of the hydroxide species, the major part of the metal was already adsorbed during the first hour, and then the process slowly approached saturation in several days.

Let us consider data on desorption in the systems in which Ni(II) was adsorbed as the ionic species $[Ni(H_2O)_6]^{2+}$. Note, first, that in this case the efficiency of desorption by the conventional methods

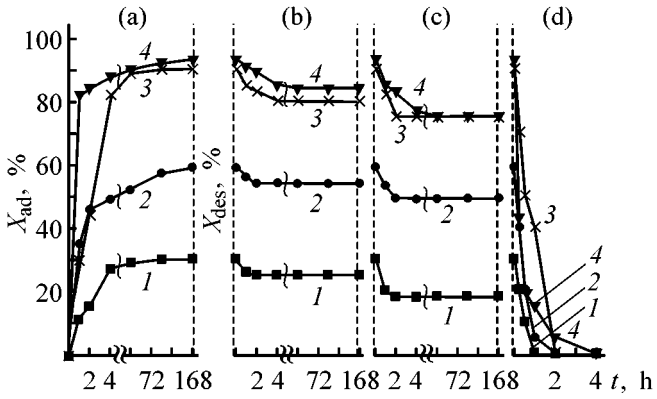

Fig. 1. Adsorption X_{ad} of Ni(II) on quartz and its desorption X_{des} vs. contact time *t*. Solution pH: (*1*) 3.0, (*2*) 5.0, (*3*) 7.2–7.4, and (*4*) 9.5. (a) Adsorption and 7-day desorption in (b) static, (c) dynamic, and (d) electroosmotic modes.

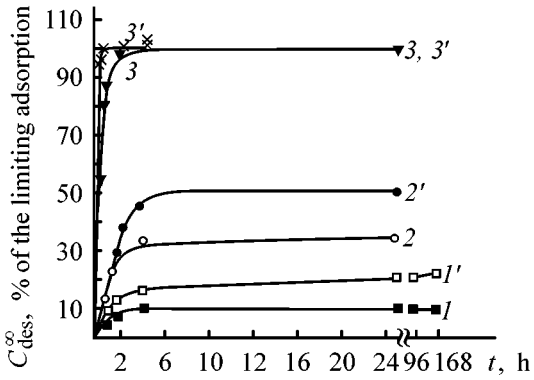

Fig. 2. Gain in the Ni(II) concentration in solution C^{∞}_{des} vs. the desorption time *t* at pH 3. Adsorption time (h): (*1*′–*3*′) 1 and (*1*–*3*) 24. Desorption technique: (*1, 1*′) static, (*2, 2*′) dynamic, and (*3, 3*′) electroosmotic.

strongly depends on the adsorption time: the longer the adsorption time, the lower the desorption rate and the limiting desorption. The effect was observed even at adsorption time longer than that in which equilibrium was attained in the adsorption stage. In electroosmotic desorption, we observed the effect of t_{ad} too, but, first, to a much lower extent and, second, for the desorption rate only.

The effect of t_{ad} is shown in Fig. 2 for system no. 1 at the shortest and the longest experimental adsorption times and for all the three desorption techniques used.

To illustrate the effects of pH, t_{des}, and the desorption technique on the desorption behavior, desorption data for all of the systems studied are given in Figs. 1b–1d for one and the same, and the longest experimental adsorption time (t_{ad} = 7 days), since this time was demonstrated to be sufficient for saturation of all interactions and surface processes occurring in the investigated systems.

Let us consider first the conventional desorption techniques. At pH 3 the efficiency of desorption by both the conventional methods is low, as clearly demonstrated by Figs. 1b, 1c, and 2. Also this fact is clearly pronounced in X^{∞}_{des}. Recalculation of X^{0}_{ad} to X^{∞}_{des} gives 73 and 45% at t_{ad} = 1 h and 90 and 70% at t_{ad} = 7 days for the static and dynamic desorption, respectively. Such a low desorption efficiency even at pH 3 is a clear indication of the occurrence of specific adsorption. According to our concept [1, 3], the crucial role in realization of specific adsorption is played by donor–acceptor interactions. When discussing data on adsorption of metals other than Ni, we suggested that donor–acceptor binding to active sites of the SiO_2 surface may initiate various chemical reactions in the adsorbate layer, thus favoring stronger fixation of the metal species. Also, we suggested that olic or oxolic bonds may be formed between the adhering species, as well as protonation and deprotonation of the adsorbate [2, 3]. In Ni(II) adsorption, these processes are unlikely. Furthermore, at small t_{ad} (about 1 h) the initiated reactions, even if occurring, could provide very low yields. It follows from these considerations that the adsorbate–adsorbent surface complex is strongly fixed on the surface by the donor–acceptor forces. The observed low efficiency of Ni(II) desorption by the conventional methods in the systems with pH 3 suggests that in this case not only $[\equiv SiO]^-$, but also $[\equiv SiOH]^0$ may by a surface ligand.

Let us now consider the desorption data obtained by the traditional methods in the systems with pH 5.0 and 7.2–7.4. In this case, we observed a stronger adsorption and a higher fraction of undesorbable Ni(II) as compared with the systems having pH 3, and also an increase in adsorption efficiency and decrease in desorption efficiency with increasing pH. In terms of our concept, these data can be attributed to the fact that, among the indicated surface ligands, $[\equiv SiO]^-$ is more likely to substitute water molecules of the aqua cation $[\equiv SiOH]^0$. It is not improbable that latter can also replace water, but an ultimate answer can be obtained only experimentally. It follows from published and our data on the electrokinetic potential of the initial quartz that the relative amount of the $[\equiv SiO]^-$ groups substantially grows in passing from pH 3 to pH 5.0 and then to pH 7.2–7.4, at the expense of $[\equiv SiOH]^0$. At the same time, as noted above, a minor amount of the hydroxo cation $[Ni(H_2O)_5(OH)]^+$ can be formed in the systems at pH 7.2–7.4. Association of such species may result in the appearance of polyhydroxo forms in the surface layer. However, we have no direct confirmation of the occurrence of these sur-

face processes. Our thought is that the conclusion about the increasing relative content of $[\equiv SiO]^-$ groups, and decreasing content of $[\equiv SiOH]^0$ groups, is sufficient for adequately interpreting the experimental data.

The electroosmotic displacement technique provides rapid total desorption of Ni(II) (in 4 h in the extreme cases) (Figs. 1d, 2). Also, the results clearly demonstrate the advantage of the electroosmotic technique over the conventional desorption methods (Figs. 1b–1d, 2). These results are well consistent with the theoretical views of the structure of electroosmotic and pressure filtration flows [9].

Let us now consider data on system no. 4. The contribution of chemical bonding to adhesion of Ni hydroxide species to the quartz surface was the most clearly pronounced in the static desorption experiments. It should be pointed out first that in the adsorption stage ζ reaches its limiting value quite rapidly, suggesting that all the transformations occurring in bond formation are localized in the interparticle contact zone only (rather than in the bulk of an adhering hydroxide species) [4, 15]. The absence of chemical transformations is probably due to the fact that the interacting dispersed species are nonisomorphous to one another. Furthermore, one may suggest on the basis of the results obtained that the contact between a $Ni(OH)_2$ particle and SiO_2 is stronger than a simple coagulation contact. To estimate the coagulation contact energy in the investigated systems, we used the method employed more than once previously in treating other systems [16, 17], relying upon the classical version of DLFO calculation. In calculations, we accepted $\zeta(SiO_2) = -70$ mV and $\zeta[Ni(OH)_2)] = -12$ mV [4]; at particle size of $Ni(OH)_2$ and quartz of 1 and 10 μm, respectively; and the Hamacker constant $A_{120} = 1 \times 10^{-20}$ J.[2] The probability of formation of a coagulation contact is controlled by $U_{max}/U_{max.crit.}$, where U_{max} is the energy barrier estimated by DLFO for the actual values of ζ of the interacting particles and $U_{max.crit.}$ is that estimated at $\zeta(SiO_2) = \zeta[Ni(OH)_2)] = -30$ mV. This procedure is based on the well-known empirical observation that, regardless of the sign of the potential, the value 30 mV is critical in the sense that at higher (or lower) absolute values of the potential coagulation does not occur (or occurs). According to our estimates, $U_{max}/U_{max.crit.}$ is somewhat above 1 for the pair SiO_2–SiO_2, below zero for $Ni(OH)_2$–$Ni(OH)_2$, and about 1.5 for SiO_2–$Ni(OH)_2$. These results show that in the framework of the classical version of the DLFO theory, aggregates consisting of only quartz particles cannot be formed in the investigated systems; nickel hydroxide particles must be strongly associated, and the $Ni(OH)_2$–quartz interaction is on the verge of probability. At the same time the equilibrium $|\zeta|$ in system no. 4 was found to be 20 mV, which is lower by 50 mV than that of the initial quartz. Such a high $\Delta|\zeta|$ clearly indicates that SiO_2 interacts with $Ni(OH)_2$ in this system. Thus, as in the case of adsorption of cationic forms of Ni(II), the experimental results for system no. 4 are inconsistent with the theoretical predictions obtained with no allowance for chemical interaction between the active interfacial centers.

Note also that the measured equilibrium ζ in system no. 4 (–20 mV) is much closer to the potential of the $Ni(OH)_2$ surface than to that of SiO_2. We estimated the coverage of the surface of the SiO_2–$Ni(OH)_2$ aggregate with $Ni(OH)_2$ particles by the equation relating the mean ζ of a two-component solid surface to ζ of the components and to the fractions of the surface occupied by them. The coverage of SiO_2 with $Ni(OH)_2$ was estimated to be 0.80–0.85. According to the microscopic data, the hydroxide species are at least 1 μm in size. The particles of this size may cover only 3–4% of the quartz surface (in this case the mean ζ would be close to that typical of quartz). The results can be accounted for on the assumption that the observed 1-μm hydroxide species are aggregates of much smaller particles and that, when approaching the surface layer, these aggregates disintegrate to give a large amount of primary particles. Such interpretation is consistent with our concept of the existence of high-energy bonds between metal hydroxide species and SiO_2 [16].

The rather low-efficient desorption by the static method in the systems with pH 9.4 can be attributed, as in our previous studies, to a significant effect of hydrogen bonding between the oxygen-containing groups on the quartz surface and the hydroxy groups of the Ni(II) hydroxide particle surface (such bonds ensure fairly strong fixation of an adsorbate on the adsorbent surface). Furthermore, accumulation of a great amount of very small hydroxide particles at the adsorbent surface could initiate their association in the surface layer, thus favoring fixation of Ni(II). Note that in many cases hydrogen bonding causes significant undesired problems in regeneration of the adsorbent surface.

As in desorption of ionic species, in the case of initial adhesion of $Ni(OH)_2$ particles, electroosmotic displacement technique provides high desorption efficiency.

[2] The Hamacker constant of $Ni(OH)_2$ was estimated by the method proposed in [18]: the Lorentz–Lorenz equation, relating the electronic polarizability to the refractive characteristics, is substituted in the relationship for the London constant.

Since in the case of dynamic desorption it is not improbable that the complex pore structure of the membranes affects the particle motion in the liquid, induced by the liquid flow, one cannot attribute the observed low efficiency of Ni(II) desorption only to the effect of hydrogen bonding. Theoretically, motion of small colloidal species within the membrane pores can be initiated by electroosmotic flow [9]. Such a strong difference between the efficiency of desorption of adhered colloidal species of Ni hydroxide, obtained in the dynamic and electroosmotic desorption experiments, provides an additional evidence in favor of the employment of electroosmotic regeneration of modified quartz.

CONCLUSIONS

(1) Quartz intensively adsorbs Ni(II); the adsorption considerably grows with ingreasing pH of the aqueous phase. The adsorption equilibrium is established in several hours (4 h and more).

(2) Desorption of Ni(II) from quartz depends on the desorption procedure used. The desorption efficiency in the conventional methods (static and dynamic) is rather low even at a desorption time as long as many days; the desorption efficiency in the dynamic mode is somewhat higher. In electroosmotic replacement, Ni(II) is totally desorbed quite rapidly (in 0.5–1 h).

(3) In the conventional desorption modes the desorption efficiency significantly depends on the adsorption time, but only slightly on the pH of the Ni-containing working solution. In the electroosmotic displacement method, the desorption efficiency is independent of these parameters.

(4) In 7 days, about 95% of Ni(II) adheres to the quartz surface. Adhesion occurs throughout the experiment; however, the main part of the hydroxide (>80%) adheres in the first hour.

(5) The trends observed in desorption of adhering Ni(II) hydroxide are quite similar to those for the case of adsorbed ionic species. The desorption efficiency is rather low in desorption by the conventional methods, while electroosmotic displacement provides rapid and total desorption.

(6) The adsorption, adhesion, and desorption behaviors of Ni(II) in quartz dispersions may be interpreted in terms of the formation of donor–acceptor bonds between Ni(II) and active centers of the quartz surface in the case of adsorption, and of hydrogen bonding between Ni hydroxide species and the active sites in the case of adhesion.

SORPTION AND ION-EXCHANGE PROCESSES

Kinetics of Heterogeneous Reduction of Red-Brown Zh Vat Dye with Rongalite in the Absence of Diffusion Hindrance

Received November 17, 2000

Abstract—The kinetics of heterogeneous reduction of red-brown Zh vat dye with formaldehyde sodium sulfoxylate (rongalite) was studied. The dye was reduced in the form of nonporous disk, which eliminates the effect of mass transfer on the reaction rate. The stages of the reduction mechanism and the reaction rate equations are proposed.

Due to wide assortment and high lightfastness and resistance to wet treatment, vat dyes are widely used in the textile industry. The main stage in the textile finishing is conversion of a water-insoluble dye into a soluble leuco compound. This reaction proceeds in the presence of sulfur- and oxygen-containing reducing agents: formaldehyde sodium sulfoxylate (FSS) or sodium dithionite [1]. The conversion of the vat dye in the leuco form is a heterogeneous reaction whose rate is determined by chemical structures of the dye and reducing agent and by reaction conditions: temperature, solution pH, reactant concentrations, and dispersion of the initial dye.

In general, the above process may involve the following stages: diffusion of molecules of the reducing agent to the surface of dye particles, sorption of the reducing agent, chemical reaction between the dye and reducing agent on the dye surface with the formation of a leuco compound, desorption of the leuco compound and oxidation products from the surface into the solution, and reverse diffusion of the oxidation products into the solution bulk.

In some works [2, 3], diffusion was suggested to be the main factor controlling the reduction rate. However, the effect of dye surface modification [4] and formaldehyde additives on the reaction rate and its nonlinear dependence on the reducing agent concentration [5, 6] suggest that the chemical stage significantly affects the total rate of the process. Since investigation of a multistage process is a rather difficult problem, the development of an adecuate kinetic model requires elimination of some stages in order to study the others.

To study the reduction kinetics, the dye was pressed in the form of a nonporous disk, which is common for electrochemical studies [7].

EXPERIMENTAL

In this study, we used red-brown thioindigo Zh dye, which was prepared from a pigment treated to remove lyophilizing and stabilizing additives. The pigment was thoroughly washed with distilled water at 80°C. The impurities were extracted with ethanol in a Soxhlet apparatus, then the dye was dried at 60°C and analyzed for the content of the pure pigment [8]. The content of the main product was 96.4%. As reducing agent we used formaldehyde sodium sulfoxylate $HOCH_2SO_2Na \cdot 2H_2O$ prepared by double recrystallization of the crude product from water. According to iodometric titration data, the content of the main compound in the recrystallized product was no less than 97.6%.

The dye was pressed at 50 kg cm^{-2} in a metallic mold as a planar nonporous disk with one open side and placed in a reaction vessel. The disk was rotated at 100–1430 rpm in an aqueous solution of the reducing agent (C_{FSS} = 0.05–0.24 M) and chemically pure grade sodium hydroxide (2.5×10^{-2}–6.25×10^{-3} M).

To prevent the oxidation of the leuco compound formed, the reduction of the vat dye was performed in

1070-4272/01/7408-1301 $25.00 © 2001 MAIK "Nauka/Interperiodica"

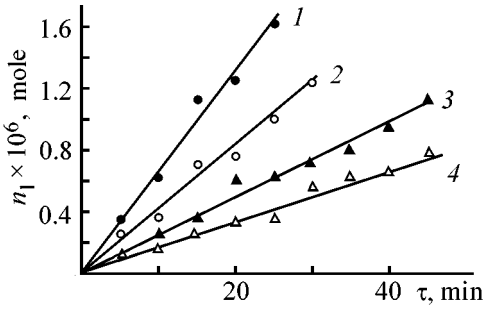

Fig. 1. Accumulation of the dye leuco form n_l vs. time τ. T 363 K, C_{FSS} 0.2, C_{NaOH} 0.025 M; N 800 rpm. Formaldehyde concentration $C_{CH_2(OH)_2} \times 10^4$ (M): (*1*) 0, (*2*) 1.15, (*3*) 3.45, and (*4*) 5.75.

a thermostated cell (±0.5 K) in an argon atmosphere. The solution volume in the cell was 100 ml. In the course of the reaction, 3.5-ml samples were taken to determine the concentration of the resulting leuco form of the dye.

The concentration of the leuco form was measured spectrophotometrically (λ_{max} = 425 nm) on an SF-46 spectrophotometer. Preliminary tests showed that the dependence of the optical density of the solution on the concentration of the dye leuco form obeys the Lambert–Bouguer–Beer law.

To determine the reaction rates from the kinetic curves, we calculated the concentration of the forming leuco compound from the following equation:

$$n_{i,l} = C_{i,l}V/1000 + n_{(i-1),l}, \quad (1)$$

where $n_{i,l}$ is the amount of the dye (mole) formed by the time of measurement (i is the measurement number); $C_{i,l}$ is the concentration of the dye determined in ith measurement (M); V is the solution volume at the instant of measurement (ml); $n_{(i-1),l}$ is the amount of dye (mole) formed by the time of the preceding measurement ($n_{0,l}$ = 0).

The typical kinetic curves of accumulation of the resulting leuco form are shown in Fig. 1. Since each curve has a linear portion, the reaction rate constant k_{app} (mol min^{-1}) was determined from the slopes, using the least-squares procedure.

To reveal the regions of the kinetic and diffusion control, we studied the dependences of the reaction rate k_{app} on the disk rotation speed N (C_{NaOH} = 0.025, C_{FSS} = 0.2 M; T = 363 K):

N, rpm	$k_{app} \times 10^8$, mol min^{-1}
100	1.6 ± 0.2
200	4.1 ± 0.2
400	4.9 ± 0.1

The above data suggest that the speed of disk rotation affects the reaction rate up to N = 400 rpm. Similar dependence is typical of heterogeneous reactions [9] and reveals regions of the kinetic and diffusion control. Our further tests were performed at a constant rotation speed N = 800 rpm, which corresponds to the kinetic control of the process in question.

It is known that the majority of reactions with FSS proceed with cleavage of the C–S bond by the following reversible reaction

$$HOCH_2SO_2^- + OH^- \underset{k_2}{\overset{k_1}{\rightleftarrows}} SO_2^{2-} + CH_2(OH)_2 \quad (I)$$

with the formation of intermediate anions of sulfoxylic acid [10]. This is confirmed by the deceleration of the reaction rate in the presence of formaldehyde, which binds the active intermediates [reaction (I)].

As seen from Fig. 1, with increasing concentration of CH_2O, which in the alkali medium occurs as $CH_2(OH)_2$, the rate of vat dye reduction decreases. This indicates that the stages of formation of SO_2^{2-} anions and their further interaction with dye should be taken into account in performing reduction of the vat dye.

Our data suggest that the reduction of the vat dye (pressed as a planar nonporous disk) in the absence of diffusion hindrance involves the following stages.

(1) Formation of active species of the reducing agent (chemical stage in solution)

$$r_1 = dC_{SO_2^{2-}}/d\tau = k_1 C_{FSS} C_{OH^-} - k_2 C_{SO_2^{2-}} C_{CH_2(OH)_2}, \quad (2)$$

where C_{FSS} is the concentration of formaldehyde sodium sulfoxylate ($HOCH_2SO_2^-$ ions) (M), C_{OH^-} is the concentration of OH^- ions or NaOH (M), $C_{SO_2^{2-}}$ is the concentration of SO_2^{2-} ions in solution (M), and $C_{CH_2(OH)_2}$ is the concentration of formaldehyde (M).

(2) Sorption of SO_2^{2-} ions onto the dye surface

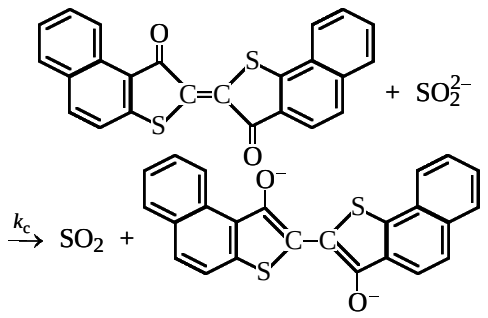
$$r_2 = dZ_{SO_2^{2-}}/d\tau = k_s Z C_{SO_2^{2-}} Sf - k_d Z_{SO_2^{2-}} Sf, \quad (3)$$

where k_s and k_d are the rate constants of sorption and desorption of SO_2^{2-} anions; Z is the number of free sorption centers on the dye surface (mol m^{-2}); $Z_{SO_2^{2-}}$ is the number of sorption centers on the surface, occupied by SO_2^{2-} anions (mol m^{-2}); S is the surface area (m^2); and f is the roughness coefficient.

(3) Chemical reaction of SO_2^{2-} anions sorbed on the surface with the dye

$$r_3 = dn_l/d\tau = k_c Z_{SO_2^{2-}} Sf, \quad (4)$$

where k_c is the rate constant of chemical reaction (II).



(II)

The kinetic equation was deduced on the following assumptions: the process occurs in the steady-state mode, which is attained in a relatively short period; the reducing intermediates SO_2^{2-} (I) in solutions are formed with attainment of quasi-equilibrium characterized by equilibrium constant

$$K_e = k_1/k_2;$$

the equilibrium is attained rapidly in the stage of sorption–desorption of SO_2^{2-} anions; and the desorption of the resulting leuco compound and of the products of FSS oxidation is fast and their further sorption is insignificant.

At sorption equilibrium the following equations are valid

$$k_s Z C_{SO_2^{2-}} = k_d Z_{SO_2^{2-}}, \quad (5)$$

$$Z = Z_\infty - Z_{SO_2^{2-}}, \quad (6)$$

where Z_∞ is the total amount of sorption centers on the dye surface (mol m^{-2}).

From Eqs. (5) and (6) follows that

$$Z_{SO_2^{2-}} = Z_\infty K C_{SO_2^{2-}}/(1 + K C_{SO_2^{2-}}), \quad (7)$$

where $K = k_s/k_d$ is the sorption equilibrium constant (mol^{-1}).

Now, substituting (7) into Eq. (4), we determine the formation rate of the dye leuco form passing into the solution:

$$dn_l/d\tau = [k_c Z_\infty K C_{SO_2^{2-}}/(1 + K C_{SO_2^{2-}})] S f. \quad (8)$$

The quasi-equilibrium conditions of stage (I) suggest that

$$C_{SO_2^{2-}} = K_e C_{FSS} C_{OH^-}/C_{CH_2(OH)_2}. \quad (9)$$

Substituting (9) into (8) and integrating it at excess of FSS and NaOH and constant content of formaldehyde [quasi-equilibrium (I)], and taking into account that $n_l = 0$ in the initial moment $\tau = 0$, we obtain the following equation:

$$n_l = A[K K_e C_{FSS} C_{OH^-}/(C_{CH_2(OH)_2} + K K_e C_{FSS} C_{OH^-})]\tau, \quad (10)$$

where $A = k_c Z_\infty S f$.

As seen from Eq. (10), the reaction rate is independent of the leuco compound concentration, which is confirmed by experimental data [Fig. 1, linear portion of the dependences $n_l = f(\tau)$]. The k_{app} value determined from the kinetic curves can be represented as

$$k_{app} = A K K_e C_{FSS} C_{OH^-}/(C_{CH_2(OH)_2} + K K_e C_{FSS} C_{OH^-}). \quad (11)$$

The linear form of Eq. (11) is given by

$$1/k_{app} = C_{CH_2(OH)_2}/A K K_e C_{FSS} C_{OH^-} + 1/A. \quad (12)$$

The experimental rate constants as functions of the concentration of some reagents (FSS, NaOH, and formaldehyde) at constant concentrations of the other components are shown in Figs. 2a–2c.

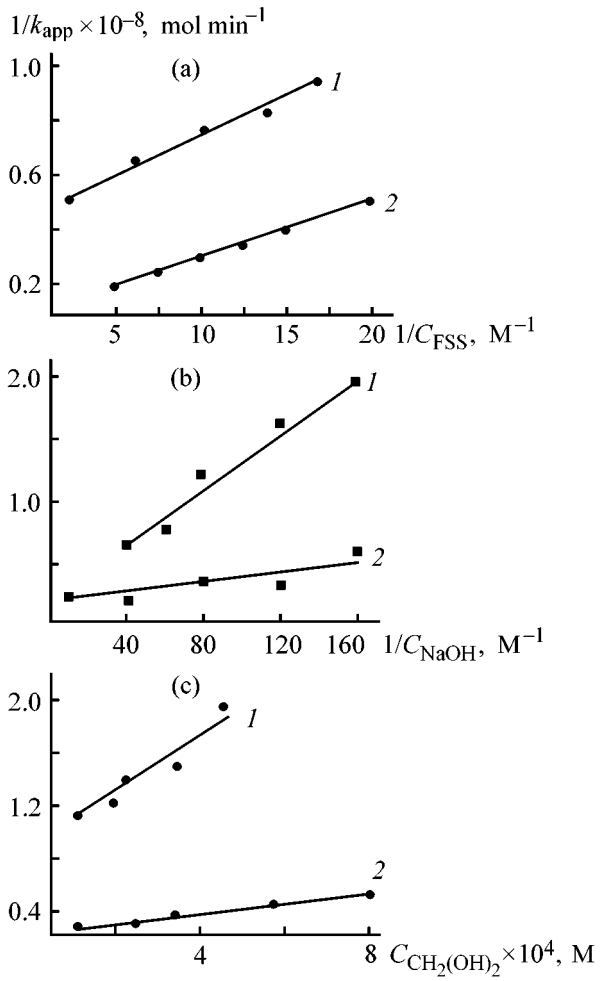


Fig. 2. Reaction rate constants k_{app} in relation to the concentration of (a) FSS C_{FSS}, (b) NaOH C_{NaOH}, and (c) formaldehyde $C_{CH_2(OH)_2}$. Concentration, M: (a) 0.025 NaOH, (b) 0.2 FSS, and (c) 0.025 NaOH and 0.2 FSS. Temperature, K: (*1*) 353 and (*2*) 363.

363	10.9 ± 1.1	6.8 ± 2.2	7.4 ± 1.5	3.7 ± 1.3	4.2 ± 1.5	7 ± 2
353	2.2 ± 0.8	1.6 ± 0.9	2.5 ± 0.6	5.2 ± 1.4	1.2 ± 0.7	14 ± 4

The linear dependences obtained in the coordinates of Eq. (12) and the close values of the parameters, calculated from these data (see table), indicate that our model adequately describes the experimental results.

The parameter A includes the rate constant of the chemical reduction of the dye by SO_2^{2-} anions on the dye surface. Therefore, using known values of A at different temperatures, we can evaluate the activation energy of this stage. According to the Arrhenius equation, the activation energy is 185 ± 10 kJ mol^{-1}.

Using the equilibrium rate constants K_e [9] for cleavage of formaldehyde sodium sulfoxylate molecules and parameters $1/KK_e$ given in the table, we calculated the sorption equilibrium constants K to be 2.73×10^4 and 4.06×10^4 mol^{-1} at 80 and 90°C, respectively.

A slight rise in K with increasing temperature indicates that the sorption is endothermic, probably owing to desolvation of the reducing agent molecules and the dye surface in the course of sorption.

CONCLUSIONS

(1) The kinetics of heterogeneous reduction of the vat dye by formaldehyde sodium sulfoxylate under kinetic control conditions was studied.

(2) Based on dependences of the reduction rates on temperature and on concentrations of the reducing agent, alkali, and formaldehyde, the mechanism of this process was proposed and the kinetic equation describing their effect on the process rate was evaluated.

(3) Experimental verification of this equation showed scheme the proposed described adequately to kinetic data.

SORPTION AND ION-EXCHANGE PROCESSES

Gallium(III) Extraction from Alkaline Solutions with 5-Amylthio-8-quinolinol

A. N. Turanov, N. K. Evseeva, and B. G. Karepov

Institute of Physics of Solids, Russian Academy of Sciences, Chernogolovka, Moscow oblast, Russia

Received November 27, 2000

Abstract—Equilibrium extraction of gallium(III) from alkaline solutions with 5-amylthio-8-quinolinol was studied.

The main source of gallium are alkaline solutions of alumina production. A promising procedure for gallium recovery from these solution is extraction [1]. The best extractants of gallium(III) from alkaline solutions are chelating agents [2, 3]. Gallium extraction with 8-quinolinol derivatives, and particularly with 7-(5,5,7,7-tetramethyl-1-octen-3-yl)-8-quinolinol produced under the trade name Kelex 100, was studied in detail in [4–8]. Extraction properties of 8-quinolinols substituted at the position 5 have been studied to a lesser extent [9, 10]. Bankovskii *et al*. prepared 5-alkylthio derivatives of 8-quinolinol [11] and studied physicochemical properties of chelates of this compounds with a number of metals [12]. It was noted that these chelates are readily soluble in low-polar organic solvents, which makes these extractants promising for application in hydrometallurgy, including gallium(III) recovery from aqueous alkaline solutions.

In this work, we studied the extraction equilibrium attained during Ga(III) recovery from aqueous alkaline solution into an organic phase containing 5-amylthio-8-quinolinol (HL) or into a phase of macroporous polymeric sorbent impregnated with 5-amylthio-8-quinolinol.

EXPERIMENTAL

As extractant was used 5-amylthio-8-quinolinol [TU (Technical Specifications) 6-09-16-1300–82, Biokhimreactiv Scientific and Production Association]. Chloroform, 1,2-dichloroethane, CCl_4, toluene, *m*-xylene, *n*-decane of chemically pure or analytically pure grade and lamp kerosene were used as solvents as received. When kerosene was used as a solvent, the organic phase was solubilized by adding 10% *n*-decanol [8].

Impregnated sorbent was prepared from nonionic macroporous styrene-divinylbenzene copolymer, Wofatit EP-60 (Bitterfeld Chemical Plant, Germany). The properties of this copolymer, presented in [13], are close to those of similar materials produced in Russia—Polisorbs [14]. The copolymer was impregnated with 5-amylthio-8-quinolinol by the procedure described in [15].

The starting Ga(III) solutions were prepared by dissolving gallium oxide of pure grade in 1 M NaOH, with subsequent dilution with water. The required pH or NaOH concentration was adjusted by adding HCl or NaOH solutions prepared from chemically pure grade chemicals. The Ga(III) content in the starting solutions was 1×10^{-3} M.

Extraction and sorption were performed under static conditions at $18 \pm 2°C$. The aqueous phase was mixed with an extractant solution or with impregnated sorbent in a mixing apparatus with stirrer rotating at 60 rpm for 3 h. Under these conditions, a constant distribution coefficient of gallium D_{Ga} was attained. The phase volume ratio in extraction and in sorption was $V_a : V_o = 11 : 1$ and $V_a : m_{sol} = 20 : 1$, respectively.

The gallium(III) content in aqueous solutions before and after extraction or sorption was determined photocolorimetrically with PAR [16] on a KFK-2MP photocolorimeter. The NaOH concentration in the aqueous solutions was determined by potentiometric titration; the pH was measured with a pH-150 pH meter.

Gallium(III) extraction with chelating extractants depends on the pH of the aqueous phase (Fig. 1, curve *6*), since the concentration of H^+ (or OH^-) ions affects both the protolytic equilibrium of the extractants and the speciation of Ga(III) in the aqueous

phase in the form of Ga^{3+} ion or hydroxo complexes $Ga(OH)_i^{(3-i)+}$, where i = 1–4.

Since the distribution factor of 5-amylthio-8-hydroxyquinolquinoline in the tested extraction system is $P_{HL} = 3.8 \times 10^5$ [12], it is present mainly in the organic phase.

The mole fraction of Ga(III) species α_i at a certain pH can be calculated from the stability constant of gallium hydroxo complexes β_i by the equation

$$\alpha_i = \frac{\beta_i [OH^-]^i}{1 + \sum_{1}^{i=4} \beta_i [OH^-]^i}. \quad (1)$$

The values $\log \beta_1 = 11.4$, $\log \beta_2 = 22.1$, $\log \beta_3 = 31.7$, and $\log \beta_4 = 39.4$ were taken from the handbook [17]. Comparison of the dependence of the gallium(III) extraction on the pH of the aqueous phase (Fig. 1, curve *6*) and diagrams of distribution of Ga(III) hydroxo complexes as a function of pH (Fig. 1, curves *1–5*) indicates that the maximum gallium(III) extraction corresponds to formation of gallium(III) hydroxo complexes in the aqueous phase.

Gindin *et al*. [18] showed that the extraction constants of metal carboxylates depend on the solubility product of the extracted metal hydroxide, i.e., extraction can be regarded as hydrolytic recovery of metal compounds into the organic phase. In terms of this assumption, gallium(III) extraction can be described by reaction of Ga(III) hydroxides with undissociated HL molecules, i.e., by neutralization reaction, as proposed in [19]:

$$Ga(OH)_i^{(3-i)+} + (3 - i)OH^- + 3\overline{HR} \rightleftarrows \overline{GaL}_3 + 3H_2O \quad (2)$$

(i = 0–4, the components of the organic phase are marked with overline).

The Ga : L ratio in the extracted complexes, determined by the equilibrium shift method [20] is 1 : 3 (Fig. 2), which is consistent with the data on saturation of an HL solution with gallium(III) (Fig. 3) and agrees with the results of [12].

The constants of Ga(III) extraction described by reaction (2) are expressed by

$$K_i = \frac{[\overline{GaL}_3]}{[Ga(OH)_i][OH^-]^{(3-i)}\,[\overline{HL}]^3}, \quad (3)$$

where the total concentration of Ga(III) in the organic phase is calculated as

$$[\overline{GaL}_3] = [\overline{HL}]^3 \Sigma K_i [Ga(OH)_i][OH^-]^{(3-i)}. \quad (4)$$

Hence, the dependence of the experimental distribution coefficient of gallium(III) on the extractant concentration in the organic phase and the OH^- concentration in the aqueous phase can be described by the equation

$$D_{Ga} = \frac{[\overline{GaL_3}]}{[Ga(III)]_a} = \frac{[\overline{HL}]^3\,[Ga^{3+}][OH^-]^3\Sigma K_i\beta_i}{[Ga^{3+}](1 + \Sigma\beta_i\,[OH^-]^i)}$$

$$= \frac{[OH^-]^3\,[\overline{HL}]^3 K'}{(1 + \Sigma\beta_i\,[OH^-]^i)} \quad (5)$$

or

$$D_{Ga} = \frac{\alpha_3 K'[\overline{HL}]^3}{\beta_3} = \alpha_3[\overline{HL}]^3 K'_{ex}, \quad (6)$$

where $[\overline{HL}] = C_{HL} - 3[\overline{Ga}]$, C_{HL} is the initial concentration of HL in the organic phase, and K'_{ex} is the extraction constant.

The distribution coefficient D_{Ga} is proportional to the mole fraction of gallium hydroxide in the aqueous phase. This indicates that the maximum extraction of gallium(III) from weakly acidic and neutral solutions is provided by chemical reaction of the extractant with gallium hydroxide. The results of a study of gallium(III) extraction with oligomeric phenolic extractant [19] confirm this assumption.

The logarithm of the equilibrium extraction constant $\log K^e_{ex}$, calculated by Eq. (6) on the basis of the data shown in Fig. 1 is 9.15 ± 0.03 and remains constant at pH ranging from 1.7 to 11.5. This fact confirms the scheme proposed for gallium(III) extraction.

We suggest that, since the HL content in the aqueous phase is low owing to the high P_{HL}, gallium(III) extraction involves (i) formation of gallium(III) hydroxide hydrated to a lesser extent as compared with ionic forms of Ga(III) and (ii) transition of gallium hydroxide from the aqueous phase to the interface. Gallium complex GaL_3 formed via neutralization of $Ga(OH)_3$ by HL at the interface passes into the organic phase. The occurrence of reaction (2) is confirmed by the fact that solid gallium oxide and hydroxide are dissolved in organic solutions of 5-amylthio-8-quinolinol to form GaL_3.

Equation (6) describes well a decrease in D_{Ga} with the concentration of OH^- ions in the aqueous phase increasing to pH 11.5 (Fig. 1). Since Ga(III) in alkaline solutions is mainly in the form of tetrahydroxogallate anion, gallium(III) extraction from alkaline solution can be described by the reaction

$$Ga(OH)_4^- + 3\overline{HL} \overset{K_4}{\rightleftarrows} \overline{GaL_3} + 3H_2O + OH^-. \quad (7)$$

With increasing OH^- concentration, the equilibrium (7) is shifted to the left, i.e., D_{Ga} decreases.

At pH > 11.5, D_{Ga} grows with increasing pH (Fig. 1). This may be due to the fact that OH^- ions formed at pH > 11.5 by reaction (7) are neutralized by HL molecules by the reaction

$$\overline{HL} + Na^+ + OH^- \overset{K_{NaOH}}{\rightleftarrows} \overline{NaL} + H_2O. \quad (8)$$

As a result, equilibrium (7) is shifted to the right, i.e., D_{Ga} increases. At excess amount of HL in the system with respect to Ga(III), the distribution coefficient D_{Ga} grows while $[\overline{NaL}] \le [\overline{Ga}]$. Then D_{Ga} decreases with pH increasing above 13.3, owing to the lowering of the HL concentration in the organic phase because of the NaL formation. In this case, the dependence of D_{Ga} on the activity of the components of the aqueous phase a and the initial concentration of the extractant in the organic phase can be expressed by the equation

$$D_{Ga} = \frac{K_4(C_{HL} - 3[\overline{GaL_3}])^3}{(1 + K_{NaOH}a^2_{OH^-})^3 a_{OH^-}\,a^3_{H_2O}}. \quad (9)$$

Thus, appreciable coextraction of sodium cations results in that gallium(III) extraction decreases dramatically with increasing NaOH concentration in the aqueous phase (Fig. 4). D_{Ga} Cannot be made higher by raising the extractant concentration in the organic phase at NaOH concentrations exeeding 1 M, owing to the low solubility of the sodium salt of the extractant (not exceeding 0.02 M) in the chosen organic solvents.

Gallium(III) extraction from alkaline solutions strongly depends on the nature of the organic diluent. The distribution coefficients D_{Ga} between 0.004 M solution of 5-amylthio-8-quinolinol and 1 M NaOH are presented below:

Diluent	D_{Ga}
Chloroform	2.72
1,2-Dichloroethane	1.12
Toluene	0.41
m-Xylene	0.28
CCl_4	0.29
n-Decane	0.04

Similar dependences were observed in Ga(III) extraction with 8-quinolinol from weakly acidic solutions [21].

Gallium(III) extraction from alkaline solutions with solutions of HL in nonpolar diluents, commonly used in extraction, is very low owing to the formation of sodium salt of the extractant, which is difficultly

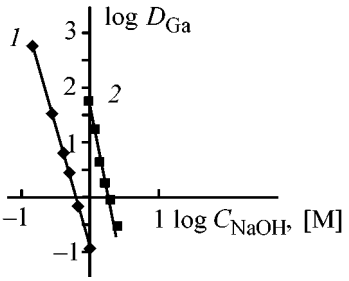

Fig. 4. Gallium(III) distribution coefficient D_{Ga} vs. the NaOH concentration C_{NaOH} in the aqueous phase in extraction with (*1*) 0.05 M solution of HL in kerosene containing 10% decanol and (2) 0.01 M solution of HL in chloroform.

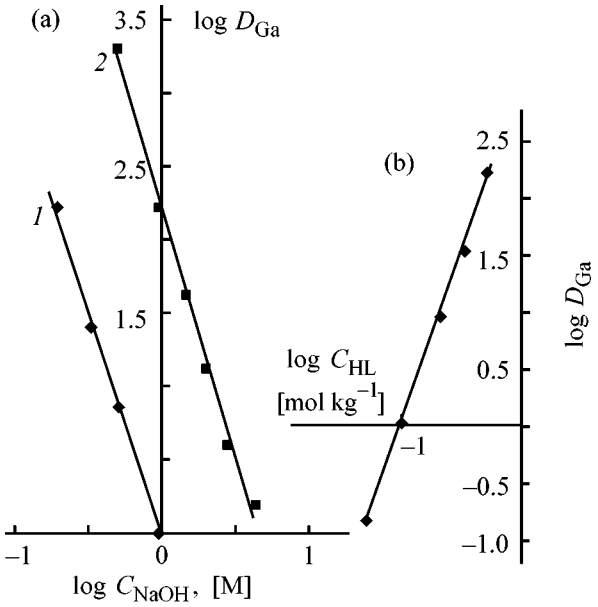

Fig. 5. Gallium(III) distribution coefficient D_{Ga} vs. (a) NaOH concentration C_{NaOH} in the aqueous phase and (b) the HL concentration C_{HL} in the sorbent phase. in sorption by impregnated sorbent. (a) C_{HL}: (*1*) 0.1, and (*2*) 0.5; (b) C_{NaOH} = 1.0 M.

soluble in the organic phase and precipitates at the interface. Addition of decanol to kerosene makes D_{Ga} higher. However, at decanol concentration higher than 10%, D_{Ga} decreases, probably owing to the formation of hydrogen bonds between the alcohol and phenol groups of the extractant.

Sato *et al*. [5] observed a similar decrease in D_{Ga} when studying Ga(III) extraction from alkaline solutions with Kelex 100 extractant in the presence of 2-ethylhexanol. It should be noted that Kelex 100 in kerosene, unlike 5-amylthio-8-quinolinol, extracts Ga(III) from concentrated NaOH solutions. This can be accounteg for by lower coextraction of sodium ions with Kelex 100, which is appreciable only at NaOH concentrations higher than 5 M, when D_{Ga} sharply decreases [6].

As seen from the dependence of D_{Ga} on the composition of equilibrium phases [Eq. (9)], to enhance Ga(III) extraction with the chelating agent from alkaline solutions, i.e., to shift the D_{Ga}–C_{NaOH} curve to higher NaOH concentrations, the structure of the extractant must change so as to decrease the stability of the sodium complex at the interface. In particular, extraction of sodium ions with phenol derivatives strongly depends on the dissociation of the extractant, which usually decreases with lengthening of the hydrocarbon radical in the extractant molecule. This probably leads to higher D_{Ga} in the system 1 M NaOH–0.01 M solution of 8-quinolinol (HOq) derivatives with increasing length of the hydrocarbon radical of the extractants in going from HOq (0.16) to 5-propylthio-8-quinolinol (2.1) and 5-amylthio-8-quinolinol (70.8). Thus, 5-amylthio-8-quinolinol derivatives with long alkyl radical are more promising for liquid extraction of Ga(III) from alkaline solutions.

We also studied Ga(III) extraction from aqueous solutions with NaOH concentrations higher than 1 M by a macroporous sorbent impregnated with 5-amylthio-8-quinolinol. The sodium salt of HL formed in alkaline solution [Eq. (8)] is fixed in the polymeric matrix. In this case, in contrast to liquid extraction, the extractant concentration in the initial impregnated sorbent can be raised to 0.5 mol kg^{-1} of dry sorbent. Since the complex of 5-amylthio-8-quinolinol with Ga(III) is appreciably stronger than that with Na(I), the following exchange reaction can occur at the aqueous phase–solid sorbent interface

$$3\overline{\mathrm{NaL}} + \mathrm{Ga(OH)_4^-} \rightarrow \overline{\mathrm{GaL}}_3 + 3\mathrm{Na^+} + 4\mathrm{OH^-}. \quad (10)$$

It should be noted that Eq. (10) is thermodynamically equivalent to Eq. (7), i.e., the dependences of D_{Ga} on the HL concentration in the solid phase (Fig. 5b) and on the NaOH concentration in the aqueous phase (Fig. 5a) in the case of sorption are similar to those in the case of liquid extraction. As seen from Fig. 5b, Ga(III) is effectively extracted from concentrated NaOH solutions at sufficiently high concentrations of HL in the solid phase.

It is known [4–6] that, in extraction of Ga(III) from alkaline solutions with Kelex 100 extractant, equilibrium is attained slowly. This process is accelerated by adding surfactants to the organic phase [22, 23]. In the case of extraction with 5-amylthio-8-quinolinol, the equilibrium is attained within 3 h. At the same time, with Ga(III) recovered with an impregnated

sorbent, D_{Ga} attains constant value after stirring the phases for 30 min. This is presumably due to the fact that hydrophilic functional groups of 5-amylthio-8-quinolinol sorbed on the polymeric matrix are oriented toward the aqueous phase [24], which strongly facilitates the ion exchange at the interface.

Thus, macroporous styrene-divinylbenzene copolymer impregnated with 5-amylthio-8-quinolinol can be used for gallium(III) recovery and concentration from aqueous alkaline solutions.

CONCLUSIONS

(1) Gallium(III) can be extracted from aqueous solutions with 5-amylthio-8-quinolinol (HL) into the organic phase or into the phase of nonionic macroporous styrene-divinylbenzene copolymer in the form of a GaL_3 complex. The extent of extraction is the highest in the pH range in which Ga(III) is present in the equilibrium aqueous phase in the form of gallium hygroxide.

(2) 5-Amylthio-8-quinolinol applied to a polymeric matrix allows effective extraction and concentration of gallium from 1–3.5 M NaOH solutions.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Voltammetric Determination of Cobalt(II) in Zinc Sulfate Solution

G. A. Borovkov and V. I. Monastyrskaya

North-Ossetian State University, Vladikavkaz, North Ossetia, Russia

Received January 16, 2001; in final form, April 2001

Abstract—A method for automated polarographic analysis for Co(II) ions in technological solutions of zinc production was developed. The influence exerted by the components of a supporting electrolyte on the sensitivity and selectivity of measurements was studied. The method is intended for determining the content of cobalt(II) in purification of a zinc sulfate solution to remove impurities and for ecological monitoring of wastewater produced at nonferrous metallurgy plants.

Thorough purification of technological solutions to remove impurities adversely affecting the process of electrolysis is the necessary condition for achieving high performance in hydrometallurgical manufacture of zinc. The impurities whose concentration in a zinc-containing electrolyte is strictly regulated include cobalt(II). At Co(II) ion content in a purified zinc sulfate solution exceeding 2 mg l^{-1}, the cathode sheet is corroded, the current efficiency markedly decreases, and energy consumption grows [1]. Use of new hi-tech purification processes makes it possible to reduce the content of Co(II) in a neutral zinc-containing electrolyte to 0.5 mg l^{-1}. In particular, a new purification method has been put into practice, based on oxidation of Co(II) to Co(III) with potassium permanganate, with subsequent removal of cobalt(III) ions from the process in the form of a poorly soluble $Co(OH)_3$.[1]

Effective purification of zinc production solutions to remove impurities is impossible without continuous or discrete monitoring of the ionic composition at the input and output of separate stages of the technological process [2]. The most complicated is the problem of selective monitoring of low concentrations of Cu(II), Cd(II), Sb(III), Pb(II), Ni(II), and Co(II) ions in purified zinc sulfate solutions.

Among physicochemical analysis methods that have found wide use in automated or proximate analysis of the ionic composition of zinc-containing solutions is differential pulse polarography (DPP) [3–5]. The problem of polarographic determination of Co(II) in zinc sulfate solutions has remained unsolved until recently because of the closeness of the reduction potentials of Co(II) and Zn(II) ions found in the overwhelming majority of supporting electrolytes employed in analytical practice.

The highest resolution of the DPP method in determining Co(II) in concentrated zinc solutions was achieved in [6], where measurements were done in a supporting electrolyte of composition 0.1 M sodium citrate $Na_3C_6H_5O_7$ + 0.1 M NH_4Cl + 0.08% dimethylglyoxime $C_4H_8O_2N_2$ (DMG). The difference of the reduction potentials of Co(II) and Zn(II) ions at the dropping mercury electrode is 240 mV (φ_p^{Co} = –1.02, φ_p^{Zn} = –1.26 V), which enables monitoring of Co(II) in the presence of a 50×10^4-fold excess of Zn(II), with lower detection limit of 2.5 mg l^{-1}. However, such selectivity and sensitivity of DPP are insufficient for determining 0.5 mg l^{-1} Co(II) in neutral solutions containing up to 150 g l^{-1} Zn(II), i.e., under the conditions of a modern high-efficiency zinc production.

In addition to Zn(II), adverse influence on voltammetric determination of Co(II) in supporting solution of composition 0.1 M $Na_3C_6H_5O_7$ + 0.1 M NH_4Cl + 0.08% DMG is also exerted by Mn(VII) and Ni(II) whose DPP peak potentials are, according to the authors' data, –0.98 and –0.97 V, respectively. It should be mentioned that the concentrations of Ni(II) and Co(II) ions in a purified zinc-containing solution are, as a rule, comparable, whereas the content of Mn(VII) exceeds that of Co(II) more than 1000-fold [7]. The cathodic voltammetric curves of Mn(VII) and Ni(II) mask the DPP peak of Co(II), and, already at concentration (mg l^{-1}) ratios [Ni] : [Co] = 4 : 1 and [Mn] : [Co] = 5 : 1, polarographic determination of Co(II) in the given supporting electrolyte becomes impossible.

A significant shortcoming of the technique proposed in [6] is that the slope of the calibration plot for Co(II) depends on the content of Zn(II) in a solution being analyzed, which inevitably impairs the accuracy of measurements. Moreover, the necessity for blowing nitrogen, for deoxygenation purposes, through a solution being analyzed markedly hinders automation of polarographic analysis under industrial conditions.

The present study established the possibility of substantially increasing the selectivity, sensitivity, and accuracy of Co(II) determination in a purified zinc solution when performing a polarographic analysis in a supporting electrolyte containing DMG and hydroxylamine hydrochloride.

The ion concentration in solutions was monitored by DPP on an AZhE-11 voltammetric analyzer equipped with a transducer with stationary dropping mercury electrode (SDME) of the valve type [8]. A three-electrode electrochemical cell was used (working electrode of the "hanging mercury drop" type, silver chloride reference electrode, glassy carbon auxiliary electrode). Rectangular 40-ms pulses with repetition period of 80 ms were applied.

The chloride-ammonia supporting electrolyte is widely used in analytical practice for determining cobalt(II) in various objects. The Co(II) half-wave potential on the background of 1 M NH_4Cl + 1 M NH_4OH is –1.3 V [9]. The sensitivity of analysis is improved dramatically upon introducing into the supporting electrolyte an alcoholic or ammonia solution of DMG [10, 11]. The height of the cathodic peak of Co(II) strongly depends on the DMG concentration and the pH of the medium. For example, in [11], a solution being analyzed was titrated with an ammonia solution to pH 9.0, prior to being subjected to polarography, in order to raise the sensitivity. A new electrochemically active complex, reduced at mercury electrode in a more positive range of potentials, is formed in a DMG-containing chloride–ammonia supporting electrolyte. It has been established that a catalytic wave, which can be used for analytical purposes, is recorded in an ammonia solution of DMG in the presence of Co(II) [12, 13]. In [14], a mechanism was proposed, describing the appearance of a catalytic current of hydrogen in an ammonia buffer solution in the presence of cobalt(II) and nickel(II) dimethylglyoximates.

It was pointed out in monograph [15] that none of DMG complexes gives a polarographic wave similar to the catalytic wave of a complex with cobalt(II). Presumably this occurs because the hydrogen ion in the complex, which is involved in the hydrogen bond,

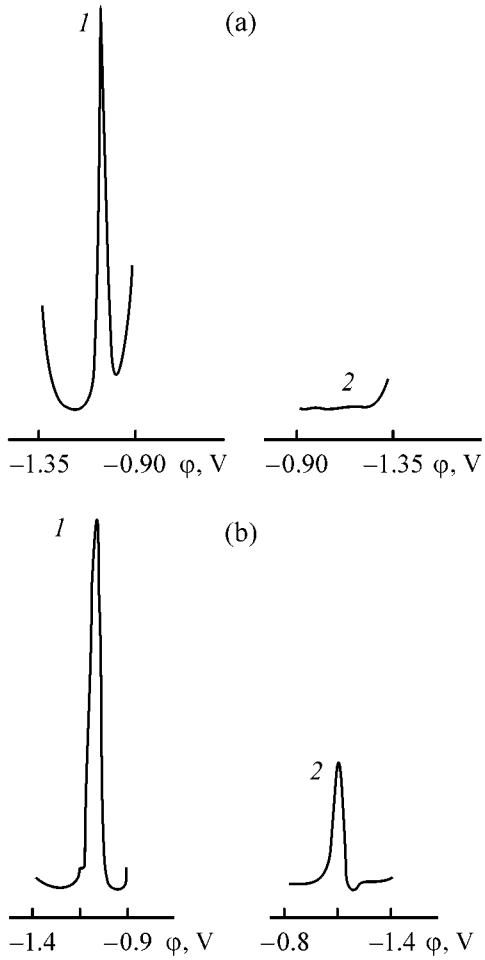

Fig. 1. DPP curves of cobalt(II). (φ) Potential; the same for Figs. 2, 3, and 6. Co(II) concentration (mg l^{-1}): (a) 0.5 and (b) 0.1. Buffer solution: (a) I and (b) II; the same for Fig. 3. Curve: (*1*) cathodic and (*2*) anodic.

is reduced, and this process is responsible for the catalytic action of the molecule of the complex. According to IR spectral analysis, the weakest hydrogen bonds are found in complexes of cobalt(II) with DMG, compared with other doubly charged transition metals. The experimental data obtained in [10] indicate that Co(II) dimethylglyoximates much exceed Cu(II) and Ni(II) dimethylglyoximates in catalytic effect.

The authors of [6] noticed that the voltammetric curves of Co(II) in the presence of 0.1 M $Na_3C_6H_5O_7$ + 0.1 M NH_4Cl + 0.08% DMG, recorded using cyclic voltammetry with triangular wave, reveal no anodic peak. This shows that reduction of Co(II) chelate with DMG is totally irreversible. A similar result was obtained in the present study in recording cathodic and anodic voltammetric curves of Co(II) with a DMG-containing chloride-ammonia supporting electrolyte

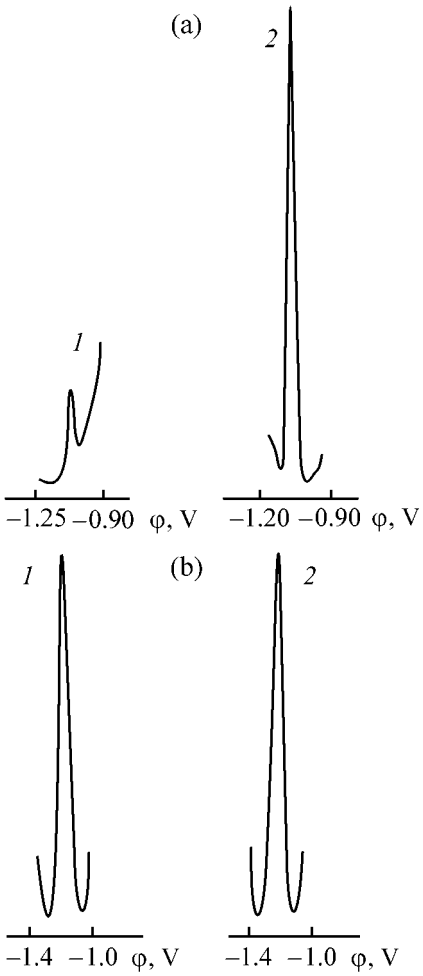

Fig. 2. Effect of $NH_2OH \cdot HCl$ on polarographic determination of (a) cobalt(II) and (b) zinc. Ion concentration (mg l^{-1}): (a) Co(II): (*1*) 0.05 and (*2*) 0.005; (b) Zn(II) 20.2. Buffer solution: (*1*) I and (*2*) II.

by DPP on SDME. The buffer solution of composition 1 M NH_4Cl + 1 M NH_4OH + 1×10^{-3} M DMG (pH 9) (I) was prepared in accordance with the methodological recommendations of [10, 11].

It can be seen from Fig. 1a that Co(II) is irreversibly reduced at SDME in solution I at a DPP peak potential of –1.04 V (curve *1*), whereas anodic curve in this range of potentials reveals no DPP peak (curve *2*). Introduction of 0.2 M of hydroxylamine hydrochloride (Fig. 1b, curve *1*) shifts the DPP peak potential of Co(II) by 60 mV into the negative range of voltages (φ_p = –1.10 V), which indicates the formation in the solution, and electroreduction at SDME, of a new complex compound. In the process, the cathodic peak height increases more than 50-fold, and a peak at –1.09 V is recorded in the anodic voltammogram (Fig. 1b, curve *2*).

An assumption can be made on the basis of the data of [16] that introduction of hydroxylamine into a DMG-containing chloride-ammonia buffer leads to formation of a complex compound of cobalt(II) with two ligands (hydroxylamine and DMG). The cathodic DPP peak of the mixed complex is characterized by the appearance of a catalytic current which much exceeds that of the complex of cobalt(II) with DMG (Fig. 2a) and, even the more so, the limiting diffusion current of the cobalt(II) ion [10]. The higher sensitivity in the case of polarography of catalytic currents of coordination compounds and the reversibility of their waves correspond to catalysis by the metal ion–ligand complex which can be formed both in the solution bulk and in the adsorption layer [17, 18]. Of fundamental importance for selectively determining Co(II) ions in zinc solutions is the fact that addition of hydroxylamine hydrochloride to a DMG-containing chloride-ammonia supporting electrolyte has virtually no effect on the height and shape of the voltammetric curve for reduction of Zn(II) ions (Fig. 2b).

In considering the mechanism of action of $NH_2OH \cdot HCl$ in polarographic determination of cobalt(II) on SDME, an assumption can be made that, in the presence of hydroxylamine, the formation of the new polarographically active complex involves DMG adsorbed onto the surface of the mercury electrode (the chemical stage preceding the reduction is of surface-heterogeneous nature). The system electrode–DMG–cobalt(II)–hydroxylamine is electrically conducting, and the reduction of the mixed complex occurs via "bridge" transfer of electron. It is assumed that electrochemically active complexes with two or more ligands (with account of the ammonia buffer in the given case), adsorbed onto the electrode surface, have a more distorted symmetry than similar complexes in the solution bulk, which must, in turn, lead to faster charge transfer rate [17] and, correspondingly, to higher catalytic current and better sensitivity of polarographic analysis.

The possibility of polarographic determination of Co(II) with supporting solution I is strongly limited by the hindering action of Mn(VII) and Zn(II) ions (Fig. 3a), similarly to the case when 0.1 M $Na_3C_6H_5O_7$ + 0.1 M NH_4Cl + 0.08% DMG is used as supporting electrolyte [6]. In the presence of manganese (VII) in a solution being analyzed, the right-hand branch of the DPP peak of cobalt(II) is distorted (curve *2*). Presence of Zn(II) ions in a solution being monitored distorts the left-hand branch of the DPP peak of cobalt (curve *3*). At a 100-fold excess of Mn(VII) and Zn(II), polarographic determination of Co(II) ions in solution I becomes virtually impos-

sible (curve *4*). When zinc(II) ions are present in a solution being analyzed, the slope of the calibration plot for cobalt(II) changes, which inevitably impairs the measurement accuracy. The masking action of Mn(VII) and Zn(II) ions in polarographic determination of Co(II) is eliminated by introduction of hydroxylamine hydrochloride into a solution being analyzed.

Redox reactions of $NH_2OH \cdot HCl$ with $KMnO_4$ were considered in [19]. In alkaline medium, hydroxylamine reduces Mn(VII) to Mn(II); the reaction rate is high since the forming Mn(II) ions catalyze the oxidation of $NH_2OH \cdot HCl$. A visual sign of the occurrence of the reaction is the virtually instantaneous decolorization of a solution of permanganate ions into which hydroxylamine is introduced.

In an ammonia-chloride electrolyte, Mn(II) is electrochemically reduced in a more negative range of potentials, compared with Co(II), and does not interfere with its polarographic determination [20]. In supporting solution I, the DPP peak potential of Mn(II) is –1.5 V. When a voltammetric curve is measured with supporting solution I containing 0.2 M $NH_2OH \cdot HCl$, no cathodic DPP peak of Mn(II) is recorded. It can be seen from the polarograms presented in Fig. 3b that the interference of excess concentrations of Mn(VII) and Zn(II) is much weakened on introduction of 0.2 M of $NH_2OH \cdot HCl$ into the supporting solution I.

The investigations performed demonstrated that, in contrast to [10, 11], polarographic determination of Co(II) in a chloride-ammonia supporting solution makes unnecessary maintaining the pH value at a strictly prescribed optimal level. The acid solution of hydroxylamine was neutralized and an alkaline medium, necessary for polarographic determination of Co(II) in the presence of DMF, was created with the use of a buffer solution containing equal molar concentrations of ammonium hydroxide and chloride.

The sensitivity and selectivity of the polarographic determination of Co(II) ions in zinc production solutions strongly depend on the concentrations of the supporting electrolyte, DMG, and hydroxylamine. With decreasing concentration of the chloride-ammonia buffer, the height of the DPP peak of Co(II) markedly grows (Fig. 4, curve *1*). However, in this case, the selectivity of cobalt(II) determination in the presence of excess amounts of zinc(II) markedly decreases. It can be seen from Fig. 4 (curve *2*) that the difference of the potentials of the cathodic DPP peaks of Co(II) and Zn(II) grows with increasing concentration of the supporting solution. Thus, high re-

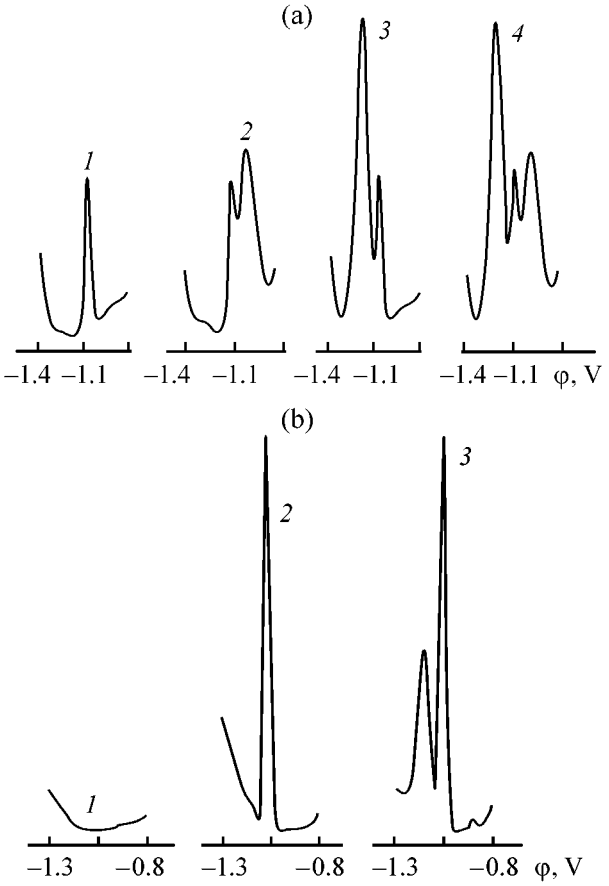

Fig. 3. Effect of accompanying ions on polarographic determination of cobalt(II). Fig. 6. DPP curves of cobalt(II) in supporting solution II. (*1*) Supporting solution; ion concentration (mg l^{-1}): (*2*) Co(II) 0.005 and Zn(II), Mn(VII) 0; (*3*) Co(II) 0.005, Zn(II) 1500, and Mn(VII) 200.

solution of the polarographic method in determining low contents of cobalt(II) in a zinc sulfate solution can only be achieved with the use of sufficiently concentrated supporting electrolytes. It was found that the optimal buffer solution is that containing 2 M NH_4Cl + 2 M NH_4OH, which enables, at appropriate choice of the DMG and hydroxylamine concentrations, polarographic determination of microscopic amounts of cobalt(II) in zinc electrolytes containing up to 150 g l^{-1} of Zn(II).

It can be seen from Fig. 5 that the sensitivity of cobalt(II) determination in a supporting solution 2 M NH_4Cl + 2 M NH_4OH markedly grows with increasing concentration of DMG (curve *1*) and hydroxylamine (curve *2*). A simultaneous increase in the concentrations of DMG and hydroxylamine improves the selectivity of voltammetric determination of cobalt(II) because of the selective rise in the height of the cathodic (catalytic) peak of Co(II) at unchanged heights of the DPP peaks of the majority of accompanying compounds. With a supporting electrolyte of composition 2 M NH_4Cl + 2 M NH_4OH + 2×10^{-3} M DMG + 0.2 M $NH_2OH \cdot HCl$ (II), direct polarographic determination of Co(II) is possible, with a lower detection limit of 0.0025 mg l^{-1} at a concentration ratio (mg l^{-1}) [Zn] : [Co] = 300 000 : 1. Raising further the concentrations of the components of the supporting electrolyte fails to offer any noticeable advantages, being, therefore, inexpedient.

The sensitivity of polarographic determination of cobalt(II) strongly depends on the rate V_s of potential sweep. With the sweep rate increasing from 0.5 to 10 mV s^{-1}, the height of the cathodic DPP peak of Co(II) varies linearly. Raising the V_s further, to 40 mV s^{-1}, exerts no noticeable influence on the sensitivity of voltammetric analysis, but may affect adversely the reproducibility of measurement results.

Based on the results of the performed experimental investigation, the following optimal conditions of polarographic determination of cobalt(II) in zinc sulfate solutions were chosen: supporting electrolyte II, initial voltage –1.05 V, cathodic potential sweep rate 10 mV s^{-1}, potential sweep 0.25 V. It can be seen from the DPP curves presented in Fig. 6 that this mode of voltammetric analysis ensures high sensitivity and selectivity of Co(II) monitoring in the presence of excess concentrations of Zn(II) and Mn(VII) ions. In a supporting electrolyte of composition 2 M NH_4Cl + 2 M NH_4OH + 2×10^{-3} M DMG, the lower detection limit of Co(II) ions by DPP on SDME is 0.4 mg l^{-1} at admissible concentration (mg l^{-1}) ratios [Zn] : [Co] = 10 000 : 1 and [Mn[: [Co] = 200 : 1, which indicates a significant decrease in the sensitivity and selectivity of analysis in the case when there is no $NH_2OH \cdot HCl$ in the supporting electrolyte.

The calibration plots for Co(II) with supporting solution (II) are linear in the concentration range 0–2.5 mg l^{-1}. Introduction of Zn(II) ions into a solution being analyzed has no effect on the slope of the calibration plot. This makes it possible to achieve a high sensitivity of polarographic determination of Co(II) irrespective of the zinc sulfate concentration in the technological solutions being monitored.

Polarographic determination of Co(II) with supporting solution II in the presence of accompanying substances

Ion	C, mg l^{-1}	E, V (silver chloride electrode)	ΔE, mV	$\alpha_{M/Co}$
Cu(II)	0.1–0.5	–0.43	720	No interference
Cd(II)	1–2	–0.75	400	"
Ge(IV)	≤0.01	–0.96	190	100 : 1
Fe(II)	30–50	–0.98	170	4000 : 1
Ni(II)	0.2–1.0	–1.00	150	400 : 1
Co(II)	0.5–2.0	–1.15	–	–
Zn(II)	(120–150) × 10^3	–1.43	280	300 000 : 1

* C is the content of ions in purified zinc-containing solution, E the DPP peak potential, ΔE the difference between the DPP peak potentials of Co(II) and accompanying ion, $\alpha_{M/Co}$ the maximum admissible ratio of concentrations (mg l^{-1}) of the accompanying impurity and Co(II).

Also, the influence of ion components that are characteristic of technological solutions used in zinc manufacture and can be electrochemically reduced at the mercury electrode in solution II: Cu(II), Cd(II), Ni(II), Fe(II), and Ge(IV) on the polarographic determination of Co(II) was studied.

It can be seen from the data presented in the table that the developed technique ensures high selectivity of Co(II) determination in the presence of the above-mentioned ions and can be used for analyzing purified zinc-containing solutions of complex composition. Microscopic amounts of Sb(III) present in a zinc-containing electrolyte are precipitated in ammonia medium [21]. Fe(III) ions are reduced to Fe(II) by hydroxylamine contained in the supporting electrolyte [19]. Arsenic(III) is reduced at mercury electrode in chloride-ammonia supporting electrolytes at a potential of –1.7 V and does not interfere with polarographic determination of cobalt(II) [22].

The developed technique for voltammetric monitoring of Co(II) ions in zinc sulfate solutions served as a basis for a Kobalt-1 automated analyzer.[2] Raw materials (concentrates) processed at the plant contain considerable amounts of water-soluble compounds of cobalt(II) affecting adversely the electrolysis of zinc.

Previously, technological solutions produced in permanganate purification at the leaching shop were analyzed photocolorimetrically with the use of a nitroso-R salt, forming in aqueous solutions a red complex salt with Co(II) ions at pH 5.5, as a selective complexing agent [23]. The photometric determination of cobalt(II) assumes a complicated procedure for preprocessing of zinc solution samples, including treatment with aggressive reagents, boiling, and cooling, which makes analysis substantially longer and virtually rules out its automation. Photocolorimetric analysis for cobalt(II) in the express laboratory of the leaching shop was made no more than three or four times per shift, which hindered purification in the optimal mode and led to over-expenditure of potassium permanganate.

The analyzer was tested on industrial samples taken from tanks for purified zinc sulfate solution. The concentration of ion components in the solutions being analyzed varied during the tests within the following ranges (mg l^{-1}): Zn(II) (130–140) × 10^3, Mn(VII) 500–1500, Ni(II) 0.2–1.0, Cu(II) 0.1–0.2, Cd(II) 0.5–1.0, Fe(II) 30–50, Co(II) 0.3–2.8, Sb(III) 0.2–0.3; As(III) 0.01–0.05.[3]

A total of 35 zinc solution samples with Co(II) ion concentration varying between 0.48 and 2.36 mg l^{-1} were analyzed. As a control was used the photocolorimetric method of analysis. The reduced rms error of Co(II) determination in the concentration range 0–2.5 mg l^{-1} did not exceed 1.7%. The maximum reduced rms deviation from the results of main and control analyses for cobalt(II) ions in a sample, characterizing the reproducibility of measurements, was 0.5%.

Automation of analysis for Co(II) ions on the basis of the developed voltammetric technique will make it possible to optimize the permanganate purification of technological solutions to remove cobalt(II) impurities and, in the end, to improve the performance in cathode zinc manufacture. The technique can be used for ecological monitoring of Co(II) in industrial wastewater discharged by plants of nonferrous metallurgy.

[2] Put in practice at the Elektrotsink plant.

[3] Data of the production control department of the Elektrotsink plant.

EXPERIMENTAL

Standard solutions of Co(II), Cu(II), Cd(II), Ni(II), Fe(II), Mn(VII), Ge(IV), and Zn(II), prepared by procedures described in [24], were used in the study. The model solutions were prepared using distilled water.

To determine Co(II) in a purified zinc sulfate solution, 0.5 ml of a sample of the zinc-containing electrolyte being analyzed was introduced in a 50-ml volumetric flask, 25 ml of a supporting electrolyte of composition 4 M NH_4Cl + 4 M NH_4OH + 4×10^3 M DMG + 0.4 M $NH_2OH \cdot HCl$ was added, and the solution was brought to the mark with distilled water. The obtained mixture was poured into an electrochemical cell and a cathodic DPP curve was measured in the potential range –1.05…–1.30 V. The potential sweeping was done at a rate of 10 mV s^{-1}, with a set of 3–5 curves obtained and height of cathodic peaks measured at a potential of –1.15 V, and the content of Co(II) in the solution was determined using a calibration plot constructed with account of a 100-fold dilution of the sample. The total duration of analysis of a sample for the content of cobalt(II) is not longer than 5–7 min with manual sample preparation.

In the case of automated analysis, dilution of a sample with water, its mixing with a supporting electrolyte, and delivery of a solution being analyzed into the flow-through voltammetric cell were done with the use of DZZh-4 three-chamber dosing devices made of chemically stable materials [8]. After the sample preparation was complete, commands of the control unit were successively executed in accordance with the preset program to discharge a spent, and form a new mercury drop and to switch-on the potential sweep and the chart strip drive. Each voltammetric curve was recorded with a newly formed mercury drop. After the computing unit calculated the parameters of the voltammetric curve, the output signal of the analyzer, proportional to the concentration of Co(II) ions in a solution being analyzed, was recorded.

CONCLUSIONS

(1) A highly selective method was developed for voltammetric determination of Co(II) ions in zinc manufacture solutions of complex composition with chloride-ammonia buffer solution containing dimethylglyoxime and hydroxylamine as supporting electrolyte.

(2) Introduction of $NH_2OH \cdot HCl$ into the supporting electrolyte improves dramatically the sensitivity and selectivity of polarographic determination of cobalt(II) in the presence of excess concentrations of zinc(II) and completely eliminates the adverse influence of permanganate ions.

(3) The developed method for voltammetric determination of Co(II) ions is easily automated and can be used for on-line monitoring of technological solutions and wastewater of plants of nonferrous metallurgy.

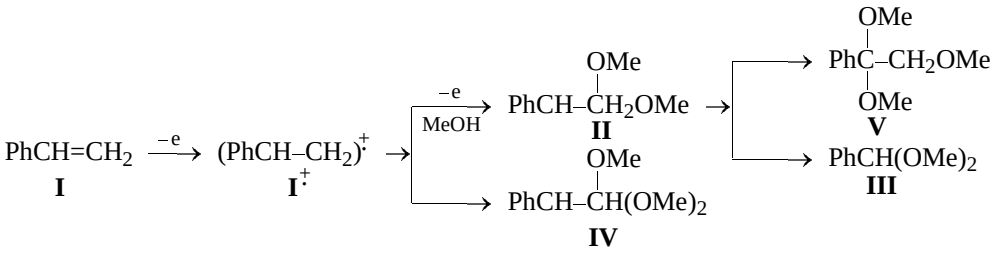
State Research Institute of Organic Chemistry and Technology, Moscow, Russia

Received February 14, 2001

Abstract—Anodic oxidation of styrene in methanol was performed in an electrolyzer with gas-lift. The possibility of carrying this process out in continuous mode with the use of technical-grade methanol was studied.

Recently, the reaction of styrene methoxylation, making possible manufacture of a number of important organic preparations, e.g., benzaldehyde and anisaldehyde, has been studied intensively. Electrochemical methoxylation of styrene (**I**) leads to formation of 1,2-dimethoxyethylbenzene (**II**) with subsequent splitting of the C–C bond and conversion of **II** into dimethylacetal of benzaldehyde (**III**):



A number of studies have been concerned with the effect of a supporting electrolyte, anode material, and other factors on the yield of the reaction products [1–5]. It was established that conversion of styrene **I** into 1,2-dimethoxyethylbenzene **II** is the most efficient in electrolysis with a platinum anode and potassium fluoride solution as supporting electrolyte. The conditions were described under which the yield of compound **III** is as high as 66%, and the current efficiency, 33%, after passing 8 F of electricity per 1 mol of styrene.

All the experiments described in the literature have been performed in a diaphragmless glass electrolyzer equipped with magnetic stirrer for solution agitation. Such an electrolyzer cannot serve as a prototype of an industrial apparatus.

In the industry, the best-developed design is the electrolyzer of filter-press type in which the electrolyte circulation is effected by gases formed in electrolysis—the gas-lift system [6]. Electrolyzers of this kind exhibit good performance in electrolysis of water. It has been shown that cathodic hydrodimerization of acetone can be performed in an electrolyzer with gas-lift system [7].

Electrochemical synthesis of compound **III** is of practical importance. In view of this fact, the present study was aimed at verifying the possibility of carrying out the given reaction in a prototype industrial electrolyzer. In order to create conditions as close as possible to those used in the industry, the process was performed in continuous mode with the use of technical-grade methanol [GOST (State Standard) 2222–95] as solvent.

EXPERIMENTAL

The experiments were carried in electrolyzer *1* (see figure) in the form of a glass cylinder 55 mm in diameter and 140 mm high. An electrode pack compris-

1070-4272/01/7408-1318 $25.00 © 2001 MAIK "Nauka/Interperiodica"

ing alternating anode and cathode plates was placed inside the electrolyzer. Two platinum plates of size 15×80 mm were used as anode, and three stainless steel plates of the same size, as cathode. The interelectrode spacing of 3 mm was ensured by fluoroplastic spacers placed at electrode edges. The installation is shown schematically in the figure. The ascending pipe of the gas-lift system had inner diameter of 6 mm and height of 1650 mm. The capacity of the whole system was 420 ml. The current density was calculated on the assumption of the uniform distribution of current over the entire surface of the cathodes.

A 20.8-g portion of styrene (0.2 mol), 1.4 g (0.02 mol) of KF, and 397 ml of methanol was placed in the system, so that it was filled to the level shown in the figure. The electrolysis was carried out at a current density of 0.1 A cm^{-2} (current strength 4.8 A), with 8 F of electricity passed per 1 mol of styrene **I** and no fresh electrolyte added. The voltage across the electrolyzer was 10 V.

After the electrolysis was complete, methanol was evaporated under a water-jet pump vacuum at a temperature of 40°C, still bottoms were extracted with hexane (20×3), and the solvent was evaporated from the extract. The still bottoms were weighed and analyzed by liquid-gas chromatography on an LKhM-8MD chromatograph (detector catharometer, carrier-gas helium, column length 1.5 m, column diameter 3 mm, support Chromaton-N-AW, immobile phase PEG-4000, flow rate 4 ml s^{-1}, sensitivity 1 : 3, column temperature 130°C, evaporator temperature 250°C).

For comparison, experiments were performed in an electrolyzer with magnetic stirrer, with design close to that described in [1–5].

Table 1 presents data on the accumulation of electrolysis products both in an electrolyzer with gas-lift and in that with mechanical stirring. It can be seen that the yield of benzaldehyde dimethylacetal **III** is nearly 14% higher in the electrolyzer with a gas-lift system, compared with that equipped with mechanical stirrer.

Further experiments were carried out in order to verify the possibility of performing the process in the continuous mode. A certain amount of electrolyte solution was removed from the electrolyzer every hour and a fresh portion of the same volume was added. Two sets of experiments were carried out with fresh electrolyte supplied at a rate of 25 ml h^{-1}.

The yield of the reaction products was found not to change substantially on passing from batch to continuous mode (Table 2). Also, the possibility was verified of conversion of the intermediate electrolysis product—1,2-dimethoxyethylbenzene, in an electrolyzer of continuous type with gas-lift. In this case, one more product of the reaction of electrochemical methoxylation of styrene—1,1,2-trimethoxyethylben-

33*	46	37	11	6	28.5*	39.5	43.5	11	6
41*	44	39	11	6	36.5*	39	44	11	6

* Addition of fresh electrolyte (styrene) was started after passing 8 F of electricity per 1 mol of styrene.

zene (**V**), is formed in yield of up to 18–22% in a continuous-type electrolyzer with gas-lift and 10% in an electrolyzer with mechanical stirring [5].

A set of experiments carried out with varied current density at a supply rate of fresh electrolyte of 50 ml h^{-1} demonstrated that the yield of the target product grows with the current density increasing to 0.2 A cm^{-2} (Table 3).

Tables 1–3 present the results averaged over three measurements. The relative error of the average is 1.6% at confidence probability α = 0.95.

The obtained data indicate that in an electrolyzer with gas-lift system, operating in the continuous mode, the process course is stable, with lower electrolyte supply rate ensuring higher yield of product **III**, virtually coinciding with that achieved in the batch mode.

CONCLUSION

Methoxylation of styrene to obtain benzaldehyde dimethylacetal can be carried out in continuous mode in an electrolyzer with electrolyte circulation effected by gas-lift.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Measurement of Electrical Conductivity of Wastewater for Fast Determination of Metal Ion Concentration

F. Prieto, E. Barrado, M. Vega, and L. Deban

University Autonoma del Estado de Idalgo, Mexico;
University Vagliadolida, Spain

Received May 15, 2000

Abstract—The possibility of determining the content of 15 toxic elements in wastewater from their electrical conductivity was studied in order to evaluate the amount of iron(II) ions required for precipitation of these toxic elements.

Treatment of wastewater to remove metal ions requires data on their total content. Convenient express method for determining the solution mineralization and concentration of metal ions is based on measuring the electrical conductivity of solutions. To determine the weight fraction of certain particles in solution, the total content of solid substance, and the content of ionized solid substance, the electrical conductivity ($\mu S\ cm^{-1}$) is multiplied by an empirical factor varying from 0.55 to 0.99, depending on the nature of dissolved components and temperature [1]. Electrical conductivity measurements are often used to determine the salinity of natural and waste waters [2]. For this purpose, various empirical equations have been obtained and salinity scales developed [3], which can be used for a wide variety of samples. For example, scales of the seawater salinity [4] including a scale for low-salinity solutions [5] have been developed.

Highly efficient treatment of wastewater containing metal ions is based on addition of Fe(II) ions to a solution under study in alkali medium in the presence of oxidants, which results in precipitation of metal ions in the form of ferrites possessing magnetic properties [6, 7]. It has been found that the highest purification efficiency and the greatest magnetic moments of the precipitates are attained when the weight concentration of Fe(II) is 15 times the total concentration of the metal ions to be removed [8, 9]. Thus, evaluation of the total content of Fe(II) that should be added to wastewater to maintain the optimal 15 : 1 ratio requires that the concentration of all metal ions in solution should be determined. However, common analytical procedures used in this case are rather laborious. Thus, development of a new fast and cheap procedure for determining metal ions in wastewater, based on measurement of its certain physicochemical properties, is rather urgent. Electrical measurements are rather simple, and the electrical conductivity correlates with the concentration of metal ions in solution. The aim of this study was to determine the empirical dependence between the electrical conductivity and the concentration of metal ions in solution and thus to evaluate the total content of metal ions and, consequently, the amount of Fe(II) necessary for *in situ* treatment of wastewater via precipitation of metal ferrites.

Previously, it has been found that compounds able to form complexes with metal ions affect the precipitation of the corresponding metal ferrites from solutions [10]. Moreover, complex formation changes the charge and size of metal-containing ions in a solution and thus affects its electrical conductivity. Hence, evaluating the effect of complex formation on how the electrical conductivity depends on the content of metal ions in solution, with the aim to determine the general empirical correlation, is equally urgent.

EXPERIMENTAL

To determine the specific electrical conductivity χ, the electrolyte solution is placed in a measurement cell (length L and cross-section A). Then the resistance R of this cell is determined and the electrical conductivity is calculated using the following expression

$$\chi = \frac{L/A}{R}. \quad (1)$$

1070-4272/01/7408-1321 $25.00 © 2001 MAIK "Nauka/Interperiodica"

Although the electrical conductivity is measured in the SI system in $S\ m^{-1}$, results are mostly given in $\mu S\ cm^{-1}$ because of the low conductivities of the systems in question.

The size of the measurement cell is fixed, and for a given cell the L/A ratio (cell constant K_c) is invariable. This constant is determined experimentally by measuring R for a solution with known χ:

$$\chi = K_c/R. \quad (2)$$

The electrical conductance G is a characteristic not only of the electrolyte solution with given concentration and temperature, but also of the cell geometry:

$$G = 1/R. \quad (3)$$

The molar electrolytical conductivity Λ ($S\ m^2\ mol^{-1}$) is a measure of the capability of a given electrolyte to carry electric current:

$$\Lambda = \chi/C \times 10^{-3}, \quad (4)$$

where $\chi = \chi(\text{solution}) - \chi(\text{solvent})$ ($S\ m^{-1}$) and C is the electrolyte molar concentration (M). The molar electrical conductivity of electrolyte is determined by the contributions of all the present ions:

$$\Lambda = \Sigma \nu_i \lambda_i, \quad (5)$$

where λ_i is the ionic molar conductivity ($S\ m^2\ mol^{-1}$) and ν_i is the number of ions (cations and anions) formed by one electrolyte molecule. The ionic molar conductivity gives quantitative information on the contribution of a given ion type to the solution conductivity. Its value depends on the total concentration of ions ($\Sigma z_i c_i$) in the solution and grows with its dilution. With increasing concentration of a strong electrolyte, χ grows because a greater amount of ions participate in the current transport. In weak electrolytes, χ also grows with increasing concentration, but Λ decreases because of the decreasing dissociation. At very high ion concentrations, Λ may decrease because of ion pair formation and increasing solution viscosity.

The electrical conductivity depends on temperature. With increasing temperature, the Brownian motion becomes more pronounced, leading to a rise in χ. The accuracy of the χ measurement is determined by the stability of temperature in the course of the tests. The temperature coefficient α of electrolyte conductivity can be expressed as follows:

$$\alpha = \frac{d\chi/dt}{\chi} \quad (6)$$

and thus

$$\chi_i = \chi_{25}[1 + \alpha(t - 25)]. \quad (7)$$

The content of metal ions in solution was determined by atomic-emission spectrometry with inductively coupled plasma (AES-ICP) on a Philips 7000 atomic-emission inductively coupled plasma spectrometer (Philips, Netherlands).

The electrical conductivity was measured with an accuracy of no less than 0.20% in the entire conductivity range, using a Crison 522 conductometric unit (Crison, Spain) with a platinum cell (K_c 1.280 cm^{-1}).

The solution pH was measured with a Crison micro-pH 2002 unit (Crison, Spain) equipped with a combination glass electrode and a temperature compensation probe.

In all the tests, analytically pure chemical reagents were used. The test solutions were prepared using deionized water (conductivity 17.2 $\mu S\ cm^{-1}$). The electrical conductivity of water was subtracted from all experimental results.

Nineteen wastewater samples were collected at laboratories of the Analytical Chemistry Department of the University Vagliodolida within one academic year. The ion concentrations of 15 toxic elements [As(V), Ba(II), Cd(II), Co(II), Cu(II), Cr(VI), Fe(III), Hg(II), Mn(II), Mo(II), Ni(II), Pb(II), Sr(II), V(V), and Zn(II)] were determined by AEP-ICP method using solutions diluted to an appropriate degree. The measurements were performed 3 times and the average concentrations of the above elements were calculated.

To determine the electrical conductivity, an aliquot (1 ml) of acidic wastewater was diluted to 50 ml with deionized water, and its pH was adjusted to 3.0 with sodium hydroxide. The measurements were carried out at a constant temperature of $20.0 \pm 0.2°C$. The tests were performed 5 times for each solution under these conditions.

The average electrical conductivities and corresponding rms errors for 19 samples in question (5 parallel tests) and the total concentrations of metal ions (3 parallel tests for each of 15 elements) are listed in the table. The total concentration of metal ions was calculated as a sum of concentrations of 15 elements studied and its rms error was evaluated. Then, using experimental concentrations, the total content of metal ions in diluted solutions was determined and the concentration dependence of the electrical conductivity was plotted (Fig. 1). For the samples in question this dependence is linear and is described by the following equation obtained by least-squares procedure ($R^2 = 0.9970$):

$$\chi = 25.104C + 909.85. \quad (8)$$

The adequacy of empirical equation (8) for determining the concentration of metal ions in wastewater from its electrical conductivity was analyzed using a model sample containing 15 above elements present in all 19 wastewater samples (the total average concentration of metal ions was 3232 mg l^{-1}, see table). The model solution was prepared by dissolving the required amounts of Cd(II), Co(II), Cr(III), Cu(II), Fe(III), Hg(II), Ni(II), Pb(II), Sr(II), and Zn(II) nitrates, Ba(II) and Mn(II) chlorides, and sodium molybdates, vanadates, and arsenates in deionized water. Then 5 aliquots of the model solution were diluted (1 : 50), the solution pH was adjusted to 3.0 using sodium hydroxide, and the electrical conductivity of the resulting solutions was measured (n = 5). The average conductivity was 2866 μS cm^{-1}. Substitution of this value in Eq. (8) gives the total concentration of metal ions of 77.9 mg l^{-1}, which corresponds to the concentration of the initial model solution (3895 mg l^{-1}). Thus, the deviation from the average concentration (3232 mg l^{-1}) is 20%. This error is rather large but positive, and thus Eq. (8) can be used to calculate the amount of Fe(II) which should be added to the wastewater to remove no less than 99% of heavy metals [Fe(II) concentration should exceed the total concentration of these metals by a factor of 15]. This equation guarantees that an excess amount of Fe(II) is added to the solution, sufficient for effective precipitation of metal ions.

Oxidants and organic compounds, which can interact with metal ions and thus hinder their precipitation as ferrites because of competitive reactions modifying the species in solutions, can strongly affect the efficiency of wastewater treatment to remove metal ions via formation of ferrites [8, 10]. It would be expected that presence of these compounds also affects the electrical conductivity and thus the feasibility of using its values to determine the total concentration of metal ions and the amount of Fe(II) required for effective wastewater treatment.

Previously [10], we simulated the effect of complexing organic compounds for the example of ethylenediaminetetraacetate ions (EDTA), which were taken because they form stable complexes with metal ions and can be analyzed as a model of the other natural ligands with similar complexing properties. To study the effect of organic ligands on the electrical conductivity of a wastewater containing metal ions, aliquots of the model solution were diluted (1 : 50), and appropriate amounts of EDTA disodium salt (from 10^{-8} to 0.5 M) were added. The solution pH was adjusted to 3.0 with NaOH, and the electrical conductivity was measured.

The logarithmic dependence of the electrical conductivity of the wastewater (n = 5) on the EDTA concentration is shown in Fig. 2. As seen, the electrical conductivity is nearly constant at EDTA concentrations lower than 5×10^{-5} M, then it sharply decreases and becomes constant at concentrations higher than 10^{-2} M. This fact can be accounted for as follows. At pH 3, EDTA participates in the competitive reactions with protons (H_3EDTA^- and H_2EDTA^{2-} are predominant) and thus the concentration of EDTA required for complexation increases. At low EDTA concentrations, only metal ions forming the strongest chelates with the organic ligand participate in complexation and the electrical conductivity remains nearly constant because the ionic composition of the solutions changes insignificantly. At higher EDTA concentrations (>10^{-2} M), almost all metal ions participate in complexation and, as a result, further increase in the ligand concentration does not affect the conductivity, because EDTA is a weak electrolyte only slightly changing the ionic composition of the solution.

At the maximum EDTA concentration studied (0.5 M), the electrical conductivity was 2631 μS cm^{-1}, which is 8% smaller than that in the absence of the complexing additive. The total concentration of metal ions in the initial model solution, calculated from

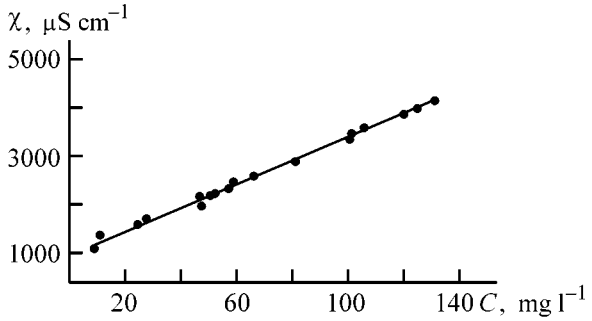

Fig. 1. Electrical conductivity χ of model wastewater vs. the total concentration of metal ions *C* in wastewater strongly contaminated with ions of 15 heavy metals. Samples diluted to 1 : 50 ratio; the same for Fig. 2.

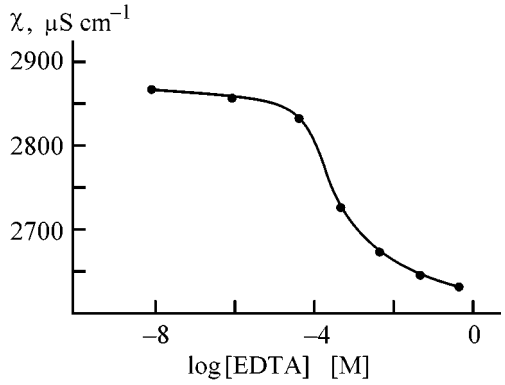

Fig. 2. Electrical conductivity χ of model wastewater containing ions of 15 heavy metals vs. EDTA concentration.

is 3428 mg l^{-1}, which is 6% greater than the real concentration (3232 mg l^{-1}). Since the possible concentration of organic ligands in wastewater is significantly smaller, such calculations give the overestimated total concentration of metal ions and thus of the amount of Fe(II) ions required for their recovery as metal ferrites, which guarantees the maximal efficiency of the treatment process.

To evaluate the applicability of the above empirical expression relating the electrical conductivity to the total concentration of metal ions in wastewater, a new sample containing the same ions (1990 mg l^{-1}) was taken in the academic laboratories. This sample was divided in two aliquots, which were diluted in 1:50 ratio for conductivity measurements. Then EDTA was added to one aliquot (5×10^{-2} M or 10^{-3} M after dilution), and the conductivity of these samples was measured. The total content of metal ions in solutions with organic ligand and without it were calculated by means of Eq. (8) to be 2231 and 2365 mg ml^{-1}. These results were used to determine the amount of Fe(II) required for water treatment, taking into account the optimal Fe/total metal content ratio of 15 : 1 [8]. Then the treatment was performed under the optimized conditions [8, 10], and its efficiency was evaluated from the content of metal ions (AES-ICP method) remaining in the solution after treatment. In both cases the purification efficiency was greater than 99%, which confirms the possibility of using the electrical conductivity measurements to determine the amount of iron(II) required for wastewater treatment to remove metal ions in the form of their ferrites.

CONCLUSIONS

(1) A linear dependence between the electrical conductivity and the total content of metal ions in solutions was established.

(2) Addition of EDTA forming complexes with metal ions decreases the electrical conductivity, but evaluation of the total content of metal ions and thus of the amount of iron(II) ions from the electrical conductivity of wastewater remains acceptable for practical use.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Effect of pH on the Flocculation of Aqueous Ocher Suspension in the Presence of Ionic Copolymers of Acrylamide

V. A. Myagchenkov and V. E. Proskurina

Kazan State Technological University, Kazan, Tatarstan, Russia

Received February 12, 2001

Abstract—The effect of pH on the kinetics of flocculation of an aqueous ocher suspension in the presence of ionic polyacrylamide flocculants was studied and their flocculation properties were compared.

Ionic and nonionic copolymers of acrylamide find increasing use as flocculants at various stages of water treatment and in other industrial processes, owing to their high performance, availability, low toxicity, and relative cheapness [1, 2]. The performance of polyacrylamide flocculants (PAAFs) is controlled not only by their chemical nature, molecular parameters, structure, and thermodynamic and kinetic flexibility of the macromolecules of acrylamide (co)polymers, but also by the properties of the particles (especially surface) of the disperse phase (DP) and dispersion medium [3]. The presence of relatively small amounts of the surfactants, electrolytes, and compounds with various functional groups able to modify the surface of the DP particles can also affect the flocculation properties of PAAFs [4, 5]. These compounds control the aggregation and sedimentation stability of the disperse system (DS) and, taking into account their effect on the conformation of macromolecules, affect the flocculation properties of PAAFs.

Although the effect of pH of the dispersion medium is important, it has been poorly studied. In this work, we studied, using a model ocher suspension in water, the effect of pH of the dispersion medium on the flocculation properties of macromolecular ionic (anionic and cationic) PAAFs.

EXPERIMENTAL

In our work, we used the ocher suspension ["golden" brand, TU (Technical Specifications) 301-10-019–90] with average particle radius $\bar{R} = 9.25 \times 10^{-6}$ m. The following ionic PAAFs were used in the tests: anionic (**A**) random copolymer of acrylamide and sodium acrylate (viscosity-average molecular weight $\bar{M}_\eta$ 5.4×10^6, content of ionic groups β 17.4%) and cationic (**C**) random copolymer of acrylamide and dimethylaminoethyl methacrylate hydrochloride ($\bar{M}_\eta$ 2.3×10^6, β 16.3%). The sedimentation kinetics of the ocher particles was studied in the mode of free (unhindered) sedimentation (the concentration of the disperse phase was C 0.8%) using a VT-500 torsion balance in a 400-ml cylinder at different pH adjusted by adding 0.1 M HCl and KOH solutions. Before tests the ocher suspensions were clarified for 1 day at each given pH. The required copolymer (0.02% aqueous solutions of **A** and **C** copolymers) was added to a supernatant volume directly before mixing of the ocher suspension by means of a perforated disk stirrer, which was slowly shifted in the cylinder 10 times in the vertical direction.

The viscosity of copolymers **A** and **C** in water was measured on an Ostwald viscometer (0.54 mm capillary diameter). The correction for the kinetic flow energy was lower than 2% and was neglected in the calculations of the reduced viscosity η_{sp}/C.

The electrophoretic mobility of the ocher particles at various pH was determined on an PARMOQUANT (Carl Zeiss, Jena) automated measuring microscope at 20°C and 10 mA current; 0.01 M KCl served as supporting electrolyte.

The kinetic curves of ocher sedimentation in solutions with various pH values are given in Fig. 1. The sedimentation kinetics was monitored using a dimensionless parameter $m(t)/m_{max}$, where $m(t)$ and m_{max} are the current and maximal weight of the pre-

cipitate on the torsion balance [5]. Ocher sedimentation significantly accelerates with pH deviation from the neutral to basic or acidic values. This is obviously due to the effect of pH on the aggregation and thus on the sedimentation stability of the DP particles, related to the changes in the structure of the electrical double layer (its size and electrokinetic potential ζ) around the DP particles. As seen from Fig. 2, this potential strongly depends on the solution pH and a certain decrease in the absolute value of the ζ potential in alkaline and acidic media well agrees with the decreasing sedimentation stability of the system at given pH (Fig. 1).

We expected that this effect of pH on the sedimentation stability of the ocher would *a priori* appear upon addition of ionic PAAFs in the system. For example, the effect of **A** and **C** PAAFs and their binary mixture on the flocculating parameters of the system at pH 3.0 is illustrated in Fig. 3. For binary PAAF mixtures, three modes of addition were used: (**A** + **C**), (**C** + **A**), and {**A** + **C**}; in the first case we initially added copolymer **A** and then copolymer **C**; in the second case, vice versa, we first added copolymer **C** and then copolymer **A**; and in the last case copolymers **A** and **C** were added simultaneously.

As seen from Fig. 3, the mode of flocculant addition affects the flocculation rate. This is probably due to the almost complete irreversibility of the PAAF sorption [6] and selective interaction between negatively (**A**) and positively (**C**) charged macroions.

Selective interaction between macroions **A** and **C** was suggested previously on the basis of viscometric and conductometric data. The data in Fig. 4 show that the experimental reduced viscosities of mixtures of **A** and **C** are significantly smaller as compared with the initial copolymers **A** and **C** (Fig. 4, curves *1, 2,* and *3*), which indicates the "contraction"

(decrease in the rms size) of macroions **A** in the presence of macroions **C** with opposite charge. It should be noted that pH significantly affects the solution viscosity of copolymers **A** and **C** and thus the effective size of the macromolecular globules, because these parameters vary in parallel [7]. To obtain the qualitative characteristics of the flocculation kinetics, we calculated the parameters of flocculation effect D and flocculation activity λ [3, 5]:

$$D = v/v_0 - 1, \quad (1)$$

$$\lambda = (v/v_0 - 1)/C, \quad (2)$$

where v and v_0 are the average rates of ocher sedimentation at $m(t)/m_{max}$ 0.7 in the presence of polymer flocculant (concentration C) and without it, respectively.

The correlated dependences $\lambda = f(\text{pH})$ for copolymers **A** and **C** and $D = f(\text{pH})$ for binary mixture of ionic PAAFs for all three modes of their addition are shown in Fig. 5. As seen, the experimental dependences $D = f(\text{pH})$ and $\lambda = f(\text{pH})$ are extremal, because the conformation of macromolecule, electric double layer parameters, and the "energy pattern" of the dispersion particle surface depends on the solution pH [3]. Naturally, the mode of copolymer addition and solution pH must also affect the adsorption interaction of macromolecule with one or several particles of the disperse phase [8]. The real mechanism of the adsorption of ionic copolymer macromolecules on the DP particles is rather complex owing to the presence of both negatively and positively charged areas on the particle surface, produced predominantly by silanol groups and Fe^{3+} cations, respectively. With account taken of the relatively low content of the ionic units in the copolymers in question, uncharged acrylamide fragments of macromolecules undoubtedly affect the adsorption interaction with one or several ocher particles [9–11]. The anionic and cationic copolymers differ significantly nature of adsorption and flocculation, which is indirectly confirmed by the difference in flocculating activity between copolymers **A** and **C**; namely $\lambda_{\mathbf{A}} > \lambda_{\mathbf{C}}$. This fact unambiguously indicates the predominantly bridging (and not neutralization) nature of the flocculation effect of copolymers **A** and **C**, because the DP particles are negatively charged in the entire pH range studied, i.e., similarly with respect to macroions **A** and oppositely with respect to macroions **C**. These data also suggest that the fraction of the effective bridging bonds for copolymer **A** is significantly greater as compared with copolymer **C**. Thus, it is apparent that the conformation state of macromolecules **A** and **C** cannot be regarded as a unique

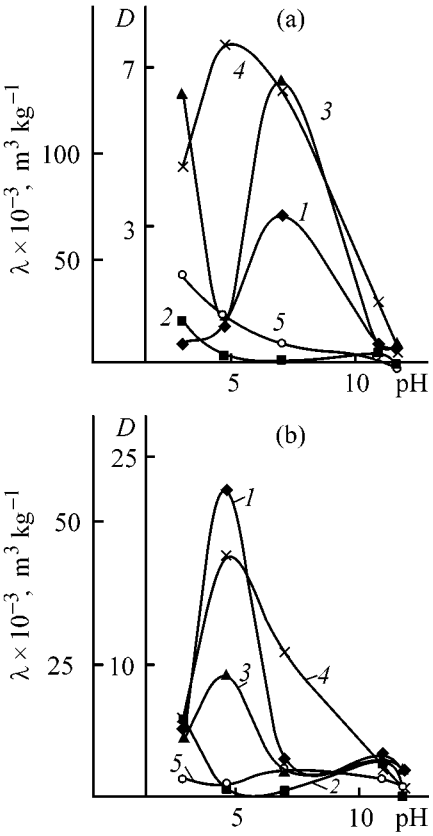

Fig. 5. Flocculation parameters (*1*, *2*) λ and (*3*–*5*) D vs. the solution pH; [PAAF] 3×10^{-5}%; [**A**]/([**A**] + [**C**]) (a) 0.25 and (b) 0.75. PAAF: (*1*) **A**, (*2*) **C**, (*3*–*5*) first, second, and third modes of copolymer addition, respectively.

parameter of the flocculation activity of PAAFs. As seen from Fig. 5, in the case of anionic PAAFs, the dependences $\lambda = f(\text{pH})$ and $D = f(\text{pH})$ are nearly parallel, whereas in the case of cationic copolymers such trends are absent. Taking into account the selective interaction of macroions **A** and **C**, we can account for the effect of how the copolymer is added to the system, namely, the fact that the parameter D is the smallest in the case of third addition mode in the entire pH range studied. It is apparent that, upon simultaneous addition of copolymers **A** and **C**, the "contraction" effect for macromolecular globules of the binary copolymer mixtures is the strongest, which was shown already by means of viscometry (Fig. 4).

Now, omitting the analysis of the rather complex mechanisms of adsorption and flocculation in the systems in question, we consider the significant effect of pH on the flocculating parameters of anionic and cationic PAAFs and compositions on their basis. Despite the predominantly correlation nature of the observed dependences $D = f(\text{pH})$ and $\lambda = f(\text{pH})$, they may be promising for optimization of the flocculation

processes not only in the model systems, but also in complex multicomponent disperse systems with varied pH.

CONCLUSIONS

(1) The kinetic parameters of flocculation of the ocher suspension in the free (unhindered) sedimentation mode in the presence of anionic and cationic copolymers of acrylamide and their mixtures (3 : 1 and 1 : 3) in solutions with various pH were studied.

(2) The flocculation parameters of polyacrylamide flocculants with respect to the ocher suspension in water strongly depends on the solution pH, which is predominantly due to the dependence of the electrochemical properties of the ocher particles and conformation of copolymer macromolecules on the pH.

Abstract—The influence of small C_{60} additions on thermal and thermal oxidative degradation of polymethyl methacrylate prepared by radical polymerization was studied by differential scanning calorimetry, thermogravimetric analysis, differential thermogravimetric analysis, and mass spectrometry.

Kashiwagi *et al.* [1], applied differential thermogravimetric analysis (DTG) to study weak bonds in molecules of atactic polymethyl methacrylate (PMMA) prepared by radical polymerization and the influence of these bonds on the thermal degradation of the polymer. In the course of heating in an inert atmosphere (N_2), they detected three peaks (Fig. 1a). Peak *I* (~165°C) was assigned to degradation initiated by head-to-head chain defects (or H–H bonds); peak *II* (~270°C), to degradation involving unsaturated terminal groups; and peak *III* (~360°C), to degradation of the main chains. In [2, 3], we studied the influence of fullerene C_{60} on thermal degradation of PMMA, using mass-spectrometric thermal analysis (MTA). In PMMA without additives we observed the same three peaks as in [1], at approximately the same temperatures (Fig. 1b). Addition of small amounts of C_{60} to PMMA led to considerable changes in the MTA patterns: Peak *I* disappeared almost completely, and peak *II* noticeably decreased in height. It was concluded from these results that C_{60} retains the products of thermal degradation, i.e., it acts as a scavenger of free radicals released in degradation. At the same time, peak *III* grew in relative intensity and shifted toward higher temperatures by approximately 15°C, which corresponds to an increase in the energy of the cleaved bonds by approximately 4 kJ mol^{-1} [3]. Thus, C_{60} stabilizes PMMA both at low and at elevated temperatures.

Note that peaks *I* and *II*, related to cleavage of specific weak bonds, were appreciably narrower than peak *III* related to random bond cleavage. Addition of C_{60} also makes the peaks narrower. Apparently, degradation pathways become more definite in the presence of C_{60}; they involve addition of PMMA radicals to C_{60}, followed by cleavage of the CC and CO bonds in the vicinity of the addition site.

Numerical estimation shows that the unit weight of a sample at 1% C_{60} concentration contains approximately equal the numbers of C_{60} molecules and PMMA macromolecules (at M = 85000). Since each C_{60} molecule can add up to 6–10 radicals, the C_{60} concentration is quite sufficient to add all the arising radicals.

The relative areas of peaks *I–III* in Fig. 1a are S_I = 0.13, S_{II} = 0.27, and S_{III} = 0.60 of the total peak area S_0. Estimation of the MTA peak areas before addition of C_{60} (Fig. 1b) gives close values: S_I = 0.10, S_{II} = 0.30, and S_{III} = 0.60. Similar estimations made after addition of C_{60} allowed determination of the fraction of PMMA molecules "trapped" by fullerene: S_{Fu} = = S_I + (S_{II} – S_{II}'), where S_{II}' is the relative area of peak *II* after addition of C_{60}. We found that $S_{Fu} \approx 20$, i.e., only about 20% of C_{60} molecules take up two PMMA radicals arising from chain cleavage, or 40% of C_{60} molecules take up one radical. Apparently, the true fraction of bound C_{60} molecules is closer to 20%, since, in cleavage of a PMMA chain, the resulting radical centers are localized practically at the same place, and the C_{60} molecule, if occurring in the vicinity of this place, takes up both radicals. Thus, at least two different types of C_{60} molecules are formed in the system: free and bound to PMMA.

The described studies of thermal degradation were mainly performed in an inert atmosphere or in a vacuum. Of no less interest, especially from the practical viewpoint, is thermal oxidative degradation in air. The presence of oxygen also results in disappearance of peak *I* (Fig. 1a) [1]. The DTG curve taken in the presence of O_2 exhibits a new strong peak at ~300°C, whose position lies between peaks *II* and *III* obtained in a nitrogen atmosphere. Kashiwagi *et al.* [1] believe that the experimentally observed peak is actually a sum of a new peak *F* and peaks *II* and *III*, with major contribution made by peak *F*. However, it is difficult, in our opinion, to reveal any contributions from peaks *II* and *III* in the curves reported in [1]. Nevertheless, a conclusion can be made that oxygen plays a dual role: It enhances the stability of the system at low temperatures but decreases it at high temperatures [1].

Naturally, the chain degradation detected by DTG and MTA can be accompanied by thermal effects which can also arise without weight loss. Thus, thermogravimetric and calorimetric methods supplement each other in studies of thermal degradation and, when used in combination, can furnish essentially new information. This is especially important when studying such complex processes as thermal oxidative degradation of PMMA which, in our opinion, must be, in the case of an open system, a superposition of at least three processes accompanied by thermal effects:

$$Q_\Sigma = -Q_D + Q_O - Q_S, \quad (1)$$

where Q_Σ is the total thermal effect, Q_D the endothermic effect due to chain degradation, Q_O the exothermic effect due to oxidation of the chains and thermal degradation products, and Q_S the endothermic effect of sublimation or vaporization of degradation products.

Addition of C_{60} to the polymer can affect these processes differently, so that it may be possible to reveal their separate manifestations. Presumably, C_{60} will compete with oxygen for free radicals and thus stabilize the system. However, since fullerene and oxygen affect high-temperature degradation differently, it was unclear whether stabilization would be observed in the entire temperature range of degradation.

The main goal of this study was to examine the influence of C_{60} on thermal oxidative degradation of PMMA using a combination of thermogravimetric analysis (TG) and differential scanning calorimetry (DSC).

The processes of thermal and thermal oxidative degradation of PMMA and polystyrene (PS) in the presence of fullerenes were studied by DSC in [4, 5], and it was concluded that fullerenes play a stabilizing role. However, with PMMA this conclusion is consistent with the results of [2, 3], whereas with PS it contradicts previous data [6]. Probably, this is due to differences in the experimental methods, molecular structure of the polymers in hand, and procedures for evaluating the thermal stability. Therefore, we gave in this work a particular attention to the methodological aspects of evaluating the thermal stability and to correlation of the TG, MTA, and DSC data.

EXPERIMENTAL

The initial fullerene C_{60} (99.7% purity) was prepared by the Huffman–Krätschmer procedure [7]. Polymethyl methacrylate with the viscosity-average molecular weight of 8.5×10^4 was prepared by radical polymerization. To introduce C_{60} into PMMAs, their toluene solutions were combined in a ratio required for ensuring the desired concentration of fullerene. Samples were prepared by casting films from these solutions. Thermal degradation of the materials was studied with an STA 429 Netzsch thermal analyzer (Germany) in air at linear heating rates of 5 and 10 deg min^{-1} in the range 20–700°C. In the course of heating, the temperature, weight variation, and ther-

mal effects were recorded simultaneously. We studied the samples of the starting powdered PMMA, films of PMMA without additives, and films of PMMA with 1 and 10% C_{60}. The sample weight was 120 mg at a heating rate of 10 deg min^{-1} (10-10 series) and 1 or 5 mg at a heating rate of 5 deg min^{-1} (5-1 and 5-5 series, respectively). From numerous experiments, we chose the 5-5 series as basic. The smaller sample weight (1 mg) and its grinding and uniform distribution over the bottom of the measuring cell, at a relatively low heating rate, allowed minimization of the possible effects of slow diffusion, low thermal conductivity, and variation of the gaseous medium in the cell due to release of degradation products; however, the intensity of the useful signals decreased simultaneously, and "weak" processes could not be revealed. In the 10-10 series, the testing conditions were the most rigorous. In this case, it is possible to "amplify" weak processes, but the results can be disturbed because of changes in the gaseous medium, especially in the range of active release of degradation products. With increasing heating rate, most of the characteristic effects shift toward higher temperatures, but, on the whole, the results remain similar. In what follows, we consider in most detail the results obtained with the 5-5 series, and other results will only be discussed when certain processes will be manifested more clearly or to confirm the results of the main series.

The baselines were plotted using the results of experiments performed under the same conditions with samples of sapphire which undergoes neither weight loss nor phase transitions in the temperature range under consideration. For all the samples, the TG curves in the range from 20 to approximately 150°C showed an apparent weight gain due to convective air flows along the vertical axis of the furnace [8]. This gain amounted to no more than 2.5% for 10-mg samples but was significant for 1-mg samples. In DSC measurements, the baseline was parabolic. However, in the temperature range of interest, its curvature was the smallest and did not distort significantly the position and shape of the peaks; therefore, in many cases the qualitative effects were revealed without "straightening" the baseline.

To characterize the thermal degradation products, we used the temperature positions of peaks, T_m, in the DTG, DSC, and MTA curves. The T_m values were determined to within ±5°C. An important characteristic of the thermal stability of a substance is the onset temperature of thermal degradation, T_0. This temperature was determined from the deviation of the weight loss from zero by a conventional value of 0.3% (method 1). The determination error was also about 5°C. Frequently, T_0 is also determined by extrapolation of the main branch of the TG curve to intersection with the baseline parallel to the abscissa (method 2). However, in this case T_0 strongly depends on the curvature of the TG curve, which can give rise to considerable systematic errors. Therefore, in what follows we determined T_0 by method 1 only.

* In sample notation, the third figure gives the C_{60} concentration in %; the "?" sign means that unambiguous determination of the peak position is impossible; the coinciding values of T_0 obtained by TG and DSC are printed italic.

** Sample of PMMA film cast from a toluene solution. In the other series, the initial powders were used as samples of PMMA without additives.

The temperatures characterizing thermal oxidative degradation of PMMA, and determined by different methods, are listed in the table.

Endothermic DSC peak and its interpretation. The DSC thermograms of all the samples exhibit a common striking feature: Approximately in the middle of the thermal oxidative degradation range, a sharp transition occurs from the heat release to heat absorption (sharp endothermic peak), which is followed by new exothermic processes and their gradual decay until

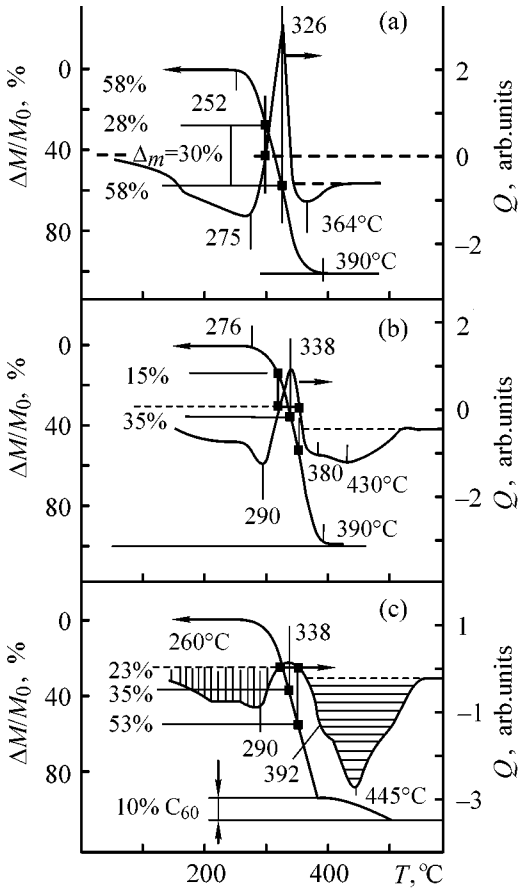

Fig. 2. Patterns of thermal oxidative degradation of PMMA in air, 5-5 series: ($\Delta M/M_0$) relative weight loss, (Q) heat flow, and (T) temperature; the same for Fig. 3. (a) PMMA film, (b) PMMA + 1% C_{60}, and (c) PMMA + 10% C_{60}. *Figures at curves* denote characteristic temperatures (°C); the same for Fig. 3. *Dashed lines* denote baselines.

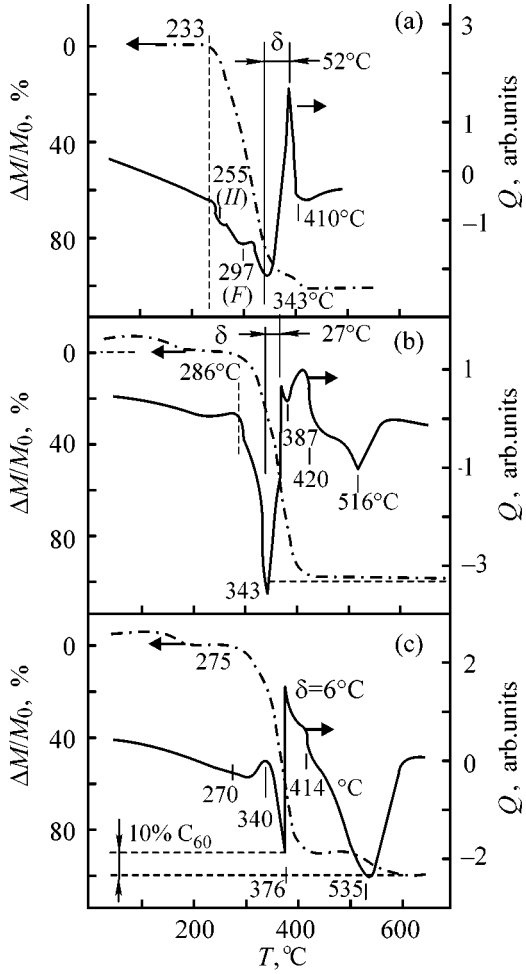

Fig. 3. Patterns of thermal oxidative degradation of PMMA in air, 10-10 series: (a) PMMA powder, (b) PMMA + 1% C_{60} film, and (c) PMMA + 10% C_{60}. The baselines were not straightened.

the degradation products are fully removed from the experimental cell. Let us consider a combination of the TG and DSC curves for PMMA films without additives (Fig. 2). An endothermic peak is observed at about 326°C. On its low-temperature side, practically from the very beginning of the experiment there is a fairly smooth increase in heat release up to 275°C. The peak at 275°C seems to correspond to peak *II*; however, we believe that its another interpretation (see below) is more probable. On the high-temperature side of the endothermic peak, there is a peak at about 364°C, i.e., in the region of peak *III*. With the temperature increasing from that of the endothermic peak to ~364°C, the major fraction of the material (the least defective and the most thermostable) is, apparently, oxidized as the polymer decomposes to the monomer, with a part of the polymer that does not decompose to the monomer (5–8% according to published estimates), and probably forms cross-linked structures, being oxidized too. This part of PMMA is revealed more clearly at higher heating rates and larger sample weight (Fig. 3a). In this case, the TG curves show gradual weight loss (up to 94%) in the range from ~230 to 360°C. Then, from 360 to 400°C, there is a step corresponding to additional 6% weight loss, and the DSC curve exhibits an exothermic peak at about 410°C. Also, three exothermic peaks at 255, 297, and 343°C are clearly seen in the DSC curves. The first peak can be related to peak *II*, and the second, to peak *F*. In the 5-5 series, peak *F* was observed in the same temperature range as the strong endothermic peak and, therefore, was not always revealed. At the same time, the exothermic peak at 343°C can hardly be related to peak *III* (~360°C), because it is observed at an appreciably lower temperature. Presumably, according to Eq. (1), competition of the endothermic effect due to sublimation of the degradation products and thermal degradation of the already oxidized products with

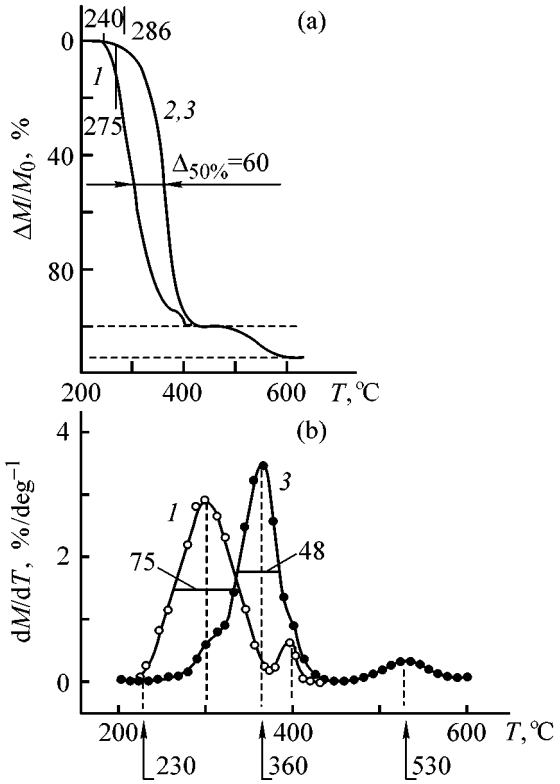

Fig. 5. (a) TG and (b) DTG curves of samples of the 10-10 series: ($\Delta M/M_0$) relative weight loss of the sample and [d($\Delta M/M_0$)dT] its derivative with respect to temperature. (*1*) PMMA powder, (*2*) PMMA + 1% C_{60} film, and (*3*) PMMA + 10% C_{60}. *Figures at curves*: (a) T_0 (°C) for PMMA powder (240), PMMA + 1% C_{60} film (286), and PMMA + 10% C_{60} film (275); (b) peak half-widths (°C).

the exothermic effect due to oxidation (Q_O sharply decreases) gives rise to an apparent peak and sharp change in the sign of the overall thermal effect. The apparent peak at 275°C in Fig. 2a has probably the same origin.

The occurrence of an endothermic effect allows us to distinguish arbitrarily three stages of thermal oxidative degradation with increasing temperature: with heat release (before the endothermic peak), with heat absorption, and again with heat release. We will analyze these stages and give quantitative estimates for them by comparing the straight samples and those containing C_{60}.

Effect of C_{60} on the temperature shift of the oxidative degradation. Figure 4 shows the temperature dependences of the weight loss. It is seen that, with increasing C_{60} concentration, the slope of the initial section of the dependences decreases. Correspondingly, T_0 determined by method 2 changes more strongly. The difference between the T_0 values determined by procedures 1 and 2 for the samples containing 0, 1, and 10% C_{60} is 18, 42, and 48°C, respectively. Variation of the curvature of the initial section of the plots is naturally due to an increase in the concentration of C_{60} retaining the degradation products. Note that, on adding 1% C_{60}, T_0 shifts to higher temperatures (from 252 to 276°C), whereas a reverse shift (to 260°C) is observed on adding 10% C_{60}. This effect is small, but it is reproduced in all the sample series (see table). It can be accounted for by assuming that, in the initial stages of degradation, C_{60} interacts with oxygen and prevents, to some extent, oxidation of the arising polymer radicals. However, degradation in the whole temperature range is not significantly affected by raising the fullerene concentration from 1 to 10%. The TG curves for the samples containing C_{60} coincide (Fig. 4d) in virtually the entire temperature range, except in the above-mentioned initial range and at temperatures above ~385°C where the C_{60} weight loss becomes appreciable. Therefore, we believe that the shift of the curves along the abscissa

axis (e.g., $\Delta_{50\%}$ at 50% weight loss) characterizes the variation of the thermal stability of the system more adequately than T_0 does. The high-temperature shift of the TG curves in going from a PMMA film without additives to the samples containing C_{60} is about 30°C, which is consistent with the MTA data [2]. Similar results were obtained with the 10-10 series. Figure 5a shows that the TG curves obtained at different C_{60} concentrations coincide, but the above-noted qualitative differences in the initial and final sections of the TG curves are preserved. Figure 3 shows particularly clearly a decrease in the slope of the initial TG front with increasing C_{60} concentration and a clear step corresponding to the release of 10% C_{60} at the end of the process. However, Fig. 5a additionally confirms the fact that the C_{60} concentration in the range above 1% has no significant effect on the thermal stability and that the temperature shift of the TG curves is a more convenient characteristic of the relative thermal stability than T_0. In the DTG curves (Fig. 5b) taken in the presence of C_{60}, the main peak shifts toward higher temperatures and becomes narrower by a factor of ~1.5; the latter fact is apparently due to addition of PMMA radical chains to C_{60}, followed by cleavage of CC or CO bonds between C_{60} and PMMA.

Three stages of thermal oxidative degradation and effect of C_{60} on them. Let us consider three stages of thermal oxidative degradation for samples of the 5-5 series as an example. Stage 1 involves oxidation of degradation products originating from the cleavage of weak bonds in the chains. The onset of the endothermic peak for PMMA without additives corresponds to approximately 28% weight loss (Fig. 2a). This value is noticeably smaller than the fraction of products formed by cleavage of weak bonds in the course of thermal degradation (~40%), as estimated from the thermograms in Fig. 1. Thus, not all the products formed by degradation of PMMA without additives via cleavage of weak bonds undergo oxidation. The fraction of oxidized products in the samples containing C_{60} decreases to 15–23% (Figs. 2b, 2c). Simultaneously decreases the heat release in the range corresponding to this weight loss: The area of the exothermic peaks in Figs. 2b and 2c decreases by 15 and 34%, respectively. This fact suggests that C_{60} prevents oxidation of PMMA, competing with oxygen for the polymer or directly interacting with oxygen. Assume as a rough estimate that about 20% of the polymer has been oxidized. This is half the weight corresponding to peaks *I* and *II*. The other half has apparently combined with C_{60}, which is consistent with the MTA estimates for the fraction of the polymer captured by C_{60}. In stage 2, the degradation products volatilize with heat absorption, rather than heat release (we arbitrarily regard as the beginning of this stage the temperature corresponding to the first intersection of the endothermic peak with the baseline, and as the end, the temperature corresponding to the endothermic minimum). These may be both unoxidized degradation products (the remaining 10–13% in the case of straight PMMA) and the products of degradation of previously oxidized chains or radicals, which undergo in this stage only thermal degradation without further oxidation. In PMMA without additives, the content of these products is about 30% of the total sample weight, and in samples containing 1 and 10% C_{60}, ~20 and ~12%, respectively, i.e., the "retaining" role of C_{60} is clearly manifested here. At the same time, these estimates show that about 20% of products formed by random chain cleavage are released from straight PMMA without oxidation. The decrease in the intensity of the endothermic peak with increasing C_{60} content also indicates that the total heat of decomposition and sublimation of the degradation products in this stage is considerably lower for the C_{60}-containing samples.

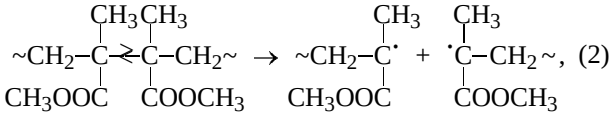
In PMMA without additives, oxidation starts again (stage 3) at about 326°C (endothermic minimum), whereas the products linked to C_{60} do not undergo oxidation up to ~338°C (Figs. 2b, 2c). In the latter case, subsequent degradation is accompanied by release of less heat than degradation of C_{60}-free PMMA. The heat is released in two stages, with peaks at 380 and 430°C for the sample with ~1% C_{60} and at 392 and 445°C for the sample with 10% C_{60}. This fact suggests the presence of two types of C_{60} molecules, those bonded and not bonded with the PMMA chains. This conclusion is consistent with MTA data. The noticeable heat release corresponding to degradation of C_{60} even at its 1% content indicates that the calorific value of C_{60} is very high. The heat released after the endothermic effect increases by a factor of approximately 5 as compared with the heat released in this range in the case of PMMA without additives. At the same time, with the C_{60} concentration raised tenfold, the heat release increases by only a factor of 3.3. This means that the evaporated products of thermal oxidative degradation of free C_{60} can also be subdivided in two groups: products that have actually underwent oxidation and degradation with heat release and C_{60} molecules volatilizing without oxidation (no less than half of their initial amount, as estimated from the thermal effects). Note also that after the endothermic peak the baseline shifts (an abrupt change in the heat capacity): the higher the C_{60} concentration, the smaller the shift.

Comparison of data obtained by different methods. The major (92 to 95%) gaseous product of PMMA thermal degradation is the monomer. This fact predetermines the good agreement between the DTG and MTA data. Naturally, the DTG curves are directly related to the TG curves. However, the run of the DTG curves may be fairly complex, so that no accurate quantitative conclusions can be made on how the thermal stability of the system changes. We believe that more adequate conclusions can be made by "aligning" the TG curves and determining their shift at 50% or any other arbitrarily chosen level of weight loss.

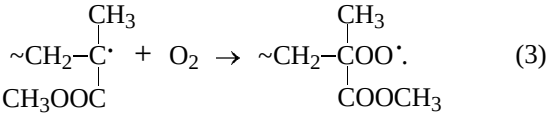
The T_0 values determined from the DSC and TG data (see table) coincide only in rare cases, mainly with PMMA powders without additives. In the presence of C_{60}, on the one hand, the slope of the thermograms decreases, complicating determination of T_0; on the other hand, if rough estimation of T_0 is still possible, the T_0 values obtained by DSC are always appreciably lower than those given by TG. Apparently, DSC detects the starting degradation and subsequent oxidation or "fullerenization" of PMMA degradation products (latent degradation), but C_{60} prevents the degradation products from leaving the system.

Mechanisms of chemical reactions in thermal oxidation of PMMA. The following elementary steps, determining the specific features of degradation, can be distinguished in thermal oxidation of PMMA.

(1) Cleavage of H–H bonds, formation of macroradicals [scheme (2)], and their stabilization in the presence of oxygen [scheme (3)] [1]:

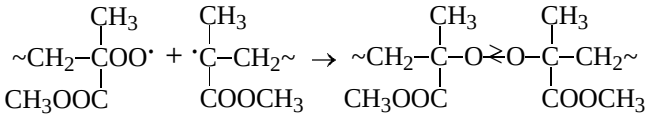


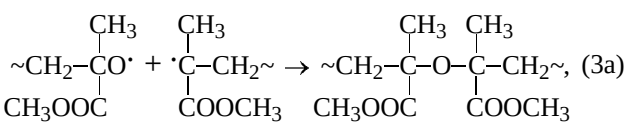
(2)



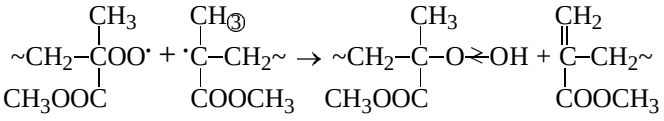
(3)

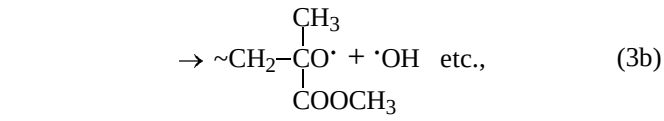
The stabilization mechanism (3) can be described by a series of reactions:



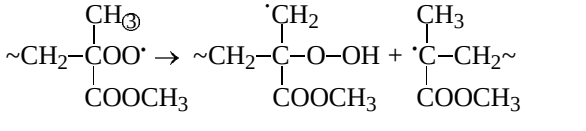


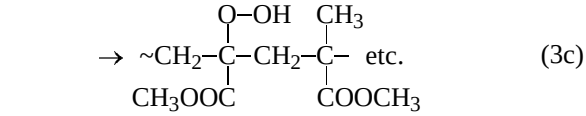
(3a)





(3b)



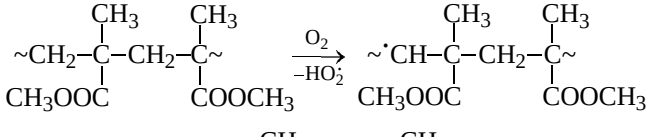


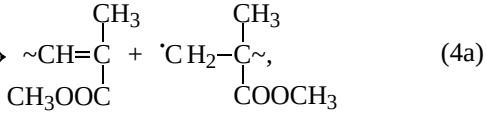
(3c)

Thus, the arising products of macroradical oxidation prevent depolymerization of PMMA. In the process, there is no weight loss, but heat is released. At higher temperatures, the products of macroradical oxidation undergo thermal degradation with heat absorption.

(2) Cleavage of β-bonds at unsaturated ends of polymer chains. Thermal degradation in the range 240–300°C, initiated by unsaturated terminal groups of the polymer chains, is apparently somewhat stabilized in the case of thermal oxidation (the peak *F* shifts toward high temperatures relative to peak *II*; see Fig. 1a). This fact can be accounted for by reactions of the arising macroradicals with oxygen, similar to reactions (3). As in the previous case, oxidation of macroradicals is apparently accompanied by heat release, and their thermal decomposition, by heat absorption. Since peak *II* lies at higher temperatures than peak *I*, oxidized macroradicals formed in the region of peak *II* (as also macroradicals added to C_{60}) undergo thermal decomposition to a greater extent as the temperature is raised further (stage 2), and peak *II* does not fully disappear from the DTG and MTA curves in the presence of oxygen and/or C_{60}.

(3) Thermal oxidation of "defect-free" PMMA molecules. At sufficiently high temperatures, defect-free sections of PMMA chains become subject to thermal oxidation [scheme (4)]. This is accompanied by weight loss and exothermic processes of stage 3:





(4a)

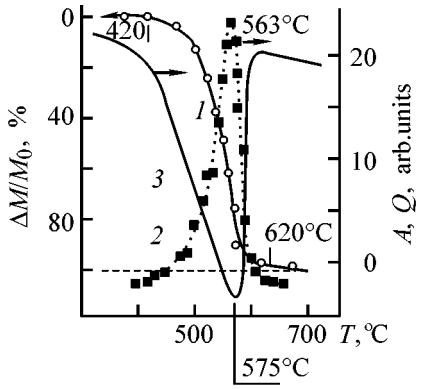


Fig. 6. (*1*) TG, (*2*) DTG, and (*3*) DSC curves of the initial fullerene C_{60}: ($\Delta M/M_0$) relative weight loss, [$A \equiv d(\Delta M/M_0)dT$] its derivative with respect to temperature, (*Q*) heat flow, and (*T*) temperature.

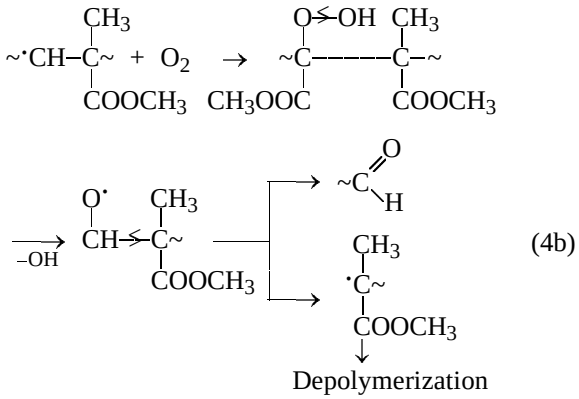
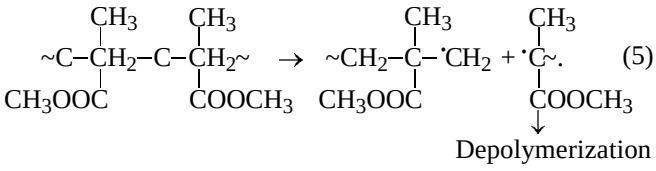


(4b)

The products of thermal oxidative degradation are the monomer, oligomers, aldehydes, ketones, CH_3OH, H_2O, CO, CO_2, etc.

(4) Thermal degradation of oxygen-stabilized chains and defect-free PMMA macromolecules [scheme (5)]. Stage 3 involves random thermal decomposition of oxygen-stabilized and main (defect-free) PMMA chains or chain sections:



(5)

As in the two preceding cases, weight loss is observed. Owing to such a diversity of reactions, the DTG curve for oxidative degradation of PMMA has a broad half-width and a somewhat unusual shape, strongly differing from the Gaussian shape; furthermore, an additional small peak is observed at about 400°C.

Let us discuss the changes in the mechanism of thermal oxidation of PMMA in the presence of C_{60}. The cleavage of the H–H bonds, the presumably, undergoes no changes. Along with stabilization of macroradicals with oxygen, they are captured by C_{60} molecules with the formation of fullerene-containing polymers (FCPs):

$$C_{60} + R^{\cdot} \rightarrow {}^{\cdot}C_{60}R + R^{\cdot} \rightarrow RC_{60}R. \qquad (6)$$

Similarly, C_{60} adds to oxygen-containing macroradicals formed by oxidation of macroradicals in any stage of thermal oxidative degradation:

$$C_{60} + R^{\cdot} + {}^{\cdot}RO \rightarrow ROC_{60}R. \qquad (7)$$

The fullerene molecule with added macroradicals $R^{\cdot}$ and $RO^{\cdot}$ becomes more susceptible to thermal oxidation because of the distortion of the conjugation system; as a result, thermal oxidation of PMMA chains (both bonded to C_{60} and free) is inhibited by the extra-chain mechanism, and the thermal oxidation of defect-free PMMA chains considerably decreases. At 300°C, the release of thermal oxidation products in the presence of C_{60} is insignificant, whereas without fullerene the rate of release of the degradation products is highest at this temperature (Fig. 5b). An alternative explanation of the inhibiting effect of fullerene on thermal oxidation of PMMA is passivation of oxygen in the presence of fullerene.

Above 300°C, thermal degradation of PMMA chains starts in both fullerene-bonded and free PMMA macromolecules. Therefore, the curve of PMMA thermal oxidation in the presence of C_{60} is close to the curve of thermal degradation in a vacuum or in an inert medium with respect to both the position (365°C) and the half-width (48°C) of the peak in the DTG curve.

Thus, the inhibiting effect of C_{60} is mainly due to FCP formation and extra-chain inhibition of thermal oxidation.

Effect of PMMA on thermal oxidative degradation of C_{60}. Figure 6 illustrates the thermal behavior of pure C_{60}. It is seen that the heat release and weight loss occur at temperatures considerably exceeding those of the peaks observed with C_{60}–PMMA mixtures. Apparently, the polymeric matrix also affects the thermal behavior of C_{60}. The influence of the polymer on the thermal behavior of C_{60} was observed in [3, 9, 10]. It was shown that, in the case of strong interactions with the polymer, C_{60} acts as a kind of microprobe and volatilizes from the system at tem-

peratures close to those at which the polymer degradation products are released. For example, in the case of covalent binding of C_{60} with polystyrene, the bimodal MTA thermograms for C_{60} resemble the bimodal thermograms of styrene monomer release [3, 9]. In reactions with halogens in the trifluorochloroethylene–vinylidene fluoride copolymer, the C_{60} thermograms reproduce the bimodal thermograms of the release of hydrogen halides formed by thermal degradation [10]. These examples give additional grounds to believe that, in the case of mixtures of C_{60} with PMMA, the two peaks in the DSC curves observed after the endothermic peak are due to sequential release of free and PMMA-bonded C_{60}.

The peak at 380°C in Fig. 2c should be assigned to degradation of C_{60}-bonded PMMA chains on the basis of its position and dome-like shape. A certain contribution to this peak is, apparently, also made by fullerene, but its weight fraction is too low (~0.2%) to significantly affect the peak shape. At higher C_{60} concentrations, the peak transforms into a well-defined shoulder of the main peak at 445°C. Thus, in this series of experiments we failed to distinguish the manifestations of PMMA and PMMA-bonded C_{60} in this series of experiments. This can possibly be done in Fig. 3b where a peak at 387°C and a shoulder at 420°C can be assigned to, respectively, PMMA and PMMA-bonded C_{60}.

CONCLUSIONS

(1) The thermal stability of polymethyl methacrylate is most adequately characterized by the temperature shift of the TG curves in the entire range of thermal oxidative degradation.

(2) Thermal oxidative degradation of polymethyl methacrylate involves three stages. In the first stage, the thermal degradation products formed by cleavage of the chains across weak bonds are oxidized with major heat release. In the second stage, the thermal degradation of the already oxidized products continues, with the overall heat consumption. In the third stage, the least defective chains of the polymer undergo oxidation and thermal degradation. Small amounts of C_{60} added to the polymer displace oxygen or partially prevent oxidation; as a result, in the first stage, the extent of oxidation and the amount of the formed degradation products decrease, whereas in the third stage, the amounts of the formed degradation products and released heat grow.

(3) Thermal oxidative degradation of polymethyl methacrylate, especially in the presence of C_{60}, involves latent degradation. Small additions of C_{60} enhance the thermal stability of the polymer and make the DTG and MTA peaks narrower because the feasible degradation pathways become fewer.

(4) A part of C_{60} introduced into the polymer is partially bound by its radicals (~20%), another part is oxidized in the course of degradation, and the remaining part volatilizes without oxidation and degradation.

(5) The inhibiting effect of C_{60} consists in the formation of C_{60}-containing polymer chains and extrachain inhibition of its thermal oxidation.

(6) The polymethyl methacrylate matrix noticeably affects the thermal behavior of C_{60}: the heat release in oxidative thermal degradation of C_{60} and the corresponding weight loss are observed at considerably lower temperatures than with pure powdered C_{60}.

Abstract—Transport characteristics of new types of bi- and multilayer composite polymer pervaporation membranes and asymmetrical membranes in separating mixtures of methanol and methyl *tert*-butyl ether were studied. The principles of design of the membranes and their mass-exchange characteristics are treated in terms of the Henis–Tripodi resistance model.

One of the most important goals of the chemical industry is to minimize the energy intensity of technological processes. In some cases, the target products form azeotropic mixtures with components of the reaction mixture, which leads to additional expenses for their separation. In particular, this is the case in synthesis of methyl *tert*-butyl ether (MTBE), which finds wide application as a pollution-free gasoline additive [1]. For example, MTBE forms azeotropic mixtures with the starting products (methanol, isobutylene), whose separation by the conventional methods requires two distillation columns. Another possible way is to use a hybrid process in which a distillation column is combined with a pervaporation unit. Such a scheme makes it possible to decrease the energy intensity in a closed separation cycle by 20% (provided that the membranes combine high permeability with high selectivity with respect to methanol [2]).

Therefore, development of new types of polymer membranes with optimal transport characteristics for pervaporation separations is an urgent problem. It is known from the available literature and patents that pervaporation membranes can be prepared for the indicated purpose on the basis of various polymers [3–5]. As a rule, the known types of membranes demonstrate high selectivity in separating methanol–MTBE mixtures, but relatively low permeability.

Previously we reported a method for preparation of a multilayer composite membrane (MCM) demonstrating high selectivity and permeability in separating mixtures of polar (methanol) and weakly polar (cyclohexane, benzene, toluene, etc.) organic liquids [6]. Such a membrane consists of a microporous support [ultrafilter fabricated from an aromatic polyamidoimide (PAI)] to whose surface is applied a two-layer coating of quaternized poly(2-dimethylaminoethyl)methacrylate (PDMA) and a ladder polyorganosiloxane (LP) as interlayer and coating diffusion layers, respectively.

In this work, we studied the transport characteristics of a multilayer composite membrane and its constituents in separating methanol–MTBE mixtures. Of particular interest was to consider in terms of the Henis–Tripodi resistance model [7] the possibility of fabricating for this purpose a high-performance MCM, using a commercial polyacrylonitrile (PAN) ultrafilter as the support.

EXPERIMENTAL

The procedures for preparing PAI supports, fabricating MCMs with PDMA and LP layers, and also carrying out pervaporation separation experiments were described elsewhere [6]. To prepare bilayer membranes and MCMs, we also used a microporous support of an HV3/T PAI ultrafilter [GKSS (Germany)] with mean pore size in the skin layer of 67 Å.

The separation factor α and permeability $\prod$ of the multilayer membrane are plotted in Fig. 1 as functions of the methanol concentration in the feed mixture. As in the case of methanol–cyclohexane mixtures [6], in our case methanol is a more penetrable component. As a result, the permeability of MCM

1070-4272/01/7408-1338 $25.00 © 2001 MAIK "Nauka/Interperiodica"

grows steadily with increasing methanol concentration in the feed mixture (curve *1*). The dependence of α on the feed composition (curve *2*) shows a maximum (α = 473) corresponding to the initial feed composition close to that of the azeotropic mixture with 14.5 wt % MTBE. It is worth noting that MCM has high permeability in general, including the case of azeotropic mixture (Π = 5.9 kg m^{-2} h^{-1}). In this parameter MCM considerably surpasses the existing membrane intended for similar purposes (see below). The reason for the observed high permeability lies in morphological features of MCM as a whole and its elements and, first of all, in the morphology of the PAI support having, according to electron microscopic data [8], finger-shaped pores in the base cross section, low thickness of the skin layer (0.1 μm), and mean pore size in this layer of about 50–60 Å. The thickness of the PDMA interlayer was demonstrated to be very small, too (0.04 μm). Furthermore, the fact that the polymer has very high molecular weight (M_w 2 × 10^6) and segment size larger than the pore size in the skin layer of the support hinders penetration of PDMA into the skin layer in the stage of interlayer formation. It is demonstrated below that this considerably decreases the resistance to mass transfer in the case of PDMA/PAI two-layer system. To conclude the analysis of the high permeability of MCM, it should be pointed out that LP, even taken as a homogenous 60-μm film, demonstrates very low resistance, i.e., very high permeability in the case of methanol–MTBE mixtures, especially at low methanol concentrations (Fig. 2, curve *1*). At the same time, the obtained results show (Fig. 2, curve *2*) that LP cannot serve as a selective polymer in separating methanol–MTBE mixtures, even when being an element of MCM, with the thickness of its layer being about 1–2 μm.

It was of interest to estimate the selectivity of other polymer layers of MCM. Figure 3 shows the dependences of α and Π on the composition of the methanol–MTBE feed for PAI homogenous asymmetric pervaporation membrane [9]. It should be noted that the permeability of the PAI membrane (Fig. 3, curve *1*) is lower than that of MCM (Fig. 1, curve *1*). The reason is the higher resistance of the diffusion skin layer (0.2 μm thick) of the PAI membrane to mass transfer of vapors and gases, which is typical of diffusion-type membranes based on polymers from the class of aromatic polyimides or PAI [10]. As for MCM, α increases with decreasing methanol concentration in the feed mixture (Fig. 3, curve *2*), but the dependence has no extremum. Comparison of α values of multilayer composite and PAI membranes in

separation of methanol–MTBE mixture of the azeotropic composition (α 412 and 164, respectively) suggests that PDMA contributes significantly to selective mass transfer across MCM. We failed to determine the mass-exchange characteristics of the PDMA interlayer, since sufficiently thick films of this polymer cannot be obtained. The contribution of PDMA to the total selectivity of MCM was estimated with the use of a composite prepared by multiple impregnation of a support of an inert cermet microfilter with 0.3% PDMA, thus eliminating the effect of the support on selective mass transfer. In separation of a model methanol–cyclohexane mixture (10 : 90 by weight) on this composite, methanol appears to be a more penetrating component at α = 9080. This value is well comparable with that obtained previously in separation of this mixture on MCM [6].

The results show that the MCM elements determining the selectivity in methanol–MTBE separation are the PDMA interlayer and the nonporous PAI support surface, while LP is not a selective polymer, but serves to cure the defects of the PDMA interlayer. The occurrence of such defects is demonstrated by the fact that a PDMA/PAI membrane is nonselective at the same thickness of the DPMA layer as in MCM. Thus, the curing effect favors the selective properties of PDMA and PAI in MCM. The mechanism of participation of LP in mass transfer across MCM is similar to that in a gas-separation composite membrane (Monsanto), where the polydimethylsiloxane coating layer support serves to cure the defects of the selective layer [11]. Therefore, in these membranes, formation of thin coating layers of a low-selective siloxane polymer (but thick enough to provide a diffusion barrier on the support surface) raises the total selectivity of the composite membrane to a value close to the inherent selectivity of the support polymer.

With the thickness of the PDMA interlayer increasing from 0.04 (in MCM) to 0.125 μm, i.e., with the formation of a defect-free skin layer, we obtained a high-performance PDMA/PAI bilayer membrane [12] in which both the polymers are selective with respect to methanol transport. The transport characteristics of this membrane in separation of methanol–MTBE mixtures are given in Fig. 3.

This bilayer membrane demonstrates very high permeability (Fig. 3, curve *3*). In separation of a mixture of the azeotropic composition, this parameter is 9.64 kg m^{-2} h^{-1}. As in the case of MCM, the dependence of α on the feed composition (Fig. 3, curve *4*) passes through a maximum (α = 248) corresponding to the azeotropic mixture.

It was of interest to compare the transport characteristics of all the PAI-based membranes studied. These data are given in the table for the case of separation of a methanol–MTBE azeotropic mixture. As an additional parameter useful in optimization of the transport characteristics (selectivity to permeability relationship) we introduced the membrane efficiency factor defined as the product $\alpha\Pi$.

Comparison of data for membrane nos. 1–3 reveals that the MCM and bilayer membranes have considerably higher efficiency. It should be pointed out also that the maximal selectivity of MCM and PAI-based bilayer membranes is observed in the case of a mixture of the azeotropic composition, which is important for practical use of such membranes.

In large-scale production of gas-separation or pervaporation composite membranes, commercial ultrafilters are mostly used as supports. In this connection, one of the tasks of this work was to fabricate analogs of the PAI-based bilayer and MCM membranes using a commercial PAN ultrafilter as a support. The prob-

lem was to obtain a skin layer with morphology close to that in PAI-based membranes. We fabricated several kinds of PAN-based bilayer and multilayer composite membranes with coating layer thickness corresponding to that of the PAI-based membranes. The selectivity of these membranes (see table, membrane nos. 4, 5) appeared to be very low, which may be due only to the negative effect (in contrast to PAI) of the PAN support on the total selectivity. This is supported by data of [12] on a homogeneous PAN film membrane (22 μm thick) with $\alpha = 0.696$ with respect to methanol in separation of a methanol–MTBE azeotropic mixture (for a PAI asymmetrical membrane the corresponding value is 164). Thus, in separation of a methanol–MTBE mixture, the PAI and PAN supports of composite membranes have opposite effects on the total selectivity, being selective with respect to methanol and MTBE, respectively.

The conclusion that the nature of a polymer of the support is important is consistent with the basic principles of the Henis–Tripodi resistance model developed for composite membranes of diffusion type [7]. According to this model, the nonporous part of the support surface also contributed to selective mass transfer. This contribution is controlled to a considerable extent by the thickness of the diffusion coating layer, as demonstrated in [11] for the example of a polysulfone/polydimethylsiloxane gas-separation composite membrane. For such a membrane the selectivity of separation of a gas mixture approaches that of a low-selective coating polymer with increasing thickness of the polydimethylsiloxane coating layer. In PAI-based pervaporation composite membranes the situation is more favorable, since both PAI and PDMA in these membranes are selective polymers with respect to methanol. Making the PDMA diffusion layer thicker can decrease only the permeability, but not the selectivity of PAI-based bilayer of multilayer composite membranes. The reverse is the case with a PAN-based bilayer membrane, and especially with a PAN-based MCM. Two elements of a PAN-based MCM (PAN and LP) are nonselective, and a thin PDMA interlayer cannot provide an acceptable selectivity. Furthermore, it is seen from the table (membrane nos. 4, 5) that α grows with increasing thickness of the PDMA layer, suggesting the need to make thicker of the PDMA coating layer in a PAN-based MCM. However, owing to the fact that this coating polymer is highly viscous, this can only be done by using such a time-consuming method as multiple layer-by-layer coating. The alternative is changing the nonselective LP coating layer for some polymer selective with respect to methanol, for example, a polyetherimide (PEI) based on dianhydride of 1,3-bis(3,4-dicarboxyphenoxy)benzene and 4,4'-bis(4''-aminophenoxy)diphenyl sulfone. A thus obtained multilayer PEI/PDMA/PAN composite membrane consists of two selective coating polymer layers formed on the support surface, which compensate the small thickness of the PDMA layer in MCM. Thus, the efficiency of PAN-based membrane no. 6 (see table) is considerably higher (5000 $kg\ m^{-2}\ h^{-1}$) as compared with the PAI-based bi- and multilayer membranes. Such a high membrane efficiency is possible in the case of a very high selectivity ($\alpha = 2940$ for a methanol–MTBE mixture of azeotropic composition). In this case, the methanol concentration in the permeate (flux passed through a membrane) is 99.8 wt %.

For comparison, the transport characteristics of known membranes intended for similar purposes are also given in the table (membrane nos. 8–10). It is seen that among them the best performance is shown by an asymmetrical aromatic polyimide membrane [3]. It is seen from the table that the permeation characteristics of bilayer and multilayer composite membranes with PAI support and of multilayer composite membranes with PAN support are superior to those of other membranes by virtue of the higher permeability and separation selectivity, respectively.

Analysis of the transport characteristics of all the investigated membranes with PAI support suggests that, to obtain a high-performance composite pervaporation membranes, it is advisable to form the membrane on a support of a polymer selective to a target component of a mixture to be separated. In this case the problem of selecting a polymer for the coating layer becomes much simpler, since even a nonselective polymer (LP) can be used for this purpose, as serving to cure the defects of the underlying two layer of the selective polymers (PAI and PDMA).

At the same time, the inverted selectivity of PAN in separating methanol–MTBE mixtures requires that the coating diffusion layer on the PAN support should be thicker, which can be attained by using a combination of two polymers (PDMA and PEI) selective with respect to methanol.

Finally, application of a thin interlayer of PDMA, having ultrahigh molecular weight, to a PAI or PAN support appears to be quite significant. This affects not only the selectivity, but also permeability of the composite membrane, as demonstrated for the example of a DPMA/PAI membrane.

To conclude, the results confirm the possibility of obtaining a series of high-performance composite membranes for pervaporation separation of methanol–

MTBE mixtures, whose transport characteristics are consistent with the Henis–Tripodi model.

CONCLUSIONS

(1) Novel types of composite membranes combining high permeability and selectivity in separation of methanol–methyl *tert*-butyl ether were prepared.

(2) The polyamidoimide and polyacrylonitrile supports of the multilayer membranes have opposite effects on the total selectivity.

(3) Introduction of an active polyamidoimide support allows use of a nonselective (with respect to methanol transport) ladder polyorganosiloxane as a coating polymer.

(4) The inert polyacrylonitrile support requires that a combination of two selective coating polymers, poly(2-dimethylaminoethyl) methacrylate and polyetherimide, shoud be used.

(5) High membrane permeability of the multilayer membranes is attained by virtue of the low thickness of the interlayer or coating diffusion layer of poly(2-dimethylaminoethyl) methacrylate, having ultrahigh molecular weight.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thin-Layer Chromatography of Neutral Sugars as Influenced by the Nature of the Cation of Impregnating Salt

K. B. Kalinina and L. S. Litvinova

Abstract—Thin-layer chromatography of neutral sugars contained in water-soluble binders (gum and honey) was studied on silica gel plates impregnated with solutions of alkali, alkaline-earth, and transition metal sulfates at different pH and concentrations.

Impregnation is one of the simplest ways to impart required properties to sorbents. Silica gel impregnated with salt solutions is used for thin-layer chromatographic (TLC) separation of sugars [1]. The major attention is given to influence of the anion nature on the properties of impregnated sorbents. The effect of the cation has not been virtually studied in this respect. However, sugars are known [2–6] to form complexes with alkali, alkaline-earth, and transition metal cations. Formation of Ca^{2+} complexes with sugars has been used in separation of sugars by column chromatography [7, 8].

Previously we found [9] that sugar sorption on plates impregnated with potassium phosphate buffer is higher, irrespective of the pH value, than that on plates impregnated with sodium phosphate buffer.

In this work, chromatographic behavior of natural sugars contained in gums and honey was studied on silica gel plates impregnated with solutions of alkali, alkaline-earth, and transition metal sulfates. The sugar retention was studied as influenced by pH, concentration of impregnating solutions, and the salt cation. We propose that the impregnation mechanism is based on specific sorption of metal cations from solution by solid oxides and on the ability of sugars to form coordination bonds with metal cations and hydrogen bonds with anions.

EXPERIMENTAL

All chemicals and solvents were of chemically pure and analytically pure grades. The following sugars were used: fucose (biochemical grade, Merck, Darmstadt, Germany), galactose, glucose, mannose, fructose, arabinose, xylose, rhamnose, and saccharose (chemically pure grade, Reakhim, Shostka, Ukraine).

Silica gel plates were impregnated with solutions of alkali, alkaline-earth, and transition metal sulfates (Na_2SO_4, K_2SO_4, $MgSO_4$, $CuSO_4$, $ZnSO_4$, $MnSO_4$, $CoSO_4$, and $NiSO_4$) with different pH values: (a) at the initial pH_{in} determined by the salt nature and its concentration in the solution; (b) at pH 3.5; (c) at pH close to pH of precipitation of the corresponding metal hydroxides (see table). Solutions with pH 3.5 were prepared by acidification with 95% H_2SO_4. Alkaline solutions were prepared by addition of 1.0 M NaOH. pH was measured with an HI-8314 pH-meter (Hanna Instrument, Germany).

Sugars were separated by ascending TLC in an N-chamber [10] saturated with eluent vapor. We used 10 × 10-cm commercial (Løene Kadeer, Estonia) glass plates with KSKG silica gel fixed by silica sol binder [11]. Prior to use, the plates were kept for 10 min in a solution of $K_2Cr_2O_7$ in H_2SO_4, washed with water to neutral reaction of wash water, and kept for 24 in a solution of appropriate salt. Then the plates were immersed in water, kept there for 2 s, and then dried and activated by heating at 120°C for 1 h in an oven.

A 0.5% sugar aqueous solution (0.5 μl) or a solution of sugar mixture (1.0 μl) containing 0.5% of each sugar was applied to a plate at a distance of 10 mm from the lower edge. The plates were eluted three times to a height of 4, 6, and 8 cm with a mixture *n*-PrOH : $CHCl_3$: H_2O = 14 : 8 : 2 vol.

Zn^{2+}	$3d^{10}4s^0$	1×10^7	5.4	6.4	5.8	5.4	5.2

The apparent retention factor $R_f(R_{f,i})$ after the third elution was calculated as the ratio between the distance from the starting line to spot center and that from the starting line to the front line.

The chromatograms of the sugars (where $R_{f,i}$ is the average of three parallel measurements) are shown schematically in Fig. 1. The relative determination error of $R_{f,i}$ did not exceed 6%. The sugar chromatograms were developed by the procedure described in [9].

Silica gel plates with silica sol binder are readily impregnated, which offers unrestricted possibilities of sorbent modification. The plates can be repeatedly used after washing with a solution of $K_2Cr_2O_7$ in H_2SO_4 and can be kept in salt solutions for a long time.

Previously we showed [9] that the retention factor of sugars on the plates with the H form of sorbent prepared by washing with solution of $K_2Cr_2O_7$ in H_2SO_4 or treatment with 0.1 M HCl is higher than that of the initial sorbent, which drastically deteriorates sugar separation. Impregnation of the plates with salt solutions yields surface groups other than ≡Si–OH (irrespective of the salt nature) and alters the chromatographic behavior of sugars. To study the influence of the cation of the impregnating salt on sugar retention, plates with the H form of the sorbent were impregnated with solutions of salts containing different cations and the same anion.

The influence of impregnation is determined by two factors: (1) specific features of interaction of new sorption centers with sugars and (2) surface concentration of these centers. The surface concentration of new centers depends on both the concentration of impregnating solution and the strength of sorption bonds between the salt and the sorbent, which, in turn, is determined by the specific sorption of the cation on the silica gel surface and the formation of hydrogen bonds between the anion and the surface groups. In the course of impregnation, metal cations are adsorbed onto the sorbent surface by electrostatic interaction and then form donor–acceptor bonds with the surface ≡Si–O^- (≡Si–OH) groups which are involved, along with ligands from the solution bulk, in substitution reactions. The possibility of formation of such a bond and its parameters depend on the following factors: (1) structure of valence orbitals of the acceptor (metal cation); (2) donor power of the competing ligands (≡Si–O^- and ≡Si–OH); and (3) lability of both the surface and unsupported complexes [12].

The surface interaction of cations having vacant *d* and *p* orbitals [13] and cations capable of hybridization (Cu^{2+}) [14, 15] is the strongest. The interaction of K^+ and Na^+ with the surface is electrostatic and hence the specific sorption of these cations is low [12, 16].

Taking into account the above considerations, the following cations, exhibiting different capacities for specific sorption, were used for impregnation: Cu^{2+}, Co^{2+}, Mn^{2+}, Ni^{2+}, Zn^{2+}, Mg^{2+}, K^+, and Na^+. Some properties of these cations and their salts are summarized in the table [17–19]. We chose SO_4^{2-} anions since they are strongly sorbed on the silica surface owing to the formation of hydrogen bonds with silica surface groups. Coordination of SO_4^{2-} promotes substitution of water in the *trans* position in the unsupported complex owing to the *trans* effect [20], which favors formation of the surface complex. In addition, sugars are known [3] to form hydrogen bonds with SO_4^{2-} anion.

Both the concentrations and the pH values of the impregnating solutions were varied, in, respectively, the ranges from 0.067 to 0.150 M and from 3.5 to

the pH of precipitation of the corresponding hydroxide. The change in the sorbent properties after impregnation and, hence, the influence of the cation nature on the sugar retention were estimated from the difference (ΔR_f) between the retention factor of sugars on the plates with the H form of the sorbent and that on a plate impregnated with appropriate salt. The arithmetic mean ΔR_f^* for all sugars at similar salt concentrations and pH was calculated by the equation

$$\Delta R_f^* = \Sigma \Delta R_{f,i}/9, \quad (1)$$

or the arithmetic mean ΔR_f^{**} for nine sugars at three concentrations and two pH values was calculated by the equation

$$\Delta R_f^{**} = \Sigma \Delta R_{f,i}/(9 \times 3 \times 2). \quad (2)$$

We found that impregnation with alkaline-earth and transition metal sulfates strongly increases the sugar retention and hence improves sugar separation, except for 0.067 M magnesium sulfates with the initial pH. Impregnation with alkali metal sulfate has virtually no effect on R_f. The chromatograms of sugars on plates impregnated with metal sulfate solutions are shown schematically in Fig. 1.

The sugar separation depends on the cation nature and concentration and on the pH of the impregnating solution. For example, at C = 0.067 M the best separation was observed on a plate impregnated with copper sulfate (pH 4.3). At C = 0.100 M, a positive result was obtained with zinc sulfate (pH 4.1) and manganese sulfate (pH 3.9). The separation on a plate impregnated with magnesium sulfate (pH 3.5) was slightly worse owing to spot smearing. At C = 0.150 M, the best separation was observed on plates impregnated with manganese sulfate (pH 3.5 and 3.8) and zinc sulfate (pH 3.5). A less successful result was obtained with magnesium sulfate (pH 3.5), and still worse result with cobalt and nickel sulfates. Sugar separation on plates impregnated with potassium and sodium sulfates was the worst at any of the tested concentrations.

The dependences of ΔR_f^* on pH and concentration of sulfate solutions are shown in Fig. 2 as a histogram. It can be seen that ΔR_f^* grows with increasing concentration and pH of the impregnating salt. After impregnation with sodium and potassium sulfates, the surface properties of the sorbent change to the least extent. This is due to lower specific sorption of K^+ and Na^+ as compared with Ni^{2+}, Co^{2+}, Mg^{2+}, Cu^{2+}, Zn^{2+}, and Mn^{2+}. The weak influence of potassium and sodium sulfates on R_f is also due to the formation of weak complexes of these cations with SO_4^{2-} [17], which can be easily confirmed by calculations.

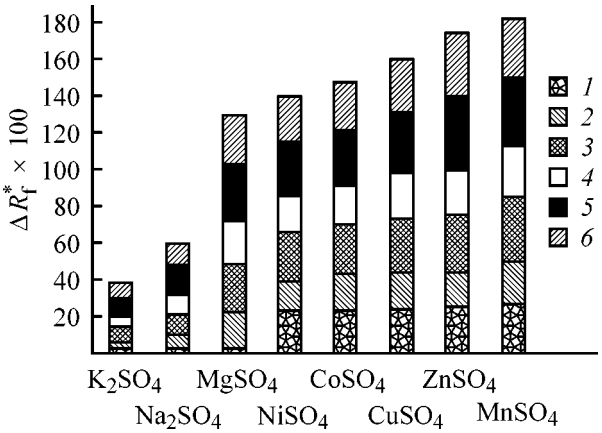

Fig. 2. ΔR_f^* as influenced by the cation nature.

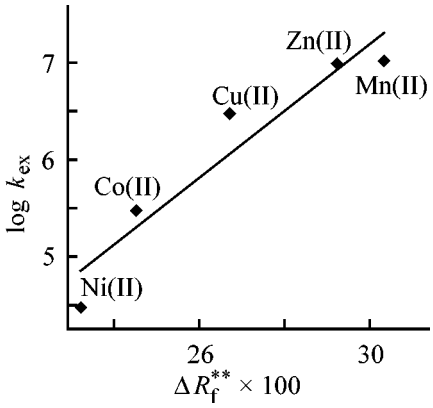

Fig. 3. Correlation between log k_{ex} and ΔR_f^{**} $y = 0.348x - 3.2351$, $R^2 = 0.9116$.

Metal ions M^{n+} in solutions are hydrated to form aqua complexes $[M(H_2O)_{6(4)}]^{n+}$ and complexes like $[MSO_4(H_2O)_{6(4)-1}]^{(4+)-2}$, with the fraction of these species in a solution depending on the salt concentration and pH. The probability of formation of stable surface complex grows with increasing content of $[MSO_4(H_2O)_{6(4)-1}]^{(4+)-2}$ owing to the *trans* effect. The relative content of the aqua and sulfate complexes in solution can be easily calculated from the stability constant of these complex ions [17]. For transition metal cations and Mg^{2+} the [aqua ion] : [sulfate complex] percent ratio is ≅ 20 : 80 within the limits of the tested concentrations and pH. For Na^+ and K^+ this ratio is inverse: [aqua ion] : [sulfate complex] ≅ 80 : 20.

A decrease in R_f with increasing pH is caused by an increase in the fraction of the ≡Si–O^- groups which are stronger donors as compared with ≡SiOH [12]. This makes larger the amount of the surface complexes, such as $[\equiv Si–O–M(H_2O)_5]^{(n+)-1}$ and $[\equiv Si–O–MSO_4(H_2O)_4]^{(n+)-3}$, affecting the separation power of silica gel.

On the basis of ΔR_f^* calculated by Eq. (2), the influence of metal cations can be arranged in order of increasing effect on the retention factor of sugar as follows: $K^+ < Na^+ < Ni^{2+} < Co^{2+} < Mg^{2+} < Cu^{2+} < Cu^{2+} < Zn^{2+} < Mn^{2+}$.

The influence of metal cations on the retention factor of sugars cannot be completely understood on the basis of data on specific sorption of the cations [12] and stability constants of sulfate complexes of these cations. Probably, direct interaction between sugars and metal cations contained in the surface complexes should be taken into account.

A coordination bond between a metal cation and a monosaccharide molecule can be formed by substitution of aqua ligand in the inner coordination sphere by monosaccharide. The probability of formation of this bond depends on the lifetime of water molecule in the hydration shell of the surface complex of the metal cation. Indeed, ΔR_f^{**} on the plates impregnated with transition metal sulfates changes in parallel with the rate constants of the inner-sphere water exchange (see table) [18, 19], described by the equation

$$[M(H_2O)_m]^{n+} + H_2O \rightarrow [M(H_2O)_{m-1}H_2O]^{n+} + H_2O.$$

The correlation between log k_{ex} and ΔR_f^{**} for the transition metals is shown in Fig. 3. This dependence indicates that the probability of interaction between metal cations and sugars grows with increasing rate constant of exchange of inner-sphere water.

Rendelman [3] showed that hydrogen bonds of sugars with OH^- groups are appreciably stronger than those with SO_4^{2-} groups. At low pH, the influence of the ≡Si–O–MOH groups can be neglected, whereas at the pH of precipitation of metal hydroxides, the presence of the above surface complex results in strong smearing of spots. Indeed, sugar separation on the plates impregnated with salt solutions with pH close to the pH of precipitation of the corresponding hydroxides is drastically deteriorated by strong longitudinal smearing of the spots. This is due to the formation of hydroxides by the majority of the tested metals at pH 6.0–10.0 on the sorbent surface.

CONCLUSIONS

(1) Retention and separation of gum and honey sugars on silica gel plates impregnated with solutions of alkali, alkaline-earth, and transition metal sulfates were studied. The influence of an impregnating salt on sugar separation depends on the ability of its cation and anion to form strong surface complexes and complexes in the solution bulk.

Sugar separation is improved after impregnation of the plates with solutions of alkaline-earth and transition metal sulfates. At low salt concentration (C = 0.067 M), the best separation is observed after impregnation with a $CuSO_4$ solution. At higher salt concentration (C = 0.150 M) the best results were obtained after impregnation with solutions of $ZnSO_4$, $MnSO_4$, and $MgSO_4$.

(2) The influence of metal cation of the retention factor increases in the following order $K^+ < Na^+ < Mg^{2+} < Ni^{2+} < Co^{2+} < Cu^{2+} < Zn^{2+} < Mn^{2+}$.

(3) A correlation was revealed between the rate constants of inner-sphere exchange of water in hydration shell of the cation (k_{ex}) and ΔR_f^{**} determined on the silica gel plates impregnated with solutions of transition metal sulfates.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Solid Macrosupports for Immunoassay, Modified with Polysaccharides

V. V. Shmanai and A. A. Litoshko

Institute of Physical Organic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received March 28, 2001

Abstract—A series of water-soluble derivatives of natural and synthetic polysaccharides (dextran, pectins, Phycoll, pullulan, hydroxyethyl starch) containing aldehyde, hydrazide, sulfonate, and hydrazine groups were prepared.

The best supports for biologically active macromolecules are natural hydrophilic polysaccharides (mainly agarose) used as microparticles and gels. Immunosorbents based on such polysuccharides are widely used in affinity chromatography, and enzymes immobilized on them are used in enzymology [1]. Covalent immobilization of proteins can be performed after preliminary chemical activation of polysaccharides. Numerous activation pathways are known [1], but the most widely used is activation of hydroxy groups by reaction with cyanogen bromide [2]. Biological macromolecules preserve their functional activity to the greatest extent when immobilized through long hydrophilic spacers [3]; the physical sorption on such matrices is considerably weaker [4], which makes it necessary to bind the reagents chemically.

Nevertheless, the most widely used material for the solid phase in immunoassay is hydrophobic polystyrene on which proteins are immobilized by passive adsorption. As a rule, pressure-cast items (macrosupports) of various shapes are used: test tubes, base tables, star-shaped articles, or spheres. The mechanism of hydrophobic sorption of proteins on such articles is not fully understood, although this has been the subject of numerous studies [5]. It is known that the process is accompanied by significant rearrangement of the protein molecule, which sometimes leads to strong denaturation of antibodies, especially those of monoclonal type [6].

The continuing use of the seemingly not quite suitable system is due, in particular, to problems with handling of microparticles (dosing accuracy, complete separation of the support from the liquid phase) and with manufacturing of molded items from polysaccharides.

Thus, it seems promising to develop new polymeric matrices with surface modified with hydrophilic polysaccharide spacers. In this case, the advantages of molded polystyrene matrices (transparency, ease and accuracy of dosing) could be combined with the functional advantages of polysaccharides (high capacity, strong binding, minimal inactivation of proteins, low level of nonspecific sorption, feasibility of oriented immobilization of reagents), and achievements in immobilization of proteins for enzymology and affinity chromatography [1, 7] could be applied to immunochemical diagnostic procedures and, in particular, to enzyme-mediated immunoassay (EMI).

The demand for molded supports for chemical immunoassay is well known and has been repeatedly stated [8, 9]. The drawbacks of hydrophobic polystyrene call for development of new approaches to preparation of solid supports for immunoreagents. The previously developed supports in the form of chemically modified polystyrene spheres (FPSSs) [10] open up wide possibilities for subsequent modification by reactions of aldehyde groups, with the aim to impart the required properties to the active surface layer of the support. Here we report on the procedures and results of preparation of polysaccharide functional derivatives and modification of FPSSs with them.

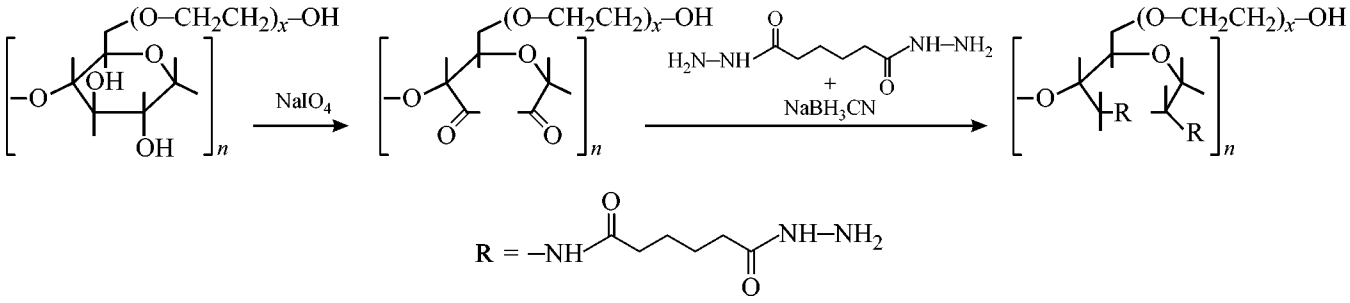
Numerous natural and synthetic polysaccharides are known; they are readily subjected to chemical transformations to obtain active derivatives. Taking into account the demands of the biochemical studies, we used in this work several substances of different structures, since the structure of polysaccharide molecules can significantly affect the properties of immobilized immunoreagents.

1070-4272/01/7408-1348 $25.00 © 2001 MAIK "Nauka/Interperiodica"

Water-soluble polysaccharides were functionalized by oxidation of a part of carbohydrate rings with sodium periodate. Further polymer-analogous transformations allow easy modification with such polymer of surfaces containing hydrazide or amino groups, e.g., polystyrene spheres [11, 12]. The electrophilic aldehyde function of a polysaccharide can be converted into a nucleophilic function by reaction with diamines, di- or polyhydrazides, or hydrazine hydrate. Furthermore, pectins containing ester groups readily react with hydrazine to form hydrazide derivatives. Finally, hydroxy groups of the polymer can be subjected to sulfonate activation without cleavage of pyranose rings.

Periodate oxidation was performed with Phycoll (synthetic sucrose polymer with a branched structure, molecular weight 400 kDa), hydroxyethyl starch (product of chemical modification of a natural polysaccharide, molecular weight 120 kDa), pullulan (linear glucose polymer prepared by microbiological synthesis, with units linked by 1→4 and 1→6 bonds, molecular weight 60 kDa), and dextran (microbiological polyglucan with 1→6 bonds).

Polysaccharides were oxidized in 0.1 M phosphate buffer solution (pH 5) at room temperature for 1 day; the molar ratio carbohydrate : periodate was 2 : 1. Hydrazide-containing polymers were prepared in a 0.1 M phosphate buffer solution by reaction of oxidized polysaccharide with an excess amount of dihydrazide, as shown below for hydroxyethyl starch.



The resulting hydrazones were reduced to substituted hydrazides with sodium borohydride or cyanoborohydride. Low-molecular-weight compounds (excess hydrazide, sodium borohydride and its oxidation products, ions of buffer solution) were removed by ultrafiltration. The reaction products were lyophilically dried and stored at 4°C.

The absence of hydrazide in the filtrate and the presence of hydrazide groups in the polymer were judged from the by formation of an intensely colored product in the reaction with trinitrobenzenesulfonic acid (TNBS) in an alkaline buffer solution [11]:

$$R–NH–NH_2 + NaO_3S–C_6H_2(NO_2)_3 \rightarrow R–NH–NH–C_6H_2(NO_2)_3,$$

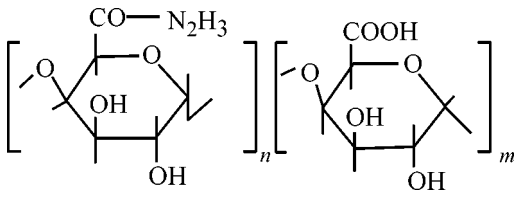
where R is the residue of a hydrazide of hydrazide-containing polymer.

All the synthesized polymers showed high activity in a qualitative reaction, indicating the presence of functional groups. A large excess of the hydrazide prevented cross-linking of the polymer molecules and allowed preparation of water-soluble products.

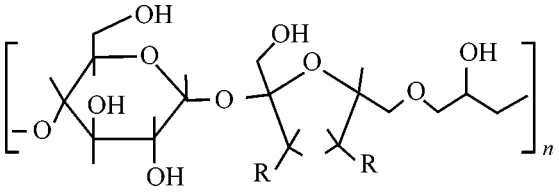
Sulfonate activation differs from the periodate activation in that the pyranose rings of the polysaccharides are not cleaved. Thus, activated products containing the same functional groups may considerably differ in the structure of their macromolecules. We studied sulfonate activation of polysaccharides for the example of reaction of dextran with tosyl chloride followed by substitution of sulfonate groups with hydrazide and hydrazine:

$$\text{Polysaccharide–OH} + CH_3C_6H_4–SO_2Cl \rightarrow \text{Polysaccharide–O–}SO_2–C_6H_4CH_3 + H_2N–NH–CO(CH_2)_4CO–NH–NH_2 \rightarrow \text{Polysaccharide–HN–NH–CO}(CH_2)_4CO–NH–NH_2.$$

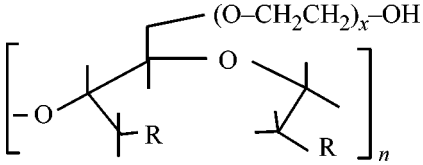
By reaction of pectin with hydrazine hydrate we prepared hydrazide-containing apple and citrus pectins. The degree of substitution of ester groups, determined by elemental analysis for nitrogen, was 65–75%. The structural formulas of the monomeric units of the resulting products are as follows:



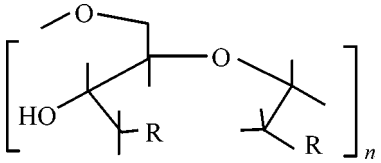
hydrazides of pectins: $n : m = 2 : 1$, citrus; $n : m = 3 : 1$, apple; content of active groups on the support surface 0.51 μmol cm^{-2};



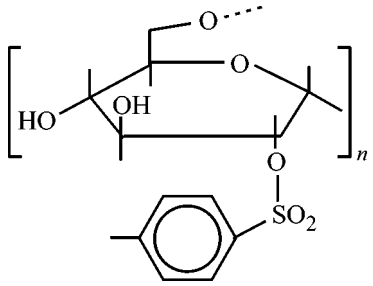
Phycoll hydrazide derivative; 0.20 μmol cm^{-2};



hydroxyethyl starch hydrazide derivative; 0.27 μmol cm^{-2};



hydrazide derivatives of dextran and pullulan; 0.3–0.5 μmol cm^{-2};



dextran sulfonate derivative

(R = NH–NH–CO–$(CH_2)_4$–CO–NH–NH_2).

By treating FPSSs with polysaccharide hydrazides, we obtained matrices containing 0.05–0.5 μmol cm^{-2} active hydrazide groups. The structures shown above are tentative. To avoid complete degradation of the polymer molecule, oxidation was performed with the periodate taken in deficiency. In Phycoll, both pentose and hexose units are subject to oxidation. The position of sulfonate groups in the structure of activated dextran was not studied and apparently was random (taking into account relative activities of hydroxy groups in different positions of the polymeric molecule).

To optimize the conditions for the reactions of hydrazide-containing polysaccharides with FPSSs, we studied, for the example hydrazide derivatives of pectin and Phycoll, how the activity of the resulting matrices depends on the solution pH and polymer concentration. We found that the highest concentration of the active groups on the support surface is attained in weakly acidic buffer solutions (phosphate or acetate) at pH 5 for Phycoll and in weakly alkaline solutions (pH 8–9) for substituted pectin.

We revealed a strong dependence of the activity of the hydrazide matrices on the polymer concentration in solution: The supports obtained at a polysaccharide concentration less than 10 mg ml^{-1} showed insignificant coloration in a qualitative reaction with sodium trinitrobenzenesulfonate tetrahydrate (TNBS; active group content less than 0.1 μmol cm^{-2}). At a polysaccharide concentration higher than 50 mg ml^{-1}, the content of active groups on the support reached 0.5 μmol cm^{-2}. Thus, the best conditions for synthesis of the hydrazide-containing matrices are as follows: 0.1 M buffer solution, pH 5, polysaccharide concentration no less than 50 mg ml^{-1}.

Preliminary experiments showed that the interaction of the prepared supports with antibodies oxidized with periodate and containing aldehyde groups results in their covalent immobilization.

EXPERIMENTAL

In our study we used general-purpose polystyrene of PSM-115 grade [GOST (State Standard) 20282–86]; polystyrene spheres 0.63 ± 0.01 cm in diameter, prepared by pressure casting followed by abrasive treatment of the surface; membranes for micro- and ultrafiltration (MIFIL, Belarus); gels for chromatography (Pharmacia, Sweden); Dowex 21-K anion-exchange resin (Serva, Germany); sodium azide, sodium borohydride, Timerosal, 3,3',5,5'-tetramethylbenzidine (TMB), glutaraldehyde (25% aqueous solution) (Serva, Germany); sodium metaperiodate (Reanal, Hungary); Tween-20 (Biorad, the United States); TRIS (chemically pure grade, Biolar, Latvia); hydrazine hydrate (pure grade), hydrogen peroxide (chemically pure grade), sulfuric acid (chemically pure grade), adipic acid (pure grade), 2,4-dinitrophenylhydrazine (DNPH, pure grade), sodium trinitro-

benzenesulfonate tetrahydrate (TNBS, pure grade) (Reakhim, Russia); polysaccharides: hydroxyethyl starch (molecular weight 120 kDa); pullulan and dextran (molecular weight 60 kDa); apple pectin (degree of esterification 60%); citrus pectin (molecular weight 150–300 kDa, ICN, the US); Phycoll 400 000 (Pharmacia, Sweden); bovine serum albumin (J.T. Baker, the Netherlands); human immunoglobulin IgG (Belarussian Republican Station for Blood Transfusion, Minsk); and horse radish peroxidase (HRP, A grade, spectral purity parameter RZ = 2.7, Biolar, Latvia).

To remove picric acid from TNBS, 1 M aqueous solution (as judged from the weighed portion) was cooled to 0°C and filtered. The TNBS concentration was determined using the mean molar extinction coefficient of the products of TNBS reaction with amino acids. Hydrazine hydrate was titrated with 0.1 M HCl with methyl orange indicator, and sulfuric acid, with 0.1 M NaOH. The concentration of hydrogen peroxide was determined by iodometric titration.

Adipic acid hydrazide was prepared by refluxing diethyl adipate with 80% hydrazine hydrate in ethanol for 3 h. After cooling, the crystals were filtered off, and the product was recrystallized from aqueous alcohol.

Buffer solutions were prepared from appropriate salts, acids, and bases of chemically pure or ultrapure grade (Reakhim). The concentrate of the phosphate–salt buffer solution (PSB) was prepared by dissolving in distilled water 80.0 g of NaCl, 2.0 g of KH_2PO_4, 13.9 g of $Na_2HPO_4 \cdot 2H_2O$, and 2.0 g of KCl. The solution volume was brought to 1 l. The PSB with pH 7.4 was prepared by tenfold dilution of the concentrate.

Phosphate buffer solutions were prepared by dilution of 1 M phosphoric acid and pH adjustment with 4 M NaOH. The carbonate buffer solution (pH 9.5) was prepared by mixing 0.1 M solutions of sodium carbonate and hydrocarbonate in a 3 : 7 ratio. Buffer solutions containing NaCl were prepared by dissolving the required amount of NaCl. In all experiments we used distilled water, and in the experiments with HRP, double-distilled water.

Immunoglobulin was isolated by ion-exchange chromatography with a 2×10-cm column packed with Sephadex G-50 equilibrated with 0.01 M phosphate buffer solution (pH 6.5), and then purified by gel filtration. The edge fractions were discarded, and the remaining fractions were combined, concentrated to 20 mg ml^{-1} with a PA-100 membrane, and filtered through a capron membrane with pore diameter of 0.22 μm. The solution was stored at 4°C. A 0.1% solution of purified IgG in PSB containing 1% glucose was used for immunization of a rabbit. As adjuvant was used a mixture of 15% lanolin and 85% Vaseline oil [13].

Immunization of a rabbit by human immunoglobulin G was performed by a standard procedure [13]. The activity of antibodies was determined by simple and double immunodiffusion and by direct EMI [13]. The antiserum was separated from the coagulum and diluted twofold with PSB, after which a saturated solution of ammonium sulfate, pH 7.0, was added with continuous stirring to 40% saturation. The stirring was continued for additional 30 min. Then the mixture was centrifuged at 6000 rpm for 15 min, the solution was removed, and the precipitate was dissolved in water. The procedure was repeated twice. All experiments were performed at 4°C. The isolated globulin fraction was purified by gel filtration and stored under the same conditions as IgG.

The IG–HRP conjugate was prepared by the periodate procedure developed by Nakane and Kawaoi [14] and modified by Wilson and Nakane [15]. Gel filtration was performed in a column packed with Sephacryl S-200 equilibrated with 0.1 M borate buffer solution, pH 7.4.

As indicator reaction in EMI we used oxidation of TMB with hydrogen peroxide, catalyzed by HRP. The reaction was stopped with 0.5 M sulfuric acid. The activity of immunosorbents was estimated from the optical density of the substrate solution at a wavelength of 450 nm and layer thickness of 1 cm.

Preparation of polysaccharide functional derivatives. Apple pectin (1.07 g; 1.0 g of the main substance) was suspended in 20 ml of 89% hydrazine hydrate; the mixture was stirred for 3 h at room temperature and for 3 h at 60°C. The solvent was removed in a vacuum, 10 ml of water was added, the mixture was again evaporated to dryness, 10 ml of water was added, and the mixture was acidified to pH 1.5–2 (the reaction product is soluble in acidic and alkaline solutions owing to the formation of salts by hydrazide and carboxy groups, respectively), and precipitated into 100 ml of alcohol; the product was centrifuged and vacuum-dried. Yield of the hydrazide derivative of apple pectin 0.63 g (65% substituted carboxy groups, according to elemental analysis for nitrogen). Hydrazide of citrus pectin was prepared similarly; yield 0.86 g, 72% substitution.

Phycoll (0.649 g; 2×10^{-4} mol of monomer units) was stirred for 3 h in 4 ml of 0.1 M phosphate buffer solution (pH 5) containing 0.214 g (1×10^{-4} mol) of

$NaIO_4$ and left overnight. To remove anions (iodate, periodate, iodide), the solution was passed through a column packed with Dowex 21-K anion-exchange resin equilibrated with the same buffer solution; 0.5-ml fractions were collected. The presence of the oxidized product was checked by the reaction with DNPH (formation of intensely colored hydrazones). The absence of periodate and iodate ions was verified by the reaction with iodide ion (formation of free iodine) in acid solution.

To prepare hydrazide-containing Phycoll, 160 mg of the oxidized polysaccharide was added to a solution of 300 mg of adipic acid dihydrazide in 0.1 M phosphate buffer solution (pH 8.5). The mixture was stirred for 3 h and left overnight. After that, 15 mg of sodium borohydride was added in three portions over a period of 3 h, the mixture was stirred for an additional 1 h, and low-molecular-weight substances were removed by threefold concentrating on a PA-100 membrane. The resulting solution was lyophilically dried and stored at 4°C. Aldehyde and hydrazide derivatives of hydroxyethyl starch (molecular weight 120 kDa) and dextran (molecular weight 20 and 60 kDa) were prepared similarly. To prepare the hydrazine-containing polysaccharide, dextran was activated by transformation of hydroxy groups into sulfonate groups, after which the polymer was treated with hydrazine hydrate [16, 17].

The reaction of FPSSs with hydrazide-containing polymers (5–50 mg ml^{-1}) was performed in 0.1 M phosphate buffer solution (pH 5.0) for 4 h with continuous shaking. The spheres were washed and analyzed for the content of the hydrazide groups on the support, as described previously [11].

CONCLUSION

A series of aldehyde-, hydrazide-, and hydrazine-containing water-soluble polysaccharide derivatives of various structures were prepared. Reactions of hydrazide- and hydrazine-containing polysaccharides with formylated polystyrene spheres yielded solid supports for immunoassay, containing up to 0.5 μmol cm^{-2} of active groups and suitable for covalent immobilization of immunoreagents, including directed immobilization of antibodies.

ACKNOWLEDGMENTS

The study was supported by the Belarussian Republican Foundation for Basic Research (project no. Kh98M-079). The authors are grateful to S.E. Bandarik for providing the possibility for immunization and for assistance in preparing the antiserum.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Copolymerization of Vinyl Monomers with Different Water Solubilities in the Presence of Manganese Sulfonate Complexes

V. G. Shibalovich, S. A. Khokhrin, and A. F. Nikolaev

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received March 5, 2001

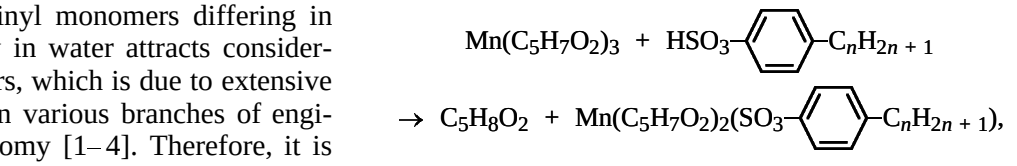
Abstract—Mixed-ligand Mn(III) complexes were prepared from manganese tris(acetylacetonate) and alkylbenzenesulfonic acid, and their surface activity and initiating power with respect to polymerization of vinyl monomers differing in reactivity and water solubility were studied.

Copolymerization of vinyl monomers differing in the polarity and solubility in water attracts considerable attention of researchers, which is due to extensive use of these copolymers in various branches of engineering and national economy [1–4]. Therefore, it is important to study the features and mechanism of formation of such polymerization systems for which, in contrast to the classical Smith–Ewart theory of emulsion polymerization, the colloidal behavior of the system and hence the polymerization kinetics are determined by the solubility of a monomer in water, its polarity, and the nature of the interphase surface formed in the process [1, 2].

It is known that, with mixed-ligand Mn(III) complexes based on acetylacetone and (in)organic acids used as water-soluble redox initiators of radical processes, it becomes feasible to perform low-temperature processes (0–30°C) at a high rate to obtain polymers of high molecular weight [5].

In this work, we prepared a mixed-ligand Mn(III) complex (MMC) from manganese tris(acetylacetonate) (MTA) and alkylbenzenesulfonic acid (ABSA) and studied its reactivity in radical copolymerization of acrylamide (AA) with oil-soluble vinyl monomers differing in reactivity and solubility in water (Table 1); the rate constant of chain propagation K_p varies within 5–18000 l mol^{-1} s^{-1}.

The MMC was prepared by mixing equimolar amounts of MTA and ABSA at 10–30°C in organic solvent (benzene, acetone) in air [6]:



where n = 10–14.

The ligand exchange occurs within 5–10 min, and green crystalline precipitates are formed in 70–90% yields.

We performed elemental microanalysis, measured the IR and UV–Vis absorption spectra of MMC, and determined its molecular weight and manganese val-

Water–BA (1 : 1)	18.5	1.8
Water–ST (1 : 1)	28.0	2.2

ence [6]. These data show that the prepared compound is monosubstituted Mn(III) complex containing two acetylacetonate and one aromatic sulfonate ligands, i.e., it is manganese alkylbenzenesulfonatobisacetylacetonate (MABS). The product is readily soluble in water and polar organic solvents (acetone, alcohol, tetrahydrofuran, dimethylformamide, etc.), partially soluble in esters, and insoluble in aliphatic and aromatic hydrocarbons. On dissolution in water, the complex undergoes hydrolysis, typical of Mn(III) sulfonate complexes, which is suppressed at pH ≤4.0.

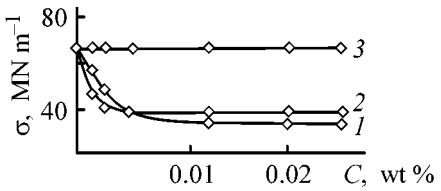

Fig. 1. Isotherms of surface tension σ at the water–air interface. (*C*) Concentration. (*1*) ABSA, (*2*) MABS, and (*3*) MTA.

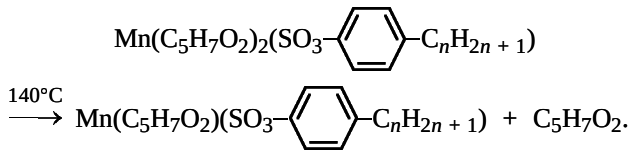
Thermal decomposition of MABS in the solid phase under argon was studied by DTA/TGA in the range 20–600°C. Examination by elemental microanalysis of the stable intermediates formed in the first stage shows that thermal decomposition involves elimination of one acetylacetonate ligand and reduction of Mn(III) to Mn(II):



Kinetic study of MABS decomposition in aqueous and organic solutions showed that the decomposition rate is determined by the nature of the coordinated ligand and solvent (monomer). The presence of the sulfonate ligand facilitates the inner-sphere redox reaction, apparently owing to a distortion of the "pseudoaromatic" character of the inner sphere; this circumstance determines the higher initiating activity of MABS as compared with MTA (Table 2).

Significant acceleration of MABS decomposition in water is probably due to specific properties of water as solvent and to specific hydration of the complex.

A study of the surface-active properties of MABS by measuring the surface tension of its aqueous solutions (ring detachment method, Fig. 1) showed that this complex exhibits high surface activity: The surface tension at the water–air interface at the critical micelle concentration (CMC) of 0.7×10^{-3} M decreases by more than a factor of 2, and that at the water–monomer interface falls to 1–2.0 mN m^{-1} (Table 3).

Manganese trisacetylacetonate shows no surface activity under similar conditions. The high surface activity of MABS is due to the presence of the aromatic sulfonate ligand with a long alkyl chain.

Thus, a combination of the high initiating power and surface activity of MABS allows its use in (co)polymerization of vinyl monomers as initiator and emulsifier simultaneously.

The kinetics of AA copolymerization with oil-soluble monomers (VA, BA, ST) was studied in aqueous solution in the presence of 0.1 wt % MABS under argon at 10–20°C and stirring rate of 2.5 rps. The copolymerization kinetics was monitored gravimetrically: Samples of the reaction mixture were precipitated into acetone in the presence of hydroquinone. In all experiments, the conversion did not exceed 10%. The composition of the copolymers was determined by elemental analysis.

A study of the copolymerization of the above-indicated monomers showed that the reaction is heterogeneous and is accompanied by an increase in the viscosity of the reaction medium and formation of fine and fairly stable dispersions which are not settled within 24 h to several days, depending on the reaction conditions.

The colloid properties of the dispersions of AA copolymers with hydrophobic monomers in the presence of MABS were studied by microscopy; the phases were colored with water- and fat-soluble dyes. We found that the systems uner study are direct oil-in-water emulsions.

The plots of conversion against time (Fig. 2) and copolymerization rate against concentration of hydrophobic monomer (M_2, Fig. 3) for the case of AA copolymerization with vinyl monomers show that both the reaction rate and the copolymer yield are the highest (curves *3*) with VA, which is the most hydrophilic.

Determination of the copolymer compositions as influenced by the composition of the initial monomeric mixture and calculation of the constants of AA (M_1) copolymerization with VA, BA, and ST by the Fineman–Ross, Mayo–Lewis, and universal methods (Table 4) allowed a conclusion that in all cases AA is more reactive than the vinyl comonomers, and the copolymers, irrespective of the composition of the initial monomer mixture, are always enriched in the more active AA.

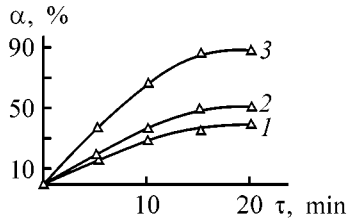


Fig. 2. Monomer conversion α vs. time τ at 20°C. Water : oil = 2 : 1; concentrations (M): monomers 1 and MABS 3×10^{-3}; the same for Fig. 3. Copolymerization of AA with (*1*) ST, (*2*) BA, and (*3*) VA; the same for Fig. 3.

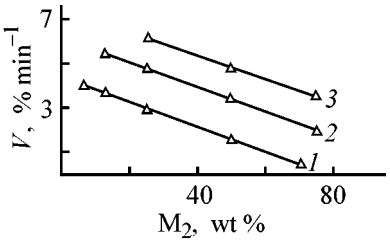

Fig. 3. Copolymerization rate *V* vs. concentration of the oil-soluble monomer M_2 at 20°C.

Table 4 shows that the copolymers with VA exhibit the greatest tendency toward alternation of units in the polymer chain, whereas in the copolymers of AA with BA and ST this tendency is weak. Nevertheless, comparison of our data on the relative activity for the system AA–ST with published data [7] shows that with MABS the reactivity of hydrophobic ST toward

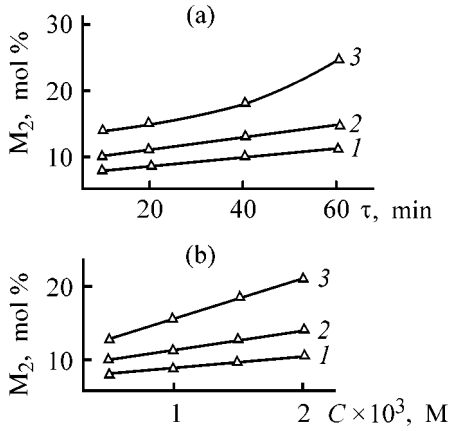

Fig. 4. Compositions (M_2 content) of copolymers (*1*) AA–ST, (*2*) AA–BA, and (*3*) AA–VA vs. (a) copolymerization time τ and (b) concentration of MABS initiator *C* at 20°C. Concentration of monomers in water 1 M. (a) MABS concentration 1×10^{-3} M; (b) reaction time 10 min.

acrylamide radical increases by more than a factor of 5. This fact is apparently due to the possible complexation of ST with MABS, which significantly affects its reactivity and copolymerization activity. Detailed comparative analysis for AA–VA and AA–BA copolymers is impossible because of the lack of published data.

Calculation of the intramolecular distribution of monomeric units in AA–VA and AA–ST copolymers (Table 5) according to [8] confirms the major contribution of the AA–AA diad to the copolymer composition, because both types of the arising polymeric radicals react preferably with AA than with VA or ST.

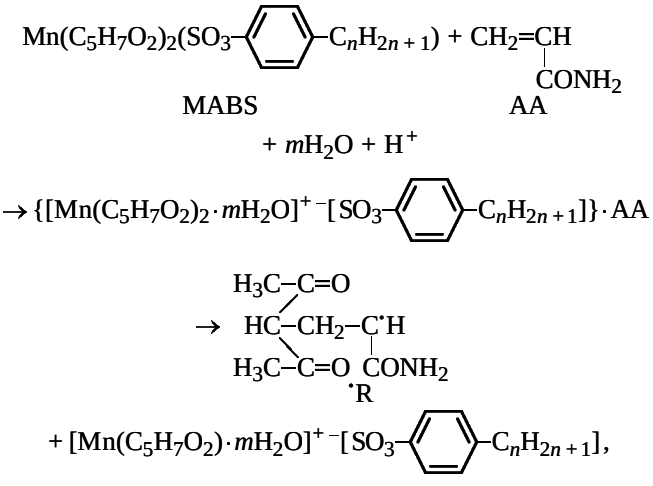
At AA content in the initial monomer mixture within 10–50 mol %, the AA–VA copolymers show the most ordered structure: The AA blocks consisting of 1–6 monomeric units are separated by 1–2 VA units. With the content of VA increasing above 50%, the tendency toward alternation becomes more pronounced increases. In AA–ST copolymers, even at a large excess of hydrophobic ST in the reaction mixture (initial monomer ratio 3 : 7),there are seven AA units per ST unit.

We studied(at equimolar ratio of the monomers in the initial mixture) how the copolymer compositions depend on the process parameters: reaction time and temperature, concentrations of initiator and comonomers. We found (Figs. 4a, 4b) that, as the reaction time and MABS concentration are increased, the content of hydrophobic monomers in the copolymer grows. This fact suggests predominant polymerization of AA; as AA is exhausted, the copolymer starts to incorporate growing amounts of the hydrophobic monomer. Also, it is seen that MABS enhances the activity of hydrophobic monomers, probably owing to donor–acceptor interaction, which is typical of Mn(III) compounds and vinyl monomers [5].

Variation of the total concentration of the monomers in aqueous solution has virtually no effect on the copolymer composition. As the reaction temperature is raised from 5 to 20°C (at monomer and MABS concentration 1×10^{-3} M), the content of vinyl acetate units in the AA–VA copolymer increases from 8 to 14 mol %, and that of ST units in the AA–ST copolymer, from 4 to 9.5 mol %.

A study of the solubility of AA copolymers with the hydrophobic monomers showed that all the copolymers (except AA–VA with VA content less than, or equal to 20 mol %) are virtually insoluble in water and in most of organic solvents. The precipitation curves for AA–VA, AA–BA, and AA–ST copolymers, obtained by fractional precipitation in the acetic acid–acetone system, are typical of copolymer precipitation, rather than of precipitation of homopolymer mixtures.

Thus, based on the results obtained, we suggest the following copolymerization mechanism: Owing to high solubility of AA and MABS in water and the possibility of their donor–acceptor interaction, initiation and the initial period of chain propagation occur mainly in the aqueous phase:



$$R^{\bullet} + M_1 \xrightarrow{k_i} RM_1^{\bullet},$$

$$RM_1^{\bullet} + nM_1 \xrightarrow{k_{11}} R(M_1)_n^{\bullet},$$

$$R(M_1)_n^{\bullet} + M_2 \xrightarrow{k_{12}} R(M_1)_nM_2^{\bullet}.$$

The oil-soluble monomer (VA, BA, ST) occurs in the form of monomer drops from which it diffuses into the aqueous phase. Owing to the high surface activity of MABS and decreased surface tension at the oil–water interface, the hydrophobic monomer molecules diffuse more readily to the active polymerization centers. As the AA concentration in water decreases, the fraction of the oil-soluble monomer in the growing radicals increases, and at a certain critical length of the oligomeric chain the growing radicals start to precipitate; thus, the process becomes heterogeneous, and polymerization continues in latex particles, following the pattern of emulsion polymerization and yielding nucleus-in-shell particles.

EXPERIMENTAL

MABS was prepared by ligand substitution: Equimolar amounts of MTA and ABSA were mixed in an organic solvent in air at 10–30°C [6].

Mixed-ligand Mn(III) complexes were studied by DTA with a Q-1500D derivatograph (MOM).

The rate constant of liquid-phase thermolysis of MABS was determined in 0.1 M aqueous CH_3COOH (pH 5) in the range 10–20°C, and that of MTA, in the range 80–100°C; the thermolysis was monitored by iodometric titration.

The surface-active properties of MABS in water were evaluated by the ring detachment method with a du Nouy device [9].

Copolymerization of vinyl monomers with different water solubilities was performed in aqueous medium in the presence of MABS under argon at temperatures of 10–20°C with stirring at 2.5 rps. The copolymerization kinetics was monitored gravimetrically. The constants of AA copolymerization with hydrophobic monomers and the intramolecular distribution of units were calculated by the Fineman–Ross and Mayo–Lewis methods [8].

CONCLUSIONS

(1) The initiating power and surface-active properties of a mixed-ligand Mn(III) complex prepared from manganese tris(acetylacetonate) and alkylbenzenesulfonic acid were studied. This complex shows high surface activity and high reactivity in copolymerization of vinyl monomers with different water solubilities.

(2) A mechanism of copolymerization of vinyl monomers with different water solubilities in the presence of manganese alkylbenzenesulfonatobisacetylacetonate is proposed. The process follows the emulsion polymerization pattern and yields nucleusin-shell particles.

Abstract—Gelation conditions in solutions of methyl cellulose in water and dimethylacetamide were studied. The gelation mechanisms were studied by X-ray diffraction and photocolorimetry, and their differences in the two systems were revealed. The physicomechanical properties of methyl cellulose films prepared from solutions with preliminary gelation were determined.

Recently there has been increased interest in self-associated polymer systems based on natural polymers, which are environmentally safe and biodegradable. It is known that a number of cellulose derivatives, in particular, methyl cellulose (MC), hydroxypropyl cellulose (HPC), hydroxypropyl methyl cellulose (HPMC), and methyl ethyl cellulose (MEC), form physical thermally reversible gels in aqueous solutions. These cellulose derivatives are widely used as gelating agents, thickeners, stabilizers, and emulsifiers in food industry, cosmetics, and perfumery [1]. The most widely used compound is MC.

The gelation mechanism in aqueous solutions of MC was studied in detail by various methods. It was found that gelation conditions depend on many factors, such as molecular weight and degree of substitution (DS) of MC, concentration of the polymer in solution, and uniformity of the substituent distribution in anhydroglucose units and along the macrochain [1–5]. There are several viewpoints on the gelation mechanism in aqueous solutions of MC. Some authors believe that gelation in aqueous solutions of MC is due to local crystallization of macrochain fragments containing predominantly trisubstituted MC units [1–4]. In other papers, it is assumed that incompletely dissolved residual crystallites of the polymer (weakly substituted or unsubstituted sections of cellulose macrochains) may exist in aqueous solutions of MC at low temperatures and initiate gelation on heating [6].

At present, it is generally believed, on the basis of numerous experimental data, that gelation in aqueous solutions of MC occurs in two stages. At low temperatures, water molecules solvate methoxy and hydroxy groups of MC, forming specific structures in solution. On heating, the H bonds between water molecules and methoxy groups are broken; as a result, hydrophobic interactions (association) are enhanced, and the size and shape of associates (clusters) in solution change (stage I). Further heating induces gelation accompanied by phase separation (stage II) [1, 6–9]. The two-stage gelation mechanism was described theoretically by Tanaka and Ishida [10].

It should be noted that gelation on heating is observed in aqueous solutions of MC only with polymer samples in which the distribution of substituents in the anhydroglucose units and along the macrochain is nonuiform, i.e., with MC prepared by a heterogeneous procedure. Methyl cellulose with uniform distribution of substituents in macromolecules does not undergo gelation in aqueous solutions (the polymer precipitates) [5]. Therefore, commercial MC prepared under heterogeneous conditions can be considered a multiblock copolymer consisting of randomly alternating blocks of unsubstituted, mono-, di-, and trisubstituted units. The diffraction patterns of the MC samples with various molecular weights and degrees of substitution in gel form are similar to those of trisubstituted MC. This fact suggests that the centers of local crystallization (formation of a new phase) are trisubstituted MC units [1, 4].

Depending on the DS and preparation procedure, MC can dissolve in other solvents, e.g., in aqueous alkalis, aqueous dimethyl sulfoxide (DMSO), aqueous dimethylacetamide (DMAA), chloroform, or acetone [1, 11–15]. In solutions of MC in DMAA, physical thermally reversible gels are also formed, but only on cooling [12–15]. Thus, it is possible to prepare physical thermally reversible gels in aqueous solutions of MC on heating (system with lower critical solution point, LCSP) and in solutions of MC in DMAA on cooling (system with upper critical solution point, UCSP). The conditions of MC dissolution in H_2O and DMAA reflect the differences between the mechanisms of solvation of polymer macromolecules and formation of physical thermally reversible gels in the above solvents. Presumably, directional variation of the structural organization of moderately concentrated solutions (heating, cooling) must affect the physicomechanical properties of films prepared from MC solutions with preliminary gelation in solutions and subsequent evaporation of solvents.

The goal of this work was to perform a comparative study of the gelation mechanisms in solutions of MC in H_2O and DMAA and examine the influence of gelation on the physicomechanical properties of films prepared from these systems. In our study, we used X-ray diffraction and photocolorimetry.

EXPERIMENTAL

As solvents we used double-distilled water and DMAA distilled in a vacuum from P_2O_5. The starting material was commercial MC (MTs-100 grade, DS 1.62). Methyl cellulose was dissolved in water, and the solutions were filtered under pressure and then centrifuged. MC was recovered from aqueous solutions by lyophilic drying. The molecular weight of purified MC was determined viscometrically from the viscosity of its aqueous solutions at 20°C, using the equation [4] $[\eta] = 2.8 \times 10^{-3} M^{0.63}$. Purified MC had M_η = 154000 (DP 830). Films were prepared from 1.5% solutions of MC in H_2O and DMAA, and the turbidity was studied with 0.5 and 2.0% solutions.

Aqueous solutions of MC were prepared by swelling of the polymer in hot water (80–90°C) followed by dissolution with cooling to 5°C and stirring for 6 h. Solutions of MC in DMAA were prepared by stirring at 90°C. Dissolution was complete in 2 h. The resulting MC solutions were filtered under pressure (aqueous solutions, at 20°C; solutions of MC in DMAA, at 60–70°C) and then deaerated for 1 h.

Films were prepared at 20°C from aqueous solutions of MC by casting onto Teflon plates through a laboratory die with adjustable clearance, with subsequent drying at 20°C. The solvent evaporated within 4 days.

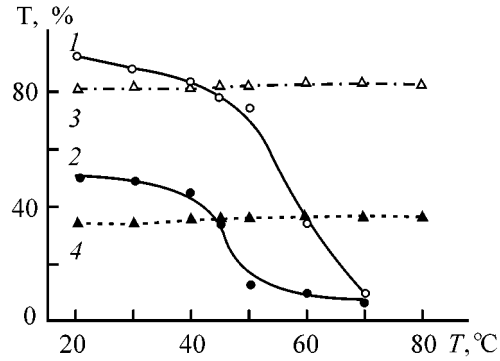

Fig. 1. Absorption spectra of (*1*) 0.5 and (*2*) 2.0% solutions of MC in H_2O and (*3*) 0.5 and (*4*) 2.0% solutions of MC in DMAA. (T) Transmission and (*T*) temperature.

Samples of films with preliminary gelation were prepared by applying the solution at 20°C onto Teflon plates, after which the plates were heated to 60°C. The film formation was complete in 4 h.

Films from solutions of MC in DMAA were prepared by applying a heated solution (70°C) to preheated plates (70°C), which was followed by evaporation of DMAA at 70°C. The film formation was complete in 6 h. Films with preliminary gelation were prepared as follows: A solution at 70°C was applied onto plates preheated to the same temperature, after which the plates were cooled to room temperature. The resulting gel was dried a 20°C for 14 days. In all the experiments, the plates were placed on a temperature-controlled table.

The resulting samples were studied by X-ray diffraction analysis on a DRON-2.0 diffractometer (CuK_α radiation, Ni filter). Samples were prepared as 1–2-mm-thick stacks of films. The diffraction patterns of thermally reversible gels were obtained in a temperature-controlled cell.

The turbidity of 0.5 and 2% solutions of MC was studied photocolorimetrically in the course of varying the temperature from the state of solution to that of gel, i.e., from 20 to 60°C for aqueous solutions of MC and from 90 to 20°C for solutions of MC in DMAA. The samples were kept at each temperature for 20 min before measurement. The measurements were performed with a KFK-2 concentration photocolorimeter with temperature-controlled cells at λ = 590 nm.

The physicomechanical properties of films were studied under uniaxial stretching with an Instron TM-SM universal tensile-testing machine at a rate of 5 mm min^{-1}.

Figure 1 shows the transmission spectra of the solutions as influenced by temperature. For a 2.0%

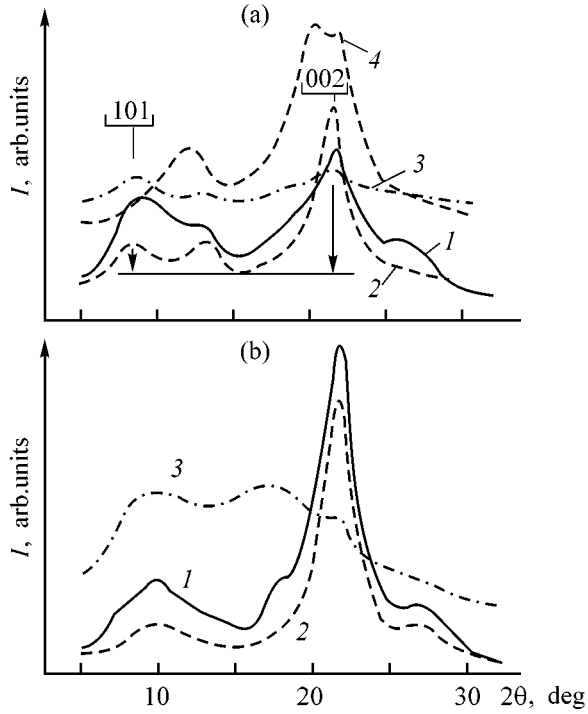

Fig. 2. Diffraction patterns of MC films prepared (a) from aqueous solutions: (*1*) without gelation, (*2*) with preliminary gelation, and (*3*) from gel at 50°C; (b) from solution of MC in DMAA: (*1*) without gelation, (*2*) with preliminary gelation, and (*3*) from gel at 20°C. aqueous solution of MC, the transmission sharply decreases (the turbidity increases) in the temperature range 45–50°C. As the solution concentration is decreased, the cloud point T_{cl} (or the phase separation point) of the aqueous solution shifts toward higher temperatures, which agrees with data in [3]. In contrast to aqueous MC solution, the system MC–DMAA shows no turbidization on cooling. The gel forming in the cell remains fully transparent and elastic. The gels formed in the systems under consideration undergo syneresis when kept for more than 2 h. The aqueous solution of MC exhibits a hysteresis loop for the transition sequence solution–gel–solution, whereas for the solution of MC in DMAA, no hysteresis is observed owing to the absence of noticeable turbidization. The absence of turbidization of the solution of MC in DMAA on transition from solution to gel may be due to at least two factors: (1) different mechanisms of MC dissolution in water and DMAA and different gelation mechanisms, and (2) smaller difference between the refractive indices of DMAA and MC, compared with the MC–H_2O system.

It was shown in [14] that the intrinsic viscosities [η] of MC in water and DMAA are close, but the viscosity of a 1.5% solution of MC in DMAA is an order of magnitude lower than that of the 1.5% aqueous solution. Such a difference in the viscosities of the moderately concentrated solutions is due to different mechanisms of solvation of the polymer macrochains with water and DMAA molecules. Water molecules can form several hydrogen bonds: with functional groups of MC (two H bonds with hydroxy groups and H bond with a methoxy group) and with other water molecules in solution, thus forming a three-dimensional (3D) system of H bonds and structurizing the solutions as a whole. DMAA molecules can form one H bond with OH groups and can interact with methoxy groups of the polymer by the dipole–dipole mechanism. In concentrated solutions of MC in DMAA, dipole–dipole and dispersion interactions between solvated macromolecules are possible. These differences between the mechanisms of solvation of MC macromolecules in water and DMAA may be responsible for different mechanisms of gelation in these systems.

It is known that, when aqueous solutions of MC are heated, the weakest H bonds between the methoxyl oxygen atoms and water molecules are broken first. As a result, the hydrophobic interactions between the solvated macromolecules are enhanced, and separate blocks of the macrochains containing predominantly trisubstituted units form a separate new phase. Dimethylacetamide is a strongly polar associated aprotic solvent, and the mechanism of H bonding between the OH group of MC and a DMAA molecule may be similar to the mechanism of solvation and dissolution of cellulose in aprotic solvents like tertiary amine *N*-oxides [16]. Self-association of solvent molecules occurs via dipole–dipole interactions. Although the H bonding is an exothermic process, it is necessary to raise the temperature (to a certain extent) for decreasing the interactions between the solvent molecules, after which H bonds with the hydroxy groups of the polymer can be formed [17, 18]. In solutions of cellulose with tertiary amine *N*-oxides, the solvent molecules separate out with decreasing temperature to form a new phase (to the point of solvent crystallization). A similar pattern (i.e., separation of solvent molecules in the form of a liquid phase) can be observed in the MC–DMAA system.

It should be noted that, although no turbidization is observed at the gelation temperature in the MC–DMAA system (as judged from the optical density of the solution), the method of polarized light scattering does detect changes in the intensity of scattered light at the solution–gel transition [15]. As the gelation temperature in the systems MC–H_2O and MC–DMAA is approached, the fluctuations of the concen-

tration of the dissolved polymer, the anisotropy of the scattering elements of the solution volume, and the mutual ordering of the anisotropic elements increase.

To elucidate the differences between the gelation mechanisms in the systems MC–H_2O and MC–DMAA, we measured X-ray diffraction patterns of the gels and films cast from solutions and prepared by preliminary gelation in solutions. For comparison, Fig. 2a shows a diffraction pattern of a hydrated cellulose (C II) film. The diffraction patterns of the films prepared by the two different procedures and of the gel (for the MC–H_2O system) are similar to those obtained in [1, 4]. The reflections at 2θ 13.1° and 26.8° correspond to water molecules retained in the films [4]. The reflections at 2θ 8.2° and 21.8° suggest that gelation is accompanied by separation into a new phase and local crystallization (ordering) of the segments of MC macrochains containing predominantly trisubstituted units, which agrees well with data in [4].

A different pattern is observed with the system MC–DMAA (Fig. 2b). The reflections at 2θ 17.5° and 27.0° belong to DMAA molecules. The position of the reflection corresponding to the 101 plane at 2θ 10.0° suggests that gelation is accompanied in this system by separation from solution into a new phase of partially substituted (and probably unsubstituted) units of MC macrochains, followed by their crystallization (ordering). This conclusion is supported by data in Table 1, illustrating the variation of the spacing in the 101 plane for MC samples with different DSs. The angle 2θ 10.0° corresponds to the medium degree of substitution, 1.0. The reflection at 2θ 21.8°–22.0° corresponds to the 002 plane. The reflections from the 002 plane for MC films obtained from aqueous solutions and from DMAA differ insignificantly and lie close to 002 reflections for C II (2θ 22.4°).

The differences in the mechanisms of solvation and desolvation of MC macromolecules with water and DMAA molecules and the differences in the gelation mechanisms must be manifested in the physicomechanical properties of films prepared directly from solution and with preliminary gelation. Table 2 shows that MC films prepared from DMAA solutions exhibit better physicomechanical properties as compared with MC films prepared from aqueous solutions. It is known that, in moderately concentrated solutions of MC in H_2O and DMAA, solvated MC macromolecules form associates of definite size, showing mutual ordering [15]. Presumably, the supramolecular organization of solutions must affect to a certain extent the structural organization of the forming films.

	From gel	123.0	19.3	3.3

* (σ) Breaking stress, (ε) elongation at break, and (*E*) modulus of elasticity.

As the polymer concentration in solution increases in the course of solvent evaporation, separate fragments of MC macromolecules undergo ordering. The mechanism of local crystallization of separate fragments is similar to the mechanisms of formation of crystallites in preliminary gelation, as indicated by the positions of the 101 and 002 reflections (Figs. 2a, 2b). In the course of film formation, the crystallites formed in solution are arranged in a certain order relative to each other, and a 3D network of intermolecular H bonds is formed.

In aqueous solutions, MC forms crystallites consisting predominantly of the trisubstituted units, but less substituted, or more hydrophilic, units also participate in the system of H bonds when a film is formed [4]. Thus, in MC films prepared from aqueous solutions, crystallites are formed via hydrophobic interactions, and fragments of MC macromolecules containing more hydrophilic units are arranged between them, forming a 3D network of H bonds which also fix the mutual arrangement of these crystallites in the films.

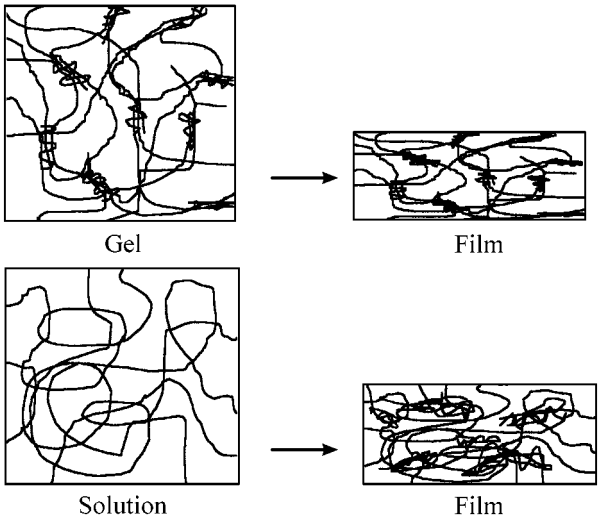
In a solution of MC in DMAA with increasing polymer concentration, crystallites are formed from mono- and unsubstituted units owing to the forma-

tion of H bonds via unsubstituted OH groups in anhydroglucose units of MC. In the course of film formation, the macrochain fragments containing more hydrophobic polymer units, remaining in solution, participate in formation of a 3D H-bond system. Thus, in films prepared from solutions of MC in DMAA, crystallites are formed from weakly substituted units having a specific structure and mutual ordering, and these crystallites are stabilized in the polymeric film matrix by more hydrophobic fragments of MC macromolecules forming a 3D network of H bonds and hydrophobic interactions.

The physicomechanical properties of the films are also influenced by the molecular weight of the polymer, degree of ordering (or crystallinity), and the system of intermolecular interactions in the films (H bonds, dipole–dipole, dispersion interactions). The size, shape, and content of crystallites and their mutual arrangement in the polymer matrix may also vary. Since solutions of MC in water and DMAA were prepared from the same polymer sample, the effect of the molecular weight and molecular-weight distribution can be ruled out. The films differ in the nature of the crystallite zones and in the systems of intermolecular 3D interactions in films. Plasticization orientation of MC films prepared from aqueous solutions is accompanied by an increase in the degree of polymer crystallinity and simultaneously by increase in the ordering of crystallites in the films [1]. These processes are accompanied by an increase in the tensile strength σ and modulus of elasticity E of the films, whereas the breaking elongation ε drastically decreases. Presumably, the higher values of σ and E for the MC films prepared from solution in DMAA, compared with the films from aqueous solution, are due to the differences between the nature of crystallites formed in the films and between the systems of intermolecular interactions in the films. The ε values of the films differ insignificantly.

It should be noted that, in both systems, films prepared with preliminary transformation of the solutions into gels and subsequent evaporation of the solvents exhibit considerably better level of all the mechanical properties. This trend is independent of the solvent, which suggests a general nature of the physical process responsible for the increase in σ and E with simultaneous significant increase in the elasticity (parameter ε). The stage of preliminary gelation accelerates formation of crystallites in the systems (Figs. 2a, 2b). With increasing crystallinity of the films (or with increasing content of crystallites in them), σ and E must increase, which is actually the case. The increase in the breaking elongation ε suggests the influence of an additional factor, characteristic of gels only. The suggested differences in the film formation from solution with and without preliminary gelation are illustrated in the scheme.

Scheme of film formation from gel and solution



Formation of films from solutions involves ordering of the forming crystallites relative to each other. In films, the orientation increases in the 101 plane and in the surface layers parallel to the support plane. Such an orientation occurs both on the film surface and on support sides [1]. With preliminary gelation, the 3D skeleton of the gel, consisting of crystallites, considerably inhibits mutual ordering of crystallites and their orientation relative to the surface of the forming film and the support. The films prepared from gels contain crystallites which are less ordered relative to each other and to the film planes as compared with the films prepared from solutions (see scheme). Therefore, in the case of tension, a major contribution to strain is made by mutual ordering of the crystallites, which accounts for the significantly higher elasticity of the films prepared with preliminary gelation.

Indeed, Figures 2a and 2b show that the formation of films from solutions of MC in H_2O and DMAA involves ordering, or crystallization, of separate fragments of MC macrochains in two planes: 101 (2θ = 8°–10°) and 002 (2θ = 20°–22°). The highest ordering occurs in the 002 plane, as indicated by the higher intensity of the reflection at 2θ = 20°–22°. The films formed with preliminary gelation show a common trend: higher ordering in the 002 plane as compared with 101. To evaluate this effect quantitatively, we measured the intensities of the peaks observed in the diffraction patterns relative to the baseline at 2θ = 15°, which was proposed as reference in determining the

crystallinity index for C II [19]. The intensity ratios I_{002}/I_{101} for the MC films prepared from aqueous solutions and gels are 1.93 and 6.14, respectively. For the films prepared in the system MC–DMAA from solution and gel, the intensity ratios are 6.48 and 11.9, respectively. This trend confirms our assumption that the skeleton of the forming gel inhibits or "freezes" mutual ordering of the crystallites in the course of film formation.

Thus, preliminary gelation in solutions has a dual effect on the physicomechanical properties of the MC films. On the one hand, gelation accelerates crystallization in solution, which increases the tensile strength and the modulus of elasticity. On the other hand, gelation prevents mutual ordering of the crystallites in the course of film formation, which considerably increases the breaking elongation of the films, i.e., preliminary gelation enhances the strength properties of MC films with simultaneous increase in their elasticity. It should be noted that the physicomechanical properties of the films can also be influenced by the type of the forming gel skeleton and by the gel morphology, which may differ significantly [20].

CONCLUSIONS

(1) Conditions were studied under which physical thermally reversible are formed gels in the systems with the lower (methyl cellulose–H_2O) and upper (methyl cellulose–dimethylacetamide) critical solution points. In contrast to aqueous solutions of methyl cellulose, gelation in dimethylacetamide solutions occurs with decreasing temperature.

(2) The gelation mechanism in the system methyl cellulose–dimethylacetamide was studied for the first time. Gelation is accompaied by separation into a new phase of partially substituted (and possibly unsubstituted) units, followed by their crystallization. Formation of thermally reversible gels is not accompanied by noticeable turbidization of solutions of methyl cellulose in dimethylacetamide.

(3) Preliminary gelation enhances the strength and elasticity of methyl cellulose films prepared in both the systems studied, which is due to a dual effect of gelation on the formation of the supramolecular structure of the films.

Abstract—The refractive indices, transmission coefficients, and other service characteristics of binary and amine-cured mixtures epoxy oligomer–glycidyl esters of phosphorus acids, proposed as optical adhesives, were measured.

Development of new polymeric optical materials, including adhesives, is an urgent problem [1]. Optical adhesives must meet specific requirements [2]: they must be highly transparent and colorless in the required wavelength range, their refractive index must fall in a definite range, the optical properties must be preserved in the working temperature range; these materials must also exhibit acceptable viscosity, high strength of adhesive joints, etc. Among the versatile adhesives are epoxy adhesives (EAs) ensuring enhanced mechanical strength of adhesive joints of optical parts [3].

Polymers with refractive index adjustable in a wide range can be prepared by copolymerization of two monomers with different n_D^{20} [4]. In the case of epoxy polymers (EPs), this is possible owing to the use of active diluents: epichlorohydrin (OK-50) and phenyl glycidyl ether (OK-72FT$_5$, OK-72FT$_{15}$) [2]. These adhesives exhibit low viscosity, high transmittance (99% at λ = 400–2700 nm), and high frost resistance. However, these formulations also have certain drawbacks: poor physicomechanical characteristics and very narrow range of refractive index variation (1.578–1.582). The authors of [5] proposed an optical adhesive with n_D^{20} 1.493–1.501, consisting of ED-20 epoxy–4,4'-isopropylidenediphenol resin modified with silanol SEDM-3, condensation product of 1,1-dihydroxymethyl-3-cyclohexane with epichlorohydrin, UP-650D agent, and diglycidyl camphorate. As a curing agent was used a mixture of 1,3-bis(aminoalkyl)-adamantane and the product of the reaction of butyl glycidyl ether with an equimolar amount of adamantanediamine. Apparent drawbacks of this compound are the multicomponent formula, complex preparation procedure, difficult availability of some components, and relatively narrow range of variation of the refractive index.

It was shown previously [6] that glycidyl esters of phosphorus acids (GEPs) are effective modifiers of epoxy oligomers (EOs), enhancing the heat and fire resistance and mechanical strength of epoxy polymers. At the same time, the refractive indices of GEPs and EOs differ significantly. Therefore, we examined in this work the possibility of preparing optical adhesives from epoxy polymers modified with GEPs.

EXPERIMENTAL

As investigation objects we chose ED-20 epoxy–4,4'-isopropylidenediphenol oligomer [GOST (State Standard) 10587–84]; curing agents diethylenetriamine (DETA) and monocyanoethyldiethylenetriamine (UP-0633M); and glycidyl esters of phosphorus acids of the general formula $RP(O)(OCH_2{-}CH{-}CH_2)_2$ (O) where R = $-OCH_2{-}CH{-}CH_2$ (O) [triglycidyl phosphate (**I**)], $-OCH_3$ [diglycidyl methyl phosphate (**II**)], and $-CH_3$ [diglycidyl methylphosphonate (**III**)]. The synthesis and properties of GEPs are described elsewhere [7].

The compounds were prepared by mixing ED-20 epoxy oligomer with various amounts of GEP and then adding a stoichiometric amount of the curing agent. The refractive index n_D^{20} was determined by the interference method [8] using IRF-22 and

IRM-1 devices for liquid and cured samples, respectively.

The electronic spectra of oligomeric samples (in quartz cells of varied thickness) and cured polymers (as ≥10-μm-thick films) were recorded on an SF-26 spectrophotometer relative to air in the range 200–1000 nm.

Figure 1 shows the transmittance of cured compounds modified with **III**. It is seen that, on adding GEP, the transmission range of the compound is extended toward shorter wavelengths, and the transmittance increases in the entire wavelength range.

It is known [9] that the refractive index n_D^{20} of optical materials can be adjusted by using glycidyl ethers or esters with appropriate refractive indices. For example, n_D^{20} can be reduced by adding butyl glycidyl ether (n_D^{20} = 1.417), butanediol diglycidyl ether (n_D^{20} = 1.459), etc. The refractive indices of the chosen glycidyl esters of phosphorus acids fall in the same range. Figure 2 shows the refractive index of EO–GEP mixtures as a function of the mixture composition. The virtually linear dependence of n_D^{20} on C_{GEP} allows fairly accurate prediction of the refractive index of the obtained polymers. The refractive indices of cured ED-20–GEP–DETA compounds are listed in Table 1. The refractive indices of the cross-linked samples were calculated using the approach suggested in [10, 11] and based on the Lorentz–Lorenz equation, on the additive principle of determination of the molecular refraction and the volume of the repeating fragment of the epoxy polymer network, and on the assumption that the molecular packing coefficient *k* is constant. However, calculation of *k* by the relation proposed in [12] showed that this coefficient may vary with the GEP content. The calculated values of the molecular packing coefficient *k* and refractive index of epoxy polymers with varied GEP content are given in Table 2. As seen, the measured and calculated values of n_D^{20} virtually coincide. Thus, by varying the GEP content, it is possible to adjust the refractive indices of optical epoxy adhesives.

Adhesive strength for a sapphire–sapphire joint (MPa) no less than	30	30	9.8
Moisture resistance (%) without failure of adhesive layer at 40°C and 98% relative humidity, no less than	56	56	70
Thermal shock resistance in the range from +60 to –60°C, number of cycles, no less than	100	100	65

When developing an optical adhesive, we took into account preliminary data on physicomechanical properties of GEP-modified EPs, according to which the high mechanical strength of the cured compounds is due to the presence of the trifunctional modifier **I**, and the required elasticity, to the presence of diglycidyl esters **II** and **III**. Therefore, to attain the best characteristics, we added simultaneously in various ratios two modifiers differing in functionality. Some properties of cured adhesives and formulas of compounds in the system ED-20–GEP–UP-0633M are given as example in Table 3.

Comparative analysis of the properties of known optical adhesives with those of the developed compounds [13] reveals advantages of the new formulations. The main distinctive feature of GEP-containing adhesives is the possibility of varying the refractive index in a relatively wide range, between 1.490 and 1.573. This was achieved by varying the ratio of modifiers with different refractive indices. The developed compounds show relatively low initial viscosity (0.05–2.1 Pa s) and satisfactory working life (30–40 min). Also, these GEP-containing adhesives exhibit high heat and fire resistance characteristic of phosphorus-containing polymers [6].

CONCLUSION

Optical adhesives were developed on the basis of epoxy oligomer–glycidyl esters of phosphorus acids–amine compounds, with the refractive index adjustable in a wide range. The materials exhibit high transmittance, resistance to heating and thermal shock, and adhesion strength.

CHEMISTRY OF FOSSIL FUEL

Influence of the Products of Chemical Modification of Atactic Polypropylene on Properties of Bitumen Binders

V. P. Nekhoroshev, A. V. Nekhorosheva, E. A. Popov, and L. P. Gossen

Tomsk State University, Tomsk, Russia

Received January 30, 2001

Abstract—The influence of low- and highly oxidized atactic polypropylene on the properties of paving and building bitumens was studied experimentally. The possibilities of commercial production of bitumen–polymer binders are discussed.

Bitumen materials used in building are mainly produced at Russian enterprises by deep oxidative dehydrogenation of vacuum residue with atmospheric oxygen. As estimated by specialists of Russian and foreign companies using bitumens in building, oxidized bitumens have low viscosity and insufficient deformability and resistance to oxidative aging; although such bitumens show better frost resistance, residual bitumens are, on the whole, preferable. It has been shown experimentally that the quality of paving bitumens prepared by the oxidation process leaves much to be desired, and the longevity of roads built with such bitumens is apparently insufficient [1]. The major line of research aimed at prolonging the service life of articles is to modify the properties of bitumen binders with the aim to increase their deformability and heat resistance, enhance the resistance to aging and cracking, and improve adhesion properties with respect to polar mineral fillers. The last property is of particular importance, since, according to the strength theory, the failure of all composite materials starts at the binder–filler interface. Enhancement of the adhesion strength of bitumen binders with fillers prolongs the service life of composite materials and articles thereof. Highly filled bitumen composites containing up to 95% inorganic fillers (e.g., asphalt concretes) should be prepared using special dressing additives enhancing the adhesion of the binder to the filler. The use of low-molecular-weight dressings is undesirable because of their tendency toward gradual diffusion to the article surface, followed by evaporation and washout with water [2].

As reported previously [3], bitumen–polymer binders (BPBs) containing oxidized atactic polypropylene (APP) exhibit enhanced resistance to thermal oxidative aging. Bitumens prepared by oxidation of vacuum residue contain graphitic crystalline structures with conduction electrons detected by ESR spectroscopy [4]. There is a direct correlation between the concentration of conduction electrons and the rate of thermal oxidative aging of bitumen binders. Addition of a small amount of oxidized APP (about 2.0%) results in disappearance of the conduction electrons (as judged from the ESR spectra), and articles prepared from such bitumen–polymer binders have a prolonged service life.

In this work we examined the effect of oxidized APP on the structure and physicomechanical and adhesion properties of bitumen binders.

EXPERIMENTAL

Atactic polypropylene (Tomsk Petrochemical Plant, Joint-Stock Company) was oxidized by bubbling of atmospheric oxygen through a polymer melt at 180 and 250°C for 2 and 6 h. Low- and highly oxidized APP was prepared. The oxidation procedure and the structure and properties of the resulting polymers are described elsewhere [5]. The moisture absorption of oxidized APP was determined gravimetrically from the weight gain of the polymer kept in water for 72 h. In our work, we used paving and building bitumens [Achinsk Oil Refinery, GOSTs (State Standards) 22 245–90 and 6617–90] prepared by high-temperature oxidation of vacuum residues of commercial West-Siberian oil. Bitumen–polymer compounds were prepared in a heated metallic reactor equipped with a stirrer and a temperature-control unit. The polymer was added to the bitumen melt at 140°C, and the mixture was stirred at this temperature for 40 min.

1070-4272/01/7408-1368 $25.00 © 2001 MAIK "Nauka/Interperiodica"

Oxidized APP completely dissolved in bitumen within 15 min, whereas the initial APP dissolved only partially because of the increased molecular weight and the presence of isotactic fraction as impurity. To record the IR spectra of BPBs, compounds were prepared without heating, by mixing at 20°C benzene solutions of bitumen and polymer of known concentrations. The IR spectra were measured on an Impact 410 Nicolet Fourier spectrometer by the multiple attenuated total internal reflection technique on a zinc selenide crystal [6]. Benzene solutions of BPB were applied to a crystal which was then kept in a desiccator under vacuum for 48 h until the solvent evaporated completely. Melts were applied to a crystal as films at 20°C and then kept for 48 h at room temperature. The measurement conditions were as follows: number of scans 36, resolution 4 cm^{-1}, amplification 4, scan frequency 0.6329, aperture 35, DTGS KBr detector, scanning range 4000 – 650 cm^{-1}. The optical density of IR absorption bands was determned from the ratio of the integral intensity of these bands to that of the C–H bending vibrations band at 1375 cm^{-1}.

The physicomechanical properties of BPBs were determined by standard procedures according to GOST 22245–90; the resistance of BPBs to thermal oxidative aging was evaluated from variation of the softening point of the binder after heating in a thermal chamber a 2-mm layer of its melt for 5 and 10 h [2, 7]. The heat resistance of BPBs was characterized by their softening point which corresponds to the upper limit of their working temperature. The adhesion of BPB to concrete and steel at normal break was determined with mushroom-shaped devices at adhesive layer thickness of 30 – 45 μm [8]. The ultimate adhesion strength was determined with an Instron 1122 tensile-testing machine at a clamp velocity of 10 mm min^{-1}. The dynamic viscosity of BPB melts was measured at 60 – 200°C with a Rheotest-2 rotary viscometer equipped with a temperature-control unit. Bitumen–polymer binders containing 3.0–5.0% polymer were used for preparing asphalt concrete of the following composition (wt %): crushed stone (5–10 mm fraction) 33.0, siftings (<5 mm fraction) 18.9, sand (<5 mm fraction) 23.5, fine mineral powder 18.9, and BPB based on BND 90/130 bitumen 5.7. Asphalt concrete compounds were prepared at 120–130°C, which corresponds to the conditions of the industrial process. The physicomechanical and strength properties of asphalt concrete compounds were determined on standard equipment according to GOST 9128–84.

Appearance of polar carbonyl and hydroxy groups does not affect the water resistance of oxidized APP, since the water absorption is the same for the initial and oxidized polymers. Oxidized APP is readily compatible in the melt with the bitumens of the examined grades. No additional dissolution of the polymer in oil cuts of petroleum is required, which simplifies the process, reduces the cost of BPB, decreases the fire hazard, and improves the service properties of BPB. In the course of prolonged storage (3 years) at temperatures ranging from –30 to +50°C, BPBs undergo no cracking or separation into ingredients.

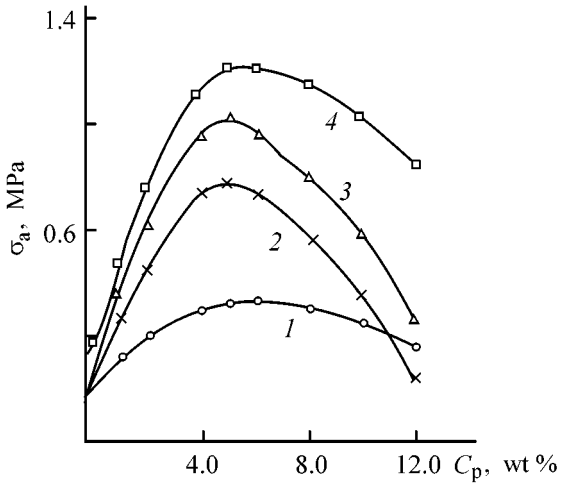

Fig. 1. Ultimate adhesion strength σ_a vs. the polymer content C_p. Support: (*1–3*) concrete and (*4*) St.3 steel. BPB: (*1–3*) BND 90/130 bitumen + APP, highly oxidized APP, and low-oxidized APP, respectively; (*4*) BN 70/30 bitumen + low-oxidized APP.

With increasing concentration of the polymer, the adhesion power of BPB (Fig. 1) is considerably enhanced, reaching a maximum in the polymer content range 4.0 – 6.0 wt %. Compounds containing oxidized APP exhibit higher adhesion to polar materials, which is due to chemical interactions of hydroxy groups of the polymer with carboxy groups of the asphaltogenic acids of bitumens, probably to give esters.

The IR spectra of BPBs, compared with the initial bitumen, contain two new bands peaked at 3280 and 1696 cm^{-1} (Table 1). The relative intensity of the broad band at 3280 cm^{-1} grows with increasing polymer concentration, which confirms the formation of hydrogen bonds between the hydroxy group of oxidized APP and carbonyl group of acids or esters. The stretching vibration band at 1696 cm^{-1} associated with the carbonyl group of the polymer, conjugated with the olefin double bond, is observed in BPB containing APP, suggesting slight oxidation of the polymer in the course of compounding in air. Cross-linking of BPB is accompanied by increase in strength,

hardness, and melt viscosity and decrease in the stretchability of BPB. Similar changes in physicomechanical properties are observed in cross-linking of rubbers and polyethylene with peroxy initiators [9], which suggests that the features of BPB cross-linking are similar. The softening point of BPB significantly deviates from the additive value calculated from the formula without taking into account the chemical interaction of oxidized APP with bitumen components (Fig. 2). Increased softening points of BPBs (i.e., their higher heat resistance) are especially important for use of these compounds in roofings and asphalt concretes, since in summer these materials warm up above the softening point of bitumen. Unoxidized APP has a Fraas brittle point of –15°C; therefore, addition of more than 2.0% polymer increases the brittle point of BPB. For example, a BPB compound containing 95.0% BND 90/130 bitumen and 5.0% low-oxidized APP has a brittle point of –15°C, which is 2°C higher than the prescribed level. The plasticity range of BPB, increases compared with the initial bitumen, by 15°C.

Table 1. Relative intensity *I* of absorption bands in the IR spectra of BPBs

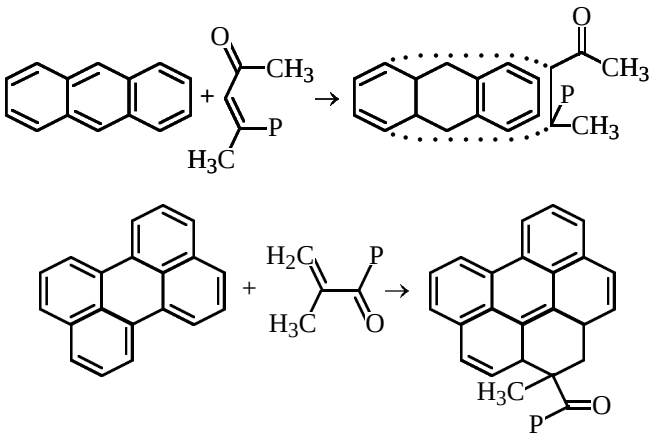
	6.0	0.09	0.52	1.75
	10.0	0.11	0.26	0.75
Highly oxidized APP	2.0	0.01	0.55	1.48
	4.0	0.02	0.56	1.33
	6.0	0.06	0.32	1.18
	10.0	0.07	0.31	0.55

The cross-linking effect of oxidized APP decreases the penetration (P) of BPB. Changes in this parameter for compounds prepared from paving bitumens are more significant than those compounds prepared from building bitumens (Fig. 3, curve *6*). Highly oxidized APP with high content of functional groups in the macromolecule exerts a stronger effect on the BPB penetration owing to chemical interaction of the ingredients in the course of compounding. The P0/P25 ratio characterizing the heat resistance of the binder first slightly decreases and then, on adding 4.0% polymer and more, starts to rapidly increase. The most

sensitive parameter, strongly depending on the content of the polymer in BPB, is the stretchability (Fig. 4), which decreases particularly sharply at 25°C. The use of low-oxidized APP in BPB has virtually no effect on the dynamic viscosity of the binder at temperatures used in industry (120–140°C) for preparing hot asphalt concretes (Fig. 5). Owing to a considerable increase in the BPB viscosity at service temperatures below 100°C, diffusion syneresis is decelerated, and the aging of bitumens is inhibited. The resistance to thermal oxidative degradation of BPB containing 3.0–5.0 wt % low-oxidized APP increases as compared with the initial bitumen by more than a factor of 2, which may be due to chemical interaction of α,β-unsaturated conjugated keto group of the polymer with paramagnetic polyconjugated structural fragments of asphaltenes, carbenes, and carboids in bitumens. Conjugated polymeric α,β-unsaturated ketones are active dienophiles in the Diels–Alder reaction, and linearly and peri-annelated polycyclic compounds of bitumens (anthracene, dibenzanthracene, tetracene, 3,4-benzotetracene, pentaphene, perylene, benzanthrene, and their heterocyclic analogs) readily react as dienes at elevated temperatures [10]. As a result of cycloaddition, the size of the polyconjugated structural fragments decreases, which is manifested in the ESR spectra as disappearance of signals from conduction electrons in BPBs modified with oxidized APP (P is a polymeric radical).



In view of the high reactivity of oxidized APP toward polyconjugated systems, further progress of the Diels–Alder reaction is possible. The adduct of perylene with oxidized APP contains three dienophilic double bonds that are not involved in the aromatic system; they can enter a dominoes-type reaction [11] which occurs between the surface layers of colloidal bitumen particles containing conduction electrons and leads to breakdown of the polyconjugated structural fragments [12]. Distortion of the conjugated chain is accompanied by disappearance of the signals from

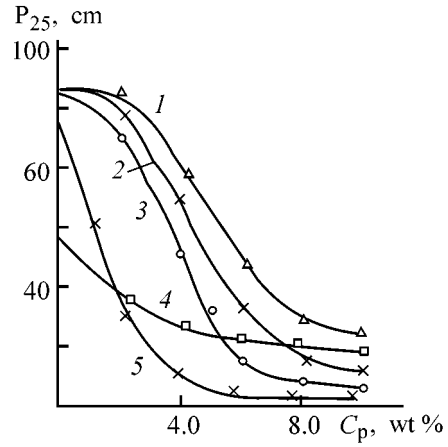


Fig. 4. Stretchability of BPB at 25°C, P_{25}, vs. the polymer content C_p. BPB: (*1–3*) BND 60/90 bitumen + highly oxidized, low-oxidized, and initial APP, respectively; (*4, 5*) low-oxidized APP + BN 70/30 and BND 90/130 bitumens, respectively.

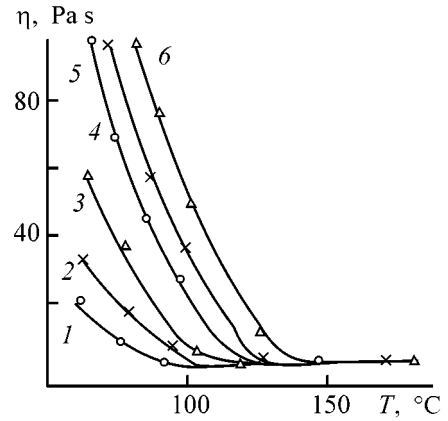

Fig. 5. Dynamic viscosity η of BPB with low-oxidized APP vs. temperature *T*. Bitumen–polymer binder with 5 wt % polymer + bitumen: (*1, 4*) BND 90/130, (*2, 5*) BND 60/90, and (*3, 6*) BN 70/30.

conduction electrons in the ESR spectra, which is experimentally shown in [3]. The proposed mechanism of reaction of oxidized APP with some bitumen components is confirmed by the IR spectra (Table 1). The relative intensity of the vibration band of the conjugated carbonyl group at 1696 cm^{-1} gradually decreases in all the samples, whereas a new band of the nonconjugated carbonyl group appears at about 1712 cm^{-1} with increasing amount of the polymer in BPB, which is consistent with the suggested reaction pattern. The decrease in the intensity of the 1600 cm^{-1} band is due to shortening of the conjugation chain involving aromatic structures. It should be noted that oxidized APP is a more effective bitumen modifier than the initial APP. In BPBs containing oxidized APP, the relative intensity of the 1600 cm^{-1} band

Table 2. Composition and properties of hot asphalt–concrete compounds*

Parameter	APP content in BPB, %			BND 90/130 bitumen
	3.0**	5.0**	3.0	
Water saturation, %	2.6	2.4	3.5	3.8
Swelling, vol %	0.30	0.30	0.65	0.90
Ultimate compression strength, MPa, at temperature, °C:				
50	1.1	1.1	1.0	1.0
20	4.5	4.6	3.8	3.5
20 (after water saturation)	4.4	4.5	3.5	3.1
0	8.3	8.5	9.7	10.0
Temperature sensitivity coefficient	7.5	7.7	9.7	10.0
Water resistance factor	0.98	0.98	0.92	0.88

* All samples show adhesion of the binder to the mineral fraction; mean density 2.3 g cm^{-3}, porosity of the mineral fraction 18.0 vol %, residual porosity 5.0 vol %.

** Low-oxidized APP.

decreases by a factor of 2.8, and in those containing the initial APP, by a factor of 1.7. Similar changes are observed with the bands at 1696 and 3280 cm^{-1}. The proposed mechanism of chemical interaction, though being a matter of discussion, accounts for plains the modifying effect of oxidized APP in bitumens prepared by oxidation of vacuum residue. Oxidized APP stabilizes the colloidal structure of bitumens and simultaneously inhibits BPB aging. Under service conditions, the thermal oxidative aging of bitumen and that of APP occur in opposite directions. Chemical transformations of bitumens involve formation of more condensed molecules and low-molecular-weight substances [2], whereas APP macromolecules are gradually oxidized under these conditions and undergo degradation to give macromolecules of lower molecular weight [5], reacting with polyconjugated bitumen structures.

The properties of hot asphalt concrete compounds are listed in Table 2. Asphalt concrete compounds with low-oxidized APP exhibit lower water saturation, lower swelling in water, enhanced strength at 20 and 50°C, and high water resistance factor. A decrease in the temperature sensitivity coefficient enhances the deformation resistance of road pavements in seasonal variations of the ambient temperature, and the low strength level at 0°C suggests enhanced crack resistance of asphalt concrete at low temperature. Complex improvement of the properties of BPBs modified with oxidized APP allows these materials to be recommended for manufacture asphalt concretes and roofing, corrosion-protecting and waterproofing materials. Oxidized APP is readily compatible in melts and solutions with styrene copolymers, polyethylene, and polyisobutylene, which are widely used for preparing BPBs.

CONCLUSIONS

(1) Oxidized atactic polypropylene is an effective modifier of bitumens prepared by high-temperature oxidation of vacuum residue.

(2) Bitumen–polymer binders containing 2.0–5.0 wt % oxidized atactic polypropylene exhibit enhanced resistance to thermal oxidative degradation and aging and high levels of adhesion, hardness, and heat resistance.

(3) A mechanism of reaction between oxidized atactic polypropylene and polyconjugated polycyclic bitumen compounds is proposed and confirmed by spectroscopic studies.

Received February 8, 2001

Abstract—Quantitative relationship between the structure of organic matter of coals and composition of functional groups in semicoking tars, on the one hand, and the capability of coals for destructive hydrogenation, on the other, was studied.

Long-term researchers' efforts have led to considerable progress in the techniques for thermal transformation of coals, but no processes economically competitive with oil refining have been developed [1–3]. This is largely due to the fact that the structure of these natural polymers is extremely complex. The reasons for high reactivity of coal on heating and for thermal transformations of the coal substance are still unclear [1].

Traditional combustion of coals for power generation [3], though remaining the major pathway of coal utilization throughout the world in the first half of the XXI century, is not already the major line in modern coal chemistry [2, 3]. Much attention is given to qualified processing of coals into carbon materials, fuels, and chemical products, and also to environmental protection. Along with the traditional methods of analysis of physical, chemical, and petrographic characteristics of coals, study of their structure in relation to reactivity has become a separate research line. These lines are prevailing in coal chemistry.

At present, there is a growing trend toward correlating the high reactivity of coals with the presence in their organic matter (OMC) of functional groups, primarily oxygen-containing groups. It is known that the content of oxygen in coals reaches 28% of OMC [4–6]. Since the nitrogen content in brown coals, as a rule, does not exceed 1%, its role is believed to be secondary and is not taken into account in most cases.

The major fraction of oxygen in brown coals (from 60 to 95 [7] or from 70 to 95% [8]) is in the form of reactive functional groups. However, a significant part of oxygen (up to 47%) is in the so-called "unaccounted for" form, i.e., in the form of functional groups and heteroaromatic fragments that are inaccessible for determination by common coal-chemical procedures [4, 7, 8].

The concentrations of various oxygen-containing functional groups in brown coals vary widely. According to [9], the content of functional groups for various deposits of the Kansk–Achinsk basin is as follows (%): –OH 5–11, –CO 3–10, –COOR 1–7, and –COOH 1–3. No ethers were detected. In contrast, according to [10], half of oxygen in the Borodinskoe deposit occurs in carboxylic acid derivatives, including $12 \pm 1\%$ free acids and $13 \pm 3\%$ calcium carboxylate; from 1 to 13% of oxygen is in ethers. The estimate of the ester and lactone content ($21 \pm 1\%$) coincides with that in [9]. The differences between data of various authors are often due to different analytical procedures.

Some researchers assess quite oppositely the influence of oxygen in coals on their transformation into final products. The only fact that is beyond any doubt is that both reactive oxygen-containing groups in coals [11–13] and oxygen in the unaccounted for form [8–11] affect the conversion of coals and the quality of the resulting products. It has been shown [8] that coals with identical main technical parameters show varied reactivity in destructive hydrogenation and that brown coals with increased content of ester and acid groups are more reactive. Conversion of coal in hydrogenation is the higher, the lower the content

1070-4272/01/7408-1374 $25.00

of the unaccounted for oxygen in its organic matter; however, the amount of the forming liquid products decreases in proportion [9]. It was found [11] that oxygen in the cyclic structures makes higher the extent of coal transformation into liquid products. The positive effect of OH [2, 14] and COOH [8, 9] groups on the degree of destructive hydrogenation of coals has been noted. The role of oxygen-containing compounds in coals is significant. They can appreciably affect the rate of coal transformations and, probably, determine the pathways of the main reactions.

The majority of researchers assess qualitatively the influence of particular oxygen-containing groups on thermal transformation of coals. Experiments performed under different conditions and with different coal samples do not allow the data to be combined and even particular oxygen-containing groups to be ranked with respect to their significance in the course of processing. It is impossible to construct quantitative correlations on the basis of these data.

Platonov *et al.* [15–21] made an attempt to assess the diversity of structural features of the OMC carbon skeleton and, in particular, of functional groups, using a large dataset and similar analytical procedures, with the aim of constructing quantitative relationships between the concentrations of particular types of OMC fragments and functional groups and elucidating their correlation with the degree of destructive hydrogenation of coal. Using IR, UV, and NMR spectroscopies, cryoscopy, elemental, quantitative chemical, and structural-group analyses, and capillary GLC, Platonov *et al.* elucidated the structure of a large number of compounds isolated from OMC [19–21] and obtained partial and general linear correlations between the degree of destructive hydrogenation and chemical composition of OMC [19].

The problem was solved in [19] in two steps. First, using data on the group chemical composition and degree of destructive hydrogenation for 27 representative samples taken from various mines, sections, and open pits of the Near-Moscow Coal Fields, for which these characteristics varied widely, Platonov *et al.* obtained separate linear correlations for each parameter (hereinafter, factor) and degree of OMC destructive hydrogenation [20]. Then, the partial dependences were used to evaluate the influence of the whole set of factors on the degree of OMC destructive hydrogenation.

The quantitative results obtained in [19] are contradictory. For example, for the effect of phenol ethers on the yield of liquid products both positive (9) and negative (–0.02) coefficients were obtained. *A* similar pattern is observed with the other factors. Therefore, it is necessary to additionally consider the available large body of experimental data and make substantiated conclusions.

For clearer presentation, let us introduce vector and matrix notations. Vector Y denotes the first column of Table 1 in [19], namely, the experimental degrees of destructive hydrogenation of coal, wt %. The vector consists of 27 components $Y = (87.4, ..., 21.0)^m$. Matrix X denotes the factor concentrations in the coals under consideration, $X \times 10^2$, wt % (Table 1 in [19]) Matrix X has 27 rows and 28 columns. In [20], Platonov *et al.* chose for the polydimensional linear regression problem the model (1) describing the yield of the products of destructive hydrogenation Y as a function of factors:

$$XA = Y. \quad (1)$$

The solution of the problem consists in finding an unknown vector A with 28 components and satisfying the system of linear equations (1). In our case, Eq. (1) has a set of solutions of the form

$$A = A_0 + tA_1, \quad (2)$$

where 28-dimensional vectors A_0 and A_1 are as follows:

A_0 = (–0.3144, –0.0435, 13.4250, 0.1931, –1.2474, 2.4186, 4.7132, 0.6225, –1.2095, –11.8149, 7.6594, –2.1403, –5.3642, –11.4610, 0.7710, –0.2677, –1.2562, –1.1687, 8.6950, –60.5206, –6.8589, –13.6322, 0.1812, 0.3123, 13.6757, 5.3166, 22.7809, 0.0000)^t,

A_1 = (0.1059, 0.1133, –1.0495, –0.0636, 0.0676, –0.1589, –0.4069, 0.1583, –0.0255, 0.7972, –0.5951, 0.3133, 0.3901, 0.7299, –0.0114, 0.0380, 0.1198, 0.0935, –0.4078, 5.6846, 0.0764, –1.7826, –0.0108, –0.1558, –0.1352, –0.4925, –2.9380, 1.0000)^t,

where t is any real number, $-\infty < t < +\infty$.

In a geometric representation, expression (2) sets a straight line in a 28-dimensional space. Each solution of system (1) is a point lying on straight line (2), and, vice versa, each point of straight line (2) is a solution of system (1). It is, however, unclear what solution from the set of possible solutions should be taken for practical use. It has been proved in the evaluation theory that the best solution in such cases is that obtained with the Moore–Penrose pseudo-inverse matrix [22].

Since the set of coefficients given in the regression equation in [19] has not been obtained with the pseudo-inverse matrix and, furthermore, it does not belong to solution (2), we determined the distance in a 28-

dimensional Euclidean space between the point with the coordinates equal to the set of coefficients in [19] and straight line (2). The square of this distance is 385.6, which by no means can be attributed to coefficient rounding in the regression equations. Therefore, the polydimensional regression equation obtained in [19] does not correspond to the initial data, and its use, in contrast to the authors' viewpoint, cannot be useful for optimizing the industrial process.

Data in [19] show that the factors (typical fragments and functional groups of OMC) affect the industrial process to varied extent, with only some of the factors exerting significant influence on the target quantity and the others being less significantly. The problem is to reveal and identify, using appropriate methods, the significant, dominating factors against the "noise" of the other factors.

To solve this problem, we first found the mean values of the yield of destructive hydrogenation products $\overline{Y}$ and the factors $\overline{X}$ by the formulas

$$\overline{Y} = \frac{1}{27}\sum_{i=1}^{27} Y_i \text{ and } \overline{X_j} = \frac{1}{27}\sum_{i=1}^{27} X_{i,j},\ j = 1, 2, \ldots, 28.$$

In the next calculation step, we determined deviations of the yields from the mean value and normalized deviations from the mean values of factors

$$\tilde{Y} = Y - \overline{Y}E,\ X = [\tilde{X} - I\mathrm{diag}(\overline{X_j})]\mathrm{diag}(1/D_j),$$

where E is a 27-dimensional unit vector; I is a 27×28 matrix consisting of unities; $\mathrm{diag}(\overline{X_j})$ is a 28×28 diagonal matrix in which the jth element on the diagonal is equal to $\overline{X_j}$;

$$D_j = \frac{1}{2}(\max X_{i,j} - \min X_{i,j}).$$

Then we found the vector of coefficients A as a pseudosolution to the system

$$\tilde{X}A = \tilde{Y},$$

i.e., $A = \tilde{X}^{+}\tilde{Y}$, where $\tilde{X}^{+}$ is the pseudo-inverse matrix to the matrix.

It should be noted that system (3) describes variation of the yield of coal destructive hydrogenation in the vicinity of mean values, variations of the factors are dimensionless, and the range of variation of each factor is close to (–1, 1). This procedure is extremely useful, since it becomes possible to directly compare the effect of various factors as dimensionless quantities on the yield of liquid products in destructive hydrogenation of coal.

The dimensionless values a of the coordinates of the vector of coefficients A obtained by solution of system (3) are listed in the table. For comparison, we

also present the coefficients a_1 of the linear regression equation obtained in [19]. The coefficients have different dimensions and, therefore, cannot be compared directly.

Comparative analysis of the coordinates of vector A shows that factor nos. 3–7, 13, 16, 23, and 26 affect the yield of the liquid products insignificantly. Therefore, in further consideration they were disregarded. With the number of factors decreased from 28 to 19 and the number of destructive hydrogenation experiments remaining the same (27), it became possible to use the least-squares procedure for subsequent analysis and calculate both the estimates of the coefficients a_i, $i = 1, 2, 3$, and the estimates of their rms deviations da_i, $i = 1, 2, 3$.

Then the problem was solved successively using the least-squares procedure with the LSCOV function (least-squares procedure in the presence of noise) of the MATLAB 5.2 software. The factors with large ratios $da_i/\lvert a_i\rvert$ were rejected three times. As a result, from we determined 11, out of 28 initial, factors that significantly affect the destructive hydrogenation and found the linear regression equation

$$Y = 10.57(X_1 - 22.05)/10.2 + 6.38(X_8 - 4.01)/2.9 + 4.95(X_{12} - 10.32)/4.6 - 6.44(X_{14} - 3.21)/2.8 + 12.67(X_{15} - 21.58)/22.4 + 9.64(X_{19} - 10.02)/5.1 - 11.15(X_{21} - 7.16)/2.9 - 8.71(X_{24} - 6.28)/3.2 + 19.72(X_{25} - 3.86)/2.6 - 12.12(X_{27} - 1.49)/1.0 + 10.06(X_{28} - 1.16)/0.8 + 49.04.$$

The estimates of the rms deviations of the regression coefficients are given in the table.

Our results considerably differ from the conclusions made in [19]. Determination of the coefficients

for the normalized factors revealed three groups of OMC fragments: those positively, negatively, and insignificantly (the largest group) affecting the destructive hydrogenation.

The positive influence, in decreasing order, is exerted by the following fragments: quinoid groups of humic acids > cycloalkanes > dihydric phenols ≈ iodine number ≈ asphaltenes > esters > organosulfur compounds.

The negative influence, in decreasing order, is exerted by the following fragments: keto groups of humic acids ≈ humic acids ≥ phenolic groups of humic acids > metal porphyrins.

The group of components that affect the process insignificantly includes phenol ethers, indanols, cresols, xylenols, alicyclic ketones, terpene derivatives, hydroaromatic hydrocarbons, carboxy groups of humic acids, and organosulfur compounds present in the benzene–ethanol extract.

A quantitative analysis also showed that, when all the factors are taken into account simultaneously, as in the general dependence in [19], the experimental data are reproduced more adequately than in the case when the estimation is made by a single parameter. Indeed, coals are "living" metastable organized systems in which any change can cause a response of the system as a whole. In this case, partial dependences are too rough and cannot describe adequately the structure–reactivity relationship for coals. Apparently, only examination of the whole set of the factors will allow solution of this problem.

The results obtained with our mathematical model suggest that it is desirable to use in destructive hydrogenation brown coals with high content of alkane and cycloalkane fragments containing double bonds, and also ester groups and oxygen-containing fragments.

A striking feature is the extremely high level of the positive effect of quinoid groups of humic acids on the destructive hydrogenation, whereas other functional groups of humic acids exert a pronounced negative effect. In combination with the positive effect of organosulfur compounds and negative effect of metal porphyrins, this fact suggests the leading role of radical processes in destructive hydrogenation of coal.

The data obtained are, of course, estimates, and they require further mathematical study and experimental confirmation, since some factors may in part duplicate each other, e.g., cycloalkanes and asphaltenes (fraction of aliphatic compounds).

CONCLUSIONS

(1) A linear quantitative correlation was found between the chemical structure parameters of brown coal and the yield of liquid products of destructive thermal hydrogenation. Confidence intervals were found for the parameters of this model.

(2) Among a large set of experimentally determined factors, the groups of significant and "noise" factors were distinguished, which allowed simplification of the general dependence.

(3) Structural parameters of the organic matter of coals, positively and negatively affecting formation of liquid products, were revealed, which allows prediction of the capability of coals for destructive hydrogenation.

(4) The functional groups and typical fragments of the organic matter of coal were ranked with respect to the extent of their effect on destructive hydrogenation of coal.

Abstract—A comparative study of elemental composition, thermal characteristics, and IR and NMR spectra of humic acids recovered from modern and fossilized soils was made. The results obtained allow reconstruction of trends in variation of the environmental conditions in the course of soil formation at lake depressions in the Khakassia over a period from 3400 to 850 years before present day.

Soil is natural matter accumulating the results of a combined action of diverse soil-forming factors, such as climate, plant and animal organisms, soil-forming rocks, relief, and time. Therefore, soil features are a peculiar memory about environmental factors controlling soil formation over periods of geological scale.

One of soil substances exhibiting the structural environmental memory is humic acid (HA) [1].

Humic acids are dark gray or reddish-brown nitrogen-containing macromolecular hydroxycarboxylic acids of variable composition. These acids are recovered from soils by treatment with alkaline aqueous solution. Dergacheva *et al*. [1–4] showed that HAs can be used for retrospective analysis of the paleoenvironment evolution.

Bioclimatic conditions that existed in the period of formation of HA macromolecules are mainly responsible for features of this soil substance, such as the ratio of unhydrolyzable and hydrolyzable parts, optical characteristics, ratio of aromatic and aliphatic fragments, degree of aromaticity, polydispersity, capability of forming organomineral complexes, etc. The aim of this work was to reconstruct the features of environmental conditions that existed in the region of lake depressions in Khakassiya during formation of fossilized soils of different ages. To solve this problem, we used previously obtained data on elemental composition, thermal characteristics, and IR and NMR spectra of HAs of well-studied soils [5].

EXPERIMENTAL

In this work, we studied humic acids recovered from soil samples taken from lake depressions located in the Khakassian steppe region (Table 1). The absolute age of these soils varies from 850 ± 45 to 3370 ± 85 years [6]. In passing from the oldest to more recent soils, the content of the total organic carbon (C_{org}) and the ratio of humic and fulvic acids (C_{HA}/C_{FA}) gradually increase. The elemental composition (C, H, N, P) and thermochemical characteristics of HA samples were studied, and the IR and ^{13}C and ^{31}P NMR spectra were recorded. To reconstruct the variation with time of the environmental features via corresponding changes in humic acid characteristics, we used previously obtained data reported in [5].

The carbon, hydrogen, and nitrogen content of humic acids was determined on a 1106 Carlo Erba elemental analyzer. The C and H content was also determined by the technique commonly used in elemental analysis of organic compounds. The total phosphorus was determined spectrophotometrically in the form of a colored complex with a vanadium-molybdenum reagent. Prior to determining phosphorus,

the humic acid samples were burned in a flask filled with oxygen and the resulting residue was dissolved.

The HA NMR spectra was recorded in a solution prepared by dissolving a weighed HA sample in 0.5 M NaOH–D_2O mixture. This solution was placed in a 5-ml cylindrical tube of external diameter 5 mm. The ^{13}C and ^{31}P NMR spectra were recorded on an DRX-500 Bruker NMR spectrometer at frequencies of 125.76 and 202.46 MHz, respectively. The Overhauser effect was eliminated by proton decoupling using the INVGATE technique. The ^{31}P NMR spectra were recorded under monoresonance conditions. In recording ^{13}C and ^{31}P NMR spectra, TMS and H_3PO_4 (85%), respectively, were used as external references. The NMR spectra were recorded with 1-s delay between pulses.

The IR spectra (KBr pellets, HA/KBr = 1 : 50) were recorded on an IR Fourier spectrometer in the 400–4000 cm^{-1} range.

Thermal analysis of HA sample placed in a platinum crucible was carried out on an MOM derivatograph (Hungary) in air with heating from 20 to 1000°C at a rate of 5 deg min^{-1}. The measurement sensitivity was as follows: TG 100 mg, DTG 1/3, and DTA 1/3.

It was found that the elemental composition of HAs recovered from fossilized soils of different ages is consistent with the HA classification proposed by Orlov [7]. It is known [2] that the chemical composition of HA depends not only on the soil type, but also on the bioclimatic conditions of soil formation. The elemental composition of HAs reflects the genet-

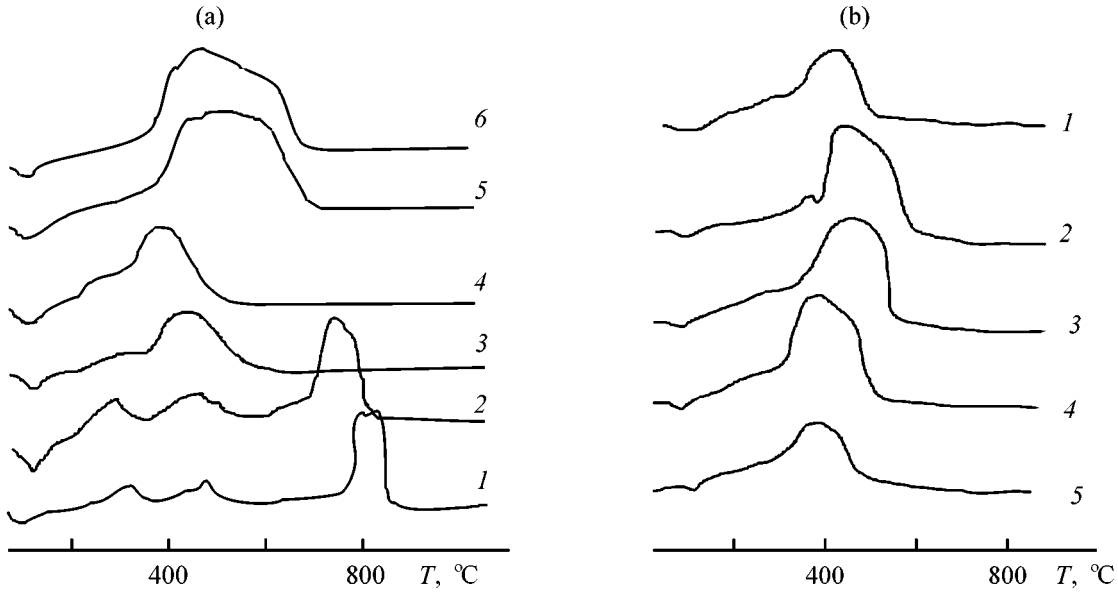

Fig. 1. DTA curves of HAs of (a) modern soils of different climatic zones and (b) fossilized soils. (*T*) Temperature. (a) Soil: (*1*) tundra 1, (*2*) tundra 2, (*3*) tundra 4, (*4*) gray-forest, (*5*) chestnut, and (*6*) south chernozem. (b) Fossilized soils (cm): (*1*) 5–15, (*2*) 7–17, (*3*) 20–27, (*4*) 32–37, and (*5*) 45–49; the same for Figs. 2 and 3.

ic features of soil and is one of the main parameters allowing reconstruction of paleoenvironmental conditions. Humic acids recovered by means of identical techniques from soil samples taken at a step of 5–10 cm from different horizons of the soil profile can be used for time reconstruction of changes in the environmental conditions in a given geographical zone.

We found (Table 2) that the elemental composition of fossilized soils is intermediate between the compositions of steppe and tundra soils. This fact shows that the paleosoils were formed under conditions differing from those for the modern soils. Table 2 shows that in passing from chernozem to tundra surface gley soil, as well as from a top to deeper horizons in a series of the paleosoils, the total carbon content decreases and both H/C ratio and the extent of carbon oxidation O/C increases. The features of paleosoil samples taken from the oldest horizon (45–49 cm) are close to those of tundra soils. The C/N ratio in a series of the humic acids exhibits irregular deviations. Elucidation of the relationship between the C/N ratio and the environmental conditions of HA formation requires further study.

There is a great body of data on HA thermochemical characteristics. These data were analyzed in detail and generalized by Orlov [8]. Thermal analysis is an efficient technique for HA identification. This technique is also promising for elucidation of the effect of artificial and environmental factors on HA composition and properties.

Figure 1a shows that the shape of the DTA curves of HAs of dry-steppe soils significantly differs from those of tundra soils. All the DTA curves show a low-temperature (100°C) endothermic effect. Figure 1 shows also that for HAs of tundra soil the heat evolution is characterized by two pronounced maxima separated by some temperature interval, whereas for HAs of chernozem the exothermic effect extends over a range from 370–400 to 700°C. We believe that this difference is due to the following factors. Decomposition of the aromatic core of HA from dry-steppe soil is accompanied by so pronounced heat evolution that the exothermic effect due to decomposition of small amounts of the aliphatic groups becomes unnoticeable. At the same time, in decomposition of HAs from tundra soil with small aromatic content, the exothermic effects due to decomposition of both the aliphatic and aromatic constituents become well resolved.

As seen from Fig. 1b, for HAs of paleo- and dry-steppe soils the exothermic effects due to decomposition of the aliphatic groups and aromatic core are not clearly resolved. Only one paleosoil sample taken from the 7–17 cm horizon exhibits a distinct exothermic effect at 360°C. We believe that this soil was formed at the middle of intermittently waterlogged flat slope. The DTA curves show also that, with increasing soil age, the temperature of complete HA decomposition decreases, and the peak in the DTA curve shifts toward lower temperatures

corresponding to less thermostable humic acids. However, the behavior of the exothermic peac for HAs from the paleosoil taken from the 5–15 horizon is an exception. It is possible that a shift of the environmental conditions toward cooling and wetting occurred within a period of 940–850 years to present day. This assumption is confirmed by analysis of these soil samples by other techniques.

The IR spectra of both the paleo- and modern soils (Fig. 2) contain a diverse set of absorption bands due due to vibrations of various atomic groups in the HA macromolecule. These spectra are characterized by several features allowing elucidation of the environmental changes over periods on the geological scale. With increasing soil age, the total intensity of the HA absorption bands gradually decreases. The IR spectra of HA of the oldest soils are close to those of the tundra soil.

The ^{13}C NMR spectra (Fig. 3) allow determination of the following functional groups in HA macromolecules: alkyl radicals (0–65 ppm), carbohydrates, alcohols and acetals (65–100 ppm), aromatic core (110–160 ppm), and carboxy groups (160–200 ppm). The above-noted ranges of the ^{13}C chemical shifts of different functional groups are commonly used in analyzing the ^{13}C NMR spectra of humic acids. However, these intervals may differ by 5–10 ppm in a number of cases.

It is known that for low-molecular-weight compounds the integrated intensity of the ^{13}C NMR spectra allows only qualitative determination of carbon atoms of different types. This limitation is caused by the significant effect of the chemical environment on the relaxation rate of the ^{13}C nucleus. However, for humic acids the difference between the relaxation parameters of ^{13}C nucleus with different kinds of environment decreases so that a 1-s delay between pulses is sufficient to ensure their quantitative determination. This is due to low mobility of humic acid molecules and presence in their composition of paramagnetic centers (mainly semiquinones and Fe^{3+} ions).

The content of various functional groups in humic acids from both the modern soils of different climatic zones and paleosoils, determined from the ^{13}C NMR spectra, is given in Table 3. These results show that, with increasing paleosoil age, the content of alkyl groups in HA macromolecule increases from 14.4 to 27.2% and the content of the aromatic core decreases from 44.7 to 25.9%. In HA from paleosoil of 850-year age, the content of alkyl groups is abnormally high (34.2%). With increasing paleosoil age, the content of polysaccharides in the humic acid increases from 10.6 to 29.8%, and the content of the carboxy groups decreases from 14.8 to 6.8%.

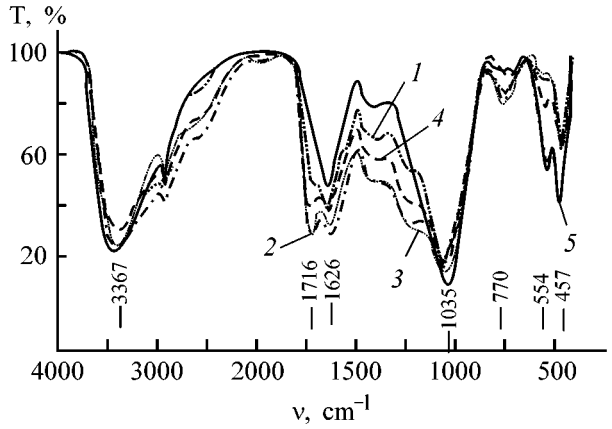

Fig. 2. IR spectra of HAs recovered from fossilized soils: (*T*) light transmission and (ν) wave number.

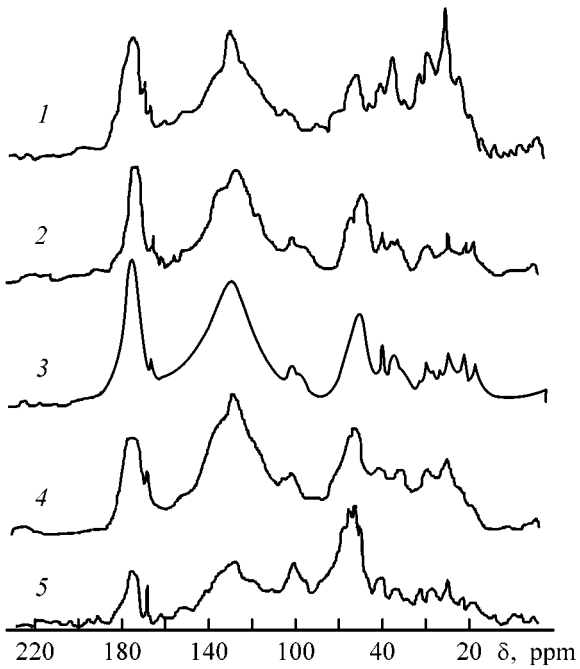

Fig. 3. ^{13}C NMR spectra of HAs of fossilized soils. (δ) Chemical shift.

The ^{31}P NMR spectra of HAs of paleosoils exhibit a broad signal of the phosphorus atoms of phosphate monoesters at about 5 ppm. All the spectra, except that of HAs of the soil sample of 850 ± 45-year age, show the presence of small amounts of diester groups. We found that, on the whole, the humic acids of modern soils contain phosphorus in smaller amounts than humic acids of older soils do.

CONCLUSION

As compared with humic acids of fossilized soils, humic acids of the modern soils are characterized by larger aromatic core, reduced aliphatic component, and modified relative contents of its separate constituents. Since fossilized and modern humic acids were recovered from soils of the same territory, we believe that the above-noted differences between their features are due to gradual warming within a period from 3000–1000 years to present day. The specific features of humic acids of the youngest fossilized soils formed about 850 years ago may indicate cooling and waterlogging that occured during the preceding 100-year period.

Received December 21, 2000

Abstract—The chemical composition of various extracts from oil shale (kerogen-70) was studied in detail.

The composition of oil shale is a subject of numerous studies [1–10]. However, there are no generally accepted views about the origin of the mother substance of kerogen (and shale in general), genetic relationship of its composition with the initial vegetable and animal material and biogeochemical transformations of this material in the course of dia- and catagenesis. There are also no common procedures for studying oil shales, which is primarily due to the complex chemical composition of their organic matter (OM).

This work is devoted to detailed and comprehensive study from the organic matter of oil shale (kerogen-70) from Leningrad oblast. This shale is a competitor formed in the lower Ordovician period and having a purely sapropelite origin. The moisture content of this shale is 25.0, and the ash content, 30.0%. The elemental composition (wt % daf) is as follows: C 69.9, H 8.1, N 0.3, and O + S 21.7. The functional composition (mg-equiv g^{-1}) is as follows: phenolic groups 0.91, keto groups 10.40, quinoid groups 5.90, carboxy groups 0.20, and iodine number 0.36.

To characterize the molecular structure of shale compounds, we used extraction, adsorption-liquid and capillary gas–liquid chromatography (CGLC); elemental, emission spectrum, X-ray fluorescence, quantitative functional, and structural-group analyses; cryoscopy; and IR and UV/Vis spectroscopy.

Extraction of oil shale was performed in a Soxhlet apparatus at the boiling points of the solvents in the sequence shown in the scheme. The yields of separate extracts, their molecular weights, and elemental compositions are given in Table 1.

In the IR spectra of the extracts, we identified the absorption bands of the following structural fragments ($\bar{\nu}$, cm^{-1}):

– aromatic rings [3000–3100, 3030–3070, doublet at 1500–1600 with higher intensity of the low-frequency component, especially for toluene and acetone extracts, which suggests prevalence of monocyclic structures (1450, 675–900)] in these extracts;

Scheme of comprehensive study of shale kerogen.

* (OMS) Organic matter of shale; (M) molecular weight, amu; (C, H, N, O, S) content of carbon, hydrogen, nitrogen, oxygen, and sulfur, wt % daf; (H/C) atomic ratio; (C_a, C_n, C_{as}) degrees of aromaticity, naphthenicity, and alkyl substitution, respectively.

mononuclear aromatic structures give rise to bands at 735 and 710. The chloroform and ethanol extracts contain bi- and tricyclic fragments;

– CH_3, CH_2, and CH groups of alkyl chains and cycloalkane rings (2926–2980, 2860, 2880, 2925, 2960, 1455, 1460, 1470, 1440, 1380, 1375, 1270, 970, 728); long-chain alkanes prevail in the toluene extract, and cycloalkanes, in the chloroform and acetone extracts;

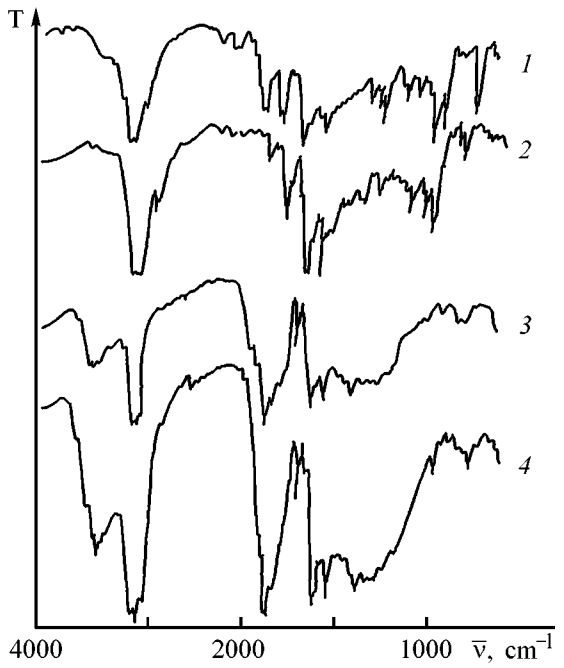

Fig. 1. IR spectra of extracts from shale kerogen: (T) transmission and ($\bar{\nu}$) wave number; the same for Fig. 3. (*1*) C_7H_8, (*2*) $CHCl_3$, (*3*) $(CH_3)_2CO$, and (*4*) C_2H_5OH.

– hydroxy groups of phenols and alcohols (3570, 3300, 1310–1410, 1360, 1330–1420, 1215, 1220, 635–660) prevailing in the acetone and ethanol extracts;

– keto groups (1695, 1705, 1715); aliphatic and alicyclic ketones prevail in the toluene, chloroform, and, especially, acetone extracts, and the ethanol extract contains mainly aliphatic ketones. The major amount of ketones is contained in the acetone extract;

– carboxy groups (2500–3000, 1705, 1715, 1410, 1200–1300, 925), mainly present in the ethanol extract containing aliphatic and alicyclic carboxylic acids. The chloroform extract contains virtually no acids;

– alkoxy groups (2900, 1200–1225, 1085, 1020–1075, 814); ester and lactone groups (1735–1750, 1000–1300, 1163), including methyl esters of long-chain fatty acids (1250, 1205, 1175);

– cyclic anhydrides and amides (1770, 1850, 3400–3450, 1690) prevailing in the acetone and ethanol extracts;

– furan (3125–3165, 1565, 1500, 1030, 885–870, 800–740), thiophene (3050–3125, 1520, 1050, 690–750, 850), and pyrrole heterocycles, amines, pyridine, quinoline, and piperidine fragments (3300–3370, 3440, 3450–3460, 1490, 1250–1350, 745); disulfides (420, 460). The content of furan heterocycles is the highest in the acetone extract; that of thiophene derivatives, in the acetone and ethanol extracts; and that of pyrrole derivatives, in the chloroform extract which also contains significant amounts of amines and various nitrogen-containing heterocyclic compounds.

The IR spectra of the extracts are shown in Fig. 1.

According to the obtained UV/Vis data, the extracts contain (band peak position, nm) unsaturated acids and their derivatives (200), flavonols (250, 370), carotenoid pigments (450, 480–494, 500–550), chlorophylls (380, 418, 428, 464, 510, 580, 675, 700), steroid diketones (280), α-diketones (466), and chromones (625).

Emission-spectral and X-ray fluorescence analyses showed that the mineral fraction of the shale contains Al, Si, S, Cl, Ca, K, Fe, Cu, Ti, Zn, Br, Sr, Pb, Mn, Ni, and V (some of these in the form of organometallic complexes).

Thus, we can conclude that the chemical composition of OMS is very nonuniform; the extracts differ considerably in elemental and functional composition, molecular weight, and nature and content of metals.

In view of the high yield of the toluene extract (Table 1), for obtaining more detailed data on the OMS composition it is appropriate to further separate this extract by adsorption liquid chromatography, with subsequent characterization of the resulting extracts by means of a set of physicochemical methods (see scheme). The yields, molecular weights, and elemental compositions of the eluates of the toluene extract are listed in Table 1.

The major fraction (76.7 wt %) of the toluene extract is eluted with hexane and benzene–hexane (1 : 1); the yield of the chloroform eluate is also rather significant (13.5 wt %, Table 1).

The hexane eluate is characterized by increased H/C ratio and presence in the IR spectrum of strong bands (cm^{-1}) of the CH, CH_2, and CH_3 groups of long alkyl chains and cycloalkane fragments (2950, 2909, 2850, 1450, 1460, 1470, 1378, 1270, 1260, 965, 728). The band at 780 indicates the presence of C_2H_5 groups. Among aromatic compounds, monocyclic compounds prevail (3030–3050, doublet at 1510–1605 with higher intensity of the low-frequency component; series of bands at 1595, 900–1200). Also detected are carotenoids (780, split band at 965, 880), double bonds (1580–1650), minor amounts of long-chain alkanoic acids (1700–1710, 1720), esters, and lactones (1795, 1745, 1760, 1790). The IR data are confirmed by the UV/Vis data. The major absorption peaks (nm) belong to λ-diketones and carotenoids (432, 598, 650), nickel porphyrins (515, 550), unsaturated acids and their derivatives (220), and enones (220, 310).

Using CGLC, we identified in the alkane fraction of the hexane eluate *n*- and *iso*-alkanes C_{11}–C_{37} with maximum at C_{16} (Table 2). The even homologs clearly prevail, and the content of C_{16}–C_{31} components is high. The coefficient characterizing the content of odd homologs is 0.52. The whole chromatogram of the alkane fraction of the hexane eluate is shown in Fig. 2.

Table 2. Content of *n*- and *iso*-alkanes in the hexane eluate

The benzene–hexane eluate, compared with the hexane eluate, is characterized by lower H/C ratio

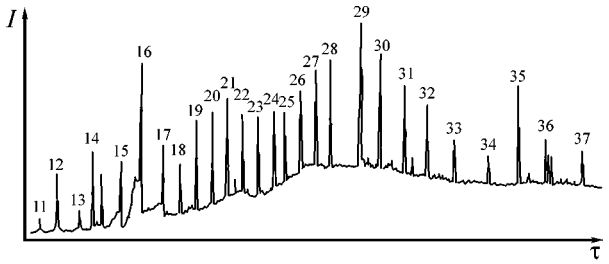

Fig. 2. Chromatogram of the alkane fraction of the hexane eluate of the toluene extract: (*I*) relative intensity and (τ) retention time.

and lower oxygen content. This fact suggests prevalence of weakly polar saturated compounds.

In the IR spectrum of the eluate, we identified the following fragments and bands ($\bar{\nu}$, cm^{-1}):

– aromatic rings, nonconjugated or characterized by low degree of conjugation (C–H stretching vibrations at 3030–3050, C=C in-plane vibrations at 1574–1606, 1480–1510);

– CH_3 and CH_2 groups of long alkyl chains and cycloalkanes (2908, 2950, 2850, 1470, 1460, 1450, 1380, 1270, 1260, 965, 720);

– unsaturated bonds in long alkyl chains; terpenes and carotenoids may also be present (3050–2970, 1850–1800, 1870–1625, 1320–1270, 968, 860, 780);

– keto groups of aliphatic ketonbes (1715, 1705);

– C=O stretching vibrations in esters and lactones (1770, 1745, 1735) and quinones (1675, 1645);

– C–O stretching vibrations and O–H in-plane bending vibrations in primary and secondary alcohols (1075–1000, 1350–1260 and 1120–1030, 1350–1260, respectively); O–H stretching vibrations in alcohols (3400 with shoulders at 3480 and 3450) involved in inter- and intramolecular hydrogen bonds.

By UV/Vis spectroscopy we detected in this eluate the following compounds (band peak position, nm): unsaturated compounds (200), naphthalene rings (200, 281, 314), steroid derivatives (284, 338), carotenoids (338, 428, 440.5); chlorophyll b (428, 465, 675), and chlorophyll (380, 418, 428, 510, 580, 700).

According to elemental analysis (Table 1), the benzene eluate, has the lowest carbon content and a significant content of oxygen and sulfur. This fact suggests that this eluate mainly consists of polar and unsaturated compounds.

According to the IR spectra, the following fragments prevail in the eluate ($\bar{\nu}$, cm^{-1}): CH, CH_2, and CH_3 groups of alkanes and cycloalkanes (2960, 2925, 2880, 1460–1470, 1475, 1380; the broad band is split, suggesting the presence of isopropyl and *gem*-dimethyl groups); band at 770–780 is characteristic of ethyl groups, and that at 735, of *n*-propyl groups; aromatic rings (3040–3045, doublet at 1500–1600, 1610, a series of bands at 900–700); aliphatic ketones (1715, 1100); ester groups (1735), three bands at 1000–1300, 1300–1310, 1000–1065; four-membered cyclic ketones (1780). The presence of the thiophene ring is confirmed by bands at 700, 1040, 1520, 3050–3125. The UV/Vis spectra (λ, nm) suggest the presence in the benzene eluate of meso-chlorins (619), chlorophyll b (442, 578, 628), carotenoids (440), cisoid cyclic diene (262) of the λ-terpinene type, flavonols (279, 380), chlorophyll b (728, 464, 675), and compounds with a thiophene ring (302).

The chloroform eluate is characterized by relatively high yield and increased H/C atomic ratio (Table 1), suggesting the presence of large amounts of aliphatic and hydroaromatic structures.

In the IR spectra, we identified ($\bar{\nu}$, cm^{-1}) alkane and cycloalkane structures (2960, 2925, 2860, 1470–1455, 1380 sharp, 1260, 970), aromatic rings (3010–3080, doublet at 1500–1600, 1580), mainly condensed, possibly with admixture of hydroaromatic rings; alkoxy (2850, 2815–2830, 1070–1150, 1070–1020), quinoid (1676, 1638), keto (1720, 1710, 1695) groups; pyridine, quinoline, pyrrole, and indole rings (3490, 3100–3125, doublet at 1500–1600, 1010–1035, 740–770, 770–830).

By UV/Vis spectroscopy, we detected in this eluate (λ, nm) steroid diketones (280), chromones (625), porphyrin rings (520, 560), carotenoids (440.5), chlorophyll a (380, 418, 428, 510, 580, 700), and chlorophyll b (428, 465, 675).

The acetone eluate is characterized by high content of oxygen and sulfur and medium H/C atomic ratio (Table 1); hence, it mainly consists of strongly polar aromatic compounds. According to the IR spectra, the content of alkyl groups is insignificant; we detected aromatic rings (3000–3060, a doublet at 1500–1600, 1200–900), including phenanthrene structures (890, 812, 800, 760). The major oxygen compounds ($\bar{\nu}$, cm^{-1}) are cyclic ethers (broad band at 1180–1290), steroid alcohols [3390, 3200, 1612, 1585, 1500, 1435–1415 (O–H groups in steroids-17), 1054, 870, 815], and ketones (1725, 1715, 1690).

According to the UV/Vis spectra, the acetone eluate contains (λ, nm) alkylbenzenes (263.5, 202); cyclic α-diketones (263.5, 323); chlorins (696); presumably, derivatives of flavonols, anthocyan (510–550), and anthocyanidins (404, 449, 346); carotenoids (440.5); chlorophyll a (388, 418, 428, 510, 580, 700); chlorophyll b (428, 465, 675).

The ethanol extract has rather high content of oxygen and sulfur and low H/C ratio, which suggests the presence of strongly polar compounds (Table 1).

According to the IR spectra, the prevailing components of this eluate ($\bar{\nu}$, cm^{-1}) are long-chain carboxylic acids, esters, ketones, lactones (2960, 2925, 2860, 1755–1770, 1715, 1720, 1730, 1740, 1780 broad,

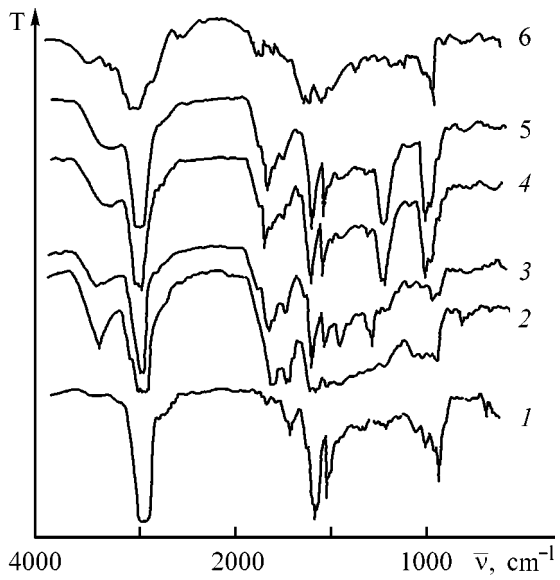

Fig. 3. IR spectra of separate eluates of the toluene extract.

1460, 1470, 1480, 1375–1380, 1260, 970, 720) and alcohols (3170, 3420, 3620, 1310–1410, 1155). By UV-Vis spectroscopy we detected (λ, nm) chlorins (698), in particular, meso-pyrroetiochlorins (642); diketones of the diterpene series (311); coumarone derivatives (shoulder at 240 and peak at 283); flavonols (251, 371, 510–540); chromone derivatives (622); pyrrole rings (214); chlorophyll b (428, 465, 675).

The IR and UV/Vis spectra of separate eluates of the toluene extract are shown in Figs. 3 and 4.

CONCLUSIONS

(1) The chemical composition of the toluene extract from oil shale (kerogen-70) was studied for the first time by using a combination of extraction, adsorption-liquid and capillary gas–liquid chromatography; elemental, emission spectrum, X-ray fluorescence, quantitative functional, and structural-group analyses; cryoscopy; and IR and UV/Vis spectroscopy.

(2) A procedure including extraction and adsorption liquid chromatography was developed for separating oil shale into fractions differing in molecular weight, elemental and functional composition, degree of aromaticity, and type of condensation.

(3) The formation of the organic matter of shale involved not only an algal material, but also a terrigenic material of higher plants, bacterial bioproduction, animal bodies, and fungi.

Refining the Phase Diagram of the System $3Al_2O_3 \cdot 2SiO_2$–ZrO_2

S. S. Ordan'yan, P. S. Gudovskikh, and O. V. Pozhidaeva

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received February 19, 2001

Abstract—The quasi-binary section mullite–zirconium dioxide in the ternary system Al_2O_3–SiO_2–ZrO_2, described by an eutectic phase diagram with T_{eut} = 1750°C, was studied experimentally.

Published ternary phase diagrams of the system Al_2O_3–ZrO_2–SiO_2 are constructed on the assumption that the section mullite–ZrO_2 is a quasi-binary system of a simple eutectic type [1]. Tentatively constructed phase diagrams [2, 3] contain no experimental data on the true composition and melting point of the eutectic in the $3Al_2O_3 \cdot 2SiO_2$–ZrO_2 quasi-binary system. Moreover, this section was not, probably for technical reasons, among the seven sections studied in detail in [4]. This made it necessary to specify the position of the eutectic point in the $3Al_2O_3 \cdot 2SiO_2$–ZrO_2 quasi-binary system, which is of great importance for fabricating refractory structural materials.

Initially, the phase diagram of this system was calculated in terms of the ideal solution approximation [5] relying upon the Schroder–Le-Chatelier equation for determining the liquidus temperatures.

According to the calculations, the eutectic contains 12 wt % ZrO_2 and its melting point is 1870°C; however, the calculated values were found to be in disagreement with experiment. For this reason, the system was studied by differential thermal (DTA), metallographic, and X-ray phase (XPA) analyses. Compositions with various weight contents of mullite and zirconium dioxide were prepared by mixing powdered starting components in isopropyl alcohol.

The differential thermal analysis was performed in molybdenum crucibles in an atmosphere of helium, using a VTA-980 high-temperature analyzer. Heating was performed to 2200°C at a rate of 10–80 deg min^{-1}.

The DTA curves of samples containing 10–70 wt % ZrO_2 showed clearly resolved peak at 1750°C ± 15°C (Fig. 1), attributable to an irreversible endothermic effect. This temperature was taken to be the eutectic melting point.

For a number of the compositions studied, another endothermic effect attributable to liquidus line crossing was recorded (see the table). This endothermic effect was not recorded for the composition containing 70 wt % ZrO_2. Thus, we can conclude that the liquidus temperature for this composition is above 2200°C. The lack of the second effect in heating the mixtures containing 30 and 35 wt % ZrO_2 can be accounted for by the impossibility of resolving by means of thermal analysis the liquidus and solidus temperatures for compositions close to the eutectic.

Thus, the performed analysis of the DTA data suggests that the eutectic in the $3Al_2O_3 \cdot 2SiO_2$–ZrO_2 system has a melting point of 1750 ± 15°C and contains 30–35 wt % ZrO_2.

The structure of samples formed upon melting and crystallization of the mixtures in the course of DTA was studied by optical microscopy. A typical eutectic structure was observed for a composition containing 30 wt % ZrO_2. In addition to the characteristic eutectic structure, excess grains of mullite could be

Thermal analysis data

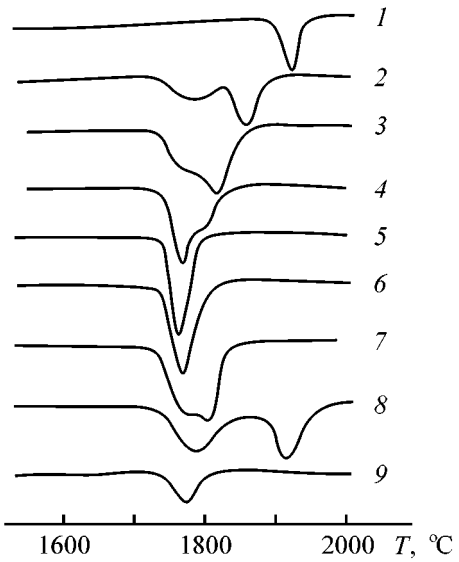

Fig. 1. DTA curves of samples of the $3Al_2O_3 \times 2SiO_2$–ZrO_2 system. (*T*) Temperature; the same for Fig. 2. ZrO_2 content (wt %): (*1*) 0, (*2*) 10, (*3*) 20, (*4*) 25, (*5*) 30, (*6*) 35, (*7*) 40, (*8*) 50, and (*9*) 70.

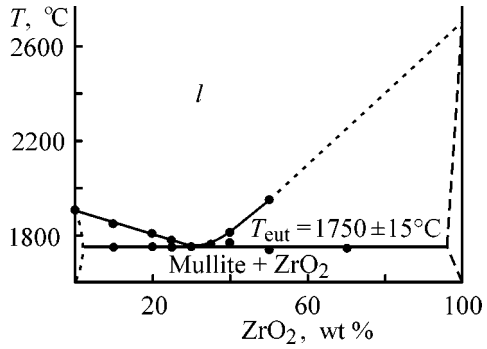

Fig. 2. Experimental phase diagram of the system mullite–zirconium dioxide.

seen in polished sections of samples containing 10, 20, and 25 wt % ZrO_2; and excess ZrO_2, in sections of samples containing 35 wt % and more ZrO_2.

According to XPA, all the samples studied are two-phase and contain only *m*-ZrO_2 and mullite, which confirms the assumed quasi-binary character of the section studied.

In constructing the phase diagram, the melting point of pure ZrO_2 was taken to be 2700°C [6, 7]. The evidence on the character and temperature of melting of pure mullite is contradictory [8]. A DTA curve of mullite preliminary obtained by solid-phase synthesis at 1600°C demonstrated another endothermic peak at 1910°C (Fig. 1a). Just this temperature was accepted as the melting point of pure mullite in constructing the phase diagram, in agreement with [9].

An experimental phase diagram of the quasi-binary system $3Al_2O_3 \cdot 2SiO_2$–ZrO_2 is presented in Fig. 2; the mutual solubility of components was not studied.

The whole set of data furnished by the differential thermal, metallographic, and X-ray phase analyses suggests that the system $3Al_2O_3 \cdot 2SiO_2$–ZrO_2 is indeed a quasi-binary eutectic system. The eutectic contains 30 wt % ZrO_2 and 70 wt % $3Al_2O_3 \cdot 2SiO_2$ and its melting point is 1750°C.

The obtained data may serve as a basis for developing high-temperature ceramic composites.

Received June 21, 2000; in final form, May 2001

Abstract—The possibility of processing aluminum sulfates into alumina with the use of calcium carbonate was studied.

Production of alumina from aluminum sulfates in processing of high-silica aluminum ores (alunites, nephelines, clays, poor-quality bauxites, siallites, etc.) is of great practical interest. The known methods to obtain alumina from aluminum sulfates have a number of shortcomings: cumbersome technological schemes, difficult deferrization of solutions, necessity for high-temperature heating of salts containing a great amount of crystallization water, evaporation of large amounts of mother liquors, and high energy expenditure for thermal decomposition of aluminum sulfates.

For example, according to the Kalunit scheme [1], dehydrated alunite ore is leached with reused sulfuric acid containing potassium sulfate. Fe(III) is removed from the sulfate solutions with dehydrated alunite ore. A more thorough removal of iron(III) from solutions can be achieved in the scheme by recrystallization of alum calcined at 1000°C. SO_2 and SO_3 gases obtained in calcination are used in production of sulfuric acid. The product of alum decomposition is leached with water, with sulfates of alkali metals dissolved and alumina remaining in a sediment.

In another method [2], clay is treated to remove Fe(III) with a weak solution of sulfuric acid, calcined, and decomposed with sulfuric acid. Aluminum and iron(III) hydroxides isolated from the sulfate solution by adding Na_2CO_3 are dissolved in alkali, and $Al(OH)_3$ is isolated by carbonization. Aluminum hydroxide is then used to obtain alumina by calcination.

Much attention has been given by researchers to processing of alunite ores [3]. Alunites are sulfated aluminates of alkali metals—$MAl_3(OH)_6(SO_4)_2$, where M = Na, K. The sulfate products obtained in ore processing are used to obtain alumina by various methods. However, all of these require improvement and simplification of their technological schemes.

The present study is concerned with the possibility of processing of aluminum sulfates with the use of calcium carbonate to obtain alumina without solution evaporation or crystallization and thermal decomposition of salts, which much simplifies the technology.

An aluminum sulfate solution to be used in the experiments was obtained by processing an alunite ore of the following chemical composition (wt %): Al_2O_3 27.5, K_2O 7.2, Na_2O 0.15, SO_3 26.3, Fe_2O_3 1.3, CaO 1.08, SiO_2 24.1, and calcination loss 12.37. The ore was sintered at 400–650°C and the resulting mass was treated with 10–20% sulfuric acid at 100°C in the reactor. The resulting suspension (sludge) was filtered to remove the solid phase (SiO_2 and its compounds). The filtrate contained sulfates of aluminum, iron(III), potassium, sodium, etc.

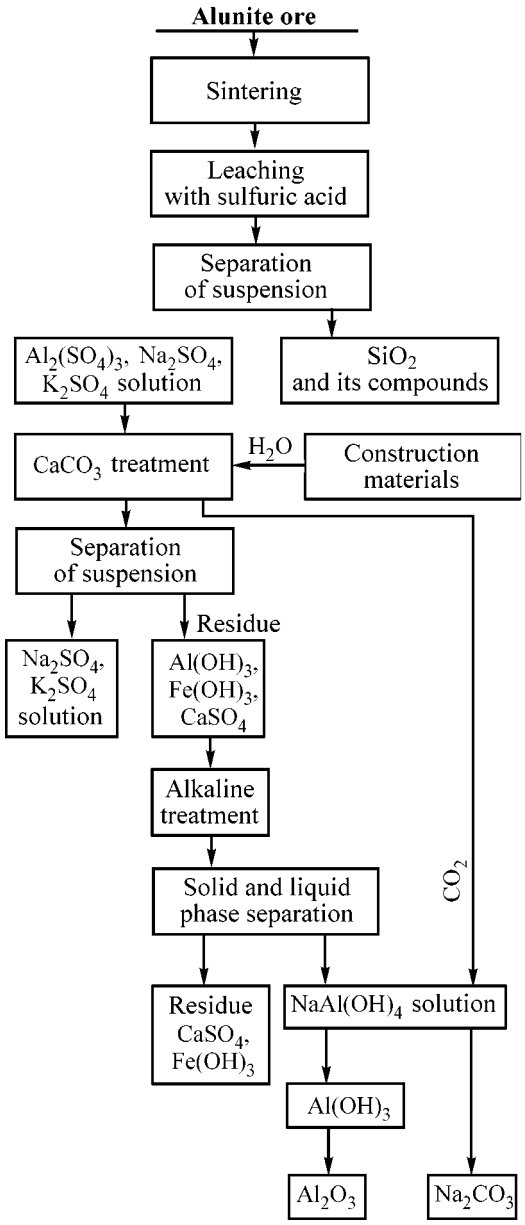
To the filtrate was added calcium carbonate for aluminum(III) and iron(III) to be precipitated in the form of their hydroxides by the reactions

$$Al_2(SO_4)_3 + 3CaCO_3 + 3H_2O \rightarrow 2Al(OH)_3\downarrow + 3CaSO_4 + 3CO_2\uparrow, \quad (1)$$

$$Fe_2(SO_4)_3 + 3CaCO_3 + 3H_2O \rightarrow 2Fe(OH)_3\downarrow + 3CaSO_4 + 3CO_2\uparrow. \quad (2)$$

The obtained mass was agitated in the reactor with a stirrer at 20–30°C for 10–30 min. Then the liquid and solid phases of the suspension were separated. The filtrate was composed of potassium, sodium, and other sulfates; the residue contained $Al(OH)_3$, $Fe(OH)_3$,

1070-4272/01/7408-1392 $25.00 © 2001 MAIK "Nauka/Interperiodica"



and $CaSO_4$. $MgCO_3$ or $CaMg(CO_3)_2$ (dolomite) could be used for the above purposes instead of $CaCO_3$.

To obtain alumina, the mixture of aluminum and iron(III) hydroxides and calcium sulfate was subjected to alkaline treatment, and then $Fe(OH)_3$ and $CaSO_4$ were separated from the aluminate solution by filtration. The sodium aluminate solution was carbonized to give $Al(OH)_3$ transformed into alumina upon dehydration at 650°C.

In the present study, the influence exerted by various factors: treatment temperature T, process duration τ, amount (dosage) of $CaCO_3$ (relative to stoichiometry) C_{CaCO_3}, mass ratio of liquid and solid phases l : s, on the degree α of $Al(OH)_3$ and $Fe(OH)_3$ precipitation from sulfate solution was studied (Table 1).

Table 1. Effect of various factors on the degree of precipitation of $Al(OH)_3$ and $Fe(OH)_3$ from their sulfates

T, °C	τ, min	l : s, by weight	C_{CaCO_3}, % relative to stoichiometry	α, %	
				$Al(OH)_3$	$Fe(OH)_3$
20	60	10 : 1	100	90.1	86.7
60	60	10 : 1	100	96.3	91.9

100	40	10 : 1	100	98.8	97.9
90	50	1 : 1	100	98.8	97.9
90	50	4 : 1	100	74.9	70.3
90	50	8 : 1	100	97.8	95.4
90	50	12 : 1	100	99.6	99.2
100	60	9 : 1	90	87.4	85.6
100	60	9 : 1	95	96.1	95.2
100	60	9 : 1	100	99.6	99.7
100	60	9 : 1	105	95.7	93.1

Table 2. Effect of various factors on recovery of aluminum(II) from solid residue in its alkaline treatment

T, °C	C_{NaOH}, g l^{-1}	Al_2O_3 recovery, %
20	250	85.4
60	250	95.7
90	250	98.9
100	50	89.4
100	100	92.8
100	200	100.0

The obtained results suggest that the optimal process conditions are as follows: T = 50–100°C, τ = 40–60 min, stoichiometric dosage of $CaCO_3$, l : s = 6 : 1–10 : 1.

Further, the process of alkaline treatment of the obtained residue, containing $Al(OH)_3$, $Fe(OH)_3$, and $CaSO_4$, was studied in order to separate the residue into components and make these marketable. For this part of the technological process, the effect of various factors on the extraction of residue components, namely, aluminum and iron, into solution was studied. The basic results for recovery of aluminum in the form of Al_2O_3 from a mixture of $Al(OH)_3$, $Fe(OH)_3$, and $CaSO_4$ in alkaline treatment are presented in Table 2.

When a mixture of $Al(OH)_3$, $Fe(OH)_3$, and $CaSO_4$ is treated with alkali, $Al(OH)_3$ dissolves in accordance with the equation

$$Al(OH)_3 + NaOH \rightarrow Na[Al(OH)_4]. \quad (3)$$

The obtained mixture is filtered, with the solid phase composed of a mixture of $Fe(OH)_3$ and $CaSO_4$, processed into a pigment (Fe_2O_3) and alabaster ($CaSO_4 \cdot 0.5\ H_2O$). The liquid phase consists of sodium aluminate. The filtrate is treated with carbon(IV) oxide formed in accordance with Eqs. (1) and (2). As a result of this treatment, $Al(OH)_3$ precipitates:

$$2Na[Al(OH)_4] + CO_2 \rightarrow Na_2CO_3 + 2Al(OH)_3\downarrow + H_2O. \quad (4)$$

Calcination of aluminum hydroxide at 550–600°C gives alumina (see the scheme).

The method also enables processing into alumina of basic aluminum sulfates, with the consumption of $CaCO_3$ markedly reduced in this case. It should also be noted that the chemical composition of potassium and sodium sulfates in the starting sludge remains unchanged. These salts are isolated from the mother liquor by crystallization.

CONCLUSIONS

(1) The optimal mode of $Al(OH)_3$ formation from $Al_2(SO_4)_3$ with the use of calcium carbonate is as follows: treatment temperature 50–100°C, process duration 40–60 min, stoichiometric dosage of $CaCO_3$, l : s = 6 : 1–10 : 1.

(2) A technique was developed for obtaining alumina from poor-quality aluminum ores.

Independent Method for Determining the Anisotropic Component of the Energy of Intermolecular Interactions in Strongly Polar Liquids

A. N. Bykov and S. M. Karabanov

OAO Ryazanskii Zavod Metallokeramicheskikh Priborov, Ryazan, Russia

Received April 26, 2001

Abstract—A simple method is proposed for determining the anisotropic component of the energy of intermolecular interactions in strongly polar liquids.

It is known [1] that the anisotropic component of the field of molecular forces affects virtually all of the thermodynamic properties of polar liquids, and, therefore, determining its value is of particular practical importance. According to the commonly accepted approach to description of the energetics of intermolecular interactions (IMI) in liquid insulators [2, 3], the IMI energy is operationally separated into the anisotropic and isotropic components—ΔU_{an} and ΔU_{is}, respectively. Then the total energy of a molecule, ΔU_s, is given by

$$\Delta U_s = \Delta U_{is} + \Delta U_{an}.$$

By ΔU_{an} and ΔU_{is} are understood the ΔU_s components which are, respectively, dependent on, and independent of the orientation of the polar molecule. This communication proposes an unsophisticated independent method for evaluation of ΔU_{an} for simple unassociated strongly polar liquids in which ΔU_{an} is determined by the orientation of dipole molecules in local molecular fields. As shown in [4], the extent of mutual compensation of dipole moments B of molecules within a sample of polar liquid, taken in a vacuum, is determined by the average strength of the local molecular field **F** created by all other particles of the system at the center of an arbitrarily chosen molecule:

$$B = \frac{\langle M_d^2 \rangle_0}{N\mu^2} = 1 - L(\alpha), \quad (1)$$

where $\langle M_d^2 \rangle_0$ is the average squared spontaneous electric moment of a macroscopic sphere in a vacuum, N the number of molecules within the sphere, μ the di-

pole moment of molecules in liquid, $L(\alpha)$ the Langevin function of α, and

$$\alpha = \frac{\mu\langle|\mathbf{F}|\rangle}{kT}. \quad (2)$$

The $\langle M_d^2\rangle_0$ value is determined by Fröhlich's strict thermodynamic relation [5]

$$\frac{\varepsilon - \varepsilon_\infty}{\varepsilon + 2} V = \frac{4\pi}{3}\frac{\langle M_d^2\rangle}{3kT}. \quad (3)$$

The μ value is given by the conventional approximation

$$\mu = \mu_0 \frac{\varepsilon_\infty + 2}{3}\,\frac{2\varepsilon + 1}{2\varepsilon + \varepsilon_\infty}, \quad (4)$$

where $\varepsilon_\infty \cong 1.05 n_D$, and n_D is the refractive index.

In the case of strongly polar liquids ($\alpha >> 1$), it can be written with sufficient accuracy that

$$L(\alpha) \cong 1 - \alpha^{-1}.$$

Then, using Eq.(1), we have

$$\alpha^{-2} - 2\alpha^{-1} + B = 0, \quad (5)$$

whence

$$\alpha = [1 - \sqrt{1 - B}\,]^{-1}. \quad (6)$$

Using Eqs. (1) and (6) for the average energy of anisotropic interaction of polar molecules in a mole of liquid, we obtain [4]

$$U_{an} = \frac{1}{2} N\langle \mu\mathbf{F}\rangle \cong \frac{1}{2} N\mu L(\alpha)\langle|\mathbf{F}|\rangle = \frac{1}{2} L(\alpha)\alpha RT$$

$$= \frac{RT}{2}\,\frac{\sqrt{1 - B}}{1 - \sqrt{1 - B}}. \quad (7)$$

At $B << 1$ we have

$$U'_{an} \cong \frac{2 - B}{2B} RT. \quad (8)$$

As shows comparison of the $\Delta U'_{an}$ values calculated using relation (8) with the result obtained in determining ΔU_{an} by another independent method [2, 3], whose efficiency was convincingly confirmed in describing quantitatively numerous processes in liquids, there is satisfactory agreement between $\Delta U'_{an}$ and ΔU_{an}. The average deviation for the nine considered liquids was about 10% (see table).

Structuring in Interphase Layer of Extraction System

N. F. Kizim, O. P. Nesterova, and V. A. Malyukova

Novomoskovsk Institute, Mendeleev Russian University of Chemical Technology, Novomoskovsk, Russia

Received December 26, 2000; in final form, April 2000

Abstract—The results of a study of the rheological properties of the interphase layer formed when an aqueous phase containing HCl and $PrCl_3$ is brought in contact with a solution of an extracting agent (nonoxymethylphosphonic acid) in toluene at varied content of the components in the system are presented.

In extraction of metal ions with organophosphorus acids, an important role is played by interphase layers within which chemical reactions between the components of the extraction system, giving rise to two-dimensional structures, can be localized [1].

The influence exerted by the content of components on the rheological properties of an interphase layer formed on bringing in contact the $PrCl_3$–H_2O–HCl system with a solution of nonoxymethylphosphonic acid (NMPA) in toluene was investigated.

The rheological parameters were found from kinetic deformation curves [2] obtained by the method of tangential displacement of a plate at 298 K and from flow curves. A 0.1-mm-thick plate 3 mm in diameter, made of a ferromagnetic material and platinum plated to improve its corrosion resistance, was used in the study.

The method consists in that the displacement of plate 1 at the phase boundary under the action of an electromagnet driven by voltage U (V) from a dc power supply was measured with a microscope at certain intervals of time t. Preliminary experiments demonstrated that the shear stress is proportional to the electric voltage across the electromagnet terminals. The measurements were done until the displacement of 1 became larger than 1 mm. The measurement error did not exceed 10%. The experimental technique was described in detail in [3].

Typical flow curves obtained at varied content of the components $PrCl_3$ and HCl and the extracting agent NMPA are presented in Fig. 1. An analysis of the rheological curves demonstrated that, under the conditions studied, the adsorption layers can be classed as systems of three types [4–6]: approximately Newtonian, Newtonian-dilatant, and weakly structured.

With increasing solution acidity, there occurs a transition from an approximately Newtonian system in a 10^{-4} M solution of HCl to a weakly structured system, disintegrating in the course of time in a 10^{-4}–10^{-3} M solution of HCl and becoming more stable at $C > 10^{-3}$ M HCl.

When the NMPA content is varied (0.2–0.4 M), weakly structured layers are formed, mainly with a structure becoming stronger with time.

The structure strengthening is presumably due to hindered diffusion and orientation of the extracting agent molecules being adsorbed, which can both dissociate at low HCl concentrations and form a polymeric structure at higher HCl concentrations.

Raising the concentration of the extracting agent makes weaker the contact interaction and leads to higher flowability and longer time of the elastic aftereffect.

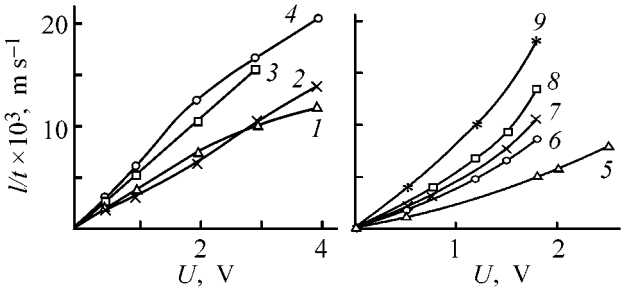

Fig. 1. Rheological flow curves for interphase layers. (l/t) Flow velocity and (U) voltage across electromagnet terminals. Time of contact between phases (h): (*1*) 9, (*2, 4*) 0.5, (*3, 9*) 4.5, (*5*) 10, (*6*) 5, (*7*) 1, and (*8*) 2.5. Concentration (M): HCl: (*1, 4–7*) 10^{-2}, (*2, 3*) 10^{-4}, and (*8, 9*) 10^{-3}; $PrCl_3$: (*1, 4*) 0.05 and (*2, 3, 5–9*) 0.75; extracting agent: (*1, 4*) 0.2 and (*2, 3, 5-9*) 0.4.

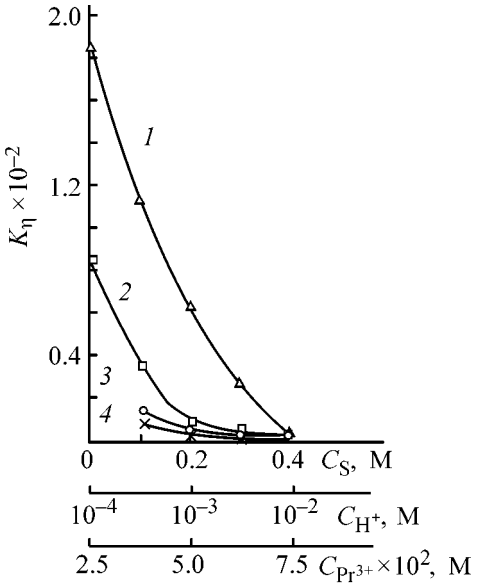

Fig. 2. Structuring factor K_η vs. the concentrations of the system's components: (*1, 2*) HCl, C_{H^+}; (*3*) extracting agent, C_S; and (*4*) $PrCl_3$, $C_{Pr^{3+}}$. Time of contact between phases (h): (*1*) 1 and (*2–4*) 4.

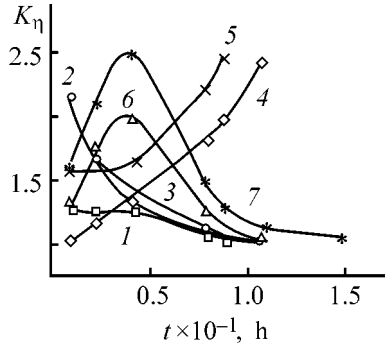

Fig. 3. Structuring factor K_η vs. the time of contact between phases *t*. Concentration (M): HCl: (*1, 4–7*) 10^{-2}, (*2*) 10^{-4}, and (*3*) 10^{-2}; $PrCl_3$: (*1*) 0.025, (*2–4, 6, 7*) 0.075, and (5) 0.05; extracting agent: (*1, 5–7*) 0.2 and (*2–4*) 0.4.

The broadest spectrum of interphase layer states is manifested when varying the salt concentration in the range $(2.5–7.5) \times 10^{-2}$ M $PrCl_3$: approximately Newtonian, Newtonian-dilatant, and weakly structured kinds of systems. In the $PrCl_3$ concentration range $(2.5–5.0) \times 10^{-2}$, slowed-down formation of the interphase layer is observed, taking 8 h. A transition to dilatant systems occurs, as shown by [5, 6], when stabilization is enhanced and nearly monodisperse systems are formed. The maximum layer flowability is observed at a $PrCl_3$ content of 5.0×10^{-2} M. At higher concentrations of the salt, the interphase layers can be regarded as weakly structured systems. Modification of the adsorption layers—"stretching"— causes irreversible disintegration of contacts, upon which the surface layer becomes a Newtonian system as regards its rheological parameters.

Viscosity is a rheological parameter that is the most sensitive to the influence of the factors under study. An estimate was made of the structuring factor K_η in relation to the concentration of the components of the system (Fig. 2).

The concentration dependence of the structuring factor indicates that introduction of acid and extracting agent makes the structuring factor lower. The dominating influence is exerted by hydrochloric acid: the K_η value decreases by nearly two orders of magnitude in the interval 10^{-4}–10^{-2} M HCl 1 h after the formation of the adsorption layer. The extracting agent also strongly affects the K_η value. In the course of time, the steep decrease in K_η slows down and the influence domain is shifted to lower HCl concentrations.

The whole set of results obtained in studying the structuring kinetics at varied content of components reveals three types of the $K_\eta = f(t)$ dependence (Fig. 3): decreasing structuring factor K_η, increasing K_η, and K_η passing through a maximum.

The decrease in K_η is observed in systems with HCl content in the range 10^{-4}–10^{-3} M HCl, with the rate of K_η variation decreasing after 4 h. An antibate run of the dependence is observed at 10^{-2} M HCl. The kinetic curves $K_\eta = f(t)$ pass through a maximum in systems containing 0.075 M $PrCl_3$ and 0.2 NMPA.

The decrease in the strength of interphase layers is presumably favored by increasing degree of dissociation of the extracting agent and the large thickness of the electric double layer at low HCl concentrations. With the content of the acid and, correspondingly, the ionic strength of the solution increasing further, the electric double layer contracts, the thickness of the diffusion layer decreases, the number of contacts between particles grows, and the structuring is enhanced.

Interphase layers possess pronounced elasticity. The degree of elasticity, calculated from kinetic deformation curves, changes with time from 90 to 70% in a system with 10^{-2} M HCl, the time of elastic aftereffect θ_2 in this system is 30–40 s, which exceeds nearly twofold that in other systems, thus confirming the development of a structure.

The obtained results may be helpful in choosing optimal conditions of formation of interphase layers with prescribed rheological properties in order to control the rate of mass exchange in combined processing of raw materials and industrial wastes.

CONCLUSIONS

(1) The interphase layers formed when a salt solution $PrCl_3$–H_2O–HCl is brought in contact with a solution of nonoxymethylphosphonic acid in toluene under the conditions studied can be classed as systems of three types: approximately Newtonian, Newtonian-dilatant, and weakly structured.

(2) From the standpoint of structuring, the optimal conditions of extraction are created in the concentration range 10^{-4}–10^{-3} M HCl, since the interphase layers disintegrate in the course of time.

BRIEF COMMUNICATIONS

Electrodeposition of Tin–Antomony–Copper Alloy from Sulfate Electrolytes with Organic Additives

G. I. Medvedev and N. A. Makrushin

Novomoskovsk Institute, Mendeleev Russian University of Chemical Technology, Novomoskovsk, Russia

Received April 12, 2001

Abstract—The process of electrodeposition of a tin–antimony–copper alloy from a sulfate electrolyte with organic additives was studied.

A Sn–Sb–Cu alloy has been recommended for improving the antiwear properties of metals [1]. This alloy is presently electrodeposited from a fluoroborate electrolyte with organic additives. As additives of this kind are used β-naphthol and joiner's glue. The process is performed at 25°C and current density of 6 A dm^{-2}, with an alloy of the following composition deposited at the cathode (wt %): Sn 88, Sb 5.1 and Cu 6.3 [2].

The present study is concerned with electrodeposition of a Sn–Sb–Cu alloy from a sulfate electrolyte with the following organic additives: 2-butyne-1,4-diol (35% solution), formalin (37% solution), and syntanol DS-10. The electrodeposition was performed in an electrolyte of composition (g l^{-1}): $SnSO_4$ 20–30, $Sb_2(SO_4)_3$ 0.5–0.8, $CuSO_4 \cdot 5H_2O$ 0.5–1.0, H_2SO_4 100–120, syntanol 1–3; 2-butyne-1,4-diol 1–50; formalin 1–10 ml l^{-1}. Antimony sulfate was prepared by dissolving metallic antimony in hot concentrated sulfuric acid. The investigations were carried out in the temperature range 18–25°C.

Polarization curves were measured in potentiodynamic mode with a P-5827 potentiostat. The alloy was analyzed by the method described in [3]. Coatings 9–30 μm thick were deposited onto copper samples.

A study of the outward appearance of the coatings in relation to current density and nature of organic substances demonstrated that poor-quality coatings are obtained in an electrolyte containing 1 to 10 ml l^{-1} of formalin, or 1 to 50 ml l^{-1} of butynediol, or both. Adding formalin or butynediol to an electrolyte with syntanol also yields matte coatings. At the same time, simultaneous presence in an electrolyte of 1 to 3 g l^{-1} of syntanol, 6 to 8 ml l^{-1} of formalin, and 40 to 45 ml l^{-1} of butynediol gives shining finely crystalline coatings. It should be noted that shining coatings are only obtained with electrolyte stirring. Without stirring, matte coatings are produced. A chemical analysis of the coatings obtained from the electrolytes studied demonstrated that a Sn–Sb–Cu alloy is formed in this case. The influence of the $SnSO_4$, $Sb_2(SO_4)_3$, and $CuSO_4$ concentrations on the alloy composition is illustrated in Table 1. It can be seen that the content of Sb and Cu in the alloy decreases with increasing i_c. Raising the concentration of $Sb_2(SO_4)_3$ and $CuSO_4$ trolyte at constant $SnSO_4$ concentration in the elecmakes higher the Sb and Cu content in the alloy. Raising the concentration of $SnSO_4$ [at constant concentration of $Sb_2(SO_4)_3$ and $CuSO_4$] leads to lower content of Sb and Cu in the alloy.

Table 1 also indicates that for the electrolytes studied the content of Sb in the alloy varies within 2.4–13.5 wt %, and that of Cu, within 3.2–28.1 wt %, at i_c = 1–4 A dm^{-2}. At i_c = 3–4 A dm^{-2} and appropriate $SnSO_4$, $Sb_2(SO_4)_3$, and $CuSO_4$ concentrations, tin babbitts can be obtained of the following compositions (wt %): B-88 brand: Sn 90.7–88.7, Sb 7.3–7.8, Cu 2.5–3.5; B-83 brand: Sn 84.5–81.5, Sb 10.0–12.0, Cu 5.5–6.5 [4].

Changing the H_2SO_4 concentration in the electrolyte from 100 to 120 g l^{-1} has not effected on change the outward appearance of the obtained coatings, but makes the Sb and Cu content of the alloy higher by 1–1.5 wt %, depending on the i_c value. The current efficiency by the alloy (CE) was measured in electrolytes that allow fabrication of shining coatings.

1070-4272/01/7408-1400 $25.00 © 2001 MAIK "Nauka/Interperiodica"

Data on how the $Sb_2(SO_4)_3$ and $CuSO_4$ concentrations affect CE at different i_c are presented in Table 2. It can be seen that the CE by the alloy decreases with increasing i_c. With increasing content of $Sb_2(SO_4)_3$ or $CuSO_4$ in the electrolyte, the CE by the alloy decreases or slightly increases, respectively.

Polarization measurements were performed in electrolytes with organic additives in electrodeposition of Sn, Sb, Cu, and Sn–Sb–Cu. As seen from the figure, the cathodic polarization curve of alloy deposition lies in a more electropositive range of potentials, compared with the curves for Sn, Sb, and Cu, i.e., Sn, Sb, and Cu are deposited into the alloy with depolarization. The depolarization in deposition of metals into the alloy is presumably due to a decrease in their partial energy of alloying [5]. To determine the rates of deposition of separate metals into the alloy, partial current densities of Sn, Sb, and Cu deposition were calculated. The calculation was done by the procedure described in [6] with account of alloy composition at different i_c, the CE by the alloy, and electrochemical equivalents of Sn, Sb, Cu, and Sn–Sb–Cu alloy. As it can be seen from the figure (curves *1*'–*3*'), at i_c = 1–4 A dm^{-2} the rate of Sn deposition into the alloy, i'_{Sn}, is higher than i'_{Sb} and i'_{Cu}, which leads to formation of tin-rich alloys. Comparison of the partial current densities of Sb and Cu deposition shows that the share of antimony in the alloy exceeds that of copper in the case of electrodeposition at i_c = 1–4 A dm^{-2} (see the figure, curves *2*' and *3*').

The investigation performed made it possible to develop a sulfate electrolyte for electrodeposition of the Sn–Sb–Cu alloy. Electrolyte composition: H_2SO_4 20–30, $Sb_2(SO_4)_3$ 0.5–0.8, $CuSO_4 \cdot 5H_2O$ 0.5–1.0, syntanol DS-10 2–3 g l^{-1}; butynediol (35% solution) 40–45, formalin (37% solution) 6–8 ml l^{-1}; i_c = 1–4 A dm^{-2}. Content of metal in the alloy (wt %): antimony 2.4–13.5, copper 3.2–28.1. Current efficiency by the alloy 92–98%.

Electrodeposition is to be performed in the temperature range 18–25°C in an agitated electrolyte. The alloy should be deposited onto copper samples. In depositing the alloy onto steel, the substrate should be preliminarily coated with copper. Anodes of pure tin are to be introduced into the electrolyte with voltage already applied to preclude contact deposition of Sb and Cu onto Sn. After the completion of an experiment, the anodes are to be removed from the electrolyte. The adjustment of the electrolyte with respect to $SnSO_4$, $Sb_2(SO_4)_3$, $CuSO_4$, H_2SO_4, formalin, and butynediol is done in accordance with chemical analysis data [7]. The electrolyte adjustment with respect

Utilization of *N*,*N*-Dichloro-*p*-chlorobenzenesulfonamide

V. K. Shiryaev

Karpov Institute of Physical Chemistry, State Scientific Center of the Russian Federation, Obninsk Branch, Obninsk, Kaluga oblast, Russia

Received November 23, 2000; in final form, March 2001

Abstract—The kinetic parameters of the reaction of *N*,*N*-dichloro-*p*-chlorobenzenesulfonamide with hydrochloric acid were determined, and the main parameters of the commercial process were estimated.

In the context of elimination of chemical weapons, a problem arises of utilization of agents used for rendering war gases harmless. One of such agents is *N*,*N*-dichloro-*p*-chlorobenzenesulfonamide (**I**, Russian commercial name DTKh-2). Owing to the high reactivity of the N–Cl bond, a promising way of its utilization is replacement of active chlorine atoms by hydrogen atoms with the formation of *p*-chlorobenzenesulfonamide (**II**), which can be used for synthesis of sulfamide drugs, dyes, and effective means for plant protection [1–3]. For this process, a reagent should be chosen that would be cheap and readily available and would give the minimum amount of minor or difficult-to-trap products. One of such agents is hydrochloric acid.

The goals of this study were to determine the kinetic characteristics of the reaction of **I** with HCl and estimate the main parameters of the commercial process.

EXPERIMENTAL

The reaction was performed in a glass vessel equipped with a jacket and a thermometer. The vessel was charged with 10 g of **I**, after which 50 ml of 2 N HCl (equivalent excess 0.34 mmol) was added, and the solution was heated to a required temperature (77 or 92°C) under stirring with a magnetic stirrer.

The experimental conditions should be chosen so as to ensure the most active reaction (i.e., to eliminate possible diffusion hindrance); the optimal temperature and concentration should be determined. Preliminary experiments showed that at a stirrer rotation rate of no less than 700 rpm the conversion is independent of the stirring rate. The suitable reaction temperature is restricted by the thermal stability of the melt of **I** under water (up to 95°C [4]); 2 N HCl is convenient as it is sufficiently concentrated, but does not fume yet. Also, it is known that in more concentrated HCl the solubility of chlorine increases, which complicates its separation.

At appropriate intervals, we sampled the reaction mixture to determine the HCl concentration by alkali titration. Samples of the solid phase were analyzed for available chlorine by iodometric titration [5] after drying to constant weight and dissolution in a 1 : 1 mixture of 1,2-dichloroethane and glacial acetic acid. When calculating the conversion, we took into account the variation of the molecular weight of the solid phase in the course of the reaction.

Amide **II** was identified by the melting point (143 ± 1°C; according to [4], 143–144°C) and IR spectrum. The IR spectra of **I** and **II** in mineral oil were measured on a Specord-80 spectrophotometer. The spectrum of **II** shows two bands (3332 and 3240 cm^{-1}) belonging to antisymmetric and symmetric stretching vibrations of the NH_2 group. Such bands are absent in the spectrum of **I**.

Figure 1 shows as a function of time τ the conversion η with respect to available chlorine (*1*, *3*) and HCl (*2*, *4*), at 92 and 77°C; the conversion with respect to HCl was calculated by the formula

$$\eta = 1 - (C - \bar{C})/(C_0 - \bar{C}), \quad (1)$$

where C, $\bar{C}$, and C_0 are the current, excess, and initial concentrations of HCl, respectively.

It is seen from the figure that the conversion is complete only with respect to dichloramide **I** (with respect to HCl, $\eta < 1$). This means that reversible reaction [4] is shifted to the right (owing to removal

1070-4272/01/7408-1403 $25.00

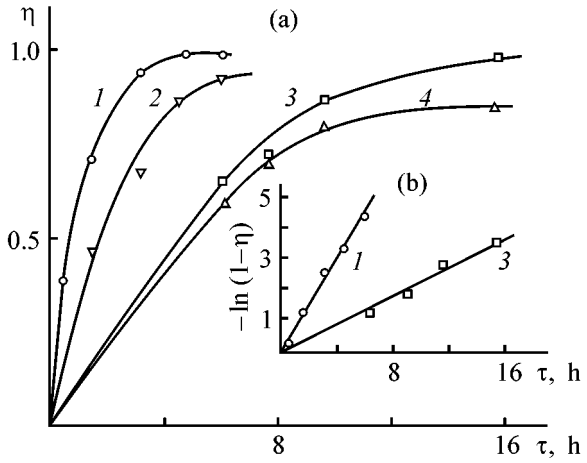

Fig. 1. (a) Conversion η with respect to (*1, 3*) available chlorine and (*2, 4*) HCl vs. time τ; (b) linearization of curves *1* and *3* in the coordinates $\ln(1 - \eta)$–τ. Temperature, °C: (*1, 2*) 92 and (*3, 4*) 77.

of chlorine) and that HCl is not only consumed, but also formed (most probably, by reaction of chlorine with water):

$$p\text{-}ClC_6H_4SO_2NCl_2 + 2HCl \rightleftarrows p\text{-}ClC_6H_4SO_2NH_2 + 2Cl_2. \quad (2)$$

Therefore, the kinetic parameters were calculated only from dependences *1* and *3* linearized in the coordinates $\ln(1 - \eta)$–τ (Fig. 1b).[1] From the slope of the straight lines we determined the rate constants of removal of available chlorine *k*, and from their temperature dependence we estimated the activation energy of the process to be 89.1 kJ mol^{-1}.

Then, in the formula for calculating the conversion of available chlorine

$$\eta = 1 - \exp(-k\tau) \quad (3)$$

the rate constant k (h^{-1}) is

$$k = 3.6 \times 10^{12}\exp(-89\,100/RT). \quad (4)$$

where $R = 8.314$ J mol^{-1} K^{-1}.

[1] Linearization of dependences *1* and *3* in the coordinates of a first-order reaction equation is probably due to the mutual compensation of two opposite processes: acceleration owing to additional formation of HCl and deceleration owing to the reaction reversibility. Therefore, the constants determined in this work should be regarded as apparent.

The experimentally estimated activation energy confirms the assumed kinetic control of the process.

Formulas (3) and (4) allow approximate estimation of the most important parameter of the commercial process, specific output *V* of a reactor of unit volume. If the reaction is performed at 92°C to 98% conversion, then, according to formulas (3) and (4), the residence time will be 5 h; hence, $V = 40$ kg m^{-3} h^{-1}, i.e., the specific output is moderate.

A significant factor in this process is stirring. Calculation of the power of the electric stirrer according to [6] gave a value of 0.65 kW m^{-3}. The heat consumption for heating of the reaction volume (1 m^3) is 0.1 Gcal. It is seen that the power consumption is low. Note also that the released gaseous chlorine can be readily absorbed in a standard alkaline absorber [7] to form a valuable product, hypochlorite.

Thus, the proposed procedure for utilization of I is attractive owing to the low power consumption and low environmental impact.

Use of Ozone in Synthesis of 5-Hydroxy-1,4-naphthoquinone

A. V. Mamchur, L. F. Gorbas, and G. A. Galstyan

Rubezhnoe Branch, East-Ukrainian National University, Rubezhnoe, Lugansk oblast, Ukraine

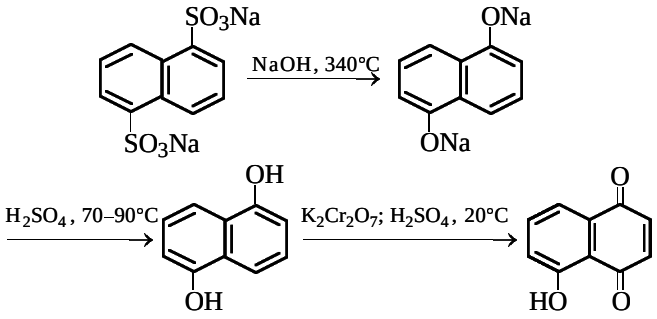
Received November 28, 2000; in final form, March 2001

Abstract—The feasibility of low-waste production of 5-hydroxy-1,4-naphthoquinone with regeneration of Cr(VI) with the use of ozone was examined. The optimal conditions were found for oxidation of Cr(III) to Cr(VI) in the presence of manganese(II) sulfate.

Oxidation of aromatic compounds with potassium dichromate is widely used in production of food additives, drugs, intermediates, and dyes. Oxidation, as a rule, occurs under mild conditions but is accompanied by the formation of large amounts of highly toxic difficultly utilizable acidic chromium-containing wastewater whose treatment requires large expenditure. A promising way to improve the environmental safety of such processes is to develop low-waste technologies using ozone [1].

In this study, we examined the feasibility of production of 5-hydroxy-1,4-naphthoquinone by a closed-loop process.

5-Hydroxy-1,4-naphthoquinone (juglone) is used as preservative for nonalcoholic drinks. It is prepared in 22.0% yield by the following scheme:



To increase the yield of 5-hydroxy-1,4-naphthoquinone, it is recommended to add 1,5-dihydroxynaphthalene in the oxidation stage without its isolation in the form of an aqueous suspension containing 1,5-dihydroxynaphthalene (1.53 M), Na_2SO_4 (1.72 M), and H_2SO_4 (0.21 M) [2]. The resulting 5-hydroxy-1,4-naphthoquinone is separated, and a mixture of the filtrate with wash water, containing $Cr_2(SO_4)_3$, sulfuric acids, and organic impurities, is subjected to ozonation.

In this study, we examined the possibility of (i) oxidizing Cr(III) to Cr(VI) by ozonation of aqueous acidic solutions of chromium sulfate obtained in filtration of 5-hydroxy-1,4-naphthoquinone suspension and (ii) utilizing the ozonized solutions for oxidation of 1,5-dihydroxynaphthalene.

According to the procedure described in [3], ozonation of wastewater was performed in a 0.4-l glass column equipped with a dispersing glass frit. The column was charged with 50 ml of the solution from the filtration stage, containing 0.127 M $Cr_2(SO_4)_3$, 0.56 M H_2SO_4, and 0.02 M $MnSO_4 \cdot 5H_2O$. The required temperature was adjusted, and an ozone–air mixture was passed through the solution at a rate of 30 l h^{-1} for 8–12 h. The gas mixture contained 1.2–1.6 vol % ozone; the degree of ozone uptake was

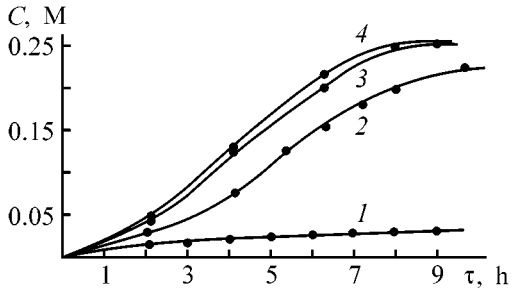


Fig. 1. Influence of the concentration of the $MnSO_4 \cdot 5H_2O$ catalyst on the rate of Cr(VI) accumulation. Solution volume 50 ml, rate of ozone–oxygen mixture feeding 30 l h^{-1}, T = 80°C, $C_{H_2SO_4}$ = 6%, $C_{Cr_2(SO_4)_3}$ = 0.127 M. Fig. 2. Influence of temperature on the rate of Cr(VI) accumulation. Solution volume 50 ml, rate of ozone–oxygen mixture feeding 30 l h^{-1}, $C_{H_2SO_4}$ = 6%, $C_{MnSO_4 \cdot 5H_2O}$ = 0.02 M. Temperature, °C: (*1*) 20, (*2*) 60, (*3*) 80, and (*4*) 100.

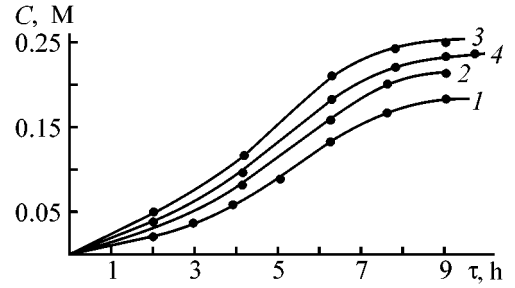

Fig. 3. Influence of the H_2SO_4 concentration on the rate of Cr(VI) accumulation. Solution volume 50 ml, rate of ozone–oxygen mixture feeding 30 l h^{-1}, T = 80°C, $C_{MnSO_4 \cdot 5H_2O}$ = 0.02 M. $C_{H_2SO_4}$, %: (*1*) 3, (*2*) 4.5, (*3*) 6, and (*4*) 9.

90–95% in the first 2–3 h and 40–45% by the end of ozonation; oxidation of Cr(III) to Cr(VI) was quantitative.

To the ozonized solution containing 0.25 M CrO_3 we added oleum to an H_2SO_4 content of 2.38 M. The resulting solution (70 ml, 2.38 M H_2SO_4, 0.25 M CrO_3, 0.02 M $MnSO_4$) was placed in a 0.5-l flask at 20°C, and a suspension of 1,5-dihydroxynaphthalene (75 ml) from the stage of sulfuric acid breakdown of the alkali fusion product was loaded. Oxidation was performed for 4 h, after which the suspension was filtered and the precipitate washed to neutral reaction. The filtrate and wash waters were combined and ozonized.

Results of 1,5-hydroxynaphthalene oxidation in a closed-loop process

Run no.	Cycle	Compensation for $MnSO_4$ loss, M	*A*, %
1	First	0.000	22.18
2	Second	0.000	22.12
3	Third	0.000	18.54
4	Fourth	0.003	23.4
5	Fifth	0.000	22.2
6	Sixth	0.000	19.1
7	Seventh	0.000	17.59
8	Eighth	0.002	23.67
9	Ninth	0.001	22.44

Figure 1 shows that inder the experimental conditions Cr(III) is not noticeably oxidized by ozone (curve *1*). Only in the presence of catalytic amounts of manganese(II) sulfate, transformation of Cr(III) to Cr(VI) is practically quantitative (curves *3, 4*). The following mechanism of the catalytic effect of manganese was suggested [4]:

$$Mn(II) + O_3 \rightarrow Mn(III) + O_3^{\cdot}, \quad (1)$$

$$O_3^{\cdot} + H^+ \rightarrow HO_3^{\cdot}, \quad (2)$$

$$HO_3^{\cdot} \rightarrow HO^{\cdot} + O_2, \quad (3)$$

$$O_3^{\cdot} + H_2O \rightarrow HO^{\cdot} + HO^- + O_2, \quad (4)$$

$$Mn(II) + HO^{\cdot} \rightarrow Mn(III) + HO^-, \quad (5)$$

$$3Mn(III) + Cr(III) \rightarrow 3Mn(II) + Cr(VI). \quad (6)$$

In the presence of manganese(II) sulfate, Cr(III) is oxidized by ozone even at room temperature, but quantitative conversion of Cr(III) to Cr(VI) takes 22–24 h (Fig. 2). Therefore, it is more appropriate to perform oxidation at elevated temperatures. For example, the reaction time is three times shorter at 80°C.

The rate of oxidation of Cr(III) to Cr(VI) also depends on the sulfuric acid concentration in the solution being ozonized, reaching a maximum in 6% acid, which is consistent with the scheme of catalysis.

Thus, oxidation of Cr(III) in chromium(III) sulfate solutions to Cr(VI) is quantitative and fast at 80°C in the presence of 6% H_2SO_4 and catalytic amounts of manganese(II) sulfate.

After being ozonized and concentrated, wastewaters were repeatedly used for oxidation of 1,5-dihydroxynaphthalene (see table). As seen from the table, the yield of 5-hydroxy-1,4-naphthoquinone decreases in run nos. 3 and 7 owing to the loss of $MnSO_4$ in the stage of filtration. Compensation for the catalyst loss in the fourth, eighth, and ninth cycles restores the yield of the target product at a level of 22–24%. The quality of 5-hydroxy-1,4-naphthoquinone met the requirements (mp 145–148°C) in all cases.

CONCLUSION

The feasibility of Cr(VI) regeneration in the course of synthesis of 5-hydroxynaphthoquinone in weakly acidic solutions by ozonation in the presence of catalytic amounts of manganese(II) sulfate was examined. The ozonized chromium and manganese compounds can be used repeatedly for oxidation of 1,5-dihydroxynaphthalene to 5-hydroxy-1,4-naphthoquinone.

Acetalization of Polyvinyl Alcohol Fiber with Aldehyde-containing Polyvinyl Alcohol Fiber

L. M. Shtyagina, V. M. Vainburg, and L. E. Vinogradova

St. Petersburg State University of Technology and Design, St. Petersburg, Russia

Reveived March 6, 2001; in final form, April 2001

Abstract—A procedure is proposed for preparing polyvinyl alcohol fiber with increased water absorption by acetalization of a freshly formed fiber with dialdehyde-containing polyvinyl alcohol fiber. The fiber characteristics were determined in relation to the acetalization conditions.

One of the ways to render polyvinyl alcohol (PVA) fiber insoluble is acetalization with aldehydes. In the case of acetalization with dialdehydes (glyoxal; maleic, glutaric, phthalic, and isophthalic dialdehydes), the presence of two reactive groups in the molecule makes intermolecular reaction the most probable. However, part of aldehyde groups remain unchanged [1–3]. The resulting fibers exhibit relatively high water-absorbing power and, at the same time, preserve the fibrous structure with active centers required for further modification, i.e., grafting of ionic vinyl polymers and covalent immobilization of proteins, enzymes, and drugs.

Acetalization with low-molecular-weight dialdehydes is performed in aqueous solutions in the presence of mineral salts (sodium sulfate) and sulfuric acid. Salts are added to decrease the swelling of the fiber, and sulfuric acid serves as a process catalyst. Among the negative features of the process are fiber degradation under the action of acid and the necessity for prolonged washing of the fiber to remove excess salt. As a result, the resulting fiber is brittle.

Instead of low-molecular-weight dialdehydes, it is possible to carry out acetalization with freshly formed PVA fiber containing terminal aldehyde groups introduced by periodate oxidation [4]. Oxidation of PVA in solutions to give PVA dialdehyde was performed by Sakurada [5]. With certain corrections, this process can be successfully carried out with freshly formed PVA fiber. Oxidation of freshly formed PVA fiber was performed in aqueous solutions of periodic acid at 20°C and liquid-to-solid ratio of 50. The conditions and results of oxidation are listed in Tables 1 and 2.

The resulting dialdehyde from PVA fiber was used for acetalization of freshly formed PVA fiber. The reaction was performed as follows: Freshly formed PVA fiber was thoroughly mixed with dialdehyde

Table 1. Influence of periodic acid concentration C_a on the characteristics of the dialdehyde from PVA fiber* (reaction time 60 min)

from PVA fiber and heated in an oven on a Teflon-coated tray. After the reaction was complete, the characteristics of the fiber were determined (Table 3; the boundary values are given).

With water absorption taken as the main criterion of fiber assessment, we can conclude that, with increasing temperature and concentration of dialdehyde from PVA fiber, the influence of acetalization time decreases considerably (run nos. 1, 8).

Originally, acetalization under these conditions seemed to be improbable. However, there is evidence that the reaction does occur. At the lowest reaction parameters (run no. 1), the fiber undergoes neither dissolution nor gelation on boiling. With increasing reaction parameters, the water absorption steadily increases, suggesting the formation of a fibrous network structure capable of water absorption. In our case this may be due to acetalization.

Fairly good results were obtained when the acetalized PVA fiber was heat-treated with IR radiation. Data on the water absorption of a thus treated fiber are given below:

C_d, %	75	50	33	25	20
W, %	590	780	845	660	510

As expected, at too high dialdehyde concentrations the water absorption decreases because of the high degree of cross-linking.

We failed to prepare by acetalization with low-molecular-weight dialdehydes a fiber with water absorption of 800–900%; the best results obtained, e.g., with maleic dialdehyde were 450–470%.

EXPERIMENTAL

Freshly formed PVA fiber (length 50–60 mm) was placed in flat-bottomed flasks with beads, and the calculated amount of periodic acid was added at 20°C. The mixture was kept for 30–120 min. After that the fiber was thoroughly washed with distilled water (the completeness of acid removal was checked with methyl orange) and dried at 20°C.

The IR treatment was performed at a wavelength of 1.2 μm for 40–80 s; a KG 220-1000-6 lamp was placed at a distance of 80 mm from the fiber surface.

The content of free aldehyde groups was determined by condensation with hydroxylamine hydrochloride [6].

To determine the water absorption, air-dry fiber (weighed with 0.005-g accuracy) was placed in a vessel with distilled water for 0.5 h. Then the sample was placed on a filter paper folded in three layers, covered with three layers of filter paper, and carefully squeezed with constant force. After that the sample was weighed, and the water absorption was calculated.

Table 3. Characteristics of PVA fiber acetylated with dialdehyde from PVA fiber

Run no.	C_d,* %	T, °C	τ, min	C_{COH}, wt %	SW, %	W, %

2	25	50	150	0.61	50	717
3	25	90	30	0.69	51	671
4	25	90	150	0.58	46	817
5	50	50	30	1.60	58	572
6	50	50	150	1.36	52	732
7	50	90	30	1.24	50	818
8	50	90	150	0.95	38	900

* (C_d) Concentration of dialdehyde from PVA fiber.

The shrinkage in boiling water was determined as follows. Fiber samples (50–60 mm) were measured at 20°C with accuracy of 0.05 cm and placed in a round-bottomed flask equipped with a reflux condenser; then distilled water at 95–98°C was added, and the flask was placed in a boiling water bath for 30 min. After that the fiber was dried at 20°C, and the shrinkage was determined.

CONCLUSION

A procedure was developed for acetalization of freshly formed polyvinyl alcohol fiber with aldehyde-containing polyvinyl alcohol fiber. The water absorption of the resulting fiber considerably exceeds that of the fiber acetalized with low-molecular-weight dialdehyde.

Synthesis of Zinc Dialkyls from Zinc and Alkyl Bromides

I. V. Eremeev, S. M. Danov, V. R. Sakhipov, and A. G. Skudin

Dzerzhinsk Branch, Nizhni Novgorod State Technical University, Dzerzhinsk, Nizhni Novgorod oblast, Russia

Received March 22, 2001

Abstract—Zinc dialkyls with linear radicals were prepared from zinc and alkyl bromides in the presence of stimulating systems based on a transition metal derivative and an organometallic compound capable of reducing the transition metal derivative under the reaction conditions.

Zinc alkyl compounds are widely used in laboratory studies and industry as starting compounds in inorganic, organic, and organometallic synthesis and as catalysts for polymerization of unsaturated compounds [1–7]. However, one of the major application fields of alkyl derivatives of nontransition metals and zinc is preparation of materials for electronics [7–22].

A procedure for preparing diethylzinc in 92% yield, involving reaction of zinc powder with ethyl bromide, was proposed in [23]:

$$Zn + AlkBr \rightarrow AlkZnBr, \quad (1)$$

$$2AlkZnBr \rightarrow Alk_2Zn + ZnBr_2. \quad (2)$$

Stage (1) is performed in the liquid phase under atmospheric pressure without solvent at 38–45°C in the presence of catalytic amounts of stimulating systems whose necessary components are a transition metal derivative and an organometallic compound (OMC). The latter should be capable of reducing the transition metal derivative under the reaction conditions. Disproportionation of alkylzinc bromide (2) with simultaneous distillation of dialkylzinc in a vacuum is performed in the same vessel at elevated temperature under isothermal conditions, or with a more sophisticated temperature schedule. This procedure eliminates the labor-consuming procedure for preparing a zinc–copper couple, the use of relatively expensive ethyl iodide, and the uncontrollable induction period in the first stage. Among a broad range of tested stimulating systems based on a transition metal derivative and an OMC (some of them are listed in patent [23]), the system copper(I) iodide–ethylzinc bromide showed high performance in synthesis of diethylzinc. However, attempts to use this system for preparing dipropyl- and dibutylzinc resulted in low yields of zinc dialkyls. Therefore, we carried out a study aimed at extending the synthetic potential of the procedure for preparing zinc dialkyls.

It is known [2, 3] that organic halides can react with OMCs. This is a complex process, and its mechanism is not still fully understood; the reactions are often accompanied by exchange, hydride reduction, and dehydrohalogenation of the organic halide. As a result, a complex mixture of products is usually formed. The reaction catalysts are commonly transition metals or their derivatives. Hence, it could be expected that the most probable reasons for low yields of dipropyl- and dibutylzinc in the preliminary experiments are side reactions of the initial alkyl bromides with the forming mono- and diorgano derivatives of zinc, yielding a mixture of hydrocarbons and zinc bromide. The other possible side reactions [reduction of copper(I) iodide with organozinc compounds or their thermal decomposition] can hardly be responsible for the poor yields of zinc dialkyls. Indeed, even complete reduction of the catalytic amounts of copper(I) iodide as a component of the stimulating system can decrease the yield of zinc dialkyl only to approximately 93%. The insignificant effect of thermal decomposition of zinc dialkyls on their synthesis follows, e.g., from the approximately equal yields of diethyl-, dipropyl-, and dibutylzinc (78–86%) in their synthesis by Noller's procedure from a zinc–copper couple and equimolar mixtures of the corresponding alkyl iodides and alkyl bromides under conditions similar to those of our experiments [1]. If this is the case, then, if unchanged alkyl bromide or a solid residue containing a transition metal and its derivative is removed from the reaction mixture before thermal disproportionation of alkylzinc bromide, the

1070-4272/01/7408-1410 $25.00 © 2001 MAIK "Nauka/Interperiodica"

selectivity of zinc dialkyl synthesis must increase considerably.

Our experiments showed that the selectivity of synthesis of alkylzinc bromides at $T \le 50°C$ is very high: The reaction mixtures contained only unchanged initial compounds (zinc and alkyl bromide) and alkylzinc bromide. The release of gaseous products was monitored with a gas meter connected to the reactor, and was insignificant. However, the conversion of alkyl halides in 4–8 h was as low as 50–80%. Subsequent thermal disproportionation of alkylzinc bromides with simultaneous vacuum distillation of zinc dialkyls from such reaction mixtures resulted in low yields of zinc dialkyls. The results of two of such experiments (nos. 1 and 3) are listed in the table. Removal of unchanged alkyl bromides from the reaction mixtures by vacuum distillation at temperatures below 50°C prior to thermal decomposition noticeably increased the yield of zinc dialkyls. Also, we found that, in the absence of other components of the reaction mixtures, the alkyl bromides in hand do not react with the corresponding organozinc compounds under the experimental conditions. Therefore, as expected, when the solid residue was removed from the reaction mixture prior to disproportionation, the yield of zinc dialkyls also increased (see table, run nos. 2 and 4). Since 5–15% of the formed organozinc compounds always remains in the reactor after the final stage of synthesis, our results show that, in the absence of alkyl bromides or substances catalyzing reaction of organic halides with OMC, disproportionation of alkylzinc bromides into zinc dialkyls is highly selective.

Thus, our study supports the above assumption concerning the reasons for the low yield of zinc dialkyls in their synthesis from zinc and alkyl halides in the presence of stimulating systems based on a transition metal derivative and an OMC. It should be noted that, to prepare high-purity zinc dialkyls, it is appropriate to use alkylzinc bromide formed in the first stage or the corresponding zinc dialkyl as the organometallic component of the stimulating system.

EXPERIMENTAL

In our experiments, we used PTs-10 zinc powder [TU (Technical Specifications) 48-4015-1/0–81] and pure grade copper(I) iodide (TU 6-09-02-437–87). Pure grade alkyl bromides were dried over calcium chloride and distilled before use. Ethylzinc bromide was prepared from zinc powder and ethyl bromide in the presence of the copper(I) iodide–ethylzinc bromide stimulating system, as described in [23]. The resulting solution of ethylzinc bromide in ethyl bromide was separated from unchanged zinc, and excess ethyl bromide was distilled off in a vacuum. The remaining crystalline ethylzinc bromide was dissolved in an appropriate alkylbromide for subsequent use as a component of the stimulating system.

Synthesis of zinc dialkyls from zinc and alkyl bromides in the presence of the copper(I) iodide–ethylzinc bromide stimulating system

Run no.	Alk_2Zn	τ,* h	Yield, %	
			AlkZnBr by analysis	Alk_2Zn
1	Pr_2Zn	7	75	30
2	Pr_2Zn	7	81	68**
3	Bu_2Zn	4	52	0
4	Bu_2Zn	8	78	66**

* (τ) Time of AlkZnBr synthesis.

** The solid residue was removed from the reaction mixture prior to disproportionation of alkylzinc bromide.

Synthesis of zinc dialkyls. A mixture of 8.76 g (0.046 mol) of copper(I) iodide and 50 g (0.765 mol) of zinc powder was vacuum-treated for 10 min, dry oxygen-free argon was passed, and alkyl bromide and a solution of ethylzinc bromide in the corresponding alkyl bromide were added. The total amount of alkyl bromide and the amount of ethylzinc bromide in the mixture were 0.66 and 0.04–0.05 mol, respectively. In the process, the reactor was protected from atmospheric moisture. Then the system was connected to a gas meter. The first stage was performed with stirring at 50°C. Then the stirring was stopped, the mixture was cooled to room temperature, and thermal disproportionation of alkylzinc bromide formed in the first stage was performed, with simultaneous vacuum distillation of zinc dialkyl. In certain experiments unchanged alkyl bromide was distilled off in a vacuum prior to disproportionation, or unchanged zinc was separated by decanting and washed with several portions of appropriate alkyl bromide. The liquid phase was separated by decanting after each washing. After combining all the liquid phases from washings and the liquid fraction of the reaction mixture, alkyl bromide was distilled off in a vacuum, and alkylzinc bromide was subjected to thermal disproportionation. The constants of the resulting dipropylzinc and dibutylzinc agreed with published data [1]. The yield of zinc dialkyls was determined from the amount of the isolated reaction products. The content of alkyl bromide in the reaction mixture was determined by GLC

on a Tsvet-110 chromatograph after hydrolysis of alkylzinc bromide and extraction of alkyl bromide with toluene [24]. The yield of alkylzinc bromide in the first stage of the synthesis was evaluated from the content of zinc ions (EDTA titration [25]) after hydrolysis of alkylzinc bromide in a solid particle-free sample of the reaction mixture and dissolution of the resulting zinc hydroxide precipitate in aqueous HCl.

CONCLUSIONS

(1) Stimulating systems based on a transition metal derivative and an organometallic compound allow synthesis of zinc dialkyls with linear radicals in high yields from zinc and alkyl halides.

(2) In thermal disproportionation of alkylzinc halides, the reaction mixture should not contain significant amounts of the initial alkyl halides.

Copolymerization of Vinyl Chloride with 1-Vinyl-1,2,4-triazole

O. V. Lebedeva, N. S. Shaglaeva, G. A. Pirogova, S. V. Fedorov, and A. K. Khaliullin

Irkutsk Institute of Chemistry, Siberian Division, Russian Academy of Sciences, Irkutsk, Russia

Received April 16, 2001

Abstract—Copolymerization of vinyl chloride with 1-vinyl-1,2,4-triazole was studied. The copolymerization constants were determined. The chemical structure of the resulting copolymers was studied by NMR and IR spectroscopy.

Polyvinyl chloride is one of the most important and widely used polymers. To modify the properties of polyvinyl chloride (solubility, processability, softening point, physicochemical properties), vinyl chloride is copolymerized with other monomers.

Previously, we have studied radical copolymerization of vinyl chloride (VC) with *N*-vinyl-4,5,6,7-tetrahydroindole [1] and with 2-methyl-5-vinylpyridine and showed that the formation of macromolecules is accompanied by dehydrochlorination, with the degree of dehydrochlorination depending on the nature of the comonomer.

In this work, we studied radical copolymerization of VC with 1-vinyl-1,2,4-triazole (VT). Preliminary experiments showed that, as expected, the degree of dehydrochlorination is lower when copolymerization is performed in solvents. Therefore, experiments on copolymerization of VC with VT were performed in solutions of *N*-methyl-2-pyrrolidone and dimethylformamide (DMF). DMF appeared to be the most suitable solvent, since double-reprecipitated copolymers prepared in *N*-methyl-2-pyrrolidone contained, according to the ^{13}C NMR spectra, fragments originating from reaction of *N*-methyl-2-pyrrolidone with HCl [2]. The copolymers prepared in DMF showed no such signals. Therefore, all further experiments on copolymerization of VC with VT were performed in DMF.

Copolymers are formed at any initial monomer ratio in the examined range (see table). Copolymerization of VC with VT yielded powdered products readily soluble in DMF, dimethyl sulfoxide, and *N*-methyl-2-pyrrolidone.

The VT units introduced into the copolymer affect its solubility: The range of solvents dissolving the copolymers extends as compared with polyvinyl chloride. Hence, new possibilities arise for processing these copolymers.

With increasing content of VT in the initial mixture, the yield of the product and its intrinsic viscosity grow.

For the system VC–VT, we determined the copolymerization constants. Their values, $r_{VC} = 0.30 \pm 0.02$ and $r_{VT} = 1.24 \pm 0.02$, indicate that the rate constant of the reaction of VC radical with VT monomer is much higher than the rate constant of its reaction with VC.

The IR spectra of the copolymers contain no absorption bands characteristic of the *N*-vinyl group (960, 1680 cm^{-1}), whereas the vibration bands of the triazole ring are preserved (1030, 1210, 1560 cm^{-1}), and a band appears at 1640 cm^{-1}, characteristic of

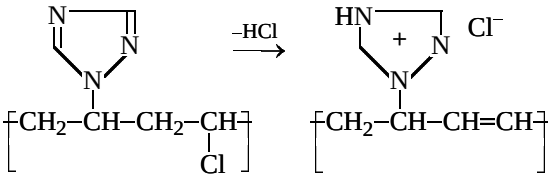
the CH=CH bonds. The ^{13}C NMR spectrum of the VT–VC copolymer contains broadened resonance signals corresponding to the carbon atoms of the triazole rings (151.91 and 144.38 ppm), a group of signals of the vinyl fragment CH=CH (127.92–127.58 ppm), and signals from the >CHCl carbon atoms (58.49–56.67 ppm), NCH group (54.6 ppm), and $>CH_2$ groups (45.4 – 41.9 ppm).

The CH=CH fragments in the copolymer originate from dehydrochlorination of VC.



The fact that signals from the CH=CH fragment appear in the ^{13}C NMR spectra directly confirms the occurrence of dehydrochlorination in the course of copolymerization. From the ^{13}C NMR spectra, we calculated the degree of dehydrochlorination Z

$$Z = a/A,$$

where a is the amount of CH=CH groups and A is the total amount of vinyl chloride and CH=CH groups.

Also, the degree of dehydrochlorination was calculated from the difference between the content of VC units in the copolymer, calculated from the chlorine content and from the content of VT units (evaluated from the nitrogen content). These two independent procedures for determining Z give reasonably consistent results. With increasing content of VT in the initial mixture, the degree of dehydrochlorination grows, reaching a maximum (15%) at a VT content of 80 mol %.

Thus, copolymerization of VC with VT in DMF occurs with insignificant dehydrochlorination. In contrast to polyvinyl chloride, the resulting copolymers are soluble in DMF and *N*-methyl-2-pyrrolidone, which extends the possibilities of processing these materials.

EXPERIMENTAL

Copolymerization of the monomers was performed in sealed ampules at 60°C in the presence of azobis(isobutyronitrile) in an argon atmosphere. The reaction mixture was dissolved in DMF, and the copolymer was precipitated with acetone. The copolymers were reprecipitated from solution into acetone and vacuum-dried to constant weight. The intrinsic viscosity was determined in DMF at 20°C by the dilution procedure.

The relative activity constants were calculated by the Fineman–Ross and Kelen–Tudos procedures [3], using the program developed by G.I. Deryabina and the Mortimer–Tidwell experimental design method. In calculations we used the results of experiments performed to no more than 10% conversion. The IR spectra were taken on a Specord 75-IR spectrometer from KBr pellets or mulls in mineral oil.

The proton-noise-decoupled ^{13}C NMR spectra of copolymer samples were recorded on a Varian VXR-500S spectrometer (125.5 MHz) from DMSO-d_6 solutions, with the relaxation delay of 2.5 s and 90° pulse. Chromium tris(acetylacetonate) (0.02 M) was used as relaxant.

The molar ratios of the copolymer components and impurities were calculated by a common procedure: The fraction of a single carbon atom in VT, q_{VT}, was taken equal to one carbon atom, which corresponds to 1 mol of VT, M_{VT}. The numbers of moles of the other components were calculated by the formula

$$M_X = q_X/q_{VT},$$

where q_X is the fraction of the carbon atom in component X; $q_X = I_X/I_{tot}$ (I_X and I_{tot} are the integral intensity of the signal from atom X and the total integral intensity, respectively).

CONCLUSIONS

(1) Radical copolymerization of vinyl chloride with 1-vinyl-1,2,4-triazole is accompanied by insignificant dehydrochlorination; the second comonomer appears to be more reactive.

(2) Introduction of 1-vinyl-1,2,4-triazole units into the copolymer improves the solubility of the polymers in organic solvents.

BRIEF COMMUNICATIONS

Synthesis of Glycol Ethers and Their Use for Intensification of Oil Recovery

N. N. Lebedeva, V. V. Mazaev, and N. Yu. Tret'yakov

Tyumen State University, Tyumen, Russia

Received March 27, 2001

Abstract—Monoalkyl ethers of ethylene and triethylene glycols were prepared and tested for intensification of oil recovery. The features of oil displacement with aqueous solutions of glycol ethers from bulk models of strata and the effect of glycol ethers on acid treatment of oil-saturated samples were examined. A correlation between the structure of ether and its performance was revealed. The interphase tension at the boundary between the aqueous solution of the glycol ether and kerosene was determined.

Glycol ethers are widely used as solvents for water–hydrocarbon systems owing to their good compatibility with the aqueous and organic phases, high hydrolytic stability, and low toxicity. In the oil recovery practice, ethylene glycol monobutyl ether (EGMBE) is used as a component of complex acid formulations for treatment of critical zones of oil strata [1]. It is known that dipropylene glycol ethers, e.g., butyl ether used in paint-and-varnish industry [2] or methyl ether used for dissolving oil components [3], surpass cellosolves in performance owing to the higher washing-out power with respect to aliphatic and aromatic hydrocarbons.

The goal of this study was to prepare a series of glycol monoalkyl ethers differing in length of the hydrocarbon radical and number of oxyalkyl units and to choose the best ethers for intensification of oil recovery.

In industry, glycol ethers are prepared by oxyalkylation of alcohols. For their laboratory synthesis, we chose another procedure involving reaction of alkyl halide with glycol in aqueous dioxane in the presence of solid alkali, followed by isolation of the product by vacuum distillation [4]. We prepared ethylene glycol monoheptyl ether (EGMHE) and triethylene glycol monomethyl, monopentyl, and monoheptyl ethers (TEGMME, TEGMPE, and TEGMHE, respectively). Their structures were proved by refractometry and IR spectroscopy (see table).

The synthesized glycol ethers, EGMBE, and ethylene glycol (EG) were tested as additives to acid solutions used in oil recovery for treatment of critical zones of the strata with the aim to improve their filtration properties and capacity. Glycol ethers decrease the interphase tension between oil and water and facilitate removal of fine particles wetted with oil and restoration of the hydrophilic properties of the surface owing to the washing-out effect. The effect of glycol ethers on acid treatment was studied under laboratory conditions using a model of carbonate rock saturated with oil and water. To a weighed portion of the rock we added a solution of HCl and glycol ether and determined the rate of CO_2 evolution. The rate of breakdown of the carbonate rock with HCl (ml CO_2/s) in the presence of various ethers was as follows: no ether, 0.3; EG, 0.26; EGMBE, 0.50; EGMHE, 0.10; TEGMME, 0.37; TEGMPE, 0.56; and TEGMHE, 0.46 (0.01 g of $CaCO_3$, 0.1–0.2 mm fraction, 5 ml of 3% HCl, 10 wt % of glycol ether).

These results show that, in the presence of glycol ethers, the rate of reaction of the acid with the rock

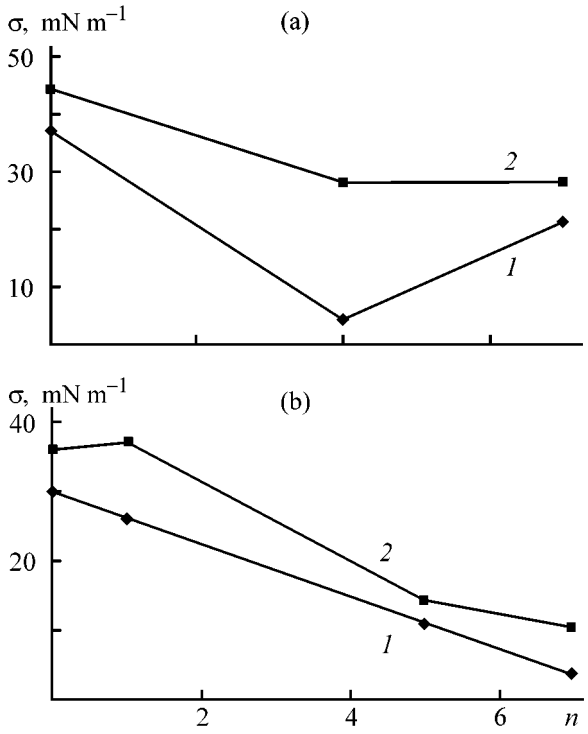

Fig. 1. Influence of the structure of (a) ethylene glycol and (b) triethylene glycol ethers on the interphase tension σ at the water–kerosene boundary. (*n*) Number of atoms in the alkyl group of glycol ether. Concentration of glycol ether, wt %: (*1*) 1 and (*2*) 10.

increases. The performance of an acid formulation depends on the structure of ether, namely, on the length of the hydrocarbon radical and the number of oxyethyl units. The breakdown of the carbonate rock was the fastest with ethers containing 4–5 carbon atoms in the alkyl group. Apparently, glycol ethers with short alkyl group dissolve oil to a lesser extent, and ethers with long alkyl group are worse miscible with the aqueous phase. Owing to their better compatibility with water and oil, triethylene glycol ethers accelerate breakdown of the oil-saturated model rock at any length of the alkyl radical.

Similar trends were obtained in studying the oil-displacing power of ether. A special column modeling an oil stratum was charged with crushed rock and brought to required temperature, after which water, oil, and again water were successively fed until the oil displacement stopped (at a constant rate of filtration of the liquids). From the volume of displaced oil we calculated the oil displacement factor K_o equal to the fraction of oil displaced from the column with water. After that, an aqueous solution of glycol ether was fed. Below are given the values ΔK_o by which the oil displacement factor increased on adding glycol (concentration of glycol ether 10 wt %; reagent volume 15% of the pore volume):

Glycol ether	EGMBE	EGMHE	TEGMME	TEGMPE	TEGMHE
ΔK_o, %	18.0	11.8	2.2	24.8	7.0

It is seen that TEGMPE and EGMBE show the best performance. Apparently, 4–5 carbon atoms in the alkyl group are sufficient to ensure the maximal compatibility of a solution being pumped-in and residual oil in the stratum model and its efficient displacement. With longer alkyl radicals, the solubility of an ether in oil becomes the prevailing factor, which results in retention of oil in the stratum model. On the whole, triethylene glycol ethers show a higher oil-displacing power owing to higher hydrophilicity.

The performance of formulations used for oil recovery is usually associated with a decrease in the interphase tension at the aqueous phase–oil boundary. Using a stalagmometer, we determined the interphase tension at the boundary between aqueous solution of glycol and kerosene. As seen from Figs. 1a and 1b, the interphase tension decreases on adding glycol ethers to water (1 or 10%). However, there is no unambiguous correlation between the interphase tension and performance of ethers in intensification of oil recovery. For example, TEGMHE considerably decreases the interphase tension but shows poor performance in oil displacement. In acid treatment, it is adsorbed on the particle surface and makes it more hydrophobic, decreasing the efficiency of reaction of acid with the rock; in oil displacement, it readily mixes with residual oil, is adsorbed on the rock, and is not displaced by liquid. The minimal interphase tension is observed with a 10% solution of EGMBE, though it is not the best oil-displacing agent. Thus, along with interphase tension, some other factors may be significant, e.g., compatibility of ethers with the aqueous and organic phases.

CONCLUSIONS

(1) Ethylene glycol monoheptyl ether and triethylene glycol monomethyl, monopentyl, and monoheptyl ethers were prepared and tested for intensification of oil recovery.

(2) Glycol ethers accelerate breakdown of oil-saturated calcium carbonate with acid formulations owing to washing-out of oil. The breakdown rate depends on the structure of an ether. The highest performance is shown by glycols containing 4–5 carbon atoms in the alkyl group.

(3) Aqueous solutions of glycol ethers make considerably higher the oil displacement factor and can be used for secondary recovery of oil. Ethylene glycol monobutyl ether and triethylene glycol monopentyl ether raise the oil displacement factor to the greatest extent.

(4) High performance of these ethers in acid treatments and oil displacement is due not only to a decrease in the interphase tension at the water–oil boundary but also to compatibility with the aqueous and oil phases.

Abstract—The surface activity of block copolymers of ethylene and propylene oxides, based on ethylenediamine, mono(ethylene glycol), and triethanolamine, was studied. Adsorption characteristics of the investigated compounds at the water–air interface are estimated.

At present, nonionic surfactants are widely used as emulsifiers, stabilizers of dispersions, corrosion inhibitors, antistatic agents, and demulsifiers [1, 2].

Both in Russia and abroad, studies of surfactants as demulsifiers revealed that the highest demulsifying effect is provided by nonionic surfactants. Furthermore, it is known that high-molecular-weight compounds of this type are more efficient than low-molecular-weight compounds [3]. However, their adsorption characteristics at the water–air interface have not been studied adequately. Therefore, we studied in this work the surface activity of newly synthesized nonionic surfactants, block copolymers of ethylene oxide (EO) and propylene oxide (PO), based on ethylenediamine (EDA), mono(ethylene glycol) (MEG), and triethanolamine (TEA), and estimated the adsorption characteristics of the investigated compounds at the water–air interface.

In the experiments, we used nonionic surfactants based on EDA (sample nos. 1–9), MEG (sample nos. 10–16), and TEA (sample nos. 17, 18), with different molecular weights M and PO/EO ratios or having the same M, but different degrees of oxyethylation. All the surfactants were developed at the NIInefteprom khim Joint-Stock Company.

EXPERIMENTAL

The surface tension of aqueous solutions of the nonionic surfactants at the water–air interface was determined by the anchor-ring method with a LAUDA tensometer without displacement, using an inductive

receiver of an amplifier, embodying the displacement angle concept. The force proportional to the surface tension is converted into electric voltage recorded by a self-recorder. Prior to each measurement, the ring was washed with bichromate and distilled water and then steamed. Each measurement was repeated at least three times at $20 \pm 2°C$.

Figures 1a–1c demonstrate the surface tension isotherms of aqueous solutions of the investigated nonionic surfactants. It should be pointed out that over the concentration range from infinite dilution to critical micelle concentration (CMC) there are two portions of the isotherms, whose position and slope depend, in our opinion, on the PO/EO ratio.

From the experimental surface tension isotherms, we estimated, using data from [4–7], the adsorption Γ, limiting adsorption Γ_m, work of adsorption W_a, molecular site area S_m, and CMC.

The adsorption Γ was estimated from the slopes ($d\sigma/d\log C$) of tangents to the initial portions of the isotherms, by substitution of these slopes in the Gibbs equation:

$$\Gamma = -\frac{1}{2.3RT}\frac{d\sigma}{d\log C}. \quad (1)$$

To determine Γ_m, the slope $d\sigma/d\log C$ of the linear section of the isotherm before CMC was substituted in Eq. (1).

The work of adsorption W_a, characterizing the surface activity, in the energy gain on passing of a mole of the surfactant from the bulk to the surface. This parameter was estimated to be

$$W_a = RT\ln(\Gamma/\delta C),$$

where δ is the thickness of the adsorption layer, determined taking into account the range of intermolecular forces at the interface (9×10^{-10} m for the water–air interface [8]).

We estimated W_a of the investigated nonionic surfactants at various concentrations C, including that at infinite dilution. In discussing the obtained results, we compared W_a values found by extrapolation to zero concentration of a surfactant.

CMC was determined from the adsorption isotherms plotted in the coordinates σ–log C, and S_m was estimated to be

$$S_m = 1/(\Gamma_m N_A).$$

The results are summarized in the table.

It was demonstrated for a series of polymeric homologs of oxyethylated alkylphenols and aliphatic alcohols [9] that S_m depends on the length of the oxyethyl chain. At low degrees of oxyethylation, S_m remains unchanged as a result of straightening of the hydrophilic chains and their vertical orientation in saturated adsorption layers. At high content of the oxyethyl groups, straightening becomes thermodynam-

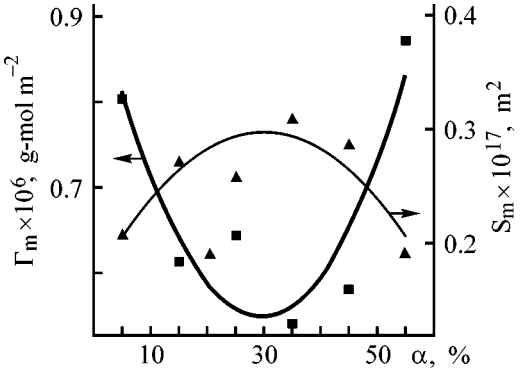

Fig. 2. Limiting adsorption Γ_m and molecular site area S_m vs. the degree of oxyethylation. (α) Degree of oxyethylation expressed as the percentage of EO (see table); the same for Figs. 3 and 4.

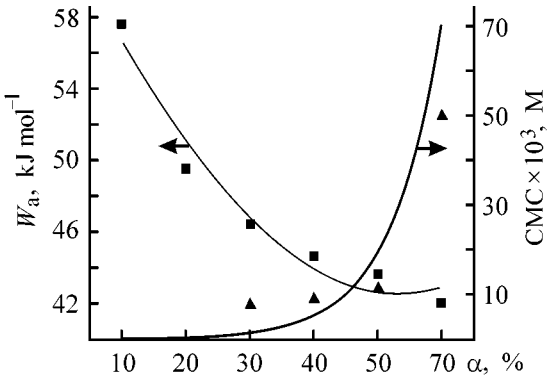

Fig. 3. Work of adsorption W_a and CMC vs. the degree of oxyethylation α.

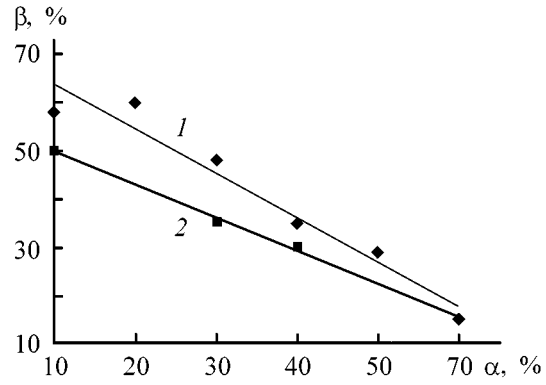

Fig. 4. Demulsifying activity β of block copolymers based on (*1*) EDA and (*2*) MEG vs. the degree of oxyethylation α.

ically unfavorable, and, in this case, S_m is controlled by the size of a convolute oxyethyl chain [9].

We found that S_m is about the same for all the surfactants studied, being only slightly dependent on their molecular weight. For EDA-based PO/EO block copolymers with MW 7000 (sample nos. 1–6), S_m depends on the degree of oxyethylation, reaching the maximum ($S_m = 0.309 \times 10^{-17}$ m^2) at PO/EO = 60/40 (Fig. 2). For MEG-based block copolymers at the same degree of oxyethylation and comparable MW (sample nos. 10–12), S_m remains unchanged, which is probably due to different molecular arrangements of the indicated block copolymers.

It is seen from Fig. 2 and the table that Γ_m shows a minimum at PO/EO = 60/40 for sample nos. 1–6. It is interesting that increased demulsifying activity of similar compounds at the same PO/EO ratio was reported in [3].

The adsorption activity of compounds is mostly characterized by S_m or Γ_m. However, it is more pictorial to express it via such energy parameter as the work of adsorption W_a. Our results showed that W_a monotonically decreases with increasing degree of oxyethylation (Fig. 3), which can be attributed to increasing degree of pulling of the hydrophilic fragment of a molecule into the aqueous phase, which results in decreasing energy gain in adsorption from water. With increasing hydrophilicity of a molecule, CMC increases (see table and Fig. 3). Such a pattern is typical of both EDA- and MEG-based block copolymers.

For the example of nonionic surfactants prepared on the basis of commercial and thoroughly dried TEA (sample nos. 17 and 18, respectively), we demonstrated the effect exerted by the composition of a starting reagent on the surface activity of the resulting block copolymers. It is seen from the table that CMC of sample no. 18 is lower by an order of magnitude than that of sample no. 17, while the other adsorption characteristics are only slightly different. Additionally we studied the demulsifying activity of a series of EDA- and MEG-based copolymers with MW 7000 and 6000, respectively, having various PO/EO ratios. Figure 4 shows the dependences of the demulsifying activity of the block copolymers on the degree of oxyethylation. The demulsifying activity decreases with increasing hydrophilicity of the samples. Finally analysis of the results obtained (Figs. 3, 4) reveals that the work of adsorption decreases together with the demulsifying activity of the block copolymers with increasing degree of oxyethylation.

CONCLUSION

With increasing hydrophilicity of nonionic surfactant molecules, their CMC grows and the work of adsorption and demulsifying activity decrease. The molecular site area and limiting adsorption are dependent on the degree of oxyethylation and steric characteristics of molecules of nonionic surfactants.

Works of Academician B. S. Jacobi in the Field of Applied Chemistry (To B. S. Jacobi's bicentennial birthday anniversary)

The scientific interests of Academician Jacobi were primarily with physics and investigations of electromagnetic phenomena and their practical applications. At the same time, he made an outstanding contribution to the development of applied electrochemistry, studied and improved chemical power sources; he also discovered galvanoplastics and promoted its wide acceptance.

Boris Semenovich Jacobi (Moritz Herman von Jacobi before acquiring Russian citizenship) was born on September 9 (21), 1801, in Potsdam (Germany) into a highly educated merchants' family. He received his primary, very high-grade education at home, studied ancient and European languages, and fundamentals of mathematics. In January 1821, after a year of military service, Jacobi entered Berlin University; however, already in August of the same year he went to Göttingen University. In October 1823, he returned to Potsdam and started working at the Building department of Prussia. In May 1829, he received Göttingen University's diploma in architecture.

Already in those years, Jacobi, dealing with building works, displayed keen interest in investigations in electricity and magnetism and studied works of such known scientists as T.J. Seebeck (1770–1831), A.M. Ampere (1775–1836), H.C. Oersted (1777–1851), and M. Faraday (1791–1867).

In 1883, Moritz Herman Jacobi moved to Königsberg, where his younger brother, Karl Gustav Jacobi (1804–1851), professor, an already known mathematician, one of creators of the theory of elliptic functions, member of the Berlin Academy of Sciences (since 1836), and a corresponding (since 1830) and full member (since 1833) of the St. Petersburg Academy of Sciences, was teaching at the University. In Königsberg, M.H. Jacobi continued working as architect and devoted his entire off-service time and the available means to problems of electrical engineering and electric motor design.

On March 1, 1833, Jacobi became a full member of the Königsberg physico-economical society. In this connection, he delivered at a meeting of the society, in June of the same year, a scientific report "On the Use of Natural Forces for Human Needs," published in the form of a separate brochure. The author appeared before the members of the Society as an excellently educated person and broad-minded engineer well familiar with the latest advances in science [1]. In May 1834, Jacobi demonstrated a prototype electric motor to a group of scientists including A. Humboldt (1769–1859), an outstanding German naturalist. Jacobi sent a report about the electric motor, invented by him, to the Paris Academy of Sciences, and later submitted there a detailed description of the invention. Jacobi's works strongly influenced further research in electric motor design in various countries [2]. In December 1834, by Humboldt's request, the Prussian government provided some funds for financing Jacobi's experiments. However, the scientist's position in Königsberg gave him no way of expanding his studies in the field of practical application of electromagnetic phenomena.

B.S. Jacobi in 1836.

1070-4272/01/7408-1422 $25.00 © 2001 MAIK "Nauka/Interperiodica"

In June 1835, Königsberg University awarded *honoris causa* the doctor of philosophy degree to Jacobi, and already in June of that year he was elected, by recommendation of known Russian scientists K.M. Ber (1792–1876) and V.Ya. Struve (1793–1864), an extraordinary professor at the chair of civil architecture at Derpt (Tartu) University (Estonia). In September 1835, Jacobi moved to Derpt, and his entire scientific and engineering activities proceeded in Russia from that time on. In May 1837, Jacobi reported to the minister of public education and, simultaneously, the president of the St. Petersburg Academy of Scientists Prince S.S. Uvarov (1786–1855) on the possibility of practical application of the electric motor. Already in June, "Committee for Application of Electromagnetism to Machine Motion by Professor Jacobi's Method" was created by the Academy [3]. The Committee included such known scientists as academicians P.N. Fuss (1798–1855), A.Ya. Kupfer (1799–1865), M.V. Ostrogradskii (1801–1861), and E.H. Lenz (1804–1865); P.G. Sobolevskii (1781–1841), a corresponding member of the St. Petersburg Academy of Sciences; and P.L. Shilling (1786–1837), inventor of electromagnetic telegraph. The Committee was headed by Admiral I.F. Krusenstern (1770–1846), an outstanding seafarer and honorary member of the Academy of Sciences.

In August 1837, Jacobi was invited to St. Petersburg to carry out experiments on use aboard ships of the motor designed by him. From that time, and till the end of his life, the scientist lived in St. Petersburg. However, till June 1840 he remained professor of Derpt University, but was relieved of delivering lectures. In November 1839, by initiative of a group of academicians headed by Fuss, Jacobi was elected an adjunct of the St. Petersburg Academy of Sciences in practical mechanics and applied mathematics. In May 1842, at a general meeting of the Academy of Sciences, Jacobi was elected extraordinary academician in applied mathematics. In February 1847, Jacobi was elected ordinary academician in technology and applied chemistry. In October 1865, in view of the opening of a vacancy after Lenz's death, Jacobi was appointed ordinary academician in physics. In April 1848, the scientist acquired Russian citizenship.

Krusenstern's committee was mainly concerned with the assessment of the possibility of applying the electric motor to ship motion; however, with galvanic cells as electric power source, this problem was unsolvable. The activities of the Committee were terminated in 1842, and its final report pointed out that the investigations carried out "aided in explanation of quantitative relations associated with the phenomenon of electromagnetism" [4].

Being very broad-minded scientifically, Jacobi was one of the first in the world to construct cable telegraph lines in St. Petersburg (1841–1846), invented about ten designs of telegraph apparatus, and performed basic research in the field of electromagnetic phenomena [5, 6]. Jacobi dealt with problems of applied chemistry, took active part in studies of ways to machine platinum, and wrote a spacious treatise "On Platinum and Its Use as Coins" (1860). Evidence on scientist's investigations in this field can be found in his correspondence with H. Saint-Claire Deville (1818–1881), a French chemist and a foreign corresponding member of the St. Petersburg Academy of Sciences [7].

The present brief essay covers only Jacobi's works in applied electrochemistry. High-power galvanic cells were necessary for feeding electric motors. The first Jacobi's paper on power sources, published in 1837 (*Pogg. Ann.*, 1837, no. 40, pp. 67–73) was written in Derpt in connection with the dispute on the so-called Becquerel circuit. A.-C. Becquerel (1788–1878), a French scientist, described a galvanic cell comprising two platinum electrodes, one in contact with concentrated nitric acid, and the other, with a concentrated solution of potassium hydroxide. The two liquids were separated by a porous clay diaphragm. According to Becquerel, neutralization was the reaction responsible for current generation. Jacobi confirmed Becquerel's experiments and studied thoroughly the gaseous products evolved on platinum, but made little progress in understanding the mechanism of the occurring electrode reactions. However, somewhat later (1841), Jacobi noted that "As regards galvanic action, platinum in nitric acid is a metal different from platinum immersed in alkali" [5].

Much greater attention was paid by Jacobi to improving the copper–zinc cell proposed in 1836 by British scientist J.F. Daniell (1790–1845). In this cell, amalgamated zinc was immersed in a sulfuric acid solution, and copper, in a copper(II) sulfate solution. The solutions were separated by a porous clay diaphragm well wettable by both the liquids. Jacobi proposed to replace sulfuric acid with an ammonium chloride solution and used in the diaphragm a material with much lower electrical resistance. As noted by W. Ostwald (1853–1932), in the understanding of the mechanism of operation of this cell "Daniell failed to make the final, decisive step, despite that he was very close to doing so... the conclusion that there is no need at all for sulfuric acid was made not by him" [8]. Jacobi improved the copper–zinc cell already in Derpt in the end of 1836 and reported on his achievement in his letter to Academician Lenz in February 1837.

Last portrait of B.S. Jacobi.

In a search for a more powerful current source, Jacobi thoroughly studied the cell proposed by English physicist W.R. Grove (1811–1896). The circuit comprised platinum, concentrated nitric acid, dilute sulfuric acid, and zinc. Grove cells were used by Jacobi in his experiments with a boat driven by electric motor. Having made a detailed theoretical analysis of the possibilities of primary galvanic cells, Jacobi came to a conclusion that their combination with electric motor is noncompetitive with steam machines.

The last Jacobi's works on chemical power sources already referred to secondary cells—batteries. As noted by Academician A.N. Frumkin (1895–1976) [5, 9], Jacobi holds priority on making an attempt to use secondary cells for practical purposes. Originally, Jacobi's battery had only platinum electrodes, which allowed accumulation of a very small amount of electricity. In experiments performed in 1870 at the suggestion of French physicist G. Plante (1834–1889), platinum electrodes were replaced by lead ones immersed in concentrated sulfuric acid. This allowed a substantial increase in the storage capacity of secondary power cells.

Jacobi's studies in the field of chemical power cells led the scientist to the discovery of galvanoplastics, made in February 1937, before moving to St. Petersburg. It is this date of the discovery that was given by Jacobi himself in a letter to M. Faraday of June 21, 1839 [5]. On October 4, 1838, Jacobi reported on his invention in an official letter to the Academy of Sciences and submitted a sample fabricated by him. In 1840, the scientist got a permission of the Russian government to publish the results of his investigations in the form of a detailed manual [10, 11]. The book *Galvanoplastics or a Method to Fabricate Prototype-reproducing Copper Articles from Copper Solutions by Means of Galvanism* was published in Russian and German simultaneously and was at once translated into English and French. Its author stated with pride: "Galvanoplastics belongs exclusively to Russia. Here it originated, and here it was developed." This was confirmed by Academician P.I. Walden (1863–1957) who paid much attention to the history of chemistry [12]. In the manual, Jacobi presented quite a number of conditions for production of good copper deposits. The author was aware of the broadest possibilities of practical application of galvanoplastics. The development of galvanoplastics in Russia during the first years after its discovery was described in detail in I.G. Spasskii's article, included as a supplement in the collection of Jacobi's works [5]. The same supplement contains other materials referring to this discovery (Jacobi's leters to Prince Uvarov, correspondence with A.N. Demidov, comments by press, opinions of scientists.

In April 1840, Jacobi was awarded Demidov Prize for the invention of galvanoplastics, but the scientist handed the entire amount of money to the Academy of Sciences. In summer of 1867, at the World Exhibition in Paris, Jacobi was awarded for his discovery the First Prize and the Major Gold Medal. In 1889, a galvanoplastics exhibition was staged in St. Petersburg, devoted to 50th anniversary of Jacobi's discovery [13].

Already after discovering the galvanoplastics, Jacobi submitted to the Academy of Sciences the results of his investigations of the processes of gilding (1842), brass coating (1844), and electrolytic recovery of iron (1868). This field of applied electrochemistry was named galvanostegy by the scientist.

A major part of Jacobi's electrochemical works was devoted to development of methods for measuring the amount of electricity, electromotive force of galvanic cells, and their internal resistance. All these works were initiated by the need to have more precise evaluation techniques on which depended the possibility of using in practice various kinds of chemical power sources [5, 14].

Jacobi took active part in the activities of the St. Petersburg Academy of Sciences; he was repeatedly elected a member of the managing committee of the Academy, was a member of a great number of various

permanent and temporary committees, and performed various tasks.

As noted by Frumkin [5], the discovery of galvanoplastics, investigation of chemical power sources, and development of methods for measuring electrochemical quantities put Jacobi to one of the first places in the electrochemical science of the XIX century.

Jacobi's merits in various fields of science and technology were highly appreciated in Russia and abroad. A full member of the St. Petersburg Academy of Sciences, he was also elected a foreign corresponding member of the Berlin Academy of Sciences, Göttingen Society of Sciences, scientific societies of Italy, honorary member of the British society for promotion of valuable arts, Scottish society of arts, a member of the Physical society in Frankfurt, Dutch society of sciences in Harlem, and other societies and institutions. By the end of his life, Jacobi had the title of Privy Counselor and had been awarded the highest Orders of Russia and orders of other countries.

Among the vast number of publications devoted to Jacobi, mention should necessarily be made of the book by M.G. Novlyanskaya [15]. The book presents lists of scientist's works (176 items) and publications about Jacobi's life and activities, which appeared during the period from 1834 till 1953 (571 items), and biographic materials covering in chronological order all his life.

Boris Semenovich Jacobi died of heart attack on February 27, 1874, at age of 72. He was buried at Smolenskoe Lutheran cemetery in St. Petersburg. A memorial plaque on an Academy of Sciences building in Vassilievsky island on a Neva embankment reminds descendants that "a famous physicist and electrical engineer Boris Semenovich Jacobi" had lived in this house.

A. G. Morachevskii

Russian Journal of Applied Chemistry, Vol. 74, No. 8, 2001, p. 1426. Translated from Zhurnal Prikladnoi Khimii, Vol. 74, No. 8, 2001, p. 1386.

BOOK REVIEWS

Aleksandrovskii, S.V., Dong Von Li, and Gopienko, V.G., *Novye protsessy polucheniya tugoplavkikh soedinenii titana* (New Processes for Producing High-Melting Titanium Compounds), Moscow: Ruda i Metally Publ. House, 2001, 128 pp.

High-melting titanium compounds—carbides, nitrides, and carbonitrides find wide use in diverse fields of new technology. All the three classes of compounds are characterized by high melting points, hardness, and wear resistance, and serve as a basis for manufacture of alloys and formulations with a required set of properties. In a small monograph by Aleksandrovskii and co-authors, the existing and prospective ways to obtain high-melting compounds belonging to the systems Ti–C, Ti–N, and Ti–C–N are considered.

The book comprises a brief introduction, three chapters, and bibliography containing 101 references to works of domestic and foreign authors. The introduction (pp. 3–5) mainly presents the fields of application of high-melting titanium compounds. The first chapter (pp. 6–25) describes the properties of the compounds under consideration—phase diagrams of the systems Ti–C, Ti–N, and Ti–C–N, wettability of the carbides and nitrides by various metals, and other physicochemical properties are discussed. The second chapter (pp. 26–34) considers the most important methods for obtaining high-melting titanium compounds. To these belong direct synthesis of titanium compounds from components, reduction of titanium dioxide by carbon, reaction of titanium tetrachloride with ammonia to give titanium nitrides, reduction of titanium dioxide by various reducing agents in atmosphere of nitrogen, and synthesis of carbonitrides by nitration of a mixture of titanium dioxide with carbon.

The third chapter, occupying the central place in the monograph (pp. 34–118), is concerned with investigations of ways to obtain high-melting titanium compounds by various new methods. In this group are placed plasmochemical synthesis of titanium carbide, synthesis of high-melting compounds in vapor phase, and self-propagating high-temperature synthesis. However, particular attention is given by the authors to synthesis of high-melting titanium compounds with the use of technologies, apparatus, and half-products of titanium-magnesium production. Manufacture of a wide assortment of various kinds of high-melting titanium compounds with relatively low production cost can be set up on the basis of a titanium-magnesium combine. The technological process can be based on thermal reduction with magnesium of titanium and carbon chlorides on standard equipment used in production of titanium sponge.

The monograph has clearly pronounced technological orientation. Thermodynamic calculations would become more thorough with the use of data presented in a monograph by A.G. Turchanin and M.A. Turchanin [*Termodinamika tugoplavkikh karbidov i karbonitridov* (Thermodynamics of Carbides and Carbonitrides), Moscow: Metallurgiya, 1991].

The book is well published and contains extensive reference material. Unfortunately, insufficient attention was given in editing the book to unity of terminology and measurement units.

Judging from the manner of presentation, the monograph by S.V. Aleksandrovskii and co-workers can be used by wide audience of specialists interested in problems of inorganic materials science.

========== BOOK REVIEWS ==========

Stiller, W., *Uravnenie Arreniusa i neravnovesnaya kinetika* (Arhenius Equation and Nonequilibrium Kinetics), Translation from English, Moscow: Mir, 2000, 176 pp.

The book is written by a known German physicist and published in English in connection with the centennial jubilee of the Arrhenius equation, celebrated in 1989. In addition to presenting the history of the equation, the book contains a brief, but informative treatise of the modern state of the theoretical foundations of nonequilibrium kinetics.

The author considers theoretically and practically important problems associated with intensively developing fields of chemistry, physics, physical chemistry, and chemical technology. Much attention is paid in the monograph to correct use of concepts and quantities in considering theoretical and practical problems.

In 1889, Svante August Arrhenius (1859–1927), an outstanding physical chemist and, later, a Nobel Prize winner (1903), published a paper "On Rates of Inversion Reaction in Cane-Sugar under the Action of Acids" (*Z. Phys. Chem.*, 1889, vol. 4, pp. 226–248) containing an expression for the reaction rate constant. This expression became widely known as the Arrhenius equation. At that time Arrhenius worked as assistant of W. Ostwald (1853–1932) at the physicochemical laboratory of Leipzig University.

In a brief foreword, the translation editor (L.S. Polak) and translator (A.V. Khachoyan) noted that by now the application domain of the famous equation has expanded considerably. The notion "Arrhenius kinetics" is used in analyzing and describing a wide diversity of processes: from stress relaxation in solids to mass transfer in gas systems.

The book comprises eight chapters, afterword, supplement, and bibliography with 231 references to works of virtually only foreign authors. The first chapter (pp. 9–24) is a historical essay covering three periods of the development of chemical kinetics: prior to Arrhenius's works (before 1889), the time when his basic works were published (1889–1900), and the later time (before 1950). The author gives a brief characterization of the main directions of physicochemical kinetics in the first half of the XX century.

The second chapter (pp. 25–43) is concerned with the present state of the Arrhenius kinetics. Primary attention is given to gas-phase reacting systems. Ion-molecular and radical-molecular reactions are considered. Problems encountered in applying the Arrhenius equation to modeling of complex reactions are discussed, methods for calculating the parameters appearing in the Arrhenius equation are presented, and possible cases of deviation from this law are analyzed.

The third chapter (pp. 44–69) considers specific features of equilibrium gas-phase kinetics for the case of moderately rarefied gases with uniform temperature. The fourth chapter (pp. 70–78) discusses nonequilibrium gas-phase systems with reactants having different temperatures (two-temperature Arrhenius equation). The fifth (pp. 79–92) and sixth (pp. 93–111) chapters present a mathematical description of the nonequilibrium kinetics of chemically reacting gas-phase systems. In the seventh chapter (pp. 112–137), the methods of nonequilibrium kinetics are applied to systems with nonthermally activated reactions (plasmochemistry, radiation chemistry, chemistry of "hot atoms").

The final, eighth chapter (pp. 138–147) is named "Prospects of the Arrhenius equation." The author discusses the possible future applications of the Arrhenius equation and its modifications in various fields of physical chemistry, physics, and biology. In the afterword to the Russian translation (pp. 148–161), the editor and translator supplement some concepts of the monograph, in the first place those concerning open systems interacting with the environment and exhibiting varied degree of departure from equilibrium, and give reference to the relevant literature.

The supplement (pp. 162–166) presents evidence concerning the chronology of Arrhenius's life and activities and a list of his basic works.

In a foreword, the editor and translator, justly note that the book is written in a concise, nearly sketchy manner and is intended for a trained reader. At the same time, regarding the nature of the problems discussed, the monograph may be of interest for a wide audience of scientists, high-school teachers, and postgraduate students specialized in chemistry and physics.

Russian Journal of Applied Chemistry, Vol. 74, No. 8, 2001, p. 1428. Translated from Zhurnal Prikladnoi Khimii, Vol. 74, No. 8, 2001, p. 1388.

BOOK REVIEWS

Prilutskii, V.S., *Vol'framovyi torirovannyi karbidirovannyi katod* (Carbidized Thoriated Tungsten Cathode), Moscow: Ruda i Metally Publ. House, 2001. 152 pp.

Thoriated tungsten (tungsten wire with ThO_2 additive) was proposed as emitter and material for fabrication of cathodes for electronic valves by Langmuir as far back as 1915. Thorium dioxide additive (1–2%) enables much stronger electron emission as compared with pure tungsten. The cathode performance can be substantially improved further by using cathodes made of thoriated tungsten whose surface layer is converted into tungsten carbide W_2C (carbidized). The monograph by Prilutskii considers from modern standpoint the theory and practice of designing and fabricating carbidized thoriated tungsten cathodes (CTTC). The book comprises introduction, nine chapters, supplement, and bibliography including 171 references to works of domestic and foreign authors.

The first chapter considers properties of tungsten carbides: phase diagram of the system tungsten–carbon, various properties of the carbides, and the nature of chemical bonding in these materials. The second chapter (pp. 21–41) is devoted to the technology of carbidization and activation of CTTCs. Among the methods for obtaining tungsten carbides, the following are discussed: synthesis from elements, reduction of carbides by carbon, chemical isolation from alloys, electrolysis of molten media, and gas-phase deposition. Also considered is the process of CTTC fabrication and optimization. A very brief third chapter (pp. 42–44) contains evidence concerning some properties of carbidized thoriated tungsten (electrical resistivity, thermal and physical and physicomechanical characteristics). The fourth chapter (pp. 45–56) discusses the physical understanding of how the CTTCs operate. Their high emissive ability is ensured by the presence on the cathode surface of a nearly monolayer-thick film of thorium atoms. The fifth chapter (pp. 57–70) is concerned with specific features of the design and calculation of CTTCs, the sixth chapter (pp. 71–81) considers the specific features of their fabrication technology.

The seventh chapter (pp. 82–107) discusses problems associated with the service life of CTTCs, determined by a combination of factors. Ways to make the service life of a cathode longer are discussed. The eighth (pp. 108–119) and ninth (pp. 120–130) chapters contain special evidence concerning the design and calculation of cathodes and their accelerated longevity tests.

The monograph as a whole gives integrated consideration to the theory and practice of CTTC design and fabrication and is largely based on the author's working experience.

In addition to accomplishing strictly specialized purposes, the evidence presented in the monograph may be of interest for specialists in inorganic materials science and technology of electronic materials.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Anomalous Phenomena in Zirconium, Hafnium, and Titanium Salt Solutions, Studied by Capillary Isotachophoresis

O. V. Oshurkova, A. I. Gorshkov, and V. P. Nesterov

Received November 29, 2000

Abstract—Capillary isotachophoresis was used to separate mixtures of solutions containing zirconium, hafnium, titanium, and aluminum salts with various anions. Anomalous phenomena occurring in separation of mixtures in solutions with medium and high concentrations are described and analyzed.

The conventional capillary isotachophoresis [1] consists in that bands of pure electrolyte solutions move in a capillary under the action of electric field at the same rate. The bands of pure solutions are formed as a result of separation of their mixture in the course of motion of the constituent ions in a separating column under the action of a dc electric field. Ionic components with only slightly differing mobilities are separated using a hydrodynamic counterflow [2] in order to have an opportunity to make longer the distance traversed by the ions relative to the solvent, without increasing the column length. For example, nearly all rare-earth elements have been separated by means of isotachophoresis under counterflow conditions [3].

The situation is somewhat more complicated in the case of isotachophoretic crystallization [4] considered in [5]. The conventional capillary isotachophoresis uses single-phase systems, liquid solutions. Isotachophoretic crystallization adds a solid phase, crystals, in one or several bands.

EXPERIMENTAL

The aim of this study was to analyze by means of cationic isotachophoresis the conditions of separation of various mixtures of solutions containing zirconium, hafnium, titanium, and aluminum salts.

A single-channel device for capillary isotachophoresis with boundary detection by means of a refraction pattern was used [6]. Experiments were done in glass and quartz capillaries with uncoated inner surface, having outer diameter of 0.2–0.6 mm and channel diameter of 0.1–0.3 mm. The strength of the electric current flowing through the capillary was in the range 0.5–3.0 mA. Isotachophoregrams obtained upon separation were interpreted using the method described in [7].

The separation was done in solutions of chloride and thiocyanate salts. As leading solution (leader), or catholyte, in separation of chlorides commonly served hydrochloric acid of concentration 4.0–8.0 M; as terminating solution (terminator), or anolyte, were used aqueous solutions of cadmium, zinc, and uranyl chlorides. In the case of thiocyanate solutions, 2.0 M solution of ammonium thiocyanate served as leader, and solutions of cadmium and zinc salts as terminators. In the experiments, terminators were acidified to hydrochloric acid concentrations of 0.03–0.2 M to make the pH lower in the bands by creating a through H^+ flow from the anolyte into the catholyte. Such a flow makes bands of pure electrolyte solutions longer owing to the fact that the mobility of H^+ is higher that that of the other ions and the electric current is largely created by motion of hydrogen ions at low pH. In the steady state, the H^+ flow is the same in any section of the column:

$$Q_i = C_i u_i E_i = \text{const},$$

where C_i and u_i are the concentration and mobility of H^+ in ith band; E_i is the electric field strength in the same band.

Lowering the pH value by a through flow of H^+ precludes precipitation of metal hydroxides in the column.

1070-4272/01/7409-1431$25.00

Separation was applied to multicomponent mixtures of substances with widely varying pH of precipitation of their hydroxides. These mixtures contained cations of potassium, sodium, calcium, samarium, magnesium, lithium, cobalt, aluminum, zirconium, hafnium, titanium, copper, and iron in various combinations. To prevent precipitation of hydroxides directly in a mixture under study prior to the experiment, it was strongly acidified to a hydrochloric acid concentration of 2.0–3.0 M. It was found that at weak, less than 0.03 M, acidification of the terminator an attempt to separate a mixture leads to solution column rupture and precipitation of some hydroxides. In the case of terminator acidification in the range 0.1–0.2 M, the mixture separation process goes till band formation, with the zirconium-containing band exhibiting unusual behavior.

Let us describe in more detail one of the experiments and consider the essence of the anomaly. A 5.4 M hydrochloric acid solution served in this experiment as leader, and a 0.9 M solution of zinc chloride acidified to a hydrochloric acid concentration of 0.1 M, as terminator. The strength of the electric current flowing through the capillary was 0.8–2.0 mA. The electric current initiated separation of the mixture and led to adjustment of electrolyte solutions in accordance with the controlling relationship [8]. In the course of separation, a sharp symmetric peak first appeared in the refraction pattern, gradually transforming into a broad zirconium band. The longer the time of mixture separation, the wider the zirconium band in the refraction pattern. The time of mixture separation varied within 3–10 h in different runs. The greater width of the zirconium band in the refraction pattern of the capillary indicates an exceedingly high refractive index of the substance in this band, evaluated as follows. It was shown in [9] that the refractive index of a solution in a band is proportional to the width of its refraction pattern. Among the available relations between the band width in the refraction pattern and the refractive index of the solution, we chose that best fitting the point corresponding to a 5.4 M hydrochloric acid solution. This linear dependence was extrapolated to refractive indices of about 1.5. The width of the refraction pattern of the zirconium band was used to evaluate the refractive index of the substance in this band to be 1.49 ± 0.02. This parameter could not be found in any other way since the volume of the zirconium band was only about 1.5×10^{-5} cm^3 and the contents of the band could not be extracted from the capillary. The refractive index of the substance in the zirconium band is close to that for glasses. Particular emphasis is to be placed on the fact that, in the course of the adjustment, the zirconium band becomes immobile relative to walls of the separation column, and adheres to them. This follows from the fact that the band does not move along the capillary when the solution levels in the electrode vessels are varied widely. The position of the band remains unchanged, either, in varying the strength of the electric current flowing through the capillary. The zirconium band is seen not only in the refraction pattern, but also simply by visual inspection. Its boundaries with neighboring solutions are well visible, whereas the boundary between the zirconium band and the capillary wall (glass or quartz) cannot be seen, apparently because of the closeness of the refractive indices. Despite the already formed gel-like zirconium band, the mixture continues to separate and ions pass through this immobilized band in both directions. In the process, pure solution bands are formed both in front of, and behind the zirconium band, being arranged between the leader and terminator in the order of decreasing mobilities of their ionic components. Raising the current strength causes an increase in the separation rate, and vice versa.

Commonly the concentration of ionic substance in a mixture being separated is chosen to be much lower than the steady-state value. This is due to the fact that at the same current strength the separation is in this case much faster than that in separating a mixture with the concentration higher than the equilibrium value. In the experiment described here the starting mixture was much more diluted than the steady-state bands.

After a mixture is separated and bands are formed, all of them remain immobile relative to the separation capillary. Creating an external pressure difference of 10–20 cm of water column did not cause hydrodynamic flow of the solution in the column and, consequently, left the bands unshifted. The solution flow in the capillary cannot be induced even upon applying a pressure difference of about 1 atm, created by a water-jet pump, to a capillary with separated mixture, extracted from the device. After the zirconium band is formed, raising the strength of the electric current flowing through the capillary to the point of overheating and rupture of the solution column does not shift the bands along the capillary, either. In fact, the formation of a gel-like band rules out any motion

of the solutions as a whole, induced by counterflow and electroosmosis.

The contents of the zirconium band had the form of a gelatinous, glassy mass. This could be ascertained by breaking the capillary at this band.

After the experiment was complete, the zirconium band and all other bands could not be removed from the capillary by conventional methods to enable its repeated use. It was necessary to pass reverse current through the column for a long time or replace the catholyte and anolyte in the electrode vessels with concentrated hydrochloric acid and then also pass current through the capillary.

Occasionally, two, rather than one, zirconium bands separated by solution were formed in separating a zirconium-containing mixture.

Similar anomalous phenomena were observed in separation of hafnium-containing mixtures. With zirconium and hafnium present simultaneously in a sample, they could not be separated, being always concentrated in a single, glassy band. In addition, a glassy band was observed when separating a mixture containing Ti(III) ions in chloride and thiocyanate solutions. The gel-like band of titanium had lower refractive index than the zirconium and hafnium bands; it was transparent, but had a violet tint characteristic of titanium solutions. A very narrow band of glassy gel was also obtained from an aluminum formate solution, but its refractive index was nearly the same as that of the other solutions. A solution of ammonium formate served as leader, and a formic acid solution, as terminator.

Let us make an attempt to explain these phenomena, uncommon for the conventional isotachophoresis, for the example of zirconium. Zirconium is contained in such cation species as Zr^{4+}, ZrO^{2+}, $Zr(OH)^{2+}$, $Zr_2O_3^{2+}$, $Zr_5O_8^{4+}$, and $ZrOOH^+$. At the initial instant of electrolysis in a strongly acidic mixture taken for separation, the equilibrium is shifted toward formation of Zr^{4+} and ZrO^{2+} ions. In further separation, H^+ ions are continuously removed from the mixture into the leading solution, with the pH in the column depending on the through flow of H^+ from the anolyte into the catholyte. This flow may also decrease in intensity, depending on the electrolysis time and other separation conditions. All this results in that the solution pH in the column grows steadily, with the equilibrium between cation species shifted toward $ZrOOH^+$ to give hydrated zirconium dioxide whose formation on raising the solution pH was described in a monograph [10], where the appropriate equations were also given:

$$ZrOCl_2 + H_2O \longrightarrow ZrOOH^+ + H^+ + 2Cl^-,$$

$$ZrOOH^+ + OH^- \longrightarrow ZrO(OH)_2 \xrightarrow{H_2O} ZrO_2 \cdot xH_2O.$$

Hydrated zirconium dioxide is composed of very fine crystals whose accretion forms the crystalline skeleton. An opinion has been reported [10] that, depending on the conditions of $ZrO_2 \cdot xH_2O$ formation (pH, temperature, etc.), there occurs dehydration accompanied by polymerization:

$$Zr(OH)_4 \xrightarrow{H_2O} ZrO(OH)_2 \xrightarrow{H_2O} ZrO_2 \cdot xH_2O.$$

Glassy gels are hydrated compounds in which water and zirconium dioxide are present in nonstoichiometric ratio.

Thus, the appearance of $ZrO_2 \cdot xH_2O$ glassy gel is presumably accounted for by the chemical properties of this amphoteric element, by the process of isotachophoretic concentration adjustment, and by the creation in the column of conditions leading to a slow increase in pH in the formed zirconium band.

The above data on zirconium refer in full measure to hafnium because of the closeness of their chemical properties and mobilities of their cation components. Similarly to zirconium, titanium can form hydrated oxides [10]. Under the conditions when hydrated oxides of zirconium, hafnium, and titanium are formed in chloride and thiocyanate solutions, aluminum concentrates into a common isotachophoretic band. The appearance of a glassy aluminum gel in the form of a narrow band in its band in aqueous formate solutions could not be accounted for as yet.

To conclude, it should be noted that gel-like bands were only observed in amphoteric substances. Probably, formation of a kind of gel-like bands would also be expected for other amphoteric compounds, e.g., organic, of the type of proteins.

CONCLUSION

Depending on the composition of mixtures being separated and separation conditions, isotachophoresis and, in particular, its capillary variety, furnishes an opportunity to obtain bands in the form of pure electrolyte solutions, glassy gels, and saturated solutions with solid crystals. Zirconium and hafnium give an immobilized glassy band in which the substance has

the refractive index close to that of a solid glass. Similar, but less pronounced phenomena are observed in separation of titanium-containing solutions.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Characteristics of Titanium(IV) Tetrakis(dialkylamide)–Benzene Systems

A. K. Baev and V. E. Mikhailov

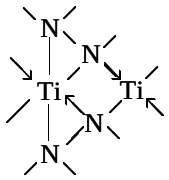
Institute of Solution Chemistry, Russian Academy of Sciences, Ivanovo, Russia
Belarussian State Technological University, Minsk, Belarus

Received December 26, 2000; in final form, May 2001

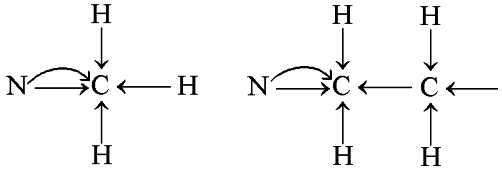
Abstract—The *p–T–x* dependences were measured in the entire concentration range of the systems $Ti[N(CH_3)_2]_4$–C_6H_6 and $Ti[N(C_2H_5)_2]_4$–C_6H_6, the enthalpies and entropies of vaporization were found, the energies of specific interactions in liquid titanium tetrakis(dialkylamides) were evaluated, and a strong intermolecular interaction between the nitrogen atom in $Ti(NR_2)_4$ and a benzene molecule was substantiated.

The developed technique for synthesizing titanium(IV) tetrakis(dialkylamides) with benzene as solvent ensures high yield of the target compounds [1]. Obtaining these compounds in high-purity state for synthesizing titanium nitride films and carbide–nitride coatings requires that the *p–T–x* dependences and thermodynamic properties of solutions containing these components should be determined. Since the observed set of changes in the solutions is associated in a certain way with the energy- and entropy-related (structural) characteristics, the thermodynamic characteristics of the solutions, combined with data on the structure of liquid components, furnish information about the mutual position of species in solution [2]. The present study, proceeding with investigations in this direction, is concerned with the *p–T–x* dependences and thermodynamic properties of solutions in the systems $Ti[N(CH_3)_2]_4$–C_6H_6 and $Ti[N(C_2H_5)_2]_4$–C_6H_6.

For dialkylamide compounds of titanium(IV), the thermodynamic characteristics of vaporization process have been obtained with good accuracy [3, 4], and the existence of monomer molecules in vapor has been substantiated. In [5], the tetrahedral structure of the TiN_4 fragment in the $Ti[N(CH_3)_2]_4$ molecule with strong bonding was established. An NMR study of $Be[N(CH_3)_2]_2$ [6] revealed the structure of the molecule. The NMR spectrum of $Al[N(CH_3)_2]_3$ shows peaks corresponding to terminal and bridging $N(CH_3)_2$ groups [6], with the bridge formation being due to the donor properties of the nitrogen atom in this group: $Al–NR_2\rightarrow Al$. The most favorable structure for liquid $Ti(NR_2)_4$ will be that with two bridging bonds $Ti–N\rightarrow Ti$ and a coordination number of six for the titanium atom:



In such a structure, each titanium atom forms two bonds with the terminal amide group and four bridging bonds. This ensures a high enthalpy of vaporization. However, it is the considerable difference in $\Delta_v H^0(T)$ and $\Delta_v S^0(T)$ between $Ti[N(CH_3)_2]_4$ (53.8 ± 3.0 kJ mol^{-1} and 107 ± 0.7 J mol^{-1} K^{-1}) and $Ti[N(C_2H_5)_2]_4$ (94.6 ± 4.0 kJ mol^{-1} and 170.2 ± 9.5 J mol^{-1} K^{-1}) that points to the essential influence of the ethyl group on the enthalpy of vaporization. The value of this parameter reflects the fact that the carbon atom of the methyl group and the terminal methyl group of the ethyl group [7] differently affect the intermolecular interaction [8]. The formation of a dative bond [7] provides for the enhanced donor properties of the methyl carbon atom in the ethyl group and, consequently, for stronger intermolecular interactions:



Therefore, at equal numbers of nitrogen atoms in the molecules of titanium(IV) tetrakis(dimethyl- and

diethylamides) and the same numbers of the Ti←N donor–acceptor bonds in the liquid state and the N←R (R = CH_3, C_2H_5) intermolecular interactions, the difference of 40.8 kJ mol^{-1} in the enthalpies of vaporization qualitatively reflects the influence exerted by the ethyl group on the stabilization of the intermolecular interaction. The question concerning the effect of the ethyl group can be elucidated using the method proposed in [9]. The energy of interaction between the alkyl group (CH_3 or C_2H_5) and the nitrogen atom of a contacting molecule is determined by the half-sum of the energies of interaction in liquid methane or ethane between $Ti(NR_2)_4$ and a similar ligand. Correspondingly, $D_{N\leftarrow CH_3}$ and $D_{N\leftarrow CH_3-CH_2}$ are 3.15 and 4.15 kJ mol^{-1}. The last two digits in the estimates can be disregarded.

With all their tentativeness, these results undoubtedly correctly reflect the behavior of real systems. With account taken of the number of N←R interactions (8) and donor–acceptor bonds (6) in solution, the energies of dissociation of the latter in liquid dimethyl- and diethylamides are 4.8 and 10.2 kJ mol^{-1}, respectively.

These values are limiting because of the unaccounted-for universal interactions. It follows from these data that the less stable dative bond in $N(C_2H_5)_2$ determines the better donor properties of the nitrogen atom and of the carbon atom in the terminal methyl group of the ethyl substituent in the formation of the bonds $D_{Ti\leftarrow N}$ and $(H_2C_2)N\rightarrow(C_2H_5)N$ of the contacting molecules in $Ti[N(C_2H_5)_2]_4$, compared with the corresponding properties of $Ti[N(CH_3)_2]_4$.

The studies were carried by the static method with a membrane null gage. The starting compounds, preliminarily degassed by freezing in a vacuum, were distilled into ampules by means of cooling with liquid nitrogen on a special manifold with ground-glass joints. All measurements were done in all-sealed systems preliminarily dried by heating with a zeolite pump. The membrane chambers were filled in a special device, with successive opening of the ampules and distillation of, first, titanium(IV) tetrakis(dialkylamide) and then benzene. Vapor pressure measurements were done in an air thermostat with a bulky metal block for equalizing the temperature along the entire membrane chamber. The vapor pressure was measured with an MChR-3 gage with a scale interval of 13.3 Pa at strictly fixed temperatures with the accuracy of controlling and measuring temperature of ±1 K.

The results obtained in measuring the total vapor pressure over solutions of varied composition are described by the dependence $\log p = f(1/T)$ in the form of straight lines arranged in a fan-like pattern, lying between the lines corresponding to the vapor pressures of the individual starting components. The experimental vapor pressures are described by the dependence $\log p = B - A/T$ whose coefficients are presented in the table.

The isotherms calculated from data on vapor pressure indicate the occurrence in the system of a positive deviation from the line representing a pressure change in accordance with the Raoult law. The system $Ti[N(CH_3)_2]_4$–C_6H_6 exhibits a stronger deviation from the additive value, increasing with temperature. The enthalpies and entropies of vaporization calculated from data on vapor pressure for various solution compositions (see table) in the form of the dependences $\Delta H^0(T) = f(x)$ and $\Delta S^0(T) = f(x)$ demonstrate a negative deviation from the additive value (Figs. 1a, 1b). Addition of 10–13 mol % benzene to titanium(IV) tetrakis(dialkylamide) leads to a dramatic decrease in the enthalpy of vaporization. The difference between the enthalpies of vaporization and the respective additive values is 24.5 kJ mol^{-1} for the $Ti\cdot[N(CH_3)_2]_4$–C_6H_6 system and 64.5 kJ mol^{-1} for $Ti\cdot[N(C_2H_5)_2]_4$–C_6H_6. The total entropy decreases in this system from 170.2 J mol^{-1} K^{-1} for $Ti[N(C_2H_5)_2]_4$ to 67 J mol^{-1} K^{-1} at 10.34 mol % C_6H_6. The information about specific features of the interaction in systems with benzene is extracted from the fact that the stability of titanium(IV) tetrakis(dialkylamides) falls dramatically upon their dissolution in benzene:

$c\{Ti[N(CH_3)_2]_4\}$, mol %	T, K	$c\{Ti[N(C_2H_5)_2]_4\}$, mol %	T, K
100	423	100	413
90.51	349	89.66	351
74.35	347	81.66	354
49.14	353	60.24	353
26.86	353	50.98	352
16.09	352	40.68	344
		19.12	355

The recorded temperature of the onset of thermal decomposition of titanium(IV) tetrakis(dimethylamide) (423 K) decreases upon its dissolution in benzene by 70–76 K. Correspondingly, the temperature of noticeable thermal decomposition of titanium(IV) tetrakis(diethylamide) (413 K) decreases in this case by 58–69 K. This fact can be accounted for by a significant change in the intramolecular bond $Ti \rightarrow N$ in the molecule of titanium(IV) tetrakis(dialkylamide), caused by the interaction between the nitrogen atom and benzene molecules.

The obtained decomposition temperatures give no way of speaking about any tendency in this influence with increasing content of benzene in solution. However, in the context of the problem considered here, an important result obtained in studying the dependence of the enthalpies of vaporization on the content of components (Figs. 1a, 1b) is that these dependences

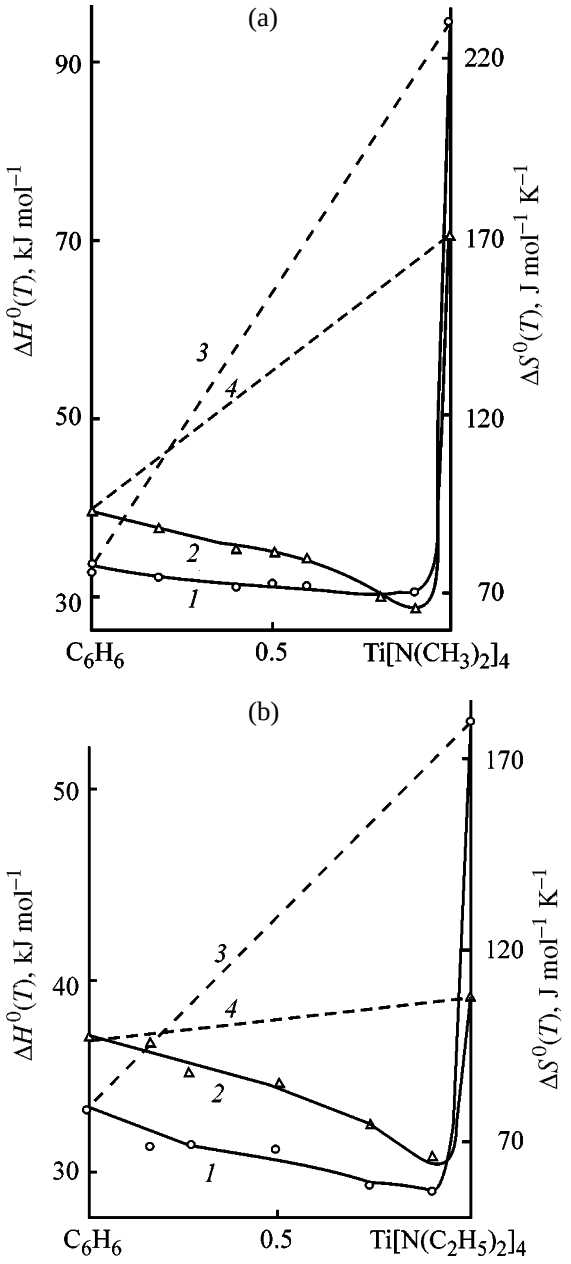

Fig. 1. (*1*) Enthalpy $\Delta H^0(T)$ and (*2*) entropy $\Delta S^0(T)$ of vaporization vs. content of $Ti(NR_2)_4$ in the systems (a) $Ti[N(CH_3)_2]_4$–C_6H_6 and (b) $Ti[N(C_2H_5)_2]_4$–C_6H_6 and (*3*, *4*) the corresponding additive values.

show a minimum at 10–13 mol % benzene, i.e., in the case when titanium(IV) tetrakis(dialkylamide) acts as a solvent. Interpreting the specificity of the interaction between the nitrogen atom and the benzene molecule is a complicated task. However, judging from its energy contribution, it must be insignificant since the minimum in the composition dependence of the enthalpy of vaporization of the solutions is observed at 10–13 mol % C_6H_6 and the contribution from in-

teractions occurring in liquid $Ti(NR_2)_4$ to the enthalpy of vaporization decreases by 24.5 and 64.5 kJ mol^{-1}, compared with the additive values, for $Ti[N(CH_3)_2]_4$ and $Ti[N(C_2H_5)_2]_4$, respectively.

CONCLUSION

The choice of a procedure for purification of titanium(IV) alkylamides is governed by the vapor pressures of the systems $Ti[N(CH_3)_2]_4$–C_6H_6 and $Ti\cdot[N(C_2H_5)_2]_4$–C_6H_6, measured in a wide temperature range, by the calculated thermodynamic characteristics of the vaporization process, and by the established fact of a decrease in the decomposition temperatures of titanium(IV) dialkylamides owing to rather strong specific interactions between benzene and the unshared electron pair of the nitrogen atom.

Abstract—Sorption properties of fibrous nitrogen-containing sorbents based on polyacrylonitrile containing diethyldithiocarbamate (TIOPAN-2) and 8-mercaptoquinoline groups (TIOPAN-6) with respect to the platinum(IV) chloride complex were studied. The effects of the temperature, platinum concentration, and acidity on the metal recovery were determined. The kinetics of sorption and sorption capacity of sorbents in hydrochloric acid and chloride solutions were established. The most probable mechanism of sorption and the composition of compounds formed in the fiber phase were proposed.

Sorbents with N,S-containing functional groups are promising materials for recovery of platinum metals from solutions [1–4]. The mechanism of sorption is of special interest. It was discussed in [5–16]. A review on sorption recovery of platinum with N,S-containing materials was made in [5].

Materials containing thioamide groups are widely used for recovery of platinum metals [6–12]. MTILON-T fiber, which is a copolymer of polyacrylonitrile (PAN) and cellulose treated with hydrogen sulfide, recovers 0.5 mmol g^{-1} of K_2PtCl_6 from 1 M HCl at 100°C. In the presence of Fe(III) and Cu(II) salts, sorption decreases by 50–70% [6]. The mechanism of platinum recovery with MTILON-T fiber was not considered.

The modified copolymer of polyvinyl alcohol with PAN (MSPVS fiber) containing thioamide groups quantitatively and selectively recovers platinum(II) and (IV) chloro complexes from HCl and NaCl solutions of various concentrations [7–12]. In 2 M HCl, the sorption capacity of the MSPVS fiber with respect to K_2PtCl_4 is 0.48 and 1.50, and with respect to K_2PtCl_6, 0.16 and 0.42 mmol g^{-1} at 20 and 98°C, respectively. It was found that the sorption in both cases proceeds with formation of a $[Pt^{2+}\{R\text{-}C(NH_2)S\}Cl_3]$ type complex, in which thioamide groups are coordinated via sulfur atoms, with the successive hydrolytic conversion of thioamide complexes into sulfides strongly retained in the fiber matrix [7]. To recover Pt(IV) complexes, Ni Cai-Hia and Xu Yu-Wu [13] proposed a chelating ion exchanger containing groups of the CH_2–CH_2–SH–CH_2–$N(C_2H_5)_2$ type, which was prepared by treating polyoxyethylene with diethylaminomethylthiirane. The composition of the sorbed complexes was not determined. Chelating resins containing dithiocarbamate groups quantitatively and very selectively recover precious metals, including Pt(IV), from solutions. The platinum species were not studied [14].

Fibrous sorbent TIOPAN-13 based on PAN with mercaptobenzothiazole functional groups very rapidly recovers Pt(IV) complexes from solutions at pH 0.5–2.0. Large amounts of heavy metals do not interfere with the recovery [15]. The mechanism of the sorption recovery was not studied.

Monivex and Srafion resins, which are styrene–divinylbenzene copolymers containing isothiourea, can recover platinum group metals, including platinum [16]. The chelating resin based on macronetwork styrene–divinylbenzene copolymer with thiosemicarbazide as a functional group quantitatively recovers platinum group metals, including Pt(IV), from hydrochloric acid solutions. The maximal sorption capaccity with respect to Pt(IV) (0.71 mmol g^{-1}) is observed in 1 M HCl, in which platinum group metals form stable complexes. It was found that the metal–thiosemicarbazide ratio in the complex formed in the sorbent phase is close to 1 : 1 [17].

Earlier we studied the sorption properties of

1070-4272/01/7409-1439$25.00

Table 1. Conditions of preparation of TIOPAN-type fibers and their properties [20]

Sorbent	Modifying reagent, wt %	τ, min, at 100°C	C_S, %	SSC_{Ag}, mmol g^{-1}
TIOPAN-1	Thiosemicarbazide, 2	15	10.0	2.04
TIOPAN-2	Sodium diethyldithiocarbamate, 8	30	14.3	1.48
TIOPAN-3	Thioacetamide, 8	60	15.5	2.59
TIOPAN-4	Thiourea, 8	40	8.7	1.48
TIOPAN-5	Ammonium thiocyanate, 4	60	7.8	1.48
TIOPAN-6	Sodium 8-mercaptoquinolinate, 3	20	4.0	1.11

GLIPAN-1 fiber (which is a fibrous sorbent based on PAN modified with thiosemicarbazide) with respect to Pt(IV) chloride complexes and showed that this fiber quantitatively recovers K_2PtCl_6 from HCl and NaCl solutions (C_{Pt} = 1–10 mM) with similar rates [18]. The maximal sorption capacity (1.35 mmol g^{-1}) is observed in 0.5 M HCl. Sorption of Pt(IV) chloride complexes with GLIPAN-1 in all cases is caused by metal complexation with sorbent as a polymeric ligand and metal reduction in the fiber phase. The complex [R–NH–C(NH–NH_2)=SPt(II)Cl_2], in which the thiosemicarbazide group is a bidentate ligand, is the final sorbed species of platinum [18].

For recovery of platinum(II) chloride complexes, we proposed fibrous nitrogen-containing sorbents of the TIOPAN type (copolymers of PAN with grafted polyglycidyl methacrylate PAN–PGMA) modified with various N,S-containing reagents (Table 1) [19–22]. High Pt(II) sorption is observed with TIOPAN-6 at room temperature and with TIOPAN-2, TIOPAN-5, and TIOPAN-6 at elevated temperatures. The static sorption capacity (SSC) of these fibers in 1 M HCl decreases in the order TIOPAN-6 > TIOPAN-5 > TIOPAN-2 at 20°C and TIOPAN-2 > TIOPAN-5 > TIOPAN-6 at 98°C (Table 2). We concluded that in all cases the Pt(II) sorption is caused by complexation with the sorbents as polymeric ligands. In the fiber phase, TIOPAN-2 forms complexes [Pt(SR_2)Cl_2], TIOPAN-5 gives [Pt(SHR)$_2Cl_2$] in which polymeric ligands coordinate via sulfur atoms, and TIOPAN-6 forms *cis*-[Pt(SQuinR)$_2Cl_2$] in which 8-mercaptoquinoline group is a monodentate ligand bonded to Pt(II) via nitrogen atom [19].

Table 2. Recovery of platinum from 1 M HCl with TIOPAN-type sorbents

Sorbent	Recovery, %		
	Pt(IV) at 98°C	Pt(II) at indicated temperature, °C [19]	
		20	98
TIOPAN-1	1	29	47
TIOPAN-2	82	15	100
TIOPAN-3	0	3	8
TIOPAN-4	19	9	25
TIOPAN-5	2	43	82
TIOPAN-6	97	100	96

In this work, we studied the sorption properties of TIOPAN-type N,S-containing fibers with respect to Pt(IV) chloride complexes and the composition of the species formed in the sorbent phase.

EXPERIMENTAL

Sorption was studied under static conditions at the continuous agitation and at 18 and 98°C. The starting Pt(IV) compound, K_2PtCl_6, was synthesized by the method described in [23]. Sorption was performed from freshly prepared 1–20 mM solutions of K_2PtCl_6 in 0.1–4.0 M HCl or 0.1–2 M NaCl. In all cases, the volume of solutions taken was 20 ml, and the sorbent sample was 0.1 g. The platinum content in solutions was determined spectrophotometrically with tin(II) chloride [24]. The amount of the metal sorbed was calculated as the difference between its content in the solution before and after sorption. The IR spectra of fibers within the 400–4000 cm^{-1} range were measured on an IKS-29 spectrophotometer, and within the 140–400 cm^{-1} range, on a Hitachi FIS-3 spectrophotometer. Samples were prepared as in [5]. X-ray photoelectron spectra (XPES) were recorded on a Perkin–Elmer PH 15400 spectrometer with excitation by Mg X-ray radiation. Spectra were treated (quantitative analysis and line separation) using standard programs. The spectra were standardized against C1*s* electron binding energy of 285.0 eV. The binding energy was determined with an error of 0.2 eV. Thermograms of sorbents were recorded on an MOM (Hungary) derivatograph within the 20–800°C range

at a heating rate of 10 deg min^{-1}. Isothermal heating of sorbents was performed on a special device equipped with a system for a qualitative analysis of the liberated gaseous products. Thermal conversion of samples (temperature of the decomposition onset) was visually controlled on a Koeffler stage.

Initially, the sorption power of TIOPAN fibers with respect to Pt(IV) at sorption from solutions of K_2PtCl_6 in 1 M HCl was studied at 98°C (Table 2). The sorption duration was 1 h, the platinum concentration in the initial solution was 1 mM. As seen, Pt(IV) is efficiently recovered with TIOPAN-2 and TIOPAN-6, and Pt(II), also with TIOPAN-5. There is no correlation between the sulfur content in the fiber and the recovery of both Pt(II) and Pt(IV) (Tables 1, 2). TIOPAN-1, TIOPAN-3, TIOPAN-4, and TIOPAN-5 fibers recover Pt(IV) poorly.

TIOPAN-2 and TIOPAN-6 fibers containing diethyldithiocarbamate and 8-mercaptoquinoline groups, respectively, were studied in detail. It was found that the time of attaining the apparent equilibrium τ_{ap} in distribution of Pt(IV) between the fiber and 1 M HCl solution is 2 h at 18°C and 1 h at 98°C for TIOPAN-6 and 2 h at 98°C for TIOPAN-2. The half-sorption time $\tau_{1/2}$ for TIOPAN-6 is 2 and 4 min at 98 and 18°C, respectively. The low rate of Pt(IV) sorption with TIOPAN-2 should be noted: $\tau_{1/2}$ is 25 min even at 98°C (Fig. 1a, Table 3).

For sorption from 0.5 M NaCl, the apparent equilibrium of Pt(IV) between the solution and sorbent in all cases is attained in 2 h, and $\tau_{1/2}$ both at 98 and 18°C is 4 min for TIOPAN-6 and ~23 min for TIOPAN-2 (Fig. 1a, Table 3). At room temperature, TIOPAN-2 recovers Pt(IV) chloride complexes neither from HCl nor from NaCl solutions.

The type of the diffusion kinetics of sorption is commonly determined using the known dependence of the exchange degree F ($F = Q_\tau/Q_\infty$, where Q_τ is sorption in time τ and Q_∞ is the equilibrium sorption) on sorption time τ [25] and the dependence on sorption time of B_τ and $-\ln(1 - F)$, where B_τ is the kinetic coefficient of sorption [$B_\tau = (F/1.08)^2$] [26]. The analysis of the kinetic curves of sorption (Fig. 1) shows mixed diffusion character of the kinetics of Pt(IV) sorption with TIOPAN-6 fiber from acid solutions. The linear sections of $-\ln(1 - F)$–τ curves indicate that the "film diffusion" is the major factor affecting the kinetics of Pt(IV) sorption with TIOPAN-2 fiber [26] (Fig. 1c).

It was found that at platinum sorption with TIOPAN-6 at 18 and 98°C (C_{Pt} = 1 mM) the Pt(IV) recovery decreases with increasing concentration of hydrochloric acid: platinum is practically completely recovered from 0.1–0.5 M HCl and to only 75–80% from 4 M HCl. The effect of HCl concentration on platinum(IV) sorption with TIOPAN-2 is even stronger. At 98°C, platinum recovery decreases from 100 to 45% in going from 0.1 to 4 M HCl.

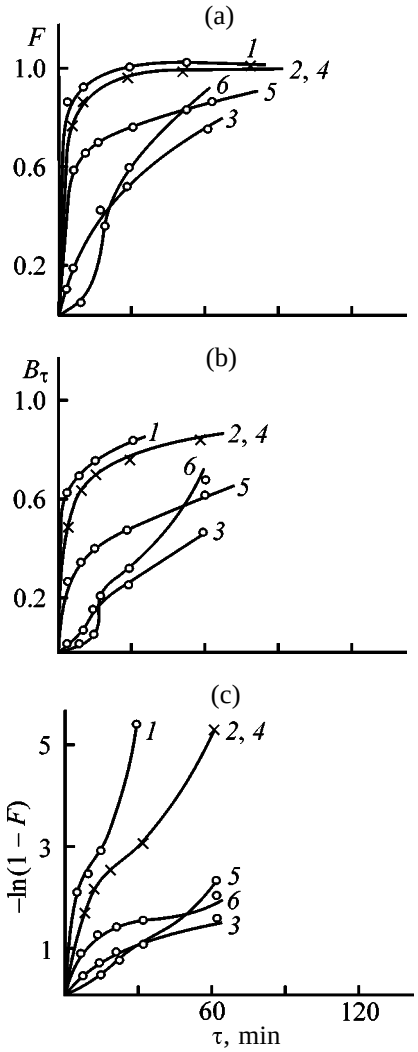

Fig. 1. Dependences of (a) F, (b) B_τ, and (c) $-\ln(1 - F)$ on the time of sorption τ of K_2PtCl_6 from 1 M HCl with (*1, 2*) TIOPAN-6 and (*3*) TIOPAN-2 and from 0.5 M NaCl with (*4, 5*) TIOPAN-6 and (*6*) TIOPAN-2. (*F*) Exchange degree; $F = Q_\tau/Q_\infty$, where Q_τ is Pt sorption in time τ and Q_∞ is equilibrium sorption; (B_τ) kinetic coefficient of sorption, $B_\tau = (F/1.08)^2$. Temperature, °C: (*1*) 3, (*6*) 98, and (*4, 5*) 18.

The dependence of SSE with respect to Pt(IV) on equilibrium metal concentration is shown in Fig. 2. Sharp slope of the isotherms of the Pt(IV) sorption from HCl solutions allows TIOPAN-2 and TIOPAN-6 to be recommended for quantitative recovery of platinum from both dilute and concentrated solutions, the

former sorbent at heating and the latter, both at room temperature and heating. The data on SSC of fibers are listed in Table 3. The platinum(IV) recovery from NaCl solutions is weaker (Table 3, Fig. 2).

Sorption of Pt(IV) with TIOPAN-2 and TIOPAN-6 is practically irreversible: only 0.6 and 1.0% of Pt is desorbed with 6 M HCl and 22 and 26% of Pt is desorbed with thiourea solution in 10% HCl from TIOPAN-2 and TIOPAN-6, respectively.

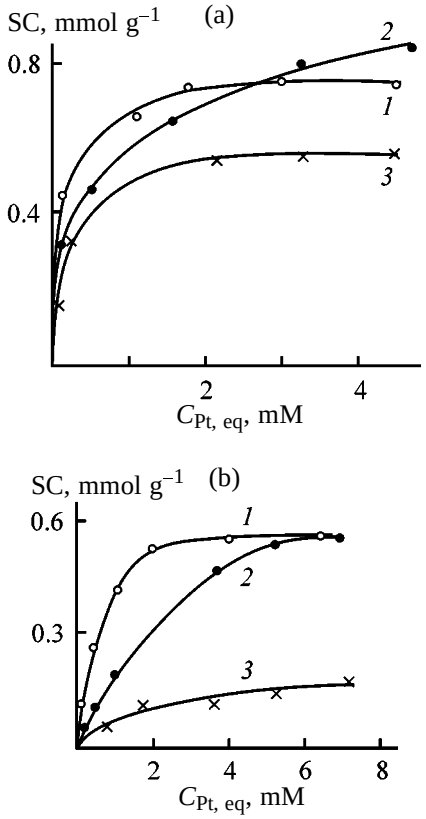

Fig. 2. Isotherms of K_2PtCl_6 sorption from (a) 1 M HCl and (b) 0.5 M NaCl at (*1*, *2*) 98 and (*3*) 18°C. (SC) Sorption capacity; ($C_{Pt,eq}$) equilibrium concentration. Sorbent: (*1*) TIOPAN-2 and (*2*, *3*) TIOPAN-6.

The comparison of the kinetic and capacity characteristics of the fibers shows that in all cases platinum(II) is recovered faster and with greater SSC as compared to Pt(IV). This may be due to two factors: (1) greater charge density on $PtCl_4^{2-}$ as compared to $PtCl_6^{2-}$, which increases electrostatic attraction of the complex anion to the protonated nitrogen atom of the fiber, and (2) greater steric hindrance in interaction of the octahedral $PtCl_6^{2-}$ complex as compared to the square-planar $PtCl_4^{2-}$ ion.

It should be noted that TIOPAN-5 containing thiol groups practically completely recovers K_2PtCl_4 [19] but sorbs K_2PtCl_6 poorly (Table 2).

The analysis of the kinetics and capacity parameters of TIOPAN-2 with respect to K_2PtCl_6 suggests that the platinum recovery from both hydrochloric acid and NaCl solutions proceeds with formation of a Pt(II) compound of the $[Pt(SR)_2Cl_2]$ type in the sorbent phase. The diethyldithiocarbamate group of the polymeric ligand coordinates to Pt(II) via sulfur atom as a monodentate ligand. The low rate of sorption, sharp temperature dependence of sorption, and comparison of the IR and far-IR spectra of fibers after sorption of K_2PtCl_6 (Figs. 3, 4) and K_2PtCl_4 [19] indicate complex formation. In both cases the spectra are similar. A strong change of the IR spectrum in the ν(CS) and ν(CN) range (1200–1600 cm^{-1}) (Fig. 3) shows formation of a covalent bond of platinum with the fiber. XPES indicates reduction of Pt(IV) to Pt(II) during K_2PtCl_6 sorption. The binding energy of the Pt4$f_{7/2}$ electron is 72.7 eV, which agrees with reference data for Pt(II) [27].

For comparison, we performed a reaction of K_2PtCl_4 with the monomeric ligand, sodium diethyldithiocarbamate. To a hot solution of K_2PtCl_4, a hot solution of sodium diethyldithiocarbamate was added gradually with stirring. The resulting pale yellow precipitate was filtered off and washed with ether. As shown by elemental analysis and far-IR and IR spectra, the compound corresponds to the previously described complex $[PtS_2N(C_2H_5)_2]$ [28] in which diethyldithiocarbamate ion coordinates to platinum atom via sulfur atom. In the IR spectra of this compound and of TIOPAN-2 fiber after K_2PtCl_6 sorption the same bands assigned to stretching vibrations of the coordinated diethyldithiocarbamate group are observed in the 1200–1600 cm^{-1} range (Fig. 3). However, their far-IR spectra differ substantially: the spectrum of the fiber after sorption of K_2PtCl_6 from 1 M HCl contains two bands at 310 and 328 cm^{-1} assigned to the stretching vibrations ν(Pt–Cl) of asymmetrical *cis*-$[Pt(SR)_2Cl_2]$. TIOPAN-2 fiber after sorption of K_2PtCl_6 from 0.5 M NaCl has the similar spectrum. In the far-IR spectrum of the chelate with the monomeric ligand such bands are absent [28]. The difference in reaction of K_2PtCl_6 with the monomeric ligand and the fibrous sorbent, both containing diethyldithiocarbamate group, may be due to two factors: (1) one of two sulfur atoms of the polymeric ligand (TIOPAN-2) is bound with the fiber matrix PAN–PGMA and cannot participate in formation of the chelate bond with platinum and (2) steric hindrances arise in interaction of the platinum atom with the bulky diethyldithiocarbamate group bonded with the polymeric matrix of the fiber.

The high rate of recovery of the platinum(IV) chloride complexes with TIOPAN-6 fiber from both acid and neutral media and weak dependence on temperature suggest that in the first stage of sorption the initial complex reacts with protonated fiber

$$2RQuinS \cdot HCl + K_2PtCl_6 \rightarrow (RQuinSH)_2PtCl_6 + 2KCl,$$

$$2RQuinS \cdot H_2O + K_2PtCl_6 \rightarrow (RQuinSH)_2PtCl_6 + 2KOH.$$

The next stage is the partial reduction of the onium platinum(IV) complex to the analogous platinum(II) complex $[(RQuinSH)_2PtCl_4]$ with 8-mercaptoquinoline groups that do not participate in sorption. The XPES data indicate the prevalence of platinum(II) complexes on the fiber. The binding energy of the Pt4$f_{7/2}$ electron of 73.1 eV is in a good agreement with the reference data for Pt4$f_{7/2}$, e.g., in K_2PtCl_4 [27]. We can assume that sorption from NaCl solutions involves in the second stage the Anderson rearrangement with formation of *cis*-$(RQuinSH)_2PtCl_4$ coordinated via the nitrogen atom:

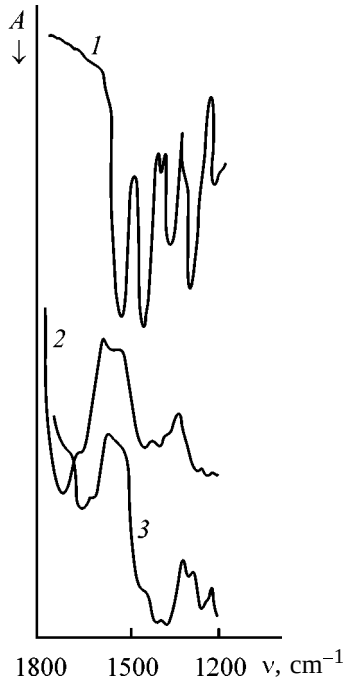

Fig. 3. IR spectra of (*1*) $[Pt(S_2N(C_2H_5)_2]$, (*2*) TIOPAN-2 fiber after K_2PtCl_6 sorption from 1 M HCl, and (*3*) sodium diethyldithiocarbamate. (*A*) Absorption and (ν) wave number; the same for Fig. 4.

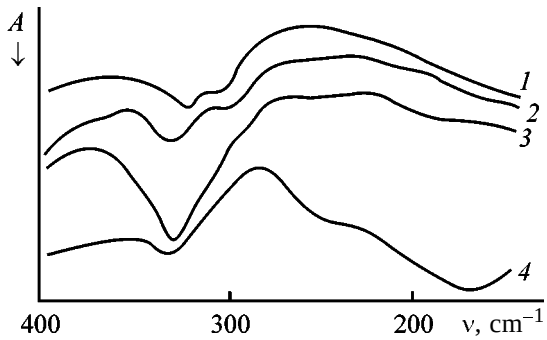

Fig. 4. Far-IR spectra of fibers after K_2PtCl_6 sorption. Sorption temperature 98°C, C_{Pt} = 8 mM. Sorption from (*1–3*) 1 M HCl and (*4*) 0.5 M NaCl. (*2*) Fiber heated at 180°C for 0.5 h. Sorbent: (*1*) TIOPAN-2 and (*2–4*) TIOPAN-6.

$$(RQuinSH)_2PtCl_4 \rightarrow cis\text{-}[Pt(RQuinS)_2Cl_2] + 2HCl.$$

Heating promotes such transformation. To simulate this reaction, we estimated the rearrangement temperature from the termogravimetric data for the fiber. In the far-IR spectrum of TIOPAN-6 fiber after sorption of K_2PtCl_4 from 1 M HCl, subjected to isothermal heating at 180°C for 0.5 h, two bands are

observed at 305 and 329 cm^{-1}, belonging to Pt–Cl stretching vibrations of the asymmetrical *cis*-dichlorodiammine complex. Formation of H bonds between protonated nitrogen of the fiber mercaptoquinoline groups and chloride ions in the inner coordination sphere of the metal complex facilitates such transformation.

It is known that in reactions of platinum complexes with 8-mercaptoquinoline and its derivatives yield the Pt(II) chelates [29]. For instance, reaction of 8-mercaptoquinoline with both K_2PtCl_4 and K_2PtCl_6 produces the compound $[Pt(SNC_9H_6)_2]$ in which the organic ligand coordinates to platinum via N and S atoms [29]. Since, when PAN–PGMA is modified with sodium 8-mercaptoquinolinate [20], the modifying agent is incorporated into the fiber matrix via the sulfur atom. The platinum atom is probably bound with the fiber via the nitrogen atom.

CONCLUSIONS

(1) Sorbents TIOPAN-2 and TIOPAN-6 (copolymers of polyacrylonitrile with grafted polyglycidyl methacrylate modified with sodium diethyldithiocarbamate and 8-mercaptoquinoline, respectively) can quantitatively recover platinum(IV) chloride complexes from acid and neutral solutions. TIOPAN-6 with high rate and quantitatively recovers Pt(IV) at 18 and 98°C, while TIOPAN-2 efficiently sorbs Pt(IV) only at heating.

(2) In all cases, Pt(IV) sorption is caused by complexation with sorbents as polymeric ligands. The platinum(IV) chloride complex reacts with TIOPAN-2 fiber with formation of the $[Pt(SR)_2Cl_2]$-type compound, in which the polymeric ligand coordinates via sulfur atom. At Pt(IV) sorption with TIOPAN-6, the onium compound $(RQuinSH)_2PtCl_4$ is formed. At heating, this compound converts into *cis*-$[Pt\cdot(RQuinS)_2Cl_2]$ in which 8-mercaptoquinoline group coordinates via nitrogen atom.

SORPTION AND ION-EXCHANGE PROCESSES

Effect of Cationic Form of a Fibrous Sulfonic Cation-Exchange Resin on Sorption of Tetramminepalladium(II) and Its Cross-Sectional Distribution

Abstract—The effect of the nature of exchangeable cation (Na^+, Mg^{2+}, Ba^{2+}, La^{3+}) in FIBAN K-1 fibrous sulfonic cation-exchange resin on sorption of tetramminepalladium(II) and its cross-sectional distribution in fabrication of Pd catalysts is studied.

Sulfonic cation-exchange resins can be used as supports in fabrication of metal-containing catalysts. For instance, it was demonstrated [1, 2] that the supported Pd catalyst based on FIBAN K-1 fibrous cation-exchange resin in the Ba form shows high activity in oxidation of hydrogen.

In the first stage of preparation of Pd catalysts palladium is incorporated in a polymeric support (fibrous cation-exchange resin) by ion exchange in a tetramminepalladium(II) chloride solution. Then the catalyst is dried, heated in a helium current, and reduced to Pd^0 in a hydrogen stream.

A review of works on sorption of $[Pd(NH_3)_4]^{2+}$ on granulated cation-exchange resins can be found in [3]. However, information on its sorption on fibrous sulfonic cation-exchange resins is lacking in the literature.

Since the catalyst activity depends not only on the Pd content and dispersity, but also on its distribution throughout the bulk of a support, in this work we studied certain features of ion exchange $M^{z+} \rightarrow [Pd(NH_3)_4]^{2+}$ (M^{z+} = Na^+, Mg^{2+}, Ba^{2+}, La^{3+}) in FIBAN K-1 fibrous sulfonic cation-exchange resin and also the effect of the cationic form of this resin on the Pd cross-sectional distribution.

EXPERIMENTAL

FIBAN K-1 fibrous sulfonic cation-exchange resin was prepared by radiation three-dimensional grafting of a copolymer of styrene (98%) and divinylbenzene (2%) to polypropylene staple fiber followed by sulfonation of the resulting matrix with concentrated sulfuric acid [4]. The grafting proceeds quite uniformly (at a 120% degree of grafting the fiber diameter is 40 ± 3 μm).

Totally substituted Na, Mg, Ba, and La forms of K-1 were prepared from the H form (exchange capacity 3.24 mg-equiv g^{-1}) by passing an excess of a 1 N solution of the corresponding metal chloride through a column packed with the resin until pH of the filtrate became equal to that of the initial solution. Then the samples were washed with distilled water to a negative reaction for chloride and air-dried at room temperature. The swellability of the samples was determined by centrifugation [5].

Ion exchange of Na^+, Mg^{2+}, Ba^{2+}, and La^{3+} for $[Pd(NH_3)_4]^{2+}$ was studied by placing a weighed portion of the resin in the corresponding form in 0.01 N tetramminepalladium(II) chloride at $n\mathrm{Pd}_0^{2+}/n\mathrm{Pd}_{max}^{2+} = 0.35$, where $n\mathrm{Pd}_0^{2+}$ is the $[Pd(NH_3)_4]^{2+}$ content in the initial solution and $n\mathrm{Pd}_{max}^{2+}$ is the limiting (estimated from the exchange capacity) content of $[Pd(NH_3)_4]^{2+}$ in the resin phase.

The resin samples (2 g) were preliminarily held in distilled water to attain the limiting swellability, and then the tetramminepalladium(II) chloride solution was added in amount estimated taking into account the exchange capacity of the given cationic form of K-1 resin. The total volume of the aqueous phase was 100 ml. Keeping in mind that the ammine complex $[Pd(NH_3)_4]^{2+}$ is stable at pH ≥ 8 [6], and also to minimize formation of lanthanum hydroxide and basic salts, ion exchange $M^{z+} \rightarrow [Pd(NH_3)_4]^{2+}$ was performed at pH 8–8.5. The experiments were carried out at room temperature with vigorous stirring (magnetic

1070-4272/01/7409-1446$25.00

stirrer). The contact time was 10 min, which was demonstrated to be sufficient for reaching the saturation. Samples (1 ml) of the liquid phase were taken at fixed intervals (10–60 s) and analyzed for Pd and the exchangeable cation. Palladium was determined spectrophotometrically [7], and Mg^{2+}, Ba^{2+}, and La^{3+}, by chelatometric titration with Na_2EDTA (Mg^{2+} and Ba^{2+} with Eriochrome Black T [8] and La^{3+} with Xylenol Orange [9]). The Na^+ concentration was determined indirectly as follows [10]: An aliquot of the solution was acidified with HCl to pH 1, evaporated to dryness, and heated at 120°C to remove HCl. Then the solid residue was dissolved in water, and the sum of chlorides was determined by Mohr titration. From this value we determined the sum of sodium and palladium in the solution. The Na^+ concentration was then estimated as the difference between this value and the Pd concentration determined spectrophotometrically.

Using the data on the M^{z+} and $[Pd(NH_3)_4]^{2+}$ concentrations in the aqueous phase, the selectivity coefficient was estimated as

$$S = \frac{\bar{X}_{Pd} X_M}{X_{Pd} \bar{X}_M}$$

where $\bar{X}$ and X are the equivalent fractions of the cations in the resin phase and solution, respectively. The equivalent fraction of palladium in the resin phase $\bar{X}_{Pd}$ was estimated as

$$\bar{X}_{Pd} = \frac{n\mathrm{Pd}_0^{2+} - n\mathrm{Pd}_{eq}^{2+}}{n\mathrm{Pd}_{max}^{2+}},$$

where $n\mathrm{Pd}_{eq}^{2+}$ is the Pd content in the equilibrium solution.

The degree of exchange with respect to M^{z+} was estimated as the ratio of the amount of the exchangeable cation in the equilibrium solution to its initial amount in the resin.

As an experimental parameter characterizing the ion-exchange rate with various exchangeable cations we selected $t_{0.9}$, i.e., the time required to reach 90% saturation of the resin with respect to $[Pd(NH_3)_4]^{2+}$.

The cross-sectional distribution of Ba^{2+} and $[Pd(NH_3)_4]^{2+}$ was studied by electron micro probe analysis (EPMA) with a Cameca MS-46 instrument. The distribution data were obtained parallelly for no less than 10 fibers of a sample. The reproducibility of the data was sufficiently high (7–8 fibers of 10 had practically the same diameters and demonstrated identical distribution curves).

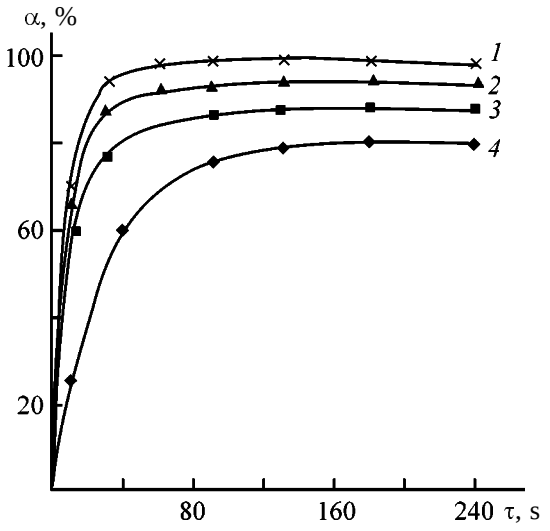

Fig. 1. Degree of sorption of $[Pd(NH_3)_4]^{2+}$ on FIBAN K-1 α as a function of time τ. Cationic form of the resin: (*1*) Na, (*2*) Mg, (*3*) Ba, and (*4*) La.

The Pd content in samples specially prepared for EPMA was about 1%. The catalyst based on the Na form of K-1 was prepared as follows. A weighed portion of the resin (2 g) was poured over with 20 ml of distilled water, allowed to stand until reaching the limiting swelling, and 13.2 ml of 0.025 N tetramminepalladium(II) chloride was added with vigorous stirring. After a 10-min contact the resin was separated from the solution, washed to remove chloride, and air-dried at room temperature. The catalysts based on the Mg and Ba forms were prepared similarly, except that the volume of 0.025 N tetramminepalladium(II) chloride added was 14.0 and 15.2 ml, respectively.

The kinetic curves of cation exchange on various cationic forms of K-1 with $[Pd(NH_3)_4]^{2+}$ are given in Fig. 1. In the case of the Na form tetramminepalladium(II) is practically totally recovered from the aqueous phase. For the Mg, Ba, and La forms the degree of exchange was found to be 95, 89, and 80% of the theoretical value, respectively. The degree of saturation of the resin phase with $[Pd(NH_3)_4]^{2+}$ is 0.35, 0.33, 0.31, and 0.28% for the Na, Mg, Ba, and La forms, respectively. The relative error of determination of the degree of saturation was within 1.5%. The degrees of exchange estimated from the $[Pd(NH_3)_4]^{2+}$ and exchangeable cation contents in the equilibrium solution were well consistent (the difference was within 1%).

Characteristics of FIBAN K-1 in various cationic forms

Cation	Swellability		$t_{0.9}$, s	S
	wt %	mol H_2O equiv^{-1} resin		
H^+	111.0	19.0	–	–
Na^+	97.0	17.8	22	>20
Mg^{2+}	91.0	16.2	25	9.4
Ba^{2+}	54.8	11.4	40	3.1
La^{3+}	54.2	10.7	72	1.5
$[Pd(NH_3)_4]^{2+}$	35.8	7.8	–	–

On passing from the Na form of the resin to the Mg, Ba, or La forms $t_{0.9}$ increased from 22 to 72 s, and the selectivity coefficient decreased (see table).

Previously we demonstrated by EPMA that in a sulfonic cation-exchange resin the cross-sectional distribution of functional groups depends on the synthesis conditions [11]. In this work with an example of the Ba form of K-1 we demonstrated that in FIBAN K-1 fibrous sulfonic cation-exchange resin functional groups are uniformly distributed throughout the cross section of its fibers (Fig. 2a). In the Na form and to a lesser extent in the Mg form the surface layer of the resin grains is enriched with $[Pd(NH_3)_4]^{2+}$ ions (Figs. 2b, 2c). In the Ba form Pd is distributed uniformly throughout the fiber cross section (Fig. 2d). The results obtained suggest that under the experimental conditions the system approaches the ion-exchange equilibrium only in the case of the Ba form. Presumably, the observed rapid exchange of Na^+ and Mg^{2+} for $[Pd(NH_3)_4]^{2+}$ results in formation of slightly swelling surface layer {see data for the $[Pd(NH_3)_4]^{2+}$ form in the table}, impeding further penetration of strongly hydrated Na and Mg cations. For the Na and Ba forms $t_{0.9}$ was found to be 22 and 40 s, respectively. This result is consistent with the conclusion made in [12]. Finally, changing the cationic form of the resin, one may control the rate of ion exchange $M^{z+} \rightarrow [Pd(NH_3)_4]^{2+}$ as well as the Pd cross-sectional distribution, which is important for fabrication of special-purpose Pd catalysts.

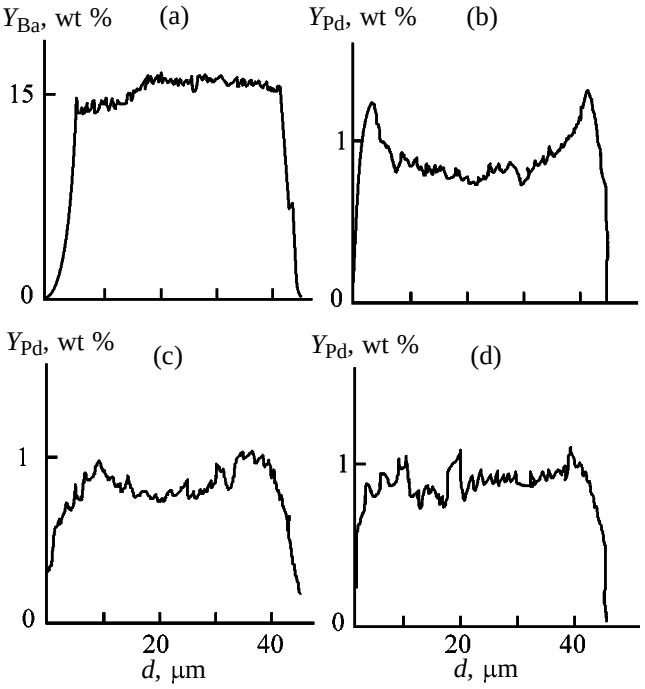

Fig. 2. Cross-sectional distribution of (a) Ba^{2+} and (b–d) $[Pd(NH_3)_4]^{2+}$. (Y_{Ba}, Y_{Pd}) Ba and Pd contents and (d) fiber diameter. Cationic form of the resin: (b) Na, (c) Mg, and (d) Ba.

CONCLUSIONS

(1) The limiting exchange capacity for $[Pd(NH_3)_4]^{2+}$ decreases on passing from the Na form of FIBAN K-1 fibrous sulfonic cation-exchange resin to the Mg, Ba, and La forms.

(2) The cross-sectional distribution of $[Pd(NH_3)_4]^{2+}$ depends on the cationic form of the resin: in the Na form Pd is concentrated in the surface layer, whereas in the Ba form it is uniformly distributed across the fiber. The Mg form takes an intermediate position.

Abstract—Low-swelling sorbent with weakly basic anion-exchange properties was prepared from clinoptilolite-containing tuffs and polyethylenimine using epichlorohydrin cross-linking agent. The properties of this sorbent (total anion-exchange capacity, swellability, etc.) were studied as influenced by the concentrations of the modifying and cross-linking agents, their ratio, period after sorbent preparation, and number of sorption–desorption cycles. The optimal conditions for modifying clinoptilolite-containing tuffs were developed and elemental composition of the resulting sorbent (with respect to C, H, and N) was determined.

At present cheap ion-exchange materials find expanding application in solving various problems in industry and ecology. These sorbents include natural zeolites such as clinoptilolite-containing tuffs (CTs) [1] and new sorbents prepared from CTs modified with amino-containing organic compounds, e.g., cheap and available hexadecyltrimethylammonium, which affects the surface properties and imparts anion-exchange properties to the natural zeolite [2–4]. However, the anion-exchange capacity of such material is rather low (0.02–0.06 mg-equiv g^{-1}). Anion exchangers based on CT were prepared by tuff impregnation with polyhexamethyleneguanidine amine-containing electrolyte (PHMG) followed by cross-linking with epichlorohydrin (ECH) [5, 6]. As a result, we obtained sorbents with a moderate exchange capacity; the anion-exchange capacity of the best samples was 0.15–0.20 mg-equiv ml^{-1}. The selectivity of these sorbents with respect to oxygen-containing anions (e.g., chromate ion [7]) was studied. The resulting sorbents preserve the cation-exchange capacity of the initial CTs [6].

In this work we studied the preparation of organozeolite with weakly basic properties and high anion-exchange capacity.

EXPERIMENTAL

As mineral support we used natural CT, an abundant zeolite. The required material containing 50–60% zeolite was supplied from the Tedzami deposit (Georgia), and its fractional composition was as follows (mm): $-1.0+0.5$ and $-2.5+1.6$ The unit cell of this zeolite can be described by the empirical formula $(K_2, Na_2, Ca)_3(Al_6Si_{30}O_{72})\cdot 24H_2O$.

As modifying agent we used polyethylenimine (PEI), which is a water-soluble polyelectrolyte with weakly basic amine groups [8]. The initial zeolite was modified with PEI by the following procedure. A weighed portion of washed CT with certain grain size was wetted with the appropriate volume of the PEI solution (the PEI concentration was varied from 15 to 33%) and thoroughly mixed. Then the cross-linking agent was added and the resulting composition was mixed. In our work we used ether ECH tetrahydrate or its 25% alcoholic solution. The PEI/ECH molar ratio was varied within 2.0–5.0. The sorbent with the modifying agent after its treatment with ECH was left overnight, and then washed with water to remove soluble and weakly bound polymer from the sorbent [8].

The quality of the resulting sorbent was evaluated using the experimental data on the anion- and cation-exchange capacity and swellability of the modified samples. The anion-exchange capacity of zeolites modified with PEI was studied using the static procedures, which allow determination of the total exchange capacity and its variation as influenced by the solution pH.

The total anion-exchange capacity of the sorbent was determined from the sorption of anions from

1070-4272/01/7409-1450$25.00

acidic solutions by the following procedure. The sorbent was preliminarily converted to the Cl form using a 0.3 M HCl solution under the static conditions (6 ml of sorbent, 90 ml of 0.3 M HCl, 48 h contact time). Then the sorbent was washed with distilled water (5 × 20 ml). The chloride anions were desorbed under the static conditions with 0.2 N H_2SO_4 (100 ml), contact time 48 h. It was found that the additional portion of sulfuric acid did not affect desorption of Cl^- anions. The amount of chloride anions in the regenerate corresponded to the total anion-exchange capacity of the sorbent. The concentration of chloride ions in solution was determined by mercurimetry [9]. The anion-exchange capacity was calculated by the following equation:

$$A_{Cl} = C_{Cl}V/w,$$

where A_{Cl} is the anion-exchange capacity (mg-equiv ml^{-1}), C_{Cl} is the concentration of chloride ions in the regenerate (mg-equiv ml^{-1}), V is the volume of 0.2 M sulfuric acid solution (ml), and w is the sorbent volume (ml).

The anion-exchange capacity at pH 6–7 was evaluated by sorption of sulfate ions at pH 6–7 and their desorption with carbonate ions using the ion chromatography [10].

The cation-exchange capacity of modified CT was measured by sorption of ammonium ions. In this case, 0.5-g sorbent sample was placed in a 0.1 M solution of ammonium chloride (25 ml), stirred for 28 days under the static conditions, and then ammonium cations were desorbed with 2 M sodium chloride solutions (50 ml) for 13 days, also under the static conditions. The content of the desorbed ammonium cations was determined with formaldehyde [11].

The cation-exchange capacity of the modified CT sorbent was calculated from the following equation:

$$A_{NH_4^+} = C_{NH_4^+}V/m,$$

where $A_{NH_4^+}$ is the cation-exchange capacity (mg-equiv g^{-1}), $C_{NH_4^+}$ is the concentration of ammonium ions in the eluate (mg-equiv ml^{-1}), V is the volume of 2 M sodium chloride solution (ml), and m is the sorbent weight (g).

The swellability of the sorbent was determined as the volume (ml) occupied by a 1-g sample of the modified CT after its preliminary swelling in water.

To determine the modification conditions, we studied the anion-exchange capacity and swellability as influenced by the concentrations of the modifying (PEI) and cross-linking (ECH) agents, the PEI/ECH molar ratio, and the time after the sample preparation. The main properties of the resulting samples are listed in Tables 1 and 2.

Table 1. Anion-exchange capacity A_{Cl} (pH 6–7) and swellability of modified CTs as influenced by the preparation conditions

Concentration, %		PEI/ECH molar ratio	Swellability, ml g^{-1}	A_{Cl}, mg-equiv ml^{-1}
PEI	ECH			
25	4	5.0	1.1	0.04
25	4	2.5	1.0	0.16
25	4	2.0	1.2	0.14
15	25	5.0	1.1	0.15
25	25	5.0	1.1	0.24
33	25	5.0	2.4	0.20
25	25	5.0	1.1	0.24
25	25	2.5	1.2	0.30
25	25	2.0	1.5	0.35

Table 2. Anion-exchange capacity A_{Cl} of modified CT as influenced by the time after the sample preparation τ, its granulation, and solution pH

Granulation, mm	τ, days	A_{Cl}, mg-equiv ml^{-1}, at indicated pH	
		2	6
0.5–1.0	6	–	0.34
0.5–1.0	270–540	0.86	0.40
1.6–2.5	4	0.48	–
1.6–2.5	28	0.63	–
1.6–2.5	62	0.67	–

As seen from Table 1, the highest anion-exchange capacity was found for the CT samples modified with 25% PEI solution and 25% ECH solution at PEI/ECH = 2.0. With increasing PEI concentration (>25%) and decreasing PEI/ECH ratio (<2.5) the swellability of the resulting sorbent significantly increases. More detailed study of the anion-exchange properties was performed using the CT samples modified with 25% PEI solution in the presence of 25% ECH solution at PEI/ECH = 2.5 and granulation of 0.5–1.0 and 1.6–2.5 mm. We studied the effect of pH on the working capacity and some other properties of the modified sorbent (time after the sample preparation and number of sorption–desorption cycles under the dynamic conditions). The results are listed in Tables 2 and 3.

Table 3. Anion-exchange capacity A_{Cl} of modified CTs as influenced by the number of sorption–desorption cycles; sorbent granulation 0.5–1.0 mm

Cycle no.	A_{Cl}, mg-equiv ml^{-1}, at indicated pH	
	6–7	2
1	0.27	–
2	0.42	–
3	0.44	–
4	–	0.75
5	–	0.90
6	–	0.86

Table 4. Theoretical (based on the data of elemental analysis) and experimental anion-exchange capacity of modified CTs

Modifying agent	Content, %			α*	A_{Cl}, mg-equiv ml^{-1}	
	H	C	N		theory	experiment
PEI	1.04	6.74	2.52	3/4	1.04	0.6–0.9
PHMG	0.34	2.33	0.96	1/3	0.21	0.15–0.20

* Fraction of nitrogen capable of ion exchange.

Table 5. Cation-exchange capacity of natural and modified CT

Clinoptilolite	PEI/ECH molar ratio	Cation-exchange capacity, mg-equiv g^{-1}
Natural	–	1.10
Modified	7.7	0.70
	2.5	0.79
	2.0	0.80

As seen, our procedure allows preparation of the sorbent with stable properties, almost independent of the time after the sample preparation and of the number of sorption–desorption cycles.

Elemental analysis for carbon, hydrogen, and nitrogen (Table 4) allows evaluation of the theoretical capacity and its comparison with the experimental data.

Our data show that the theoretical values of the anion-exchange capacity of CT modified with PEI or PHMG are fairly close to the experimental results. The anion-exchange capacity of CT modified with PEI exceeds the capacity of CT modified with PHMG by a factor of 3 and 6 in neutral and acidic solutions, respectively.

The sorbent properties listed in Table 5 indicate that the cation-exchange capacity of the modified sorbent is slightly smaller than the cation-exchange capacity of the initial zeolite, which is probably due to partial blocking of the zeolite surface with the modifying agent.

CONCLUSIONS

(1) Modification of clinoptilolite with polyethylenimine followed by cross-linking with epichlorohydrin yields sorbents exhibiting the properties of weakly basic anion exchangers but retaining the cation-exchange properties of the initial clinoptilolite-containing tuffs. The anion-exchange capacity depends on the solution pH, and the highest capacity is attained in a weakly acidic medium.

(2) The total anion-exchange capacity (0.6–0.9 mg-equiv ml^{-1}) of the resulting sorbent is significantly higher than the capacity (0.15–0.20 mg-equiv ml^{-1}) of the sorbent prepared by modification of clinoptilolite-containing tuffs with 15% polyhexamethyleneguanidine solution.

(3) The cation- and anion-exchange capacities of the resulting sorbent are comparable.

SORPTION AND ION-EXCHANGE PROCESSES

Effect of Oxidizing Treatment of Walnut Shell on the Properties of Activated Carbon

Abstract—The effect of oxidizing treatment of walnut shell on the yield of activated carbon and on its pore structure was studied.

We have shown recently that active carbons (AC) with acceptable structural and sorption characteristics can be obtained by a traditional procedure (carbonization with subsequent activation) from walnut shell (WS) with the yield of about 10%. At the same time, it is known that fruit kernels and various nut shells are cellulose materials [2], and the procedures conventionally used in their heat treatment can be extended to the technology of obtaining AC [3].

Preliminary oxidation is one of the methods for the treatment of cellulose materials with the aim to improve the pore structure and increase the yield of AC obtained from them [[2]. In this case we must distinguish between the action of oxygen as an external agent, the excess of which will result in complete combustion of a polymer, and the action of oxygen incorporated into elementary units of a polymer and taking part in the material cross-linking on heat treatment. In the latter case oxygen promotes formation of intermediate bridges and intra- and intermolecular cross-links determining the formation of the molecular structure of a carbon material.

Within limited temperature and concentration ranges atmospheric oxygen also can play the same role, but its excess is undesirable, since it decreases the carbon yield at the expense of incontrolled degradation of the polymer and ultimately results in a loss of the AC quality. In view of the aforesaid the method of "sparing" oxidizing heat treatment found use in obtaining carbon fibers [7] and also synthetic AC (SKN and SKS) [8].

In this work we studied the effect of preliminary oxidizing treatment on preparation and properties of AC based on WS.

EXPERIMENTAL

The installation and procedures for oxidizing treatment of WS, the carbonization of the oxidized material, and the activation of the resulting carbonizates were described earlier [1]. WS was preoxidized in air at 150–330°C for 1–10 h and carbonized in flowing argon at a heating rate of 5 deg min^{-1}. The samples were kept at 800°C for 1 h. To obtain AC with various degrees of combustion loss, the activation was carried out in steam under a pressure of 0.1 MPa at 750°C for 0.1–2 h.

In this work after each stage of heat treatment we measured changes in the weight X_m (%) and volume X_V (%) of the samples under study (weight and volume combustion loss), the pore volume with respect to benzene V_s (%) ($cm^3\ g^{-1}$), and also the yield of AC R (%). The parameters of the pore structure of the samples in various stages of the thermolysis: the micropore volume V_{mi} ($cm^3\ g^{-1}$), the sorption pore volume V_s ($cm^3\ g^{-1}$), and the specific surface area S_{BET} ($m^2\ g^{-1}$), were determined from the isotherms of carbon dioxide adsorption at 0°C and of nitrogen adsorption at –196°C. The isotherms were treated by generally accepted procedures of the modern adsorption theory [9, 10].

Structural changes resulting from the heat treatment of the products were studied by X-ray diffraction (a DRON-2 diffractometer), and the interplanar spacings d_{002} (Å) were calculated. The static exchange capacity (mg-equiv g^{-1}) of the materials based on WS was determined by alkali titration. In this work averaged data of 3–5 experiments are given.

Oxidation of WS was accompanied by weight loss and contraction of the material. Figure 1 gives the

** The values for preoxidized samples are given in parentheses.

data on the kinetics of the weight loss during WS oxidation in air. At 150°C (curve *1*) the weight loss of WS is slow, and even in 10 h less than 10% is lost. At 200°C (curve *2*) the kinetics of the process is sharply changed: in 1 h the WS weight loss is already about 40% and in the subsequent 9 h it attains almost 60%. At 300°C and higher the weight loss in 1 h exceeds 70%. The oxidation is accompanied by contraction of the material, which attains about 30% in 1 h at 200°C.

We emphasize that the heat treatment of the initial WS in argon at 200°C for 10 h [1] results in an increase in the pore volume and in the static exchange capacity (SEC) of the material to 0.04 $cm^3\ g^{-1}$ and 0.45 mg-equiv g^{-1}, respectively. Carbonization decreases the yields to 25% and increases V_s to 0.05 $cm^3\ g^{-1}$. After activating the carbonizate to the combustion loss of 63%, the resulting AC has the pore volume of 0.77 $cm^3\ g^{-1}$, and its yield is 9.3%. These data suggest that the heat treatment of WS in an inert medium results in a decrease in V_s and in the AC yield compared to the AC samples obtained from WS preoxidized at 200°C for 10 h. The characteristics of the initial WS and that oxidized under the above-mentioned condition are given in Table 1. The pore volume by benzene in both initial and oxidized WS samples is 0.01–0.02 $cm^3\ g^{-1}$, i.e., no micro- and mesoporous structure is developed during the WS oxidation.

Preliminary heat treatment of cellulose materials in air allows the structural defects resulting from degradation to be "healed" at the expense of the formation of intermolecular bonds, "oxygen bridges" among them [4]. The degradation of cellulose on heating in air yields oxycellulose [11] containing carboxy groups. Typical of the oxycellulose thermolysis are hampering of depolymerization [5] and intensification of dehydration [12], occurring both intramolecularly to give the >C=O and >C=C< groups and intermolecularly with cross-linking.

In fact, the measurements (Table 1) have shown that the static exchange capacity increases from 0.23 to 0.68 mg-equiv g^{-1} during the WS oxidation, which points to the formation of phenol and carboxy groups on the material surface. Therefore, after oxidation of the initial WS we obtain another material, so-called oxidized WS (Table 1).

On carbonization and activation of the initial and also preoxidized WS samples we obtained materials whose properties are given in Table 2 and Fig. 2. On carbonization of WS a further weight loss occurs: up to 69.8% in oxidized WS and up to 72.3% in the initial WS [1, 13]. Therefore, the yield increases even

in the stage of the carbonization of preoxidized WS, as compared to the carbonization of the unoxidized samples (Table 2).

Table 2 also shows that on the carbonization of the initial and oxidized WS samples their porous structure develops differently. The carbonization of the preoxidized samples, as compared to the initial samples, results in the development of larger micropores, as determined by nitrogen adsorption (0.18 and 0.03 $cm^3 g^{-1}$, respectively). The volumes of smaller micropores, determined by CO_2 adsorption, appear to be approximately the same for the oxidized and unoxidized carbonizates (~0.19 $cm^3 g^{-1}$). At the expense of larger volume of coarse micropores in the carbonizates obtained from oxidized WS, their S_{sp} appears to be higher than in the carbonizates obtained from unoxidized WS (350 $m^2 g^{-1}$ compared to 70). It is known that the volumes and the average size of micropores determined from N_2 adsorption isotherms for carbons with high combustion losses (50–70%) considerably (sometimes twice) exceed the corresponding values calculated from the data on CO_2 adsorption. Such a difference is determined by the formation of large micro- and supermicropores in which the CO_2 adsorption at 0°C occurs partially by the mechanism of superficial and not only volume filling [14].

We emphasize that no mesoporosity develops in the stage of carbonizing materials obtained from both the initial and preoxidized WS. As for V_s, preoxidation of WS results in the increase in the pore volume of the carbonizate from 0.06 for unoxidized samples to 0.15 $cm^3 g^{-1}$ for preoxidized samples (Table 2).

During carbonization of carbon-containing materials the precursors of AC are formed. Their properties largely determine the properties of AC [15]. The yield of carbonizates obtained from the oxidized material somewhat increases (30.2% compared to 27.7%), and a more developed porous structure is formed, as compared to carbonizates based on the initial WS (Table 2).

In the activation stage, the differences in the properties of materials obtained from preoxidized and unoxidized WS become substantial. The yield of activates-1 (Table 2, combustion loss 23–25%) from the oxidized material is 23.3% and from the unoxidized material, only 20.8%. But even when the combustion loss is 58–60% (activates-2), the yield also appears to be higher for preoxidized samples compared to unoxidized ones (12.1 and 11.6%).

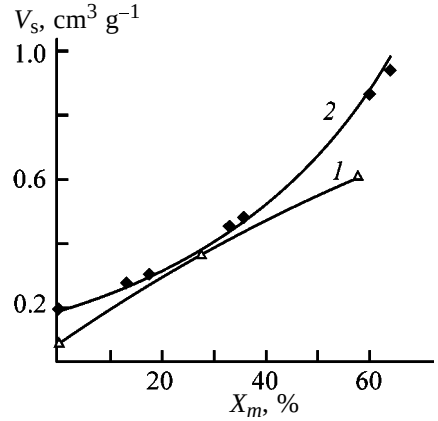

Fig. 2. Plot of pore volume V_s vs. the degree of combustion loss X_m on activation of WS carbonizates. Samples: (*1*) unoxidized and (*2*) oxidized.

Testing activates-1 with the 25% combustion loss for N_2 and CO_2 adsorption (Table 2) showed that the preoxidized samples have a more developed porous structure compared to the samples obtained from unoxidized WS and, as a consequence, a larger specific surface area (800 and 700 $m^2 g^{-1}$, respectively). The distinctive feature of activates obtained from oxidized WS is formation of mesoporosity in them, as demonstrated by the difference between the volumes of sorption pores and micropores (Table 2).

Testing activates-2 for nitrogen adsorption showed a more developed porous structure in them. In the activates obtained from the oxidized WS samples the specific surface area exceeds 1000 $m^2 g^{-1}$, whereas in the activates obtained from the unoxidized materials the specific surface area is 720 $m^2 g^{-1}$. The dependence of the pore volume on the combustion loss in activation (Table 2, Fig. 2) shows that in AC with the combustion loss of 30–40%, obtained from both preoxidized and unoxidized WS, the pore volume is approximately the same (Fig. 2, curves *1, 2*). The differences appear in the samples with the combustion loss more than 40%. For example, when the combustion loss is more than 60%, the AC samples from unoxidized WS have $V_s \sim 0.60$ $cm^3 g^{-1}$, whereas in AC from preoxidized WS $V_s = 0.95$ $cm^3 g^{-1}$.

It is known [16] that the X-ray patterns of cellulose materials, WS among them, are characterized by strong (101) and (002) relfections, which point to a regular structure. The X-ray patterns of heat-treated WS samples (preoxidized WS, carbonizate, and also the activate obtained from it) are shown in Fig. 3. Structural changes in WS occur during both its con-

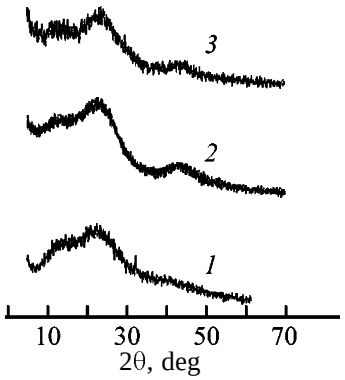

Fig. 3. X-ray diffraction patterns of carbon materials in various stages of WS heat treatment. (2θ) Bragg's angle. (*1*) Oxidized sample, (*2*) carbonizate, and (*3*) activate.

ventional heat treatment [1] and the treatment with preoxidation (Fig. 3).

It is essential that in oxidized WS (Fig. 3, curve *1*) the cellulose structure appears to be preserved; the carbon structure also is not formed, in contrast to WS carbonization in argon at 700°C [1]. The carbon structure is formed in preoxidized WS samples only on their carbonization (Fig. 3, curve *2*). A similar structure of carbonizates is also observed in the samples obtained by the conventional procedure [1]. During carbonizate activation under these conditions no essential structural changes occur in the material (Fig. 3, curves *2*, *3*).

An important characteristic of structural changes in carbon materials is the interplanar spacing. Preoxidation of WS results in a decrease in the interplanar spacings of its crystal lattice from 4.16 to 3.52 Å (Table 1). This occurs at the expense of linking of lattice planes by oxygen bridges. The heat treatment of WS in an inert medium decreases the interplanar spacings only to 4.10 Å [1].

It was shown previously that the WS carbonization results in a decrease in the interplanar spacings: on the carbonization of the initial WS (800°C) the interplanar spacing decreases to 3.87 Å. The carbonization of preoxidized WS results in the increase in the interplanar spacings to 3.93 Å compared to the carbonizates obtained from the initial WS (Table 2), which is due to expansion of the interplanar space of the sample crystal lattice at the expense of the loss of a part of bridging oxygen groups formed during WS oxidation. In this case the carbonizates obtained from both preoxidized and unoxidized WS have close interplanar spacings of ~3.90 Å (Table 2). The activation of carbonizates to high degrees of combustion loss (activates-2), both preoxidized and unoxidized, results in the minor increase in the interplanar spacings, to 4.01 and 3.99 Å (Table 2).

Thus, the cross-linked structural units in the composition of oxidized materials have a considerable effect on the properties of not only carbonizates, but also of activates. The preoxidation of WS allows preparation of AC with a more developed porous structure and with pores of particular size, with retention of structural carbon and increased yield of AC.

CONCLUSION

The effect of oxidizing treatment of the walnut shell on the properties and yield of the resulting activated carbons was studied. The preoxidation promotes the development of micro- and mesoporosity of carbons (the total volume of micro- and mesopores attains 0.9–1.0 $cm^3 g^{-1}$, S_{sp} by BET is within 1000–1100 $m^2 g^{-1}$). The yield of the product is 12%.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Chlorobenzene on V_2O_5/γ-Al_2O_3 Catalyst

Abstract—Isotherms of chlorobenzene adsorption on V_2O_5/γ-Al_2O_3 catalyst within the 0.07–18 Pa range of adsorbate partial pressure were measured, and certain thermodynamic characteristics of adsorption were found.

The V_2O_5/γ-Al_2O_3 catalyst can be used for deep oxidation of chlorobenzene (ChB). The kinetics of this process was studied in [1]. Davidenko *et al.* [2, 3] examined the mechanism of ChB adsorption on the above catalyst using IR spectroscopy and temperature-programmed desorption. At the same time, data on ChB equilibrium adsorption on oxide vanadium–aluminum catalyst are lacking. This problem is studied in the present work.

EXPERIMENTAL

Synthesis of γ-Al_2O_3 used as a support is described in [4]. Vanadium(V) oxide (5% of the support weight) was applied to aluminum oxide by impregnation with aqueous solutions of pure grade NH_4VO_3. Then the catalyst was dried at 373 K and annealed in air at 673 K for 5 h. The specific surface area of the catalyst sample found by nitrogen thermal desorption was 115 $m^2\ g^{-1}$.

Adsorption isotherms were measured chromatographically [5] on a Tsvet-500 chromatograph equipped with a flame-ionization detector. Helium additionally dried over aluminum oxide and CaA zeolite was used as a carrier gas; its flow rate was 30 $ml\ min^{-1}$. A 0.200–0.315-mm catalyst fraction and a 35 cm × 4 mm stainless steel column were used. The catalyst sample in the column was 1.183 g. Before the experiment, the column was conditioned at 573 K for 6–8 h.

Chemically pure grade chlorobenzene was additionally distilled and kept in hermetically sealed flasks over freshly calcined NaA zeolite. The samples of the adsorbate vapor were introduced into the column through a heated dosing cock. The vapor–helium mixture was prepared by mixing pure helium and helium saturated with the ChB vapor in a temperature-controlled saturator.

Adsorption isotherms (figure, Table 1) were measured within the 463–513 K range. The error of determination of the adsorbate partial pressure p (Pa) and excess adsorption Γ ($mol\ m^{-2}$) was less than 5%. In the above temperature interval, the chromatograms showed no evidences of chemical conversion of chlorobenzene.

The adsorption isotherms are characterized by slight nonlinearity and are well (determination coefficient $r^2 > 0.999$) approximated by the Freundlich equation of the adsorption isotherm $\Gamma = Cp^{1/n}$, where C and n are coefficients depending on temperature T (K). Within the temperature range studied, the dependence of C on T can be described by the function $C(T) = 5.06 \times 10^{-8} - 5.23 \times 10^{-5}/T + 0.0135T^2$ ($r^2 = 0.997$), and the dependence of n on T, by the function $n(T) = 0.234 + 425/T$ ($r^2 = 0.88$).

The isosteric heats of the ChB adsorption q_{st} calculated from the isotherms obtained are listed in Table 2 for certain Γ values. The q_{st} values for ChB on the

1070-4272/01/7409-1458$25.00

supported catalyst coincide within the experimental error with the heats of ChB adsorption on neat support [4]. Hence, vanadium oxide on the γ-Al_2O_3 surface does not generate more active adsorption centers than those on the surface of the initial support. Spiridonova *et al*. [6] studied pyridine adsorption on V_2O_5/γ-Al_2O_3 catalyst and concluded that vanadium ions do not affect the character of Al_2O_3 acidity: the total number of the acidic centers does not change, but the fraction of weaker (relative to pyridine) centers increases. Taking into account the difference in the nature of adsorbates, we can suggest that the data of [6] are consistent with our results.

The change of the differential excess entropy of adsorption [7] $\Delta\bar{S}^s$ is equal to $-q_{st}/\hat{T}$, where $\hat{T}$ is the average temperature of the interval studied, $\hat{T}$ = 488 K. Transition from the change of the differential entropy to the change of the average molar entropy $\Delta\tilde{S}^s$ for the case when adsorption is described by the Freundlich equation is realized by the equation [8]

$$\Delta\tilde{S}^s = \Delta\bar{S}^s + R[n(\hat{T}) + Tn'(\hat{T})],$$

where $n'(T)$ is the derivative of $n(T)$ function in the point $\hat{T}$; the second term of the equation (right part) amounts to 2 J mol^{-1}K^{-1}.

Certain information on the behavior of ChB molecules in the adsorption layer can be obtained by comparing the experimental $\Delta\tilde{S}^s$ values and those theoretically calculated from the model of ideal two-dimensional gas [4, 9], $\Delta\tilde{S}^s_{calc}$. These values for certain Γ are listed in Table 2. As seen, $|\Delta\tilde{S}^s_{calc}| < |\Delta\tilde{S}^s|$. This inequality can be explained by assuming that the motion of ChB molecules along the surface is not absolutely free, as it is assumed in the model of ideal two-dimensional gas, and hence spaces with elevated adsorption potential exist. They retain the adsorbate molecules for a some time, which is less than the residence time of the molecule on the surface. Changes in the inner (rotational and vibrational) degrees of freedom at adsorption are also possible. However, thermodynamic characteristics are insufficient to make unambiguous conclusion about the redistribution of adsorbate molecules with the respect to the degrees of freedom in the adsorption field. Since the measurements are related to very small values of adsorption, all deviations from ideality are caused by adsorbent–adsorbate interactions.

The difference between the calculated and experimental entropy decreases (in parllel with q_{st}) as the degree of surface filling increases, i.e., the state of the

real adsorption layer approximates the state of the ideal one. This also shows that ChB molecules adsorbed on the active centers from the first adsorbate portions are less mobile than those adsorbed from the successive portions.

CONCLUSIONS

(1) Vanadium oxide on the surface of $\gamma\text{-}Al_2O_3$ generates no adsorption centers more active with respect to chlorobenzene.

(2) Within the studied interval of adsorption values the state of the chlorobenzene adsorption layer differs from that of the ideal two-dimensional gas, but approaches it with increasing degree of filling.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodeposition of Rhenium onto Oriented Rhenium Foils from Salt Melts[1]

N. O. Esina, L. M. Minchenko, A. A. Pankrat'ev, V. A. Isaev, and N. G. Molchanova

Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia

Received April 10, 2001

Abstract—Epitaxial growth of rhenium layer electrodeposited from chloride melts onto single-crystal and polycrystalline rhenium substrates with orientations $(10\bar{1}0)$, $(11\bar{2}0)$, and (0001) was studied. Conditions for epitaxial growth on single-crystal rhenium foil with orientation (0001) were found. The surface morpholgy of rhenium deposits was studied and microhardness of single-crystal and polycrystalline rhenium layers with orientation (0001) was measured.

Previously, a number of experiments have been carried out in order to study the growth of molybdenum and tungsten in deposition from oxide and chloride solutions onto crystalline molybdenum substrates of various orientations. These studies revealed fundamental aspects of the epitaxial growth of metals with body-centered crystal lattice in electrocrystallization from salt melts [6]. It has been shown for molybdenum that the mechanism of transition from epitaxy to growth texture includes two stages. The first stage consists in formation of grains in twinning positions, and the second involves preferential growth of grains in twinning position with their simultaneous gradual and continuous inclination within 15° in the direction of the texture growth axis characteristic of these conditions [3]. This suggested the possibility of epitaxial growth of bent monoface single-crystal coatings of small thickness (up to 1 mm). Coatings of this kind were obtained with molybdenum and tungsten.

It seems of interest to study the influence exerted by the symmetry of a metal being deposited and its physicochemical properties on the mechanism of epitaxial growth. In contrast to molybdenum and tungsten, rhenium crystallizes to give a more complex face-centered close-packed lattice and possesses a unique combination of physicochemical properties: ultrahigh temperature resistance, room-temperature plasticity, and chemical inertness (except toward oxygen).

This study is concerned with the structure, texture, and morphology of the growing surface and the microstructure of epitaxial rhenium layers electrodeposited from chloride melts onto planar and bent single-crystal and polycrystalline substrates of various orientations.

[1] Reported at X Kola Symposium "Electrochemistry of Rare Metals," Apatity, December 4–7, 2000.

EXPERIMENTAL

Experiments were performed in a hermetically sealed quartz cell. A $CsCl–Cs_2[ReCl_6]$ electrolyte was placed in a crucible made of pyrocarbon-densified graphite, with side walls screened by a rhenium ring whose upper edge was above the electrolyte level. The ring served as reference electrode. A rhenium billet was used as anode.

The supporting electrolyte CsCl was dried under vacuum and then remelted in air. The rhenium salt was prepared by chlorination in a melt. The rhenium concentration in the electrolyte was 3–5 wt %, as determined analytically. The difficulty consisted in that cesium hexachlorohenate is poorly soluble in water. A weighed portion of the salt was heated in distilled water until rhenium(IV) hydroxide was formed and then dissolved in hydrogen peroxide [7]. Rhenium was determined by atomic-absorption spectroscopy in an N_2O–acetylene flame on a 403 Perkin–Elmer spectrophotometer (λ = 346.0 nm). The relative determination error did not exceed 3%.

The inert gas (argon) passing over the melt was purified to remove traces of oxygen with a solid-electrolyte electrochemical pump; the gas purity at the cell inlet was monitored with an electrochemical transducer. A weak flow of argon was continuously passed through the cell during its operation.

1070-4272/01/7409-1461$25.00

The studies were carried out in the temperature range 720–920°C at current densities of 0.01–0.20 A cm^{-2}. The deposition was done onto substrates of annealed dense graphite, single-crystal rhenium foil with orientation (0001), and polycrystalline rhenium foils with orientations (0001), $(11\bar{2}0)$, and $(10\bar{1}0)$. The cathode area did not exceed 2 cm^2. Prior to deposition, rhenium substrates were polished in an electrolyte of the composition $K_3[Fe(CN)_6] : CH_3COOH : H_2O$ and then washed in distilled water. A part of rhenium foil substrates was bent, with the bending radius ranging from 3 to 10 mm. The structural perfection and texture of the obtained rhenium layers and their surface morphology were studied by X-ray structural, metallographic, and optical-goniometric methods on DRON-3 and DRON-3M diffractometers, Neophot-32 optical microscope, and Camebax scanning electron microscope. To study the microstructure of deposits and determine their microhardness, metallographic cross sections of the samples studied were prepared by mechanical grinding with abrasive paper and diamond paste and subsequent chemical etching with $K_3[Fe(CN)_6] : NaOH : H_2O$ etchant with the components taken in appropriate proportions.

Polarization curves were measured in the galvanostatic mode with a PI-50 potentiostat, and E–τ curves were recorded with an S9-8 digital storage oscilloscope. The current densities were in the range 0.005–0.100 A cm^{-2} at a pulse duration of 0.1 s. To preserve the electrode surface, an anodic pulse was applied after each cathodic pulse, with the amplitude and duration equal to that of the cathode pulse. The electrode potential, monitored with a digital voltmeter, did not differ from its initial value by more than 2 mV at high current densities.

The investigations performed revealed that rhenium deposits on graphite mainly had growth texture $(10\bar{1}L)$, where $3 \le L \le \infty$. With increasing temperature and decreasing deposition current density, $L \to \infty$ and the texture is transformed into (0001). At low temperatures (720–750°C) and high current densities (0.1 A cm^{-2} and more) a growth texture (1120) was formed in the deposits. If the rhenium substrate orientation coincided with the growth texture direction, epitaxial growth of the deposit was observed till termination of electrolysis (400 μm). The epitaxial growth was disrupted and growth texture formed in a rhenium layer being deposited in the case of misalignment of the substrate orientation and the direction of the growth texture axis. Epitaxial growth on single-crystal rhenium foils with (0001) orientation was observed at 870–920°C and cathodic current densities in the range 0.01–0.10 A cm^{-2}. Similar results were obtained on bent single-crystal substrates with (0001) orientation at any bending radii. In depositing rhenium onto polycrystalline foils with orientations $(11\bar{2}0)$ and $(10\bar{1}0)$ under the above conditions, a (0001) growth texture was formed, as also in the case of graphite substrates [8]. Under the conditions when a $(11\bar{2}0)$ texture was formed, epitaxial growth was observed on the substrates with the same orientation. No rhenium deposits with $(10\bar{1}0)$ growth texture were obtained in the studies, and, therefore, there was no epitaxial growth on foils with $(10\bar{1}0)$ orientation. In this case, rhenium deposits with $(11\bar{2}0)$ and $10\bar{1}L$) textures were obtained.

The morphology of the growing surface of rhenium layers was studied. Growth pyramids faceted with $(10\bar{1}3)$ planes were formed on the surface of polycrystalline deposits obtained under the conditions of (101L) growth texture. In the case of epitaxial growth on a planar or bent single-crystal foil with orientation (0001), growth pits appeared on the surface. They had the form of 6–12-face inverse pyramids faceted with $(10\bar{1}1)$ and $(10\bar{1}2)$ planes. Some of them had blunted vertex (Fig. 1a). Under the conditions when $(11\bar{2}0)$ texture was formed at 750°C and cathodic current densities in the range 0.1–0.2 A cm^{-2}, skeletal growth forms were observed on a $(10\bar{1}0)$ substrate (Fig. 1b). In this case, the rate of the deposit growth in the direction perpendicular to the substrate exceeded that along the substrate. With increasing temperature and decreasing deposition current density, holohedral pyramids appeared, faceted with $(10\bar{1}1)$, $(10\bar{1}2)$, and $(10\bar{1}3)$ planes (Fig. 1c). The inclination of the faceting planes with respect to the substrate plane is dependent on the deposition current density. With increasing cathodic current density, the angle of inclination grows too. The surface morphology of rhenium deposits is the same on planar and bent foils with identical orientations and is independent of the foil bending radius.

Metallographic studies of cross sections and fractures of rhenium deposits demonstrated that, in the case of epitaxial growth, the deposit–substrate boundary was either absent at all, or was observed in the form of a step (Fig. 2a). A clearly visible boundary between the deposited rhenium and the substrate is present in samples having no epitaxial layer (Fig. 2b). The structure of deposits on graphite is columnar, the grain size is 20–30 μm (Fig. 2c, thickness 50 μm). As seen from Figs. 1a and 1c, the types of fracture of rhenium deposits are different. In the case of a single-crystal epitaxial deposit, a pitted relief, characteristic

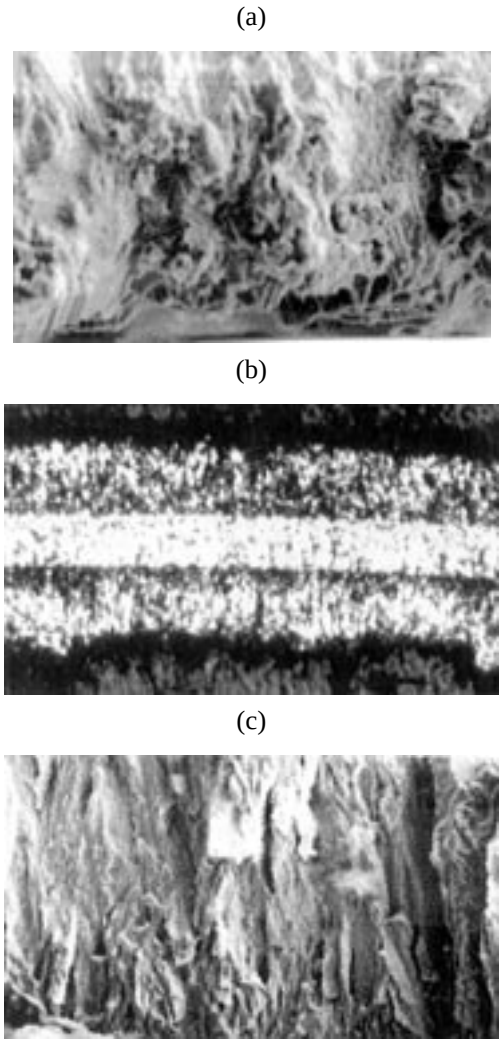

Fig. 2. Cross-sectional micrographs of rhenium deposits. Magnification: (a, c) 400 and (b) 300. (a) Fracture of rhenium deposit on single-crystal (0001) rhenium substrate, (b) metallographic cross section of rhenium deposit on (10$\bar{1}$0) polycrystalline rhenium substrate, and (c) fracture of (11$\bar{2}$0) rhenium deposit on graphite.

of ductile fracture, is observed. For polycrystalline rhenium deposit on graphite, a mixed type of fracture is observed: brittle intergrain fracture with regions of ductile detachment and minor regions of brittle cleavage.

The microhardness was measured on metallographic cross sections of polycrystalline and single-crystal rhenium deposits with (0001) orientation. Its values were in the range 240–270 kg mm^{-2}, which indicates the high purity of the obtained rhenium layers. It has been shown previously that the polarization of the rhenium electrode depends on its orientation and grows in the order (10$\bar{1}$0) → (11$\bar{2}$0) → (0001). The overall polarization also grows with improvement of the (0001) texture to reach the maximum value for the single-crystal electrode of the same orientation [9]. In the present study, anodic and cathodic polarization curves (Fig. 3) were obtained on planar and bent single-crystal electrodes with (0001) orientation. Comparison of the obtained data suggests that the overall polarization is lower on the bent electrode, especially in the anodic region, which may be due to build-up of elastic deformation and increasing number of active sites.

CONCLUSIONS

(1) The possibility is demonstrated of obtaining relatively thick (400 μm) epitaxial single-crystal rhe-

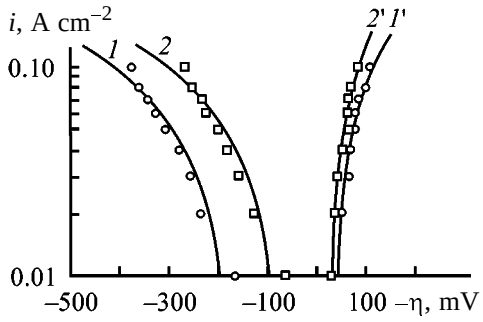

Fig. 3. Polarization curves for rhenium on (*1*, *1*') planar and (*2*, *2*') bent (0001) single-crystal substrates at 780°C. (*i*) Current density and (η) overvoltage. Curves: (*1*, *2*) anodic and (*1*≅ *2*') cathodic.

nium layers by electrodeposition onto single-crystal rhenium foils from salt melts.

(2) The surface morphology of a growing rhenium deposit depends on both the substrate orientation and the electrolysis conditions. For example, with increasing deposition current density, the surface is smoothed and growth pits and pyramids become smaller. However, the deposit structure is independent of the substrate bending radius.

(3) The microhardness of rhenium deposits with (0001) orientation is within the range 240–270 kg mm^{-2}. This indicates that the electrodeposited rhenium is comparable in purity with that of the metal obtained by electron-beam zone melting.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodeposition of Tin–Antimony Alloy from Sulfate Electrolytes with Organic Additives

Received November 28, 2000; in final form, March 2001

Abstract—Electrodeposition of the tin–antimony alloy from sulfate electrolytes containing $SnSO_4$, $Sb_2(SO_4)_3$, H_2SO_4, syntanol, formalin, and coumarin was studied. The electrolyte composition and electrodeposition conditions allowing deposition of lustrous coatings of tin–antimony alloy of controllable composition were determined.

Previously, the electrodeposition of the Sn–Sb alloy from sulfate electrolytes in the presence of syntanol, formalin, butynediol, and benzyl alcohol has been studied [1–3]. It was shown that syntanol, formalin, butynediol, and benzyl alcohol contained in electrolytes favor formation of lustrous alloy coatings at i_c = 0.5–12 A dm^{-2}. Proceeding with these investigations, we studied the electrodeposition of the Sn–Sb alloy from a sulfate electrolyte in the presence of syntanol, formalin, and coumarin. As is known [4], coumarin is a luster-producing additive to nickel plating electrolytes.

The electrodeposition was performed from an electrolyte of the composition (g l^{-1}): $SnSO_4$ 5–50, $Sb_2(SO_4)_3$ 0.1–0.8, H_2SO_4 100–120, syntanol (DS-10) 1–3, and coumarin 0.1–2; formalin (37% solution) 1–10 ml l^{-1}. The process temperature was 18–20°C. Coatings were deposited onto copper substrates to a thickness of 1–20 μm.

Polarization curves were measured by the potentiostatic method with a P-5827 potentiostat. The alloy composition was analyzed by the technique described in [5]. Antimony(III) sulfate was prepared by dissolving metallic antimony in hot concentrated sulfuric acid.

The leveling power of the electrolytes was found by direct prophilography [6]. The throwing power was determined in Mohler's slit cell [6]. The microhardness of Sn–Sb alloy deposits was measured on a PMT-3 device. The internal stress was measured by the method of deformation of a flexible cathode [7]. The electrical resistance of the coatings was measured in accordance with GOST (State Standard) 9.302–79. The solderability was determined using a soldering iron in accordance with GOST (State Standard) 20-57.406–81. An X-ray diffraction analysis of Sn–Sb alloy deposits was made on DRON-3 X-ray diffractometer in CuK_α radiation.

A study of the influence exerted on the outward appearance of coatings by organic additives in the electrolyte (g l^{-1}): $SnSO_4$ 5–50, $Sb_2(SO_4)_3$ 0.1–0.8, and H_2SO_4 100, demonstrated that high-quality lustrous coatings can only be obtained in the simultaneous presence of 2–3 g l^{-1} of syntanol, 6–8 ml l^{-1} of formalin, and 1.5–2 g l^{-1} of coumarin. Going beyond these concentration limits leads to deposition of silvery matte coatings. It should be noted that 1–20-μm-thick lustrous coatings can be obtained with electrolyte stirring. Without stirring, lustrous coatings are only formed to a thickness of 1–3 μm.

It was found that the i_c range in which lustrous coatings are obtained is determined by the $SnSO_4$ concentration in the electrolyte. At concentrations of $SnSO_4$ 5–20 and $Sb_2(SO_4)_3$ 0.1–0.8 g l^{-1}, lustrous coatings are obtained at i_c = 1–5 A dm^{-2}. Raising the $SnSO_4$ concentration to 30–50 g l^{-1} expands the i_c range in which lustrous coatings are obtained to 2–10 A dm^{-2}. A chemical analysis of the electrolytic deposits obtained from the electrolytes under study demonstrated that an Sn–Sb alloy is formed in this case.

Data on the influence exerted by the concentrations of $SnSO_4$ and $Sb_2(SO_4)_3$ in the electrolyte and the current density on the alloy composition are presented in Table 1. It can be seen that, with increasing $Sb_2(SO_4)_3$ concentration in the electrolyte (at constant

$SnSO_4$ content), the content of antimony in the alloy grows. Raising the concentration of $SnSO_4$ [at constant content of $Sb_2(SO_4)_3$] and the current density leads to lower content of antimony in the alloy.

The effect of the H_2SO_4 concentration on the outward appearance of coatings and the alloy composition was also studied. It was found that raising the H_2SO_4 concentration in the electrolyte from 100 to 120 g l^{-1} does not change the i_c range in which lustrous coatings are obtained, but leads to an increase in the antimony content of the alloy by 0.5–1.0 wt % [depending on the $Sb_2(SO_4)_3$ concentration in the electrolyte and the current density]. Such an influence of the H_2SO_4 concentration on the alloy composition can be accounted for by a change in the ion composition of the electrolyte with increasing H_2SO_4 concentration. In this case, a complex ion, $Sn[Sn(SO_4)_2]$, is probably present in the electrolyte together with Sn(II) and Sb(III) ions [8]. The presence of such a complex in the electrolyte leads to lower activity of tin(II) ions and a shift of its reduction potential to negative values, with kinetic hindrance to Sn(II) discharge enhanced and the alloy enriched in antimony.

The current efficiency (CE) was measured in electrolytes allowing deposition of lustrous Sn–Sb alloy coatings. The data on how the electrolyte composition and current density affect the CE are presented in Table 1. It can be seen that, with the $Sb_2(SO_4)_3$ content of the electrolyte increasing from 0.1 to 0.8 g l^{-1} and growing current density, the CE decreases. With the concentration of $SnSO_4$ increasing from 5 to 50 g l^{-1}, the CE becomes higher.

Raising the concentration of H_2SO_4 from 100 to 120 g l^{-1} lowers the CE by 1–1.5%.

The microhardness of the obtained deposits was measured. It can be seen from Table 2 that the microhardness increases with growing content of $Sb_2(SO_4)_3$ in the electrolyte and decreases with increasing current density. The increase in the microhardness of the alloy is associated with its growing antimony content (Table 1).

As is known [9], for alloys of the type of mechanical mixture, a linear relationship must exist at a constant current density between the logarithms of the ratio of metal contents in the alloy and the ratio of the concentrations of their cations in the electrolyte. In the case of electrodeposition of an intermetallic compound or a solid solution the type of dependence is different.

The dependence $\log([Sn]/[Sb])$–$\log([Sn^{2+}]/[Sb^{3+}])$ for Sn–Sb alloys deposited from the electrolyte under study at an $Sb_2(SO_4)_3$ content ranging from 0.1 to 0.8 g l^{-1} and i_c 2–8 A dm^{-2} is presented in Fig. 1 whence follows that it is nonlinear. These data suggest that an intermetallic compound or a solid solution is formed in the course of Sn–Sb electrodeposition.

Table 2. Alloy microhardness in relation to $Sb_2(SO_4)_3$ concentration C in the electrolyte and current density i_c Electrolyte composition, g l^{-1}: $SnSO_4$ 30, H_2SO_4 100, syntanol 2, coumarin 2; formalin 6 ml l^{-1}; mechanical stirring

0.3	590.0	550.1	510.0	440.1
0.5	627.2	558.6	519.4	490.0
0.8	656.5	617.4	588.0	558.6

An X-ray diffraction analysis of the alloy composition demonstrated that a solid solution of antimony in tin (α-phase) is, indeed, formed in all of the electrolytes studied at an Sb content of 2–5 wt % in the alloy. At an antimony content of 10–25 wt %, a two-phase system (mechanical mixture), solid solution of antimony in tin and intermetallic compound SnSb ($\alpha + \beta$ phases), is formed, in agreement with the phase diagram of the Sn–Sb system [10].

The dependences in Fig. 1 allow prediction of the composition of the Sn–Sb alloy in relation to the concentration of deposited components in the electrolyte.

		1	2	3	4	5	6	7	8
10	TP_c	36.4	34.7	32.8	30.3	25.0	–	–	–
	TP_m	32.8	31.6	29.5	28.0	20.2	–	–	–
	TP_{th}	33.2	32.0	29.9	28.5	20.6	–	–	–
30	TP_c	–	33.0	21.0	16.9	15.5	14.8	13.0	11.4
	TP_m	–	31.7	19.2	15.9	14.5	13.3	12.1	10.8
	TP_{th}	–	32.2	21.0	16.5	14.8	13.9	12.8	11.3

The leveling (LP) and throwing (TP) power values were measured in electrolytes that yield lustrous coatings. It was found that the sulfate electrolytes yielding lustrous coatings possess leveling power. The dependence LP–i_c is presented in Fig. 2. It can be seen that the LP value is determined by the $SnSO_4$ concentration in the electrolyte. At an $SnSO_4$ concentration of 10 g l^{-1} the LP–i_c dependence passes through a maximum (P = 0.8) at i_c = 3 A dm^{-2} (curve *1*). At an $SnSO_4$ concentration of 30 g l^{-1} the leveling power decreases from 0.35 to 0.18 (curve *2*). The different leveling power values of sulfate electrolytes with organic additives at $SnSO_4$ concentrations of 10 and 30 g l^{-1} are possibly due to changing conditions of adsorption–diffusion processes involving the organic additives [11].

Data on the throwing power of the electrolytes studied are presented in Table 3. It can be seen that the TP decreases with increasing cathodic current density and increases with decreasing $SnSO_4$ concentration in the electrolyte.

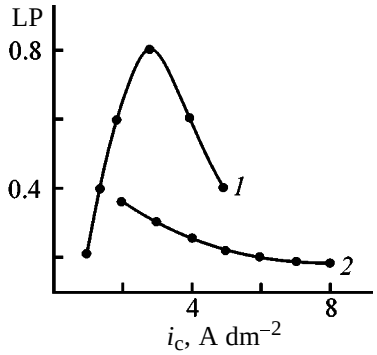

Fig. 2. Leveling power LP of sulfate electrolyte vs. current density i_c for electrodeposition of the Sn–Sb alloy. Electrolyte composition (g l^{-1}): $Sb_2(SO_4)_3$ 0.8, H_2SO_4 100, syntanol 2, coumarin 2; $SnSO_4$ (*1*) 10 and (*2*) 30; formalin 6 ml l^{-1}.

The data in Table 3 indicate that $TP_m < TP_c$, $TP_{th} > TP_m$, although the current efficiency by the alloy decreases with increasing i_c. This is due to the fact that, with increasing i_c, the alloy is enriched in tin having higher electrochemical equivalent and density, compared with antimony.

Lustrous alloy coatings were tested for adhesion strength, porosity, and solderability, and their internal stresses and electrical resistance were measured. It was found that Sn–Sb alloy coatings firmly adhere to the substrate and have no pores at thicknesses exceeding 3 μm. Weak internal compression stresses appear in the alloy deposits, decreasing from 6.6 to 2.8 MPa with increasing i_c. The solderability tests with samples coated with the Sn–Sb alloy demonstrated that coatings with antimony content of 5–10 wt % are well solderable. At an Sb content of 15 and 20 wt %, soldered samples have rough surface, which does not conform to GOST (State Standard) requirements.

The electrical coating resistance R_c of lustrous tin and Sn–Sb alloy coatings was measured. It was found that the R_c of the Sn–Sb alloy is somewhat higher than that of pure tin. R_c grows with increasing content of antimony in the alloy. For example, at antimony content in alloy of 5, 10, and 15 wt % and a load of 10 g at a current of 50 mA the R_c value increases from 6 to 8 mΩ.

The anodic process was studied with tin and antimony as anode. It was found that the anodic dissolution of tin occurs with weak polarization and current efficiency of 100%. The anodic dissolution of antimony proceeds with strong polarization as a result of surface polarization. In view of this fact, it is recommended to use pure tin as anode. The anodic current density should be 1.3 times less than the cathodic current density. To preclude contact deposition of

Table 4. Main characteristics of sulfate electrolytes with organic additives for electrodeposition of the Sn–Sb alloy

antimony, tin anodes are to be introduced into, and removed from the bath with voltage applied. To prevent electrolyte contamination through sludge formation, the anodes are to be placed in sheaths of polypropylene fabric.

Based on our results, we developed sulfate electrolytes with organic additives for electrodeposition of lustrous Sn–Sb alloy coatings. The compositions and the main characteristics of the electrolytes are presented in Table 4.

Sulfate electrolyte no. 1 is more dilute. This reduces the consumption of reagents for its preparation and the loss of tin(II) and antimony(III) with processed articles and their accumulation in washing water, which improves the environmental safety of the process.

Sulfate electrolytes allow preparation of Sn–Sb alloy coatings with an antimony content of 15–30 wt %, exhibiting better physicomechanical characteristics and suitable for use instead of tin coating.

Sn–Sb alloy coatings are to be deposited onto copper substrates or steel substrates with preliminarily deposited 2–3-μm-thick copper layer. The electrolysis is to be carried out at room temperature with electrolyte stirring. The content of $SnSO_4$, $Sb_2(SO_4)_3$, H_2SO_4, formalin, and coumarin in the electrolyte is to be adjusted in accordance with chemical analysis data [12]. The adjustment of the syntanol content is done by introducing into the bath its additional amount of 1 g l^{-1} after passing 80 A h l^{-1} of electricity.

CONCLUSIONS

(1) A study of the electrodeposition of the Sn–Sb alloy from sulfate electrolytes in the presence of organic substances demonstrated that high-quality lustrous coatings are obtained in an electrolyte containing $SnSO_4$, $Sb_2(SO_4)_3$, and H_2SO_4, and also organic additives: syntanol, formalin, and coumarin.

(2) The content of antimony in the alloy grows with increasing concentration of $SnSO_4$ and H_2SO_4 in the electrolyte. Raising the $SnSO_4$ concentration leads to lower content of antimony in the alloy. With increasing current density, the content of antimony in the alloy decreases.

(3) The investigations performed made it possible to develop sulfate electrolytes for electrodeposition of an Sn–Sb alloy with controllable composition.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrolytic Preparation of Vanadium(V) Oxide from Oxovanadium(IV) Sulfate Solutions in the Presence of Sodium Ions

V. M. Nagirnyi, R. D. Apostolova, and E. M. Shembel'

Ukrainian State University of Chemical Engineering, Dnepropetrovsk, Ukraine

Received September 19, 2000; in final form, April 2001

Abstract—Effect of various factors on the character of anodic processes and the properties of vanadium(V) oxide deposits electroplated from oxovanadium(IV) sulfate solutions in the presence of sodium ions was studied.

Because of high electrochemical characteristics, vanadium(V) oxide electroplated from aqueous solutions of oxovanadium sulfate, including that plated in the presence of sodium ions, is efficient cathode material of lithium batteries [1–3]. The preliminary experimental tests showed that compact coatings and dispersed deposits of vanadium(V) oxide can be obtained in a quantitative yield from a 0.15–0.3 M oxovanadium sulfate solutions (pH 1.6–2.0) at 75–85°C and an anodic current density of 7–12.5 mA cm^{-2}. The use of gauze or smooth anodes made of 12Cr18Ni9Ti steel, in contrast to gold and platinum anodes used in [3, 4], make the given conditions of the electrolysis suitable for industry. However, in this case the corrosion resistance of the anode material during electrolysis becomes a factor of particular importance. These data and data on the effect of sodium ions on the character of anodic processes in electroplating of vanadium(V) oxide from vanadium sulfate solutions are lacking. The presence of sodium ions can change not only the nature of the electrode process but the properties of the formed deposits as well.

It was appropriate to study in detail the electrolysis conditions in the above solutions, including those containing sodium ions, taking into account their effect on the properties of anodic deposits and the corrosion of anode material.

Solutions were prepared from an equimolar mixture of crystalline vanadium(V) oxide and oxalic acid sintered at 125–135°C. The resulting dark blue sinter contained vanadium dioxide VO_2 as the main product and vanadium oxide V_2O_3 as the main by-product. Solution of oxovanadium sulfate $VOSO_4$ containing vanadium(III) sulfate impurity $V_2(SO_4)_3$ was prepared by dissolving the sinter in distilled water with added sulfuric acid. To prepare solutions, we used pure and analytically pure grade reagents and distilled water.

The electrolysis was performed in a temperature-controlled glass cell of 0.25 dm^3 volume from the solutions containing 0.15, 0.25, and 0.35 M oxovanadium sulfate at pH 1.6–2.0, 85°C, and I_a = 0.5–35 mA cm^{-1}, and also in the presence of sodium sulfate (0.025–0.4 M). Compact coatings of vanadium(V) oxide were deposited on gauze and smooth two-side anodes made of 12Cr18Ni9Ti steel of 10 × 10 × 0.15 mm size (gauze cell 0.04–0.1 mm), to which thin-plate current leads made of the same steel were welded. Preliminarily, the electrodes were degreased with Vienna lime and activated in concentrated hydrochloric acid. Smooth plates made of the above steel were used as cathodes.

The electrolysis efficiency under the given conditions was determined from the yield of the anodic deposit as a function of current, assuming that the whole efficient current is spent for oxidation of oxovanadium(IV) ions and formation of vanadium(V) oxide (electrochemical equivalent 3.4 g h^{-1}). The current efficiency was measured with a copper coulometer.

The polarization curves were taken in the range I_a = 0.5–3.5 mA cm^{-2} at 85°C and different sodium sulfate concentrations in the solution on the surface of a 12Cr18Ni9Ti steel electrode. The curves were taken with a temperature-controlled glass cell. A plate of VT-1 commercial titanium with a ratio of the anodic and cathodic surfaces of 1 : 2 served as a cathode. The anode potentials were measured relative to silver

1070-4272/01/7409-1470$25.00

chloride reference electrode (φ_{ref} = 0.225 V) using a P3003 voltage comparator and then were recalculated to hydrogen scale. The external appearance of the deposits and the microstructure of the surface of the corresponding thin-film (1.5–2.5 μm thick) oxide coatings were studied with an MBI-1 microscope. The adhesion and mechanical resistance of the deposits were estimated from the weight loss of a 20 × 10 × 0.3-mm sample with an oxide coating at a 180° bending. The phase composition of the deposits was determined by X-ray diffraction (DRON-2 diffractometer).

The current efficiency as a function of the current density, pH, and sodium ion concentration in oxovanadium sulfate solution at its constant concentration and temperature is plotted in Figs. 1 and 2. Irrespective of the presence of sodium ions, the current efficiency in the range pH 1.6–2.0 markedly increases, reaching the limiting value at pH 1.8–2.0 (Fig. 1a). The current efficiency increases jumpwise in the range I_a = 5–15 mA cm^{-2}, passes through a maximum at 7.5 and 10 mA cm^{-2} at the sodium sulfate concentrations below and above 0.1 M, respectively, and then decreases to a certain constant value (Fig. 1b). It should be noted that under the same conditions the rate of the vanadium oxide deposition attains the maximal value at the currant densities of 10–15 and 15–20 mA cm^{-2} (5.5 and 2.5 mg cm^{-2} h^{-1}, respectively). In the range of the oxovanadium sulfate concentrations of 0.15–0.35 M the efficiency of the anodic process is affected slightly. When small amounts of sodium sulfate (up to 0.05 M) are added to a solution with a constant concentration of oxovanadium sulfate (0.25 M), the current efficiency slightly increases as compared to that in the initial solution containing no additive. As the Na_2SO_4 concentration is increased further, to 0.15–0.2 M, the current efficiency decreases nearly twofold and then gradually approaches the lowest value at the supporting electrolyte concentration above 0.4 M (Fig. 2). This result is responsible for the enhanced tendency to corrosion of the anode material during electrolysis, which is due to the longer time from the instant of the current switching on to the formation of a continuous oxide film on the anode. This results in the accumulation of iron, nickel, and other ions in the solution, destabilization of electrolysis, and contamination of anodic deposits by foreign impurities.

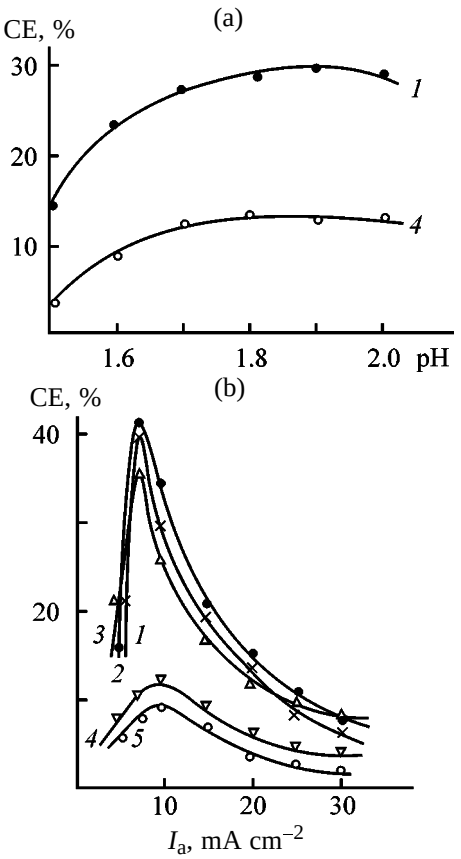

Fig. 1. Current efficiency CE by V_2O_5 vs. (a) pH and (b) anodic current density I_a in electrolysis of 0.25 M $VOSO_4$ solutions. T = 85°C; (a) I_a = 10 mA cm^{-2}; (b) pH 1.8. Na_2SO_4 concentration, M: (*1*) 0, (*2*) 0.05, (*3*) 0.1, (*4*) 0.2, and (*5*) 0.4.

Table 1 shows how the rate of the gauze electrode dissolution depends on the electrolysis time in oxovanadium solution containing 0.43 M sodium sulfate at pH 1.8 and 2.0. As seen, the weight loss of the anode mainly occurs in the initial period of the electrolysis and is terminated after a continuous oxide film is formed on the surface. Correspondingly, the shortening of this time at higher pH markedly de-

Table 1. Dissolution of a gauze electrode made of a 12Cr18Ni9Ti steel during anodic deposition of V_2O_5 from a 0.25 M $VOSO_4$ + 0.43 M Na_2SO_4 solution at T = 85°C and I_a = 10 mA cm^{-2}

creases the corrosion rate. The calcination of the anode support at 300°C for 1–1.5 h increases the corrosion resistance owing to the formation of the protective passivation film. In this case, even in solutions with a high sodium sulfate concentration (0.4 M), the weight loss of the anode decreases to difficultly detectable values (0.1–0.3 mg cm^{-2} h^{-1}). Under the similar electrolysis conditions, the corrosion rate of the smooth platelike anode made of the same steel is two times lower than that of the gauze anode.

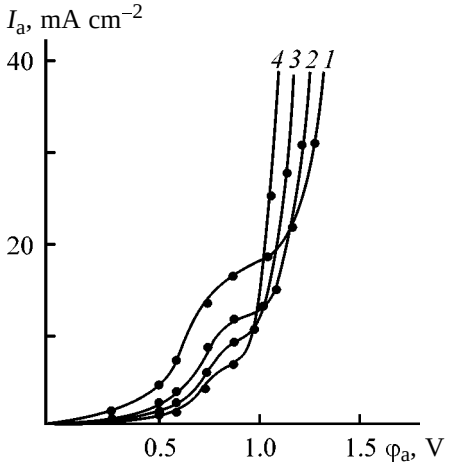

Fig. 3. Voltammetric curves of the anodic process in electrolysis of 0.25 M $VOSO_4$ solutions in the presence of Na_2SO_4. T = 85°C, pH 1.8. (I_a) Anodic current density and (φ_a) potential. Na_2SO_4 concentration, M: (*1*) 0, (*2*) 0.1, (*3*) 0.2, and (*4*) 0.4.

Under similar other conditions, the electrolysis stability is largely determined by the ratio of the anode to cathode surfaces. This is caused by the change in the dynamic equilibrium established in the solution between the vanadium compounds of various oxidation states, depending on the relative rates of electrode reactions. For example, apart from oxovanadium oxidation and the side reaction of oxygen evolution, the following reactions can also occur:

$$V^{3+} + 2H_2O - 2e \rightarrow VO_2^+ + 4H^+, \quad (1)$$

$$V^{3+} + H_2O - e \rightarrow VO^{2+} + 2H^+. \quad (2)$$

Owing to the high concentration of oxovanadium ions in the solution and their directional migration toward the cathode, the occurrence of reverse reaction (2) with a sufficient intensity is also probable on the cathode. Therefore, at $I_a \approx I_c$ the V^{3+} ions accumulate in the solution, which decreases the yield of the anodic products and causes hydrolysis of vanadium sulfate, with the solution becoming turbid. In the presence of sodium ions, the intensity of these processes increases owing to alkalization of the near-cathode space and larger extent of the hydrolytic processes. This is confirmed by the observed decrease in the current efficiency with respect to the anodic deposit at the decreased relative cathode surface (Table 2). The comparison of data in the table shows that the ratio $S_a : S_c = 1 : (\geq 5)$, at which the rate of the side cathodic reactions decreases to minimum, is optimal.

For the identical electrolysis conditions, the dependences considered agree satisfactorily with the corresponding voltammetric curves of the anodic process (Fig. 3). It is notable that the curves have two ascending branches with a transition plateau between them. The anodic current densities corresponding to the extreme points and the relative positions of the upper and lower sections of the curve strictly correlate with the concentration of sodium ions in the solution. The higher the concentration, the lower the limiting transition current and the larger the shift of the lower and upper sections toward higher and lower anode potentials, respectively.

It is quite evident that the nature of the anodic processes in the region of the above sections is different. For example, the lower sections predominantly reflect formation of vanadium(V) oxide at a weakly competing reaction of oxygen discharge. When the diffusion-limited current of this process is attained, the anode potential shifts toward positive region (the limiting plateau) to the values corresponding to oxygen evolution under the given conditions. This process

Table 3. Comparative characteristics of the V_2O_5 anodic deposits plated from the 0.25 M $VOSO_4$ solutions at T = 85°C, I_a = 10 mA cm^{-2}, and pH 1.8

Deposit characteristics	Na_2SO_4 concentration in solution, M

External appearance of deposits ($\delta \geq 10$ μm)	Very rough, with developed surface; marked edge effect	Rough, fairly compact, uniform	Dull, smooth, compact, uniform, slight pitting
Microstructure of the surface of thin-film coatings ($\delta \geq 5$–2.5 μm)	Amorphous, with highly developed microrelief	Crystalline with a random orientation of grains and a marked microrelief	Crystalline, with ordered structure and regular sequence of microprotrusions and concaves
Adhesion and mechanical resistance, as estimated from the weight loss at bending of 15–17 mg cm^{-2} coating, wt %	12–15	7–9	5–7

process becomes potential-determining in the region of the upper sections of curves. Hence, it follows that the retardation of the vanadium(V) oxide formation and the decrease in the limiting transition current density with increasing sodium concentration are governed by the increase in the anodic polarization and by the creation of more favorable conditions for oxygen evolution [5]. This can explain why the lower sections of curves shift toward higher anode potentials. The acceleration of oxygen discharge and the corresponding shift of the upper sections toward lower anode potentials are evidently caused by deceleration of the anodic deposit formation and by weakening of the shielding effect initiated by it.

The vanadium(V) oxide deposits electroplated in the presence of sodium ions have essentially different quality and structure. This is clearly seen from comparison of some characteristics of the deposits plated from the solutions with and without sodium ions (Table 3). In this case, sodium ions actively affect the phase formation process. This is manifested in formation of anodic deposits, which, unlike amorphous deposits formed without additive, are characterized by ordered crystalline structure enhancing their mechanical resistance and adhesion. The phase composition of the deposits which, according to X-ray diffraction analysis, mainly consist of an $Na_xV_2O_5$-type compound (x = 0.22–033), changes simultaneously. The latter compound heat-treated at 500–520°C is clearly identified as sodium–vanadium bronze. At the sodium sulfate concentration above 0.1 M the phase composition of the deposits remains unchanged. This is quite important for preparation of ballastless cathodes of lithium batteries by deposition of oxide coatings of the given phase composition on gauze or smooth stainless steel support, providing enhanced adhesion and mechanical resistance and a highly developed specific surface area of coatings, with the high efficiency of the anodic process being preserved.

The optimal conditions for electrolytic preparation of the corresponding oxide materials are anodic deposition from the solutions containing 0.2–0.25 M oxovanadium sulfate and 0.05–0.1 M sodium sulfate at 80–85°C, I_a = 7.5–12.5 mA cm^{-2}, pH 1.8–2.0, and $S_a : S_c$ = 1 : 5 and subsequent heat treatment at 500–520°C for 5–7 h.

CONCLUSIONS

(1) Upon electrolysis of oxovanadium sulfate solutions in the presence of sodium ions, the deposits qualitatively different from those prepared without additives are formed on the anode.

(2) According to X-ray diffraction analysis, the deposits heat-treated for 5–7 h at 500°C are sodium–vanadium bronzes of the composition $Na_xV_2O_5$ characterized by enhanced electrochemical activity and showing promise as cathode material of lithium batteries.

Received February 12, 2001

Abstract—A study was made of the voltammetric characteristics and dependences of the deposition rate and current efficiency on the electrolysis conditions in anodic deposition of vanadium(V) oxide on a stainless steel support from saturated solutions of ammonium vanadate, including those containing active and supporting additives.

Vanadium(V) oxide can be electroplated, preferably in a cyclic mode, from saturated neutral aqueous solutions of ammonium metavanadate in the presence of conducting additives, Na_2SO_4 and K_2SO_4, at 40–60°C and a current density of 1–4 mA cm^{-2} on gold, platinum, and stainless steel supports [1–3]. The resulting product is crystalline vanadium pentoxide containing ammonium ions and water, which are partially removed at 300°C. However, data on the effects of the electrolysis conditions, including current density, temperature, time, active and supporting inorganic additives, on the process stability are lacking. This was the subject of the present work.

Test solutions were prepared from analytically pure and pure grade reagents and distilled water. The electrolysis was performed in a 200-ml temperature-controlled open glass cell with symmetrically arranged cathodes (smooth plates of stainless steel or VT-1 titanium alloy) at 20, 30, 50, and 85°C. The sample to be plated was inserted between them so as to maintain a 15-mm interelectrode spacing and the ratio $S_a : S_c$ = 1 : 5. To prepare the saturated solution, a calculated volume of water with an excess of the salt was heated at 50–55°C for 2.5 h on a water bath. Inorganic additives were added into the solution after preliminary dissolution in a small volume of water with stirring and moderate heating to 30–40°C. The deposition rate V_{dep} (mg cm^{-2} h^{-1}) of vanadium oxide was estimated from the weight gain of the deposit after electrolysis and then recalculated per unit surface and unit time. The current efficiency (CE) was measured with a copper coulometer. The anode potential was measured relative to silver chloride reference electrode (E = +0.225 V) in the range I_a = 0.1–7.0 mA cm^{-2} with a Shch-4315 digital voltmeter. The X-ray structural analysis of the deposits was done on a DRON-2 diffractometer. The microrelief and microstructure of the surface of deposits were studied by a nanoscope.

A specific feature of the electrolytic preparation of anodic vanadium oxide deposits from ammonium metavanadate saturated solutions is the necessity of their preliminary "development" to accelerate deposition. Below we show how the deposition rate V_{dep} and the current efficiency by vanadium(V) oxide vary with electrolysis time τ in a solution freshly prepared for each experiment (pH 6.5, 85°C, I_a = 4 mA cm^{-2}, $S_a : S_c$ = 1 : 5, anode load 1 dm^2 dm^{-3}):

τ, min	V_{dep}, mg cm^{-2} h^{-1}	CE, %
15	1.3	8.7
30	2.1	14.5
45	3.0	21.0
60	3.5	24.5
75	4.3	30.1
90	4.7	33.0
120	5.0	35.0
150	7.1	42.0

The data obtained show that the yield of the anodic product increases with increasing electrolysis time. This results from gradual accumulation in the solution of vanadium ions of the lower oxidation state, among which the oxovanadium ions VO^{2+} formed by cathodic reduction of vanadium(V) are predominant:

$$VO_3^- + 4H^+ + e \rightarrow VO^{2+} + 2H_2O. \quad (1)$$

During 50–60 min of development, the solution

1070-4272/01/7409-1474$25.00

color changes from pale yellow to green. In the developed solution (without taking into account development period) the anodic product yield reaches 60% (V_{dep} = 9.0–9.5 mg cm^{-2} h^{-1}).

The relationships presented can vary depending on various factors, including volume load, current density, cathode material, ratio of electrode surfaces, etc. For example, a twofold increase in the anodic current density and anodic load corresponds to a nearly twofold shortening of the development time. This indicates that the vanadium oxide formation under the conditions considered is mainly limited by oxidation of oxovanadium ions accumulated in the solution by reaction (1):

$$2VO^{2+} + 2H_2O - e \rightarrow 2VO_2^+ + 4H^+, \quad (2)$$

$$2VO_2^+ + H_2O \rightarrow V_2O_5 + 2H^+ \quad (3)$$

$$2VO^{2+} + 3H_2O - 2e \rightarrow V_2O_5 + 6H^+ \quad (4)$$

which agrees with the data of [4]. However, along with these reactions, vanadium oxide(V) can be deposited on the anode owing to the adsorption-molecular interaction of HVO_3 forming in the near-electrode space, by analogy with reaction (3):

$$HVO_3 \rightarrow V_2O_5 + H_2O. \quad (5)$$

The occurrence of this reaction is confirmed to a certain extent in the case of electrolysis with the anode and cathode spaces separated by ceramic partitions. In the process, the current efficiency by the anodic product markedly exceeds that attained in the same time without separation of the electrode spaces, despite the lower rate of delivery of oxovanadium(IV) ions formed on the cathodes and a less intense change in the solution color near the anode. Even after 1 h of electrolysis the corresponding deposition rate reaches a maximum value for the developed solution (9.5 mg cm^{-2} h^{-1}).

The rate of the vanadium oxide(V) deposition V_{dep} from unsaturated solution of NH_4VO_3 (pH 6.5) is a function of the current density I_a and temperature T:

I_a = 4 mA cm^{-2}

T, °C	V_{dep}, mg cm^{-2} h^{-1}
25	0.9
35	2.0
50	3.5
75	8.2
85	9.0
90	8.7

T = 85°C

I_a, mA cm^{-2}	V_{dep}, mg cm^{-2} h^{-1}
0.5	3.0
1.0	5.0
2.0	6.7
3.0	8.5
4.0	9.0
5.0	9.5
7.0	8.6
10	7.3

The data presented show that with increasing temperature and current density the rate of the anodic product formation grows to a certain maximum and then decreases.

The deposition rate is affected by pH insignificuntly in the range pH 6–7 and decreases at higher pH, especially at pH > 7.5. When the solution is adjusted with sulfuric acid to pH < 6.0, the electrolysis is destabilized, which is manifested as formation of flaky particles of vanadium oxide.

Correspondingly, the external appearance and quality of the anodic deposits change. In the range of moderate current densities (2–4 mA cm^{-2}) and high temperatures (>75°C), the vanadium oxide deposits are compact and uniform and have enhanced adhesion, which allows mechanically resistant coatings up to 20–25 μm thick to be deposited onto smooth stainless steel plates. At current densities exceeding 10 mA cm^{-2} the anodic deposits, even thin (10–15 μm), are loose, and their adhesion is considerably worse. Decreasing electrolysis temperature produces the similar effect. The vanadium oxide deposits formed under the conditions have a color from light orange to light brown and are crystalline. These deposits strongly differ from black deposits with a comparatively developed structure, plated from acid solutions [5].

The supporting and active inorganic additives significantly affect electrolysis under the conditions considered.

The rates of vanadium oxide deposition from saturated solution of ammonium metavanadate containing 0.3 and 0.1 M Na_2SO_4 are given in the table. As seen, in the presence of sodium ions the deposition rate is lower than in the initial ammonium vanadate solution, and it decreases with growing concentration of the supporting electrolyte. The highest V_{dep} is attained at comparatively high current densities (5.0 mA cm^{-2}). The appearance of the deposits does not essentially

Rate V_{dep} of vanadium(V) oxide deposition from saturated solutions of NH_4VO_3 containing Na_2SO_4 at 85°C and pH 6.5

6.0	7.0	6.7
7.0	6.7	6.2

change in the process. At the same time, the deposits are more fine-grained and more compact and exhibit higher chemical resistance and stronger adhesion to the support than those deposited from the initial solution.

With the nitrate ions added into the solution in the form of 0.1–0.4 M sodium salt, V_{dep} decreases by a factor of nearly 5 compared to the optimal values, but the adhesion and uniformity of the deposits are improved. At the same time, the high oxidizing power of nitrate ions produces the negative effect on electrolysis stability.

The active components under study were manganese, nickel, and cobalt sulfates and cobalt nitrate.

Study of the V–Mn system under various electrolysis conditions, even at a low (0.005–0.01 M) concentration of manganese sulfate, shows that after 7–10 min of switching on the current the solution becomes turbid and the electrolysis destabilizes. In the process, an abundant brown deposit precipitates on the cell bottom. A brown film on the anode is formed at a rate of 1.0–1.5 mg cm^{-2} h^{-1}.

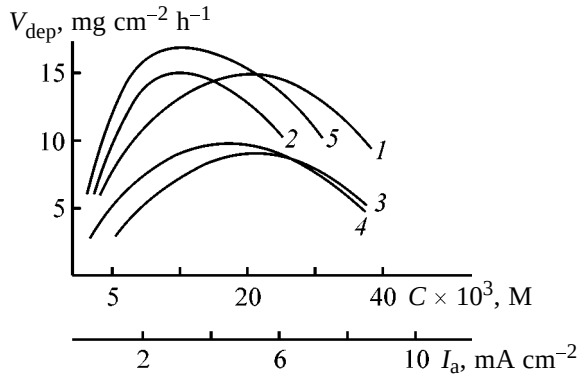

Fig. 1. Deposition rate V_{dep} of vanadium(V) oxide vs. (*1*) $CoSO_4 \cdot 7H_2O$ concentration at I_a = 4 mA cm^{-2} and (*2–5*) current density I_a. (*1, 4*) Saturated NH_4VO_3 solution; additive (M): (*2*) 0.02 $CoSO_4 \cdot 7H_2O$, (*3*) 0.04 $CoSO_4 \cdot 7H_2O$, and (*5*) 0.02 $Co(NO_3)_2 \cdot 6H_2O$. Temperature 85°C, pH 6.5; the same for Figs. 3 and 4.

In the presence of $NiSO_4 \cdot 7H_2O$ (concentration range 0.004–0.02 M), formation of the anodic deposit is fully suppressed. Under the electrolysis conditions optimal for the solution studied, a thin opalescent passivating oxide film is formed on the anode in the presence of nickel ions. In this case, oxygen evolution on the anode is the predominant process.

Among the systems considered, only the system V–Co is electrolytically compatible. When even small amounts (<0.02 M) of cobalt in the form of sulfate or nitrate are added to the solution, the nature of the anodic process and the structure and composition of the anodic product change. Figure 1 shows the rate of the anodic deposit formation in the saturated solution of NH_4VO_3 as a function of the cobalt sulfate concentration (curve *1*) and of the current density for the initial solution (curve *4*) and for those containing cobalt sulfate (curves *2, 3*) and cobalt nitrate (curve *5*). Curves *1* and *2* pass maxima at V_{dep} = 15 mg cm^{-2} h^{-1}, which is by a factor of 1.5 higher than in the initial solution. With the cobalt sulfate concentration increased twofold (curve *3*), V_{dep} decreases to a similar extent, with the maximum shifted toward higher current densities. In the presence of cobalt nitrate in the similar concentration, the maximum in the V_{dep}–I_{an} curve reaches 16 mg cm^{-2} h^{-1}, which confirms the positive effect of nitrate ions on the anodic formation of the corresponding oxides (curve *5*). At the same time, nitrate ions adversely affect the electrolysis stability and the solution performance owing to spontaneous sedimentation of cobalt nitrate crystals and corrosion of the anode support. In the presence of cobalt ions, anodic deposits are always uniform and grayish black with a lusterless smooth surface. The black color becomes more intense at higher cobalt concentrations. At lower concentrations (<0.04 M) fairly uniformly distributed inclusions of orange-brown crystals and spheroidal throwings are clearly revealed on the surface of deposits under a ×100 magnification. At higher concentrations of the additive this effect becomes less pronounced. This shows that at a certain stage of the deposition vanadium oxide is formed before its codeposition with cobalt oxide.

The above-noted character of the deposits forming in saturated ammonium vanadate solutions correlates

with the microstructure of their surface (Figs. 2a–2d). As seen, the structure and formation of the vanadium oxide deposits are strongly affected by the electrolysis conditions. For example, the deposits obtained in acid solutions of oxovanadium sulfate (pH 1.8–2.0) have a highly developed surface and a rather developed microrelief (Fig. 2a) [5]. The deposits obtained in the ammonium vanadate solutions studied have a crystalline structure with well-faced crystals growing in the parallel directions (Fig. 2c). After the deposits are cathodically treated in the same solution for a short time (0.3–5 min, depending on thickness), the edges of the crystal faces become smoother and the surface relief, slightly more developed (Fig. 2b). In the presence of cobalt ions the finely grained anodic deposits with a highly developed microrelief in the form of randomly oriented globular grains are formed (Fig. 2d). Evidently, this is a result of the interaction of anodically codeposited oxide phases, which is manifested, e.g., as suppressed growth of vanadium oxide crystals forming simultaneously with cobalt oxide nuclei. The coexistence of cobalt oxide in the anodic deposit with vanadium oxide V_2O_5 and the compound CoV_2O_5 was confirmed by X-ray diffraction (Fig. 3).

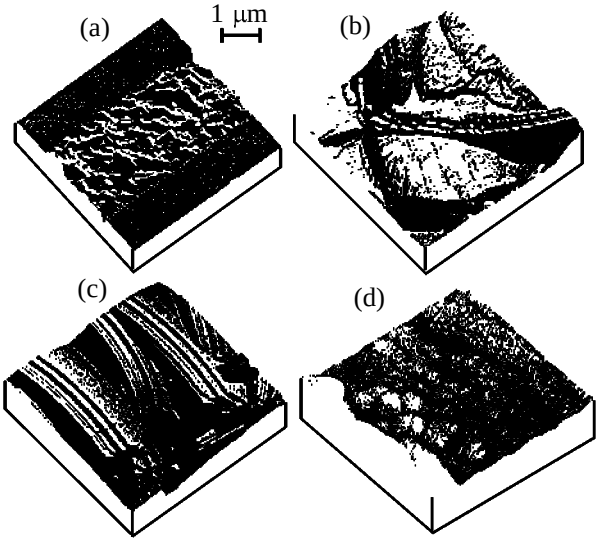

Fig. 2. Microstructure of the surface of vanadium(V) oxide deposits obtained under different conditions: (a) in acid solution of oxovandium sulfate and (b–d) in saturated NH_4VO_3 solution (T = 85°C, I_a = 4 mA cm^{-2}, pH 6.5), with subsequent cathodic treatment for a short time (c) in the same solution and (d) in the solution containing 0.02 M $CoSO_4$.

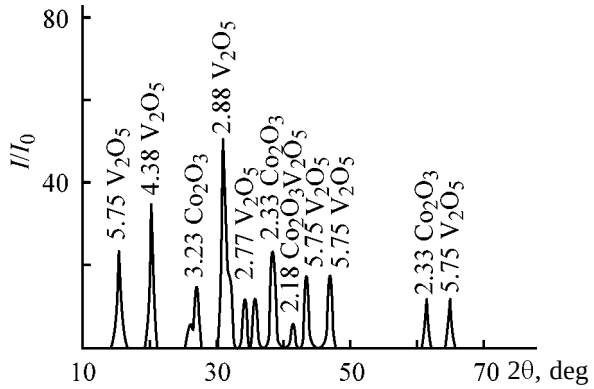

Fig. 3. Diffraction pattern of the anodic deposit obtained from the NH_4VO_3 saturated solution containing 0.02 M $CoSO_4$ at I_a = 4 mA cm^{-2} with subsequent heat treatment at 300°C for 7 h in air. (I/I_0) Relative intensity and (2θ) Bragg angle.

The above data are consistent with the voltammetric characteristics of the processes, taken under similar conditions. The typical I_a–E graphs for the developed solutions are shown in Fig. 4. At the optimal temperature (85°C) the dependence obtained for the initial solution on the initial surface of a stainless steel anode (V7 grade roughness) has two ascending sections separated by a limiting-current plateau (Fig. 4, curve *1*). For the anode surface preliminarily coated with a continuous vanadium oxide film, the similar dependence gradually passes from the lower mildly sloping section to the ascending section without inflections, with the relative shift toward positive values exceeding 200 mV (Fig. 4, curve *2*). Evidently, such a significant difference is caused by the fact that after the potentials of the onset of the vanadium oxide formation and oxygen evolution (the first ascending section) are attained, the anodic process on the initial surface occurs without overvoltage with increasing current (first ascending section), since in this case oxidation of oxovanadium ions to the corresponding oxide is the potential-determining reaction. Owing to diffusion and partial shielding of the anode by an oxide film, a further increase in the current density, after the limiting current of this reaction is attained, is accompanied by the shift of the anode potential (limiting plateau) to the values at which the vanadium oxide deposit is formed with a more intense oxygen evolution. When the passivating film on the anode is continuous, this process occurs without intermediate transitions, with the oxygen evolution additionally hindered. As a result, the anodic polarization increases. The relative decrease in the anode potential on the initial surface of the anode at the temperature decreased to 30°C (Fig. 4, curve *3*) evidently results from the predominant oxygen evolution on a stainless

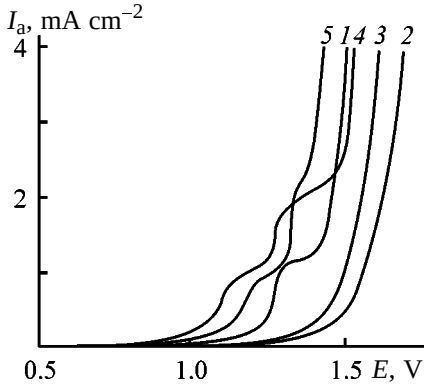

Fig. 4. I_a vs. E curves obtained in saturated NH_4VO_3 solutions on a 12Cr18Ni9Ti steel (*2*) straight and (*1, 3–5*) precoated with a vanadium oxide film. (*3*) T = 30°C. Additive (0.02 M): (*4*) $CoSO_4 \cdot 7H_2O$ and (*5*) $Co(NO_3)_2 \cdot 6H_2O$.

steel support under a weak influence of the concurrent reaction of vanadium(IV) oxidation without formation of a stable oxide film. In the presence of cobalt ions, the corresponding dependences consist of three ascending sections separated by steps (Fig. 4, curves *4, 5*). In a solution containing cobalt nitrate, the lower sections of curve *5* are located in the region of more positive potentials than those in a solution containing cobalt sulfate (Fig. 4, curve *4*). Correspondingly, the upper ascending sections of curves *4* and *5* are arranged in the opposite order with a relative shift of 100 mV, with the anode potentials lower than that in the ascending section of curve *1* for the pure solution. The stepwise character of these dependences confirms the different nature of the anodic processes for different polarizing currents. Apparently, for cobalt-containing solutions, the lower ascending sections of the curves reflect the simultaneous process of vanadium oxide deposition and oxygen evolution. With the limiting current of the oxovanadium(IV) oxidation attained, the polarization increases and the anode potential shifts toward positive values at which the cobalt(II) oxidation, being the main anodic reaction in the second ascending section, becomes feasible. The fact that the lower sections of curve *5* are located at more positive potentials for nitrate- than for sulfate-containing solution is due to the probable effect of nitrate ions. Their high oxidizing power can facilitate accelerated formation of anodic oxide film and inhibit the oxygen discharge even at low polarizing currents. As a result, the anodic polarization increases. The limitation of the cobalt ion transfer and the corresponding redistribution of the rates of simultaneous anodic reactions results in an additional jump of the anode potential (the second step) to the values favorable for accelerated oxygen evolution. In this case, vanadium and cobalt oxides in the upper ascending sections of the curves are formed more intensely owing to minimal diffusion. In this range the anodic process is conrolled by the slowest reaction of cobalt(II) oxidation accelerating in the presence of nitrate ions. This fact is probably responisble for the relative shift to less positive anode potentials of the corresponding section of curve *5*, which is to a certain extent confirmed by comparison of the V_{dep}–I_a plots for solutions containing equal concentrations of cobalt sulfate and cobalt nitrate (Fig. 1, curves *3, 5*).

CONCLUSIONS

(1) Saturated ammonium vanadate solutions show promise in electrolytic synthesis of high-performance cathode materials for lithium batteries. The complex V–Co oxide systems produced by anodic codeposition of vanadium and cobalt oxides from ammonium vanadate solutions in the presence of cobalt ions are of particular interest.

(2) The main electrolysis conditions for the systems studied are as follows: temperature 80–85°C, current density I_a 2–7 mA cm^{-2}, and pH 6–7. To enhance the specific surface area of the pure deposits of vanadium oxide, it is appropriate to use cathodic treatment for a short time (3–5 min) under the same electrolysis conditions.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of Electrolyte Composition on the Performance of Electrodes in Nickel–Zinc Batteries

Z. P. Arkhangel'skaya, R. P. Ivanova, T. B. Kas'yan, and L. B. Raikhel'son

Rigel' Joint-Stock Company, St. Petersburg, Russia

Received December 2, 1999; in final form, March 2001

Abstract—Variations in the electrolyte composition on cycling of nickel–zinc batteries were studied, and ways for its stabilization and service life prolongation were revealed.

The service life of a nickel–zinc (NZ) battery is usually determined by the negative electrode. When it works in combination with a nickel oxide electrode (NOE), its capacity on cycling decreases faster owing to gradual redistribution of its paste on the surface ("shape loss") and to the subsequent progressing local passivation [1, 2].

Therefore, when selecting an electrolyte composition, specific features of its interaction with a zinc electrode are taken into account to decrease inter- and intraelectrode zinc transfer; in particular, solutions are used in which the solubility of zinc oxide compounds is reduced. For example, the service life of batteries was prolonged by using solutions containing 3–5 M KOH and 3–4 M K_2CO_3 [3] instead of 7–8 M KOH solutions [4].

However, the suitability of electrolytes with reduced KOH concentration for NZ batteries is not obvious, as the processes on NOE are accompanied by a considerable change in the concentration of OH^- ions in the reaction zone. The concentration of hydroxide ions in NOE pores is considerably reduced on its anodic polarization even in electrolytes with a high KOH content (7–8 M) [5, 6], which hampers charging of deep layers of the electrode. On cycling the deficiency of the OH^- ions increases, as in NZ batteries the KOH concentration is reduced owing to the formation of CO_3^{2-} ions and to accumulation of potassium carbonate in the electrolyte [7].

NZ-25 batteries were manufactured of standard materials under conditions of industrial production. The negative electrodes 1.4 mm thick were prepared by roll-forming of the paste on a conducting framework. The paste consisted of a mixture of Zn and ZnO, corrosion inhibitors, and also binders and surfactants. The positive electrodes with a cermet base were 1 mm thick and were used in pairs. The ratio of capacities of the negative and positive electrodes was 3 : 1. A set of separators consisted of an alkaliproof paper and a hydrated cellulose film on the negative electrode and of nonwoven polypropylene on the positive electrode.

We studied batteries with three formulations of electrolyte, differing in the KOH and LiOH concentrations (Table 1). The concentration of LiOH corresponded to its maximum solubility in the electrolyte at the corresponding KOH concentration. The concentration of K_2CO_3 (as an impurity) in the starting electrolyte did not exceed 10 g l^{-1}.

We charged the batteries in a three-stage mode, with decreasing current in each subsequent step after attaining a voltage of 1.98 V (Table 1). Such an optimized mode allowed us to reduce substantially the oxygen evolution on NOE and to balance the main and side processes on the positive and negative electrodes. The imparted capacity was limited by the positive electrode, which allowed us to control its performance.

Table 1. Composition of electrolytes and modes of testing NZ-25 batteries

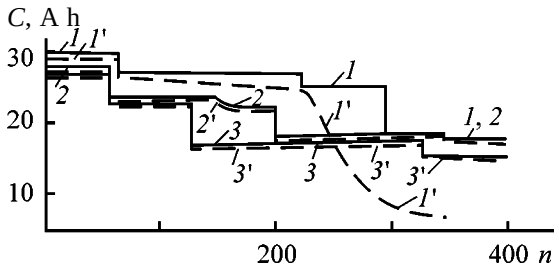

Fig. 2. Variation of the (*1*–*3*) charging and (*1*'–*3*') discharging capacities *C* during cycling of NZ-025 batteries. (*n*) Number of cycles; the same for Fig. 4. Electrolyte, g-equiv l^{-1}: (*1*, *1*') KOH 8.5 and LiOH 0.6; (*2*, *2*') KOH 6.8 and LiOH 1.0; (*3*, *3*') KOH 5.0 and LiOH 1.2.

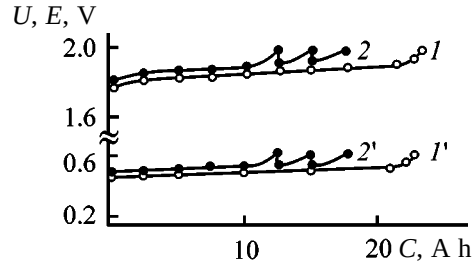

Fig. 3. Variation in the 150th cycle of the (*1*, *2*) voltage *U* and (*1*', *2*') potential *E* of NOE on charging of NZ-25 batteries containing electrolytes of different concentrations. (*C*) Capacity. Electrolyte, g-equiv l^{-1}: (*1*, *1*') KOH 6.8 and LiOH 1.0; (*2*, *2*') KOH 5.0 and LiOH 1.2.

However, even in this charging mode the oxygen evolution was not eliminated completely (Fig. 1). In batteries no. 1, starting from the charging degree of 0.6 of the nominal capacity, oxygen was formed in larger amounts than in batteries no. 2, whereas the volumes of the evolved hydrogen were the same, i.e., the degree of balance of the processes on the positive and negative electrodes increased as the KOH concentration decreased.

This conclusion is also confirmed by the minimal difference between the discharging and charging capacities for batteries nos. 2 and 3 (no more than 1–2%, Fig. 2), which allowed us to maintain an equal degree of charging of the positive and negative electrodes.

The discharging capacity of batteries no. 1 in the initial cycles is lower by 4–5% than the capacity imparted on charging, which points to the consumption of the corresponding current fraction for oxygen evolution on NOE and to the incomplete balance of the main processes on the positive and negative electrodes. The disbalance between the charging and discharging capacities increased to 8–10% to the 200th cycle. Simultaneously the "shape" of the zinc electrode changed, and in further cycles the capacity of the batteries of this type progressively decreased owing to passivation of the zinc electrode.

When charging of batteries nos. 2 and 3, as the number of cycles increases, problems arose, manifested as an increase in the potential of the positive electrode and in the corresponding increase in the voltage in the final stage of charging (Fig. 3). In this connection it was necessary to reduce the charging capacity.

The origin of these problems can be elucidated when comparing Figs. 2 and 4. A decrease in the KOH concentration with increasing K_2CO_3 concentration, which is shown in Fig. 4, is the reason for the increase in the NOE potential in the final charging stage, when a deficiency of hydroxide ions arises in the NOE pores [5, 6].

The main changes in the electrolyte composition occur in the initial cycling stage, and further changes are slower. The first decrease in the charging capacity for all the batteries takes place between the 50th and 60th cycles (Fig. 2). It results from a considerable decrease in the KOH concentration in the electrolyte to this moment (Fig. 4), especially in NOE pores [6].

In the subsequent cycling, batteries no. 3 required a decrease in the capacity on the 120–140th cycle, and batteries no. 2, on the 200th cycle (Fig. 2). The capacity of these batteries was stabilized at the level of 60% of the nominal value at the KOH concentration in the electrolyte of 2.5–3.0 g-equiv l^{-1} (Fig. 4). However, to charge batteries no. 3 to the level of 60% of C_n, it appeared necessary to add concentrated KOH solution to the electrolyte after 140 cycles to maintain its content at the level of 2.5–3 g-equiv l^{-1} (Fig. 4, curve *3*).

In batteries no. 1 the KOH concentration decreased

to 4 g-equiv l^{-1} and the necessity in correcting the charging capacity did not arise in the period from the 60th to the 200th cycle (Fig. 2). However, by the end of this period the battery capacity progressively decreased because of disbalance between the charging and discharging capacities. We have found out that the capacity of the batteries was not stabilized in the case of the initial KOH concentration of 8.5 g-equiv l^{-1} owing to the changes in the state of the negative electrode (shape losses).

Thus, we have revealed a certain relation between the change in the KOH concentration in the electrolyte and the capacity that can be imparted on charging the NZ battery to a feasible voltage when the maximum of the current is spent for the main process and the minimum, for oxygen evolution.

The transfer of impurities of metal carbonates from the paste into the electrolyte and the oxidation of organic substances contained in the battery and of the separator materials is the main factor responsible for the decrease in the KOH concentration in the electrolyte during cycling [7]. The initial content of carbonates in the zinc electrode in terms of CO_3^{2-} was 3%, the content of carbonates in NOE (after forming) was no more than 0.5%, and the K_2CO_3 concentration (as an impurity) in the initial electrolyte did not exceed 10 g l^{-1}.

It was shown earlier [7] that in batteries with the electrolyte containing 8.5 g-equiv l^{-1} KOH about 50% of the total amount of carbonates originates from the electrode paste. Because of their transfer into solution, the K_2CO_3 concentration increased to approximately 2 g-equiv l^{-1}. In the course of the subsequent 100–150 cycles the concentration of carbonates in the electrolyte increased further by a factor of almost 2, after which the content of carbonates in the electrolyte remained practically unchanged, though they were accumulated in the NOE paste.

The study of batteries with electrolytes of different concentrations, on the whole, confirmed these conclusions (Fig. 4), but it showed that the dynamics of K_2CO_3 accumulation and decrease in the KOH content in these batteries differ from each other. In batteries nos. 2 and 3 the carbonate was accumulated more slowly, and its content was about half that in batteries no. 1.

These data can be explained by considering specific features of the K_2CO_3 formation in NZ batteries. The increase in the K_2CO_3 concentration may be due to three processes.

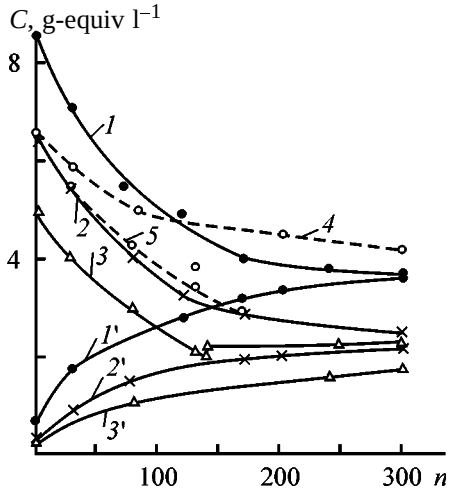

Fig. 4. Change in the concentration *C* of (*1*–*5*) KOH and (*1*'–*3*') K_2CO_3 in the course of cycling of NZ-25 batteries at various initial KOH concentration. Electrolyte, g-equiv l^{-1}: (*1*, *1*') KOH 8.5 and LiOH 0.6; (*2*, *2*', *4*, *5*) KOH 6.8 and LiOH 1.0; (*3*, *3*') KOH 5.0 and LiOH 1.2. (*4*, *5*) Calculated curves [(*4*) according to reaction (1) and (*5*) taking into account reaction (3)].

(1) First dissolves K_2CO_3 formed in the positive electrode from potassium hydroxide that remained in pores (after forming and washing) as a result of its reaction with atmospheric CO_2 before assembling the battery. This process is not accompanied by a decrease in the KOH concentration in the electrolyte.

(2) Further increase in the K_2CO_3 concentration is due to oxidation of organic substances with oxygen evolved on NOE. Thus, the KOH concentration changes in accordance with the reaction

$$2KOH + CO_2 \rightarrow K_2CO_3 + H_2O. \quad (1)$$

The rate of this process was found [7] to increase as the content of the products of separator breakdown in the electrolyte increases. It also depends on the amount of evolved oxygen, which is much less in batteries nos. 2 and 3 than in batteries no. 1 (Figs. 1, 2).

(3) Metal carbonates (basically $ZnCO_3$) contained in the paste of the negative electrode are also a source of K_2CO_3 accumulation. Its amount in the battery under study (in terms of CO_3^{2-}) is about 5 g (0.83 mol).

Zinc carbonate participates in the processes occurring on the zinc electrode [7], and the K_2CO_3 content in the electrolyte of a charged battery is higher than for an uncharged battery. Hence, on charging a battery, along with reaction (2)

$$Zn(OH)_2 + 2e \rightarrow Zn^0 + 2OH^-, \quad (2)$$

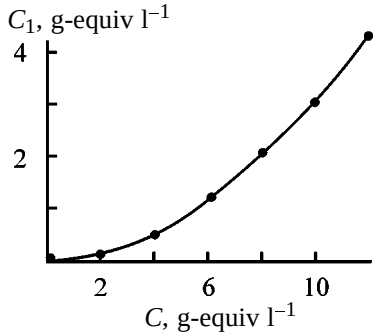

Fig. 5. $Zn(OH)_4^{2-}$ concentration C_1 as a function of the KOH concentration C.

occurs reduction of zinc carbonate by reaction (3):

$$ZnCO_3 + 2e \rightarrow Zn^0 + CO_3^{2-}. \quad (3)$$

The feasibility of reaction (3) is due to higher solubility of $ZnCO_3$ in water (solubility product SP 1.5×10^{-11}) as compared to the solubility of $Zn(OH)_2$ (SP $= 7 \times 10^{-18}$) [8].

A comparison of the amount of carbonates (in terms of CO_3^{2-}) contained in the negative electrodes of the batteries and the amount of K_2CO_3 accumulated in the electrolyte (1.7 g-equiv l^{-1}) of batteries no. 3 suggests that almost all carbonate ions pass into the electrolyte. The participation of the evolved oxygen in the formation of potassium carbonate is insignificant.

The formation of CO_3^{2-} ions in batteries no. 2 is also predominantly associated with the processes on the zinc electrode, and only a small part of them was formed by redox processes.

The K_2CO_3 content in batteries no. 1 is approximately twice that in batteries nos. 2 and 3 (Fig. 4). This fact suggests that in batteries with a high concentration of alkali, formation of about 50% of CO_3^{2-} ions is associated with evolution of a significant amount of oxygen on discharging.

As the cathodic reduction of zinc from $ZnCO_3$ is not accompanied by the formation of OH^- ions in the electrolyte, their concentration in the vicinity of the zinc electrode increases to a lesser extent than at the zinc reduction from $Zn(OH)_2$. Calculations, similar to those carried out in [6] for the zinc electrode, with consideration for the data of Fig. 5, showed that the transfer of CO_3^{2-} ions into the electrolyte results not only in the decreased release of OH^- ions from the electrode, but also in the decreased equilibrium concentration of $Zn(OH)_4^{2-}$ ions owing to a shift of the equilibrium of the chemical reaction accompanying the electrochemical process:

$$Zn(OH)_2 + 2OH^- \rightarrow Zn(OH)_4^{2-}. \quad (4)$$

The decrease in the concentration of OH^-- ions by 2 g-equiv l^{-1} within the range from 10 to 6 M results in a reduction by no less than 1 g-equiv l^{-1} of the content of $Zn(OH)_4^{2-}$ ions formed by the chemical reaction (Fig. 5). Thus, the increase in the K_2CO_3 concentration owing to reaction (3) is accompanied by an almost twofold decrease in the concentration of OH^- ions.

This is confirmed by the data of Table 2 summarizing the effect of reaction (3) on the change in the concentration of OH^- ions in batteries no. 2 in 30 cycles. The initial electrolyte concentration is 6.5 g-equiv l^{-1}. The electrolyte volume in the batteries under study is 100 ml. The volumes of pores of the positive (33 ml) and negative (28.5 ml) electrodes, and also of separators (28.5 ml) correspond to the values found in [6]. The calculations are based on the assumption that all CO_3^{2-} ions accumulated within this period (2.58 g, or 0.086 g-equiv l^{-1}) are formed by reaction (3) and pass into the electrolyte during one charging (Table 2). The charging capacity is 1 F (26.8 A h).

In the calculations we took into account variations in the concentrations of the OH^- and $Zn(OH)_4^{2-}$ ions in pores of electrodes during charging and discharge of the batteries due to electrochemical processes, migration, and also to the dissolution of zinc carbonate and chemical decomposition of $Zn(OH)_4^{2-}$ ions. The amount of forming and decomposing zincate ions was determined from Fig. 5. The transfer number of K^+ ions was taken to be equal to 0.25 [6], that of OH^- ions, to 0.7, and that of $Zn(OH)_4^{2-}$ ions, to 0.05–0.06, taking into account the most probable ratio of the diffusion coefficients of these ions of 4 : 1 and the ratio of their concentrations in the electrolyte (Fig. 5). Diffusion of the ions was not taken into consideration, as its effect in NZ batteries is insignificant [6].

We took into account the contents of components in separators when determining the average KOH concentration in the electrolyte. We assumed that their contents remain unchanged on charging and discharge, as the amount of ions entering the zone on migration and leaving it should be the same. In the calculation of the averaged KOH concentration we also took into account the release of water on charging (1 mol per 1 F) and its similar removal on discharge [5].

Owing to a number of assumptions and also to instability of the zincate complex, we can consider the

Table 2. Change in the content of OH^- ions during charging–discharge of an NZ-25 battery

* ZE is zinc electrode.

resulting KOH concentrations only as approximate. However, according to Table 2, the difference between the initial KOH concentration and its final value, calculated without taking into account participation of the CO_3^{2-} ions, is approximately 1%, indicating the reliability of the calculations. The arrangement of points in curves *2* (experimental) and *5* (calculated) in the 30th cycle differs insignificantly (Fig. 4). The KOH concentrations in the 80th and 130th cycles were calculated similarly, which allowed us to determine the arrangement of curve *5* up to 170 cycles.

We did not carry out calculations for a larger number of cycles, as this part of curve *2* is parallel to calculated curve *4* (Fig. 4), the slope of which is determined by the formation of CO_3^{2-} according to reaction (1). The slopes of curves *2* and *2'* in this case should be close to each other, but opposite in sign, which is actually observed.

Thus, the dynamics of decrease in the KOH concentration in the electrolyte of the NZ battery is determined by the contributions of reactions (2) and (3).

In batteries no. 1 the passing of CO_3^{2-} ions from the electrode paste makes a smaller contribution, which is due to the preferential and considerable formation of K_2CO_3 by reaction (1).

Thus, our data suggest that the initial KOH concentration of 7 M is optimal for the batteries under study, having a considerable thickness of NOEs (2 mm) and a noticeable content of carbonate impurities in zinc electrodes (up to 3%).

The use of an electrolyte with a higher KOH concentration results in an increase in the oxygen evolution, despite the use of the optimized three-stage charging mode. Furthermore, it is evident from Fig. 2 that the charging capacity should be limited, as in the final period of charging the battery to a specified voltage of 1.98 V the concentration of the OH^- ions in the zinc electrode increases during the initial cycles to 10–11 M, which promotes a change in its shape.

CONCLUSIONS

(1) Hampering of the anodic process on the nickel oxide electrode in the cycling nickel–zinc battery is associated with a decrease in the KOH concentration due to formation of carbonate ions.

(2) A decrease in the KOH concentration in the electrolyte is different depending on its initial content and is determined by the ratio of the rates of oxygen evolution and of passing of carbonates from the electrode pastes into the electrolyte, which is accompanied by breaking of the balance between the arrival of OH^- ions from the electrodes and their consumption in electrochemical processes.

(3) Stabilization of the capacity on prolonged cycling of the batteries under study at a level of about 60% of C_n was provided at the initial KOH concentration of 7 M, which decreased to 3 M by the end of the cycling.

(4) An increase in the initial KOH concentration to compensate for the observed changes is unfavorable for the zinc electrode because of increased loss of its paste and acceleration of processes leading to a progressing decrease in its capacity.

(5) To increase the service life of nickel–zinc batteries, it is necessary to reduce to a minimum the content of carbonates in the electrode paste. This will make narrower the range within which the KOH concentration varies in the electrolyte.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Express Voltammetric Control of Permanganate Ions in Process Solutions from Zinc Production

G. A. Borovkov and V. I. Monastyrskaya

North-Ossetian State University, Vladikavkaz, North Ossetia, Russia

Received January 18, 2001

Abstract—Express voltammetric analysis of zinc sulfate solutions for manganese(VII) ions was developed. The influence of the components of the supporting electrolyte on the measurement sensitivity and selectivity was studied. The method is intended for automated control of the permanganate treatment of the zinc electrolyte to remove cobalt(II) ions.

In modern industry, metallic zinc is usually produced by hydrometallurgical method, in which the most important stage is treatment of the solution to remove impurities. Among impurities producing the strongest interfering effect on electrolysis is cobalt(II). At a Co(II) content exceeding 2 mg l^{-1} the current efficiency drastically decreases, and corrosion of a zinc plate is observed [1].

The Co(II) ions from highly concentrated process solutions are removed by the so-called permanganate method involving their oxidation with MnO_4^- and precipitation of the resulting Co(III) ions in the form of the hydroxide $Co(OH)_3$, which can be easily removed from the process solution during concentrating and filtration.

One of the necessary conditions for optimizing permanganate treatment of zinc sulfate solutions to remove cobalt(II) is express control of the residual concentration of MnO_4^- ions. Maintenance of the permanganate concentration at a prescribed level ensures the necessary degree of Co(II) removal from the zinc electrolyte. This procedure can also be used for controlling $KMnO_4$ consumption during purification. For example, in reprocessing of cobalt(II)-rich concentrates, to reduce the Co(II) concentration in the purified zinc solution to 0.5 mg l^{-1}, the residual concentration of Mn(VII) should be maintained at a level of 500–700 mg l^{-1} (hereinafter, the Mn(VII) concentration is in terms of metal).[1]

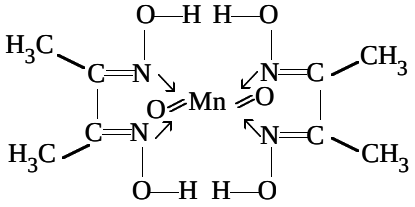
The main method of express control of the ionic composition of hydrometallurgical solutions is voltammetry [2–4].

Various polarographic procedures are successfully used for the automated control of zinc electrolytes for the content of Cu(II), Cd(II), Pb(II), Co(II), In(III), and Ni(II) ions. However, data on using voltammetric methods for measuring the concentration of permanganate ions in zinc sulfate solutions are lacking.

Polarographic determination of manganese(VII) in aqueous solutions involves certain problems [5–7]. Firstly, several reduction waves are recorded, which are expanded along the potential scale and are hardly suitable for analytical purposes. Secondly, the analysis results are poorly reproducible. As a rule, voltammetric determination of permanganate ions is performed in acid supporting electrolytes on solid indicator electrodes.

In this work we examined the possibility of monitoring by differential pulse polarography (DPP) the manganese(VII) ion in an NH_4Cl + NH_4OH solution on a stationary dropping mercury electrode (SDME). Permanganate ions in an NH_4Cl + NH_4OH solution do not produce a proper polarographic wave, but a readily resolved DPP cathodic peak proportional to the Mn(VII) concentration in the test solution was recorded upon addition of dimethylglyoxime (DMG) into the electrolyte.

In alkaline medium permanganate ion is reduced to manganese dioxide. Presumably, MnO_2 reacts with DMG to form the complex



[1] According to data of the pilot shop of the Elektrotsink plant.

1070-4272/01/7409-1485$25.00

Fig. 1. DPP curves of manganese(II) in the 0.8 M NH_4Cl + 0.8 M NH_4OH + 2×10^{-3} M DMG supporting electrolyte. Manganese(VII) concentration 10 mg l^{-1}. (φ) Potential; the same for Fig. 3. Curves: (*1*) cathodic and (*2*) anodic.

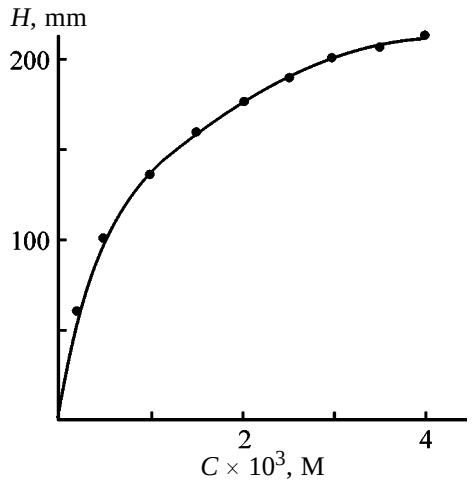


Fig. 2. Height of the DPP peak *H* of manganese(VII) vs. DMG concentration *C* in the 2 M NH_4Cl + 2 M NH_4OH supporting electrolyte.

We found that the complex of manganese dioxide with DMG is reversibly reduced on SDME in an NH_4Cl + NH_4OH solution, whereas Mn(II) does not produce analytical signal under these conditions.

Figure 1 shows the cathodic and anodic DPP curves of Mn(VII) (10 mg l^{-1}) in the 0.8 M NH_4Cl + 0.8 M NH_4OH + 2×10^{-3} M DMG electrolyte, recorded on an AZhE-11 voltammetric analyzer [3]. The potentials of the cathodic and anodic peaks are virtually the same ($\varphi_p^c = -0.98$ V and $\varphi_p^a = -0.97$ V), and the heights of the voltammetric curves differ by a factor of no more than 1.3.

The polarographic analysis of the solutions was performed in a three-electrode electrochemical cell with SDME indicator electrode, silver chloride reference electrode, and carbon glass auxiliary electrode. The DPP peaks were recorded in the automated mode at a potential sweeping rate of 10 mV s^{-1}. The amplitude of the pulsed polarizing voltage was 20 mV. The rectangular pulses of 40 ms length were applied at an 80-ms period.

The DPP cathodic peaks of Mn(VII) (10 mg l^{-1}) in the 2.0 M NH_4Cl + 2.0 M NH_4OH + 2×10^{-3} M DMG electrolyte taken before and after 40 mg l^{-1} of Mn(II) was added into the analyzed solution show that Mn(II) does not interfere with the Mn(VII) determination, making possible selective voltammetric control of permanganate ions in the solutions containing both manganese forms.

The sensitivity of the polarographic determination of MnO_4^- ions is largely dependent on the DMG concentration in the test solution and considerably increases as this concentration increases from 0.2×10^{-3} to 2×10^{-3} M. A further increase in the DMG concentration does not noticeably increase the amplitude of the Mn(VII) peak (Fig. 2). Therefore, the DMG concentration in the solution was maintained at a level of 2×10^{-3} M.

The possibilities of polarographic determination of Mn(VII) in the NH_4Cl + NH_4OH supporting electrolyte containing DMG are limited by the influence of various concomitant elements, firstly, of Zn(II), Co(II), Ni(II), and Fe(II). Therefore, for Mn(VII) monitoring in process solutions of zinc production, the analysis in the presence of excess Zn(II) should be sufficiently selective.

In NH_4Cl + NH_4OH solutions containing surfactants, Zn(II) produces a pronounced wave, which is used for analytical purposes [5]. Despite the fact that in an NH_4Cl + NH_4OH solution Zn(II) is electrochemically reduced at a more negative potential than the Mn(VII) complex with DMG, even a comparatively small excess of zinc(II) results in a drastic deterioration of the selectivity of polarographic determination of permanganate ions. For example, in a 0.1 M NH_4Cl + 0.1 M NH_4OH + 2×10^{-3} M DMG solution the potentials of the Mn(VII) and Zn(II) DPP peaks are –1.014 and –1.142 V, respectively. As seen from Fig. 3a, the DPP peak of manganese is markedly distorted even at equal concentrations of these ions in the test solution (curve *2*), and at a concentration ratio (mg l^{-1}) [Zn] : [Mn] = 10 : 1 the polarographic determination of permanganate ions becomes virtually impossible (curve *3*).

It is known that with increasing ammonia concentration the half-wave potential of zinc shifts toward negative values [5]. Therefore, we examined the possibility of enhancing selectivity of Mn(VII) determination in the presence of Zn(II) by increasing the concentration of the supporting electrolyte. We found that, as the (NH_4Cl + NH_4OH) concentration is increased from 0.25 to 2.0 M, the potential of the DPP peak of Mn(VII) changes from –1.01 to – 0.98 V, and that of Zn(II), from –1.20 to –1.36 V. As seen from Fig. 4, with increasing solution concentration the difference between the reduction potentials of the above ions regularly increases, i.e., the selectivity of determination of Mn(VII) in the presence of Zn(II) increases. We found that the variation of the supporting electrolyte concentration does not noticeably affect the sensitivity of Mn(VII) determination in the presence of Zn(II). For example, as the concentration of the supporting electrolyte components (NH_4Cl + NH_4OH) increases from 0.25 to 2.0 M, the intensity of the DPP peak of Mn(VII) remains unchanged, whereas that of Zn(II) increases by a factor of more than 1.7. Thus, the high resolution of polarographic determination of permanganate ions in zinc-containing solutions can be attained only with the use of sufficiently concentrated supporting electrolytes.

In a 2 M NH_4Cl + 2 M NH_4OH + 2×10^{-3} M DMG solution the direct polarographic determination of Mn(VII) is possible with a detection limit of 0.5 mg l^{-1} at [Zn] : [Mn] = 7500 : 1. Figure 3b shows the DPP peaks of Mn(VII) (92 mg l^{-1}) in a 2 M NH_4Cl + 2 M NH_4OH + 2×10^{-3} M solution before (curve *2*) and after 12 000 and 16 000 mg l^{-1} of zinc(II) is added into the test solution (curves *3* and *4*, respectively).

To concomitant substances appreciably interfering with the polarographic determination of permangante ions in NH_4Cl + NH_4OH solutions containing DMG belong Co(II) and Ni(II). Cobalt(II) and nickel(II) form with DMG stable complexes catalyzing hydrogen evolution on a mercury electrode. The strongest catalytic effect was observed in taking polarographic curves of nickel and cobalt dimethylglyoximates in NH_4Cl + NH_4OH buffer solutions with a sensitivity of the Co(II) and Ni(II) determination at a level of 1×10^{-8} M. The catalytic currents are used in voltammetric control of cobalt and nickel microconcentrations in various natural objects, for example, in the atmosphere [10].

In a supporting electrolyte of the composition 2 M NH_4Cl + 2 M NH_4OH + 2×10^{-3} M DMG, the DPP peak potential of Ni(II), Mn(VII), and Co(II) is –0.95, –0.98, and –1.14 V, respectively. The DPP peaks of Ni(II) and Mn(VII) are summed up, and the left descending branch of the resulting peak is distorted by the presence of cobalt(II) in the solution. This pattern is observed at the concentration ratio (mg l^{-1}) [Mn(VII)] : [Ni(II)] : [Co(II)] = 25 : 5 : 1. Naturally, at further growth of the Ni(II) and Co(II) concentrations their negative effect on the MnO_4^- determination increases.

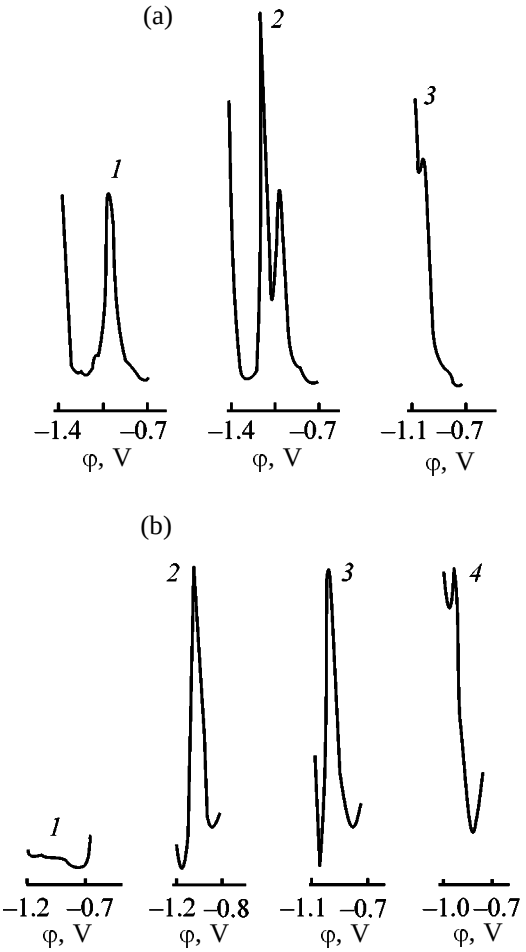

Fig. 3. Effect of Zn(II) concentration $C_{Zn(II)}$ (mg l^{-1}) on the polarographic determination of manganese(VII). (a) Supporting solution 0.1 M NH_4Cl + 0.1 M NH_4OH + 2×10^{-3} M DMG. Ion concentration (mg l^{-1}): (*1*) Mn(VII) 10 and Zn(II) 0; (*2*) Mn(VII) 10 and Zn(II) 10; and (*3*) Mn(VII) 10 and Zn(II) 100. (b) Supporting solution 2 M NH_4Cl + 2 M NH_4OH + 2×10^{-3} M DMG. (*1*) Supporting solution; ion concentration (mg l^{-1}): (*2*) Mn(VII) 2 and Zn(II) 0, (*3*) Mn(VII) 2 and Zn(II) 12 000, and (*4*) Mn(VII) 2 and Zn(II) 16 000.

Our study showed that the interfering effect of nickel(II) and cobalt(II) in polarographic determination of permanganate ions can be eliminated by addition of EDTA, which forms stable elecrtochemically

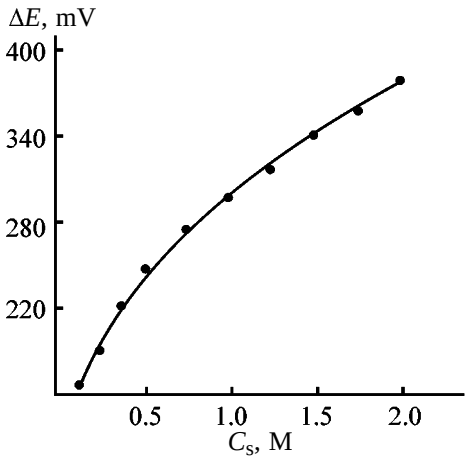

Fig. 4. Difference ΔE between the DPP peak potentials of manganese and zinc as a function of the concentration of the NH_4Cl + NH_4OH supporting electrolyte C_s. Concentration: 10 mg l^{-1} Mn(VII) and Zn(II) and 2×10^{-3} M DMG.

inactive complexes with Ni(II) and Co(II) [8, 11], but does not affect voltammetric determination of Mn(VII). In the case of MnO_4^- ions the effect of Ni(II) and Co(II) is suppressed completely. We found that in the electrolyte of the composition 2 M NH_4Cl + 2 M NH_4OH + 2×10^{-3} M DMG + 2×10^{-3} M EDTA, voltammetric determination of Mn(VII) is feasible at a 5-fold excess of Co(II) and a 50-fold excess of Ni(II).

Moreover, addition of EDTA into the supporting electrolyte made it possible to eliminate a hindering effect of Fe(II) ions. It is known that in an NH_4Cl + NH_4OH solution the Fe(II) ions are reduced electrochemically on a mercury electrode at high negative potentials. For example, the half-wave potential of Fe(II) in the 1 M NH_4Cl + 1 M NH_4OH supporting electrolyte is –1.52 V [12]. We found, however, that in the NH_4Cl + NH_4OH electrolyte containing DMG Fe(II) forms a purple complex which is polarographically reduced at a more positive potential. For example, in the 2 M NH_4Cl + 2 M NH_4OH + 2×10^{-3} M DMG electrolyte, the DPP of Fe(II) on SDME is recorded at a potential of –1.15 V.

The presence of Fe(II) in the test solution causes distortion of the Mn(VII) peak, but this distortion is completely eliminated by addition of EDTA. We found that in the 2 M NH_4Cl + 2 M NH_4OH + 2×10^{-3} M DMG + 2×10^{-3} M EDTA electrolyte a 10-fold excess of Fe(II) does not interfere with determination of permanganate ions and at the EDTA concentration increased to 4×10^{-3} M the Mn(VII) determination becomes possible even at a 20-fold excess of Fe(II).

Typical components of hydrometallurgical solutions of zinc production are also Cu(II), Cd(II), Sb(III), and As(III). In the 2 M NH_4Cl + 2 M NH_4OH + 2×10^{-3} M DMG + 2×10^{-3} M EDTA electrolyte, the DPP peak of cadmium(II) was not recorded experimentally at its concentration of 250 mg l^{-1} (in the purified zinc solution the Cd(II) content does not commonly exceed 1–2 mg l^{-1} [1]). The Sb(III) ions present in the zinc electrolyte are deposited in an ammonia solution [13]. The Sb(III) ions in the NH_4Cl + NH_4OH supporting electrolytes are reduced on a mercury electrode at a potential of –1.7 V [17] and do not interfere with the polarographic determination of Mn(VII).

The calibration curve of Mn(VII) in the 2 M NH_4Cl + 2 M NH_4OH + 2×10^{-3} M DMG + 2×10^{-3} M EDTA electrolyte is linear in the concentration range 0–25 mg l^{-1}. Solutions containing more than 25 mg l^{-1} manganese(VII) require dilution before analysis.

Our results allow development of a procedure for quantitative polarographic determination of permanganate ions in various objects including process solutions and sewage of zinc production.[2]

The method of standard additions served as control. A total of more than 30 test solutions of zinc electrolyte with the Mn(VII) concentration varied from 760 to 1180 mg l^{-1} were analyzed. The test solutions were diluted with water by two orders of magnitude. The measurements were done on an AZhE–11 voltammetric analyzer. The rms error of the Mn(VII) analysis in the concentration range 0–25 mg l^{-1} did not exceed 2.4%. The highest rms deviation of the main and control analyses of the same test solution, characterizing the reproducibility of measurements, was 0.7%.

The method developed can be used for the automated or express analysis of permanganate ions in process solutions and sewage of zinc production, which will enhance the efficiency of their treatment to remove impurities.

EXPERIMENTAL

We used standard solutions of Mn(VII), Co(II), Ni(II), Zn(II), and Fe(II) prepared by methods described previously [15]. The model solutions were prepared in double-distilled water.

The mixture for determining Mn(VII) in purified

[2] The method was tested with industrial zinc sulfate solutions at the Elektrotsink plant.

zinc sulfate solutions was prepared in a 100-ml volumetric flask from a test solution (1 ml) of zinc electrolyte and 50 ml of the supporting electrolyte of the composition 4 M NH_4Cl + 4 M NH_4OH + 4×10^{-3} M DMG + 4×10^{-3} M EDTA, to which distilled water was added to the mark. The mixture was poured into an electrochemical cell, in which cathodic voltammetric curves were taken in the potential range from –0.8 to –1.2 V with a potential sweeping rate of 10 mV s^{-1}. The amplitude of the DPP peaks at a potential of –0.98 V was measured, and the concentration of the Mn(VII) ions in the test solution was determined from the calibration plot. The total time of analysis for manganese(VII) did not exceed 7 min for one test solution.

When analysis was done in the automated mode, dilution of test solution with water, its mixing with the supporting electrolyte, and delivery of the test solution to the cell of a voltammetric sensor were performed with DZZh-4 three-chamber membrane batchers made of corrosion-resistant materials [3]. After the test solution was prepared, the spent mercury drop was dumped, then a new drop was formed, and the potential sweeping mechanism and the diagram tape driver of the secondary device were sequentially switched on by the control unit in accordance with the given program. Each voltammetric curve was recorded on a renewed mercury drop. After the parameters of the voltammetric curve were calculated by a computing device, the output signal of the analyzer, proportional to the Mn(VII) concentration in the test solution, was recorded with a secondary device.

CONCLUSIONS

(1) The possibility of selective polarographic determination of permanganate ions in the presence of Zn(II) in the NH_4Cl + NH_4OH supporting electrolyte containing dimethylglyoxime was established.

(2) The selectivity of the Mn(VII) analysis in the presence of excess Zn(II) ions is enhanced with increasing concentration of the supporting electrolyte. The negative effect of Co(II), Ni(II), and Fe(II) ions is eliminated by their complexation with EDTA to form electrochemically inactive species.

(3) The developed method of voltammetric determination of permanganate ions can be recommended for the automated or express analysis of multicomponent process solutions and sewage of zinc production.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Principles Determining the Current Modes of Solid-State Integrator Operation

I. E. Shpak and A. M. Mikhailova

Saratov State Technical University, Saratov, Russia

Received March 2, 2001

Abstract—The polarization resistance of integrator, electrolyte conductivity, electrolyte decomposition voltage, and residual current of integrator were determined in a wide range of temperatures by the method of rectangular pulse and cyclic voltammetry.

Complete removal of silver from the inert electrode of an $Ag\,|\,RbAg_4I_5\,|\,Au$ integrator is accompanied by a steep rise in the electrode potential, which is the output signal of the integrator, used to control external devices. The natural current limits depend on side processes occurring in the integrator. The lower limit is determined by the residual current, and the upper, by the electrolyte decomposition voltage (ca. 670 mV for $RbAg_4I_5$) [1, 2]. These limits are temperature-dependent.

The voltage drop across the integrator, ΔU, is constituted by the voltage drop in the electrolyte and across the electrode|electrolyte boundaries: $\Delta U = IR_e + IR_F$ (here a steady current not affected by charging of non-Faraday capacitances is meant). The polarization resistance R_F is a complex function of charging current, temperature, electrode charge, etc. [3], whereas R_e is independent of charge, but depends on temperature. Determining R_F precisely under flowing current conditions, i.e., the conditions characterized by pronounced departure from equilibrium, poses severe technical difficulties.

EXPERIMENTAL

The most acceptable method for determining the polarization resistance is the rectangular current pulse technique [4]. Using the parameters of the voltage response of an electrochemical system under study to a current pulse passed through it, the polarization resistance of the electrode, R_e, and some other characteristics can be calculated using the equations

$$R_e = \Delta U/(|I_{ch}| + |I_d|), \quad (1)$$

$$R_F = (\Delta U_2/|I_{ch}|) - (\Delta U_1/(|I_{ch}| + |I_d|), \quad (2)$$

$$C_d = |I_d|/|dU/d\tau|_u, \quad (3)$$

where $|dU/d\tau|$ is taken at the instant of time when $\Delta U = \Delta U_2 - \Delta U_1$ is reached.

However, the validity of the results obtained with this method depends on whether it is possible to provide steep leading fronts of the charging and discharge currents, ensure that the equality $|dU/d\tau| = 0$ holds at the instant when the ohmic components ΔU_1 and ΔU_2 are measured, and use sufficiently fast measuring apparatus. The existence of strict limitations imposes stringent requirements on the measurement procedure and equipment used. To meet these requirements, a special apparatus was developed (see figure).

The apparatus was used to study integrator samples in a wide range of currents and temperatures. The results obtained for one of the samples at temperatures of +20 and –50°C are presented in Table 1.

Similar results were obtained for all other temperatures (–20.0 and 50°C). Data on the dependence of the integrator voltage on the charging current in the entire temperature range are presented in Table 2.

Table 1. Integrator parameters in charging with different currents. Q_{ch} = 1 μC, I_d = 1 mA

I_{ch}, mA	τ_{ch}, s	ΔU_2	ΔU_1	R_F	R_e	$R_{ext} = R_F + R_e$
		mV		Ω		
			20°C			
20	0.05	200	110	4.8	5.2	10
10	0.10	140	63	8.3	5.7	14
1	1	60	–	–	–	60
0.6	1.67	55	–	–	–	91.7
			–50°C			
20	0.05	550	340	11.3	16.2	27.5
10	0.10	380	190	20.8	17.2	38
1	1	170	50	153	25	170
0.6	1.67	145	30	224	18.7	241
0.1	10	105	10	148	9	165

The *I*–*U* dependence, which is nonlinear at small currents, becomes linear at currents exceeding 5 mA. This means that, at charging current of up to 20 mA, electrolyte decomposition is virtually impossible at any of the temperatures studied. However, with account of the fact that at –50°C the voltage across an integrator being charged with a current of 20 mA becomes as high as 0.55 V, i.e., approaches the upper limiting voltage of the system under study (0.6 V), the maximum admissible, for the temperature range in question, current should presumably be not higher than 20 mA.

To elucidate the mechanism underlying the effect of current and temperature, it is advisable to consider the behavior of separate components of the electrode system with these factors. The results of the experiments performed indicate that the dependence of the charging current on the polarization resistance R_F is well approximated by a linear equation in log–log coordinates. The plots of the dependence $\log I_{ch} = f(\log R_F)$ are presented in Fig. 1. Hence follows that at T = const

$$R_F = K_1 I_{ch}^{-K_2}. \quad (4)$$

Calculation of the coefficients K_1 and K_2 on the basis of the plots in Fig. 1

T, °C	K_1	K_2
50	39.49	0.793
20	54.95	0.800
0	73.00	0.806
–20	98.31	0.805
–50	130.8	0.804

shows that K_2 is virtually temperature-independent and equal to 0.8, whereas the temperature dependence of K_1 is linear in the range from 50 to –20°C in the $\log K_1 - 1/T$ coordinates (Fig. 2). The temperature at which a deviation from the linear run of the dependence is observed coincides with the dew point (ca. –20°C) in the box used to assemble the integrator. Probably, crystallization of trace amounts of atmospheric moisture, which found their way into the sample in assembling the integrator, at the electrode | electrolyte interface can change the activation energy of the electrode reaction on passing to temperatures lower than the dew point. With account taken of the slope of the linear portion in the $\log K_1 - 1/T$ dependence in Fig. 2, the following expression is valid for K_1:

$$K_1 = 0.832 \exp(0.103/KT), \quad (5)$$

where the Boltzmann's constant $K = 8.6 \times 10^{-5}$ eV deg^{-1}.

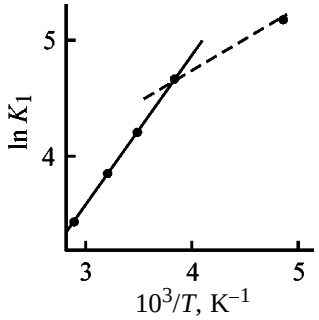

Fig. 2. Temperature dependence of the coefficient K_1 of Eq. (4).

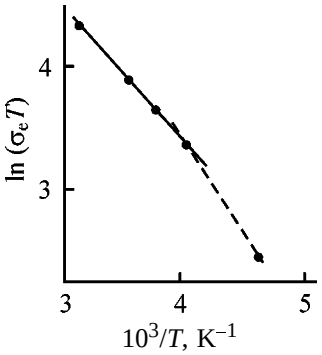

Fig. 3. Temperature dependence of $\sigma_e T$.

The activation energy is in good agreement with the activation energy of conductivity, obtained for $RbAg_4I_5$ in [5]. This suggests that the parameter K_1, determining the behavior of R_F, is related to the nature of the electrolyte.

The temperature dependence of the electrolyte conductivity σ_e in integrators, obtained by measuring the electrolyte resistance by the rectangular pulse method (Table 1), indicates that $\sigma_e \to 0$ at a temperature of about –75°C. This temperature is rather close to the temperature of phase transition of $RbAg_4I_5$ to a virtually nonconducting modification (ca. –65°C according to [6, 7]). Analytically, this dependence is described by the expression

$$\sigma_e = 1/R_e = -0.387 + 1.98 \times 10^{-3} T. \quad (6)$$

In the coordinates $\ln(\sigma_e T)$–$1/T$ (Fig. 3), the plot of the dependence shows two linear portions with a transition point lying at about –20°C, as in Fig. 2. For the linear portion in the temperature interval from 50 to –20°C we have

$$\sigma_e T = 3.3 \times 10^{-3} \exp(-0.1038/KT), \quad (7)$$

i.e., the activation energy of the conductivity of the electrolyte is 0.1038 eV, which virtually coincides with the value found from the dependence of the polarization resistance R_F on current and temperature [Eq. (4) for K_1].

Knowing the behavior of R_F and R_e as functions of current and temperature, we can write the general expression for the voltage drop across the integrator:

$$\Delta U = I(R_F + R_e) = K_1 I^{0.2} + IR_0 \exp(E'/KT). \quad (8)$$

The value of K_1 can be readily found using Eq. (5). Expression (8) not only fully describes the voltage across the system in integrator charging for the entire range of currents and temperatures, but also accounts for the nonlinearity of current–voltage characteristics of the samples at small currents (Table 2). It can be seen that, with the charging current increasing in this range, the polarization resistance R_F of the inert electrode decreases by 4–5 orders of magnitude and, beginning with a current of 5 mA, the electrolyte resistance remains virtually the only factor limiting the rate of the electrode process.

In the general case, the most probable residual current components for a system with solid electrolyte are the current of electronic conduction, Faraday current of minority carriers, and adsorption currents caused by crystal lattice relaxation in the contacting phases on changing the electrode potential and the capacitance of the electrode | electrolyte interface. The flowing of these currents, shunting the main anodic process during formation of a voltage step in readout

of the charge imparted to the integrator, introduces a certain positive error, which is the larger, the closer are the readout and residual currents.

The residual current of the integrators was determined using a method based on analysis of potentiodynamic characteristics of samples at various potential sweep rates. Direct measurement of steady-state residual currents at fixed electrode potentials failed to ensure sufficient reproducibility in view of the indeterminate stationarity conditions for the system under study. A set of potentiodynamic curves measured on one of the samples at 20°C is presented in Fig. 4. Equipotential points in these curves were used to plot the dependence of the current on the potential sweep rate (Fig. 5). Extrapolation to zero sweep rate (steady state) gave the residual current at a given potential.

The residual current depends in a complicated manner on the potential of the gold electrode: at potentials lower than 25 mV it is negative, i.e., silver is deposited at the electrode. At higher potentials the current passes through zero and, at around 50 mV, a first anodic current peak is observed, which is presumably due to dissolution of deposited silver.

In the range 150–200 mV, i.e., in approaching the resting potential of the inert electrode (100 ± 20 mV), the residual current falls virtually to zero. Finally, at potentials exceeding 200 mV the residual current grows following a nearly quadratic law. At a potential of 400 mV the residual current is within 0.2 μA for all of the samples studied.

It should be noted that any set of potentiodynamic curves contains two points (Fig. 4, points *A* and *B*) at which all the curves intersect. Apparently, the current at these points is independent of the sweep rate, and, consequently, corresponds to the residual current at intersection point potentials. Below are given the residual currents at various inert electrode potentials at 20°C (U_A = 31.25, U_B = 417.5 mV; I_A = 0.05, I_B = 0.2 μA):

U, mV	I_{res}, μA
50	0.05
100	0.025
150	0.000
250	0.05
350	0.055
400	0.15
425	0.25

Similar data were obtained for other temperatures within the working interval. A steeper increase in the residual current at $U > 400$ mV makes necessary setting the cutoff level at $U \le 400$ mV.

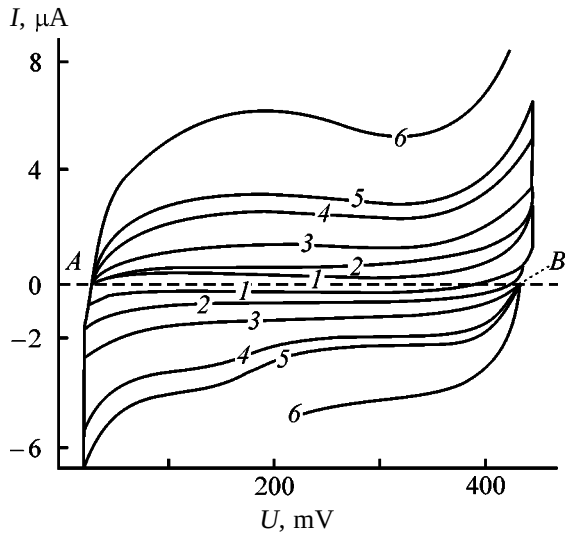

Fig. 4. Potentiodynamic characteristics *I*–*U* of Au | $RbAg_4I_5$ system at 20°C. Potential sweep rate, mV s^{-1}: (*1*) 2.6, (*2*) 5.2, (*3*) 10.4, (*4*) 20.8, (*5*) 26, and (*6*) 52.

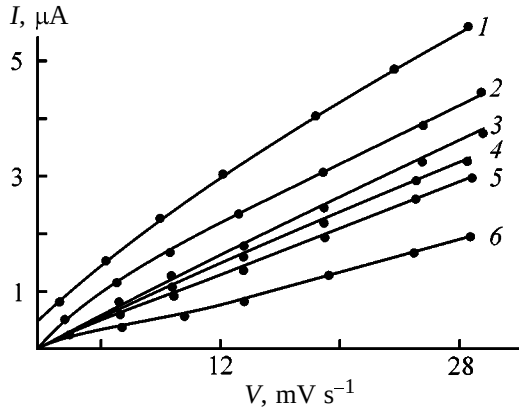

Fig. 5. Anode current *I* vs. potential sweep rate *V*. Inert electrode potential, mV: (*1*) 425, (*2*) 400, (*3*) 300, (*4*) 200, (*5*) 100, and (*6*) 50 (*T* = 20°C).

Extrapolation of potentiodynamic characteristics plotted in the *I*–*V* coordinates (*V* is the potential sweep rate) can be applied to find the residual currents at any working electrode potential. The residual currents of prototype samples of integrators, computed using special linear extrapolation software (at $V \to 0$, U = 350 mV), are the following:

T, °C	I_{res}, μA
–50	0.0102
–20	0.069
20	0.126
50	0.320

In view of the requirements that the minimum

readout current must be, as a rule, an order of magnitude higher than the residual current of integrator, we can take for the minimum acceptable working current a value of 1–2 μA at room temperature, and a higher value of 3–4 μA at 50°C.

CONCLUSIONS

(1) The obtained experimental data indicate that the dependence of the polarization resistance R_F on the charging current can be well approximated with a linear equation in log–log coordinates.

(2) The activation energy of the electrolyte conductivity (0.1038 eV) virtually coincides with the values determined from the dependence of the polarization resistance R_F on current and temperature.

(3) Residual currents, which flow in the system and shunt the main anodic process during the formation of a potential step in readout of the charge imparted to the integrator, introduce a certain positive error, which is the larger, the closer are the readout and residual currents.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Diffusion Coating of Nickel with Tantalum in Chloride–Fluorotantalate Melts[1]

Abstract—The effect of temperature and time on the diffusion saturation of nickel with tantalum in molten salt mixture NaCl–14 mol % K_2TaF_7 in the presence of metallic tantalum powder was studied, and characteristics of the obtained diffusion coatings were analyzed.

Owing to its corrosion resistance, nickel is frequently used as structural material in contact with molten salts, including preparation of sodium-reduced tantalum powders for capacitors. The content of nickel in such powders is strictly regulated by technical specifications. In this connection, it is urgent to develop protective diffusion coatings on the nickel surface, which diminish the apparatus corrosion and thereby prevent contamination of tantalum powders with nickel in the course of their manufacture.

Previous analysis of chronopotentiograms of free corrosion [1, 2] demonstrated that the potentials of nickel and tantalum in a chloride–fluorotantalate melt start to come closer 0.5 h after a nickel electrode is brought in contact with the melt, and only after 2 h a solid intermetallic protective layer of Ni_3Ta starts to grow. Such a prolonged contact of nickel with the melt before the beginning of formation of a protective layer leads to contamination of the melt and, consequently, of the obtained metal with nickel.

In this connection, it was necessary to accelerate the formation of surface diffusion-formed alloy coatings in molten salts. This can be achieved by introducing powdered tantalum into the melt [3], because in this case the surface area of tantalum in contact with the melt increases manyfold. This ensures an extremely fast saturation of the melt with tantalum ions in lower oxidation state and eliminates limitations on the overall process rate. Previous investigations confirmed the efficiency of the proposed technique [4].

In this study we examined the effect of temperature, time, and also concentration and dispersity of the tantalum powder introduced into the melt on the diffusion saturation of nickel with tantalum in a molten salt mixture and analyzed the characteristics of the obtained diffusion coatings.

EXPERIMENTAL

Experiments were performed in a hermetically sealed steel retort under helium at 950–1050 K. As containers for the melt served SU-2000 glassy carbon crucibles. Sodium chloride of ultrapure grade was dehydrated in air by heating to 900 K and then fused under pure helium. Working samples were cut from rolled nickel of N0 brand (thickness 0.4 mm, 99% purity), treated with a mixture of acids, washed with alcohol, and dried. As reference electrodes served chemically polished tantalum rods. A PI-50-1.1 potentiostat and a PDA-1A self-recorder were used. The parameters monitored in the experiments included the sample weight before and after the tests, variation of the working electrode potentials with time, and presence of impurities in the melt. X-ray phase analysis (XPA) of the samples and potassium fluorotantalate was made on a DRON-2 diffractometer (CuK_α radiation). The coating structure was studied on metallographic sections of the samples with a Neophot optical microscope and a Hitachi scanning electron microscope. The roughness was measured with a profilograph–profilometer manufactured by the Kalibr plant (model 250). As roughness parameters were chosen the mean-arithmetic profile deviation R_a and roughness profile amplitude at 10 points, R_z. The R_a and R_z values were calculated from the results of 12 measurements done in two perpendicular directions. Element distribution profiles in nickel samples were

measured on a Cameca X-ray microanalyzer. The microhardness was measured on a PMT-3 microhardness meter (20-g load).

The high-purity tantalum powder used in the experiments was obtained by sodium reduction [5] and contained the following amounts of controlled impurities (wt %): Fe 7×10^{-4}, Si 1.7×10^{-4} , Cr $\leq 2 \times 10^{-4}$, C 6×10^{-4}, Ni 7×10^{-4}, Zr $< 5 \times 10^{-4}$, and Nb 3×10^{-3}. The bulk density m_{sp} and specific surface area S_{sp} of the powder are given below in relation to the fractional composition:

Fraction, μm	m_{sp}, g cm^{-3}	S_{sp}, cm^2 g^{-1}

The results of experiments on determining how the specific weight gain $P = \Delta m/S$ (Δm is the increase in the weight of a nickel sample as a result of diffusion saturation, S is the sample surface area) depends on the time τ of keeping in a melt with addition of powder of varied fractional composition at different temperatures are presented in Fig. 1. P is related to τ by the equation

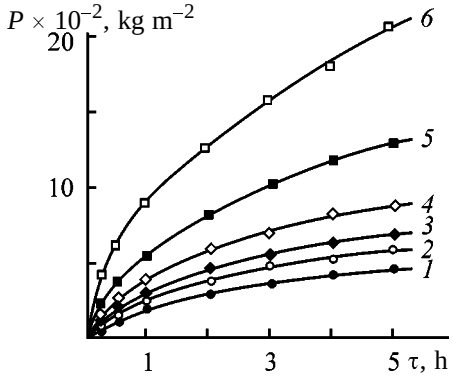

Fig. 1. Specific weight gain P for nickel samples vs. time τ of keeping in NaCl–K_2TaF_7 melt. Temperature, K: (*1–4*) 950 and (*5, 6*) 1050. Initial content of Ta powder in melt, wt %: (*1, 3, 5, 6*) 0.8 and (*2, 4*) 3.0. Ta powder fraction, μm: (*1, 2, 5*) –50 and (*3, 4, 6*) +63.

$$P = k\tau^{1/2}, \quad (1)$$

where $k = k_0 \pm \Delta k$ is an empirical coefficient which depends on the melt temperature and the amount and fractional composition of the powder (in this study the amount of powder introduced into the melt was expressed in weight percent relative to the mass of K_2TaF_7 salt in a melt under study).

Under the conditions studied, the dependence of the specific weight gain on the process temperature can be described by the equation

$$P = A\exp(-E/RT), \quad (2)$$

where R is the universal gas constant, $A = A_0 \pm \Delta A$ is an empirical coefficient which depends on time and the fractional composition of the employed tantalum powder, and $E = 70 \pm 5$ kJ mol^{-1} is an empirical coefficient which has the meaning of the apparent activation energy of diffusion saturation.

The coefficients of Eqs. (1) and (2) are given in the table for different conditions of interaction between nickel and melt.

XPA of the coatings demonstrated that the diffusion layer is composed of two phases (Fig. 2). As

follows from the phase diagram, there are five intermetallic compounds in the system nickel–tantalum: Ni_8Ta, Ni_3Ta, Ni_2Ta, NiTa, and $NiTa_2$ [6]. Among these, the compound Ni_3Ta is the most stable (at 1020 K, $\Delta G = -112 \pm 28$ kJ mol^{-1} [7], maximum growth rate constant $k = 1.3 \times 10^{-12}$ [8]). Previously, with compact metal used as a source of tantalum in NaCl–K_2TaF_7 melt (2.5 mol %), formation of just this compound on the nickel surface was observed [1]. In a melt with a higher content of potassium fluorotantalate (14 mol %), saturated with tantalum powder, Ni_2Ta is formed in addition to Ni_3Ta (Fig. 2).

It should be noted that the formation of coatings under study is based on an electroless transport process that is due to the presence in the melt of ions (in varied oxidation state) of the metal being deposited [9]. Raising the content of K_2TaF_7 and replacing compact tantalum with powdered metal create more favorable conditions for growth of Ni–Ta layers because of the increasing rate of melt saturation with tantalum ions in lower oxidation state. The possible mechanism of coating formation is as follows. After an intermetallic layer, the richest in nickel, is formed, tantalum continuing to be deposited reacts with this layer to form other compounds, which can be represented in a simplified form as the following sequence [2]:

$$2Ni_3Ta + Ta \rightleftarrows 3Ni_2Ta,\ \Delta G = -86.8 \text{ kJ g-at}^{-1}\ Ta,$$

$$Ni_2Ta + Ta \rightleftarrows 2NiTa,\ \Delta G = -21.4 \text{ kJ g-at}^{-1}\ Ta,$$

$$NiTa + Ta \rightleftarrows NiTa_2,\ \Delta G = 27.7 \text{ kJ g-at}^{-1}\ Ta.$$

Formation of Ni_2Ta is more thermodynamically favorable than that of Ni_3Ta, which is confirmed by the experiment (Fig. 2). The growth kinetics of a surface compound is governed by diffusion of nickel as a more mobile component into the surface layer. Nickel atoms have much higher diffusion mobility in Ni_3Ta and Ni_2Ta lattices, compared with heavier tantalum atoms. The results obtained in this study suggest the following: nickel is not subject to corrosive dissolution in tantalum-containing melts with high potassium fluorotantalate content, which are in equilibrium with metallic tantalum. Just the opposite, in the case of electroless deposition of tantalum ions, protective layers composed of Ni_3Ta and Ni_2Ta are formed on the nickel surface.

According to X-ray fluorescence microanalysis of samples with electroless coatings of thickness $\delta \geq 15$ μm, the content of tantalum in these coatings is 51.7–53.7 wt % (Fig. 3), in agreement with XPA data.

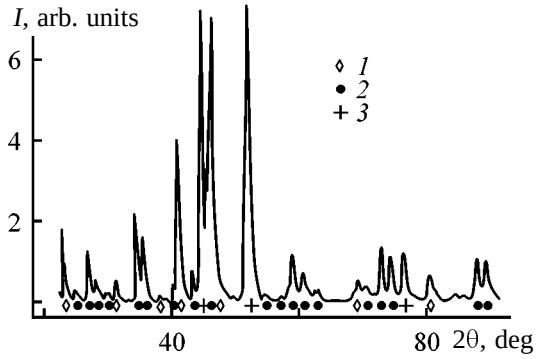

Fig. 2. X-ray diffraction pattern for Ni–Ta coating on nickel. (*I*) Intensity and (2θ) Bragg angle. (*1*) Ni_2Ta, (*2*) Ni_3Ta, and (*3*) nickel base.

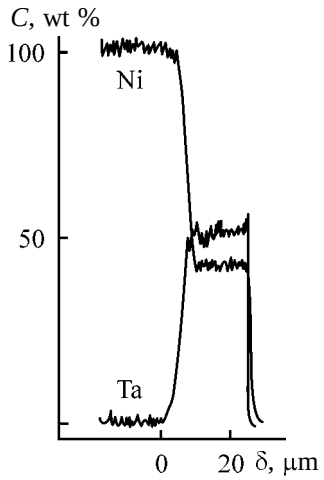

Fig. 3. Element depth profile for an Ni–Ta coating on nickel. (*C*) Concentration and (δ) thickness.

A study of the microstructure of the coatings with an optical microscope demonstrated uniformity of their thickness. Also, the previously established relationship between the sample weight gain and Ni–Ta layer thickness [4] was confirmed:

$$\delta = 1.8\ (\Delta m/S) \times 10^{-4}, \quad (3)$$

where δ is the coating thickness (μm), Δm is the weight gain (kg), and S is the sample surface area (m^2).

The nature of the surface relief was analyzed and the coating microstructure studied in more detail by means of electron microscopy. Figure 4 shows micrographs of (a) nickel substrate and surface of (b) thin and (c) thick diffusion Ni–Ta coatings. It can be seen that the thin coating is fine-grained and possesses a large covering power. The roller traces on the nickel base surface are smoothed out, and, gradually, a low-

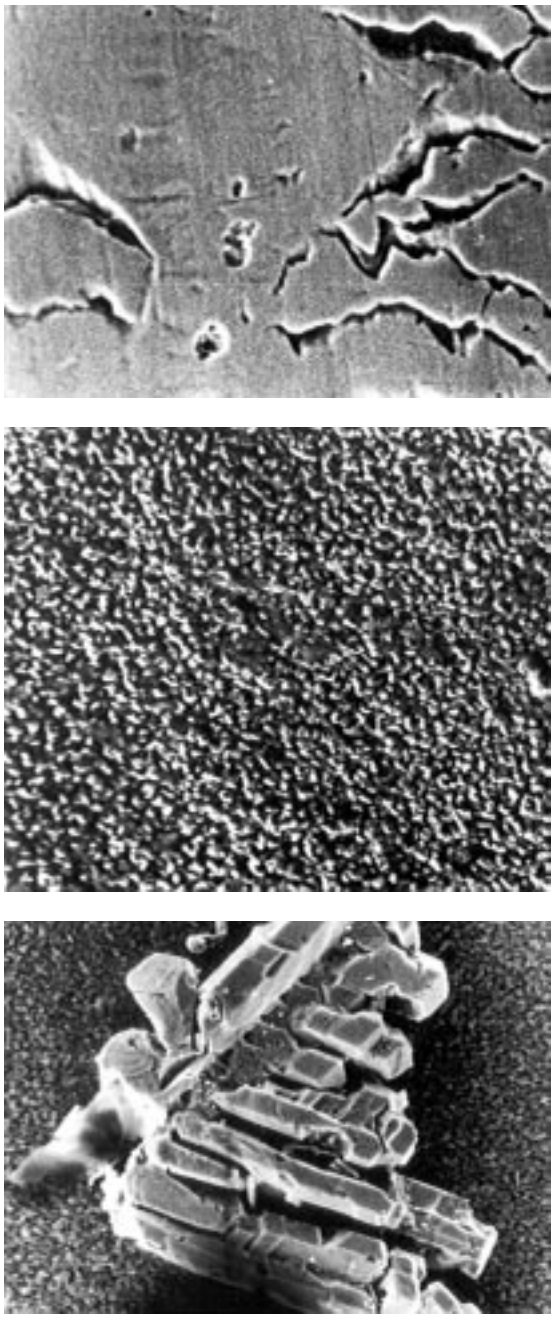

Fig. 4. Micrographs of substrate and Ni–Ta coatings (× 1000 magnification). Surface: (a) nickel substrate, (b) thin coating ($\delta \approx 500$ Å), and (c) thick coating ($\delta \approx 20$ μm).

roughness coating is formed over the entire surface. With increasing thickness of a coating, its roughness becomes more pronounced and formation and growth of separate dendrites are observed (Fig. 4c). The electron-microscopic data are confirmed by roughness measurements with a profilograph-profilometer. It can be readily seen (Fig. 5) that, for samples with coating thickness of less than 4–5 μm, R_a and R_z are much

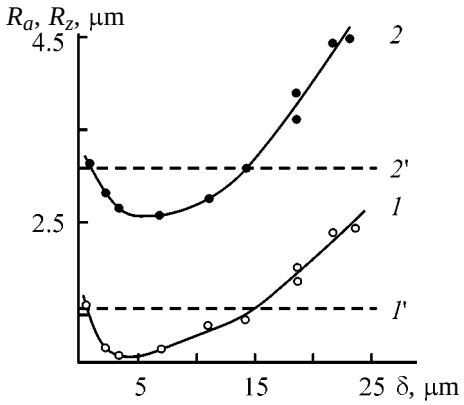

Fig. 5. Surface roughness parameters (*1*) R_a and (*2*) R_z vs. thickness δ. *1'* and *2'* denote, respectively, the R_a and R_z values for the initial substrate.

lower than the values for the initial nickel surface, and only at thicknesses exceeding 15 μm the roughness parameters of the coating become higher than those for the initial substrate.

The microhardness H_μ of the coatings (5100 ± 400 MPa) is independent, within measurement error, of the coating thickness and exceeds more than fourfold the microhardness of the nickel base (H_μ = 1150 ± 50 MPa). The coating microhardness values are in agreement with the results of X-ray fluorescence microanalysis (Fig. 3) which demonstrated that there is no variation, either, of the sample composition across the thickness within the experimental error. Comparison of the data in Figs. 2 and 3 indicates, as also do the results of metallographic studies, that the coating is a mixture of Ni_3Ta and Ni_2Ta phases, rather than a two-layer structure.

CONCLUSIONS

(1) It is shown that a coating containing, together with Ni_3Ta, Ni_2Ta is formed on the nickel surface in chloride–fluorotantalate melts that contain a large amount of potassium fluorotantalate and are in equilibrium with metallic tantalum.

(2) With tantalum used in the form of powder, rather than compact metal, the rate of formation of a diffusion layer can be markedly raised. In this case, the process of coating formation is affected not only by melt temperature, but also by the amount and fractional composition of the powder added to the solution.

(3) The forming coatings exhibit high covering power, which protects nickel from corrosive dissolu-

tion. At coating thicknesses of less than 10–15 μm, a polishing effect is observed, which consists in a decrease in the surface roughness parameters. The microhardness H_μ of the coatings is 5100 ± 400 MPa and does not vary, within the measurement accuracy, across the layer thickness.

(4) The obtained results make it possible to propose a practicable method for corrosion protection of nickel used as structural material in contact with molten salts.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Acridine Derivatives as Inhibitors of Copper Dissolution

V. V. Ekilik, A. G. Berezhnaya, and M. N. Svyataya

Rostov State University, Rostov-on-Don, Russia

Received December 8, 2001

Abstract—Copper dissolution in an acidified chloride solution containing or not containing some acridine derivatives and potassium iodide was studied as influenced by the potential, stirring of the solution, time, and temperature.

Acridines inhibit corrosion and anodic dissolution of a number of metals, primarily iron [1] and some alloys [2–5]. The influence of these compounds on particular steps of copper dissolution was not studied.

EXPERIMENTAL

To study copper dissolution, chronoammograms at constant potential E and polarization curves at the potential increasing stepwise were recorded in 1 M NaCl + 0.01 M HCl solutions purged with purified argon or neon. Prior to the measurements, a Teflon-reinforced copper disk electrode with the working surface area of 0.2 cm^2 was trimmed at a rotation rate m = 1050 rpm with an abrasive paper with a grain size decreasing form 2 to 0, polished with an MgO suspension applied on chamois, and polarized at the cathodic potential E lower by 200 mV than the corrosion potential E_{corr}. The measurements were performed on stationary and rotating (m = 270–1050 rpm) electrodes in a three-electrode cell with separated catholyte and anolyte. A saturated silver chloride electrode was used as the reference electrode. The copper oxidation state n was determined by coulometry under galvanostatic conditions with control of E.

10-Methylacridinium iodide (no. 1), acridinium chloride (no. 2), 9-aminoacridinium chloride (no. 3), 9-aminoacridine (no. 4), and, for comparison, 10^{-4} M KI (no. 5) were used as inhibitors. In some cases the concentration dependences were studied.

The inhibitor efficiency was estimated from the deceleration coefficient K, i.e., the factor by which the process is decelerated.

Prior to the study of the inhibitor efficiency, let us consider the kinetics and mechanism of anodic dissolution of copper, which appreciably determines the inhibiting power of the additives. The degree of deceleration of hydrogen depolarization also affects E_{corr} and hence the corrosion resistance of copper.

The anodic polarization curves recorded on a stationary electrode (Fig. 1) can be separated into several characteristic sections. Tafel straight lines with angular coefficient b_a = 60 mV, observed in the potential range from –0.2 to –0.1 V, indicate reversible dissolution to form Cu^+ [6, 7]. Then the curves pass

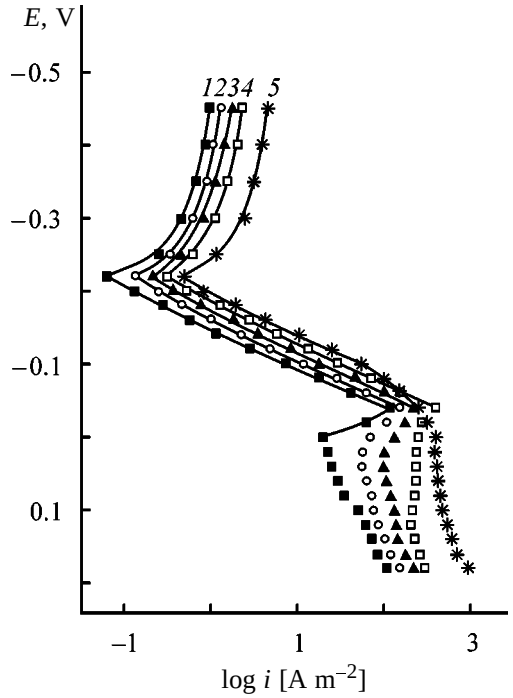

Fig. 1. Polarization curves at (*1*, *5*) 25, (*2*) 35, (*3*) 45, and (*4*) 55°C and a rate of the disk electrode rotation of (1–4) 0 and (*5*) 1050 rpm in the solution free from the inhibitors. (*E*) Potential and (*i*) current density.

1070-4272/01/7409-1500$25.00 © 2001 MAIK "Nauka/Interperiodica"

through a maximum followed by a section of the limiting current at increased temperature T and rotation rate (m > 200 rpm). This indicates the salt passivation. On a stationary electrode, the process is accelerated with further increase of E. This can be explained by the results of the coulometric study: At the potential ($E \le 0.02$ V) lower that that of the current density minimum i, Cu^+ (n = 0.95–1.05) chloride complexes pass into the solution, whereas at $E > 0.02$ V more readily soluble Cu^{2+} (n = 1.9–2.0) compounds are formed. On a rotating disk electrode the current density i increases aslo, but at higher potential E, which is due to different conditions of formation and degradation of the salt film.

The activation energy W calculated from the temperature dependence of i measured on the cathodicaly polarized electrode is 11.4 kJ mol^{-1} and corresponds to slow diffusion into the bulk of the solution. At the anodic polarization, W is approximately two times higher in almost entire potential range, which can be due to hindered diffusion through the film of the forming anodic products.

The anodic chronoammograms of the stationary electrode (Fig. 2) have the sections of nonstationary and stationary diffusion, separated by a small transition section. At the beginning of the process the i vs. $\tau^{-1/2}$ dependence is described by the equation

$$i = nFC_S(D/\pi\tau)^{-1/2} = \gamma\tau^{-1/2} \quad (1)$$

and is extrapolated to the origin. This indicates that the diffusion coefficient D is independent of time τ, since the concentration of anodic products C_S on the electrode surface is constant.

The dependence of the nonstationary currents on E within the i–$\tau^{-1/2}$ straight line range at τ = constant is a Tafel straight line with $b_a \sim 60$ mV, which agrees with the above consideration. The E–logγ straight line in accordance with Eq. (1) has the same slope (Fig. 3a).

The second section of the anodic chronoammogram is a horizontal straight line with stationary i_{st}. The slope of the E–logi_{st} straight line (Fig. 3b) is also $b_a \sim 60$ mV.

Since copper dissolution is controlled by diffusion [6–8], the i–m dependence is described by the equation [9]

$$i = 0.62nFC_S D^{2/3}\nu^{-1/6}\omega^{1/2} = \lambda m^{1/2}, \quad (2)$$

where ν is the kinematic viscosity and $\omega = 2\pi m$.

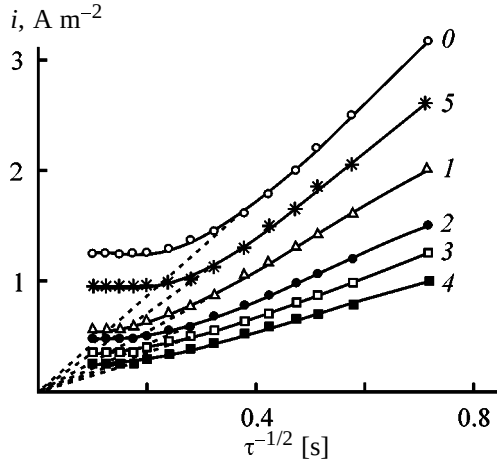

Fig. 2. Anodic chronoammograms recorded on a stationary electrode at –0.15 V in solutions (*0*) with no inhibitor and (*1–5*) containing the respective inhibitor. Inhibitor concentration 10^{-4} M; temperature 25°C; the same for Figs 3, 4. (i) Current density and (τ) time.

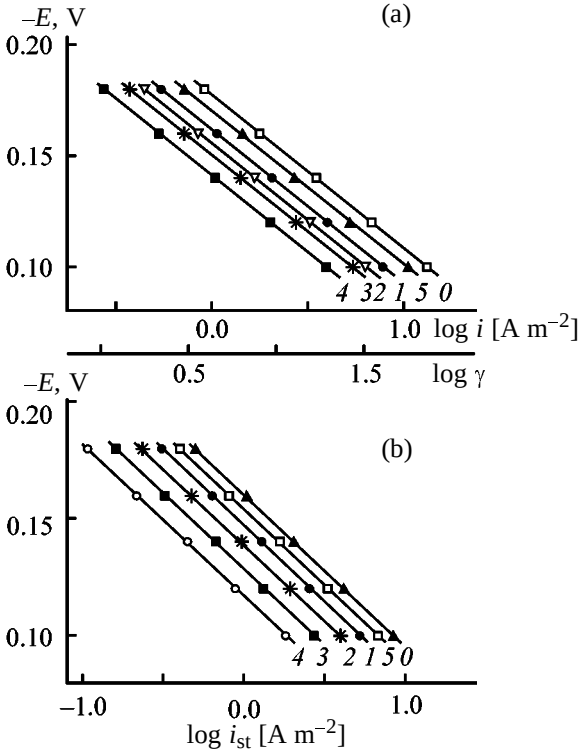

Fig. 3. Polarization curves of stationary electrode, constructed form the anodic chronoammograms recorded in solutions (*0*) with no inhibitor and (*1–5*) containing the respective inhibitor. (E) Potential; (i) Current density in 10 s; (i_{st}) stationary current density.

Parameter λ is 2.9, 157, and 165 A s$^{1/2}$ m^{-2} at E = –0.15, 0.05, and 0.2 V, respectively. The similar dependence was obtained at hydrogen liberation (λ = 0.35 A s$^{1/2}$m^{-2} at E = –0.4 V), which is reasonable

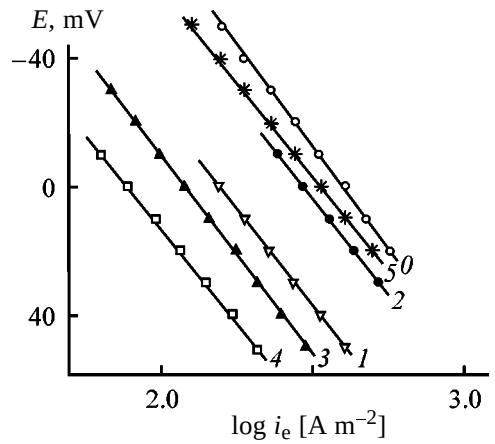

Fig. 4. Polarization curves recorded in the solution (*0*) with no inhibitor and (*1*–*5*) containing the respective inhibitor. (*E*) Potential and (i_e) rate of the electrochemical step.

for weakly acidic solutions. As follows from Eq. (2), the slope of the E–$\log\lambda$ straight line in the Tafel region (E from –0.2 to –0.1 V) is also 60 mV.

Generally, the measured anodic current density distorted by the concentration polarization is related to the diffusion rate i_d and the rate of electrochemical reaction i_e by the approximate equation [10]

$$i = i_e i_d (i_e + i_d)^{-1}. \quad (3)$$

Since $i_e \gg i_d$, in the above cases $i \sim i_d$ and i is appreciably lower than the exchange current density i_0. However, the diffusion control can give way to the electrochemical control with increasing i [11]. It also should be taken into account that b_a in the case of the diffusion control is 2 times lower than that at the electrochemical control. Hence, the factor by which $\log i_d$ increases with increasing anodic polarization ΔE_a is 2 times higher compared to $\log i_e$. In this case the process can be controlled by both the diffusion and the electrochemical reaction. However, whereas i_e steadily increases with increasing ΔE_a, i_d and correspondingly i measured on a rotating disk electrode will reach the limiting values (Fig. 1). The region of the mixed kinetics of $Cu \rightarrow Cu^+$ oxidation should be manifested on the curvilinear section of the polarization curve between the Tafel straight line and the section with the limiting i_d. This agrees with the fact that the i–$m^{1/2}$ dependences in the range of E from –60 to +10 mV are curvilinear. The i_e was determined from the segment intercepted on the ordinate by extrapolation of the i^{-1}–$m^{-1/2}$ straight lines to $m^{-1/2} = 0$. The results confirmed that the examined reaction is of the first order and Eq. (3) describes well the relation between i, i_d, and i_e. As expected, the range of the potentials E corresponding to the mixed kinetics increases with increasing m. The values of i_d and i_e are comparable. As seen from Eq. (2), $i_e = i_d$ at $m_1 = (i_e/\lambda)^2$. m_1 ranges from 210 to 320 rpm and depends on E insignificantly. The slope ($b_a \sim 120$ mV) of the E–$\log i_e$ Tafel straight line (Fig. 4) indicates the one-electron copper ionization.

Thus, effective inhibitors of dissolution of copper electrode should decelerate the diffusion step. Taking into account that $i \sim i_d$ at $m = 0$, to study the diffusion deceleration, the anodic chronoammograms in the Tafel region (E from –0.2 to –0.1 V) and the polarization curves were recorded on stationary and rotating disk electrodes.

The results of the potentiostatic measurements partially presented in Fig. 2 show that the additives inhibit nonstationary and stationary diffusion (Table 1).

As expected, K_d^1 and K_d^2 are independent of E and τ. Generally, the performance of the additives is determined by a change in D and C_S owing to formation of polymolecular films and a change in the nature of diffusing particles. Complexation in the bulk of the solution and on the electrode surface should strongly affect the inhibition. Since $K_d^2 > K_d^1$, the deceleration increases in the transition region of τ. If the additional protecting film is formed on the electrode at these τ values, its microcrystallinity will increase in the presence of the inhibitors owing to their surfactant properties.

When dissolution of a copper anode is decelerated at the potentials of the Tafel section, the additives can affect E_{lim} and i_{lim} of the salt passivation, which correspond to the maximum of the polarization curve at $m = 0$. Indeed, acridinium chloride and 9-aminoacridine increase E_{lim} by 25–80 mV and decrease i_{lim} by 20–60%. In the presence of 9-aminoacridine E_{lim} increases to the greatest extent and falls within the range of Cu^{2+} formation. As a result, the maximum on the anodic curve disappears almost completely, especially at elevated temperatures. The exception is KI which decreases i_{lim} and has virtually no effect on E_{lim}. The additives weakly increase (by 1–2 kJ mol^{-1}) the activation energy of copper dissolution W and increase by a factor of almost 2 that of hydrogen liberation, which can be due to formation of an inhibitor film at the cathodic polarization. As for adsorption inhibitors, the concentration dependence of K is described by the equation

$$\log K = \log K_{C_0} + \beta \log C/C_0, \quad (4)$$

where C_0 is the standard concentration (10^{-4} M) corresponding to K_{C_0}.

The constants K_{C_0} and β presented in Table 1 show that the effect is the strongest and is the most sensitive to C at the potentials of the Tafel region of the anodic curve. As also seen from Table 1, the protecting effect depends on the conditions of film formation at potentiostatic polarization and step change in the potential. The data for the rotating disk electrode (Table 2) show that the coefficient of the diffusion deceleration K_d depends on the process conditions.

The fact that K_d of copper dissolution (E = –0.15 V) is higher than that of hydrogen liberation (E = –0.4 V) (Table 2) indicates that the protecting film is mainly formed by reaction of the inhibitors with the anodic reaction products. If the influence of electrostatic adsorption were strong, the relation between the K_d values would be inverse, taking into account the zero-charge potential of copper (–0.48 V) [12]. The sharp decrease in K_d in the range of limiting current i_d of salt passivation (E = 0.05 V) indicates hindered inhibition of copper dissolution at intense salt formation. Conversely, K_d slightly increases after partial destruction of the salt film at E = 0.2 V.

The influence of the inhibitors on the diffusion and electrochemical steps of copper dissolution was estimated from i_d and i_e in the mixed kinetic region. The values of $K_d = i_d/i_{d,i} = \lambda/\lambda_i$ and $K_e = i_e/i_{e,i}$ (index i denotes the presence of the inhibitor) are summarized in Table 3.

The coefficients K_d and K_e are comparable, with E = 0 V being approximate boundary between the regions of $K_d > K_e$ and $K_e > K_d$. As follows form Eq. (3), the coefficient of deceleration of copper dissolution $K = i/i_i$, K_d, and K_e are related to each other by the equation

$$K = K_d(1 + \gamma_i)/(1 + \gamma) = K_e(1 + 1/\gamma_i)/(1 + 1/\gamma), \quad (5)$$

where $\gamma = i_d/i_e$, $\gamma_i = i_{d,i}/i_{e,i}$, $\gamma_i/\gamma = K_e/K_d$.

Although K_e, K_d and i_e remain the same with an increase in m, i_d and $i_{e,i}$ increase to a variable extent. As a result, K depends on m. Since i_d and and i_e as well as K_e and K_d are comparable, K, being intermediate between K_e and K_d, should weakly depend on m. The type of the K–m dependence is determined by the ratio between K_e and K_d and hence by the ratio of γ_i and γ. If $K_e < K_d$, K should decrease with an increase in m as i_d increases. At $K_e > K_d$ the K–m dependence is inverse and at $K_e \sim K_d$ $K \neq f(m)$ (Table 4).

Since $K_e \neq f(E)$, the decrease in K with increasing E is due to the diffusion component described above.

Comparison of the performance of potassium iodide (no. 5) with that of 10-methylacridinium iodide (no. 1) (Tables 1–4) reveals the predominant role of the organic cation in inhibition of the copper dissolution. 10-Methylacridinium iodide is a more powerful inhibitor than KI in the ionization step (Fig. 3). This

* A dash corresponds to diffusion control of the process at the indicated potential in solutions containing the inhibitors.

fact can be explained as follows. Both additives decelerate the electrochemical step owing to blocking of the surface active centers. However, the 10-methylacridinium cation additionally decelerates the process owing to an increase in the ψ_1 potential. The I^- anion of the organic salt is a bridge between the cation and the positively charged copper surface. The I^- anion of KI decreases the ψ_1 potential, thus accelerating the process.

An introduction of additional coordination and adsorption center (amino group) in an acridine molecule increases K, K_e, and K_d (additive nos. 2 and 3). The difference in the performance of additive nos. 3 and 4 in freshly prepared solution (Tables 1–4) should also be noted. In acidic chloride solution they should exist in the similar state and provide the same K, K_e, and K_d. We suggest that this difference is due to decelerated protonation of 9-aminoacridine, which is indicated by lower solubility of this compound as compared to that of its hydrochloride. Hence, 9-aminoacridine is more stable in the solution, is more readily salted-out and adsorbed, and is a stronger inhibitor of copper dissolution. The leveling-out of the inhibiting power of additive nos. 3 and 4 after aging of their solution for several days confirms the above assumption.

CONCLUSIONS

(1) Copper dissolution on a stationary copper electrode is controlled by diffusion and is characterized by the maximum of the salt passivation current. Degradation of the protecting layer is due to an increase in the copper oxidation state and formation of more soluble products.

(2) As the potential increases, copper dissolution from a rotating disk electrode is controlled by diffusion, then by diffusion and chemical reaction, and finely by diffusion again, at limiting current of salt passivation.

(3) In the region of the mixed kinetics the acridine derivatives comparably inhibit the ionization and diffusion steps. The ratio between these effects depends on the potential and the nature of the additives but is independent of the rotation rate of the disk electrode.

(4) The inhibiting effect of salt additives, especially with respect to the ionization step, is mainly due to the organic cation.

(5) The inhibiting power of the tested additives increases with time at potentiostatic polarization and

decreases with an increase in the anodic polarization under conditions of salt passivation.

Abstract—The temperature dependence of the degree of CO oxidation with atmospheric oxygen on copper–cement catalysts was studied.

In a series of previous publications we suggested and substantiated a new concept explaining the origin of temperature-hysteresis effects observed in various heterogeneous catalytic reactions. This concept was described in the most detail in [1]. According to this concept, when an exothermic heterogeneous catalytic reaction reaches a certain rate, the amount of heat liberated on the active reaction center becomes too large to be dissipated in the environment. This is usually due to a low heat conductivity of a porous support or of an inactive catalytic mass in which active centers are disseminated. Therefore, the actual "point" temperature of the reaction on the active center becomes much higher than the average temperature in a catalyst bed, usually measured with a thermocouple and treated as the "reaction temperature." At the expense of local overheating of active centers, the degree of conversion becomes higher than that corresponding to a given measured temperature. It increases the heat evolution even more and, therefore, the temperature of the active center, and as a result, the conversion in a narrow temperature range rapidly increases. After reduction or even full termination of the heat input from the outside (i.e., on cooling a reactor), the excessive heat, which had no time to be dissipated because of a poor heat removal, makes it possible to support a higher actual temperature of the active center than the temperature detected by a thermocouple. In this case the descending branch of the temperature dependence of the conversion degree is displaced to the left on the scale of the measured temperature relative to the ascending branch, i.e., an "anti-clockwise" hysteresis loop is observed.

Ukharskii and Berman [2] have similar views on the causes of the temperature hysteresis in the benzene oxidation on supported platinum catalysts. They have calculated theoretically that platinum particles can be overheated relative to the support by 150–200°C (it is necessary to remember that the thermal effect of benzene oxidation is much higher than that of CO oxidation, 3267 and 283 kJ mol^{-1}, respectively). According to the classic concept of Frank-Kamenetskii [3], the temperature hysteresis in heterogeneous catalysis is a consequence of the macrokinetic transition from the kinetic to the diffusion mode. In this case the whole active surface of a catalyst is considered as an entity. However, we focus our attention on local overheating of active centers containing a restricted number of atoms, which are surrounded by the main inactive mass of a catalyst or support.

According to our concept, the temperature hysteresis phenomenon can be characteristic of only exothermic heterogeneous catalytic reactions, which was confirmed by both our experiments and examination of published data [1].

It follows from this concept that the variation of the catalyst activity depending on the content of an active component should also affect the value of temperature-hysteresis effect. In fact, an increase in the content of an active component is accompanied by an increase in the number of active centers and consequently in the amount of thermal energy evolved in the exothermic reaction. Therefore, we can expect that, if the temperature hysteresis effect took place, it should become stronger.

To check this assumption, we studied the temperature dependences of the degree of carbon monoxide oxidation with atmospheric oxygen on a series of copper-containing catalysts on a cement support. These catalysts are highly stable, and their preparation is a routine practice [4, 5].

1070-4272/01/7409-1506$25.00

EXPERIMENTAL

Three samples of copper–cement catalysts with increasing CuO contents were tested. To prepare them, we used copper and zinc carbonates, talum (a mixture of calcium mono- and dialuminates), and a 25% solution of NH_4OH. According to the X-ray phase analysis, the samples obtained by mixing the components without calcination contained the phases of zinc hydroxoaluminate, calcite, aragonite, and gibbsite [5]. The resulting catalysts had the following composition (wt %):

Sample no.	CuO	ZnO	Al_2O_3	CaO
1	6.3	47.9	33.4	10.8
2	28.3	22.5	32.7	14.6
3	50.5	28.3	13.9	6.9

The specific surface area of all the three samples was within 60–80 $m^2\,g^{-1}$.

The experiments on the CO oxidation with atmospheric oxygen were carried out in a catalytic semiautomatic circulation installation ensuring controllable supply of mixture components into a reactor and smooth inertialess variation of the reactor temperature. The weight of each sample loaded into the reactor was 0.5 g. The molar ratio $CO : O_2$ in the starting reaction mixture was varied in separate experiments from 1 : 5 to 5 : 1 at a total flow rate of 8 l h^{-1}. Before loading in the reactor each sample of the catalyst was treated in an air flow at 300°C for 4 h.

The mixture leaving the reactor was analyzed for the CO content using a gas-chromatographic column packed with Porapak Q.

The temperature dependences of the degree of CO oxidation at various $CO : O_2$ ratios on three studied samples with different copper content are shown in Figs. 1a–1c. Figure 1a corresponds to a large excess of oxygen (~1 : 5, whereas the stoichiometric ratio is 2 : 1), Fig. 1b, to its moderate excess (~1 : 2), and Fig. 1c, to the stoichiometric ratio (~2 : 1, curves *2* and *3*) and even at an overstoichiometric CO content (~5 : 1, curve *1*). It is evident that in all the cases without exception there is a pronounced temperature hysteresis, and at the stoichiometric and higher ratios the process turns to a self-sustained mode, when even the full termination of heating does not result in reaction termination or even in a reduction in the conversion degree. The temperature required for the CO oxidation is supported at the expense of the reaction heat.

On the whole, the observed pattern completely

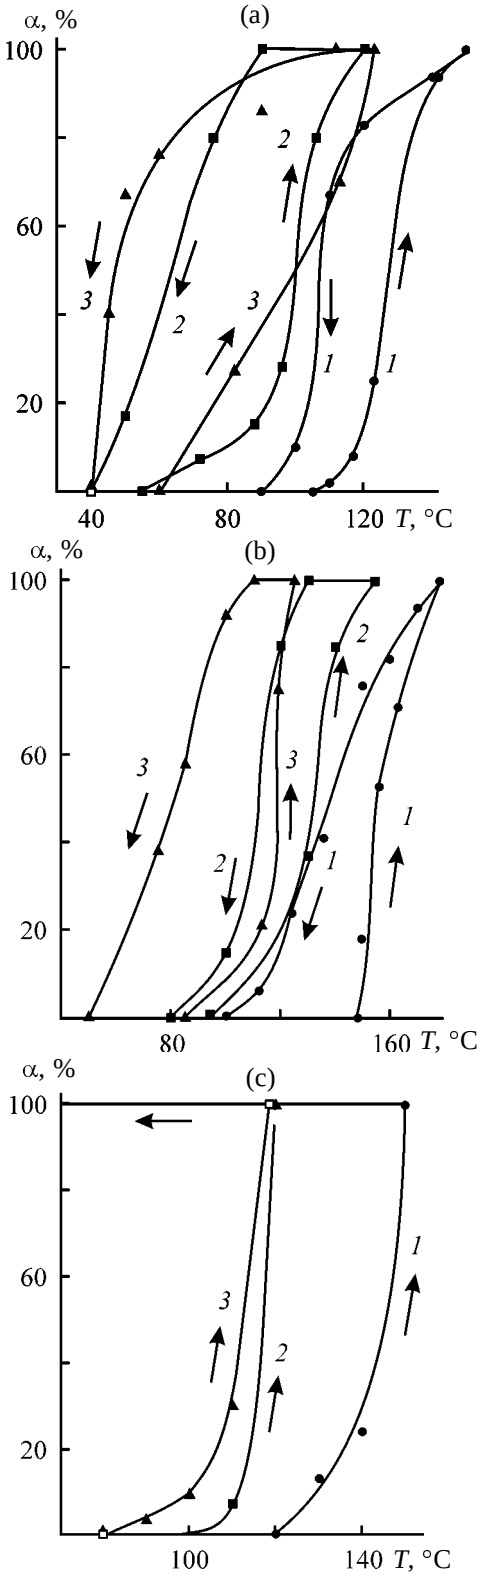

Fig. 1. Degree of CO oxidation α on copper-containing catalysts as a function of temperature *T*. CuO content (%): (*1*) 6.3, (*2*) 28.8, and (*3*) 50.5. $CO : O_2$ ratio: (a) ~1 : 5; (b) (*1*, *2*) ~1 : 2 and (*3*) ~1 : 1.5; (c) (*1*) ~5 : 1 and (*2*, *3*) ~2 : 1.

meets the expectations following from the above-described concept of local overheatings. As the copper(II) content increases, i.e., the number of active centers of the catalyst increases, the area of the reaction occurrence shifts to lower temperatures, and the hysteresis effect somewhat decreases. The extent of the effect can be estimated in various ways, for example, by the width of the hysteresis loop, namely, by the temperature difference ΔT in the ascending and descending branches of the dependence for the same conversion degree. In this case we selected the 50% conversion. With this criterion, the width of the hysteresis loop ΔT_{50} in Fig. 1a is 17, 23 and 35°C for the catalysts with the CuO content of 6.3, 28.8, and 50.5%, respectively, and that in Fig. 1b is 21, 37, and 55°C, respectively. When the ratio $CO : O_2$ approaches the stoichiometric value, this difference levels out, and the estimation of the width of the hysteresis loop in the mode of a self-sustained reaction becomes difficult.

It is most likely that the growth of the copper(II) content accompanied by an increase in the number of active centers results in increased reaction rate and hence in increased heat evolution. This gives rise to a greater local overheating of active centers and, therefore, to a stronger hysteresis effect.

Comparison of Figs. 1a and 1b demonstrates that an increase in the CO fraction in the reaction mixture shifts the area of reaction occurrence on the same catalyst to lower temperatures and promotes an increase in the width ΔT_{50} of the hysteresis loop. This can also be due to an increase in the reaction rate and hence in the amount of evolved energy, as the CO concentration increases. The kinetic data confirm the fact that the rate of CO oxidation on copper-containing catalysts is proportional within certain limits to the partial pressure of CO [6].

Our attention was engaged by a specific "sharp" shape of the temperature dependences obtained on a catalyst with the lowest copper(II) content (Figs. 1a and 1b, curves *1*). These curves contain no horizontal part, which is observed in other curves at the beginning of cooling of the reactor (initial parts of descending branches). This may be due to relatively small local overheating of active centers at their relatively low concentration, though the hysteresis loop itself on this catalyst is quite clearly seen.

On the whole, our data completely agree with the concept of the local overheating of active centers as the main cause of the temperature-hysteresis phenomena in heterogeneous catalysis.

CONCLUSIONS

(1) The value of the temperature hysteresis in CO oxidation on copper–cement catalysts increases with increasing CuO content.

(2) An increase in the CO fraction in the reaction mixture shifts the area of reaction occurrence to lower temperatures and increases the width of the hysteresis loop.

(3) The data obtained support the concept of the local overheating of active centers as the main cause of the temperature hysteresis in heterogeneous catalysis.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Detoxication of Aqueous Cyanide Solutions with Oxygen in the Presence of S(IV) and Cu(II) Compounds

D. V. Kharchenko, I. A. Agapov, and N. V. Vorob'ev-Desyatovskii

Navy Engineering Institute, St. Petersburg, Russia

Received June 18, 2001

Abstract—Oxidation of cyanide anions with atmospheric oxygen in aqueous solutions in the presence of Na_2SO_3 and $NaHSO_3$ mixture and $CuSO_4$ as a catalyst was studied. The reaction mechanism was proposed.

Cyanide solutions are widely used in electroplating and mining. Usually they contain from hundreds of milligrams to tens of grams per liter of NaCN and cyanide complexes of transition metals [Cu(I), Zn(II), Cd(II), Ni(II), Fe(II), Fe(III), Cr(III), etc.] and also some impurities like $NH_3 \cdot H_2O$, HCO_3^-, SCN^-, and $HCOO^-$ [1, 2]. Detoxication of these solutions is an important task, which can be solved by numerous ways. In general there are six main approaches to this problem [3, 4].

(1) The passive detoxication is based on the reduction in the concentrations of free and coordinated CN^- ions in solutions upon prolonged staying under natural conditions owing to a combination of photolysis, oxidation (including biological oxidation), precipitation (in the case of complex ions), and hydrolysis caused by gradual pH reduction on the dilution of solutions by rain and water from thawed snow and by salt freeze-out in wintertime.

(2) Distillation of HCN from acidified solutions and its subsequent sorption by alkaline solutions.

(3) Sorption of CN ions and complex cyanide anions on activated carbons in the presence of Cu(II) compounds and on ion-exchange resins.

(4) Electrochemical anodic oxidation of free and bound in relatively weak complexes CN^- ions. The oxidation can be either direct or can accompany anodic oxidation of chloride ions if they are present in the same solution.

(5) Biological transformation (oxidation and hydrolysis) of free and bound cyanides with the use of microbial biocenoses (associations of aerobes and anaerobes in the form of activated sludge), biosorbents, immobilized microorganisms, or specific bacterial enzymes (rhodonase and cyanide hydratase).

(6) Reagent detoxication, which can be subdivided into binding of CN^- ions in nondissociated or difficulty soluble compounds [treatment with CH_2O, Fe(II) salts] and oxidation of free and bound CN^- ions with elemental chlorine in an alkaline medium or with calcium (or sodium) hypochlorite prepared in advance, and also with hydrogen peroxide in the presence of Cu(II), with ozone or atmospheric oxygen in systems containing aqueous solutions of S(IV) and Cu(II) compounds (INCO and Noranda processes).

The use of each of these methods is determined by climatic and economical conditions and also by local legislation regulating wastewater discharge. Recently the detoxication of free and bound cyanide ions by their oxidation with atmospheric oxygen bubbled through aqueous solutions of S(IV) and Cu(II) compounds received growing use in cold-climate countries. However, the information on this method can be found only in patents and special mining literature, and available data [2] give no way of developing the method because they cannot reveal its chemical essence and potential. In this work we studied the detoxication of cyanide solutions obtained after electrochemical deposition of noble metals from agitation cyanide leaching solutions of concentrates of Dukat ore mining and concentrating enterprise. The solution composition is given below.

We tested $Na_2S_2O_5$ and its mixture with Na_2SO_3 as a source of S(IV). Weighed samples of solid salts were placed into a 0.5-l sample to be neutralized, and then 0.11 g of the catalyst $CuSO_4 \cdot 5H_2O$ was added. The flask was closed, and air was blown through it with a rate of 2.5 l min^{-1}. The residual concentrations of CN^- ion and other simple and complex ions were determined 1 h after the start of detoxication.

* With respect to the starting substance, which does not exist in the solution.

The concentrations of CN^- ions above 4 mg l^{-1} were determined by the titration with $AgNO_3$ solution in the presence of KI as an indicator [5]. In the case of lower concentrations of cyanide ions their content was determined by photometry on a KFK-3 instrument using the pyridine–barbiturate reaction [6].

The concentrations of metal and nonmetal ions in solutions before and after neutralization were determined by atomic absorption spectroscopy on Varian AA 110 and AA 220 (Australia) instruments.

Formally the use of pure sodium disulfite is very successful, as it reduces residual NaCN concentrations. However, according to analysis of the gas phase, it contains significant amounts of HCN, which results from a strong acidification of the solution caused by the HSO_3^- formation and its subsequent oxidation.

If pH is reduced to 8, 94% of free cyanide ions are in the form of HCN, which is blown off from the solution by air current [4]. We note in addition that the reactivity of HCN, as compared to CN^- ion itself, with respect to the action of electrophilic reagents is much lower. Therefore, in all subsequent experiments we used a mixture of Na_2SO_3 and $Na_2S_2O_5$, thoroughly keeping pH of 10.0 ± 0.3.

The data on the neutralization of a solution containing 2200 mg l^{-1} of CN^- ions with a mixture of Na_2SO_3 and $Na_2S_2O_5$ at pH 10.0 are shown in Table 1.

A comparison of our data with published data [2] suggests that solutions containing less than 1 g l^{-1} of free CN^- ions are the most suitable for the neutralization. An increase in the CN^- concentration is accompanied by an increase in the S(IV) consumption and leads to relatively high residual CN^- concentrations exceeding its maximum permissible concentration (0.1 mg l^{-1}).

In going to a solution containing cyanide compounds of other elements in addition to NaCN, the situation becomes even more complicated (Table 2).

The solution was treated at pH ~10.0 with a mixture of 59.4 g l^{-1} of Na_2SO_3 and 9 g l^{-1} of $Na_2S_2O_5$ (Table 1).

Tables 1 and 2 show that the residual CN^- concentration is approximately doubled on passing from pure NaCN to a real solution containing significant amounts of impurities. The degree of detoxication with respect to free CN^- ions was 0.987. Furthermore, it follows from Table 2 that the concentrations of Fe(II), Cd(II), Mn(III), Hg(II), Pb(II), As(III), Cr(III), and Se(II) in the solution became several times lower after the neutralization. The Zn(II) concentration decreased by 28%, the concentration Ni(II) remained almost unchanged, whereas the Cu(I) concentration increased, which is indicative of an unjustified excess of the catalyst in the experiment.

Let us consider available information on the process mechanism. Free CN^- ions are known to have significant reducing power [7] and to be oxidized with Cu(II) salts in aqueous solutions. The primary product of the CN^- oxidation is the CN radical, which can dimerize (with further disproportionation in alkaline medium) or react with a water molecule to give finally the CNO^- ion. Complexes of Cu(II) with cyanide ions in the inner sphere have been described in the literature [8], with the cyanide ligands undergoing intramolecular oxidation. This process should not be fast at room temperature. In spite of the fact that this process results in decreasing concentration of free CN^- ions, it cannot form a basis for the detoxication, because with excess cyanide ions copper(I) forms stable $[Cu(CN)_n]^{(n-1)-}$ complexes (n = 2, pK_{inst}^{1-2} ~24; n = 3, pK_{inst}^{1-3} ~28.6; n = 4, pK_{inst}^{1-4} ~30.3). These complexes cannot be oxidized in solution to copper(II) compounds with atmospheric oxygen.

In this work we studied the oxidation of cyanide ion with atmospheric oxygen using the acrylonitrile test for the radical reaction mechanism. We found that acrylonitrile does not noticeably polymerize in air in a solution containing only NaCN, $CuSO_4$, and acrylonitrile. Atmospheric oxygen does not oxidize cyanide ions in the presence of a mixture of SO_3^{2-} and HSO_3^- anions with acrylonitrile either. However, introduction of hydrated Cu^{2+} ions into the mixture almost im-

(N/d) Not detected within experimental error.

mediately results in appearance of a white flaky precipitate of polyacrylonitrile.

Its formation is accompanied by a sharp decrease in the NaCN concentration in solution, which suggests that the initiating stage of the process under consideration is the one-electron oxidation of SO_3^{2-} or HSO_3^- ions with Cu^{2+} aqua ions:

$$SO_3^{2-} + Cu^{2+} \rightarrow SO_3^- + Cu^+, \quad (1)$$

$$HSO_3^- + Cu^{2+} \rightarrow HSO_3^- + Cu^+. \quad (2)$$

Such one-electron redox processes have been well studied [9, 10]. The reaction of the above-mentioned radical anions or radicals with oxygen dissolved in water results in the formation of peroxomonosulfate radical anions in alkaline media [11, 12].

$$SO_3^- + O_2 \rightarrow SO_5^-, \quad (3)$$

$$HSO_3^- + O_2 \rightleftarrows HSO_5 \xrightarrow[-H_2O]{+OH^-} SO_5^-. \quad (4)$$

Radical anions of Caro's acid are powerful oxidants in alkaline solutions, capable of converting cyanide anions to cyanate anions:

$$SO_5^- + CN^- \rightarrow CNO + SO_4^{2-}, \quad (5)$$

$$CNO + Cu^+ \rightarrow CNO^- + Cu^{2+}. \quad (6)$$

Furthermore, reaction (6) regenerates Cu^{2+} ions required for the catalytic process. We also point out that, according to the one-electron oxidation potential $E^0_{1e}CNO/CNO^- = 2.66$ V, the cyanate radical CNO is a powerful oxidant [13, 14].

The proposed mechanism of detoxication of cyanide ions allows us to make certain assumptions concercning the optimal pH and the required Cu^{2+} content in solution. The pH must be selected so as to prevent formation of $Cu(OH)_2$, which removes copper(II) ions from the reaction sphere. Furthermore, it is necessary to take into account possible loss of Cu^{2+} due to formation of difficulty soluble salts like $Cu_2[Fe(CN)_6]$, $Cu_3[Cr(CN)_6]_2$, $Cu[Hg(CN)_4]$, etc.

CONCLUSIONS

(1) Atmospheric oxygen was shown to oxidize cyanide ions at pH 10.0 in the presence of SO_3^{2-} ion and catalytic amounts of Cu^{2+}.

(2) Oxidation of cyanide ion was found to occur by the radical mechanism.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Deamination as a Method of Pretreatment of Nitrogen-Containing Wastewater before Biological Treatment

I. L. Glazko, S. V. Levanova, M. G. Pechatnikov, A. B. Sokolov, A. L. Kanaev, and A. S. Krizhanovskii

Samara State Technical University, Samara, Russia

Received April 11, 2001

Abstract—A deamination method was proposed for pretreatment before biological treatment of process nitrogen-containing wastewater from caprolactam production.

Russian enterprises producing nitrogen-containing organic compounds such as caprolactam (CL), acetonitrile, etc. generate large amounts of wastewater to be subjected to biological treatment, involving nitrification and denitrification [1, 2]. Biological treatment has doubtless advantages over thermal methods from both economic and environmental viewpoints, though poses rigid requirements on the chemical composition of the initial wastewater. In many cases, wastewater subjected to treatment does not satisfy modern environmental standards on biological treatment because of increased content of ammonium ions in the wastewater after denitrification. For example, wastewater from caprolactam production contains a total of 36.6 mM of ammonium ions, which exceeds the permissible level by several orders of magnitude. This shifts the living activity balance of microorganisms and affects their species ratio, and thus affects the treatment quality on the whole and increases the content of ammonium ions in the water leaving the treatment works. In this situation enterprises often prefer to burn such wastes.

Experts in chemical and related branches of industry in various countries of the world have convincingly proven the need in and advantage of the approach based on solving industrial environmental problems at their origination site. To this end, combined treatment procedures are finding ever wider application in wastewater treatment. Examples are combinations of biological and physicochemical methods (e.g., treatment in bioadsorbers and filtration tanks) or combinations of biological and chemical methods (chemically modifying the wastewater composition so that the prepared wastes meet the requirements at a given wastewater treatment works).

Zlateva [3] showed that CL when in concentrations over 200 mg l^{-1} and ammonium salts with ammonium ion in concentraitons ranging from 0.6 to 8.3 mM inhibit the activity of nitrifying bacteria. Ammonia and nitrous acid also can exert an inhibiting effect. Laboratory and industrial investigations by Anthonisen and Loehr [4] revealed the concentration ranges within which ammonium and nitrous acid exert an inhibiting effect. When in concentrations within 0.6–8.3 mM, NH_4^+ inhibits nitrite bacteria, and within 0.006–0.06, nitrate bacteria. Nitrous acid exerts an inhibiting effect on nitrate bacteria when in concentrations from 0.22 to 0.28 mg l^{-1}.

In this work, we propose a procedure for pretreatment of nitrogen-containing wastewater to decrease the NH_4^+ ion concentration virtually to zero before biological treatment. The raw material was the wastewater from CL[1] production before burning; it had the following composition, %: CL 1.037, $(NH_4)_2SO_4$ 2.2 (chemical oxygen demand COD 56000 mg l^{-1}). Also, we used nitric acid condensate (NAC) with the total content of acids, as recalculated for HNO_3, of 3.03% and a 3% Na_2CO_3 solution.

The method proposed by us involves treating wastewater with nitric acid or its salts at 150–220°C (the temperature should not exceed 310°C) and elevated pressure ensuring existence of a liquid phase at this temperature.

Deamination of CL-containing wastewaters was studied by chemical and physicochemical methods. Dichromate oxidizability (COD) of waters and the content of ammonium sulfate in solutions were determined by standard procedures. CL was determined in

aqueous solutions chromatographically. Though well-known, this method is of a limited application as it suffers from two drawbacks: columns fail rapidly and the CL peak is blurred and asymmetric because of high polarity of CL. We developed an improved chromatographic procedure. We tested various supports and liquid phases. The peak was symmetric only with strongly silanized supports when the amount of a liquid nonpolar phase was large. The best results were obtained with a 1-m column, 15% Apiezon-L on a Chromaton N-AW-DMCS; column temperature 170°C, vaporizer temperature 250°C; helium as carrier gas with the flow of 25 ml min^{-1}. The column is stable in 3-month operation. Analysis was carried out on a Tsvet-100 chromatograph with a flame-ionization detector. The chromatographic data were quantitatively calculated by the external reference method. The reaction products were identified by direct introduction of pure authentic components.

Pretreatment of wastewater involves three stages: deamination of wastewater with NAC, neutralization of the reaction mixture by an Na_2CO_3 solution to pH 9–10, air blowing of the ammonia formed and its absorption with water, and neutralization of the pretreated wastewater to pH 7–7.5 with nitric acid or NAC.

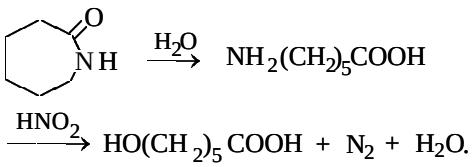
We found that deamination proceeds under the action of not only NAC but also 2–3% nitric acid (Fig. 1a). On heating the reaction mixture, nitric acid, possibly, converts to nitrous acid, which is active species in deamination. The transformations in the system HNO_3–HNO_2–H_2O can be represented by the scheme

$$4HNO_3 \rightleftarrows 4NO_2 + 2H_2O + O_2,$$

$$2NO_2 + H_2O \rightleftarrows HNO_3 + HNO_2.$$

Nitrous acid rapidly reacts with CL or its oxidation products. Such reactions occur also on boiling wastewater with NAC, as the COD of the wastewater significantly decreases. For example, after boiling the wastewater (COD 56000) with a twofold (by volume) excess of NAC and subsequent neutralization with one volume of a 3% Na_2CO_3 solution, the COD of the resulting solution was 4000.

Deamination of CL with nitrous acid can be represented as



Hydrolysis of CL gives ε-aminocaproic acid which transforms into ε-hydroxycaproic acid by reaction with nitrous acid [5]. Thus, the products of wastewater pretreatment can include sodium salts of ε-aminocaproic and ε-hydroxycaproic acid.

Analysis of the kinetic curves of CL consumption showed that initially (on mixing of CL and NAC solutions) the CL concentration sharply decreases (Figs. 1a, 1b). The magnitude of this decrease depends, above all, on the volume ratio n = NAC/CL solution (ml/ml). For example, with a 2–3-fold excess of NAC, up to 50% of CL is consumed immediately after mixing. Further deamination proceeds at a rate corresponding to the reaction with nitric acid (Fig. 1a). Probably, even at 20–230°C the nitrous acid contained in NAC is exhausted. Further deamination involves conversion of nitric acid.

We also studied how the deamination rate varies with temperature at the atmospheric pressure (Fig. 1c). With decreasing temperature from 100 to 70°C, the reaction rate decreases 10–20-fold. To study how the deamination rate is affected by the CL concentration, we conducted experiments on model solutions with the CL concentration of 1–3% (Fig. 1d). We found that the reaction orders with respect to acid and CL are close to unity.

In view of the fact that the real wastewater contains up to 3 wt% of ammonium sulfate, we performed experiments with introducing ammonium sulfate into CL solutions. We found that ammonium sulfate inhibits deamination: both the initial rate and the secondary reaction rate decrease (Fig, 1e). The equation for the deamination reaction rate has the form

$$r = k_1[\mathrm{CL}][\mathrm{NO_3^-}] - k_2[\mathrm{NO_3^-}][\mathrm{SO_4^{2-}}].$$

The experimental data obtained (Fig. 2) were used for calculating the constants in the equations for the deamination rate of caprolactam-containing wastewater: $k_1 = 1.07 \times 10^{-2}$ and $k_2 = 1.18 \times 10^{-3}$ min^{-1}.

We also performed experiments with additions of other inorganic compounds: ammonium nitrate and sodium sulfate. The former does not affect the deamination rate, and sodium sulfate inhibits the reaction similarly to ammonium sulfate (Fig. 1e). Thus, an inhibiting effect is exerted specifically by the sulfate ions. For treating wastewater containing up to 3–4% ammonium sulfate, the contact time should be increased to 10 h and more.

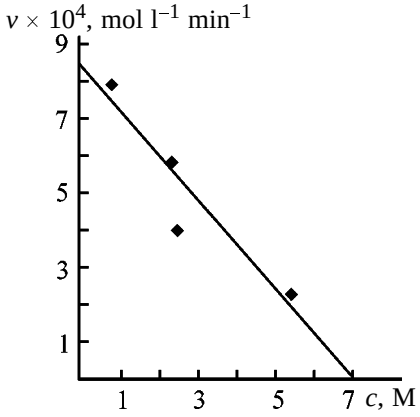


Fig. 2. CL deamination rate v as a function of the total concentration of the nitrate and nitrite ions c.

We checked our results on a laboratory setup under conditions of a continuous process. The setup involved two main reactors (deamination and neutralization reactors), a system for reactor heating, a cooling system, a unit for supply of the initial mixture, and a system for absorption of exhaust gases. A mixture of caprolactam-containing wastewater and NAC was supplied by a pump via feedline to the deamination reactor. The total time of deamination was 10 h. From the deamination reactor the mixture came to the neutralization reactor, into which a 3% Na_2CO_3 solution was added for neutralizing unchanged NAC and removing ammonium salts (1 ml ml^{-1} of wastewater). Also, nitrogen was supplied to the neutralization reactor for removing waste gases. The reaction time was 2–3 h. Waste gases from the reactors passed through reflux condensers and entered the trap system. Wastewater freed from ammonium was subject to biological treatment. The conversion of CL was 98.0–98.5%, and the leaving water contained no NH_4^+ ions.

In industry, the ammonia water yielded by absorption of waste gases can be utilized in an ammonia production shop.

The wastewater freed from ammonia was adjusted to pH 7 with nitric acid. The treated wastewater is characterized in the table.

The table shows that chemical treatment of the wastewater decreased the CL content by a factor of 52 and that of ammonium, virtually to zero.

Characteristization of caprolactam-containing wastewater before and after chemical treatment

Component	Content, mg l^{-1}	
	before treatment	after treatment
Caprolactam	10421	1200
SO_4^{2-}	14764	5500
NO_3^-	0	15000
NH_4^+	5537	0
COD	56000	4000
pH	7–8	7.0

The pretreated wastewater can be subject to biological treatment. When in concentrations of up to 200 mg l^{-1}, caprolactam does not exert an inhibiting action on denitrification. In the course of denitrification the nitriate ions are reduced to molecular nitrogen [6], and this involves oxidation of organic impurities by oxygen contained in NO_2^- and NO_3^- anions. Miyaji and Kato [7] found that nitrates are converted according to the equation

$$2NO_3^- + H_2O = N_2 + 2OH^- + 5O.$$

The following conditions of the above-discussed process were found to be optimal: temperature 100°C, NAC/CL molar ratio 4.5. The sulfate ions present in wastewater inhibit the process, which calls for rigid regimes.

CONCLUSION

An effective and inexpensive procedure was proposed for pretreatment, before biological treatment, of caprolactam-containing wastewater by deamination with nitric acid condensate forming as caprolactam-containing waste.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Use of Piezoelectric-Crystal Microbalance for Analyzing Phenol and Its Nitro Derivatives in Air

Ya. I. Korenman, Zh. Yu. Kochetova, and T. A. Kuchmenko

Voronezh State Technological Academy, Voronezh, Russia

Received January 15, 2001; in final form, June 2001

Abstract—A piezielectric-crystal resonator was used for analyzing phenol and nitrophenols in air. The resonator electrodes were modified with Triton X-100, beewax, and bee glue (propolis). Sorption conditions ensuing reproducibility of the results were optimized uner static conditions.

Development of sensitive, prompt, and economically feasible procedures for air analysis is an urgent task. In this connection, ever growing researchers' attention is attracted by piezoelectric-crystal microweighing. This method is suitable for determining with high precision microconcentrations of organic substances in air [1–3].

The subjects of investigation were phenol, 2-nitrophenol, and 2,4-, 2,5-, and 2,6-dinitrophenols. These toxic compounds disturb the functions of the nervous, blood-circulation, and respiratory systems and exhibit a cumulative action. The MPCs in the working zone are 0.3, 5.0, and 0.05 mg m^{-3} for phenol, 2-nitrophenol, and dinitrophenols, respectively [4, 5].

One of the methods of determining volatile organic compounds in air with the use of piezoelectric-crystal microbalance is that involving modification of the resonator electrodes with a sorbent solution and thermal removal of solvent, injection of an air sample into the detection cell, and recording of the analytical signal, which is a function of the sorbate concentration [6–8].

The selectivity of sensors is governed primarily by the nature and properties of the coating (modifier) of the piezoelectric-crystal quartz resonator (PQR) [9]. An important requirement to the modifier is a high sorption capacity with respect to individual components or groups of related compounds. In this work, we tested new non-conventional sorbents as PQR electrode modifiers with the aim to selectively determine the phenol content in air in the presence of nitro derivatives.

EXPERIMENTAL

Experiments do not require special expensive equipment. The experimental setup involved a temperature-controlled detection cell manufactured from glass or stainless steel, 20–50 cm^3 in volume, with a polyurethane plug for injection of air samples at the level of resonator electrodes. The temperature of the detection cell was $25 \pm 1°C$. A PQR connected to the excitation scheme was fixed on the cell cover in a holder. The vibrational frequency F, Hz, was measured with a frequency meter whose frequency fixing range was 5 s.

The PQR electrodes were modified by uniformly applying with a microsyringe acetone, chloroform, and ethanol solutions of Triton X-100, beewax, and propolis, respectively (10 mg cm^{-3}). For solvent evaporation, PQR was kept for 30–45 min in a desiccator at $45 \pm 5°C$. The degree of solvent removal was controlled from the time stability of the analytical signal ΔF, Hz (variation of the vibrational frequency within 3 Hz min^{-1}).

The analytical signal is related to the masses of the modifier film and the substance sorbed on PQR electrodes by Sauerbrey equation [10]

$$\Delta F_s = -km,$$

where m is the film (sorbate) mass, μg, and k is the propotionality coefficient taking into account the intrinsic vibrational frequency and the frequency characteristic of quartz, its nature, and electrode area.

A required air volume was sampled with a syringe from flasks containing saturated vapor of chemically

* ΔF_s is the analytical signal, a is the sorption capacity of the modifier, S is the sensor sensitivity, S_r is the relative standard deviation.

pure preparations and introduced into the detection cell at the level of PQR electrodes. This decreased the phenol loss by adsorption on the cell walls. The piezoelectric-crystal resonator was arranged linearly along the flow of the sample introduced, which decreased the sorption error due to nonuniform distribution of the sorbate in the near-surface air layer and increased the sensor sensitivity and reproducibility of the analytical signal.

The limiting concentration of vapor was calculated by the Mendeleev–Clapeyron equation [11]

$$C_i = 1.22 \times 10^7 P_i M/PT,$$

where P_i is the partial pressure of the sorbate vapor, Pa; M is the molecular weight, g mol^{-1}; P is the external pressure, Pa; and T is the temperature, K.

The initial concentrations of phenols in the detection cell was calculated by the dilution method, taking into account the volumes saturated with sample vapor. The kinetic parameters of sorption were estimated from the time of exhaustive sorption τ and half-sorption $\tau_{1/2}$, s, and the sorption constant k^+, i.e., change in the analytical signal at the initial moment, 5 s, corresponding to the smallest influence of desorption on the total rate of the process. The sorption efficiency of the modifiers is characterized by the sorbent sensitivity

$$S = \Delta F_{si}/C_i,$$

Hz dm^3 mol^{-1}, and sorption capacity a (the sorbate–sorbent mass ratio).

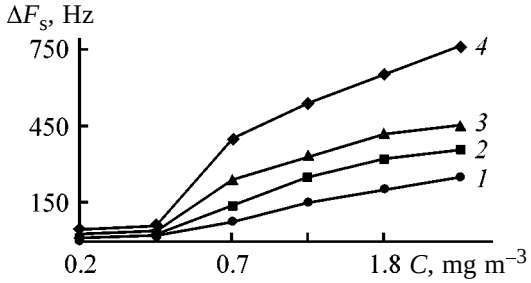

Fig. 1. Isotherms of phenol sorption on Triton X-100 films. (ΔF_s) Analytical signal and (C) phenol concentration. Film mass, μg: (*1*) 2.5, (*2*) 4.6, (*3*) 15.0, and (*4*) 36.5.

A major parameter essential for optimizing phenol detection conditions in air is the sorbent mass determining the regime and stability of the PQR operation (Table 1).

The modifiers studied in this work exhibited a decrease in the sorption capacity with increasing coating mass. This can be explained by the decay of the acoustic wave in the pre-electrode layer of the sorbent and by a decrease in its effective mass at $m > 10$–20 μg. This is consistent with the known data from [12]. Increase in the film mass decreases the reproducibility of the results S_r, %, as only a part of the modifier volume participates in sorption. This increases the contribution from the quenching of the volume-acoustic waves in the preelectrode sorbent layer. For coating with the optimal mass of 5–20 μg the reproducibility of sorption is within 7.8%.

With the phenol–Triton X-100 system as an example, we plotted sorption isotherms for film coatings with different masses (Fig. 1) [13]. With increasing m, the analytical signal (sensor sensitivity) is enhanced. With microamounts of phenols (under these conditions, the analytical signal is indistinguishable), it is necessary to use sorbent films with $m > 20$ μg for obtaining a reliable signal. For determining phenol on the MPC level (0.3 mg m^{-3}), with account of continuous sorption of 2–3 air samples (without sorbent regeneration), the use of a beewax film can be recom-

mended (m = 27.0 μg); in this case the sensor response is reproduced in a reliable way (the average root-mean-square error is ≤2.9%). When sensor further operates in such a regime, the sensor sensitivity gradually decreases. The amount of phenol (contained in air in different amounts) absorbed by a beewax film exceeds approximately twofold the mass of the coating itself (m = 27.0 μg).

Increase in the mass of the sorbed phenol relative to that of the sorbent film, evidently, suggests a layer-by-layer sorption of phenol to form a condensed phase on the sorbent surface. This can be interpreted as additional modification of the film surface. This suggestion is confirmed by phenol sorption not only on Triton X-100, beewax, and propolis, but also on other polar sorbents [14].

The kinetic sorption parameters τ, $\tau^{1/2}$, and k^+ also vary with the nature of the component of the sorbate–sorbent system and the analysis conditions (sorbent mass, sorbate concentration), and with increasing phenol content C_{ph} in the sample they regularly increase (Table 2).

The phenol sorption rate was at a minimum on the Triton X-100 film ($\tau_{1/2max}$ = 90 s) and at a maximum, on the propolis film ($\tau^{1/s}$ < 5 s). The interaction mechanisms differ for these systems: The time and rate of phenol sorption on the propolis film is independent of the analysis conditions, while the kinetic characteristics of sorption on the Triton X-100 film are strongly affected by the film mass and phenol concentration.

Nitrophenols exhibit similar relationships, the sorption affinity for Triton X-100 and propolis being weaker compared to phenol-containing systems. As to beewax, phenol and its nitro derivatives exhibit identical sorption affinities.

Sorption of nitrophenols is affected by the number of NO_2 groups in them, which governs the dipole–dipole interactions between the sorbate and the sorbent (Fig. 2). Phenol exhibits the smallest steric hindrance to sorption on the sorbents studied (one substituent in benzene ring), and dinitrophenols, the greatest. With decreasing polarity of sorbents in the Triton X-100 > propolis ≈ beewax series the influence of the pattern of electron density distribution in the sorbate molecules weakens, and the differences in the sorption efficiency of phenol and its nitro derivatives smoothen.

The sorption relationships established are suitable for qualitatively predicting the features of phenol sorption in systems with other sorbents. It is impossible to

Table 2. Kinetic parameters of the phenol sorption on a beewax film with a mass of 2.0 μg

C_{ph}, mg m^{-3}	ΔF_s, Hz	τ, s	$\tau_{1/2}$, s	k^+
0.1	33	15	<5	7.8

a priori estimate quantitatively the sorption efficiency for phenol and mono- and dinitrophenols on test modifiers because of the lack of identical physicochemical characteristics. As test sorbents we chose polyethylene glycol-2000 (PEG-2000), polyethylene glycol succinate (PEGS), and polystyrene (PS) which are similar in polarity to Triton X-100, propolis, and beewax, respectively. With respect to the efficiency of sorption of phenol, the sorbents can be ranked in the following order: PEG-2000 > PEGS > PS. The relationships established were experimentally substantiated (Fig. 2, curves *4*–*6*). Thus, knowing the quantitative criteria of phenol distribution in systems with modifiers of different polarities, it is possible to predict their sorption efficiency on films of other sorbents.

Using the internal reference method, we estimated the selectivities of the sorbents with respect to the phenols under conditions corresponding to the natural concentration of the air pollutants at 20°C (Fig. 3). Propolis is the most efficient sorbent in the case of detecting phenol in a mixture with nitro derivatives (the interference of nitrophenols is at a minimum). In the case of a beewax film selective detection is im-

possible, and in the case of a Triton X-100 film, the dinitrophenols virtually do not affect phenol determination.

CONCLUSION

Conditions of analyzing phenol in a mixture with mono- and dinitro derivatives using piezoelectric-crystal microbalance and modifiers of resonator electrodes of different polarities (Triton X-100, beewax, and propolis) were optimized. Phenol can be selectively analyzed in mixtures with nitrophenols on a propolis film.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Comparative Study of Water Softening with Granular and Fibrous Ion Exchangers

V. S. Soldatov, A. A. Shunkevich, and V. V. Martsinkevich

Institute of Physical Organic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received July 26, 2000; in final form, February 2001

Abstract—Comparative study of softening of model hard water with both strongly acidic fibrous FIBAN K-1 and granular KU-2 ion exchangers was carried out. The influence of the filter-bed height, packing density of fibrous ion exchangers, volume sorption capacity, and filtering rate on the efficiency of calcium removal from model hard water was analyzed.

Owing to a favorable combination of features, textile ion exchangers are more preferable in conducting several processes than granular resins. Textile ion exchangers consist of separate thin threads of equal diameter (5–50 μm) forming a material with uniform thickness. These structural features ensure fast ion-exchange and sorption kinetics. Another important advantage of textile ion exchangers is very high stability against osmotic processes. The fibers of fibrous ion exchangers are not noticeably broken after repeated drying–moistening cycles [1]. Data on synthesis and features of the main types of fibrous ion-exchange materials such as weakly and strongly basic anion exchangers, weakly and strongly acidic cation exchangers, polyampholytes, and complexing sorbents were reported in [2–4]. The most available among these sorbents are FIBAN AK-22 weakly basic anion exchanger and FIBAN K-5 and FIBAN K-4 weakly acidic ion exchangers which are used for air treatment to remove impurities and also serve as filter in Akvapor, Mifil and Krinichka filtering units for purification of household and drinking water for individual and collective use [5]. In spite of considerable advantages of fibrous ion exchangers, these sorbents have not found use in industrial water treatment. Currently ion-exchange water softening and demineralization is performed with granular ion exchangers [6, 7].

The fiber diameter of fibrous ion exchangers is comparable with that of microspherical grains of resins commonly used in analytical practice. Both these resins exhibit similar sorption kinetics. Owing to high filter resistance and difficulties in fixation of microspherical sorbent (200–400 mesh) within a column, it is unlikely that microspherical ion exchangers can be used on an industrial scale. Short-cut fibrous ion exchangers are free of these drawbacks. The permeability of the filtering bed prepared from this material can be readily controlled by variation of the packing density so as to satisfy the process requirements [8].

The aim of this work was to study water softening with FIBAN K-1 strongly acidic fibrous ion exchanger and evaluate its sorption efficiency as compared to KU-2 granular resin.

EXPERIMENTAL

The comparative experiments on water softening were performed using FIBAN K-1 fibrous sulfonic cation exchanger based on graft copolymer of polypropylene and polystyrene prepared in a laboratory and standard commercial KU2 × 8 cation exchanger. The characteristics of these resins are given in Table 1.

The model solutions simulating hard water were prepared by addition of $CaCl_2$ and NaCl to distilled water to concentrations of 13.7 and 0.87 mg-equiv dm^{-3}, respectively.

* (V_1, V_2) Volumes of softened water related to the column volumes; (E_1, E_2) dynamic sorption capacities by the moment of Ca^{2+} breakthrough.

In our experiments a fibrous ion exchanger sample was placed in a column 12.5 mm in diameter. The fibers were compacted with a perforated piston to reach the required thickness and density of the filtering bed. The solution flow rate was controlled with a peristaltic pump.

The ion exchanger tested was converted to the Na form with 4% NaCl aqueous solution. Thereafter, without washing off excess NaCl, the model hard water was passed through the column. The eluate was analyzed for Ca^{2+} by complexometric titration with Acid Chrome Dark Blue indicator. From these data the output sorption curves were obtained and the following sorption characteristics were calculated: the volumes of softened water per unit of volume of sorbent V_1 and V_2, the sorption capacities of sorbent by the moment of Ca^{2+} breakthrough E_1 and E_2, and the efficiency of the column operation λ_1 and λ_2. The lower index 1 relates to highly softened water containing no more than 0.02 mg-equiv dm^3 Ca^{2+}, which corresponds to the Ca detection limit by complexometric titration. The lower index 2 relates to poorly softened water containing 7 mg-equiv dm^3 of calcium, which corresponds to 5% calcium content relative to the initial hard water. In accordance with recommendations reported in [9], water containing no more than 0.02% mg-equiv dm^3 Ca is considered to be highly softened water. Water of such quality can serve as heat carrier for thermal and nuclear power plants. Water containing from 0.02 to 0.7 mg-equiv dm^3 Ca is hard water suitable for replenishment of cooling systems and for household consumption.

Commercial FIBAN K-1 fabric is nonwoven needle-punched loose material with the bulk density of 0.1 g cm^{-3}. In the use of this sorbent (200–400 mesh) for water softening its performance can be improved by compacting fibers within a column. This procedure increases the volume capacity of the ion exchanger, decreases its free volume, and increases the packing density to 0.27 g cm^{-3}.

The efficiency of Ca removal from the model hard water was studied as a function of variation of the following factors: the ion exchanger bed height (h) from 7 to 40 mm, the packing density E_V from 0.21 to 0.92 mg-equiv cm^{-3}, and the water flow velocity from 4 to 37 cm min^{-1}. The main parameters characterizing the efficiency of water softening are listed in Table 2.

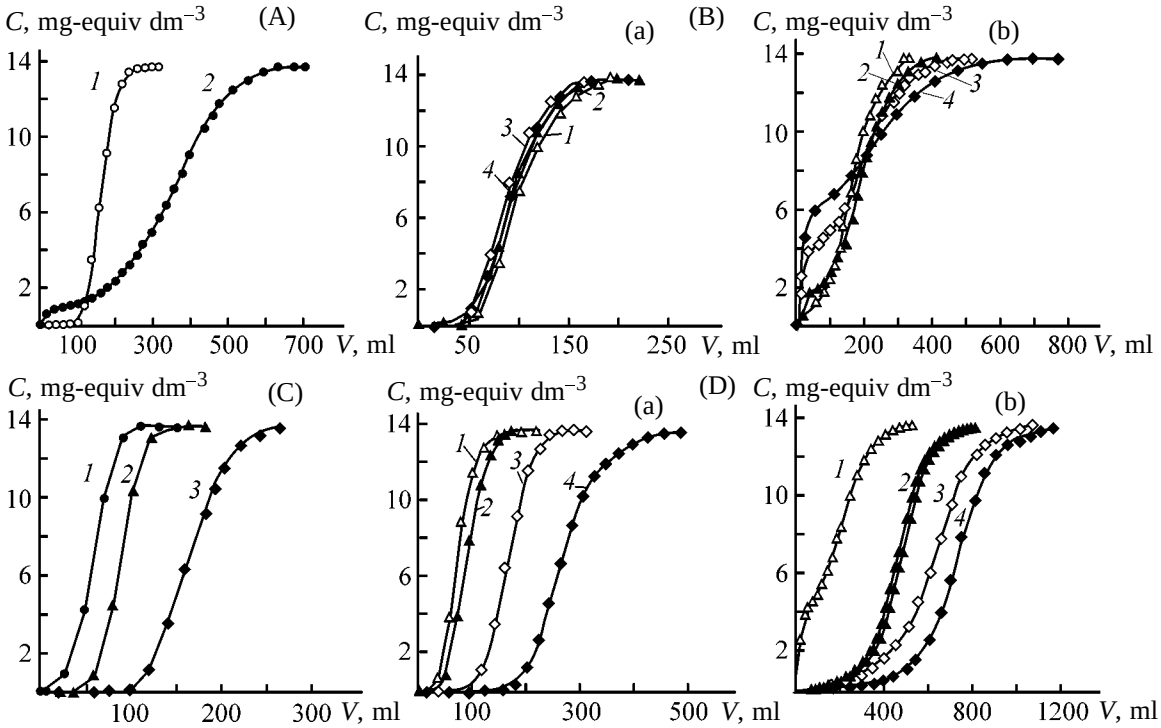

Fig. 1. Output curves of Ca^{2+} sorption: (*C*) Ca^{2+} concentration; (*V*) solution volume passed through column. (A) Thickness of filtering bed h = 20 mm, flow velocity v = 16.4 cm min^{-1}. Ion exchanger: (*1*) FIBAN K-1 and (*2*) KU-2. (B) (a) FIBAN K-1 and (b) KU-2; h = 10 mm. v, cm min^{-1}: (*1*) 4.0, (*2*) 8.0, (*3*) 16.4, and (*4*) 37.0. (C) FIBAN K-1, h = 20 mm. Packing density of sorbent E_V, mg-equiv cm^{-3}: (*1*) 0.21, (*2*) 0.42, and (*3*) 0.83. (D) (a) FIBAN K-1 and (b) KU-2; v = 16.4 cm min^{-1}. h, mm: (a) (*1*) 7, (*2*) 10, (*3*) 20, and (*4*) 30; (b) (*1*) 10, (*2*) 28, (*3*) 32, and (*4*) 40.

These data show that the compacted fibrous ion exchangers ensure efficient water softening even at a filtering bed height as small as 10 cm and high flow velocity v = 37 cm min^{-1}. Under these conditions we prepared a large batch of softened water, a portion of which was highly softened. As seen from Table 2, the efficiency of the column calculated as the ratio of its sorption capacity by a moment of calcium breakthrough to the total sorption capacity was fairly high (λ_1 = 0.32 and λ_2 = 0.64). Our results show that the most favorable conditions for water softening are ensured by a column packed with highly compacted strongly acidic fibrous ion exchanger at the bed height (h) of 20–30 mm and a water flow velocity of 16–37 cm min^{-1}.

With granular strongly acidic ion exchangers calcium breakthrough occurs right after the start of filtration. Therefore, in preparation of deeply softened water the filtering bed of the granular ion exchanger must be higher than 40 mm. This is evident from the shape and mutual arrangement of the output curves of calcium sorption on fibrous and granular ion exchangers at a bed height of 20 mm (Fig. 1A). For example, in the RECOFLO process based on water softening on granular ion exchangers the high efficiency of operation is reached at the filtering bed height no less than 7.5 cm [10].

The dependence of the output curves of calcium sorption on FIBAN K-1 and KU-2 strongly acidic ion exchangers on the flow velocity of water through the 10-cm sorbent bed is shown in Fig. 1. In the case of FIBAN K-1 the output sorption curves are symmetrical, and their initial portion indicates the absence of calcium breakthrough into the eluate. Thus, fibrous sulfonic cation exchanger exhibits excellent kinetic features which allow water softening even in filtration through 10- or 20-mm filtering bed at a high flow velocity.

It was found that a 10-fold variation in the filtration rate insignificantly influences the calcium removal in water softening on fibrous ion exchanger. With increasing the flow velocity from 4 to 37 cm min^{-1} the efficiency of calcium removal decreases from 0.53 to 0.32 at high (λ_1) and from 0.86 to 0.64 at low (λ_2) degrees of water softening.

Filtration of the model hard water through a thin bed (10–20 mm) of the standard KU-2 cation exchanger does not ensure water softening even at minimal flow velocity. The output curves of calcium sorp-

tion lack portion corresponding to the calcium-free eluate. We found that calcium breaks through even in the first eluate fractions.

The effect of the compaction degree of the fibrous ion exchanger on the efficiency of water softening at a sorbent bed height of 20 mm and a flow velocity of 16.4 cm min^{-1} is shown in Fig. 1B.

These results show that even noncompacted fibrous ion exchanger with the volume sorption capacity of 0.21 mg-equiv cm^{-3} exhibits fairly large dynamic sorption capacity E_2. With increasing the packing density of fibrous ion exchanger from 0.21 to 0.83 mg equiv cm^{-3} the efficiency of the column λ_2 increases from 0.62 to 0.78 (Table 2).

The output curves of calcium sorption by fibrous and granular ion exchangers are compared in Fig. 1D for different bed thicknesses at a flow velocity of 16 cm min^{-1}. These curves show that the standard KU-2 granular cation exchanger has higher volume sorption capacity and smaller free volume than the fibrous cation exchanger. The volume sorption capacity of KU-2 is 1.7–1.9 mg-equiv cm^{-3}, which is more than twice that of the close-packed FIBAN K-1 fibrous cation exchanger (0.83 mg-equiv cm^{-3}).

It is possible that the advantages of granular sorbents can be used for water softening at a higher filtering bed. For example, higher volume sorption capacity of granular cation exchanger allows preparation of water of low softening degree containing 0.7 mg-equiv dm^{-3} Ca with a filtering bed higher than 32 mm. In spite of a low efficiency of this process (λ_2 is 0.35 and 0.62 at the filtering bed height of 32 and 40 mm, respectively), it allows preparation of larger volume of softened water than with the fibrous cation exchanger of equal bed height. However, in obtaining deeply softened water, granular cation exchanger exhibits very low efficiency. Filtration of water through 20-mm and thinner bed of the fibrous cation exchanger ensures more efficient removal of calcium from water.

In water softening with the granular ion exchangers under identical conditions calcium breaks through in the first eluate fraction. At the same time, fibrous FIBAN K-1 cation exchanger ensures exhaustive removal of calcium from the first eluate fractions even at a sorbent height as small as 7 mm (Table 2). The efficiency of this process is sufficiently high (λ_2 = 0.34). All the tested fibrous sulfonic cation exchangers, irrespective of the bed height, are more efficient sorbents for preparation of deeply softened water than the granular resin.

Based on experimental results, we evaluated that a filtering unit for water softening equipped with the filtering bed with a surface area of 1 m^2 and 20 mm high ensures preparation of 600 l of deeply softened water within 20 min at the initial water hardness of 14 mg-equiv dm^{-3}.

Our experiments showed that the use of the filtering beds prepared from close-packed thin-fiber ion exchangers can be promising in development of small high-performance filtering units for deep water softening.

CONCLUSIONS

(1) Owing to excellent ion-exchange kinetic characteristics of thin (40 μm) fibers in the fibrous FIBAN K-1 ion exchanger, this sorbent can be used for efficient water softening.

(2) The use of thin-fiber close-packed fibrous ion exchangers considerably simplifies control of the permeability and hydrodynamic resistance of filtering beds to ensure the required conditions for water softening.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Treatment of the Wastewater of Finishing-and-Dyeing Production Using Polyelectrolyte Flocculants Based on Nitron Fiber Scrap

V. I. Grachek, A. A. Shunkevich, O. P. Popova, and S. E. Radkevich

Institute of Physical Organic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus

Received April 4, 2001

Abstract—The performance of FK-1 and FK-3 cationic polyelectrolytes and of new AMF-2 amphoteric polyelectrolyte in treatment of the wastewater of finishing-and-dyeing production was studied as influenced by the concentrations of flocculant and coagulant.

Due to the increasing environmental pollution, including pollution of natural waters, development of new effective reagents for treatment of wastewaters is very urgent. Wastewater of the finishing-and-dyeing production of textile industry contains various dyes (up to 40% of the amount used) and concomitant chemicals (such as sodium chloride, soda ash, sodium hydroxide, acetic acid, etc.).

Such wastewaters are often treated with water-soluble polyelectrolytes based on polyacrylonitrile [1, 2]. It is known [3] that dyes are removed from water using aliphatic or aromatic amines.

In this work we studied the performance of new flocculants based on Nitron fiber scrap[1] (NFS) in treatment of the wastewaters from finishing-and-dyeing production[2].

EXPERIMENTAL

In our work we used FK-1 cationic flocculant [4], FK-3 cationic flocculant prepared by amidation of NFS with 3-dimethylaminopropylamine [5], and new AMF-2 amphoteric polyelectrolyte.

The AMF-2 polyelectrolyte was prepared in two stages. In the first stage NFS was aminated with 3-dimethylaminopropylamine to the exchange capacity of 5.0–5.5 mg-equiv g^{-1}. The resulting product was washed with water to remove excess amine and then hydrolyzed with 2–3% alkali at 95–100°C for 2–3 h.

The resulting AMF-2 polyelectrolyte was studied by IR and ^{1}H NMR spectroscopy. The IR spectrum contains a broad band at 3400 cm^{-1} belonging to the stretching vibrations of the NH group and strong bands at 1650 and 1710 cm^{-1} typical of the –C=O vibrations in the amide and carboxy groups, respectively. The bands at 1540 and 1400 cm^{-1} are due to the asymmetric and symmetric vibrations of the $–COO^-$ group.

The ^{1}H NMR spectrum ($CDCl_3$) contains the signals at 7.5 (–NHCO group), 3.20–3.25 (methylene protons in the $–CH_2NHCO$ group), and 2.2 ppm (CH_3 groups). Some properties of the polyelectrolytes are listed in Table 1.

Table 1. Properties of the polyelectrolytes*

Polyelectrolyte	[η], cm^3 g^{-1}	Exchange capacity, mg-equiv g^{-1}
FK-1	42	SEC_{amine} = 7.0
FK-3	48	SEC_{amine} = 5.2
AMF-2	36	SEC_{COOH} = 2.3, SEC_{amine} = 5.0

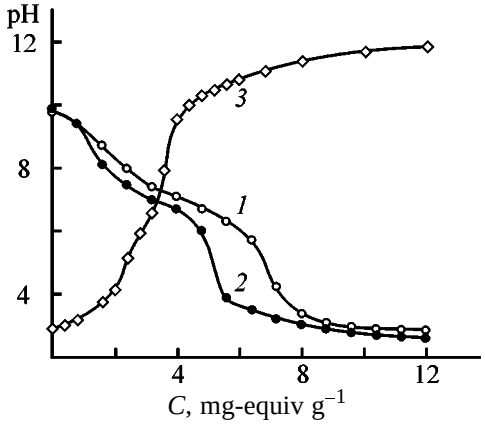

Fig. 1. Potentiometric titration curves of polyelectrolytes. (*C*) Concentration (mg-equiv of titrant per gram of flocculant). Polyelectrolyte: (*1*) FK-2, (*2*) FK-3, and (*3*) AMF-2; the same for Fig. 2.

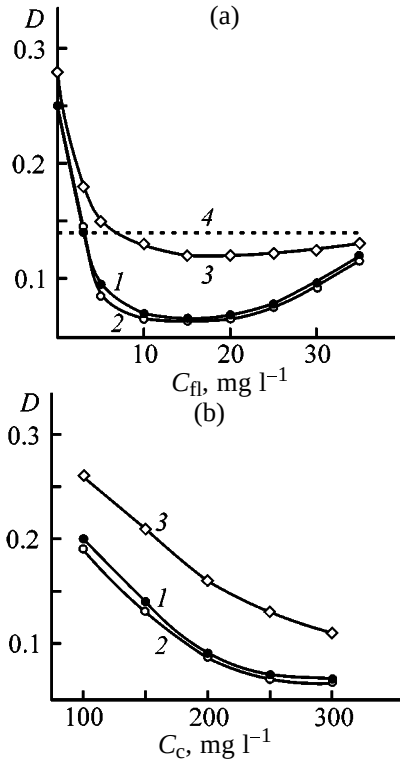

Fig. 2. Degree of wastewater clarification as influenced by concentrations of (a) flocculant C_f and (b) coagulant C_c. (a, *4*) C_c = 200 mg l^{-1}, and (b) C_f = 10 mg l^{-1}. (*D*) Optical density.

The exchange capacity of cationic electrolytes was determined from the inflection in the potentiometric titration curve. A weighed portion of a polyelectrolyte was titrated with a 0.1 M solution of hydrochloric acid in a potentiometric cell [6] equipped with an I-130 M ionometer. The exchange capacity of the amphoteric polyelectrolyte was determined by the procedure given elsewhere [7].

In our work we used pure grade $Al_2(SO_4)_3 \cdot 18H_2O$ and $Ca(OH)_2$, distilled water, and other chemically pure grade reagents. The intrinsic viscosity of the polymer solutions [η] was measured on an Ubbelohde viscometer at 20°C (d_c = 0.56 mm).The optical density was measured on a KFK-2 photocolorimeter (λ = 440 nm); the content of the petroleum products and surfactants was determined on a Flyuorat 02 liquid analyzer.

The chemical oxygen demand (COD) was measured by the bichromate oxidation procedure [8]. The amount of bound chromium (hereinafter chromium) was determined by titration [9]; and the water color index was determined by the procedure used at the plant, which is analogous to the procedure described in [9].

The titration curves of the polyelectrolytes in question are shown in Fig. 1. The FK-2 and FK-3 flocculants are the cationic polyelectrolytes containing weakly basic amino groups. The content of the amino groups per gram of the polymer dried to constant weight at 80°C was calculated from the inflection points in the titration curves.

The inflection points in the titration curve of the amphoteric polyelectrolyte are ill-defined, and thus the content of amino and carboxy groups in this polymer cannot be determined directly from the titration data.

The flocculation activity of polyelectrolytes was evaluated using the real wastewater of the finishing-and-dyeing production. First we determined the flocculation activity as influenced by the nature and concentration of the polyelectrolytes in question. The test mixtures were stored for 1 h before measurements, because previously we found [7] that at simultaneous addition of the flocculant and coagulant nearly 60-min storage is required for efficient purification of the wastewater.

The dependences of the optical density on the concentration of polyelectrolytes at constant concentration of the coagulant C_c = const are shown in Fig. 2a. With the cationic flocculants the degree of water clarification is greater than with the amphoteric polyelectrolyte. At the same time, the clarification degrees for FK-1 and FK-3 flocculants are similar. As seen from Fig. 2a, the highest flocculation efficiency is observed at concentrations of 10–20 and 10–30 mg l^{-1} for cationic and amphoteric polyelectrolytes, respectively. At these concentrations polyelectrolyte macromolecules have the optimal ratio between the sign and density of the charge and the extent of unfolding of the macromolecular chains, providing interaction with

the greatest number of the dispersed particles. With increasing concentration above the optimum the degree of water purification decreases, and this decrease is more abrupt with cationic flocculants as compared with the amphoteric polyelectrolyte.

The effect of the coagulant $Al_2(SO_4)_3$ concentration in the 100–300 mg l^{-1} range was studied at constant flocculant concentration C_f = const (Fig. 2b). As seen, the total flocculation effect for all polyelectrolytes increases with increasing coagulant concentration, which is obviously due to more efficient coagulation of the disperse phase.

The wastewater of the dyeing production contains chromium, which occurs in the oxidation states (3+) and (6+) depending on the nature of the dyes used, petroleum products, and other organic compounds. Therefore, we studied the performance of FK-1, FK-3, and AMF-2 flocculants in treatment of wastewaters to remove these pollutants. The results are summarized in Table 2. As seen, the effect of FK-1 and FK-3 in water treatment is similar, and the chromium concentration in water depends only on the content of the cationic polyelectrolytes added. In the course of treatment the chromium concentration decreases to 0.12–0.11 mg l^{-1} (i.e., by a factor of 2.7) at FK-1 and FK-3 concentrations of 10–15 mg l^{-1}. However, the decrease in the chromium concentration is the most abrupt at the cationic polyelectrolyte concentration of 5 mg l^{-1}, and further increase in the flocculant concentration only slightly affects the chromium content in the solution. At FK-1 and FK-3 concentrations of 10–15 mg l^{-1} the content of petroleum products decreases by a factor of 3.7–4.2 and COD decreases by a factor of 2.5–3.6. In the case of amphoteric polyelectrolyte, the content of chromium and COD decreases by a factor of 1.7 (to 0.18 mg l^{-1}) and 1.9, respectively. The effect of the amphoteric flocculant on the petroleum products is similar to that of the cationic polyelectrolytes.

Based on laboratory tests, FK-3 flocculant was selected as optimal, its pilot batch was prepared, and the industrial trials were carried out.

During industrial trials of the treatment process we studied industrial wastewater containing dyes without chromium. This wastewater was a dark cherry liquid with characteristic odor. In the industrial process of water treatment used at the plant $Al_2(SO_4)_3$ coagulant is added in combination with calcium hydroxide alkalizing agent. In the case of FK-3 flocculant, we used only the coagulant because in the presence of this polyelectrolyte the constant pH of the purified water was attained. The results of industrial trials listed in Table 3 are the averages of 5–6 measurements. As seen from Table 3, simultaneous use of the coagulant and calcium hydroxide did not provide the required quality of purified water, which was determined by the color index and content of organic compounds (COD). At the same time FK-3 flocculant used in combination with the coagulant allowed deodoration,

* Characteristics of wastewater before treatment: pH 6.5, dilution factor β = 1 : 55, content of anionic surfactants C = 0.025 mg ml^{-1}, COD = 320 mg O_2/l.

** Before treatment pH 6.6.

*** Treatment was performed in the presence of calcium hydroxide suspension (125 mg l^{-1}).

decolorization (dilution factor decreased from 1 : 55 to 1 : 10–1 : 12), decrease in COD by a factor of 2.0–2.3, and decrease in the amount of the coagulant used in the process.

Thus, FK-3 flocculant provides better purification of the wastewater of the finishing-and-dyeing production as compared with the existing processes.

CONCLUSIONS

(1) The flocculation activity of polyelectrolyte flocculants prepared from Nitron fiber scrap in the treatment of wastewaters of the finishing-and-dyeing production depends on the concentration of the polyelectrolytes and changes in the following order: FK-3 = FK-1 > AMF-2.

(2) Industrial trials showed that the wastewaters of the finishing-and-dyeing production are efficiently purified with FK-3 flocculant at a concentration of 10 mg l^{-1}.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Absolute Measurements of the Combustion Heat of Natural Gas

Yu. I. Aleksandrov and V. P. Varganov

Mendeleev Russian Research Institute of Metrology, State Unitary Enterprise, St. Petersburg, Russia

Received April 28, 2000; in final form, July 2001

Abstract—A new isothermal calorimetric method for measuring the combustion heat of gas, relying upon the operation principle of the heat pipe, is considered together with the sequence of thermal processes occurring when this method is used. The functional diagram of the calorimeter is analyzed. Two procedures for measuring the heat effects are presented.

The increasing cost of natural gas has always resulted, and does so now, in that the requirements to the accuracy of measurement of its calorific value tend to become increasingly stringent.[1] At present, only four studies concerned with precision measurement of the combustion heat of methane are known [2–5]. Three of these [2–4] served as a basis for recommendations concerning calculations of the combustion heat of natural gas with an error of 0.12% [6] from results of gas-chromatographic analysis of natural gas composition.[2]

Lowering the error in determining the combustion heat of methane requires that a set of investigations should be carried out, comprising three independent stages: (i) developing a method for absolute measurements of the combustion heat of fuels,[3] (ii) designing a gas calorimeter to be used in this method, and (iii) developing a procedure for measuring the combustion heat of natural gas.

Despite significant differences in design, all the known types of calorimeters possess a common feature: necessity for calibration, either electrically or with the use of appropriate pure gases and gas mixtures. This procedure makes an additional contribution to the total error of determining the combustion heat.

Therefore, developing a combustion heat measurement technique requiring no calorimeter calibration will favor, all other conditions being the same, higher measurement accuracy.

The following requirements to the method of combustion heat measurement and the gas calorimeter to be used in the process were formulated: the combustion heat is to be measured in strict conformity with the regulations, with an error of no more than 0.1%, and absolute measurements (i.e., those without any kind of calibration) are to be done at combustion heats of gaseous fuels in the range 20–50 MJ m^{-3}. The measurement technique operating in the isothermal mode was chosen. As shown by Weber [9], it is preferable to perform in this case direct measurements by the compensation method. Such measurements can be, under certain conditions, rather accurate and well reproducible, especially when the Peltier effect is employed to compensate heat released in exothermic reactions.

The main difficulty encountered in developing an isothermal gas calorimeter is the nonuniform distribution of temperature in the combustion chamber. This problem has been solved by fast and loss-free conversion of the combustion heat into the phase transition heat compensated by means of the Peltier effect [10].

For this purpose, the calorimeter design is based on the principle of operation of the heat pipe characterized, on the one hand, by high heat conductivity and, on the other, by the possibility of collecting heat scattered over a large area and concentrating it in a rather limited prescribed surface [11, 12].

Three zones can be distinguished in the heat pipe: those of evaporation and condensation, and the inter-

[1] In the US, the combustion energy of natural gas is to be established in conformity with the "Gas Act" adopted by the Congress of the United States in 1978 with an error of no more than 0.1% [1].

[2] As far back as 1968, specialists pointed to the necessity for performing new investigations in order to reduce the error in question [7], which is only possible with fundamentally new method and equipment.

[3] To absolute measurement techniques are referred methods in which the property being measured is related to basic units by a known theoretical dependence [8].

1070-4272/01/7409-1529$25.00

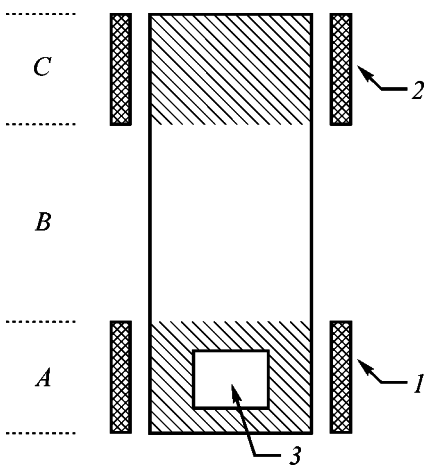

Fig. 1. Schematic of the heat pipe. Zone: (*A*) evaporation, (*B*) transport, and (*C*) condensation. (*1*) Heater, (*2*) Peltier elements, and (*3*) gas burner.

mediate zone. It is this specific feature of the heat tube, and also the possibility of virtually zero-loss and high-rate transfer of heat from the evaporation zone into the condensation zone, that were used to ensure absorption of heat released in gas combustion in the evaporation zone, conversion of this heat into vaporization heat, and transfer of the vapor into the condensation zone, where the condensation heat was compensated by means of the Peltier effect.

Thus, the following sequence of thermal processes occurs when the method in question is used:

$$Q_{comb} \rightarrow Q_{vap}, T_{ph.tr} \rightarrow Q_{cond}, T_{ph.tr} \leftarrow Q_{P.eff}, \quad (1)$$

where Q_{comb} is the heat of combustion of the gas, Q_{vap}, $T_{ph.tr}$ is the heat of vaporization of the working liquid at the phase transition temperature, Q_{cond}, $T_{ph.tr}$ is the heat of condensation of the working liquid at the same phase transition temperature, and $Q_{P.eff}$ the heat absorbed by the Peltier elements.

Taking into account that $|Q_{vap}, T_{ph.tr}| = |Q_{cond}, T_{ph.tr}|$, we have $|Q_{comb}| = |Q_{P.eff}|$. Consequently, the calculation equation for measuring the amount of heat released in gas combustion by the given method is as follows:

$$Q_{comb} = \eta \int_{t_{in}}^{t_{fin}} I(t)dt - Q_{idle}, \quad (2)$$

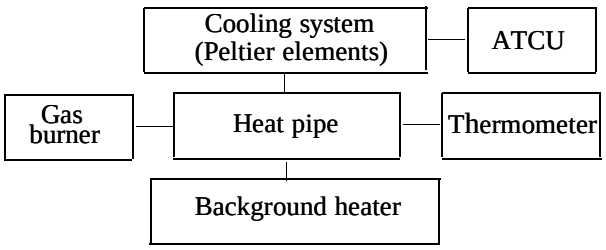
where η is the Peltier coefficient of the given battery at the boiling point of the working liquid; I is the current fed into the Peltier elements to maintain constant pressure or temperature, corresponding to a prescribed boiling point of the working liquid in the heat pipe; t_{in}, t_{fin} are the instances of current switching on and off in performing compensation; and Q_{idle} is the thermal energy consumed by the heat pipe in the idle mode.

To illustrate the set of operations constituting the given method for measuring the combustion heat, we use the functional scheme of the calorimeter shown in Fig. 1.

The calorimeter design is based on a heat tube with evaporation zone *A*, in which a background heater for heating the working liquid to its boiling point and a gas burner are placed, and transport zone *B* through which the evaporated working liquid is fed into condensation zone *C* and the condensate returns into evaporation zone *A*. Peltier elements are placed in condensation zone *C* in order to remove the heat released in condensation of an excess amount of vaporized working liquid. The vapor spaces of all the three zones are interconnected.

The isothermal conditions are ensured by maintaining prescribed vapor pressure of the working liquid or its prescribed boiling point (condensation temperature). We chose to maintain constant the temperature in one of three zones mentioned above. The control and measurement circuits are shown schematically in Scheme 1, where ATCU is the automated temperature control unit.

Scheme 1.



Control circuit of isothermal gas calorimeter.

Initially, the heat pipe is "turned on," with the Peltier current leveling-off at switched-on background heater and working control system, which indicates that the calorimeter has attained thermodynamic equilibrium.

After ignition, the gas combustion heat is utilized in the evaporation zone of the heat tube. As a result, a certain part of the working liquid is vaporized and the vapor passes through transport zone *B* into the con-

densation zone *C*. Simultaneously with evaporation, the vapor pressure of the working liquid and, correspondingly, its boiling point rise, which is compensated for by ATCU. The Peltier current necessary for this purpose is recorded and integrated.

The gas combustion heat can be measured in two gas feed modes: discrete and continuous. In the discrete mode, portions of gas are burnt, whose precise amount, Δm, is determined, e.g., by weighing the gas cylinder before and after an experiment. The combustion heat ΔH is calculated in this case by the equation

$$\Delta H = Q_{comb}/\Delta m.$$

In the continuous mode, it is important to maintain constant, with required accuracy, the flow rate G of all gases fed into the burner. Here, the quantity being measured is thermal power P (W), rather than amount of heat Q (J). The combustion heat is then calculated using the equation

$$\Delta H = P_Q/G_{CH_4}.$$

Thus, the quantity directly measured for maintaining the isothermal conditions in a calorimetric experiment is either the current passed through the Peltier elements (discrete gas feed mode) or power consumed by these elements (continuous gas feed mode).

To achieve the highest possible accuracy in measuring the gas combustion heat, it is necessary to determine sufficiently accurately the Peltier coefficient η, on the one hand, and take into account the dependence of the heat-eliminating power of Peltier elements on the supply current, on the other. This dependence is presented in Fig. 2.

Below are presented the results obtained in measuring the thermal power of the background heater and the current fed to the Peltier elements under the given thermostating conditions (24.800 ± 0.001°C):

I_P, A	$P_{b.h}$, W
1.4918 ± 0.0001	55.554 ± 0.004
1.5912 ± 0.0001	58.505 ± 0.005
1.6907 ± 0.0001	61.378 ± 0.004
1.5912 ± 0.0001	58.517 ± 0.005
1.4917 ± 0.0001	55.568 ± 0.004
1.3926 ± 0.0001	52.531 ± 0.005
1.2932 ± 0.0001	49.399 ± 0.005
1.3926 ± 0.0001	52.531 ± 0.005
1.4918 ± 0.0001	55.569 ± 0.004

Mention should be made here of the rather high reproducibility of measurement results. The maximum deviation of power values obtained under similar measurement conditions was 0.015 W (≤0.03%).

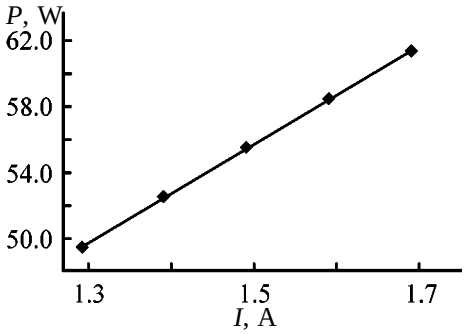


Fig. 2. Thermal power P necessary to maintain the given thermostating level (T = 24.800 ± 0.001°C) vs. current I passed through the Peltier elements.

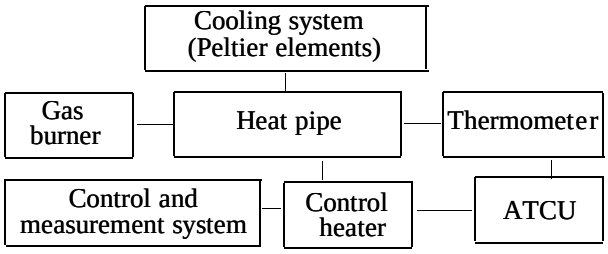
However, high measurement accuracy can also be achieved in another way: by eliminating the effect of the given dependence on gas combustion heat measurements. This can be done by controlling the power fed into the background heater, provided that constant heat removal is ensured by Peltier elements through which the maximum stable current is passed. Its value is chosen such that the heat pipe should transfer a thermal power exceeding that released in combustion of a gas supplied at the maximum admissible rate. With this method of temperature control, the background heater acquires control functions and, therefore, the control circuit was modified to that shown in Scheme 2.

Scheme 2.



Modified control circuit of isothermal gas calorimeter.

At constant electric power P_{cool} fed into the Peltier elements, a constant power, named initial electric power $P_{in,Ti}$, is to be supplied to the electric heater in order to maintain constant temperature in any zone of the heat pipe.

Let us introduce one more, in addition to the control heater, heat source, gas burner, into the evaporation zone of the heat pipe. Operating burner releases

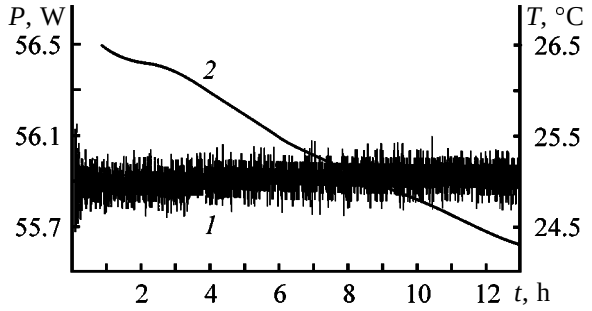


Fig. 3. (*1*) Long-term stability of the initial thermal power P_{in} in idle operation of the heat pipe at room temperature varying within 25 ± 1°C. (*2*) Temperature curve. (*P*) Power, (*T*) temperature, and (*t*) time.

thermal power P_Q. In this case the control system changes the control heater power P_{run} in such a way that the total power released by the two heat sources remains constant and equal to the initial power $P_{in,Ti}$ of the heater:

$$P_{in,Ti} = P_Q + P_{run}. \quad (5)$$

Thus, the thermal power P_Q released in gas combustion is defined as the difference between the initial power of the control heater and the power of the same heater at operating burner:

$$P_Q = P_{in,Ti} - P_{run,Ti}. \quad (6)$$

The main requirement to be met in measuring the thermal power P_Q released by the second thermal power source is long-term stability (constancy) of the total thermal power P_{in} at a given thermostating level.

With all other thermostating conditions preserved, P_{in} must remain constant regardless of whether only the main heater is switched on, or there are additional sources of thermal energy in the evaporation zone of the heat pipe. Whether or not the measurements of the thermal energy released by such sources are correct depends on the extent to which the above requirement is satisfied.

Figure 3 presents as illustration of the long-term stability of $P_{in,Ti}$ the results of measurements in the course of 13 h. It can be seen that measurement fluctuations are randomly distributed, which makes it possible to find the mean value of $P_{in,Ti}$ to be 55.920 ± 0.001 W. The standard deviation from the mean can be regarded as the characteristic of instability of the initial electric power, equal in the given case to 0.002%.

To pass from the heat power P_Q, measured using Eq. (6), to combustion heat of a gas, it is necessary to satisfy some conditions following from the adopted definition of the given quantity [5].

This refers in the first place to the requirement that the temperature of gases at the calorimeter inlet should be equal to that of combustion products at the calorimeter outlet. In addition, it is necessary to diminish the influence of evaporation or condensation (depending on experimental conditions) of part of water formed in combustion and take into account the possible partial loss of this water with combustion products.

CONCLUSION

A new isothermal calorimetric method was suggested for measuring the combustion heat of gases, relying upon the heat pipe principle and operating in both discrete and continuous modes.

Received April 28, 2000; in final form, June 2001

Abstract—A novel burning calorimeter design based on a heat pipe is presented. A circuit for automated control over operation of the proposed device is considered. The stability of the results is assessed. Several accessory parameters affecting the reproducibility of measurement results are evaluated. One of recent designs of the KTT-7 calorimeter, based on a thermosiphon, is analyzed. The uncertainty in heat power measurements on KTT-7 is evaluated.

A new isothermal method, described in detail in [1], was used in designing a gas calorimeter. It was necessary to design such a heat pipe that could accommodate a gas burner and ensure continuous removal of water formed in gas burning. The desire to diminish the error in measuring the heat energy released in gas combustion to a level not exceeding 0.1% imposed additional requirements to the calorimeter design and choice of measuring equipment. To achieve complete utilization of heat released in gas burning and its transfer with minimum loss to the condensation zone, a heat pipe was developed in the form of a thermosiphon presented in Fig. 1.

Gas burner *1* is situated within heat exchanger *2*. The heat exchanger is close in its design to the known combustion chambers used in industrial gas calorimeters. The heat exchanger is situated in the heating zone of thermosiphon *3* and is submerged in the working liquid, for which freon was chosen.[1]

Control heater *4* is also submerged in freon whose boiling temperature is measured with thermometer *5* placed directly in the bulk of the heat-transfer agent. Battery *6* of Peltier elements is situated at the opposite end of the thermosiphon, with the Peltier elements mounted within a special hollow forming the condensation zone. The temperature of the heat-transfer agent is measured with thermometer *8* whose signal is employed by the control circuit.

All specific design features of the calorimetric unit were aimed (i) to reduce to the maximum possible extent the heat loss both in the heat carrier evaporation zone and in the condensation zone and (ii) to

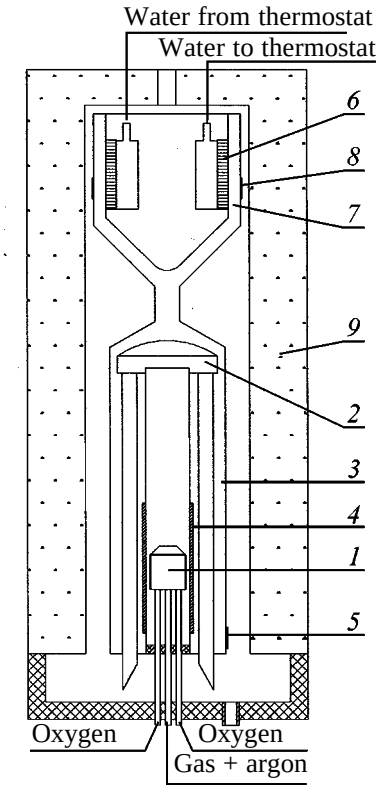

Fig. 1. General view of the calorimetric unit.

[1] The choice of Freon-11 as working liquid was primarily made for the following two reasons. First, it is incombustible, which is of no small importance when employing a gas burner. Second, this substance happily combines a boiling point close to the standardized 25°C and small, compared with that of water, heat of vaporization.

1070-4272/01/7409-1534$25.00

achieve the maximum possible similarity between the heat-transfer agent flows from the evaporation zone to the condensation zone in two operation modes: that with control heater ("idle mode") and that with a switched-on additional heat source.[2]

Water and other combustion products are removed through lateral tubes surrounding the central pipe of the heat exchanger, as this is done in industry. The condensate is collected in a receiver, which is situated below the thermosiphon and serves as a hydroseal, and removed from the calorimeter when accumulated in sufficient amounts. Gaseous combustion products ascend along the outer wall of the thermosiphon in the clearance between the thermosiphon and its casing *9*, which is intended to reduce heat loss, and removed through the upper opening in the casing.

The automated system controlling the operation of the measuring converter in the electric unit is based on a Proterm 100 microprocessor temperature controller with U10-15 power amplifier. As control transducer serves ESP-01 100-Ω platinum resistance thermometer calibrated in the temperature range 0–30°C. To ensure long-term stability of temperature, the thermometer must be, in its turn, sufficiently stable, which was verified. A 24-h variation of the thermometer resistance did not exceed, in terms of temperature, 0.1 mK. The transducer is connected in an arm of a measuring bridge operating on a type 373 power cell with a voltage of 1.5 V. An R4830/1 resistance box is connected in the standard arm of the measuring bridge. The output signal of the bridge is fed into the analog input of the temperature controller. The power amplifier at the output of the temperature controller is a thyristor amplifier with pulse-width modulation.

The control heater operates from a dc voltage varying between 0 and 30 V. This voltage is supplied to the heater through a shunt, reference resistance standard of 0.1 Ω, with a 1 : 100 potential divider comprising two reference resistance standards of 10 and 1000 Ω of 0.01 grade of accuracy connected in parallel to the heater.

The Peltier elements were fed from a B5-47 stabilized dc power source. Four in-series connected Peltier elements (K-1-127-1.4/1.5) were used. The current from the power source was supplied to the elements through a shunt. The current passing through the Peltier elements was determined by measuring the voltage drop across this shunt. The temperature of the hot junctions of the Peltier elements was set to be 25°C and was maintained constant to within 0.005°C by means of thermostating.

[2] As such an additional heat source can serve a gas burner or electric heater used in experiments aimed at checking the correctness of heat power measurements.

The measuring part of the control unit is based on an AK-6.20 (Aksamit) computerized measuring system with IBM PC. The limits of the admissible basic error of voltage measurement by Aksamit were $\pm(100U + 1)$ μV. The power of the control and additional (in verifying the method adequacy) heaters was measured with the same known technique.

Tests of the KTT-7 calorimeter were commenced with determining the long-term stability of the initial heat power P_{in} transferred by the thermosiphon under prescribed conditions (Table 1). In preliminary experiments, the time in which thermal equilibrium is attained was found to be 1 h. Therefore, account was taken of measurements obtained after 1 h, which is reflected in Table 1.

The average (over 9 h) initial heat power ($\bar{P}_{in}$) was calculated from 1-h average values presented in Table 1, rather than from the entire data array whose values were measured at intervals of 1 s. The presented results confirmed high stability of the initial heat power of the KTT-7 calorimeter.

In the next stage, accessory parameters (thermostating temperature T_c; prescribed current passed through the Peltier elements, I_P; and prescribed temperature of hot junctions of the Peltier elements, T_P) were studied in detail.

As prescribed thermostating temperature was chosen, on the basis of preliminary experiments, T_c = 24.900°C. To determine the effect of deviations of T_c

within its controlled variation range (±0.001°C) on the stability of P_{in}, a set of measurements was carried out. The change of the thermostating level from the prescribed value was chosen to be 0.200°C. The obtained results are presented in Table 2.

Thus, with T_c maintained constant within ±0.001°C, the heat power varies within ±0.002 W.

The current I_P passed through the Peltier elements was measured with the use of B5-47 high-stability dc power sources. The prescribed current was maintained to within ±0.0001 A. The variation of the $\Delta P/\Delta I$ coefficient with current strength is due to the nonlinear dependence of the Peltier effect on current. Nevertheless, the obtained results allow evaluation of the possible fluctuations of P_{in}, caused by the instability of current passed through the Peltier elements. In the case in question, these fluctuations did not exceed ±0.004 W or 0.008% (Table 3).

The temperature T_P of the hot junctions of the Peltier elements was maintained constant by their thermostating with a water thermostat. To assess the influence exerted by the instability of the hot junction temperature on the possible heat power fluctuations, a set of measurements of the initial heat power P_{in} was performed at different thermostat temperatures.

As follows from Table 4, when the temperature of water thermostating the hot junctions is maintained constant within ±0.005°C, the fluctuations of the heat power transferred by the calorimetric unit will be ±0.008 W.

The estimate of the conversion coefficient and assessment of the influence exerted by the stability of accessory parameters made it possible to formulate requirements to the equipment used in the control and measurement unit of the calorimeter.

The next stage in studying the calorimeter was verification of the adequacy of measurement of the heat power P_Q. For this purpose, the gas burner was replaced with an additional electric heater-simulator. A constant electric power was fed into the heater. Simultaneously, all gases (with the exception of the combustible gas) were supplied into the calorimeter at such rates that their total amount corresponded to the amount of combustion products formed at the maximum flow rate of the combustible gas. In parallel, the electric power fed into the simulator was measured by the known direct method [1].

The set of measurements consisted in alternating operation of the calorimetric unit in the "idle" mode and with switched-on simulator. The duration of work in each mode was 3 h. The data for the last two hours were used for further calculations. The obtained results are presented in Table 5 and Fig. 2.

As P_{in} was taken the average value for the stage preceding the simulator switch-on and that following the simulator switch-off. The electric power supplied to the simulator was taken to be the true value $\bar{P}_{tr}$ = 25.510 ± 0.006 W. The average heat power released at the simulator and transferred by the thermosiphon was found to be $\bar{P}_Q$ = 25.503 ± 0.014 W.

As follows from the performed set of measure-

Table 5. Comparison of measured electric power P_{tr} fed into the simulator with the heat power P_Q transferred by the thermosiphon

P_{in}	P_{run}	$P_Q = P_{in} - P_{run}$	P_{tr}	$\delta = P_{tr} - P_Q$

ments, the discrepancy between the electric power P_{tr} fed into the simulator and P_Q established in calorimetric measurements was as low as 0.007 W or 0.03%, which is within a random error. The obtained results point to the absence of any systematic error in measuring the heat power on the given calorimeter. Thereby, prerequisites were created for passing to measurements of the gas combustion heat.

However, before passing directly to the procedure of gas burning it was of interest to evaluate the uncertainty of measurement of the heat power P_Q in the KTT-7 calorimeter [2]. In view of the fact that the random error can be reduced by increasing the number of observations, let us estimate the number of observations [2] necessary for reducing the random error to a desired value. For this purpose, let us use the equation presented in the ISO standard [3]:

$$n^{1/2} = ts/d = 30,$$

where d is the desired value of the random error (0.01 W), n is the number of measurements, s is the standard deviation of a single measurement (≤0.15 W for KTT-7), and t is Student's number (taken to be 2 because of the large number of measurements).

Thus, it suffices to have 900 points in measurements with KTT-7 in order to obtain a random error of measurement not higher than 0.01 W, which constitutes about 0.04% of the value being measured. The duration of measurement should be greater than, or equal to 135 min. In the reported set of measurements, the duration of each stage was 3 h, of which two were used for processing.

In evaluating the measurement uncertainty, it is important to escape "double counting" of uncertainty

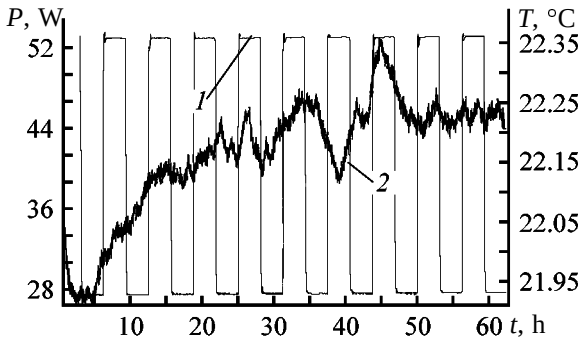

Fig. 2. Variation with time of the (*1*) power of the controlling heater in idle mode and with switched-on additional heater-simulator (P_{tr}) and (*2*) casing temperature. P_{tr} = 25.510 ± 0.006 W. (*P*) Power, (*T*) temperature, and (*t*) time.

components [2]. As applied to the obtained results, this means that the uncertainties due to the accessory parameters considered above should not be taken into account separately in group B, but are part of the uncertainty evaluated in group A in the form of a standard deviation $\bar{U}_A(P_Q) = 0.014$ W or $\tilde{U}_A(\bar{P}_Q) = 0.05\%$.

With account of the metrological characteristics of the equipment used in power measurements, the total standard uncertainty for group B, U_B, was found, using the calculation procedure described in [4], to be $\tilde{U}_B = 0.01\%$.

Thus, the total standard uncertainty in heat power measurement with a KTT-7 calorimeter

$$\tilde{U}_C = (\tilde{U}_A^2 + \tilde{U}_B^2)^{1/2} = 0.05\%.$$

In principle, this is sufficient for passing to development of a procedure for measuring the combustion heat of gases with an error of about 0.1%.

CONCLUSION

As a result of the investigations performed, a calorimeter design was developed, which allows the heat released in gas combustion to be measured by the absolute method with required accuracy ($\pm 0.1\%$).

Abstract—Factors that are to be taken into account in developing a calorimetric technique are considered. The possible deviations of temperatures at the inlet and outlet of gases in the calorimeter from the nominal values are evaluated and an example of such estimate is given for the case of methane burning in batch and continuous operation modes. The necessity for taking into account the humidity of gases fed into the calorimeter burner is demonstrated. The proposed method was used to perform absolute measurements of the combustion heat of methane.

The proposed technique for measuring the combustion heat of natural gas was developed for an isothermal calorimeter of original design, described in detail previously [1, 2]. Our goal was to make introduction of any corrections unnecessary. In this case, the gas combustion heat can be calculated from the amount of burnt gas and the measured heat power P_Q released in its combustion.

From the existing wide variety of definitions of the notion "combustion heat of a gas" [3–11] follows that, to solve the problem in question, it is necessary (1) to refine the temperature to which the combustion heat is reduced and (2) to ensure, taking into account item 1, that the temperatures of gases fed into the burner and discharged combustion products are equal.

Further, the following standard combustion conditions were used: T_c = 25°C, p_c = 101.325 kPa.

Another important factor to be taken into account in developing a calorimetric technique is the content of water vapor in the gas being burnt. The following variants are distinguished [5]: (1) gas to be burnt is saturated with water vapor prior to being fed into the calorimeter; in this case, combustion heat related to 100% humid gas is measured; (2) gas to be burnt is dried prior to being fed into the calorimeter; the obtained combustion heat is related to dry gas [5]; and (3) gas to be burnt is fed into the calorimeter with the humidity it has; the measured value is the combustion heat of real gas.

Thus, the above circumstance is to be taken into account in comparing gas combustion heat values obtained by different methods. The most logical and promising method is direct measurement of the combustion heat of a real gas.

The measured heat effect in gas burning may be over- or underestimated for internal or external reasons. To internal factors are related effects depending both on the difference of heat capacities of gases fed into the calorimeter and combustion products and on heat of vaporization (condensation) of water vapor arriving at the calorimeter together with feed gases and formed as a combustion product. Therefore, the calorimetric procedure should reduce the effect of internal factors to the maximum possible extent.

External effects are associated with heat exchange between the calorimeter and the environment. Their influence can be substantially reduced by heat insulation, and attention was given to this fact in designing the calorimeter.

Gases fed into the calorimeter were preliminarily thermostated in a water thermostat at 25°C. The temperature maintained in the KTT-7 calorimeter was chosen in such a way that the temperature in the heating zone of the thermosiphon was close to 25°C. The combustion products at the heat-exchanger outlet acquired a temperature close to this value. Below, we estimate possible deviations of the above temperature from the nominal value on condition that the error associated with such a deviation does not exceed 0.01%.

Let us calculate the correction for deviation of the temperature of incoming gases and combustion gases

1070-4272/01/7409-1539$25.00

from 25°C in methane burning

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O. \quad (1)$$

The additional amount of heat entering the calorimeter with each of the incoming gases or absorbed by each of these is given by

$$Q_{in,j} = n_{in,j} C_{P,j} (T_{h.p.} - T_{in}), \quad (2)$$

where $n_{in.j}$ is the number of moles of a gas fed into the calorimeter, $C_{P,j}$ is the molar heat capacity of a given kind of gas, $T_{th.t}$ is the heat pipe thermostating temperature, and T_{in} is the temperature of gas at the inlet of the gas pipe.

The amount of heat removed from the calorimeter with each of the combustion products is

$$Q_{fin.j} = n_{fin,j} C_{P,j} (T_{fin} - T_{h.p.}), \quad (3)$$

where $n_{fin.j}$ is the number of moles of combustion products and T_{fin} is the outlet temperature of the combustion products.

Thus, the total measured amount of heat, which either arrives at the calorimeter or is removed therefrom with each kind of gas, is given by

$$\Delta Q_j = n_{in,j} C_{P,j} (T_{h.p.} - T_h) + n_{fin,j} C_{P,j} (T_{fin} - T_{h.p.})$$
$$= C_{P,j} (n_{in,j} - n_{fin.j}) T_{h.p.} + n_{fin} T_{fin} - n_{in} t_{in},$$
$$\Delta Q_j = C_{P,j} [(V_{in,j} - V_{fin.j}) T_{h.p.} + V_{fin.j} T_{fin} - V_{in,j} T_{in}]/V_0, \quad (4)$$

where V_0 is the true molar volume of a given kind of gas.

The gas volumes at the inlet and outlet may coincide, differ, or even be zero for one of the gases.

Let us evaluate, for the example of methane burning, the effect of deviation from 25°C of the temperature of gas at the calorimeter inlet and that of combustion products at its outlet.

(1) Methane CH_4:

$$V_{CH_4,in} = V_{CH_4}, \quad V_{CH_4,fin} = 0,$$
$$\Delta Q_{CH_4} = [C_P^{CH_4} (T_{h.p.} - T_h) V_{CH_4}]/V_0.$$

(2) Oxygen O_2: (a) oxygen entering into reaction in accordance with the equation

$$V_{O_2,eq.in} = 2V_{CH_4}, \quad V_{O_2,eq.} = 0,$$
$$\Delta Q_{O_2,eq} = [C_P^{O_2} (T_{h.p.} - T_{in}) 2 V_{CH_4}]/V_0.$$

(b) oxygen supplied in excess:

$$V_{O_2,ex} = V_{O_2,\Sigma} - V_{O_2,eq} = V_{O_2,\Sigma} - 2V_{CH_4},$$
$$\Delta Q_{O_2,ex} = [C_P^{O_2} (T_{fin} - T_{in})(V_{O_2,\Sigma} - 2V_{CH_4}).$$

(3) Argon:

$$V_{Ar,in} = V_{Ar,fin} = V_{Ar}.$$

As shown below, the optimal conditions of burning are those with the volume (flow rate) of argon equal to that of methane, and, therefore, we take $V_{Ar} = V_{CH_4}$:

$$\Delta Q_{Ar} = [C_P^{Ar} (T_{fin} - T_{in}) V_{Ar}]/V_0$$
$$= [C_P^{Ar} (T_{fin} - T_{in}) V_{CH_4}]/V_0.$$

(4) Carbon dioxide CO_2:

$$V_{CO_2,in} = 0, \quad V_{CO_2,fin} = V_{CH_4},$$
$$V_{CO_2} = [C_P^{CO_2} (T_{fin} - T_{h.p.}) V_{CH_4}]/V_0.$$

(5) Water H_2O: (a) water formed by oxidation (condensate). Taking into account that $V_{H_2O} = 2V_{CH_4}$, we have for the mass of condensed water

$$m_{H_2O,l}^{con} = M_{H_2O} V_{H_2O}/V_0 = 2M_{H_2O} V_{CH_4}/V_0,$$
$$V_{H_2O} = m_{H_2O,l}^{con} C_{P,l}^{H_2O} (T_{fin} - T_{h.p.}) \quad (5)$$

where $C_{P,l}^{H_2O}$ is the heat capacity of water (J g^{-1} K^{-1}).

(b) Water vapor corresponding to saturated state of gases fed into the calorimeter burner and of combustion products. Assuming that the amount of water vapor fed into the calorimeter with water-saturated oxygen is equal to the amount of water vapor removed from the calorimeter, we have

$$V_{H_2O,vap} = m_{H_2O,}^{vap} C_{P,l}^{H_2O} (T_{fin} - T_{in}) \quad (6)$$

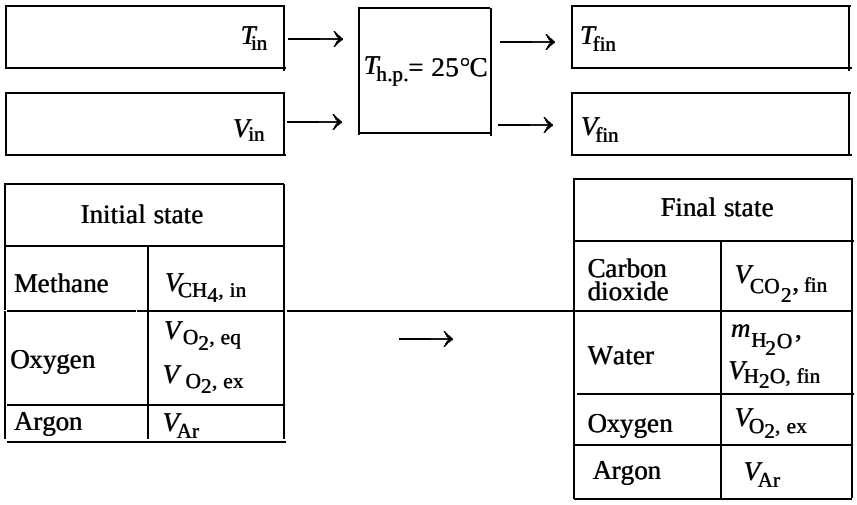
where $m_{H_2O}^{vap} = a V_{O_2,\Sigma}$, and a is the content of water in a saturated gas at a given temperature [12]:

T, °C	20	24	25	26	30
a, g m^{-3}	17.29	21.77	23.04	24.37	30.37

The conditions when this assumption is valid are given below.

In addition, one more assumption is made, consisting in that the saturated vapor pressure of water in

Scheme of gas feed



oxygen and combustion products is taken to be constant in the considered range of deviations (~0.1°C) of T_{in} and T_{fin} from 25°C.

(c) Evaporation or condensation of water present in combustion products in the liquid or gas phase as a result of the above deviation of temperature:

$$V_{H_2O}^{ph.tr} = (a_{T_{fin}} - a_{T_{in}}) V_{\Sigma}^{c.pr} q, \quad (7)$$

where q is the specific heat of the liquid←→vapor phase transition, 2.44 kJ g^{-1} at 25°C; and $V_{\Sigma}^{c.pr}$ is the total volume of gaseous combustion products.

The presented formulas for evaluating the effect of deviation of the temperatures of gases fed into the calorimetric cell and combustion products removed from the cell refer to the case of calorimeter operation in the batch mode. However, the continuous mode is preferable under industrial conditions, since it allows permanent control over the calorific value of gases. In this case, heat power P (W) should be substituted in the above equations instead of Q_j (J), and the respective gas flow rates G_j (l h^{-1}), instead of volumes V_j (l).

Let us consider burning of methane in the continuous mode at constant (2, 2.5, or 3.0 l h^{-1}) flow rate G''_{CH_4} of the gas (see scheme).

The flow rates of primary (G'_{O_2}) and secondary (G''_{O_2}) oxygen are chosen in accordance with the recommendations given in [13] and presented Table 1, which also lists the flow rates of the other gases.

To prevent additional condensation of water vapor or condensate evaporation, argon was fed into the burner simultaneously with methane and the whole amount of oxygen was preliminarily saturated with water vapor at 25°C. In methane burning at a flow rate of 2 l h^{-1}, a heat power of 22.13 W is to be released. As a result of the above-considered deviation of temperature (±0.10°C) from T_c = 25°C, a decrease or increase in the measured heat power will be $\pm 1.06 \times 10^{-3}$ W, which corresponds to a relative error of 5×10^{-3}%. The relative error will be the same at other methane flow rates (e.g., 3 l h^{-1}) if the mentioned relations between the flow rates of gases fed into the calorimeter are observed.

Thus, to confine the effect of deviations of the temperatures of gases fed into the calorimeter and combustion products discharged from the calorimeter to within 0.01%, it suffices to maintain this temperature deviation equal to, or less than 0.10°C.

From Tables 2 and 3 follows that about 50% of the correction is accounted for by evaporation or condensation of water, $\Delta P_{H_2O}^{ph.tr}$. And this occurs on the assumption that there is no water condensation due to a decrease in the volume of gaseous combustion products, compared with that of the gases entering the reaction.

Let us consider the conditions under which this assumption is valid. For this purpose, let us revert to the three possible gas burning conditions, but consider only two of these: (1) combustible gas and oxygen are completely saturated with water vapor at T = 25°C and (2) combustible gas and oxygen are completely dried. In doing so, we will take into account not only the humidity of the gas being burned, but also that of oxygen.

Variant 1. Let us take the methane flow rate to be

Table 1. Overall balance of gases and combustion products in relation to methane flow rate

2.5 l h^{-1} at an excess of oxygen equal to 50%. Both methane (G_{CH_4} = 2.5) and oxygen ($G_{O_2,\Sigma}$ = 7.5 l h^{-1}) are saturated with water vapor at T = 25°C. In this case, a water vapor flow ($G^{vap}_{H_2O}$ = 0.2304 g h^{-1}) is fed into the burner together with the mentioned gases (G_Σ = 10 l h^{-1}). At the same time, a water vapor flow ($G^{vap}_{H_2O}$ = 01152 g h^{-1}) is discharged from the calorimeter together with the combustion products, whose total flow rate is 5 l h^{-1}, including 2.5 l h^{-1} of $O_{2,ex}$ and 2.5 l h^{-1} of CO_2. Thus, the decrease in the combustion product volume leads to continuous condensation of excess water vapor, accompanied by additional heat power release $\Delta P^{ph.tr}_{H_2O}$ = 0.078 W. This additional heat power constitutes 0.28% of the heat power (27.66 W) released in combustion of methane delivered at a rate of 2.5 l h^{-1}. It is by this value that the measured combustion heats will be overestimated when not only methane, but oxygen, too, are completely saturated.

Variant 2. The flow rates of methane and oxygen remain the same. However, neither methane nor oxygen are saturated with water vapor, but are, contrastingly, subjected to complete drying. In this case, no water vapor is delivered to the burner with the given gases. However, we have at the calorimeter outlet, in addition to the formed CO_2 and excess amount of oxygen (with the flow rates of these two remaining equal to 5 l h^{-1}), also a water vapor flow discharged from the calorimeter at the same rate of 0.1152 g h^{-1} owing to saturation of these gases with water formed in methane combustion. It is by this value (0.28%) that the results of methane combustion heat measurements will be lower than its true value.

Variant 3. To eliminate the effect of changes in the volumes of combustion products on the results of combustion heat measurements, the following procedure is proposed: only the flow of oxygen (both primary and secondary) is saturated with water vapor, with the flow rates of methane (2.5 l h^{-1}) and oxygen (taken in 50% excess) remaining unchanged. However, an additional amount of dry argon with the flow rate equal to that of methane is delivered. The last two factors play the key role in the process under consideration.

Thus, the following flows are fed into the burner:

$$G_{\Sigma,\text{inlet}} = G_{CH_4} + G_{\Sigma,O_2,\text{inlet}} + G_{Ar} = 2.5 + 7.5 + 2.5 = 12.5 \text{ l h}^{-1}.$$

Together with these, a water vapor flow is delivered:

$$G_{H_2O,\text{inlet}} = aG_{\Sigma,O_2,\text{inlet}} = 0.02304 \times 7.5 = 0.1728 \text{ g h}^{-1}.$$

The flow of combustion products will be

$$G_{\Sigma,\text{out}} = G_{CO_2} + G_{O_2,ex} + G_{Ar} = 2.5 + 2.5 + 2.5 = 7.5 \text{ l h}^{-1}.$$

Together with this flow, a flow of water vapor is discharged:

$$G_{H_2O,\text{out}} = aG_{\Sigma,\text{out}} = 0.02304 \times 7.5 = 0.1728 \text{ g h}^{-1}.$$

In the proposed variant of gas feed into the burner, both water vapor condensation (as in Variant 1) and evaporation (loss) of water (as in Variant 2) can be completely eliminated.

These conditions served as a basis for a technique of gas burning, and it is these conditions that were taken into account in evaluating the effect of deviation of the temperatures T_{in} and T_{fin} from T_c = 25°C.

Thus, the developed technique for gas burning with the use of the designed isothermal calorimeter (1) enables continuous measurements of the combustion heat; (2) eliminates condensation of water vapor and evaporation of water, both of these resulting from changes in the volume of combustion products; and (3) reduces to a negligible minimum (<0.01%) the effect of differences between the heat capacities of gases at the inlet and outlet of the calorimeter at deviation of the temperatures of these gases and combustion products by less than ±0.10°C from 25.00°C.

Continuous measurements are enabled by using modern electronic units for control over mass flow rates of gases. The most stringent requirements are imposed on the flow rate control unit of the combustible gas. The optimal case is that when the flow rate control units ensure for the combustible gas an error of no more than 0.05% at gas flow rates in the range 1–4 l h^{-1}. It suffices to maintain the flow rates of the other gases constant with an error of no more than 1%.

To implement the proposed technique, the calorimeter was equipped with a unit for gas preparation and processing, which included electronic flow rate controllers for the combustible gas, primary oxygen, secondary oxygen, and argon; vessels for saturation of primary and secondary oxygen with water; and four heat exchangers in a thermostat, used for thermostating at 25°C of each of the above-mentioned four

Table 4. Heat power released in calorimeter in methane combustion. Methane flow rate 2.5009×10^{-3} m^3 h^{-1}

52.276	24.526	27.750	11.096

gases prior to their being delivered to the combustion chamber.

To ensure complete saturation at 25°C, both oxygen flows (primary and secondary) were preliminarily saturated with water vapor at 40–50°C prior to being delivered into the thermostat. The temperature of the combustion products at the calorimeter outlet was maintained constant in such a way that its deviation from 25.00°C did not exceed 0.10°C.

The combustion heat of methane was measured with pure (no worse than 99.95%) methane purchased from Linde Co. in a 40-l cylinder.

The gas flow rate was controlled by electronic control units manufactured by Bronkhorst High-Tech BV. The control unit for methane was additionally calibrated at a single point (50%) using a primary gas flow rate standard. At this point, the mass flow rate was found to be, according to 10 measurements, 4.9844×10^{-4} g s^{-1}, and the volumetric flow rate, calculated with account of the methane density of 0.7175 kg m^{-3} under normal conditions, was 2.5009×10^{-3} m^3 h^{-1}. The calibration uncertainty was 0.17%. The measurement conditions were as follows:

Controlled temperature T_{contr}	24.900 ± 0.001
Current passed through Peltier elements, I_P, A	1.20 ± 0.0001
Temperature of hot junctions of these elements (T_P)	25.00 ± 0.002
Temperature of gases at calorimeter inlet, T_g	25.00 ± 0.002
Temperature of combustion products at outlet, $T_{comb.pr}$	25.0 ± 0.1
Methane flow rate G_{CH_4}, m^3 h^{-1}	2.5009×10^{-3}
Flow rate of primary oxygen, G'_{O_2}, saturated with H_2O, m^3 h^{-1}	1.00×10^{-3}
Flow rate of secondary oxygen, G''_{O_2}, saturated with H_2O, m^3 h^{-1}	5.00×10^{-3}
Flow rate of dry argon, G_{Ar}, m^3 h^{-1}	2.50×10^{-3}

With the data of Table 4 used, the average methane combustion heat H_V^{calc} was found by means of the equation $H_V^{calc} = P_Q/G_{CH_4}$ to be 11.068 kW h m^{-3} with a standard deviation of 0.009 kW h m^{-3}, or 0.08%.

A calculation of the uncertainty of this result, done in conformity with international recommendations [15], demonstrated that (1) the uncertainty u_A, calculated following pattern A and numerically equal to the standard deviation, was 0.009 kW h m^{-3}, or 0.08%; (2) the uncertainty u_B, calculated following pattern B, was 0.011 kW h m^{-3}, or 0.10%; (3) the total standard uncertainty, calculated by the formula $u_C = (u_A^2 + u_B^2)^{1/2}$, was 0.014 kW h m^{-3}, or 0.13%.

The deviation of the obtained combustion heat of methane (11.068 kW h m^{-3}) from the value recommended by ISO 6976:96 (11.064 kW h m^{-3}) was as small as 0.004 kW h m^{-3}, or 0.04%.

CONCLUSIONS

(1) The proposed method does enable absolute measurements of the combustion heat, i.e., those requiring no calibration (electrically or with pure methane).

(2) The developed design of an isothermal gas calorimeter makes it possible to measure the heat power released in gas combustion without any significant systematic errors (≤0.01%).

(3) The developed technique for measuring the gas combustion heat is used with all requirements following from the definition of this quantity satisfied. No corrections are to be introduced into the measured heat power, the determined combustion heat is in agreement with the combustion heat of real gas.

(4) The error in measurement of the combustion heat of methane was 0.04%, and the uncertainty of the measured methane combustion heat, 0.13%. This value can be reduced by improving the accuracy of determining the amount of burnt gas.

Abstract—A series of new synergistic polyfunctional stabilizing compositions phenol–phosphite for polyolefins were developed. Their performance as antioxidants, color stabilizers, and agents preventing thermomechanical degradation was quantitatively evaluated.

Despite numerous papers published in the field of polymer stabilization [1, 2], search for effective stabilizers remains an urgent problem. Growing attention is given to synergistic mixtures of stabilizers, i.e., to mixtures whose performance under certain conditions exceeds the additive value. Of particular importance are papers aimed at search for synergist intermediates of antioxidation processes, since specifically these processes are most often responsible for preservation of valuable physicochemical properties of polymers [3, 4].

According to the existing theory [5], the most effective compositions inhibiting polymer oxidation are those in which one of the components terminates oxidation chains be decomposing hydroperoxides and the other reacts with peroxy radicals to form inactive products. It is known that phenolic stabilizers inhibit polymer oxidation by decomposing peroxy radicals, and phosphites decompose hydroperoxides [5]. Furthermore, phosphite-containing stabilizing compositions exhibit one more valuable property: they preserve the polymer color in storage, processing, and service, which is very important for production of competitive items [6].

In this work we studied a series of new stabilizing phenol–phosphite mixtures.

EXPERIMENTAL

As phenolic oxidation inhibitors we tested Irganox 1010 (**I**, ester of pentaerythritol and 2,6-di-*tert*-butyl-4-hydroxyphenylpropionic acid, mp 120°C), Agidol 2 [**II**, 2,2-methylenebis(4-methyl-6-*tert*-butylphenol), mp 128–129°C], and Agidol 5 (**III**, 4,4'-dihydroxy-3,3',5,5'-tetra-*tert*-butyldiphenyl, mp 180–181°C).

As organophosphorus component we tested a new stabilizer, Stafor 24 [**IV**, tris(2,4-di-*tert*-butylphenyl) phosphite, mp 175–183°C) [7].[1]

Tests were performed with high-density polyethylene (HDPE) of 289-73 grade [TU (Technical Specifications) 6-05-1870-804) and polypropylene (PP) (TU 2211-015-00203521–95).

The antioxidative performance of the stabilizers was evaluated by the duration of the induction period of oxidation in oxygen [8] under rigorous conditions: 165°C for PP and 195°C for HDPE.

The color stability of the polymers in the course of oxidation in air (PP at 165°C and HDPE at 195°C) was evaluated in a 10-point color scale (white, 1; black, 10).

The efficiency of thermomechanical stabilization was evaluated from variation of the torque M_t in time [9].

The tensile strength of the polymers was evaluated as described in [10]. A polymer sample subjected to thermomechanical degradation was subjected to single sheeting with laboratory rollers (clearance 1.5–2 mm), after which 20–30-mm strips were cut. These strips were subjected to extrusion on the extrusion machine of a Brabender plasticorder with a stock worm diameter of 20 mm and a length-to-diameter ratio of 22 : 1. Samples were formed with a slit head 50 mm wide at a rotation rate of 60 rpm and the following zone tem-

[1] The commercial synthesis procedure was developed at the Kazan State Technological University; the production was mastered at the Kazan'orgsintez Joint-Stock Company.

peratures (°C): for PP, feed 170 (T_1), mixing 190 (T_2), plastication 210 (T_3), and head 200 (T_4); for HDPE, T_1 150, T_2 170, T_3 190, and T_4 180. The extruded material was fed to the receiving transporter and pressed with a 2-kg drum. From the resulting strips, blades were cut for strength determination.

We found that, among the individual antioxidants, the longest induction periods of polymer oxidation were obtained with Irganox 1010 (**I**) (Table 1). Agidol 2 (**II**) is somewhat inferior to Irganox 1010. Agidol 5 (**III**) has a high lower critical concentration and does not ensure the required stability at a dosage less than 0.2 wt %. The required stabilizing effect is attained only at an Agidol 5 dosage of 0.3 wt %. The induction periods of polyolefin oxidation appreciably increase when phenol–phosphite mixtures are added (Table 1), i.e., a synergistic effect is observed.

The synergistic effect of inhibitor mixtures [8] was quantitatively characterized by the practical synergism S_{pr} defined as

$$S_{pr} = \tau_m/\tau_1^0,$$

(τ_1^0 is the induction period of polymer oxidation in the presence of the more effective component added in the molar concentration taken for the inhibitor mixture) and by the synergism S defined as

$$S = \frac{\tau_m - (\tau_1 - \tau_2)}{\tau_1 + \tau_2},$$

where τ_m is the induction period of polymer oxidation in the presence of the inhibitor mixture; τ_1 and τ_2 are those in the presence of the respective inhibitors taken separately in the concentrations corresponding to their mole fraction in the mixture.

A combination of synergism and practical synergism allows fairly adequate characterization of the performance of antioxidant mixtures.

In all cases phenol–phosphite mixtures exerted a stabilizing effect on the polymer color in the course of oxidation, although Agidol 5 imparts a yellowish initial color to the polymer (Table 1).

Experimental data clearly demonstrate the high performance of the Irganox 1010–Stafor 24 mixture. The highest synergistic effect is observed at a component ratio of 3 : 2.

This mixture, along with the antioxidative performance, was tested for the capability to prevent thermomechanical degradation of the polymer. The stabilizing effect against thermomechanical degradation was evaluated from the variation of the torque with time, monitored with a Brabender plasticorder. Since the torque, at equal other conditions, is determined by the molecular weight of the polymer [9], there is a direct relationship between the degree of degradation and torque (a sample that is more resistant to thermomechanical degradation will show a higher torque after treatment for a given time) and hence the strength characteristics of the polymer.

In Table 2 are given the torques of PP and HDPE after processing for 6, 12, and 15 min in a Brabender plasticorder in the absence and in the presence of stabilizers. The time at which the torque was recorded was determined by the residence time of polymers in the mixing chamber in production of thermoelastoplastics from the polyolefins in hand.

Addition of Irganox 1010 (**I**), Stafor 24 (**IV**), or their mixtures has no significant effect on the torque at the initial instant of time. As the time of thermomechanical degradation of the polymers is increased (12–15 min), the torque of the stabilized samples becomes significantly different from that of the control sample without stabilizers. Polypropylene and HDPE containing **I** and **IV** are considerably more resistant to thermomechanical degradation, as seen from data on M_t. The temperature in the chamber remains at the same level.

In parallel, we tested these polymers for the tensile strength, since the degree of the polymer degradation directly correlates with the polymer strength. Figures 1a and 1b show that a mixture of **I** and **IV** ensures preservation of the strength of PP and HDPE at higher level as compared to the stabilizers taken separately, which is apparently due to the synergistic effect detected in thermal oxidation. The optimal content of the stabilizing composition is 0.2 wt %.

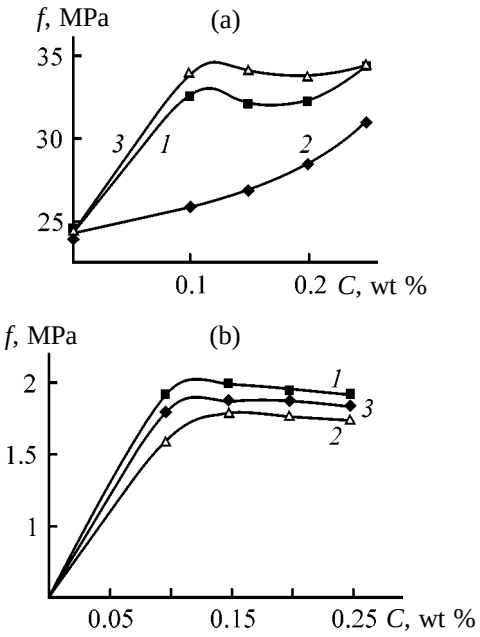

Fig. 1. Tensile strength f of (a) PP and (b) HDPE 289-73 after thermomechanical degradation in a Brabender plasticorder as a function of the stabilizer content C. Stabilizer: (*1*) **I**, (*2*) **IV**, and (*3*) **I** + **IV** (3 : 2).

Thus, new stabilizing compositions phenol–phosphites (Stafor 24) show promise as means to enhance the resistance of polyolefins to oxidative and thermomechanical degradation.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Polyurethane Binders for Condensed High-Energy-Content Systems

V. V. Bestuzheva, N. K. Nalimova, and I. V. Tselinskii

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received May 10, 2001

Abstract—A procedure was developed for preparing poly(ethylene, butylene) glycol adipate urethane plasticized with 1,5-diazido-3-nitrazapentane. The correlation between the conditions of the polymer synthesis and its physicomechanical properties was studied, and the prospects for using the product as a component of condensed high-energy-content systems were evaluated.

Because of the specific features of preparation and use of mixed solid propellants (MSPs), the polymeric combustible binders used as their components should exhibit a wide set of difficultly compatible properties. The most important of them are high levels of energetic and physicomechanical parameters, operation at both positive and negative temperatures, low initial viscosity, and the capability to polymerize at moderate temperatures.

During the progress of rocket engineering, several generations of MSPs have changed. These MSPs were based on polyurethanes [1–3]. An interest in polyurethanes as MSP components is due to the possibility of controlling their characteristics by varying the nature and ratio of the reactants (mainly polyesters and diisocyanates) involved in the elastomer formation [4].

With time, the possibilities of traditional polyurethanes with respect to energetic characteristics became exhausted, and efforts were made for their modification. As a rule, the modification involved introduction of high-energy-content groups (nitro, nitrato, azido) into the polyester moiety of the macromolecule or plasticization of hydrocarbon polyurethane elastomers with high-energy-content compounds, mainly with nitrate esters of polyhydric alcohols [5].

One of the major principles of formulating propellants of a new generation is decreasing the content of toxic and smoke-forming elements in the combustion products. Such elements give rise to environmental problems, reveal the missile on the flight trajectory, and comlicate the use of modern optical, laser, and infrared guidance means. From the viewpoint of the composition of combustion products, of particular interest among high-energy-content compounds are azides. A combination in a binder formulation of the advantages of polyurethanes with the possibilities of azide compounds appreciably improves the principal service characteristics of MSPs based on such binders.

In this work we studied the conditions for preparing poly(ethylene, butylene) glycol adipate urethane plasticized with 1,5-diazido-5-nitrazapentane within a single process by the reaction of urethane formation in a medium of the low-viscosity plasticizer. Improvement of combustible polyurethane binders by their plasticization seems to be one of the most promising routes, because the raw materials are available and the existing production facilities are suitable for the process.

EXPERIMENTAL

The choice of the initial components was governed by their energetic performance, availability, and expected capability to ensure the highest possible level of physicomechanical properties of the products.

As hydroxy component we chose P6-BA linear polyester, which is prepared by reaction of ethylene and butylene glycols with adipic acid, following a common pattern of polycondensation of dihydric alcohols with dibasic acids [6]. We took into account the facts that polyesters, as compared to polyethers, form more robust macromolecules in reactions with diisocyantes; that the molecular weight of the hydroxy component plays a decisive role in formation of elastic properties; and that bifunctional polyesters, as compared to trifunctional compounds, can giver a wider set of three-dimensional structures owing to the use of

MDI	1.1	0.23	600
	1.2	0.27	610
	1.3	0.34	750
	1.4	0.36	750

* Plasticizer content 50 wt %, triol mole fraction 0.3, catalyst DBTDL (0.3 wt %).

cross-linking additives. The characteristics of P6-BA were as follows: *M* 2000, density 1200 kg m^{-3}, enthalpy of formation –4300 kJ kg^{-1}; prior to reaction with the diisocyanate the oligomer was dried to a moisture content no higher than 0.04 wt %.

The following diisocyanates, purified by distillation, were used: aliphatic hexamethylene diisocyanate (HMDI), aromatic 2,4-toluylene diisocyanate (TDI), and alkylaromatic 4,4'-methylenebis(phenyl isocyanate) (MDI).

As cross-linking agents we used glycerol (Gl) and trimethylolpropane (TMP), which were preliminarily dried over P_2O_5, and as catalyst, dibutyltin dilaurate (DBTDL).

As plasticizer we used 1,5-diazido-3-nitrazapentane (AP) purified chromatographically in a column packed with OU activated carbon of grade A; the properties of the compound were as follows: refractive index at 20°C 1.5260, density 1330 kg m^{-3}. bp 124°C/5 Pa, enthalpy of formation 2490 kJ kg^{-1} [7].

The procedure for preparing plasticized polyurethanes was as follows: A sample of the polyester was heated in a vacuum at 110°C to remove moisture and then cooled to 60°C, after which the required amounts of the diisocyanate, triol, and catalyst were added. After mixing of the components, the plasticizer was added, and the mixture was kept under the same conditions for 15–20 min and then either kept in sealed fluoroplastic molds at 60 ± 2°C for 10 days to obtain polyurethane samples for tests or transferred into a mixer to prepare the fuel compound.

The cured polyurethanes were tested by generally accepted procedures: the ultimate tensile strength and the relative elongation were determined according to GOST (State Standard) 269–66, the glass transition point, according to GOST 12254–66, and the density, according to GOST 267–73. The enthalpy of formation was calculated from the structural formulas of the compounds taking into account thermodynamic corrections for specific groups and bonds [8].

The shock sensitivity was evaluated with a K-44-II impact machine by the lower limit in device no. 2; the friction sensitivity, with a K-44-III pendulum impact machine; and the gas release at static heating, with a Burdon gage.

The goal of this study was to obtain in a single process polymeric plasticized binders with a high level of energetic properties and satisfactory physicomechanical characteristics. For this purpose, it was necessary to reveal the qualitative and quantitative composition of the polymeric component ensuring formation of a maximally strong three-dimensionally cross-linked matrix capable of retaining the maximal amount of the plasticizer.

For tentative quantitative evaluation of the extent of thermodynamic compatibility of the chosen polymer and plasticizer, we prepared a cured polyurethane by reaction of poly(ethylene, butylene) glycol adipate with TDI in the presence of TMP (molar ratio P6-BA : TMP = 70 : 30, NCO : OH = 1 : 1). For this product we determined the limiting content of the plasticizer by equilibrium swelling [9]. We found that the system under consideration preserves its physical stability at 20°C at an azide content of up to 69.8 wt %. Since in what follows we used a procedure involving formation of the macromolecular matrix under conditions when the plasticizer was present in the reaction medium, which ensured more favorable spatial distribution of the solid and liquid phases, we expected that the structure formed in this case would be no less stable thermodynamic ally.

However, before synthesizing compounds with the maximal plasticizer concentration, it was necessary to optimize their physicomechanical parameters depending on the nature and ratio of the reactants forming the polymeric matrix.

To determine how the ultimate tensile strength *X* and relative elongation ε of the plasticized polyurethane are influenced by the nature and amount of the diisocyanate used, we prepared elastomers whose composition and properties are listed in Table 1.

When the ratio of the isocyanate and hydroxy groups in the reaction mixture is less than 1.1, mech-

anically strong samples cannot be prepared under the chosen curing conditions, irrespective of the nature of the diisocyanate. At the molar excess of the diisocyanate increased to 1.3, both the strength and elasticity of polyurethanes increase. Further increase in the NCO : OH ratio have no noticeable positive effect. The best physicomechanical properties, under equal other conditions, are attained with TDI; with HMDI and MDI the results are worse.

Our results show that, to prepare elastomers with the required set of properties, it is appropriate to use toluylene diisocyanate and take it in a 30% molar excess relative to the polyester.

The effect of cross-linking agents on the physicomechanical characteristics of the combustible binders is seen from Table 2.

The polyurethanes prepared with TMP surpass in the strength and elastic parameters the samples prepared with glycerol as the cross-linking additive; the optimal mole fraction of triol relative to a total of hydroxyl-containing agents, when urethane synthesis is performed in the medium of the chosen plasticizer, is 0.30–0.35.

Our next goal was preparation of physically stable elastomers containing an increased amount of the plasticizer. In Table 3 are given data characterizing, along with the strength and elasticity, also the density (ρ), frost resistance (T_g), and enthalpy of formation (ΔH) of polyurethanes containing bound AP (50–75 wt %).

The shock sensitivity of the cured samples (fall of a 10-kg load from a height of 250 mm) is 20–30% depending on the plasticizer content. The gas release at 60°C in 20 days does not exceed 5 $cm^3\ kg^{-1}$.

Thus, the main energetic and service parameters of the plasticized polymers prepared make them promising as MSP components.

CONCLUSIONS

(1) By directed formation of a three-dimensional polymer network, it is feasible to prepare in one process thermodynamically stable poly(ethylene, butylene) glycol adipate urethane modified with 50–75% 1,5-diazido-3-nitrazapentane.

(2) The high-strength elastic matrix ensures the required set of physicomechanical properties, and the azido nitro plasticizer, the high energy content and favorable composition of the combustion products. These factors make the developed compounds promising as combustible binders for mixed solid propellants.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Regiospecificity of Reactions of Vinyl Chloride–Maleic Anhydride Copolymer with Dimethylformamide

M. S. Safronova, E. M. Berezina, G. A. Terent'eva, E. B. Chernov, and A. G. Filimoshkin

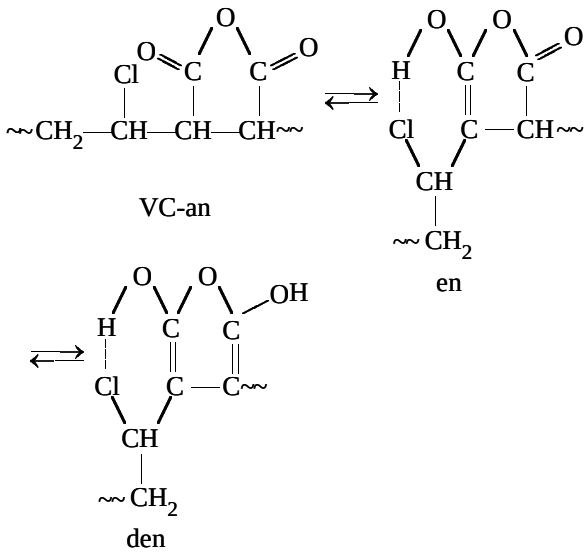
Tomsk State University, Tomsk, Russia

Received January 26, 2001

Abstract—Interaction of macromolecules of vinyl chloride–maleic anhydride copolymer with dimethylformamide molecules was studied by kinetic, thermodynamic, and spectroscopic methods.

Polymers and copolymers of maleic anhydride exhibit a wide spectrum of valuable properties and show much promise. For example, copolymers of maleic anhydride (MA) with vinyl chloride (VC) readily enter into various reactions and are convenient initial substances for synthesis of new copolymers used as carriers for biologically active substances and enzymes, ion exchangers, photographic and pharmaceutical materials, blowing agents, lubricants, etc. [1, 2].

Macromolecules of VC–MA copolymer in organic solvents exhibit cyclic anhydride–enol tautomerism (CAET) with spontaneous formation from VC and anhydride (an) units of enol (en) and dienol (den) units [3, 4]:



The latter species, for example, instantaneously react with sodium azide in dimethylformamide (DMF) to form structures that immediately decompose, acting as intermediates in dehydrochlorination of VC–MA [5].

Dimethylformamide as bipolar aprotic solvent is widely used in industry, scientific research, and laboratory practice. Interaction of VC–MA with DMF is of scientific and practical interest. VC–MA copolymer readily dissolves in DMF; within 10–15 min, the solution becomes colored, and two new overlapping absorption bands (λ_{max} 530 and 560 nm) appear in the electronic spectra. The optical density of these bands reaches a maximum in several hours and remains constant for 5 days, which suggests formation of stable solvation complexes of DMF molecules and en and den tautomers [6]. At the same time, evolution of HCl is detected throughout the observation period. Comparison of these two facts suggests that, in contrast to reactions with sodium azide, dehydrochlorination and solvation of VC–MA macromolecules with DMF occur concurrently in different units of microstructurally nonuniform VC–MA macromolecules and are regiospecific.

By regiospecificity we mean a definite orientation (among numerous alternatives) of DMF molecules relative to the corresponding units of microstructurally nonuniform VC–MA macromolecules, with subsequent concerted rearrangements of atoms and bonds. Typical regiospecific reactions are, e.g., the Diels–Alder reaction and 1,3-dipolar cycloaddition [7].

In this study we examined qualitatively and quantitatively the regiospecificity of solvation and dehydrochlorination of VC–MA macromolecules in DMF.

1070-4272/01/7409-1554$25.00

EXPERIMENTAL

VC–MA was prepared and identified according to [3]. We used the copolymer with an equimolar ratio of VC and an units. Dimethylformamide was thoroughly purified [8]. The degree of dehydrochlorination was determined by potentiometric titration with an $AgNO_3$ solution (I-120 pH meter, silver electrode).

For kinetic studies, a 0.2200-g sample of the copolymer was dissolved in 22 ml of temperature-controlled DMF. At definite intervals, 2-ml samples were taken, to which 16 ml of water was added, and the solution was quickly titrated with an $AgNO_3$ solution. Experimental points in the kinetic curves were obtained from no less than three runs.

The ^1H NMR spectra of a 1 m solution of VC–MA in DMF-d_7 were taken on a Tesla BS-487 spectrometer (100 MHz, HMDS).

The time dependence of the optical density originating from the accumulated solvation structures [VC–MA·DMF] at a fixed wavelength (λ = 560 nm) was described previously [6].

As already noted, in solutions of VC–MA in DMF the solvates are formed concurrently with dehydrochlorination. An attempt to describe the kinetic curves of HCl accumulation (Fig. 1) by the equation [9]

$$[HCl] = [HCl]_{max}[1 - \exp(-k\tau)]$$

failed, which indicates that HCl is released in several parallel reactions and/or its elimination is preceded by a catalytic process. We suggested that HCl is released both from VC units under the action of DMF, which is known to exhibit a high dehydrochlorinating power, in particular, toward PVC [10], and from the solvates [VC–MA·DMF] (S) when they are decomposed with water prior to titration. Dehydrochlorination of VC–MA could be adequately described with the equation

$$[HCl] = [HCl_{VC}]_{max}[1 - \exp(-k_{HCl}\tau)] + [S]_{max}[1 - \exp(-k_S\tau)],$$

where [HCl] is the concentration of HCl eliminated from VC units (HCl_{VC}) and solvates (HCl_S) under the action of water, assuming that $[HCl]_S = [S]$; k_{HCl} and k_S are the rate constants of dehydrochlorination and solvate formation, respectively; $[HCl]_{max}$ and $[S]_{max}$ are the concentrations of HCl and the solvates, respectively, at $\tau \to \infty$.

Computer decomposition of experimental kinetic curves of HCl elimination (Fig. 1) into the curves corresponding to the two above-mentioned pathways allowed construction of the calculated kinetic curves of HCl_{VC} elimination from VC–an units (Fig. 2) and of the solvate accumulation (Fig. 3).

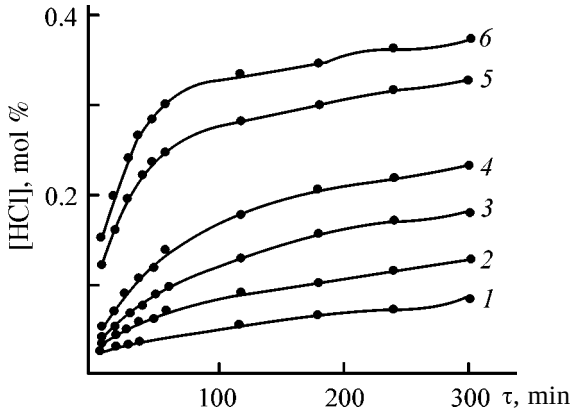


Fig. 1. Concentration of HCl [HCl] released in total from VC–an units and from solvate structures as a function of time τ. Temperature, °C: (*1*) 14, (*2*) 25, (*3*) 34, (*4*) 44, (*5*) 64, and (*6*) 74; the same for Figs. 2 and 3.

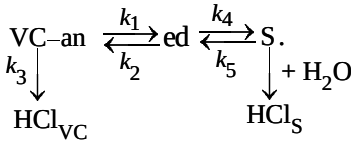
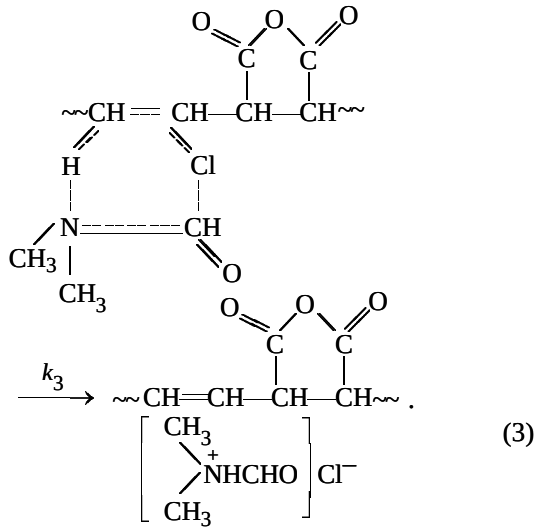
28 models including elementary stages with participation of VA–an, en, den, and ed units (ed denotes en and den in total). The smallest dispersion between the calculated and experimental data (Fig. 1) was obtained for the model



(2)

The mechanism of dehydrochlorination of VC–an units under the action of DMF, by analogy with the mechanism of PVC dehydrochlorination [10], can be represented as follows:



(3)

The kinetic curves (Fig. 1) were processed using a system of differential equations

$$d[VC–an]/d\tau = -(k_1 + k_3)[VC–an] + k_2[ed],$$

$$d[ed]/d\tau = k_1[VC–an] + k_5[S] - (k_2 + k_4)[ed],$$

$$d[HCl]/d\tau = k_3[VC–an],$$

$$d[S]/d\tau = k_4[ed] - k_5[S],$$

which was integrated by the Rosenbrock's implicit method at the initial concentrations $[S]_0 = [HCl]_0 = 0$. The initial concentrations $[VC–an]_0$ and $[ed]_0$ were determined by the optimization procedure [5]. In the range 14–44°C they correspond to $[VC–an]_0$ and $[ed]_0$ in the initial solid sample of the copolymer [11, 12]. A sharp increase in $[ed]_0$ above 44°C at the expense of decrease in $[VC–an]_0$ (see table) may be due to a catalytic effect of DMF on conformational and configuration transitions resulting in additional formation at these temperatures of CAET products, ed tautomers (1), whose content approaches the maximum possible level. Further increase in the content of such fragments is hindered thermodynamically (see table, k_1 values at T = 14–73.9°C).

Calculations showed that formation of ed forms (2) is irreversible, $k_2 \approx 0$. This may be due to formation of a stable six-membered ring with an intramolecular hydrogen bond (IMHB) C–O–H···Cl, ultimately stabilizing the quasiaromatic den structure (1). The high stability of these ensembles may be due both to the cooperative effect of regiospecific interaction of ed tautomers with DMF molecules [6], manifested in the solvates, and to delocalization of the electron density in conjugated five- and six-membered rings (1) [13].

With increasing temperature, the inter- and intramolecular hydrogen bonds become weaker, and k_1, correspondingly, decreases (see table). The constants k_3 remain practically constant up to 44.2°C, being about 1×10^{-4} s^{-1}, and above this temperature the rate of dehydrochlorination by mechanism (2) increases by a factor of approximately 6.

The complex temperature dependence of the order n of solvate formation reaction

T, °C	14.0 ± 1.0	25.5 ± 0.1	34.4 ± 0.1
n	0.28	0.43	0.68
T, °C	44.2 ± 0.1	64.1 ± 0.1	73.9 ± 0.1
n	0.96	0.94	1.44

and of the experimental coefficient of the reaction rate k_e, calculated from the equation

$$d[S]/d\tau = k_e[S]^n,$$

suggests occurrence of an effect apparently related to regiospecific concerted interactions of the reactants, similar to those observed in enzymatic or homogeneous catalytic reactions. For the latter case, Arrhenius dependences are not followed even in a narrow temperature range [14]. Furthermore, on heating the rotation of the dimethylamino [$(CH_3)_2N$] and aldehyde (CHO) groups around the N–C bond in DMF molecules becomes sufficiently fast, and at temperature of about 100°C the shape of the methyl proton signals in the ^{1}H NMR spectrum of neat DMF changes considerably. This fact suggests that at elevated temperatures the molecular structure of DMF changes. The difference between the structures of DMF molecules at low and high temperatures consists in that the conformers become indiscernible in the NMR time scale [15].

The solvates dissociate into the initial components at a rate considerably exceeding the rate of their formation: $K = k_4/k_5 < 1$. The equilibrium constant K slightly increases with temperature (see table); the activation energy E_a of the direct reaction of formation of the solvate structure is as low as 2597 J mol^{-1}, and that of the reverse reaction, 1366 J mol^{-1}. To compare, the activation energy of dehydrochlorination of VC–an units is about 40 000 J mol^{-1}, and that of dehydrochlorination of VC units of PVC in DMF solution, 92 000–97 000 J mol^{-1} [10].

The very low free energies, ΔG_T from 5378 to 3963 J mol^{-1}, of formation of the solvation structures characterize the process as practically equilibrium, with ΔH = 1186 J mol^{-1} and ΔS = 23.54 J mol^{-1} K^{-1}. That is, the solvate formation is entropy-controlled, i.e., it involves a definite favorable ($\Delta S > 0$) orientation of the partners prior to the reaction. It is interesting to compare the reactions of VC–MA with sodium azide, which, despite a phenomenologically similar reaction pattern, show significant quantitative differences. Comparison at similar temperatures of the rate constants and free energies of solvate formation of VC–MA with DMF, on the one hand, and of reactions of VC–MA with NaN_3 [5], on the other hand, shows that the latter reaction is by a factor of almost 3300 faster than solvate formation of VC–MA with DMF: $k_{DMF} = 4.8 \times 10^{-6}$ s^{-1} and ΔG_{DMF} = 5378 J mol^{-1} (see table); $k_{NaN_3} = 1.57 \times 10^{-2}$ s^{-1} and ΔG_{NaN_3} = –19 900 J mol^{-1} [5].

Scheme (2) contains no information about the nature of solvates formed by DMF molecules with ed tautomers containing OH groups. These groups, apparently, play a decisive role in regiospecific interactions with DMF, similar to their role in enzymatic or homogeneous catalytic processes. The ^{1}H NMR monitoring of the interaction of VC–MA with DMF showed that, on storage of the solution for 620 h, the signal of the OH protons is significantly (by 3.76 ppm) shifted downfield, with its integral intensity remaining practically constant:

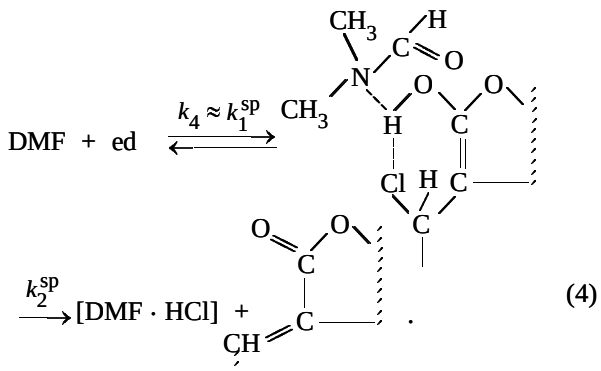
τ, h	0	6	29	163
δ, ppm	7.74	8.28	9.26	10.70
Δδ, ppm	0	0.54	1.52	2.96
τ, h	285	360	456	620
δ, ppm	11.10	11.26	11.35	11.50
Δδ, ppm	3.44	3.52	3.61	3.76

Computer simulation of the time dependence of Δδ was performed by the equation describing two parallel reactions:

$$\Delta\delta = \Delta\delta_1[1 - \exp(-k_1^{sp}\tau)] + \Delta\delta_2[1 - \exp(-k_2^{sp}\tau)],$$

where $\Delta\delta_1$ and $\Delta\delta_2$ are the changes in the chemical shift at $\tau \to \infty$ due to the first and second reactions, respectively; k_1^{sp} and k_2^{sp} are the rate constants, determined by ^{1}H NMR spectroscopy, of the reactions responsible for the shift of the enol proton signals.

Calculation showed that the chemical shift of the OH protons changes owing to two parallel reactions with the rate constants differing by almost an order of magnitude: $k_1^{sp} = 0.093 \times 10^{-4}$ and $k_2^{sp} = 0.01 \times 10^{-4}$ s^{-1}. A striking feature is coincidence of the rate constants at 25.5°C: $k_4 = 0.1 \times 10^{-4}$ and $k_1^{sp} = 0.093 \times 10^{-4}$ s^{-1}, with the first constant (constant of formation of the solvate structures) being determined from the potentiometric titration data with subsequent mathematical simulation and the second, by ^{1}H NMR spectroscopy. Apparently, solvate formation (2) involves proton transfer from the hydroxy group of the ed forms to the nitrogen atom of DMF. Then this solvate spontaneously, at an order of magnitude lower rate ($k_2^{sp} = 0.01 \times 10^{-4}$ s^{-1}), decomposes to give DMF hydrochloride and the elimination product which is an isomer of the product shown in scheme (3):



(4)

The regiospecificity of the interaction of VC–MA with DMF at 25.5°C was quantitatively characterized by a higher (by a factor of 7.3) rate of dehydrochlorination of VC units (3) as compared to the rate of solvate formation (4): $k_3 = 0.73 \times 10^{-4}$ and $k_4 = 0.1 \times 10^{-4}$ s^{-1}, respectively. The curve of dehydrochlorination of the VC–an units flattens out within 60 min in the entire temperature range studied (Fig. 2), whereas the curve of the solvate accumulation reaches saturation at 74°C only in 300 min (Fig. 3). It is important that the apparent rate coefficients k_e of formation of the solvation structures, one of which was determined from the potentiometric titration data in this work and the other, by electronic spectroscopy in [6], are close: 0.68×10^{-4} and 0.60×10^{-4} s^{-1}, respectively.

CONCLUSIONS

(1) Cyclic anhydride–enol tautomeric transformations of monomeric units in macromolecules of vinyl chloride–maleic anhydride copolymers in dimethylformamide occur irreversibly with subsequent regiospecific formation of long-lived solvate structures involving dimethylformamide molecules and ed forms of the microstructurally nonuniform macromolecules.

(2) The vinyl chloride–an units that do not participate in prototropic transformations undergo dehydrochlorination in dimethylformamide at 25.5°C by a factor of 7.3 faster as compared to formation of the solvate structures between the ed units and dimethylformamide molecules.

(3) Dehydrochlorination of different segments of the microstructurally nonuniform vinyl chloride–maleic anhydride copolymer yields different isomers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Ionic Strength on the Degree of the Form Asymmetry *p* of Poly-2-acrylamido-2-methylpropanesulfonic Acid Macromolecule in Dilute Aqueous-Salt Solutions

S. V. Valueva and A. I. Kipper

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received April 10, 2001

Abstract—Dilute aqueous-salt solutions of macromolecular flexible-chain polyelectrolyte, poly-2-acrylamido-2-methylpropanesulfonic acid, were studied by the method of flow birefringence, viscometry, and light scattering. The degrees of the form asymmetry *p* of poly-2-acrylamido-2-methylpropanesulfonic acid macromolecules determined by this method for ionic strengths I = 1–0.05 M were compared with the main results of theoretical and experimental studies of the *p*–*I* dependence.

The activity of ionic polymers is known to be dependent not only on the properties of their macromolecules (chemical composition, molecular weight, ridigity, conformation, content of ionic groups) but also on the characteristics of the medium (ionic strength I, pH, etc.).

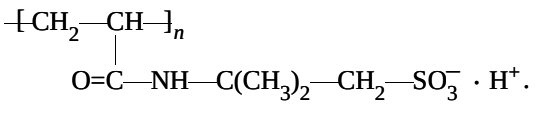
Water-soluble polymers based on acrylic compounds are widely used in diverse branches of economy. High degree of dissociation of poly-2-acrylamido-2-methylpropanesulfonic acid (PAMPS) makes it, e.g., an efficient coagulant able of operating in a wide range of I and pH values [1].

In [2] we studied the degree of form asymmetry *p* of macromolecule of 2-acrylamido-2-methylpropanesulfonic acid copolymer with acrylamide [P(AMPS–AA)] as dependent on the ionic strength. The content of ionic groups amounted to 20%.

The aim of this work is to quantitatively determine by the method of flow birefringence (BR) the degree of the form asymmetry *p* of the PAMPS homopolymer macromolecule (content of ionic groups 100%) at I = 1 M (the case of suppressed electrostatic interactions) and in the region of moderate ionic strengths (0.1 and 0.05 M). As known [3–5], the major role here is played by long-range electrostatic interactions (bulk effects in macromolecules of electrostatic nature), and the percolation effect (changes in the equilibrium rigidity of the polymer chain A) is negligible (A = const).

EXPERIMENTAL

The subject of the study was macromolecular ($M_w = 4.6 \times 10^6$) flexible-chain (A = 2 nm [1]) homopolyelectrolyte PAMPS



The PAMPS polymer was obtained by a standard procedure [6] by radical polymerization using the Co(III)–glycine system. The residual monomer and other impuruties were removed by dialysis of the resulting product. The polymer was isolated by lyophilic drying.

The flow BR Δn as dependent on the rotor rotation rate gradient g, polymer concentration c, and ionic strength of the medium l was measured by a procedure reported in [7]. We used a titanium dynamooptical caliper with an 4-cm-high internal rotor and the rotor–stator gap of 3×10^{-2} cm. The inaccuracy in measuring the intrinsic flow BR $[n]$ (or optical shift coefficient $[n]/[\eta]$) was about 10%.

The experimental $[n]$ value (in the general case of $dn/dc \neq 0$, where dn/dc is the increment of the refractive index of solution) is composed of three effects: $[n] = [n]_e + [n]_{fs} + [n]_f$, where $[n]_c$ is the intrinsic anisotropy, $[n]_{fs}$ is the micro form effect, and $[n]_f$ is the macro form effect [7]. The full segment anisotropy $[n]_e + [n]_{fs}$ is governed by the parameter A and structure of the monomer unit. The $[n]_f$ parameter is re-

1	5.0	24.0	120	2.4
0.1	9.0	78.0	702	5.6
0.05	10.5	90.5	950	6.7

where M is the molecular weight, n_s is the refractive index of the solvent, T is the absolute temperature, R is the universal gas constant, and $f(p)$ is the tabulated function of the relation of the axes of rigid (not flown through by the solvent) ellipsoid approximating the macromolecule [7].

For high-molecular-weight flexible-chain polymers with low weight and insignificant anisotropy of monomer unit, holds $[n]_e \ll [n]_f$, $[n]_{fs} \ll [n]_f$ (or at $[n]_e < 0$ and $[n]_e \approx [n]_{fs}$), the approximate relation $[n] \approx [n]_f$ holds, which allows indirect determination of the parameter p from the experimental data [7].

The molecular weight M_w was determined by the light scattering method [7] using a Fica photogoniodiffusometer at the wavelength of vertically polarized incident light of 546.1 nm in the concentration range $c \sim (0.01–0.1) \times 10^{-2}$ g cm^{-3} (we studied dilute solutions with $c \le c^*$, where c^* is the concentration of units in a polymer globule [8]) and angles (relative to the direction of incident light) θ = 30°–150°. The refractive index increment dn/dc was determined from refractometric measurements on an IRF-23 instrument. The experimental results were proceesed by the Simm's double extrapolation method [9]. The measurements inaccuracy was about 10%.

Viscometric measurements were carried out in an Ostwald capillary viscometer with the water outflow time of 120±0.2 s at 21°C. The intrinsic viscosity $[\eta] = [(\eta_r - 1)/c]_{c\to 0} = (\eta_{sp}/c)_{c\to 0}$ (ν_r is the relative viscosity) was determined accurately to within 3%. We studied dilute solutions only.

Experimental dependences of the reduced viscosity η_{sp}/c on the polymer concentration show that for aqueous-salt solutions of PAMPS at $c \le c^* \sim 1/[\eta]$ and I = 1–0.05 M η_{sp}/c is a linear function of c (Fig. 1). This fact suggests that the size and form of the polyions remain unchanged after dilution of the solution [10–12]. Viscometric data (see table) evidence a fairly strong polyelectrolytic swelling of the polyions with decreeasing I.

PAMPS solutions exhibit positive flow BR over the whole region of c and I studied. The $\Delta n = f(g)$ dependences for $g < g_k$ (g_k is the rate gradient corresponding to flow turbulence) are linear and pass through the origin, whatever the c ($c \le c^*$) and I values. This suggests the molecular dispersity of solutions [7] (e.g., Fig. 2 presents the dependences for PAMPS in 0.05 M $NaNO_3$ solution).

Figure 3 presents the concentration dependences of the reduced anisotropy $\{\Delta n/[g\eta_0(\eta_r - 1)]\}_{g\to 0}$ (η_0 is

the solvent viscosity) for PAMPS at $c \le c^*$ and I = 1–0.05 M. It is seen that the $\{\Delta n/[g\eta_0(\eta_r - 1)]\}_{g\to 0}$ parameter in all cases decreases with increasing polymer concentration. As known [7], such a dependence in the region of relatively small concetrations c ($c \le c^*$) is due to a decrease in the anisotropy of the polymer molecule form (macro form effect) in the solvent with $dn/dc \neq 0$ (for PAMPS dn/dc = 0.133 cm^3 g^{-1}). This is typical for flexible-chain polymers. This phenomenon is due to the fact that enhancement of the "optical interaction" of macromolecules with increasing solution concentration is responsible for a decrease in the effective form anisotropy of the coil Θ_1^* (anisotropy of the macro form at the final value of the solution concentration) [7].

Thus, for solutions studied the macro form effect plays the decisive role.

The table presents the optical coefficient of the shift $[n]/[\eta] = \{\Delta n/[g\eta_0(\eta_r - 1)]\}_{g\to 0}$, as well as the intrinsic flow BR $[n]$ values for different I values. It is seen that the parameter $[n]/[\eta]$ (and especially $[n]$) significantly increase with unfolding of the polyions owing to long-range electrostatic interactions.

In [13], we showed that at I = 1 M for PAMPS $([n]_e + [n]_{fs}) \ll [n]_f$, i.e., the approximation $[n] \approx [n]_f$ holds. The lack of percolation effect ($A \sim$ const) in the I range investigated makes this approximation valid for the ionic strengths of 0.1 and 0.05 M, respectively.

The table and Fig. 4 (curve *1*) present the degrees of the form asymmery p of the macromolecule obtained using relation (1) for PAMPS at different I values. It is seen that p increases by a factor of 2.8 (from 2.4 corresponding to the Gaussian coil to 6.7 corresponding to unfolded asymmetric coil) with the ionic strength decreasing from 1 to 0.05 M. This fact evidences a fairly strong influence of electrostatic interactions on the form of polyions, suggesting that bulk effects in poly ions differ from those in nonionic polymers, where swelling of the polymer coil owing to long-range forces does not markedly change the parameter p [7].

Thus, the conformation of macromolecular flexible polyion in dilute solutions with moderate ionic strengths differs significantly from both that of rigid rod with $p \gg$ 2–2.5 [10, 14–17] and that of Gaussian coil with p = 2–2.5 [18]. Our data confirm the conclusions made in [2, 19, 20] for flexible-chain polymers.

The increase in the parameter p in the region of moderate ionic strengths by a factor of almost 1.5 in

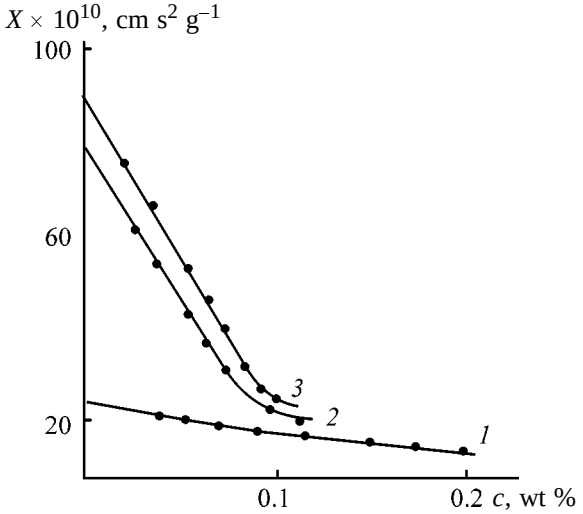

Fig. 3. Reduced anisotropy« $\{\Delta n/[g\eta_0(\eta_r - 1)]\}_{g\to 0} \equiv X$ as a function of polymer concentration c for PAMPS solutions of various ionic strengths.

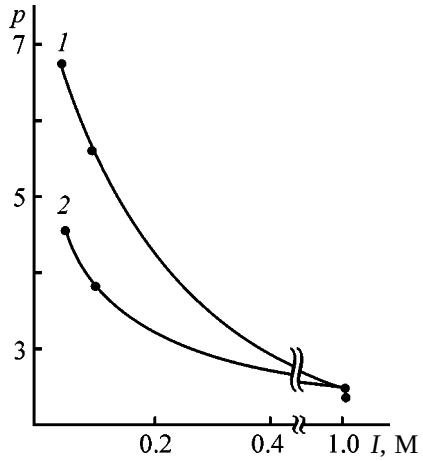

Fig. 4. Degree of form asymmetry p of macromolecules as a function of the ionic strength I for (*1*) PAMPS and (*2*) P(AMPS–AA) [2].

going from P(AMPS–AA) to PAMPS (Fig. 4) is due to increase in the amount of ionic groups (and, consequently, the degree of ionization of macromolecules in solution). As known [14, 21, 22], the number of ionic groups in homopolyelectrolytes of various structures that actually participate in polyelectrolytic swelling (groups with noncondensed counterions) is equal to 30–40%, which exceeds by a factor of 1.5–2 the amount of ionic groups in P(AMPS–AA) copolymer studied by us in [2].

CONCLUSIONS

(1) In the region of ionic strengths I = 1–0.05 M the degree of form asymmetry p of the of poly-2-

acrylamido-2-methylpropanesulfonic acid macromolecules varies from $p = 2.4$ corresponding to suppressed electrostatic interactions (Gaussian coil) to $p = 6.7$ at $I = 0.05$ M (unfolded asymmetric coil).

(2) The change in the parameter p of polyions with decreasing I correlates with the amount of ionic groups that actually participate in polyelectrolytic swelling (groups with noncondensed counterions).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Structural Transformation of Starch Hydrogels Exposed to Strong Mechanical Field

I. M. Lipatova, A. A. Yusova, S. V. Blokhina, and A. P. Moryganov

Institute of Solution Chemistry, Russian Academy of Sciences, Ivanovo, Russia

Received February 5, 2001; in final form, April 2001

Abstract—Structural transformations of starch hydrogels during mechanical preparation of starch gelatinous materials with a rotary pulse apparatus were studied. Two concentration regions distinguished by the structural transformations of starch hydrogels under high shearing stress were revealed.

Gelatinous materials prepared by cooking of starch dispersions to the required degree of cleavage are widely used in various branches of industry (textile, food, paper, building industry, etc.). One of the procedures for preparing finely dispersed starch gels is treatment of prepasted starch in a rotary pulse apparatus (RPA) operating well under industrial conditions, in particular, in mechanical preparation of starch schlich [1].

Previously we studied the degree of dispersion of starch grains, the size of colloid particles, the content of the water-soluble fraction, and the degree of starch cleavage as influenced by the conditions of mechanical treatment of starch pastes in RPAs. The aim of this work was to study the features of dynamic structurization of starch hydrogels under high shearing stresses and mechanical vibrations generated in RPA.

The behavior of a polymer–solvent system in a mechanical field is extensively studied [3–6]. The majority of works on this point concern conformational transformations of rigid- and flexible-chain polymers in dilute solutions [4, 5]. The influence of the shearing stresses on abnormally viscous polymeric systems was studied to a lesser extent. In particular, one of these works concerns phase transformations of ordered solutions of polymers, initiated by a mechanical field [6].

The influence of a mechanical field on such practically important systems as starch hydrogels was not studied comprehensively. This is likely due to the fact that starch hydrogels are very difficult to study owing to their fractional and phase nonuniformity, ready degradation, and the presence of chemical impurities which cannot be removed.

EXPERIMENTAL

We studied corn starch [GOST (State Standard) 7697–82]. Starch hydrogels (3–8 wt %) to be mechanically treated were prepared by cooking of a starch suspension on a water bath at T = 90°C for 7 min.

The starch hydrogels were mechanically treated at 80°C for 10 s on a laboratory rotary pulse activator (RPA) [2] at the rotor rotation rate of 3500 rpm, providing a 6×10^4 s^{-1} rate gradient.

Starch hydrogels were thermally hydrolyzed in the presence of NaOH and Chloramine B at concentrations of 0.1 and 0.12 g l^{-1}, respectively. The process was performed until Chloramine B was completely consumed.

The content of the water-soluble fraction of starch A (%) was determined by hot extraction [7]. The extract composition was analyzed by absorption of iodine complexes [8]. The content of the water-soluble fraction was expressed as the percent of the total starch concentration. The optical densities of the solutions were measured on a Specord M40 spectrophotometer.

Rheological properties of the starch hydrogels were determined with the aid of a Rheotest-2 rotary viscometer with a coaxial working unit. The rate gradient ranges from 1.5 to 1312 s^{-1}.

The sorption properties of starch before and after mechanical treatment were studied at 60–89°C on a Chrom-5 chromatograph with a flame ionization detector. Starch hydrogel (10.8 wt %) was applied to solid Chromaton N-AW support (0.25–0.31 mm) by evaporation of its solution. We used 1 m × 0.3 mm metal columns. The dead retention time was deter-

1070-4272/01/7409-1563$25.00

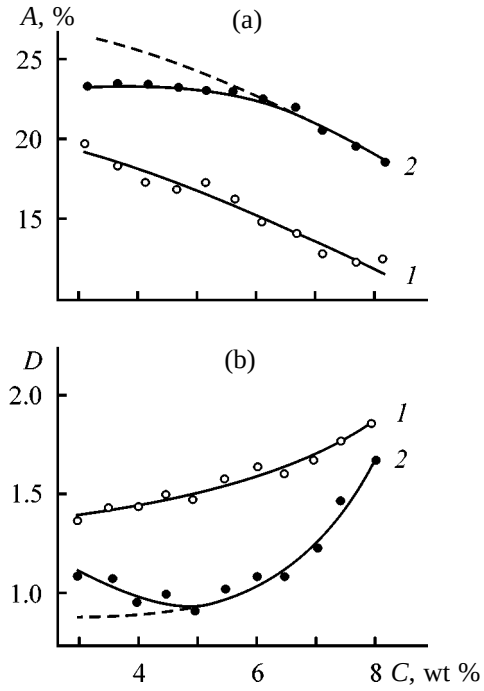

Fig. 1. (a) Content of the water-soluble fraction *A* and (b) optical density of starch hydrogels *D* (λ = 500 nm) as functions of the starch concentration *C* in (*1*) initial and (*2*) mechanically treated hydrogels.

mined with methane. X-ray diffraction study were performed on a DRON-2 diffractometer using CuK_α radiation. The degree of starch crystallinity was 16%.

The surface tension of starch hydrogel at the interface with air was measured with the aid of a Rebinder device [9].

The physicomechanical properties of the films prepared from starch hydrogels were determined on a PM-3-1 tensile-testing machine. Prior to the measurements the films were conditioned at 65% humidity in a hydrostat for 1 day. The film thickness was measured by a Schopper thickness gage.

The reactivity of mechanically activated starch was studied on a model reaction of starch oxidation with potassium permanganate in an acidic solution. The reaction rate was calculated from the decrease in the permanganate concentration measured spectrophotometrically on a Spekol 221 spectrophotometer at λ = 530 nm and *T* = 303 K [10].

The initial starch hydrogels (pastes) are microheterogeneous systems in which swollen starch grains are dispersed in true solution of the water-soluble fraction. Previously we showed [11] that starch grains are completely cleaved to form a new structure within the first 2–3 s of mechnaical treatment of starch hydrogels under definite conditions. We also found [2] that mechanically initiated chemical processes (degradation, cross-linking, oxidation) either do not occur or occur to a negligible extent at the above shearing stresses in the absence of chemical reagents. Thus, strong changes in the properties of starch hydrogels at shearing stress are mainly due to their structural transformations.

Mechanically treated starch hydrogel is also a microheterogeneous system in which the colloid-dispersed phase formed by fragments of starch grains is dispersed in the true solution of the water-soluble fraction. The content of water-soluble amylose in the initial samples monotonically decreases with increasing starch concentration (Fig. 1a, curve *1*) owing to decrease in its solubility. The diffusion of amylose macromolecules in the solution is facilitated and the fraction of the water-soluble polymer increases in the course of breakdown of starch grains during the mechanical treatment (curve *2*). In the absence of phase transformation in the dispersed phase of the hydrogel, curve *2* (Fig. 1a) should pass (dashed line) similarly to curve *1*, since in this case the amylose content in the solutions is determined only by its solubility which increases with decreasing total starch concentration. However, at low starch concentrations the fraction of water-soluble amylose is appreciably lower than the expected value. This fact can be explained as follows. Rigid-chain polymers including starch form aqueous systems with strong particle anisotropy and are readily oriented and associated [3]. At high shearing stresses produced in RPAs, asymmetric particles and separate molecules are ordered to form new supramolecular structures in starch hydrogel. As a rule, mechanically initiated association of polymers in solutions is an irreversible process [12]. Hence, in this concentration range the content of water-soluble amylose determined by the extraction procedure is underestimated.

This assumption is also confirmed by the concentration depenedences of the optical density of the initial and treated starch hydrogels (Fig. 1b). The treated hydrogels are more transparent owing to mechanical breakdown of the primary structure of the initial gels. However, the optical densities of hydrogels with low starch concentrations are lower than the expected values. This also indicates ordering and association processes in this concentration range. An increase in the optical density may be due to formation of solid nucleus. Both in the first and the second cases phase transformations under shearing stress become noticeable at the hydrogel concentrations lower than 5.5 wt %. Curiously, this concentration coincides with

that of the inflection point of the $\log\eta = f(\log C)$ function for the initial starch gels (Fig. 2) at two temperatures. This dependence is graphical interpretation of the Houwink–Klassen equation [13]. The inflection point of the curves shown in Fig. 2 separates two concentration regions with different flow mechanisms. The change in the flow mechanism with increasing starch concentration is due to formation of fluctuation physical network preventing ordering and association of the macromolecules.

Practical application of starch hydrogels (schlich and thickening) involves their drying at high temperatures. It is important to find out whether the structure with increased intermolecular interaction is retained in the dried films. Here we studied this problem by gas–liquid chromatography (GLC).

The main gas-chromatographic parameters are specific retention volumes V_g and differential heat of solution of a volatile standard (*n*-alkanol) in a polymeric amorphous phase ΔH. These parameters were calculated by the equation

$$\log V_g = -\Delta H/RT + B.$$

The contribution of the specific interaction to the total energy of solution was calculated as the difference of ΔH of the standard (*n*-alkanol) and *n*-alkane (which is dissolved without specific interactions) with the same length of the carbon chain or the same polarizability. The experimental and calculated data for the starch–*n*-alkane and starch–*n*-alkanol systems with the starch concentration in the initial and treated hydrogels of 3, 5, and 7 wt % are presented in Table 1.

As seen from Table 1, the mechanical treatment of pasted starch increases its nonspecific interaction with *n*-alkanes. This is due to degradation of the natural structure of starch grains during the mechanical treatment. The less pronounced effect was observed for the gels with the starch concentration of 7 wt %. This is likely due, as noted above, to the decrease in the degree of mechanical degradation of the initial structure with increasing starch concentration. The interaction of starch with aliphatic alcohols can be estimated from the difference $-\Delta\Delta H = \Delta H_2 - \Delta H_1$. The fact that starch retains *n*-alcohols by not only formation of hydrogen bonds with their hydroxy groups but also host–guest complexation with amylose [14] should be taken into account. As determined by the light absorption of iodine–starch complexes, the ability of starch to form inclusion compounds does not change after the mechanical treatment [2]. This indicates that the spiral sections of amylose macromolecules, involved in the complexation, are preserved after conformational transformations caused by shearing stress [8]. Hence, the decrease in the energy of specific interaction of mechanically treated hydrogels with *n*-alkanols is only due to rupture of the hydrogen bonds between the hydroxy groups of starch and the alcohols.

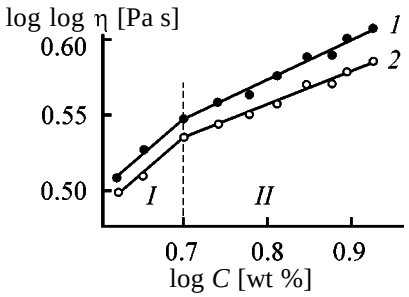

Fig. 2. Viscosity of starch hydrogels at (*1*) 30 and (*2*) 80°C as a function of the starch concentration *C*.

As seen from Table 1, the interaction of 3% gel with *n*-alkanols decreases to the greatest extent after mechanical treatment of the gel. This effect is considerably weaker for 5% gel and is almost absent in

the case of 7% gel. Thus, the GLC data suggest that mechanical treatment of starch hydrogels with low starch concentration decreases the number of free hydroxy groups in the starch. This effect decreases with increasing starch concentration.

The most important, from the viewpoint of practical application (in particular, in smoothing), structure-sensitive properties of mechanically cleaved starch gels are surface tension, film-forming ability, and, in some cases, reactivity of the starch. In this work we studied these properties as influenced by the structural transformations of starch hydrogels occurring in RPA.

One of the macroproperties of liquid polymeric systems, determined by intermolecular interaction, is surface tension. The surface tension of starch hydrogels can be higher or lower than that of water (σ^{80} = 6.26×10^{-2} N m^{-1}), depending on the energy of intermolecular interaction and the hydrogel structure. We measured the surface tension of mechanically treated and thermochemically cleaved starch hydrogels with various starch concentrations. The results are presented in Fig. 3. As seen from Fig. 3, there are two concentration regions. In the first region the surface tension of mechanically treated samples with low starch concentration is higher than that of thermochemically cleaved hydrogels. Conversely, at the starch concentration higher than 5.5 wt % the surface tension of mechanically treated hydrogels is lower than that of thermochemically cleaved samples. Thus, in the first concentration region the intermolecular interaction in the polymer–water system increases after the mechanical treatment, whereas in the second region the mechanical treatment weakens the intermolecular interaction.

Profound changes in the structure of starch hydrogels and in the phase composition of the system under strong shearing stress affect the film structure. The mechanical properties of the films are determined by the polymer cohesion. The concentration dependences of the physicomechanical properties of the films cast from mechanically treated starch hydrogels are shown in Fig. 4. The similar dependence for thermochemically cleaved starch is presented for comparison. The strength and elongation at break of the hydrogel with a low starch concentration slightly decrease after the mechanical treatment. We suggest that this is due to residual tension in the structure owing to incomplete relaxation after application of the shearing stresses. As noted above, this concentration region is characterized by the most pronounced conformation transformations.

The influence of mechanical treatment of starch hydrogels on the reactivity of starch hydroxy groups was estimated by starch oxidation with potassium permanganate in an acidic solution. For this purpose the reagents were introduced in a starch hydrogel immediately after its mechanical treatemnt. The results of the kinetic experiments are presented in Table 2.

As seen from Table 2, in the first concentration range (C = 3 wt %) the mechanical activation negatively affects the oxidation; in the boundary region the mechanical treatment has no effect on the starch reactivity; and in the second concentration range the starch reactivity increases after the mechanical pretreatment. One of the factors determining the rate of a chemical reaction is the accessibility of the functional groups, in our case, hydroxy groups. Under strong shearing stress at mechanical treatment, these groups can be released owing to degradation of the old structure and can form hydrogen bonds in the new structure. The decrease in the starch reactivity in the first concentration range can be due to a decrease in the number of accessible OH groups owing to mechanically induced

Table 2. Influence of mechanical pretreatment (MP) on the oxidation of starch with potassium permanganate

association to form new intermolecular hydrogen bonds. Since the associates formed under shearing stress are impermeable for chemical reagents, which is indicated by a decrease in the starch reactivity, they can be considered as crystallite-like structures.

The presence of three-dimensional fluctuation network in the second concentration region prevents ordering of the macromolecules and formation of new hydrogen bonds between dehydrated OH groups. As a result, the starch reactivity in the preactivated hydrogel increases owing to degradation of the initial structure.

CONCLUSION

Starch hydrogels can be subdivided into two groups by the nature of structural transformations occurring in these gels during treatment in a rotary pulse apparatus. In the first group (starch concentration 3–5 wt %) the surface tension increases, the starch reactivity decreases, and the film-forming properties are deteriorated after the treatment. In the second group (the starch concentration of 5–8 wt %) the surface tension decreases, the starch reactivity increases, and the physicomechanical properties of the films are improved after the treatment.

Abstract—Evolution of the supramolecular associate structure of moderately concentrated aqueous methyl and propyl methyl cellulose solutions, as dependent on the degree of substitution by propyl groups, is studied by the polarized light scattering using the Debye–Bueche–Stein theory.

Moderately concentrated aqueous solutions of cellulose mixed ethers, classified with self-associated polymeric systems, demonstrate a series of useful properties based on the possibility of forming physical thermally reversible gels. Methyl cellulose (MC) and propyl methyl cellulose (PMC) are gel-forming materials [1, 2]. The gelation temperature in aqueous MC solutions is influenced by such factors as the polymer concentration, degree of substitution, and degree of uniformity of substituent distribution in anhydroglucose units and along the macrochain [3].

Introduction of propyl groups into MC macromolecules decreases the gelation and phase separation temperatures, and increasing degree of substitution by propyl groups (DS_{Pr}) increases the solution viscosity, viscous flow activation enthalpy, and degree of structurization of the solution [2]. In this connection, it appeared interesting to study the effect of DS_{Pr} on the structure of the initial 1.5% aqueous PMC solutions using the polarized light scattering method (PLS).

Treatment of PLS data in terms of the Debye–Bueche–Stein statistical theory allows characterization of the supramolecular correlation in the structure of condensed polymeric systems using structural parameters determined from the experimental indicatrices of the isotropic V_V and anisotropic components (H_V) of light scattering in the range of large scattering angles (40°–140°). It was demonstrated previously [4–6] that data obtained by PLS allow also prediction of the structure of polymer solutions on the basis of the morphological characteristics of the polymer in the condensed state.

Gelation in moderately concentrated aqueous MC solutions is a two-stage process, as demonstrated by viscometry and the dynamic and low-angle neutron scattering methods [7, 8]. In the first stage (T < 45–50°C) hydrophobic supramolecular association occurs, resulting in formation of clusters. In the second stage (T > 45–50°C) a gel is formed. In this stage phase separation of the liquid–liquid type is accompanied by considerable change in the structural parameters of the system. Previously [9] these processes were studied by PLS in 1.5% solutions of MC in water and dimethylacetamide. Thus, the initial stage of gelation may be judged from data on the solution structure in the subgel range at 20°C.

In this work we studied the effect of DS_{Pr} on the structural features of 1.5% aqueous MC and PMC solutions at 20°C.

EXPERIMENTAL

The mixed propyl methyl cellulose ether was prepared from MTs-100 commercial water-soluble methyl cellulose [degree of polymerization (DP) 830; degree of substitution by methoxy groups (DS_{Me}) 1.62] according to the procedure described in [2]. The total degree of substitution was estimated as DS_t = 1.62 + DS_{Pr}. At DS_{Pr} > 0.35 PMC becomes insoluble in water as a result of considerable shift in the hydrophilic–hydrophobic balance of the macromolecules toward higher hydrophobicity. The structure at 20°C of conditioned 1.5% aqueous solutions of MC and PMC with DS_{Pr} of 0.09, 0.13, and 0.30 was studied by PLS with an FPS-3M photoelectric nephelometer. In experiments we used vertically polarized light (λ 546 nm) and measured the angular dependences of the anisotropic (H_V) and isotropic (V_V) components of the scattered light. Calibration was made by scattering in benzene. The Rayleigh ratio for benzene with incident

1070-4272/01/7409-1568$25.00

natural light was found to be 16.4×10^{-6} cm^{-1}. To characterize the supramolecular structure of the solutions, we estimated the parameters of the system in frameworks of the statistical theory [10] as applied to moderately concentrated solutions [11]. From the linear dependence $1/(V_V - 4/3H_V)^{0.5}$ vs. $\sin^2(\theta/2)$ we determined parameters characterizing the isotropic structure: mean squared fluctuation of the polarizability (density) $\langle\eta^2\rangle$ and the radius of the polarizability fluctuation correlation a_V characterizing the degree of inhomogeneity of the system and its correlation size.

From the linear section of the angular dependences of $1/(H_V)^{0.5}$ we determined the parameters characterizing the microanisotropic structure: mean squared density of the optical anisotropy of a scattering element of the bulk $\langle\delta^2\rangle$ and the orientation correlation radius a_H, characterizing the degree of structurization of the system and the dimensions of the oriented domains.

The angular dependences of the V_V component of scattering for 1.5% solutions reveal (Fig. 1a) that introduction of propyl groups changes the position and, to somewhat extent, slope of the curves; in the initial MC and at low DS_{Pr} the slope increases in the low-angle range (40°–90°). Similar data were obtained in [8] by the neutron scattering for moderately concentrated aqueous MC solutions at 20°C, indicating nonuniform spatial distribution of intermolecular interactions in the system. These results suggest that a wide series of associated structures exist in the subgel range. At the same time, dynamic light scattering in dilute solutions of MC reveals two populations of accociated macromolecules [12].

Anisotropic scattering data are given in Fig. 1b. It should be pointed out that the angular dependence of H_V for MC and PMC solutions with small amount of the propyl substituents passes through a maximum in the scattering angle range below 80°. In the high-angle range the intensity of anisotropic scattering H_V abnormally increases, which is not typical of polymeric systems with random fluctuations of the anisotropy. This fact can be attributed to the specific structural features of this MC sample, which contains nuclei of a microcrystalline phase, consisting essentially of trisubstituted MC units, in addition to large ordered associated structures [3. 7, 8]. With increasing fraction of the propyl groups the maximum in the angular dependence degenerates. Nevertheless, the shape of the H_V curve reveals two types of oriented domains in the system [5].

To understand whether such a distinct deviation of the angular dependence of H_V from linearity is associated with the solution structure or this effect is a consequence of incomplete dissolution of the polymer microparticles, all solutions were converted into gels by heating to 70°C and then frozen and allowed to stand for 1 day at –6°C and for 30 days at +5°C, to eliminate hysteresis of characteristics of the system on passing from the solution state to the gel state and backwards [9]. It is known that at low temperatures in solutions of macromolecules containing both hydrophilic and hydrophobic fragments, water molecules form chamber-like structures, surrounding hydrophobic (in our case the methyl and propyl substituents) fragments, thus eliminating the effect of the nonpolar groups on the polar solvent and providing preservation of the hydrophilic–hydrophobic balance [13]. At temperature of about 0°C the solubility of MC and PMC in water increases. On heating the

weakest H bonds between water molecules and oxygen atoms of the methoxy and propoxy groups break down, which results in strengthening of interactions between the macromolecules by their fragments mainly containing essentially highly substituted units. Thus, hydrophobic self-association of MC and PMC macromolecules occurs, initiating aggregation and phase separation.

The reversibility of the structural transformations in the systems was proved by manifold repetition of the cycle solution–gel–freezing–solution. The angular dependences of the H_V and V_V components of scattering for solutions of PMC with $DS_{Pr} < 0.3$ coincided within the experimental error. For the systems with $DS_{Pr} = 0.3$, i.e., at the critical content of the propyl groups (with regard to the solubility in water), we observed reproducible changes in the scattering intensity (Figs. 1a, 1b; curves *5*). Note that in frozen 1.5% MC and PMC solutions we observed a fine ice texture with well distinguished crystals. On cooling the solutions to 0°C the solubility of MC and PMC increases by virtue of hydration of the polymer macromolecules. At temperature below 0°C H bonds between water molecules and functional groups of the polymers break down, which results in formation of fluctuating domains of displaced structured water serving as nuclei of crystalline phase of ice [13].

The statistical parameters characterizing the effect of substitution of the hydroxy groups of MC by the propyl groups on the structure of the 1.5% aqueous solutions are given in Figs. 2 and 3. The results show that introduction of additional hydrophobic groups provides a three fold increase in $\langle\eta^2\rangle$ (Fig. 3, curve *1*) and increase in a_V from 400 (MC) to 700 Å (PMC; $DS_{Pr} = 0.30$) (Fig. 2, curve *1*). Note that previously we demonstrated that increasing content of the propyl groups in the macromolecules provides increase in the viscosity and degree of structurization of their solutions [2]. These results can be attributed to increasing intermolecular hydrophobic association with increasing DS_{Pr}, which is accompanied by separation of the solvent into particular domains [13]. The domains of intermolecular associates and solvent-rich domains have different polarizabilities, and with increasing a_V of denser domains (due to higher content of propyl groups) the microheterogeneity of the system $\langle\eta^2\rangle$ correspondingly increases. In [14] it was demonstrated that cellulose-based polymers containing critical (for solubility) content of hydrophobic groups are converted into gels at lower temperature, and the resulting gels have lower strength because of relatively higher heterogeneity of the system.

It is known that introduction of bulky alkoxy substituents into the cellulose macromolecule increases its equilibrium rigidity and changes the macrochain conformation, affecting the microanisotropic structure of moderately concentrated polymer solutions. Previously [9] we reported that in moderately concentrated MC solutions fluctuations of the anisotropy and orientation occur, and increasing amount of the propyl groups in the MC macromolecule provides growth in the intensity of anisotropic scattering in the experimental angle range. Thus, over the angle range from 40° to 80° $\langle\delta^2\rangle$ increases by more than an order of magnitude from 1.2×10^{-9} to 1.6×10^{-8} (Fig. 3, curve *2*). As noted above, it follows from the abnormal shape of the angular dependence of the anisotropic H_V component of scattering that the structure of the system can be described by two types of correlations (random and nonrandom) of orientation of optical axes of elementary scattering volumes. The parameters of microanisotropic structure of the first

type ($\langle\delta^2\rangle$ and a_H) were estimated from the initial slope of the H_V curve (Fig. 1b). The estimated values correspond to ordered regions 250–300 Å in size, which, in principle, is consistent with the Kuhn segment length of an individual macromolecule of a cellulose ether (a_H tends to decrease with increasing fraction of the propyl groups). This is caused by hindered orientation of coarser scattering elements (their anisotropy increases with increasing DS_{Pr}) as a result of reorganization of the system of polymer–solvent H bonds. Structures of the second type cannot be quantitatively characterized by PLS. However, X-ray diffraction analysis data for MC gels revealed that there are points of an ordered structure (crystallites) consisting of essentially trisubstituted MC units. The nature of intermolecular interactions of PMC chains in ordered (anisotropic) and amorphous (isotropic) domains can be different [3]. Therefore, it is a valid conclusion that two types of orientation correlation coexist in the solution: one near the nucleation centers of the microcrystalline phase and another in associates formed through hydrophobic association of macromolecular fragments. The experimental data show (Fig. 1b) that the inflection on the angular dependence of the H_V component of scattering becomes less pronounced with increasing fraction of the propyl groups, i.e., the effect of nucleation centers of the microcrystalline phase of MC on the nature of anisotropic scattering somewhat decreases with introduction of an additional hydrophobic substituent.

Turning to the study of the reversibility of the structure of 1.5% solutions of the mixed cellulose ethers, it should be pointed out that the statistical parameters of their structure are practically coincident at low DS_{Pr}.

At $DS_{Pr} = 0.3$ (critical value for solubility) freezing has an effect on both the isotropic and anisotropic structures: $\langle\eta^2\rangle$ and $\langle\delta^2\rangle$ tend to decrease, suggesting that performing the cycle solution–gel–freezing–solution makes the system more homogeneous and the scattering elements, less anisotropic. This is probably due to restoration of hydrogen bonds between OH groups, oxygen atoms of the methoxy and propoxy groups, and clusters of the polar solvent (water) which restores its tetrahedral structure at low temperature also [13]. At lower DS_{Pr} the structure of the polar associated solvent apparently plays a less significant role.

CONCLUSIONS

(1) Treatment of the structure of moderately concentrated methyl and propyl methyl cellulose solutions at 20°C (subgel region) in terms of the statistical theory of polarized light scattering revealed that increasing fraction of propyl groups, introduced as an additional hydrophobic agent, considerably increases the correlation size of microheterogeneity of the solution as a result of hydrophobic association.

(2) The solutions have a microanisotropic structure. The shape of the angular dependence of the H_V component of the light scattering suggests two types of orientation correlation of scattering elements in the bulk. The first type is associated with random fluctuations of orientation at distances of about 200–250 Å corresponding to the length of the rigid part of an individual macromolecule of propyl methyl cellulose in the solution. Ordered regions of the second type may be regarded as nucleation centers formed as a result of hydrophobic interactions of highly substituted polymer units. Increasing fraction of the propyl substituents in the macromolecules results in considerable growth of the mean density of the optical anisotropy in parallel to development of supramolecular structure in the system.

(3) At low content of propyl substituent in mixed propyl methyl cellulose ethers the cycle gel–solution–freezing–solution does not change significantly the structure of their aqueous solutions. The system with the critical content of the propyl groups (with regard to the solubility in water) becomes more homogeneous and less anisotropic after this cycle is performed.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Composite Fibers Based on Chitin and Cellulose

G. M. Mikhailov, M. F. Lebedeva, L. A. Nud'ga, and V. A. Petrova

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received March 23, 2001

Abstract—Composite fibers were produced by mixing of chitin and cellulose solutions with subsequent molding from these solutions under standard conditions. The effect of composition of systems on the structural modification and the deformation-strength characteristics of the fibers was studied.

Cellulose and chitin are the most important renewable natural fiber-forming polysaccharides. With the rational use their resourses are unexhaustible. A wide variety of materials based on cellulose and its ethers have been developed and are produced.

At the same time, chitin fibers are not produced commercially anywhere in the world. This is due to the ability of chitin macromolecules to spontaneous crystallization to form fibers of the band-fibrillar morphology characteristic of rigid- or semirigid-chain polymers [1, 2]; therefore, the resulting fibers are highly friable. Contrary to cellulose, chitin is biologically active. This explains the growing researchers' interest in fibers and materials based on chitin.

Polysaccharides can be blended by mixing their solutions. Both chitin and cellulose can be dissolved in a complex solvent such as a solution of lithium chloride in dimethylacetamide (DMAA/LiCl) [3, 4].

Addition of polyvinylpyrrolidone or methyl cellulose to the spinning solution can significantly improve the deformation-strength characteristics of the fibers [5].

It is well known that polymers are well compatible in solutions of cellulose–chitin blends [6]. Therefore, it seems appropriate to study the effect of the composition of blends on the deformation-strength characteristics of fibers based on both chitin modified with cellulose and cellulose modified with chitin.

EXPERIMENTAL

In the study we used dimethylacetamide (DMAA) dehydrated and distilled in a vacuum, bp 42°C/7 mm Hg; lithium chloride crystal hydrate dehydrated at 400°C; chitin produced from crab armor by the SONAT Joint-Stock Company, ash content 0.02%, protein-free, degree of polymerization (DP) 678, molecular weight M 137000 D, $[\eta]$ 8.4 dl g^{-1}; and cellulose produced by the Svetogorsk Pulp and Paper Plant, wood, sulfite, whitened, ash-free, DP 680, M 110000 D, $[\eta]$ 3.36 dl g^{-1}.

The intrinsic viscosity of chitin solution was determined in DMAA + 5% LiCl. The molecular weight was evaluated by the formula [3]

$$[\eta] = 2.4 \times 10^{-3} M^{0.69}.$$

The intrinsic viscosity of cellulose was determined in a solution in cadoxene. The molecular weight M was evaluated by the formula [7]

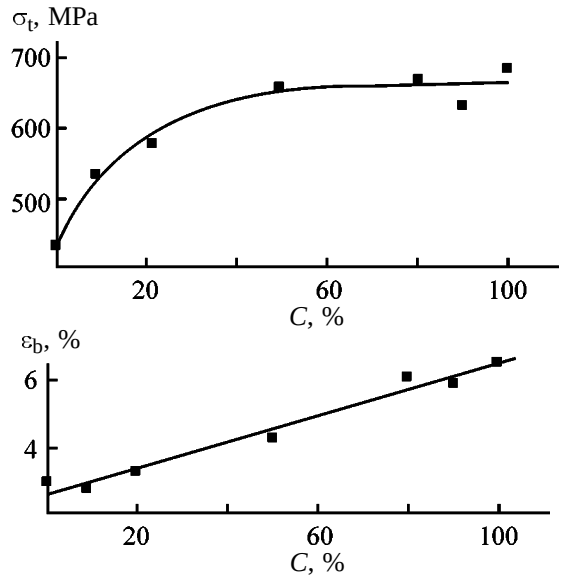
$$[\eta] = 5.93 \times 10^{-5} M^{0.94}.$$

The fiber was formed on a PIFV-01 setup using a dosing syringe and a 1/04 spinneret. The precipitation bath was a mixture of ethanol and ethylene glycol at the volume ratio of 1 : 1. The plasticization bath was water. The fiber was washed with hot water to remove lithium chloride to a total absence of chloride ion in the wash water (test with silver nitrate). The fiber was air-dried at room temperature.

For more precise estimation of the effect of modifying additives on the mechanical characteristics of the fibers the conditions of fiber production were standardized.

The mechanical tests were carried out on an Instron universal tensile-testing machine. The stress–strain diagrams were obtained with a 50-mm sample at the loading rate of 5 mm min^{-1}. Before testing the samples were kept in a desiccator for 24 h over concentrated aqueous solution of magnesium acetate, i.e., at a relative humidity of 65%.

1070-4272/01/7409-1573$25.00



Tensile strength σ_t and elongation at break ε_b of the fibers as functions of the cellulose concentration *C*.

Chitin and cellulose were dissolved by the procedure described in [8]. The content of lithium chloride in the solvent was 9%. Cellulose and chitin were dissolved in a DMAA/LiCl mixture to attain the concentration of each component of 3%. This condition was followed to provide the constant total concentration of the polymers in the spinning solution, 3%, on addition of modifying additives. To obtain the required systems, a calculated amount of the modifier solution was added. The mixture was thoroughly mixed, degassed in a vacuum, and used in forming of the fiber.

To accelerate the dissolution, with the aim to improve the accessibility of the reaction centers, polysaccharides, e.g., cellulose, are commonly treated with water and then methanol; the latter is replaced with DMAA. This procedure allows preparation of a transparent solution of a polysaccharide with a higher concentration of the polymer in a shorter time. The larger the molecular weight of the polymer, the longer the time of solution preparation.

To produce solutions of polysaccharides, the mixture was heated to 150°C [8] and then the transparent solutions were obtained by slow cooling under nitrogen to protect the system from thermal oxidative degradation [8]. In this work we used this procedure to obtain cellulose and chitin solutions from which the fibers were produced.

The figure presents the strength and deformation characteristics of the fibers produced from crab chitin, sulfite cellulose, and their mixtures of various compositions, as functions of the cellulose concentration.

An increase in the strength of the fibers σ_t is usually related to an increase in the total energy of intermolecular interaction. In our case the strength of composite fibers increases with increasing content of cellulose (rigid-chain polymer). Thus, for chitin fibers it increases to 660 MPa with increasing content of cellulose to 50%, after which the curve flattens out (see figure).

The elongation at break ε_b increases practically linearly with increasing concentration of cellulose, and at a 50% cellulose content in the mixture of polymers it is 4.4–4.8% (see figure).

However, in this part of the study of modification of chitin fibers with cellulose and cellulose fibers with chitin at low content of modifiers (no more than 5% of both cellulose in chitin and chitin in cellulose) we observed sharp deviations from the monotonic dependences for the tensile strength and elongation. These deviations are presented in the table.

Characteristics of polysaccharide fibers at low content of modifier

Content, %	σ_t, MPa	ε_b, %
Cellulose in chitin:		
0	436	2.9
0.5	526	2.4
2.5	457	2.2
4.8	482	3.2
9.0	536	2.9
Chitin in cellulose:		
0	651	6.7
0.5	530	11.0
2.5	595	7.7
5.0	617	6.8
10.0	640	6.0

The table shows that on addition of only 0.5% of cellulose to chitin the tensile strength of the fibers increases by 23% and at the modifier content of 2.5% it decreases to almost the initial level. This local maximum of the tensile strength is accompanied by the minimum of the elongation at break.

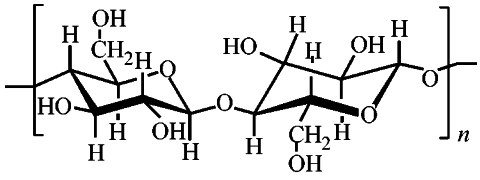
In modification of cellulose with chitin the situation is opposite: addition of the same amount of modifier (0.5%) results in an abrupt increase in the elongation at break, which reaches 11%, i.e. increases by more than 50%. This abrupt increase is accompanied by the local minimum of the tensile strength.

These extrema in the deformation-strength charac-

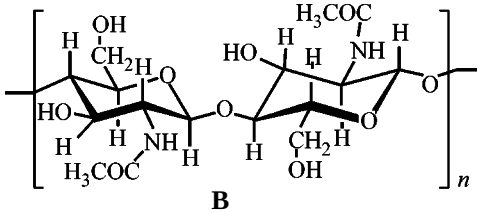
teristics of fibers at low content of modifiers can be questioned. However, the studies of the structure of similar solutions of these polysaccharides [10] and unoriented films produced from the similar systems [11] support these results. For example, the study of films preliminarily swollen in heavy-water vapor with various chitin : cellulose ratio showed that the amount of sorbed D_2O vapor decreases on addition of 0.5% of cellulose to chitin and, contrary, increases on addition of 0.5% of chitin to cellulose. The study of these films by the low-angle neutron scattering showed that the minimum size of scattering heterogeneities is typical for the films with a low content of any one of the components. We also observed a sharp local decrease in the size of the scattering heterogeneities. At the content of cellulose in chitin film of 0.5% the size of heterogeneities substantially decreases, their number increases, and the structure of the films becomes more homogeneous. Such homogeneous, though less pronounced, structure of the films takes place at a low (0.5%) content of chitin in cellulose. In [11] we noted that at small additions of chitin and cellulose variations in the structure in both solutions and solids are opposite, and a more heterogeneous structure is formed on addition of chitin to cellulose than on addition of cellulose to chitin.

When considering the chemical structure of chitin and cellulose, we can reveal the driving forces that govern the morphology of modified fibers.

As follows from the presented fragments of cellulose (**A**) and chitin (**B**) macromolecules, the only distinction is that one hydroxy group in the pyranose ring in chitin is replaced by acetamide group:



A



B

These groups will hamper packing of macromolecules in a blend of polysaccharides and affect the characteristics of hydrogen bonds in the system.

Small amounts of cellulose added to chitin can form a layer on the surface of supramolecular structures of chitin, enhancing the interstructure interaction owing to "additional" hydroxy groups. It is just this effect that should result in an increase in the rigidity of the system, which is reflected in decrease in the elongation at break (see table). Thus, small additions of cellulose to chitin act as an antiplasticizer. On the contrary, addition of chitin to cellulose should decrease the intermolecular interaction at the interface of the structural elements, since acetamide groups of chitin will hinder sterically the packing of cellulose macromolecules. Therefore, small additions of chitin will act as a plastizicer. This can explain the increase in the elongation at break of cellulose fibers containing small amounts of the modifier.

Thus, the effect of small additions to the polymer, substantially affecting its characteristics, should be explained by their role in variation of supramolecular ordering of highly arranged polymer systems. It is believed that the origin of these phenomena is as follows. The arrangement of a modifier over the interface of structural supramolecular elements of polymer results in some cases in decrease in the surface energy and thus promotes mobility of its structural elements. In this case, the structural plasticization of the modified system takes place. In other cases, when the energy of interaction of interstructural elements increases, the structural antiplasticization of the polymer with the modifying additive takes place. However, the necessary condition of interpretation of these phenomena is the presence of interfaces of the structural elements of the polymer. This suggests that the system must be heterogeneous, which is in a good agreement with the Papkov's conclusion [12]. These phenomena are manifested in formation of heterogeneous systems with structural elements corresponding to "macroscopic level" of the structure.

The modifier is localized at the interface of macroscopic elements of the supramolecular structure of the polymer. This case can be regarded as formation of a heterogeneous system with the interface at the site of the modifier location. However, probably, for such related polymers as chitin and cellulose having polymeric chains formed by glucopyranose rings we cannot speak of heterogeneity in the generally accepted sense. Actually, the concentration of hydrogen bonds at the surface of micro- and macrofibrils significantly changes. In modification of cellulose with microamounts of chitin this concentration decreases, and in modification of chitin with cellulose, increases.

In this respect we would like to call attention to the specific feature of cellulose satellites, hemicelluloses,

which, being natural structural modifiers, affect the deformation-strength characteristics of plant materials. Therefore, a special attention should be given to the history of the polymer sample subjected to structural modification and procedures of its recovery and pretreatment, which govern its purity and polydispersity and, hence, characteristics of the fibers produced from this polymer.

CONCLUSIONS

(1) The structural modification of chitin fibers with cellulose and cellulose fibers with chitin was carried out.

(2) In modification of chitin fibers with small amounts of cellulose the latter acts as structural antiplasticizer, which forms epitaxial layer at the interface of supramolecular elements and increases the energy of interstructural interaction owing to increase in the density of the network of hydrogen bonds between supramolecular formations.

(3) In modification of cellulose with chitin, small additions of chitin act as structural plasticizer of cellulose fibers. The plasticizing effect is caused by increased energy of hydrogen bonds at the interface of supramolecular structures of cellulose with acetamide groups of chitin.

(4) Addition of cellulose to chitin fibers substantially improves their deformation-strength characteristics.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Inhibited Polymerization of *N*,*N*,*N*-Trimethylammonioethyl Methacrylate Methyl Sulfate

F. V. Ermilov, V. G. Shibalovich, and A. F. Nikolaev

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received March 5, 2001

Abstract—The kinetic features of initiation of *N*,*N*,*N*-trimethylammonioethyl methacrylate methyl sulfate polymerization in the presence of manganese(III) bis(acetylacetonate) nitrate and *p*-nitrosoaniline were studied by the inhibited polymerization method. The kinetic parameters of initiation were calculated, and participation of the monomer in the initiation stage was established.

In radical polymerization, the initiation stage is the most energy-consuming and the slowest, as compared to chain propagation and termination, and, as a rule, it determines the overall polymerization rate [1].

A kinetic study of inhibited polymerization of *N*,*N*,*N*-trimethylammonioethyl methacrylate methyl sulfate (TMAEMA–MS) under the action of manganese(III) bis(acetylacetonate) nitrate (MN) was performed in aqueous solution in the temperature range 20–40°C in the presence of radical scavenger, *p*-nitrosoaniline (*p*-NA). The concentrations of the reactants (M) were as follows: inhibitor 6×10^{-7}–5×10^{-5}, initiator 6.3×10^{-4}, and monomer 1.41–2.82.

With *p*-NA added, we observed a clearly pronounced induction period τ_{ind} (Figs. 1a, 1b) within which no polymerization occurred, and after exhaustion of *p*-NA the copolymerization occurred at a constant rate equal to the polymerization rate in the absence of the inhibitor.

The duration of the induction period linearly depends on the inhibitor concentration, which suggests the absence of side reactions between the inhibitor and monomer (Fig. 2).

The constancy of the ratio $[Z]/\tau_{ind}$ ([Z] is the inhibitor concentration) suggests that the inhibitor is consumed only in reactions with primary radicals generated by decomposition of MN.

The facts that the induction period is proportional to the initial inhibitor concentration and that after the end of the induction period no inhibition is observed in the examined concentration range allow us to use the following equation [1] for calculating the initiation constants:

$$v_{in} = [Z_0]/\tau_{ind},$$

where v_{in} is the initiation rate (mol l^{-1} s^{-1}), $[Z_0]$ is the initial *p*-NA concentration (M), and τ_{ind} is the induction period (s). The initiation constant K_{in} (s^{-1}) can be

1070-4272/01/7409-1577$25.00

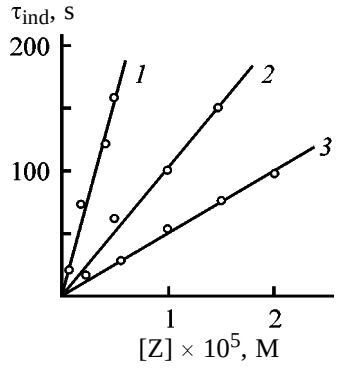

Fig. 2. Induction period τ_{ind} as a function of the inhibitor (*p*-NA) concentration [Z] at (*1*, *3*) 20 and (*2*, *4*) 40°C. Concentration of TMAEMA–MS, M: (*1*, *2*) 1.49 and (*3*, *4*) 2.82.

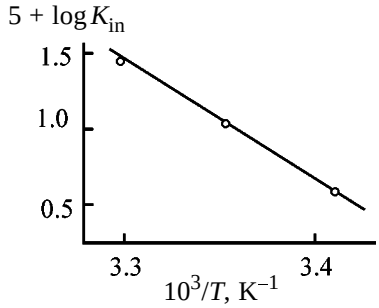

Fig. 3. Rate constant of TMAEMA–MS polymerization initiation K_{in} as a function of temperature *T*. MN concentration 6.3×10^{-4} M.

calculated by the equation

$$K_{in} = v_{in}/[I],$$

where [I] is the initiator (MN) concentration (M).

The initiation efficiency *f* was evaluated by the equation

$$f = v_{in}/K_h[I],$$

where K_h is the rate constant of homolytic decomposition of MN, $K_h = 7.34 \times 10^{-4}$ s^{-1}.

The reactivity of the primary radical in initiation of TMAEMA–MS polymerization in the presence of MN was evaluated by the equation [2]

$$f = v_{in}/(v_{in} + v_{sr}) = [M]/([M] + K_{sr}/K_h),$$

where v_{sr} is the rarte of the side reaction of the primary radical (mol l^{-1} s^{-1}), [M] is the monomer concentration (M), and K_{sr} is the rate constant of the side reaction of the primary radical (s^{-1}).

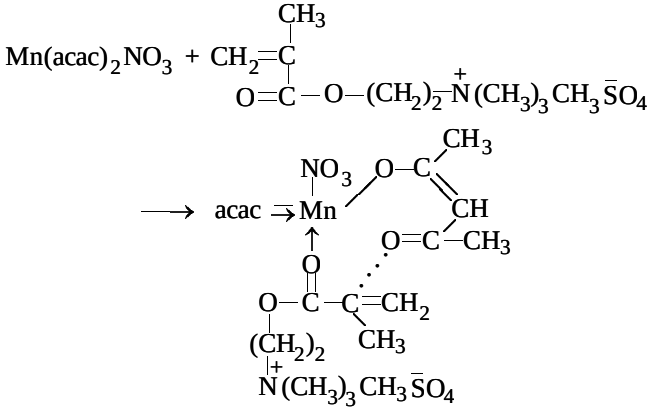
We found that the calculated initiation constants can be satisfactorily fitted by the Arrhenius equation (Fig. 3). The apparent activation energy of the initiation of TMAEMA–MS polymerization with MN is 40.3 kJ mol^{-1}, which is a typical value for polymerization of such monomers as acrylamide and acrylic acid in the presence of acido derivatives of manganese(III) bis(acetylacetonate) [3].

Experimental data (see table) show that the initiating power of MN, evaluated by K_{in}, *f*, and K_{sr}, significantly depends on the concentration of TMAEMA–MS monomer, which suggests participation of the monomer in the initiation stage.

The initiation efficiency of 0.5, and the high rate constants of the side reaction of the primary radical, comparable with the initiation constants, suggest a high reactivity of the primary radical.

A UV examination of dilute solutions of MN and TMAEMA–MS and of their equimolar mixture (concentration 5×10^{-4} M) showed (Fig. 4) that (1) the band at 47000 cm^{-1} (ε = 19140 l mol^{-1} cm^{-1}), characteristic of TMAEMA–MS in aqueous solutions, shifts to 45100 cm^{-1} (ε = 20100 l mol^{-1} cm^{-1}) in the spectrum of the equimolar mixture of TMAEMA–MS with MN; (2) the *π*–*d* charge-transfer band at 31400 cm^{-1}, characteristic of MN in aqueous solution, shifts to 29800 cm^{-1} upon interaction with TMAEMA–MS; (3) the molar extinction coefficient of the band at 36800 cm^{-1} (ε = 14700 l mol^{-1} cm^{-1}) characteristic of intraligand π–π* transitions in MN decreases upon interaction with TMAEMA–MS by a factor of 2 to 7400 l mol^{-1} cm^{-1}.

The UV data suggest that interaction of TMAEMA–MS with MN involves inner-sphere coordination of the monomer with the complex, which, as shown in numerous papers [6], is possible for such acrylic monomers as acrylamide, acrylic acid, and methyl methacrylate. When considering decomposition of MN in aqueous solutions, account should be taken of the fact that the Mn^{3+} ion has vacant *d* orbitals, which can favor formation of an inner-sphere complex in solution [6]. Thus, interaction of MN with TMAEMA–MS can be described by the following scheme:



Inhibited polymerization of TMAEMA–MS in the presence of MN and *p*-NA (initiator concentration 6.34×10^{-4} M)

[M], M	*T*, °C	$[Z] \times 10^6$, M	τ_{in}, s	$v_{in} \times 10^{-8}$, mol l^{-1} s^{-1}	$K_{in} \times 10^4$, s^{-1}	*f*	$K_{sr} \times 10^5$, s^{-1}	K_{in}/K_{sr}	E_{in}	E_a	$E_r - 0.5E_0$
									kJ mol^{-1}		
1.49	20	0.62	25	2.48	0.395	0.05	1.56	2.53	40.3	51.8	31.65
	20	1.25	75	2.08							
	20	5.00	100	3.12							
	40	5.00	55	9.10	1.55	0.17	4.68	3.32			
	40	10.00	115	8.70							
	40	20.00	170	10.20							
2.82	20	10.0	60	16.60	3.06	0.41	7.51	4.07	–	47.9	–
	20	20.0	90	22.20							

It should be noted that monomers of the aminoalkyl (meth)acrylate series and their derivatives tend to form intermediate donor–acceptor complexes with initiating systems [7, 8]. This property affects the reactivity of the monomer and initiator and determines the specific features of their behavior in the polymerization medium.

EXPERIMENTAL

The kinetics of the inhibited polymerization of TMAEMA–MS was studied by the inhibition procedure in aqueous solution under oxygen at 20°C in the presence of the mixed-ligand manganese(III) complex MN and the radical scavenger *p*-NA [2].

The UV spectra of the compounds (aqueous solutions, pH 4) were taken on a Specord spectrophotometer.

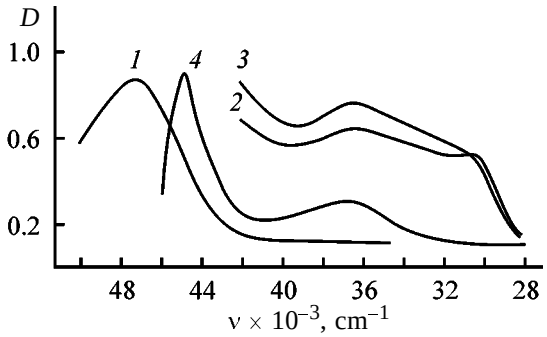


Fig. 4. UV absorption spectra of TMAEMA–MS and MN in aqueous solution (pH 4.0). (*D*) Optical density and (ν) wave number. (*1*) TMAEMA–MS, (*2*) MN, and (*3*, *4*) MN : TMAEMA–MS = 1 : 1 (mol : mol), 1.5 and 10 min after mixing, respectively.

CONCLUSIONS

(1) The kinetic parameters of initiation of *N,N,N*-trimethylammmonioethyl methacrylate methyl sulfate: K_{in}, v_{in}, *f*, and E_{in}, in the presence of manganese(III) bis(acetylacetonate) nitrate and *p*-nitrosoaniline were determined by the method of inhibited polymerization. It was found that manganese(III) bis(acetylacetonate) nitrate exhibits a high initiating activity, which significantly depends on the monomer concentration.

(2) The UV spectra of the compounds and reaction systems show that interaction of *N,N,N*-trimethylammonioethyl methacrylate methyl sulfate with manganese(III) bis(acetylacetonate) nitrate involves formation of a donor–acceptor complex, which determines the specific features of their behavior in the course of polymerization.

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received March 27, 2001

Abstract—The viscosity, lifetime, and structure of melts of supramolecular H-bonded complexes of acid diethyl and dimethyl esters of 3,3',4,4'-(diphenyl oxide)tetracarboxylic or 3,3',4,4'-diphenyltetracarboxylic acids with aromatic diamines (diaminodiphenylmethane or *m*-phenylenediamine) are studied.

Polyimide binders for fibrous composite materials are often obtained by acylation of diamines with acid esters of tetracarboxylic acids. In this case the best prepregs can be prepared from powder-like hydrogen-bonded complexes (H complexes) separated in drying of alcoholic solutions of acid esters of tetracarboxylic acids and diamines [1, 2]. In contrast to mechanical mixtures of acid esters of tetracarboxylic acids with diamines, H complexes can be converted to polyimides under mild conditions (at temperature below 220°C) practically without any side reactions [3]. The H complexes are characterized by low melting point (90–130°C) [4], which allows easy impregnation of various reinforcing materials, for example, polyimide felt, and preparation, after further thermal treatment of the resulting prepreg in a die mold (but without applying pressure load), of durable, light, thermostable, heatproof, and cryostable foamed composites, having good sound-proofing properties and applicable as structural materials [5].

Previously, to optimize the conditions of preparation of polyimide foamed composites, we thoroughly studied the viscous characteristic of H complexes based on acid diesters of 3,3',4,4'- benzophenonetetracarboxylic acid (BP) [6]. It was demonstrated that melts of the H complexes have an ordered structure (the exponent in the Ostwald–de-Wille equation

$$\eta \sim \dot{\gamma}^{-n}, \quad (1)$$

where η is the viscosity of the melt of the H complex and $\dot{\gamma}$ is the shear rate, is above 0.7) [7, 8].

The H complexes represent supramolecular structures, which are converted into polyimides by thermal treatment. It is known [9] that the structure of a polyimide is determined primarily by the nature of an acylating fragment of the polyimide chain, and its basis is formed even at the prepolymer stage. The polyimides based on 3,3',4,4'-(diphenyl oxide)tetracarboxylic acid (DPO) are mostly flexible-chain polymers, which is caused by the presence of a hinge oxygen atom between the phenyl radicals. The polyimides based on 3,3',4,4'-diphenyltetracarboxylic (DP) acid are mostly rigid-chain polymers with an ordered supramolecular structure. Therefore, it is interesting to study the effect of the nature of diesters of the indicated tetracarboxylic acids on the supramolecular structure of melts of the H complexes.

In this work we studied the H complexes formed by dimethyl esters of DPO or diethyl esters of DP and 4,4'-diaminodiphenylmethane (DADPM) or *m*-phenylenediamine (MPDA).

EXPERIMENTAL

The H complexes were prepared as follows. The dianhydride of DPO (0.1 mol) or DP (0.05 mol) was dissolved with stirring in the presence of benzimidazole (3 wt %) in 50 ml of methanol or ethanol containing 10–15 vol % water at the boiling temperature of the alcohol. The solution of the acid diester of the tetracarboxylic acid was cooled to room temperature, and the equimolar amount of a diamine was added with stirring (or the two diamines were added one after another). The H complexes formed after homogenization of the solution were isolated as solids by vacuum removal of the solvent at room temperature.

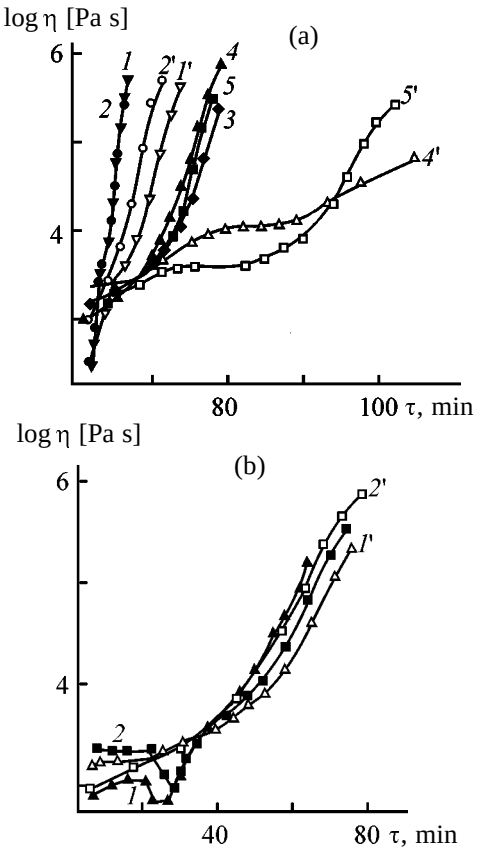

Fig. 1. Viscosity η of melts of H complexes as a function of time τ. $\log\dot{\gamma}$ = –1.88 (s^{-1}); the same for Fig. 4. (a) (*1*, *1*') DPOMe–DADPM, (*2*, *2*') DPOMe–(DADPM + MPDA), (*3*) DPOEt–DADPM, (*4*, *4*') DPOEt–(DADPM + MPDA), and (*5*, *5*') DPOEt–MPDA; (b) (*1*) DPEt–DADPM, (*1*') DPOEt–DADPM, (*2*) DPEt–(DADPM + MPDA), and (*2*') DPOEt–(DADPM + MPDA). Temperature (°C): (a) (*1*–*5*) 105 and (*1*', *2*', *4*', *5*') 95; (b) 105.

The dianhydride of DPO [TU (Technical Specifications) TSR 2159–69; 40 g] was recrystallized from a mixture of *o*-xylene (100 ml) and acetic anhydride (20 ml); mp 226–227°C. The dianhydride of DP was heated at 250°C (4 mm Hg); mp 297–298°C. 4,4'-Diaminodiphenylmethane was purified by vacuum distillation at 1–3 mm Hg (mp 90–92°C), and *m*-phenylenediamine, by vacuum distillation from Zn powder (mp 63°C).

The viscosity of melts of the H complexes was measured at 95 and 105°C with a PIRSP flowmeter with a cone–plane working unit (cone vertex angle 1°; cone diameter 40 mm) [10].

Thermal analysis was carried out with a MOM Model C instrument (Hungary). The sample weight was 50 mg; heating rate 5 deg min^{-1}.

The infrared spectra were registered with a Bruker spectrometer using the KBr technique.

In the molten state the H complexes undergo both physical and chemical transformations caused by such processes as structurization of the melt, imidization, foaming due to the presence of low-molecular-weight imidization products, gelation, and solidification. These processes are interrelated and superimposed. The processes dominating over each fixed time interval can be judged from the time dependences of the viscosity.

We studied the viscosity of melts of the H complexes formed by diethyl ester of DPO or DP with DADPM or (and) MDPA, and also by dimethyl ester of DPO with DADPM or an equimolar mixture of DADPM and MDPA (the indicated H complexes are designated as DPOEt–diamine, DPEt–diamine, and DPOMe–diamine, respectively) at 95 and 105°C. Below the selected temperature range H complexes often do not melt, and above it they form a solid in a short time, i.e., have a short lifetime, which does not permit us to follow the dynamics of the viscosity variation.

Evolution in time of the melt viscosity and lifetime depends to the most extent on the diester used. It was demonstrated with an example of H complexes of DPO diesters with various diamines (DADPM, MPDA, or their mixture) that the lifetime of the H complexes with the dimethyl esters (Fig. 1a, curves *1*, *1*', *2*, *2*') is considerably shorter as compared to those with the diethyl esters (curves *3*, *4*, *4*', *5*, *5*'), which is due to the fact that the imidization rate constant for the former compounds is by several times higher [3].

Changing the acylating fragment in the H complex (DPO diethyl ester for DP diethyl ester) does not affect the viscosity and lifetime of the melt (Fig. 1b, curves *1*, *1*', *2*, *2*'). The only difference is that the kinetic curves at 105°C of the viscosity of the H complexes DPEt–diamine pass through a minimum at 20–40 min. This result can be attributed to more extensive foaming, accompanied by separation of the alcohol and water, as compared to the H complex DPOEt–diamine. It should be pointed out that the viscosity and lifetime of melts of the investigated H complexes differ considerably from those of melts of the BP diesters [6]: the viscosity of the H complexes DPOMe–diamine, DPOEt–diamine, and DPEt–diamine is lower and the melt lifetime is longer than for the H complexes BPMe–diamine and BPEt–diamine.

It is seen from Fig. 1b that at 105°C the viscosity of melts of the H complexes DPOEt–diamine and DPEt–diamine remains practically unchanged in the

first 40 min. The plateau in the viscosity curve is more clearly pronounced at 95°C (Fig. 1a, curves *4'*, *5'*). The processes occurring in various time intervals can be judged from the coefficient *n* in Eq. (1). This parameter, characterizing the supramolecular structure of the melt, was estimated from the dependence of the viscosity on the shear rate at 95°C at fixed times. Such a dependence is presented in Fig. 2 for the H complex DPEt–(DADPM + MPDA).

In Fig. 3 are given the time dependences of the parameter *n* for H complexes of various compositions. Initially the melt had no ordered supramolecular structure ($n < 0.7$). Gradually such a structure was formed, as seen from the evolution of the parameter *n*, and after 30–40 min all the investigated melts got an ordered supramolecular structure ($n > 0.7$). With further time this structure became more and more perfect. The variations in *n* and η for the H complex DPEt–(DADPM + MPDA) are presented in Fig. 3 (curves *3* and *5*, respectively). It follows from the comparison of these curves that the melt gets an ordered structure after reaching the viscosity of about 10^4 Pa s, which is typical of the other investigated H complexes too.

The forward (with increasing shear rate) and backward runs (with decreasing shear rate) of the dependence $\log\eta$–$\log\dot\gamma$ for the H complex DPOEt–(DADPM + MDPA) 30 and 75 min after the beginning of the experiment are given in Fig. 4. Over this time interval the viscosity changes insignificantly. The parameter *n* (determined as the slope of the curve) is relatively high at $\tau = 30$ min, being unchanged for both forward and backward runs of the curve (Fig. 4, curves *1*, *2*). Therefore, the ordered structure of the melt is not changed even at sufficiently high shear rates ($3\log\dot\gamma = 0.5$ s^{-1}). With time the structure of the melt becomes more perfect, as demonstrated by Fig. 3 (*n* increases). Further increasing shear rate provides partial degradation of the supramolecular structure (at $\tau > 75$ min the slope of the backward run of the dependence $\log\eta$–$\log\dot\gamma$ is lower than that of the forward run (Fig. 4, curves *3*, *4*), i.e., *n* decreases ($n_3 = 1.16$, $n_4 = 0.88$).

Therefore, the initial insignificant change in the viscosity of the melt with time is caused by formation of an ordered supramolecular structure and its further perfection.

The rapid final increase in the viscosity (Figs. 1a, 1b) is associated with partial imidization. The time dependences of the viscosity at 95, 105, and 120°C are presented in Fig. 5 for the H complex DPOEt–

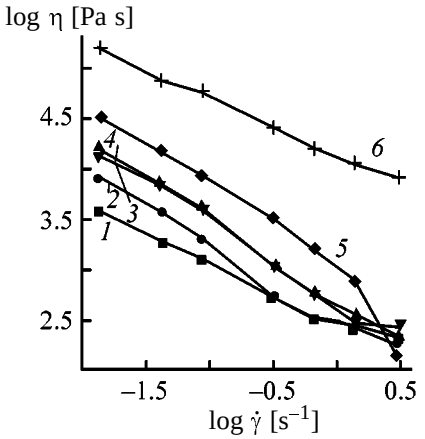

Fig. 2. Viscosity η of the melt of the H complex DPEt–(DADPM + MPDA) as a function of the shear rate $\dot\gamma$ at 95°C. Time (min): (*1*) 20, (*2*) 43, (*3*) 64, (*4*) 84, (*5*) 104, and (*6*) 124.

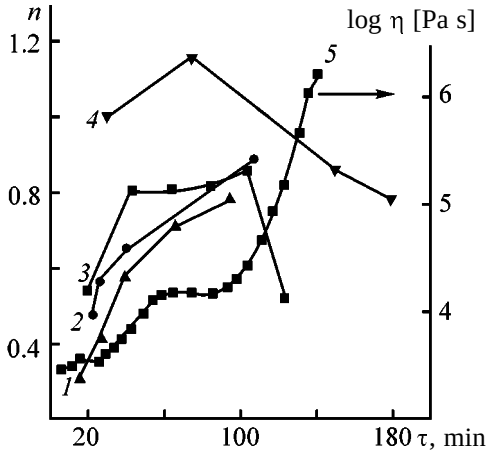

Fig. 3. (*1–4*) Parameter $n = \Delta\log\eta/\Delta\log\dot\gamma$ and (*5*) viscosity η of melts of H complexes as functions of the time τ at 95°C. (*1*) DPEt–DADPM, (*2*) DPOEt–DADPM, (*3*, *5*) DPEt–(DADPM + MPDA), and (*4*) DPOEt–(DADPM + MPDA).

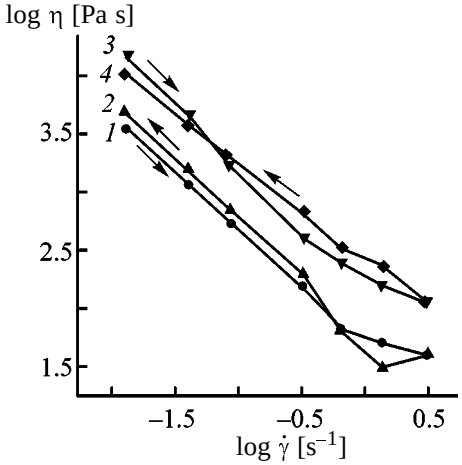

Fig. 4. Viscosity η of the melt of the H complex DPOEt–(DADPM + MPDA) as a function of the shear rate $\dot\gamma$ at 95°C. $n_1 = n_2 = 1$ at $\tau = 30$–40 min; $n_3 = 1.16$; and $n_4 = 0.88$ at $\tau = 75$–88 min.

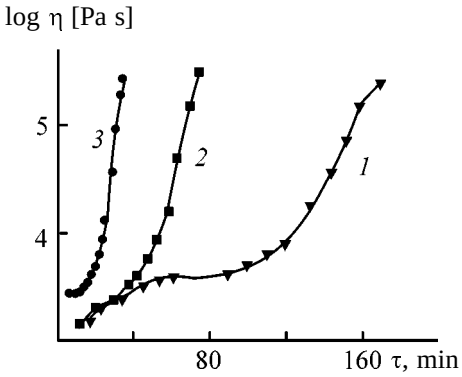

Fig. 5. Viscosity η of melt of H complex DPOEt–MPDA as a function of time τ. Temperature (°C): (*1*) 95, (*2*) 105, and (*3*) 120.

MDPA. As the temperature rises, the lifetime of the melt decreases and the slope of the final section of the curve increases. The samples after the experiment were characterized by TGA. The results showed that the weight loss due to imidization of the initial H complex DPOEt–MDPA corresponds to the theoretical value (see table). From the TGA data we estimated the degree of imidization. The samples after the rheological experiments (heated at 95, 105, and 120°C) appeared to be partially imidized (see table).

The conclusion about partial imidization of the H complexes at the experimental temperatures was confirmed by the IR data. The imidization was monitored by the absorption bands of the carbonyl groups of the imide ring at 725 and 1780 and 1720 cm^{-1} (doublet). In heated samples (95°C, 205 min) we observed the bands at 720 and 1780 cm^{-1}, i.e., the imide rings appear, which were lacking in the initial H complex.

The observed decrease in the parameter *n* in the final section of the time dependence of η (Fig. 3, curves *3*, *5*) reveals that thermal imidization is responsible for degradation of the ordered supramolecular structure ($n < 0.7$).

Degree of imidization α of DPOEt–MDPA samples

T, °C	τ, min	Weight loss due to imidization, %	α
25 (initial sample)	0	24*	0
95	180	18	23
105	75	15	38
120	36	15	38

* The theoretical value is 25%.

CONCLUSIONS

(1) The lifetime of the melt of the H complexes based on dimethyl esters of 3,3',4,4'-(diphenyl oxide)-tetracarboxylic acid is considerably shorter than that of the H complexes based on diethyl esters of this acid and 3,3',4,4'-diphenyltetracarboxylic acid. The viscosity and lifetime of the melts of the H complexes based on acid diesters of 3,3',4,4'-(diphenyl oxide)-tetracarboxylic and 3,3',4,4'-diphenyltetracarboxylic acids are similar.

(2) It is typical for melts of all the H complexes studied that the degree of ordering increases in time until imidization starts.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Structure of Free Radicals Formed under X-ray Irradiation of Organic Polymeric Acids

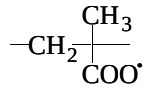
Abstract—The structure of free radicals formed under X-ray irradiation of polyacrylic and polymetharcylic acids and poly-3-vinyltetrazole was studied by ESR spectroscopy. In polymerization of polymethacrylic acid, the conditions of the polymer recovery from the solution affect the nature of the radiolysis products.

The search for efficient methods preventing spontaneous deterioration of polymers requires exhaustive knowledge of possible reactive species in a solid polymer, free radicals. Under standard conditions the degradation effects initiated by the action of the environment are so small that cannot be detected by the ESR technique. Formation of free radicals in polymers is enhanced by radiolysis [1]. Free radicals formed under these conditions can serve as spin markers, which furnishes valuable information on molecular and supramolecular structure of polymers.

Here we present the results of ESR study of free radicals formed under X-ray irradiation of polyacrylic (PAA) and polymethacrylic (PMAA) acids, poly-5-vinyltetrazole (PVT), and their complexes with Cu^{2+}, Ni^{2+}, and Co^{2+} ions.

After irradiation in an inert atmosphere of PMAA freshly synthesized and dried in air, we recorded intensive asymmetrical ESR signal (Fig. 1a) characteristic of free radicals, in which unpaired electron is localized on the oxygen atom (oxygen radical) [2]. Contrary to PMAA, in PAA and PVT under similar conditions we registered carbon-centered free radicals whose ESR spectra exhibit a resolved hyperfine structure (HFS) due to two equivalent protons (Figs. 1b, 1c). Relatively large linewidth in the triplet suggests the presence of unresolved additional HFS. Spectra in Figs. 1b and 1c did not change for 1–2 h at room temperature. The spectra as a whole also remained practically unchaged. These data strongly suggest that the registered paramagnetic species are stabilized in the bulk of polymers. One of the possible reasons of formation of oxygen radicals can be incorporation of atmospheric oxygen into the polymeric chain in polymerization [3]. However, since the synthesis conditions for PMAA and PAA are the same but the resulting free radicals are essentially different, it can be assumed that oxygen radicals in PMAA originate from carboxy groups. The following structure of the oxygen radical can be suggested:



I

The triplet signal in Fig. 1b was observed previously in photopolymerization [3] and polymerization of acrylic acid under hard γ-irradiation [4, 5] and also in PAA subjected to γ-irradiation [5–7]. In [5–8] the

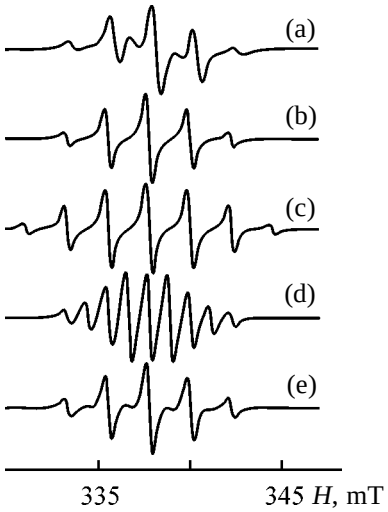

Fig. 2. (a) Experimental ESR spectrum of irradiated PMAA preliminarily dissolved in water and dried in air, (b–d) calculated spectra of conformers, and (e) the total spectrum.

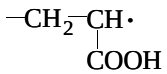
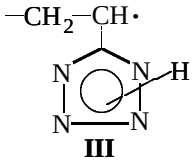
signal shown in Fig. 1b was assigned to free radical of the following type:



II

The HFS of signal in Fig. 1b is caused by the hyperfine interaction (HFI) of unpaired electron with two protons in α- and β-positions. The second β-proton does not interact with unpaired electron since it is located in the plane of the radical center [3]. The presence of poorly resolved inflections at the ends of signal b (Fig. 1) suggests the anisotropy of the hyperfine interaction with α-proton. For example, the main components of the HFI tensor for α-proton in polyethylene macroradicals are [9] a_x = 1.07, a_y = 1.93, and a_z = 3.42 mT.

Taking into account the similarity in signals b and c (Fig. 1), signal c in PVT can be assigned to macroradical of the following type:

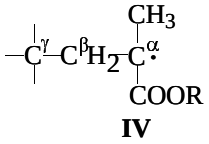


III

The HFS in macroradical **III**, as well as in PAA, is caused by interaction with two protons located in α- and β-positions.

It should be stressed that only secondary radical products of radiolysis, which are stabilized in the bulk of the polymer, are registered under the selected conditions of irradiation (25°C). Significant distinction of PMAA from PAA and PVT is the presence of side methyl groups, which are responsible for distinctions in the structure of macromolecular globules of these polymers. It is evident that in synthesis of PMAA in hydrocarbon medium hydrophilic carboxy groups are concentrated in the inner areas of the globules, which provides the contact of hydrophobic methyl groups with hexane. On the other hand, areas with the increased concentration of oxygen-containing groups, appearing in the polymer, promote formation of oxygen-containing radicals. At the same time, the main chain of PAA is less hydrophobic and less prone to cross-linking.

When PAA and PVT, preliminarily dissolved in water and dried in air, are subjected to irradiation, the same signals b and c are registered again (Fig. 1). In the case of PMAA, instead of asymmetrical signal a (Fig. 1), a symmetrical multiplet appears, which can be considered as a superposition of at least three signals: quintet b with binomial distribution of the intesities 1 : 4 : 6 : 4 : 1 from four equivalent protons with the HFI constant a(H) = 2.23 mT; sextet c with the equidistant lines at 2.23 mT; and weak signal d, whose HFS is registered between the intense lines of signals b and c (Fig. 2). Quintet b was observed previously in photopolymerization of methacrylic acid or methyl methacrylate [8] and also in polymethyl methacrylate subjected to γ-irradiation [3] or mechanochemical treatment [8, 10, 11]. In the series of works [3, 8, 10, 11] quintet b (Fig. 2) is assigned to macroradical of the following type:

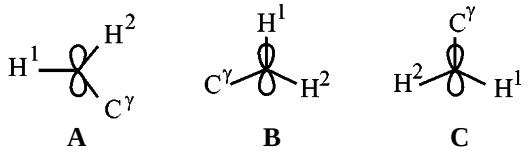


IV

The multiptet consisting of five lines is caused by the interaction of unpaired electron with three equivalent protons of the freely rotating methyl group and one proton of the methylene group. The second proton of the methyl group does not participate in HFI, which suggests its location in the plane of the radical center [3].

Three multiplet signals registered in our case are apparently due to coexistence of three conformers of radical **IV**, differing in the spatial arrangement of protons of the methylene group with respect to the π orbital occupied by the unpaired electron. The limiting structures of conformers corresponding to signals b–d (Fig. 2) can be presented as **A**–**C**, respectively, with the carbon atoms C^{α} and C^{β} aligned with the line

perpendicular to the figure plane:



For three selected models we can evaluate the HFI constants for H^1 and H^2 using the well-known relation [12]

$$a(\mathrm{H}) = B\cos^2\varphi,$$

where B is the maximum value of the isotropic constant of HFI with β-proton (5.0 mT), and φ is dihedral angle between the $C^{\alpha}C^{\beta}H$ and $C^{\alpha}C^{\beta}\pi$ planes (π is the symmetry axis of the orbital occupied by unpaired electron).

When the dihedral angle between the $C^{\alpha}C^{\beta}H^1$ and $C^{\alpha}C^{\beta}H^2$ is taken equal to 120°, we obtain (mT) for conformer **A**, $a(H^1) = 0$, $a(H^2) = 3.75$; for conformer **B**, $a(H^1) = 5.0$, $a(H^2) = 1.25$; and for conformer **C**, $a(H^1) = a(H^2) = 1.25$.

Figure 2 presents the calculated ESR spectra of three model structures, which most closely agree with the experimental spectrum, and also the total spectrum e with the weight coefficients b : c : d = 10 : 2 : 1. The calculated HFI constants (mT) are (b) a(3H) = 2.23, a(1H) = 2.23, a(1H) = 0; (c) a(3H) = 2.23, a(1H) = 4.46, a(1H) = 2.23; and (d) a(3H) = 2.23, a(1H) = 1.11, a(1H) = 1.11. The calculation was carried out using the software described in [13]. In all calculations the width of the individual Lorentz line δH = 0.35 mT.

To conclude the studies of the structure of free radicals as influenced by the procedure of sample preparation for analysis, it should be noted that recovery of PMAA from water results in rearrangement of the supramolecular structure of the polymer: the hydrophobic part of the polymer is localized in the inner part of the polymer globule, and the hydrophilic part is localized in the periphery. Contrary to PMAA, recovery of PAA and PVT, containing no hydrophobic radicals, from water does not alter the nature of the stabilized radicals.

When after dissolving in water the polymers are dried lyophilically, the X-ray irradiation gives the same result as after drying of the polymers in air. The only difference was increased intensity of the ESR spectra of the hydrocarbon radicals owing to formation of more friable samples. Hence, supramolecular structure of the polymers is not significantly affected by lyophilic drying.

Fig. 3. ESR spectra of free radical **IV** recorded at 1-min intervals at 343 K. The spectrum with the minimum intensity was obtained after 11 min.

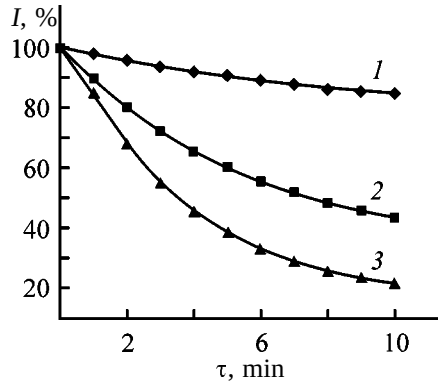


Fig. 4. Reduced intensity I of signal a (Fig. 2) as a function of time τ at (*1*) 343, (*2*) 373, and (*3*) 403 K.

To elucidate the mechanism of recombination of macroradicals **IV**, we studied the process kinetics in the stepwise heating mode [1]. A series of ESR lines recorded after 1 min at 343 K is presented in Fig. 3. Figure 4 shows variation with time of the total intensity of signals a (Fig. 2) reduced to 100% at the initial instant of time for each temperature. Analysis of the initial recombination rates allowed evaluation of the reaction order and activation energy. It was

found that the order of recombination is more than 1 and less than 2, which suggests more complicated mechanism of the process than mechanisms of monomolecular or bimolecular reactions. The activation energy is 44 kJ mol^{-1}, which is close to the activation energy of recombination of alkyl radicals in irradiated polyethylene [1, 14], in which the contact of free radicals is realized by migration of the free valence by the chain reaction

$$\dot{R} + H_2 \rightarrow RH + \dot{H},$$

$$\dot{H} + RH \rightarrow \dot{R} + H_2.$$

Apparently, the same mechanism forms the basis for recombination of radicals **IV** in the case of PMAA.

When PMAA with preliminarily incorporated Cu^{2+} ions in the ratio Cu : Ac ≥ 1 : 10, where Ac is the acyl group of PMAA, is subjected to irradiation, free-radical ESR signals are not registered and only the characteristic signal of the Cu^{2+} carboxylate complex is observed [15]. Weak free-radical signal a (Fig. 2) (10^{16} spin g^{-1}, two orders of magnitude lower than that of the initial polymer) can be registered only with decreased concentration of Cu^{2+} ions in PMAA (Cu : Ac < 1 : 10). It should be noted that under these conditions individual signal c without superposition of signals b and d is registered (Fig. 2). In addition, irradiation results in insignificant decrease in the intensity of the signal from Cu^{2+}, which is apparently caused by partial reduction of Cu^{2+} ion to diamagnetic Cu^{+}. Hence, Cu^{2+} ions in PMAA play a role of a radioprotector significantly decreasing the radiation yield of free radicals owing to redox processes, which results in variation of the oxidation state of the transition metal, e.g., by the scheme

$$\dot{H} + Cu^{2+} \rightarrow R^{+} + Cu^{+}.$$

Contrary to Cu^{2+} ions, Co^{2+} and Ni^{2+} ions incorporated into PMAA in the same amounts do not decrease noticeably the radiation yield of free radicals, but also signal c is mainly registered (Fig. 2). In addition, some broadening of the HFS lines of signal c (Fig. 2) is observed at high concentrations of ions (M^{2+} : Ac > 1 : 10), which suggests magnetic interaction between free radicals and ions of transition metals. Hence, Co^{2+} and Ni^{2+} ions in PMAA do not enter into redox reactions with free radicals, at least at room temperature.

EXPERIMENTAL

We used PAA and PMAA synthesized by polymerization of acrylic and methacrylic acids in hexane at 343 K for 2 h with azobis(isobutyronitrile) (AIBN) as initiator. The concentration of methacrylic and acrylic acids was 10%, and that of AIBN, 0.5% of the polymer weight.

Poly-5-vinyltetrazole was produced by the reaction of polyacrylonitrile with sodium azide at the Sibreaktiv Joint-Stock Company (Angarsk). The commercial sample was purified by double reprecipitation from alkaline solution (2 g l^{-1} PVT and 0.5 g l^{-1} NaOH) into a twofold excess of hydrochloric acid solution (50 g l^{-1}). PVT recovered by this procedure is insoluble in water. To produce water-soluble PVT, it was dissolved in water with addition of NaOH (10% of the amount of tetrazole units) and neutralized by slow addition of 0.1 N HCl. The solution was purified to remove the impurity of sodium chloride by dialysis through a cellophane membrane and subjected to lyophilic drying.

Metal nitrates of chemically pure grade were recrystallized from aqueous solutions before use.

Complexes were synthesized by mixing PMAA, PAA, and PVT solutions with solutions of Cu^{2+}, Co^{2+}, and Ni^{2+} nitrates. The concentration of PMAA, PAA, and PVT was 0.05 M, and the concentration of nitrates was 0.04 M. The resulting soutions of polymers and their complexes were subjected to lyophilic drying and dried in air.

Ampules with samples were evacuated at 10^{-3} mm Hg, bubbled with an inert gas, sealed, and then subjected to radiolysis with X-rays at room temperature for 10 min with an FRA-20 Carl Zeiss X-ray spectrometer equipped with W anode at a voltage of 40 kV and a current of 20 mA; the exposure dose was 10^{5} Gy.

The ESR spectra of solid polymers and their complexes were recorded on a PS-100X spectrometer (operation frequency 9.6 GHz) at room temperature. Mn^{2+} in MgO and diphenylpicrylhydrazyl were used as references. The concentration of free radicals in the irradiated polymers was 10^{18} spin g^{-1}.

CONCLUSIONS

(1) Irradiation of polyacrylic acid and poly-5-vinyltetrazole results in the rupture of the main polymer chain and generation of hydrocarbon radicals which are stabilized in the polymer bulk.

(2) The behavior of polymethacrylic acid in radiollysis is governed by the conformational features of its macromolecules. The polymer synthesized in hexane (hydrophilic carboxy groups are concentrated in the inner areas of globules) gives oxygen radicals. In recovery of polymethacrylic acid from aqueous solutions the association of hydrophobic methyl groups is preserved in the solid sample. After irradiation the resulting radicals are localized at the α-carbon atom of the methacrylic acid unit.

(3) Complex formation of polymeric acids with Cu(II) ions results in inhibition of radiolysis owing to oxidation of the resulting radicals with metal ions.

Received April 26, 2001

Abstract—A process was developed for production of dicyclopentadiene from the C_5 fraction of hydrocarbon pyrolysis. Conditions were found ensuring production of high-purity dicyclopentadiene.

Cyclopentadiene (CPD) and dicyclopentadiene (DCPD) are important monomers in polymer chemistry. Dicyclopentadiene and ethylidenenorbornene produced from CPD are widely used as comonomers in production of SKEPT rubbers [1], which are named rubbers of XXI century. Metathesis of DCPD allows production of materials with high physicomechanical properties [2–6]. Copolymerization of ethylene with norbornene derivatives prepared by the Diels–Alder reaction with CPD allows production of unique polymers exhibiting high transparency and impact resistance [7–14]. Norbornenedicarboxylic anhydride prepared by the Diels–Alder reaction from CPD and maleic anhydride is used in synthesis of norbornene polyester resins which exhibit enhanced physicomechanical properties as compared to phthalate resins [15–17].

CPD and DCPD used in these syntheses should exhibit a high (≥99 wt %) purity. Preparation of DCPD of so high purity is a difficult problem for industrial organic chemistry. Although some approaches to this problem have been outlined [18, 19], there is still no complete solution.

This work concerns production of high-purity DCPD. The major source of DCPD is the C_5 fraction of hydrocarbon pyrolysis.[1] Its quantitative composition depends on the nature of the raw material and processing features, but the qualitative composition remains the same. Below is given the approximate composition of the C_5 fraction used for recovery of DCPD [19].

The main problem related to recovery of DCPD from the C_5 fraction is that common separation procedures do not allow preparation of the high-purity target product. Therefore, additional chemical processes should be performed. The main principles of our approach are as follows.

Component	Content, wt %
3-Methyl-1-butene	0.09
1,4-Pentadiene	1.30
Isopentane	12.94
n-Pentane	24.81
1-Pentene	4.08
2-Methyl-1-butene	8.70
trans-2-Pentene	3.59
cis-2-Pentene	2.48
2-Methyl-2-butene	1.87
Piperylene (*cis* and *trans*)	11.91
Isoprene	12.58
Cyclopentadiene	13.14
Cyclopentene	2.51

(1) Cyclopentadiene in the C_5 fraction is dimerized into DCPD. The boiling points of DCPD and the remaining components of the C_5 fraction differ considerably, and DCPD can be readily separated by distillation. However, DCPD formed by primary dimerization is contaminated with Diels–Alder adducts of CPD with isoprene and piperylene. Therefore, further procedures with "crude" DCPD should involve separation of these impurities.

(2) The crude DCPD formed by primary dimerization is subjected to retrodiene syntheses (monomerization). Adducts of CPD with isoprene and piperylene are more stable than DCPD. Therefore, pure CPD can be recovered by incomplete conversion of crude DCPD. The low boiling point of CPD allows its separation from the high-boiling components.

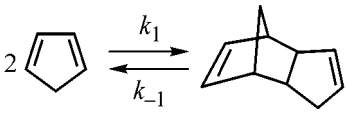
(3) Dimerization–monomerization of CPD and

[1] We used the C_5 fraction of hydrocarbon pyrolysis from the Nizhnekamskneftekhim Joint-Stock Company.

1070-4272/01/7409-1590$25.00

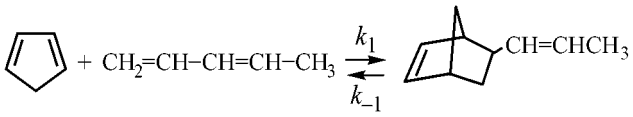
DCPD should be repeated until the required purity is attained. The optimal conditions for each stage can be chosen on the basis of kinetic and thermodynamic parameters of the transformations. Below are given the Arrhenius parameters for direct and reverse Diels–Alder reactions [19] involved in the process for production of high-purity DCPD.

(1) Dimerization–monomerization of CPD and DCPD



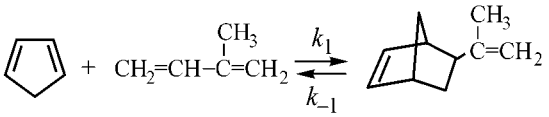
$$k_1 = 1.2 \times 10^6 \exp(-16\,400/RT),$$
$$k_{-1} = 2.6 \times 10^{13} \exp(-34\,000/RT).$$

(2) Reactin of CPD with piperylene



$$k_1 = 2.2 \times 10^4 \exp(-19\,000/RT),$$
$$k_{-1} = 2.6 \times 10^{13} \exp(-38\,900/RT).$$

(3) Reaction of CPD with isoprene



$$k_1 = 3.2 \times 10^5 \exp(-18\,800/RT),$$
$$k_{-1} = 1.02 \times 10^{13} \exp(-39\,400/RT).$$

These data show that the rate constants of CPD dimerization are higher than those of reactions of CPD with isoprene and piperylene; isoprene in the reaction with CPD is more active than piperylene; the difference between the rate constants of CPD dimerization K_{CPD} and of the competing Diels–Alder reactions of CPD with isoprene K_{isop} and piperylene K_{pip} increases with decreasing temperature. Quantitative data on the rate constant ratios are given below:

T, °C	K_{CPD}/K_{isop}	K_{CPD}/K_{pip}
100	95.7	1820
50	159	3150
0	316	6670

These data show that the first stage in the synthesis of high-purity DCPD, dimerization of CPD in the C_5 fraction, should not be performed to full exhaustion. Initially, while the CPD concentration is high, the resulting dimerizate will be enriched in DCPD. As the CPD concentration will decrease, the rate of CPD dimerization, in accordance with the law of mass action, will decrease, whereas the rate of reaction of CPD with isoprene and piperylene will remain relatively high (as the concentration product of the reactants is high). To prepare pure DCPD, low temperatures are preferable.

As already noted, further purification of DCPD can be performed in the course of monomerization of crude DCPD. This process also should not be performed to 100% conversion, lest the impurities present in DCPD would pass to CPD. The above kinetic data show that DCPD decomposes to give CPD more readily than adducts of CPD with isoprene and piperylene. The lower the temperature of the retrodiene synthesis, the larger the difference between the rate constants of these reactions. In retrodiene transformations, the adduct of CPD with isoprene is more stable than that with piperylene. This is a favorable fact, since in the dimerization stage the adduct of CPD with isoprene is the major impurity. Thus, limited conversion and low temperature are prerequisites for increasing the content of CPD in monomerization of crude DCPD.

In the course of the second dimerization, it becomes possible to prepare DCPD with the main substance content of 99.8–99.9 wt %. In this stage DCPD can be separated from low-boiling hydrocarbons by distillation.

The suggested process for production of high-purity DCPD from the C_5 fraction involves the following stages: (1) dimerization of CPD in the C_5 fraction, (2) distillation of crude DCPD to separate low-boiling hydrocarbons of the C_5 fraction, (3) monomerization of crude DCPD, (4) second dimerization of CPD, and (5) distillation.

To confirm our suggestions, we chose the optimal conditions for each stage of the process to obtain 99.5 wt % pure DCPD.

First we studied how the temperature, time, and conversion in dimerization of CPD in the C_5 fraction affect the composition of the resulting product. The results are listed in Table 1.

The experimental data show that the content of CPD adducts with isoprene and piperylene increases with temperature, dimerization time, and conversion of CPD to DCPD. GLC shows that the major impurity

Table 1. Influence of the conditions of CPD dimerization in the C_5 fraction on the DCPD quality

Dimerization conditions		Conversion	DCPD content	Content of impurities	Yield of crude DCPD	DCPD sample no.
T, °C	τ, h	wt %				
50	110	95	88.8	11.2	90.9	1
110	3.5	92	85.8	14.2	84.6	2
110	5	95	83.8	16.2	93.5	3

Table 2. Influence of the conditions of crude DCPD monomerization on the CPD quality

DCPD sample no.	*T*, °C	Conversion	Content of CPD + DCPD	Content of impurities	Yield of CPD	CPD sample no.
		wt %				
1	165–200	90	99.26 + 0.44	0.304	83	1'
	240–250	90–95	82.21 + 2.89	14.90	–	
2	165–200	90	94.07 + 2.84	3.09	86	2'
	240–250	90–95	78.54 + 2.34	19.12	–	
3	165–200	90	86.44 + 3.48	9.96	88	3'

in crude DCPD is the adduct of CPD with isoprene. The experimental results confirmed our assumptions.

Samples of crude DCPD (nos. 1–3) were subjected to monomerization. A fraction of CPD boiling in the range 41.5–42.5°C was taken. The results are listed in Table 2.

As seen from Table 2, the monomerization conditions largely affect the CPD quality. As the monomerization temperature and conversion of DCPD to CPD are increased, the content of impurities in the monomerization products decreases. The best results were obtained in monomerization of sample no. 1: At the monomerization temperature of 165–200°C and conversion of DCPD to CPD to 90% the main substance content was 99.7%. Because of dimerization under ambient conditions, CPD always contains DCPD. Therefore, in Table 2 is given the total content of CPD and DCPD.

Table 2 shows that from 88–89% pure DCPD it is feasible to obtain CPD with the main substance content after monomerization exceeding 99.7%. To this end, dimerization of CPD in the C_5 fraction should be performed at 50°C for 110 h. However, long reaction time prevents to a certain extent commercial implementation of this procedure. In view of the high content of DCPD in sample nos. 2 and 3, it is more appropriate to perform dimerization at 110°C for 3.5–5 h. The purity of CPD after monomerization of these samples is considerably lower than in the case of sample no. 1. Therefore, to prepare DCPD with the main substance content exceeding 99%, it is necessary to perform the second dimerization of CPD at lower temperatures.

The second dimerization of CPD was performed at 50°C for 14–18 h. The conversion of CPD to DCPD was maintained in the range 95–99%. The results are listed in Table 3.

After the second dimerization, the product contains an isoprene impurity. Distillation of the dimerizate in all the three cases yields DCPD with the main substance content of 99.5–99.9%, according to the GLC and NMR data. The total yield of DCPD from the C_5 fraction in our process was 65–70%.

In production of high-purity DCPD, formation of high-molecular-weight polymers (bottoms) in the monomerization stage gives rise to serious problems which have not yet been solved. In the existing commercial processes the amount of bottoms in the monomerization stage reaches 50%. The extent of side processes in monomerization largely depends on the DCPD concentration in the reaction mixture. Therefore, monomerization was performed in a high-boiling inert solvent, heptadecane, in an inert atmosphere in the presence of radical scavengers. As a result, the amount of by-products formed in the monomerization stage was considerably reduced, and their total content did not exceed 10–15%.

The developed process allows production of DCPD

Table 3. Influence of conditions of the second dimerization of CPD on the DCPD quality

CPD sample no.	Dimerization conditions		Conversion	Content of DCPD + CPD	Content of impurities	Yield of DCPD
	T, °C	τ, h	wt %			
1'	50	18	99	98.84 + 1.16	–	94
2'	50	14	99	92.26 + 3.07	4.67	97
3'	50	14	95	96.21 + 3.36	0.33	97

from the C_5 fraction of hydrocarbon pyrolysis with the main substance content exceeding 99.5%.

EXPERIMENTAL

In our study we used laboratory installations for dimerization of the C_5 fraction, monomerization, and distillation of DCPD. Monomerization was performed in a high-boiling solvent, heptadecane, in the presence of hydroquinone under argon. The C_5 fraction, CPD, and DCPD were analyzed with a complex consisting of a Kristall-2000 M chromatograph (30 000 × 0.32-mm capillary column coated with SE-54, 0.5 μm), a Pentium III-500 computer (Chromatec-Analytic software for processing chromatograms, measurement error 0.2%), a Hitachi mass spectrometer, and a Gemini-200 high-resolution NMR spectrometer.

CONCLUSION

A procedure was developed for production of dicyclopentadiene in a 65–70% yield with a purity higher than 99.5% from the C_5 fraction of hydrocarbon pyrolysis. Proper choice of the dicyclopentadiene monomerization conditions allows the amount of bottoms to be reduced to 10–15%.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Features of Radical Polymerization of Vinyl Chloride in the Presence of Nitroxyl Radicals

D. F. Grishin, L. L. Semenycheva, M. V. Pavlovskaya, and K. V. Sokolov

Research Institute of Chemistry, Nizhni Novgorod State University, Nizhni Novgorod, Russia

Received April 25, 2001

Abstract—Radical polymerization of vinyl chloride in the presence of *C*-phenyl-*N*-*tert*-butylnitrone, 2-methyl-2-nitrosopropane, and 1-*tert*-butyl-3-phenyl-1-oxytriazene as potential sources of free radicals was studied.

Radical polymerization is one of the major procedures for preparing polyvinyl chloride (PVC). It is known that the main drawback of radical polymerization is that the kinetic parameters of the process and the molecular-weight characteristics of the resulting polymers are difficult to control because of the high reactivity of radical species. One of the ways to solve the problem is based on the new concept, which is being actively developed, of controllable "pseudoliving" radical polymerization. By performing radical polymerization in the "living" chain mode, it is feasible to prepare polymers of definite structure and molecular weight and hence with the preset properties [1–3]. The known chain-terminating agents, stable radicals and iniferters [2,2,4,4-tetramethyl-1-piperidyloxyl (TEMPO), alkoxyamines, alkylthiocarbamates, etc.], are effective only at relatively high temperatures (100–130°C) and are unsuitable for the gaseous monomer vinyl chloride (VC).

Previously, to prepare polymethyl methacrylate with a relatively narrow molecular-weight distribution (MWD), it was suggested to use *C*-phenyl-*N*-*tert*-butylnitrone (PBN), 2-methyl-2-nitrosopropane (MNP), and 1-*tert*-butyl-3-phenyl-1-oxytriazene (BPT) [4–6], which act as chain-terminating agents at lower temperatures (50–70°C). It is known [7] that MNP and PBN react with radicals, including polymeric radicals, to give nitroxyl spin adducts containing a macromolecular tail. Such sterically hindered stable radicals allow control of the radical polymerization of (meth)acrylic monomers at lower temperatures compared to TEMPO.

Therefore, it seemed promising to study polymerization of VC in the presence of MNP and PBN as potential sources of free radicals, and also of BFT which was successfully used previously as iniferter in low-temperature (50°C) controlled radical polymerization of (meth)acrylic monomers [6].

EXPERIMENTAL

Purification and dosage of vinyl chloride were based on standard procedures [8]. The initiators and solvents were purified by common procedures. Postpolymerization was performed as follows: An ampule at a definite conversion of VC was frozen and attached to a vacuum unit, the residual VC was distilled into the trap, and a new VC portion was added (equal to the initial portion), after which the ampule was again sealed and placed in a thermostat. PBN, MNP, and PBT were prepared by the procedures described in [9–11]. The kinetics of VC bulk polymerization was monitored gravimetrically, dilatometrically [12], and calorimetrically [13]. The Fickentscher constant K_F and the intrinsic viscosity [η] were determined visometrically [14]. The MWD of polyvinyl chloride was analyzed by GPC on an installation equipped with a set of five Styrogel columns with the pore diameter of 1×10^5, 3×10^4, 1×10^4, 1×10^3, and 250 Å (Waters, the United States). As detector was used an R-403 differential refractometer (Waters). The eluent was tetrahydrofuran. The device was calibrated with narrow-disperse polystyrene references [15]. The syndiotacticity index was determined by IR spectroscopy from the ratio of the integral intensities D_{635}/D_{693} [16].

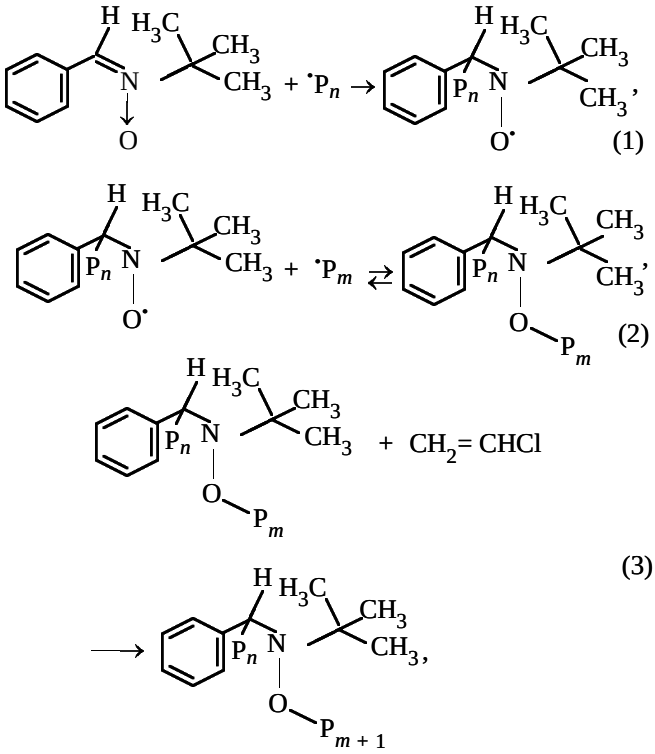
We found that PBN efficiently controls the chain propagation in VC polymerization in the presence of dicyclohexyl peroxydicarbonate (CPC).

Polymerization of VC in the presence of PBN additives (0.01 and 0.05 mol %) occurs with a short induction period (5–15 min); the initial rate is 3.0 and

1070-4272/01/7409-1594$25.00

0.7 mol l^{-1} s^{-1}, respectively, which is lower than in the absence of the additive (9.1 mol l^{-1} s^{-1}). This is apparently due to reaction of oligomeric and polymeric PVC radicals with nitrone as radical scavenger. The differential kinetic curves of VC polymerization, obtained by the calorimetric procedure in the presence and in the absence of PBN (Fig. 1), show that addition of 0.005 mol % PBN results in slight deceleration of the polymerization and noticeable decrease in the gel effect (Fig. 1, curve *2*), as compared to the process performed in the absence of PBN (Fig. 1, curve *1*) in which a pronounced gel effect is observed at a 60–80% conversion. As the PBN concentration is increased to 0.01 mol %, the reaction rate slightly decreases also (Fig. 1, curve *3*), the gel effect is practically fully suppressed, and the process, similar to that with CPC, occurs to high conversions (~90%). The calorimetric data were confirmed by gravimetric monitoring of the polymerization kinetics.

Thus, in polymerization of VC PBN suppresses undesirable autoacceleration. Apparently, similar to the system with MMA [4], in the first stage PBN reacts with the propagating macroradical to form the stable nitroxyl radical [reaction (1)]; then the nitroxyl spin adduct reacts with the propagating radical to form a labile bond [reaction (2)] into which the next monomer molecule can be inserted [reaction (3)]:



where P_n, P_m, and P_{m+1} is the propagating macroradical.

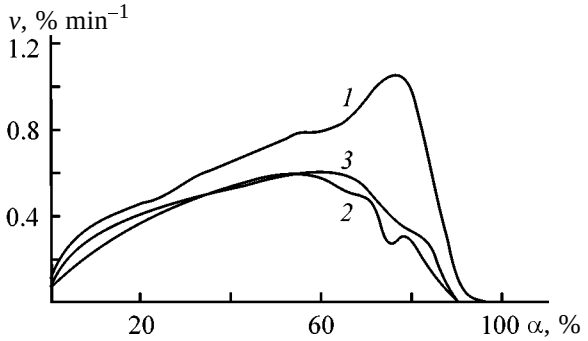


Fig. 1. Differential kinetic curves of VC polymerization in the presence of PBN at 50°C. Initiator CPC, 0.1 mol %; the same for Figs. 2 and 3. (*v*) Polymerization rate and (α) conversion. [PBN], mol %: (*1*) 0, (*2*) 0.005, and (*3*) 0.01.

The reinitiation of polymer chains by reaction (2) is the most significant feature of pseudoliving radical polymerization.

It is known that in pseudoliving polymerization the molecular weight of the polymeric products linearly depends on the conversion, and the polydispersity coefficients of the resulting samples are low. However, it should be noted that a well-known feature of radical polymerization of VC, in contrast to acrylic and some other vinyl monomers, is the high constant of chain transfer to the monomer (K_{ct} ~1×10^3), which ultimately determines the molecular weight of the resulting PVC [16]. Therefore, in radical polymerization of VC the molecular weight of the polymer remains the same irrespective of conversion [16, 17], in contrast to polymerization of acrylic monomers whose molecular weight sharply increases in the stage of the gel effect [18]. The rate constant of the reaction of PBN with secondary alkyl radicals, including the polyvinyl chloride macroradical, is 6.8×10^4 l mol^{-1} s^{-1} [17]. It is almost two orders of magnitude higher than the constant of chain transfer to the monomer. Therefore, if the controllable chain propagation by the mechanism of pseudoliving polymerization actually takes place, in the case of VC the molecular weight should also linearly increase with conversion.

The molecular-weight characteristics of PVC synthesized in the presence of PBN were studied viscometrically and by GPC. It is known [16] that the molecular-weight characteristics of PVC are usually evaluated from the viscosity data using the Fickentscher constant K_F, which is determined from the relative viscosity of a PVC solution of a standard concentration [16], rather than from the Mark–Kuhn–Houwink equation, because of problems with calculation of K and α. The dependence of the number-average molecular weight M_n on conversion for poly-

merization of VC in the presence of PBN is plotted in Fig. 2. The intrinsic viscosities [η] and the molecular-weight characteristics determined from GPC data are listed in Table 1. These data show that the molecular weight of PVC synthesized in the presence of PBN uniformly grows with increasing VC conversion. The changes in the molecular weight are more pronounced at increased content of PBN in the polymerization products.

Figure 3 shows the MWD curves of polyvinyl chloride prepared in the presence of 0.01 (Fig. 3a, curves *1*–*6*) and 0.05 mol % PBN (Fig. 3b) at various conversions. It is seen that all the curves are unimodal and that with increasing conversion of VC the mode successively shifts to the higher molecular weights. Such a dependence is also one of the evidences of

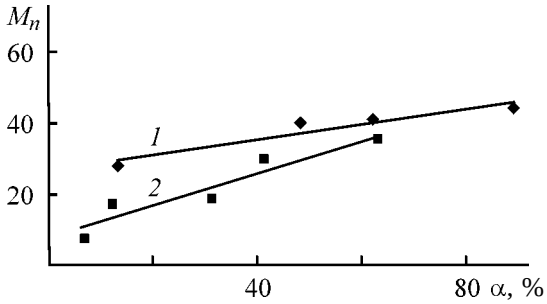

Fig. 2. Number-average molecular weight M_n of PVC prepared in the presence of PBN as a function of conversion α. [PBN], mol %: (*1*) 0.01 and (*2*) 0.05.

pseudoliving polymerization. In the case of a common radical polymerization of VC, no similar shift of the mode of the MWD curves is observed [16, 17].

Table 1 shows that the polydispersity M_n/M_w, where M_w is the weight-average molecular weight, of the polymer prepared in the presence of 0.01 mol % PBN does not change significantly in the range of conversions 4–48%, being in the range 1.7–1.8. With the conversion increasing further, the polydispersity of PVC increases but remains considerably lower than in common radical polymerization (3.7 at high conversion) [17, 19]. In our case, at 89% conversion M_w/M_n = 2.2 (Table 1). Similar trends are observed at a PBN concentration of 0.05 mol %. Such an increase in the polydispersity of the polymers at >50% conversion was observed in polymerization of acrylic monomers by the mechanism of pseudoliving chains in the presence of triphenylmethyl radicals [20, 21]; it suggests decreased contribution of pseudoliving polymerization at high conversions.

Thus, the kinetic data on VC polymerization in the presence of PBN and the molecular-weight characteristics of the resulting PVC show that in the presence of PBN VC polymerizes by the mechanism of pseudoliving chains.

Our results open the possibility for controlling the chain propagation and the molecular weight of PVC in the course of its synthesis. It is known [2] that

postpolymerization and syntheses of block copolymers, star copolymers, etc. are performed by living cationic and anionic polymerization. The possibility of radical polymerization of VC by the mechanism of pseudoliving chains (it is known [16] that vinyl chloride polymerizes only by the radical mechanism) can extend the field of practical applications of PVC, as the polymer with the molecular weight controllable in a wide range will become available. In this context, it seemed interesting to perform postpolymerization of VC in the presence of PBN. For this purpose, to the VC polymer prepared in the presence of PBN we added a new portion of VC. For the polymer samples obtained by postpolymerization, we determined the molecular-weight characteristics by viscometry and GPC. The MWD curves of these samples, similar to those of the polymer obtained in the presence of PBN, are unimodal (Fig. 3a, curves *7*, *8*), and with increasing conversion of VC the mode successively shifts to higher molecular weights. Table 1 shows that the molecular weight of the polymer in this case increases, and the polydispersity M_w/M_n of the polymer prepared by postpolymerization in the presence of 0.01 mol % PBN (sample nos. 7, 8) is comparable with that of PVC at high conversions of PBN (sample no. 6). The M_n values for PVC fall on the extension of the linear dependence of M_n on conversion for PVC prepared in the presence of PBN. These data also support the pseudoliving mechanism of postpolymerization.

An important experimental characteristic of PVC is the syndiotacticity index, i.e., the ratio of the optical densities of the absorption bands of the C–Cl stretching vibrations at 635 and 693 cm^{-1}, D_{635}/D_{693}. This index correlates with such characteristics of PVC as crystallinity, heat resistance, and softening point [16]. From the IR spectra of PVC samples of various conversions, prepared with additions of PBN, we calculated the syndiotacticity indices (Table 1). As seen from these data, the syndiotacticity indices are essentially the same for various PVC samples prepared in the presence of PBN and without additives. This fact shows that the presence of PBN has no effect on formation of syndio- and isotactic fragments in the polymer, as it takes place, e.g., in polymerization in the presence of organometallic compounds [22].

Experiments on the VC polymerization initiated with dicetyl peroxydicarbonate (DPC) with addition of MNP and BPT showed that, in contrast to PBN, in the presence of catalytic amounts of MNP (0.01–0.1 mol %) and BPT (0.01–0.05 mol %) the controllable chain propagation is not realized. According to the kinetic data (Fig. 4), MNP acts as a common

inhibitor: At the beginning of the process an induction period is observed, after which the process kinetics, up to high conversions, becomes similar to that in the absence of the additive (Fig. 4, curves *2*, *1*, respectively; the kinetic curve of VC polymerization in the presence of DPC and hexane coincides with that in the

absence of hexane). The induction period increases from 2 to 4 and 15 h on adding, respectively, 0.01, 0.03, and 0.05 mol % MNP. On adding 0.03 mol % BPT the induction period is 1 h. The polymerization rate slowly increases, and after reaching a 30% conversion the pattern becomes identical to that in the presence of MNP. This may be due to the fact that MNP is formed in the course of polymerization by the scheme suggested in [4, 5]. As a result, the process slightly decelerates.

The molecular weight data for the polymer prepared in the presence of MNP and BPT are well consistent with the kinetic data: The molecular weight of PVC characterized by the intrinsic viscosity and K_F (Table 2) is the same irrespective of the VC conversion, which is typical of common polymerization of VC [16].

The different effects of MNP and PBN on the kinetic and molecular-weight characteristics of the PVC synthesis are probably due to essentially different constants of acception of secondary radicals (in this case, VC propagation radical) by MNP and PBN: For MNP they are higher than for PBN by two orders of magnitude [7]. Therefore, in polymerization of VC MNP acts exclusively as inhibitor.

CONCLUSIONS

(1) Studies of the polymerization kinetics of vinyl chloride, molecular-weight characteristics of the resulting polymer, and postpolymerization of vinyl chloride in the presence of *C*-phenyl-*N*-*tert*-butylnitrone show that in these systems the reaction occurs by the mechanism of pseudoliving chains. It should be noted that the revealed possibility of controlling the chain propagation and molecular weight in the course of synthesis of polyvinyl chloride is the first example of realization of the pseudoliving chain mechanism in polymerization of vinyl chloride.

(2) Our results allow *C*-phenyl-*N*-*tert*-butylnitrone to be considered as agent controlling the propagation and lifetime of the polymeric chain under energetically favorable conditions; they can serve as a basis for development of efficient procedures for preparing polyvinyl chloride with a wide range of molecular weights.

(3) In contrast to *C*-phenyl-*N*-*tert*-butylnitrone, catalytic amounts of 2-methyl-2-nitrosopropane and 1-*tert*-butyl-3-phenyl-1-oxytriazene do not control the propagation of the polymeric chain in polymerization of vinyl chloride under radical initiation conditions.

Abstract—The efficiency of water purification at simultaneous use of Praestol macromolecular flocculants, iron(II) sulfate coagulant, and calcium hydroxide alkalizing agent was studied as influenced by the nature (cationic and anionic), chemical composition, and conformational state of the flocculant macromolecules in solution and by the concentrations of the flocculant and coagulant.

Only highly purified water can be used for feeding of boilers at heat and electric power plants (HEPPs). The treatment of natural waters often involves preliminary reagent purification and several stages of demineralization with ion-exchange resins. During preliminary purification water is alkalized to decrease its hardness and treated most commonly with iron(II) sulfate to promote coagulation. Precipitate forming in the treated water by hydrolysis of the coagulant and subsequent interaction of hydrolysis products with suspended and colloidal dispersed particles is removed using clarifiers and filters. Thus, in the first stage water is treated to remove coarse and colloidal particles, iron compounds, and organic admixtures, which poison ion-exchange resins in the course of further water treatment and promote corrosion and damage of the boilers and pipelines. Preliminary water treatment can be intensified by simultaneous use of coagulants and flocculants [1]. Among polyacrylamide flocculants widely used in water treatment, macromolecular Praestols[1] are the most promising [2, 3]. It was found [4, 5] that the Praestol anionic flocculant used simultaneously with aluminum sulfate at the water-treatment plants provides efficient purification of natural water for drinking water supply.

In this work we studied the performance of Praestol anionic and cationic flocculants at their simultaneous use with iron(II) sulfate (coagulant) and calcium hydroxide (alkalizing agent) in the water treatment at HEPP.

[1] Produced by Moscow–Stockhausen–Perm Russian–German Joint-Stock Company.

EXPERIMENTAL

In the tests we used commercial iron(II) sulfate [GOST (State Standard) 6981–75], saturated solution of construction lime (GOST 9179–77), and commercial Praestols: anionic [copolymers of acrylamide (AA) with sodium acrylate (Na-AA)] and cationic [copolymers of AA with trimethylammoniopropylacrylamide chloride (TMAPAC)]. The properties of these polymers are listed in the table. Solutions were prepared in distilled water; all other reagents were of analytically pure or chemically pure grade. The reagent water pretreatment was studied using river water from the process cycle of the Kazan HEPP-2 (total hardness 4.1 mg-equiv l^{-1}, alkalinity 2.85 mg-equiv l^{-1}, pH 8.34, SiO_2 content 6.05 mg l^{-1}). The samples of natural water were clarified in a 250-ml cylinder. For this purpose natural water was successively treated with lime solution (235.2 mg l^{-1}), iron(II) sulfate (66.9 mg l^{-1}), and Praestol flocculant (0.4 mg l^{-1}); the reagent concentrations given above provide the most efficient water purification and were used in all the tests. Then the cylinder was turned over 10 times, and the variations in the optical density of clarified natural water were registered on an LAM-1 device (λ 670 nm, l 35.2 mm). The measurements were carried out in the same cylinder (at the depth of 90 mm from the surface) after its installation in the

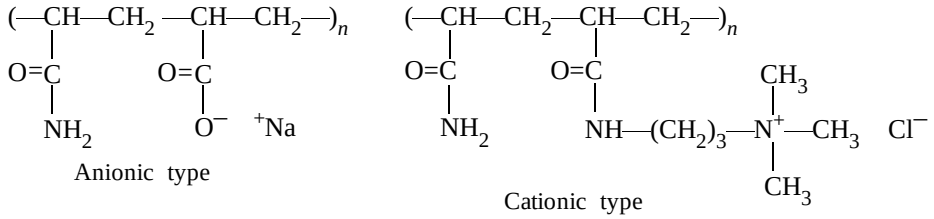
* Structures of macromolecules:



device. After sedimentation the precipitate was filtered off on a paper filter, and the resulting filtrate was analyzed for the iron content and permanganate oxidizability according to the procedures given elsewhere [6]. The reduced viscosity of the Praestol solutions η_{sp}/C_p was measured using a VPZh-3 viscometer (d_c = 0.54 mm) at C_p 0.002% and 25°C.

First we evaluated the effect of the chemical composition of the cationic and anionic Praestols on the sedimentation of the dispersed phase in natural water. The tests were carried out at constant concentrations of the alkalizing agent, coagulant, and flocculant. Typical kinetic curves of the variations in the water turbidity in the presence and absence of flocculant, registered by the turbidimetric procedure, are shown in Fig. 1. As seen, anionic Praestol flocculant being added to water significantly decreases its turbidity, accelerating sedimentation of the dispersed particles. Hydrolysis of iron(II) sulfate after its addition into the alkalized water yields positively charged colloidal aquahydroxy complexes of iron, which neutralize negatively charged particles of colloidal humus and dispersed mineral particles in natural water. As a result, the neurtralized colloidal particles form coarse aggregates and fall down. Further flocculant addition results in formation of large aggregates, which increases the precipitate density and accelerates water clarification. The flocculation factor D used as a criterion of the flocculation effect is defined as follows:

$$D = (V - V_0)/V_0,$$

where V_0 and V are the rates of the 50% change in the water turbidity in the absence and in the presence of Praestol.

The dependences of the flocculating factor D on the content of ionic units α in the macromolecules of anionic and cationic Praestols are shown in Fig. 2. As seen, the $D = f(\alpha)$ dependence passes a maximum for both anionic and cationic flocculants. This is probably due to the similar dependence of the effective size of macromolecular globules $(r^2)^{1/2}$ on α, which is confirmed by the dependence of the reduced viscosity η_{sp}/C_p (determined in water at C_p = const) [7, 8] on

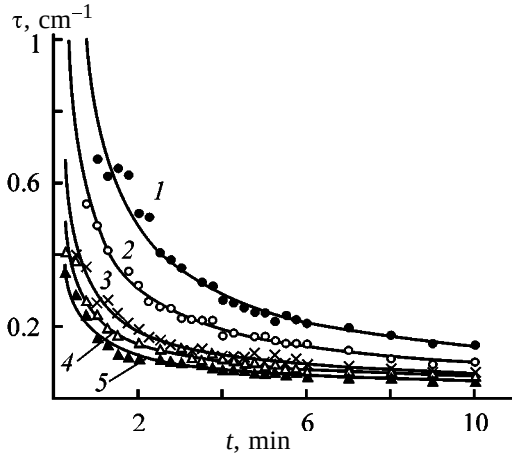


Fig. 1. Water turbidity τ as a function of the sedimentation time t in the course of liming with coagulation of natural water in the (*1*) absence and (*2*–*5*) presence of anionic Praestols. Sample: (*2*) A-1, (*3*) A-2, (*4*) A-3, and (*5*) A-4.

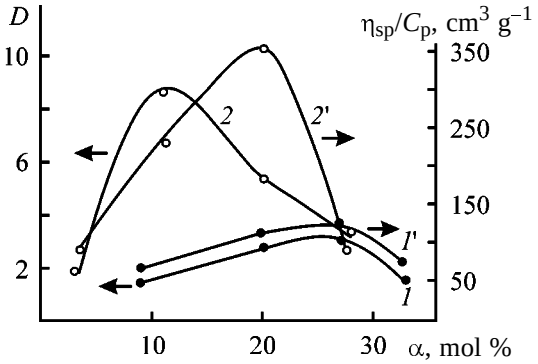

Fig. 2. (*1*, *2*) Flocculation factor *D* and (*1'*, *2'*) reduced viscosity η_{sp}/C_p of flocculant solutions as functions of the content of the ionic fragments α for (*1*, *1'*) anionic and (*2*, *2'*) cationic Praestols.

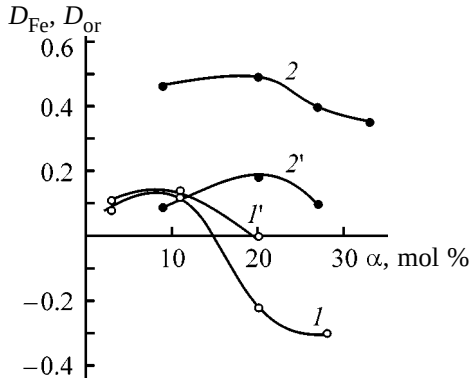

Fig. 3. Recovery of (*1*, *2*) iron D_{Fe} and (*1'*, *2'*) organic compounds D_{or} as a function of the content of ionic fragments α in (*1*, *1'*) anionic and (*2*, *2'*) cationic Praestols; η_{sp}/C_p was determined in water at C_p 0.002% and 25°C.

α for anionic (Fig. 2, curve *1'*) and cationic (curve *2'*) Praestols. The highest flocculation effect *D* (Fig. 2) is observed for anionic Praestol with α 11 mol % (A-2 sample) and for cationic Praestol with α 20 mol % (C-3). Apparently, such composition of macromolecules provides the optimal ratio between the charge density and chain flexibility, which ensure the highest $\langle \bar{r}^2 \rangle^{1/2}$. As a result, a macromolecule with the largest $\langle \bar{r}^2 \rangle^{1/2}$ interacts with a larger number of the dispersed particles causing aggregate coarsening and accelerating their precipitation.

Comparison of the experimental data for the same α (Fig. 2) shows that anionic Praestols provide the greater flocculating effect as compared with the cationic flocculants. This is due to the larger [η] for anionic Praestols (see table) and thus to higher molecular weights *M*, because, according to the Mark–Houwink–Kuhn equation, [η] ~ *M*. With increasing *M* $\langle \bar{r}^2 \rangle^{1/2}$ increases, which promotes interaction of the flocculant with a larger number of particles of the dispersed phase in water and thus enhances the flocculation effect.

We also studied the effect of Praestol flocculants on the recovery of iron compounds and organic impurities from treated water. The tests were performed at a fixed concentrations of the alkalizing agent, coagulant, and flocculant. The efficiency of the iron recovery was evaluated from the following equation:

$$D_{Fe} = (C^0_{Fe} - C_{Fe})/C^0_{Fe},$$

where C_{Fe} and C^0_{Fe} are the contents of iron in water after coagulation in the presence and absence of Praestol as compared with the initial water (%).

The recovery of organic compounds was evaluated by the following parameter:

$$D_{or} = (C^0_{ox} - C_{ox})/C^0_{ox},$$

where C_{ox} and C^0_{ox} are the permanganate oxidizability of water in the presence and absence of Praestol as compared with the initial water (%).

The dependences of D_{Fe} and D_{or} on α for anionic and cationic Praestols are shown in Fig. 3. As seen, the highest D_{Fe} and D_{or} for anionic and cationic Praestols are observed with samples A-2 and C-3 with α = 11 and 20 mol %, respectively. Though the trends in Fig. 3 are weakly pronounced, they agree well with the data presented in Fig. 2, and therefore they can be explained by the same reasons. Moreover, cationic flocculants more efficiently remove iron and organic compounds from water as compared with anionic Praestols (Fig. 3). This is obviously due to the formation of interpolymeric complexes [9] between the positively charged macromolecules of cationic Praestol and negatively charged macromolecules of the humic and fulvic acids and their complexes with iron present in natural water alkalized to pH 11.

Figures 2 and 3 show that the Praestol cationic flocculant with α 20 mol % (C-3 sample) is the most promising for preliminary purification of natural water. For this sample we studied the efficiency of the recovery of iron compounds and organic impurities as influenced by the concentrations of the coagulant (Fig. 4) and flocculant (Fig. 5). As seen from Fig. 4, at fixed concentrations of the flocculant and alkalizing agent the efficiency of recovery of iron compounds and organic impurities decreases with decreasing flocculant concentration from 67 to 15 mg l^{-1}. Figure 5 shows that, at fixed concentrations of the coagulant and alkalizing agent, with decreasing concentration of the Praestol cationic flocculant in the 1.0–0.2 mg l^{-1}

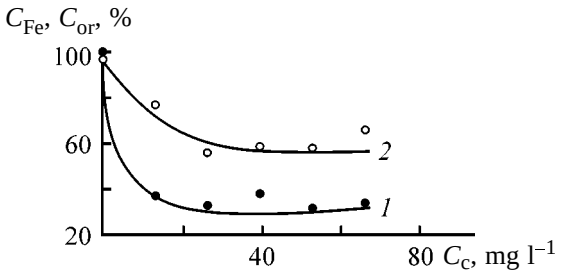

Fig. 4. (*1*) Concentration of iron C_{Fe} (%, with respect to initial) and (*2*) organic compounds C_{or} (%, with respect to initial) as a function of iron(II) sulfate coagulant concentration C_c. Lime concentration 232.5 mg l^{-1}, flocculant concentration 0.4 mg l^{-1}; initial water: iron concentration 194 μg l^{-1}, oxidizability 7.6 mg O per liter.

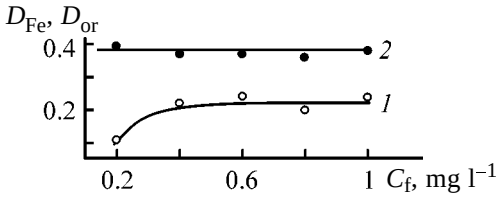

Fig. 5. Recovery of (*1*) iron D_{Fe} and (*2*) organic compounds D_{or} as a function of Praestol cationic flocculant concentration C_f; sample C-3. Lime concentration 232.5 mg l^{-1}, coagulant concentration 66.9 mg l^{-1}.

range the efficiency of recovery of iron compounds decreases at low flocculant concentrations, whereas the content of organic impurities remains almost unchanged. The above data show that under the experimental conditions with cationic Praestol (α 20 mol %) the lower limits of the coagulant and flocculant concentrations ensuring efficient purification of water are 15 and 0.4 mg l^{-1}, respectively.

CONCLUSIONS

(1) In the course of water treatment with Praestol flocculants at constant concentrations of alkalizing agent (calcium hydroxide) and coagulant [iron(II) sulfate] the dependences of D, D_{Fe}, D_{or}, and η_{sp}/C_p (at C_p const) on the content of the ionic fragments are due to the change in the effective size of macromolecules in solutions and pass a maximum at α 11 and 20 mol % for anionic and cationic Praestols, respectively.

(2) The values of D increase on passing from the cationic to anionic flocculants, whereas D_{Fe} and D_{or} decrease.

(3) In the presence of cationic Praestol (α 20 mol %) the lower limits of the coagulant and flocculant concentrations ensuring efficient purification of water are 15 and 0.4 mg l^{-1}, respectively.

BRIEF COMMUNICATIONS

Alkylation of Crystalline Salts of 1,3-Thiazolidine-2,4-diones with Alkyl Halide Vapors

A. I. Ginak, E. B. Aronova, and M. V. Rutto

St. Petersburg State Technological Institute, St. Petersburg, Russia

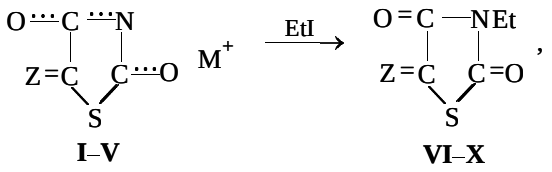
Received April 9, 2001

Abstract—Alkylation of 1,3-thiazolidine-2,4-diones with alkyl halide vapors was performed. The composition of the reaction mixtures was determined by thin-layer chromatography.

Alkylated derivatives of 1,3-thiazolidine-2,4-diones are promising compounds exhibiting antibiotic, acaricidal, herbicidal, and other useful properties. However, the traditional procedure of their synthesis by alkylation of alkali metal and ammonium salts of 1,3-thiazolid-4-ones yields a mixture of isomers originating from addition of the alkyl radical to the heterocyclic nitrogen atom and exocyclic oxygen atom at the 2-position. The latter reaction yields 2-alkoxy-Δ^2-1,3-thiazolin-4-ones, unstable by-products decomposing in the course of the reaction, which results in decreased yield and contamination of the target products. The side addition of the alkyl radical to the exocyclic oxygen atom is quite natural, since 1,3-thiazolidine-2,4-diones are ambifunctional compounds showing dual reactivity in nucleophilic substitutions in solutions [1]. Attempts to affect the isomer ratio by varying the nucleophilicity of the substrate, polarizability of the reagent, and polarity of the medium have not improved the situation; in all the cases either an isomer mixture was formed or the alkylation rate drastically decreased; therefore, alkylation in solutions was considered to have no practical significance [2].

A successful attempt of selective synthesis of alkyl derivatives of 1,3-thiazolin-4-ones by a solid-phase reaction [3–5] creates a prerequisite for purposeful synthesis of 3-alkyl-substituted 1,3-thiazolidine-2,4-diones by solid-phase synthesis. 1,3-Thiazolidine-2,4-diones form a close-packed crystal lattice with the space group *Pbca* in which the molecules are packed in the form of planar hydrogen-bonded (N^3–H···O^2–C^2) dimers [6]. In their alkali metal salts, the counterion is equidistant from the O^2 and N^3 reaction centers [7], which makes the nitrogen atom accessible for the electrophilic attack by an alkyl group, whereas shielding of the O^2 atom prevents formation of by-products.

To confirm this assumption, we alkylated the crystalline alkali metal salts with ethyl iodide vapor:



I–V **VI–X**

where Z = H_2 (**I**, **VI**), PhCH (**II**, **VII**), 4-$NO_2C_6H_4CH$ (**III**, **VIII**), 4-$(CH_3)_2C_6H_4CH$ (**IV**, **IX**), 4-$CH_3C_6H_4$·CH (**V**, **X**); M = Li, Na, K.

Crystals of **I**–**V** were treated with ethyl iodide vapor. Special experiments showed that the result is independent of the amount of the alkylating agent and reaction conditions.

The composition of the reaction mixture was determined by quantitative thin-layer chromatography (TLC). We found that the reaction yields only the products of addition of the alkyl group at the N^3 atom (see table). Quantitative analysis shows that the material balance is well kept throughout the experiment, i.e., the "initial" concentration calculated from the weight of the salt sample is equal to the sum of the running concentrations of the salt and reaction product. These concentrations were measured with an error of $\leq$5%.

We also examined the effect of the counterion in the substrate on its reactivity and revealed no difference in the reaction pathway between the Li^+, Na^+, K^+, and Cs^+ salts.

EXPERIMENTAL

1,3-Thiazolidinedione and its 5-arylmethylene derivatives were prepared according to [8]. The compounds were recrystallized from ethanol and identified

Abstract—The structure of the copolymer prepared by radical copolymerization of vinyl chloride with 1-vinyl-1,2,4-triazole was studied by quantitative ^{13}C NMR spectroscopy. The structural unit of the copolymer consists of the units of vinyltriazole and quaternized vinyltriazole, vinyl group, and four vinyl chloride units.

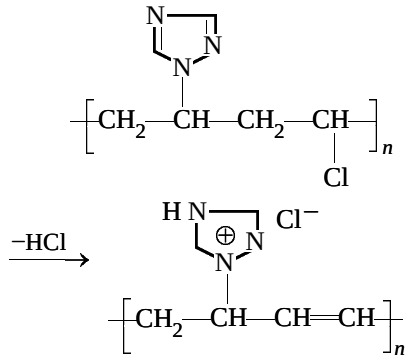
The most widely used procedure for preparing modified polyvinyl chloride is copolymerization of vinyl chloride (VC) wirth various monomers. It was shown previously that radical copolymerization of VC with *N*-vinyl-4,5,6,7-tetrahydroindole is accompanied by dehydrochlorination [1].

In this work we studied by ^{13}C NMR spectroscopy the structure of the copolymer prepared by radical copolymerization of VC with 1-vinyl-1,2,4-triazole (VT).

Copolymerization of VC with VT was performed in *N*-methylpyrrolidone with azobis(isobutyronitrile) initiator.

The IR spectra of the resulting copolymers contain no bands characteristic of the *N*-vinyl group (960, 1680 cm^{-1}), but the vibration bands of the triazole ring (1030, 1210, 1560 cm^{-1}) are preserved, and a band characteristic of C=C bonds appears at 1640 cm^{-1}. The ^{13}C NMR spectrum of the VC–VT copolymer contains broadened signals of the carbon atoms of the triazole ring (151.91, 144.38 ppm), a group of signals of the vinyl moiety –CH=CH– (128.03–127.58 ppm), and carbon signals of the >CHCl (58.49–56.57 ppm), –N–CH– (54.6), and >CH_2 (45.4 – 41.9 ppm) groups. Along with the above signals, the spectrum contains narrow signals corresponding to the carbon atoms of *N*-methylpyrrolidone (17.21, 27.03, 30.73, 48.56, 173.90 ppm), probably chemisorbed on the copolymer surface. It should be noted that the polymer was reprecipitated two times and vacuum-dried to constant weight.

The vinyl fragments incorporated into the copolymer are formed by elimination of hydrogen chloride from VC in the course of its copolymerization with VT. Hydrogen chloride can be bound by the triazole ring:



The quantitative analysis of the ^{13}C NMR spectrum showed that the molar ratio of the VC and VT units, vinyl groups, and *N*-methylpyrrolidone is 1.00 : 2.67 : 0.619 : 0.254. The elemental composition and content of each component (wt %) were calculated from the ^{13}C NMR spectra assuming that (1) VT does not bind hydrogen chloride, (2) all VT rings bind hydrogen chloride, and (3) only 0.619 mol of VT binds hydrogen chloride. The results are listed in the table.

The results of chemical analysis are consistent with the composition calculated from the ^{13}C NMR spectrum with assumption 3 (data are printed bold in the table). When calculating the copolymer composition from the elemental analysis data, we took into account the total content of chlorine (both organic and ionic) in the final product; therefore, the content of VC units calculated from the ^{13}C NMR spectrum differs from that calculated from the analytical data.

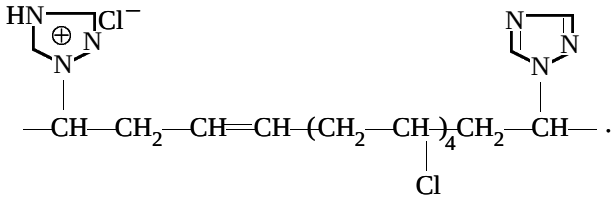
From the results of quantitative analysis we calcu-

1070-4272/01/7409-1606$25.00

Elemental composition of VC–VT copolymer; relative content of comonomers, vinyl group, and *N*-vinylpyrrolidone in the sample

Element, fragment	Composition, wt %			
	^{13}C NMR spectrum			chemical methods
C	46.91	41.86	**43.65**	43.40
H	5.45	5.16	**5.27**	5.76
N	15.03	13.41	**13.99**	14.81
O	1.34	1.20	**1.25**	1.26 (from difference)
Cl	31.27	38.36	**36.04**	34.77
VT	31.34	27.97	**29.17**	29.42 (by chlorine) 24.91 (by nitrogen)
VC	55.05	49.14	**51.23**	70.58 (by chlorine) 75.09 (by nitrogen)
–CH=CH–	5.31	4.74	**4.94**	4.51 (from difference between copolymer compositions calculated by chlorine and nitrogen)
N-Methyl-pyrrolidone	8.30	7.40	**7.72**	–

lated the structural unit of the copolymer consisting of the VT unit, quaternized VT unit, vinyl group, and four VC units:



The elemental composition of the structural unit of the copolymer (wt %) is as follows: C 42.99, H 4.98, N 16.71, and Cl 35.32; the content of fragments in the structural unit of the copolymer is as follows (wt %): VC 49.75, VT18.90, quaternized VT 26.17, and CH=CH 5.18.

EXPERIMENTAL

Copolymerization was performed in sealed ampules at 60°C in the presence of azobis(isobutyronitrile) (1.5 wt % relative to comonomers) under argon. The reaction mixture was dissolved in dimethylformamide (DMF), and the copolymer was precipitated with acetone. Then the copolymer was reprecipitated two times from solution in DMF into acetone and vacuum-dried to constant weight. The copolymer composition was determined by elemental analysis following the standard procedure [2]. The content of the –CH=CH– was calculated from the difference between the compositions calculated by nitrogen and chlorine (e.g., 75.09 – 70.58 = 4.51 and 29.42 – 24.91 = 4.51).

The IR spectra were taken on a Specord IR-75 spectrometer (KBr pellets or mulls in mineral oil).

The ^{13}C NMR spectrum of the copolymer sample was taken on a Varian VXR-500S spectrometer (working frequency 125.5 MHz) in DMSO-d_6 at a relaxation delay of 2.5 s and 90° pulse. As relaxant was used chromium tris(acetylacetonate) (0.02 M). The molar ratios of the copolymer components and *N*-methylpyrrolidone were calculated by a common procedure: The fraction of one carbon atom of VT q_{VT} was taken equal to one carbon atom, which corresponds to 1 mol of VT, M_{VT}. The number of moles of the other components was calculated by the formula

$$M_x = q_x / q_{VT},$$

where q_x is the fraction of the carbon atom of component x, $q_x = I_x/I_{tot}$ (where I_x and I_{tot} are the integral intensity of the signal of atom x and the total integral intensity, respectively).

The relative error of the quantitative determination of the relative content of comonomers (wt %) and elemental composition of the copolymers does not exceed 6.7%.

CONCLUSIONS

(1) Radical copolymerization of vinyl chloride with 1-vinyl-1,2,4-triazole in *N*-methylpyrrolidone is accompanied by dehydrochlorination.

(2) The composition of the copolymer, calculated from the ^{13}C NMR spectrum and from elemental analysis data, shows that the released hydrogen chloride protonates approximately each second triazole ring.

Synthesis of *N*-Vinylpyrrolidone–Vinyltrimethoxysilane Copolymers

M. N. Gorbunova, V. D. Surkov, and M. S. Fedoseev

Institute of Technical Chemistry, Ural Division, Russian Academy of Sciences, Perm, Russia

Received March 6, 2001; in final form, April 2001

Abstract—*N*-Vinylpyrrolidone–vinyltrimethoxysilane copolymers were prepared by radical copolymerization. The composition of the copolymer was studied in relation to the reaction temperature and composition of the initial mixture. The kinetic parameters of the monomer activity were calculated.

Unique properties of polyvinylpyrrolidone (PVP) such as good solubility in water and organic solvents, high complexing power with respect to a wide range of inorganic, organic, and biological objects, and the lack of toxicity allow wide use of PVP in engineering, medicine, pharmacy, and agriculture [1–3]. Therefore, there is a growing interest in syntheses of new polymers based on *N*-vinylpyrrolidone (VP) by copolymerization with other polyfunctional monomers. Of particular interest in this respect are copolymers with a labile organosilicon moiety, capable of further polymer-analogous transformations.

It is known that alkenylsilanes show poor activity in radical polymerization because of the steric and electronic effect of the silicon atom, but they relatively readily copolymerize with acetonitrile, styrene, vinyl acetate, and vinyl chloride [4–6].

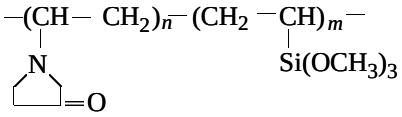
This study is aimed at synthesis of VP–vinyltrimethoxysilane (VTMS) copolymers, which practically have not been studied previously.

EXPERIMENTAL

The initial monomers VTMS and VP (commercial products) were vacuum-distilled before use. VTMS: bp 122°C, n_D^{20} 1.390 (cf. bp 52.9°C/49 mm Hg n_D^{20} 1.390 [7]); VP: bp 65°C/1.5 mm Hg, n_D^{20} 1.5117 (cf. bp 71–72°C/2.5 mm Hg, n_D^{20} 1.5117 [1]). Azobis(isobutyronitrile) (AIBN) of cp grade was used without additional purification.

The copolymers were prepared by radical copolymerization in the bulk by heating with AIBN in sealed glass tubes in the presence of atmospheric oxygen. The copolymer was dissolved in acetone and reprecipitated into diethyl ether. After filtration and drying with diethyl ether, the copolymers were dried in an oven at 45°C to constant weight.

Table 1. VP–VTMS copolymers [initiator AIBN (0.05%), reaction time 3 h]



Content of monomers, mol %		*T*, °C	Yield, %	Found N, %	Copolymer composition, mol %	
VP	VTMS				VP	VTMS

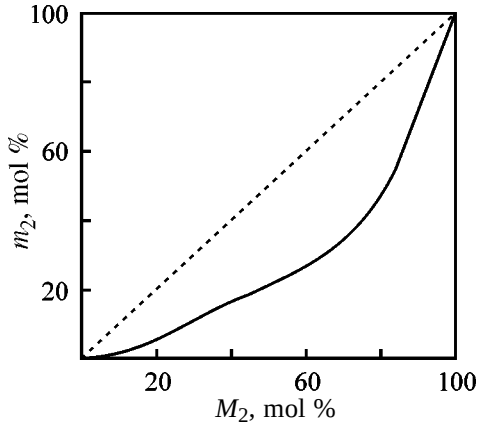
66.67	33.33	60	71.0	9.39	79.58	20.42
25.00	75.00	60	30.7	6.79	60.91	39.09
84.21	15.79	80	82.9	9.73	81.88	18.12
84.21	15.79	100	80.9	8.95	76.57	23.43

1070-4272/01/7409-1608$25.00



Composition of VP–VTMS copolymers as a function of the monomer ratio. Reaction temperature 60°C, reaction time 3 h. (m_2) Content of VTMS in copolymer and (M_2) content of VTMS in the initial mixture.

The IR spectra were taken on a UR-20 spectrometer. Samples were prepared as mulls in mineral oil. The copolymer composition was calculated from data of elemental analysis for nitrogen.

The copolymers are gelatinous substances soluble in acetone, ethanol, and chloroform; after reprecipitation with diethyl ether and drying in an oven they transform into a white powder. After reprecipitation and drying, the solubility in organic solvents is lost, probably owing to formation of siloxane cross-links. The characteristics of the copolymers are listed in Table 1. The formation of the copolymers was confirmed by the IR spectra, which contain absorption bands at 1680 (VP C=O bonds) and 1094 cm^{-1} (VTMS Si–O bonds).

The bands at 1600 and 1628 cm^{-1}, characteristic of the double bonds in VTMS and VP, respectively, are lacking in the spectra of the copolymers, which confirms occurrence of the radical copolymerization through the double bonds.

Table 2. Parameters of monomer activity*

Calculation method	r_1	r_2	Q_2	e_2
FR	3.64 ± 0.07	0.21 ± 0.02	0.02 ± 0.002	–0.62 ± 0.06
KT	1.44 ± 0.14	0.16 ± 0.02	0.02 ± 0.002	+0.07 ± 0.007

* Q_1 = 0.14, e_1 = –1.14 [9].

The composition of the copolymers as a function of the composition of the initial mixture is shown in the figure.

As seen from the composition diagram, VP forms with VTMS random copolymers enriched in VP units. The copolymerization constants r_1 and r_2 calculated by the Fineman–Ross (FR) and Kelen–Tudos (KT) methods are listed in Table 2. These data were obtained at monomer conversions not exceeding 50%, which is acceptable in calculations of r_1 and r_2 by the Kelen–Tudos method [8].

In this case, the Alfrey–Price *Q*–*e* reactivity parameters of VTMS were as follows: Q_2 = 0.02 and e_2 = 0.07; the published values for VP are Q_1 = 0.14 and e_1 = –1.14 [9].

Thus, we prepared VP–VTMS copolymers and determined the activity parameters of the monomers in radical copolymerization.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Professor Gustav Tammann (To 140th Birthday Anniversary)

Similarly to a number of his contemporaries, prominent chemists of the late XIX century–early XX century, Gustav Tammann had rather wide scientific interests. He made an outstanding contribution to investigations of solutions, heterogeneous equilibria, and crystallization processes and studies of metal systems, glassy state, and solid solutions.

Gustav Heinrich Johann Tammann was born on May 28, 1861, in Jamburg, St. Petersburg Province (now Kingisepp, Leningrad oblast). His father, Heinrich Tammann (1833–1864) was of Estonian peasant origin. He graduated from the faculty of medicine of Derpt (Yuryev, Tartu)[1] University in 1857 and worked as a physician first in Jamburg and then at Gorki, Mogilev Province (now Gorki, Mogilev oblast, Belarus). At the same place, Heinrich Tammann taught applied medicine at Gorigoretskii Agricultural Institute [1, 2]. Gustav Tammann's mother, Matilda Schünmann, was of German origin. After Heinrich Tammann's death, his family moved to Derpt. Despite the more than modest means at family's disposal, Gustav Tammann successfully finished gymnasium and entered the physicomathematical faculty of Derpt University in 1879. One of the oldest in Russia, the University was opened in April 1802 (the history of this educational institution dates from 1632, but later its functioning was interrupted for a long time). In 1802–1850, the University did not train specialists in chemistry. The chair of chemistry, formed in 1804, mainly satisfied the demand of medicine and pharmacology [3, 4]. In 1850 the physicomathematical faculty including a chemical department was created, and training of specialists in chemistry was commenced. According to the available data [5], 58% of those studying at the chemical department during the period from 1850 till 1917 were from Baltics, 41% from other provinces of Russia, and 1% from abroad. About 60% of those graduated from the chemical department received a degree of candidate of science.

[1] In 1893, the town of Derpt (Dorpat) was given its previous (1030–1224) name of Yuryev; in 1919, it became Tartu. Correspondingly changed the name of the University.

During G. Tammann's education at the University, all chemical disciplines were taught by professor Carl Schmidt (1822–1894), a known scientist of that time, educated at German universities.[2] Schmidt was a representative of the scientific school created by such prominent chemists of the XIX century as J. Liebig (1803–1873) and F. Wöhler (1800–1882). C. Schmidt became extraodinary professor at the chair of pharmacology in 1850, and ordinary professor of chemistry and head of chemical laboratory in 1852. In 1873, C. Schmidt was elected a corresponding member of the St. Petersburg Academy of Sciences for his works in the field of hydrochemistry.

The main Schmidt's investigations were done in the field of physiological chemistry and also analytical chemistry, hydrochemistry, and agricultural chemistry. Among his widely known works were, in particular, his studies of the chemical composition of chernozem soils of the European Russia. Schmidt's

[2] A major contribution to studies of the life and activities of chemists from Tartu University of the XIX century, C. Schmidt, G. Tammann, W. Ostwald, and others, was made by Ugo Vol'demarovich Palm (1933–1989), professor of the same university, known electrochemist and historian of chemistry.

1070-4272/01/7409-1610$25.00 © 2001 MAIK "Nauka/Interperiodica"

laboratory at Derpt University was a recognized center of the most precise chemical analyses of a wide variety of natural objects: clays, minerals, soils, fertilizers, and water.

At the time of G. Tammann's education at the University, laboratory works with students were conducted at the chair of chemistry by young teachers, among whom mention should be made of J. Lemberg (1842–1902) and W. Ostwald (1853–1932), Derpt University graduates and Schmidt's pupils. Lemberg taught applied chemistry and soil science and exerted a profound influence on the development at the chair of physicochemical investigations, which became the leading direction in the scientific work of the chair beginning in the 1880s. In 1888, Lemberg was elected a professor of the chair of mineralogy and petrography and was the first in Russia to carry out experimental studies in this field, having laid foundations of "chemical geology." Lemberg's works were highly appreciated by F.Yu. Levinson-Lessing (1861–1939) and V.I. Vernadsky (1863–1945) [9].

Ostwald graduated from Derpt University in 1875 and worked at the chair of physical chemistry till 1881, when he became professor of chemistry at Riga Polytechnic Institute. In 1887, he became a university professor in Leipzig (Germany) where he founded the first world's chair of physical chemistry. Ostwald was among those who founded the first journal of physical chemistry (*Zeitschrift für physikalische Chemie*). He was awarded Nobel Prize in 1909.

The development of G. Tammann's scientific interests was also much affected by A. von Oettingen (1836–1920), professor of physics, well educated and all-round scientist. In 1883, G. Tammann received a diploma of a candidate of chemistry and started working at the laboratory of his teacher, Schmidt, as laboratory assistant; he became a privat-docent in 1887 and docent in 1889. In 1890, G. Tammann backed his doctoral dissertation *Über Metamerie der Metaphosphate* (On Metamerism of Metaphosphates). Upon Schmidt's retirement in 1892, G. Tammann took his position of a director of the chemical laboratory at Derpt University and was elected extraordinary professor. In 1894, he became an ordinary professor. G. Tamman's promotion was favored by recommendations of leading Russian scientists N.N. Beketov (1827–1911) and D.I. Mendeleev (1834–1907). G. Tammann delivered all the main courses of lectures on analytical, inorganic, organic, and physical chemistry. The transition of the educational process from German to Russian posed certain difficulties to G. Tammann and some other lecturers, but he got through in the course of time. Frequent trips to St. Petersburg and meetings with colleagues allowed him to master Russian. Nevertheless, the volume of his pedagogical activities was so large that he could not give sufficient attention to scientific studies. Probably, this was the main reason why G. Tammann accepted in December 1902 invitation to head the Institute of Inorganic Chemistry at Göttingen University (Germany). Among those who recommended G. Tammann was W. Nernst (1864–1941), a professor of the same university, physicist and physical chemist, Nober Prize winner (1920), member of many academies, including the Academy of Sciences of the USSR (since 1926). In 1905, Nernst moved to Berlin, and G. Tammann headed in 1907 the Institute of Physical Chemistry of Göttingen University. G. Tammann worked at that university till his retirement in 1930.

Having left Russia, the scientist continued to maintain close scientific relations with his Russian colleagues. Already in 1880 he became a member of the chemical department of the Russian Physicochemical Society by recommendation of D.P. Konovalov (1856–1929), N.A. Menshutkin (1842–1907), and V.E. Tishchenko (1861–1941) [10]. In 1908, he was one of very few foreign chemists who were elected honorary members of this society. In December 1901, G. Tammann took part in the XI Congress of Russian naturalists and physicians and presented a report *On the Relationship between the Crystalline and Liquid States* [11]. The report was highly appreciated by Mendeleev. Much attention was given to Tammann's works in *Osnovy khimii* (Foundations of Chemistry). It is known that Mendeleev called Tamman "... my dear friend" and believed that he developed "...extraordinarily interesting fields of physical chemistry" [10]. Correspondence between G. Tammann and Mendeleev commenced in 1887 and was related to the vapor pressure in the system sulfuric acid–water. Tammann's investigations and conclusions were in agreement with the hydrate theory of solutions, developed by Mendeleev [12]. Later, the scientists met more than once, the last time in 1902 in Derpt (Yuryev) at the centennial anniversary of the resumption of the University's functioning. In 1903, Mendeleev was elected honorary member of Yuryev University.

G. Tammann took part in the II Mendeleev Congress on General and Applied Chemistry in St. Petersburg in December 1911. He reported the results obtained in determining the molecular weight of crystalline substances. There is evidence [13] that in 1909 G. Tammann was offered to stand for election as ordinary academician (full member) of the St. Peters-

burg Academy of Sciences, which, however, involved, in the case of his being elected, obligatory moving to St. Petersburg. At the same time, his work at Göttingen University was quite successful and G. Tammann refused. Another known physical chemist, P.I. Walden (1863–1957), professor of Riga Polytechnic Institute, was elected to fill the vacancy in 1910. In December 1912, Tammann was elected, as a foreign scientist, a corresponding member of the St. Petersburg Academy of Sciences, and in December 1927, an honorary member of the Academy of Sciences of the USSR.

Very sympathetic recollections of G. Tammann were written by N.I. Nikitin (1890–1975, corresponding member of the Academy of Sciences of the USSR since 1939) who worked, by recommendation of Academician N.S. Kurnakov (1860–1941), at G. Tammann's laboratory in Göttingen in 1923–1924 and attended his lectures [14].

When still in Russia, G. Tammann maintained most friendly relationships and repeatedly met with the leading Western scientists of that time: J.H. van't-Hoff (1852–1911), S. Arrhenius (1859–1927), W. Nernst, and G.W.B. Rosenboom (1854–1907). Together with Nernst, G. Tammann carried out a joint investigation into the effect of pressure on the displacement of hydrogen from solutions by metals (1891). The most cordial were G. Tammann's relations with Arrhenius and Nernst [13]. In 1900 in Paris, G. Tammann became acquainted with H.-L. Le Chatelier's (1850–1936) works.

As already noted, G. Tammann's scientific activities were exceedingly versatile. The most important directions of research included: dilute and concentrated solutions (depression of the saturated vapor pressure, osmosis, internal pressure in solutions), heterogeneous equilibria (one-component systems, polymorphism, crystallization processes), glassy state, theory of thermal analysis, phase diagrams of metal systems, nature and corrosion behavior of solid solutions, problems of biochemistry, etc. The most comprehensive analysis of G. Tammann's scientific activities can be found in [15, 16]. More concise evidence was given in a scientific-biographical dictionary [1] and numerous publications devoted to jubilees of the scientist or his death [17–19].[3] Separate directions of G. Tammann's scientific activities, mainly those concerned with solutions, were analyzed in domestic monographs devoted to the history of chemistry [20–22]. Tammann's works carried out before his departure from Russia were considered by U. Palm [23, 24] and N. Ryago [25]. The role of Tammann in the development of physical metallurgy in Germany was discussed by U. Dehlinger [26]. To the sixty-fifth birthday of the scientist was devoted a special volume of *Z. anorg. allg. Chem.* (1926, vol. 154, pp. 1–455) presenting works of his colleagues and pupils. Among the authors were known Russian chemists Nikitin, N.A. Tananaev (1878–1959), and G.G. Urazov (1884–1957, academician of the Academy of Sciences of the USSR since 1946). In connection with G. Tammann's seventieth birthday, a series of papers analyzing his works in the field of structure and properties of metals and alloys was published in *Z. Metallkunde* (1931, vol. 23, no. 5, pp. 134–146).

The most complete list of published G. Tammann's works is given in the reference book [27]. Papers published in the early stage of his scientific activities (before 1901) are listed in the biographic dictionary [28]. We now consider only briefly some results of the versatile activities of the scientist during 55 years, from 1883 till 1938.

In the 1880s, one of the main directions of research in physical chemistry was investigation of dilute electrolyte solutions. In those years, Tammann carried out at the chemical laboratory of Derpt University high-precision measurements of the saturated vapor pressure over solutions and hydrates. Already in 1885, before the appearance of basic van't-Hoff's works, Tammann suggested that the molecular depression of the saturated vapor pressures of similar salts is about the same. To the same period of time belongs a series of Tammann's works concerned with osmosis and properties of semipermeable membranes. He made an important conclusion that the saturated vapor pressures of aqueous solutions with equal osmotic pressures are the same.

By the 1890s, a large group of Tammann's pupils was involved in his investigations, among whom mention should be made in the first place of A.D. Bogoyavlenskii (1868–1940), G. Landesen (1867–1935), and, later, R.F. Hollman (1877–1921) and V.A. Borodovskii (1878–1914). Owing to their participation, Tamman could extend the number of physicochemical problems studied. In 1893–1896, a seriers of investigations of concentrated solutions was performed and an original opinion about their nature was voiced. The developed approach was based on the concept of a gain in the internal pressure of a solution as compared with straight solvent.

Together with studying solutions, Tammann and co-workers commenced investigations of phase tran-

[3] A list of papers devoted to G. Tammann's life and scientific activities is given in the Dictionary of Scientific Biography [1].

sitions and phase equilibria in one-component systems (1897–1902). These studies resulted in a book *Kristallisieren und Schmelzen* (Crystallization and Melting) published in Germany in 1903. In a monograph [20], this series of investigations is characterized as "outstanding in both theoretical and experimental regards."

One of important, although not indisputable Tammann's conclusions was that no critical point at which the crystal becomes identical to its own solution can appear in the fusion curve. Tammann's studies concerned with the full phase diagram of water, which led to the discovery of polymorphous modifications of ice, became widely known (1900). These studies were performed on a unique, by that time, high-pressure (up to 4000 atm) installation. It was demonstrated in studying the kinetics of phase transitions that the crystallization rate depends on the rate of nucleation and linear velocity of crystal growth.

The studies of phase diagrams of metal systems, extensively developed already after G. Tammann moved to Göttingen, were also commenced in Russia. The first paper on metal alloys *On the Structure of Alloys*, concerned with the depression of the melting point of mercury and sodium upon introduction of minor amounts of various metals, was published already in 1889 (*Z. Phys. Chem.*, vol. 3, pp. 441–449). The main goal of the author was to reveal the extent to which general laws established for other types of solutions are applicable to solutions of metals in metals. The second paper in this series, devoted to determining the composition of chemical compounds without chemical analysis, was also prepared before departure to Germany (*Z. Anorg. Chem.*, 1903, vol. 37, pp. 303–313). Later, Tammann was the first to propose the term "thermal analysis" and developed its fundamentals (*Z. Anorg. Chem.*, 1905, vol. 45, pp. 24–38). The contribution made by Tammann, together with other scientists, to the development of the thermal analysis technique was considered in detail by B.N. Menshutkin [20]. G. Tammann gave detailed recommendations as to how cooling curves should be studied and phase diagrams be constructed on their base, and proposed a method for determining the composition of eutectic mixtures. During a short time of his work in Göttingen, Tammann and coworkers studied more than 100 binary metal systems. These works in Germany were conducted in parallel with large-scale investigations of Kurnakov and his closest associates (S.F. Zhemchuzhnyi, N.A. Pushin, N.I. Stepanov, *et al.*) in higher school institutions in St. Petersburg. Based on investigations of a wide variety of properties of metal alloys and salt systems, Kurnakov and Zhemchuzhnyi formulated general principles of physicochemical analysis in 1913. It is known that G. Tammann highly appreciated Kurnakov and his works [14]. It seems inappropriate to speak about any kind of priority in comparing these two most prominent scientific schools [30].

When studying the chemical stability of binary metal solid solutions, Tammann established in 1919 an important relationship between the composition of an alloy and its chemical properties. It was shown that the corrosion resistance (limits of action of chemical reagents) changes stepwise at compositions which are multiples of 1/8 mol of the least active component ("Tammann's *n*/8 law"). This law is applicable not only to metal solid solutions, but also to solubility and some chemical properties of salt solid solutions. The Tammann theory relates the existence of limits to chemical action to the arrangement of atoms in the crystal lattice of a solid solution. The action limits are also revealed in studying the anodic behavior of solid solutions. A detailed analysis of the "*n*/8 law" can be found in a paper by V.V. Schorcelletti and A.I. Shultin [31].

In studying the aggregative states of substances and phase transitions, G. Tammann investigated crystallization of glass-forming liquids and melts. He regarded the glass as a supercooled fluid. Particular attention was given to changes in properties of glass in its transition onto a liquid state ("softening range"). The results of these works were summarized in the monograph *Der Glasszustand* (The Glassy State), published in 1933.

After German professor O. Lehman (1855–1922) made quite certain that liquid crystals do exist and published a series of papers on this question, Tammann was the first Russian scientist to became interested in this problem. In a paper *On the So-Called Liquid Crystals* (*Ann. Phys.*, 1901, vol. 4, pp. 524–530), Tammann made quite a number of critical remarks. He insisted that the samples studied by Lehman are heterogeneous and contain impurities. Simultaneously, he entrusted one of his pupils, F.F. Rotarskii (1874–1912),[4] with a task of carrying out experimental studies and purification of compounds forming liquid crystals. It so happened that Rotarskii did most part of this work in St. Petersburg. Rotarskii graduated from the chemical department of the Physicomathematical Faculty at Yuryev (Derpt) University

[4] Tadeusz Rotarskii, of Polish origin, adopted the name Faddei Feliksovich in Russia.

in 1900, having received a candidate of science degree, and, had on-the-job training at Krakow and Göttingen Universities by G. Tammann's recommendation. He became a laboratory assistant at the chair of physiological chemistry of Women's Medical Institute in 1902 and junior laboratory assistant at the chair of analytical and organic chemistry at St. Petersburg Polytechnic Institute in May 1904 [32]. Together with other young teachers (F. Dreier, Zhemchuzhnyi, L.A. Rotinyants), Rotarskii carried out, by Tammann's initiative, quite a number of studies of thoroughly purified liquid crystals and described their specific features. Only during the period of time from 1905 till 1909, 9 papers concerned with liquid crystals were published in *Izvestiya S.-Peterburgskogo Politekhnicheskogo Instituta* (Bulletin of St. Petersburg Polytechnic Institute). Rotarskii started working on a special monograph, but, because of severe illness, had to return home, to Warsaw, already in October 1909. Rotarskii's colleagues prepared for publication and published the first chapter of the intended monograph, where, in particular, Tammann's views on the problem of liquid crystals were presented in ample detail [33]. Rotarskii's works were supported by Kurnakov and V.A. Kistyakovskii (1865–1952), professors of the Polytechnic Institute. Later, this series of investigations was continued at the St. Petersburg Electrotechnical Institute by N.A. Pushin (1875–1947), a closest Kurnakov's associate, and I.V. Grebenshchikov (1887–1953). These studies were commenced in 1912.

The constructive criticism by Tammann of the concept of liquid crystals and his many years' dispute with Lehman favored the development of research in this field [34].

During the initial period of his scientific activities, G. Tammann, following the example of his teacher Schmidt, studied biochemical objects. The mechanism and kinetics of enzymatic processes were interpreted in purely chemical terms, with the use of the Arrhenius equation. Tammann took part in discussions of physiological problems at meetings of the Society of Naturalists at Derpt University, whose member he was since 1890 (honorary member since 1903).

The scientific legacy of G. Tammann is enormous. Science-statistics data and the number of papers published by G. Tammann on one or another research direction are presented in the dictionary of scientific biographies [1]. A number of the most important scientist's works: *Metallography* (1931), *Physical Metallurgy* (1935), *Handbook of Heterogeneous Equilibria* (1935), and *The Glassy State* (1935), have been translated into Russian.

During his entire life, Gustav Tammann received a great number of honorary titles, prizes, and decorations. He was member of numerous Academies all over the world, an honorary member of the Bunsen Society, German Society of Physical Metallurgists, British Institute of Metals, and Royal Chemical Society of Great Britain.

G. Tammann died on December 17, 1938, at the age of 77. Till the last days of his life he retained vivacity and was always available for scientific discussions. Already in the end of the XIX century he made an invaluable contribution to the development of physical chemistry as independent scientific discipline and, together with his pupils, faithfully served to science during his whole life.

Received December 7, 2000

Abstract—SnO_2 xerogels were obtained by the sol–gel technique from alcoholic solutions of tin(II) and (IV) salts and used as model systems for studying the behavior of SnO_2—the main material of gas sensors, in the course of formation and operation under the action of temperature.

The impact on the environment poses the problems of on-line ecological monitoring ensuring the safety of humans under household and industrial conditions. The problem of obtaining the necessary data on the state of the environment can be solved by using analytical monitoring systems based on sensors for gases and liquids. As primary sensitive elements in these systems are used metal-oxide semiconducting compounds, such as SnO_2, ZnO, Fe_2O_3, etc. [1]. Among the materials mentioned, tin dioxide is the most promising material for creating sensor systems for monitoring of various gas media. By combining tin dioxide with other elements, sensors sensitive to most gases can be obtained (CO, H_2S, etc.) [2]. The gas-sensitive SnO_2 material can be used, depending on the design of the monitoring device, as bulk samples or layers. At present, preference is given to thin tin dioxide layers on various substrates because of their sensitivity, determined to a greater extent by the surface, high speed of response, smaller size, and low energy consumption. The methods used to obtain tin dioxide layers can be divided into two groups. The first group is constituted by techniques relying upon physical growth processes, such as reactive cathode sputtering, rf magnetron sputtering, electron-beam evaporation, thermal oxidation, etc. [3–7]. The mentioned methods for obtaining tin dioxide are far from always involving a simple technological process and require complex equipment. On this background, a less numerous group of chemical methods for tin dioxide deposition, based on sol–gel process, yields, at simpler technology, high quality of the material as regards purity, composition, and structural uniformity. This group of methods includes SnO_2 deposition either from solutions of inorganic tin salts, mostly halides [8–10], or from organic tin derivatives, which have not gained wide recognition because of the complexity of synthesis of substances and their high cost.

Analysis of published data suggests that the main attention is given to the possibility of using tin dioxide obtained by one or another method for particular determinations of dynamic characteristics of gas media without evaluation of changes in physicochemical properties under the influence of temperature conditions, varying in structure formation and in the course of device operation.

In this study, tin dioxide was obtained chemically in the form of thin-layer coatings and powders from the liquid phase by sol–gel process from salts with different tin oxidation states—$SnCl_2 \cdot 2H_2O$ and $SnCl_4 \cdot 5H_2O$. Comparative studies of changes in the properties of oxide materials synthesized from two kinds of salts were performed on gel powder samples in relation to synthesis conditions and subsequent thermal treatments. Studies of powders allow modeling of processes occurring in thin SnO_2 layers whose analysis is commonly hindered by the small mass of a substance under study. Gel powders were subjected to differential-thermal (DTA) and X-ray phase analyses (XPA).

Powders of tin dioxide gels were obtained from homogeneous solutions-sols of $SnCl_2 \cdot 2H_2O$ and $SnCl_4 \cdot 5H_2O$. The salt concentrations in the starting

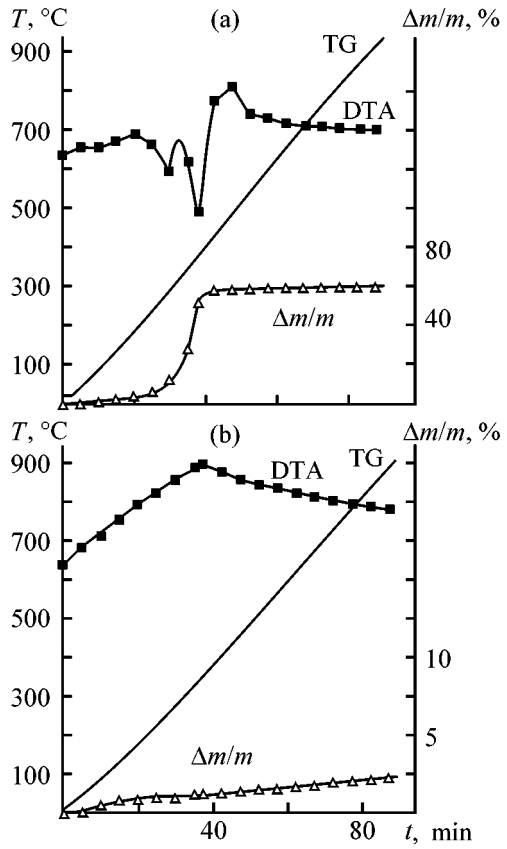

Fig. 1. TG and DTA curves of (a) SnO_2(II) xerogel and (b) that after thermal treatment. (T) Temperature, ($\Delta m/m$) mass loss, and (t) time. Treatment temperature (°C) and time (h): (a) 100, 10; (b) 100, 10; 600, 1.

solutions was 50 g l^{-1}. As solvent served *n*-butyl alcohol. The solutions-sols were homogenized, to ensure complete dissolution of the salts, by vigorous stirring and keeping a solution-sol at room temperature for 10–15 min before its being converted into gel. The medium of the starting solutions was acidic (pH 2–3) without additional introduction of acid. The conversion into gels was done by adding a 1 M aqueous solution of ammonia to the starting solutions-sols of tin salts and adjusting the pH value to 9–10. The obtained humid gels were subjected to two-stage thermal treatment: first, drying at 100°C for 10 h and then keeping in isothermal mode for 1 h at each of the following temperatures—300, 600, and 900°C. The solutions-sols of the $SnCl_2 \cdot 2H_2O$ salt and gels obtained from them were designated SnO_2(II), with $SnCl_4 \cdot 5H_2O$ used as the starting salt the designation was SnO_2(IV).

A DTA of changes occurring in the gels under varied thermal treatment conditions was performed with an MOM derivatograph (Hungary) in the dynamic mode at heating rate of 10 deg min^{-1} in the range from room temperature to 1000°C. As reference served powdered aluminum oxide. An XPA of gel powders was done on a DRON-2 instrument (Cu_{K_α} radiation). The crystalline phases were identified using the ASTM file.

Acid solutions of $SnCl_2 \cdot 2H_2O$ and $SnCl_4 \cdot 5H_2O$ salts in n-butyl alcohol pass into a jelly-like state on pouring-in an aqueous solution of ammonia. In aqueous solution, tin(IV) salts form tin(IV) hydroxide which has clearly pronounced gel nature, with $xSnO_2 \cdot yH_2O$ formula ascribed to it [11]. The gel is based on polymeric formations with ≡Sn–O–Sn≡ bonds appearing as a result of oleation of hydroxo complexes $Sn(OH)_n$, with the subsequent polymerization occurring with splitting-off of water molecules. The increase in the number of bridge bonds, occurring in the gelation stage, is also continued under the action of temperature in the course of thermal treatment. The dehydration process can be described by the scheme [12]

$$2(\equiv Sn\text{–}OH)_n = (\equiv Sn\text{–}O\text{–}Sn\equiv)_n + nH_2O.$$

Being a strong reducing agent, Sn(II) is readily oxidized in acid medium to Sn(IV) [11], with the oxidation process enhanced by atmospheric oxygen and light. In the case of Sn(II) oxidation to Sn(IV), the gelation of $SnCl_2 \cdot 2H_2O$-containing solutions is also accompanied by the formation of ≡Sn–O–Sn≡ bonds, as in the process of gelation with the use of $SnCl_4 \cdot 5H_2O$.

The inorganic network of freshly prepared gels retains a considerable amount of the liquid phase composed of water and organic solvent. In passing from a humid gel to dry xerogel powder in the first stage of drying at 100°C for 10 h, the major part of the liquid phase is removed. However, the TG curves for SnO_2(II) and SnO_2(IV) preheated at 100°C for 10 h show, with increasing temperature, a continuing loss of mass of reaction products retained by the inorganic network of the xerogel. The loss of mass continues for xerogel powders to 440–460°C and constitutes 60.9 wt % for SnO_2(II) (Fig. 1a) and 84.6 wt % for SnO_2(IV). The shape of the DTA curve (Fig. 1) indicates that the enthalpy of the substance under study strongly fluctuates in this temperature interval, which is accompanied by alternation of exo- and endothermic peaks. The endothermic effects in the low-temperature region are most frequently attributed to substance mass loss; however, exothermic processes (T = 320°C) (Fig. 1a) occur simultaneously with the mass loss, which may be due to the onset of crystallization. In xerogels dried at 100°C (100 h) and 600°C (1 h), the mass loss is significantly smaller: 2.41 wt % for SnO_2(II) (Fig. 1b)

and 4.78 wt % for SnO_2(IV). The DTA curve in Fig. 1b shows endothermic processes with a peak at 340°C. DTA curves for SnO_2(IV) are similar to the curves for SnO_2(II), with a shift to higher temperatures by 20°C (not presented here).

The similar nature of thermal effects in the DTA of SnO_2(II) and SnO_2(IV) xerogels indicates that, irrespective of the different oxidation states of tin in the starting salts, xerogels treated under identical temperature conditions have similar nature.

XPA data for SnO_2(II) and SnO_2(IV) xerogels are presented in Figs. 2a and 2b. Analysis shows a strong similarity between the processes of structure formation in xerogel powders obtained from different salts. Upon treatment at 100°C (10 h), X-ray diffraction patterns of SnO_2(II) and SnO_2(IV) show rather strong reflections (Figs. 2a and 2b, curves *1*) (2θ 23.2°, 32.9°, 47.2°) attributed to a crystallized form of NH_4Cl, reaction product formed in reaction of NH_4OH used as precipitating agent with tin chlorides retained by the network structure of the SnO_2 gel. With the xerogel treatment temperature raised to 300°C (1 h), the reflections related to NH_4Cl disappear from the XPA curves of SnO_2(II) and SnO_2(IV) (Figs. 2a and 2b, curves *2*) as a result of its complete removal from the gel structure under the action of temperature. SnO_2(II) and SnO_2(IV) xerogels treated at 100°C (10 h) cannot be considered completely amorphized. The X-ray patterns of both gels (Figs. 2a and 2b curves *1*) show broadened reflections which become, with the xerogel treatment temperature raised to 300, 600, or 900°C, clear narrow reflections characteristic of the crystalline form of SnO_2 in tetragonal modification. The XPA data indicate that, irrespective of the oxidation state of tin in the starting $SnCl_2 \cdot 2H_2O$ and $SnCl_4 \cdot 5H_2O$ salts, thermally treated gels crystallize to form tin dioxide in tetragonal modification, with, however, the process of SnO_2(II) crystallization being more vigorous than that for SnO_2(IV) (Figs. 2a and 2b).

Thin SnO_2 layers were deposited onto semiconducting silicon wafers, glass, and glass ceramics from alcoholic solutions-sols of $SnCl_2 \cdot 2H_2O$ and $SnCl_4 \cdot 5H_2O$ salts. The deposition was done by pouring a solution and subsequent centrifugation at a rate of 2000 rpm. According to ellipsometric data, the obtained films were 50–70 nm thick.

CONCLUSIONS

(1) Irrespective of whether chlorides of doubly or quadruply charged tin are used as starting substances, thermal treatment of xerogel powders leads to formation of SnO_2 of the tetragonal modification.

(2) SnO_2 crystallization in the tetragonal modification in gel powders obtained with the use of tin(II) chloride $SnCl_2 \cdot 2H_2O$ occurs at lower temperatures, compared with the case of $SnCl_4 \cdot 5H_2O$, which allows layer deposition at lower temperatures. This makes simpler the technology of gas sensor fabrication.

Abstract—Mg–Al and Zn–Al hydrotalcite-like layered double hydroxides of various compositions were synthesized and characterized. A detailed comparative analysis of the structure and composition of starting and reconstructed layered double hydroxides was made.

Synthetic layered double hydroxides (LDHs), or so-called hydrotalcite-like materials, arouse increased interest as sorbents [1, 2], anion exchangers [3, 4], catalysts [5, 6], and catalyst precursors [7, 8]. The idealized LDH formula is as follows: $[M^{2+}_{1-x}M^{3+}_{x}(OH)_2]^{x+}A^{z-}_{x/z}\cdot mH_2O$, where M^{2+} is Mg^{2+}, Ni^{2+}, Zn^{2+}, ...; M^{3+} is Al^{3+}, Fe^{3+}, Ga^{3+}, ...; and A^{z-} is CO_3^{2-}, NO_3^-, Cl^-, ... [8]. The unit cell is formed by brucite-like layers separated by interlayer gaps. The doubly charged cations, M^{2+}, bound to six oxygen atoms, form primary octahedral fragments joint to form networks [5]. These networks are mutually superimposed in the form of H-bound brucite-like layers. Isomorphic replacement of M^{2+} by differently charged cations, e.g., by Al^{3+}, results in the appearance of a positive charge, which is compensated by the anions localized in the interlayer gaps [5].

Layered double hydroxides are solid bases, which predetermines their use in basic catalysis [4–8]. In most cases, LDHs are used in calcined form [8]. Recently, the feasibility has been shown, however, of using uncalcined LDH catalysts in a number of organic syntheses [4, 6, 7]. At the same time, there is increased interest in materials with reconstructed structure, obtained using the so-called memory effect [4], i.e., the ability of heat-treated LDH to recover the initial hydrotalcite-like structure upon rehydration [5]. In this case, the degree of recovery of the LDH structure depends on the temperature of preliminary heating and the chemical composition of LDH [5]. Despite the fact that the memory effect has been known for more than 20 years and its importance for preparing new catalysts grows [4], the number of works concerned with fundamental aspects of this phenomenon is insufficient [7, 9–12].

In this study, LDHs of different compositions were synthesized and a comparative analysis of their structure before and after transformation was made.

EXPERIMENTAL

As objects of study served Mg–Al and Zn–Al LDHs. Synthesis of these materials with atomic ratios M^{2+}/Al^{3+} of 2, 3, and 5 was described in [7, 13]. The materials prepared are designated as Mg2Al, Mg3Al, and Mg5Al, or Zn2Al, Zn3Al, and Zn5Al, where the digit stands for the atomic ratio Mg/Al or Zn/Al. The residual anions (NO_3^-) were removed by ion exchange for CO_3^{2-} [14].

A part of the LDHs prepared was calcined in thin bed at 673 or 773 K (heating rate 180 deg h^{-1}) for 16 h in a flow of N_2, cooled, and stored in sealed ampules in argon. These materials are designated by index C. The reconstruction of LDHs was performed as described in [15], i.e., 1 g of calcined LDHs was suspended in 100 ml of deionized water, heated to 373 K, kept there for 40 min with stirring, cooled, filtered, and dried at 383 K for 12 h. The materials thus prepared are denoted by index R.

Table 1. Chemical formula, M^{2+}/Al^{3+} atomic ratio, structural parameter *a*, and crystallite size ε of the synthesized LDHs

Sample	Formula	M^{2+}/Al^{3+}	*a*	ε
			nm	
Mg2Al	$[Mg_{0.668}Al_{0.332}(OH)_2](CO_3)_{0.166} \cdot 0.56H_2O$	2.01	0.3042	18.5
Mg3Al	$[Mg_{0.751}Al_{0.249}(OH)_2](CO_3)_{0.125} \cdot 0.62H_2O$	3.02	0.3061	19.9
Mg5Al	$[Mg_{0.833}Al_{0.167}(OH)_2](CO_3)_{0.084} \cdot 0.64H_2O$	4.98	0.3086	20.7
Zn2Al	$[Zn_{0.669}Al_{0.331}(OH)_2](CO_3)_{0.166} \cdot 0.46H_2O$	2.02	0.3071	44.8
Zn3Al	$[Zn_{0.748}Al_{0.252}(OH)_2](CO_3)_{0.126} \cdot 0.45H2O$	2.97	0.3080	40.3
Zn5Al	$[Zn_{0.837}Al_{0.163}(OH)_2](CO_3)_{0.081} \cdot 0.43H_2O$	5.13	0.3088	47.0

X-ray diffraction analysis (XDA) of the materials studied was done on DRON–3 and Philips 1170 diffractometers (Cu_{K_α}-radiation, λ = 0.154178 nm, Ni-filter) with oriented samples. The size of the LDH crystallites along the *a* axis was determined using the Scherrer equation [7], high-purity grade α-SiO_2 served as standard. IR spectra were recorded with a FTIR Perkin–Elmer 2000 spectrophotometer, using samples prepared by compaction of pellets of a material under study with thoroughly dried KBr (1 : 60 ratio). The ^{27}Al NMR spectra were obtained with magic angle rotation on an AMX 300 WB Bruker spectrometer (*H* = 78.20 MHz, $[Al(H_2O)_6]^{3+}$ standard).

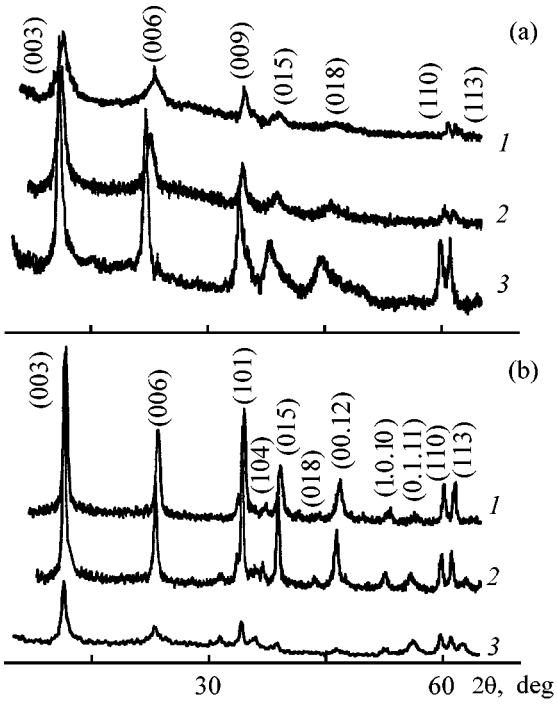

Fig. 1. Diffraction patterns of LDHs synthesized. (2θ) Bragg angle; the same for Figs. 3, 5. (a) (*1*) Mg2Al, (*2*) Mg3Al, and (*3*) Mg5Al; (b) (*1*) Zn2Al, (*2*) Zn3Al, and (*3*) Zn5Al; the same for Figs. 2, 3.

The chemical composition of the materials studied was determined by atomic absorption spectroscopy (AAS) on a Perkin-Elmer 3030 spectrophotometer. The rehydration of calcined LDHs was studied by the method of water absorption on a CIsorp installation (C.I. Electronics Ltd).

The chemical formulas of the materials synthesized (Table 1) show good agreement between the predicted and experimentally found compositions. X-ray diffraction patterns of the obtained LDHs (Fig. 1) contain basal reflections typical of hydrotalcite [5]. As known, the intensity of the (110) reflection is proportional to half the structural parameter *a* of the LDH unit cell, which corresponds to the spacing between the neighboring cations in the brucite-like layer [5]. For the materials studied, this parameter grows with increasing M^{2+}/Al^{3+} atomic ratio (Table 1). Such a dependence was observed on replacing Al^{3+} structural cations with cations of larger ionic radius (Mg^{2+} or Zn^{2+}) [16, 17] and, consequently, confirms their localization in the LDH structure. The crystallite size of these materials along the *a* axis also grows with increasing M^{2+}/Al^{3+} ratio (Table 1).

The IR spectra of the synthesized LDHs in the wave number range 4000–2000 cm^{-1} contain a broad absorption band (AB) peaked at 3600–3650 cm^{-1}, related to OH vibrations in the brucite-like layer [5]. With increasing M^{2+}/Al^{3+} ratio, the position of the band maximum shifts steadily to higher frequencies for Mg–Al and to lower frequencies for Zn–Al. This is reasonable, since a similar absorption band was noted at 3700 and 3620 cm^{-1} for magnesium and zinc hydroxides, respectively. As known, the narrower the full width at half-maximum (FWHM), $I_{1/2}$, of a band, the more ordered is the cation distribution in the LDH structure [5, 18]. For the materials studied, the $I_{1/2}$ parameter grows with increasing Mg^{2+} and Zn^{2+} content. As a result, the distribution of structural cations becomes less ordered. It should be noted that the ab-

sorption band related to $Mg(OH)_2$ impurity is absent. Unfortunately, the similarity of the vibration frequencies of $Zn(OH)_2$ and Zn–Al LDHs makes identification of the zinc hydroxide phase impossible.

In the range 1400–200 cm^{-1}, the IR spectra of LDHs contain a strong band at around 1368–1376 cm^{-1} (Fig. 2), attributed to ν_3 bending vibrations of CO_3^{2-} anions [14, 19]. Weakly resolved shoulders at 1090, 1050–1056, and 860–880 cm^{-1}, attributable to ν_1 and ν_2 vibrations of CO_3^{2-} [12, 19], are also present. The shoulder at 790 cm^{-1} (Al–O– bond vibrations [12]) was noted solely for the Mg2Al sample, evidently indicating the presence of a certain amount of the $Al(OH)_3$ impurity. The absorption band at 760–765 cm^{-1}, attributable to Zn–Al–O vibrations inside the brucite-like layer, is also present in the Zn–Al LDHs IR spectra. In addition, the IR spectra contain absorption bands at 668–624 cm^{-1} (Mg–Al LDH), 612–620 cm^{-1} (Zn–AL LDH; ν_4, bending vibrations of the carbonate bond), and 580–560 cm^{-1}. The last absorption bands are typical of brucite-like layer (stretching and bending vibrations of M–O, M–O–M, and O–M–O bonds) [20]. With increasing content of the M^{2+} cations in LDH, the positions of the 428–396-cm^{-1} bands (vibrations of hydrotalcite octahedral networks [19, 20]) steadily shift to lower frequencies, approaching the value found for brucite (364 cm^{-1}).

The ^{27}Al NMR spectra of the materials studied are similar to those obtained previously for synthetic hydrotalcite [17, 21]. They contain only one strong resonance related to Al^{3+} octahedrons with chemical shift of 7.9 and 14.0 ppm for Mg–Al and Zn–Al, respectively. This implies that, in the LDHs studied, aluminum(III) atoms are localized in octahedral positions of brucite-like layers.

The whole set of the obtained results characterizes the synthesized materials as LDHs with hydrotalcite structure.

As expected, calcination at $T > 573$ K results in amorphization of the LDH crystalline structure. The diffraction patterns of calcined samples contain reflections that can be assigned to MgO or ZnO (Fig. 3). It is quite reasonable that their intensity grows with increasing M^{2+}/Al^{3+} ratio (Fig. 3).

The calcination of Mg–Al and Zn–Al LDHs at 600–773 K yields double oxides, Mg(Al)O or Zn(Al)O, nearly isostructural to MgO or ZnO [7, 12, 21, 22]. Degradation of the Zn–Al LDHs is observed at 573 K, irrespective of the Zn/Al ratio [12]. The presence of the amorphous Al_2O_3 phase or zinc aluminate on the surface of ZnO particles is possible.

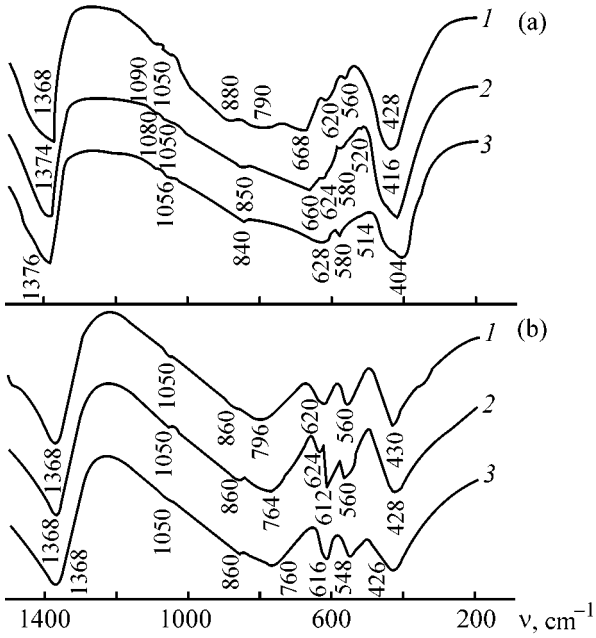

Fig. 2. LDHs IR spectra. (ν) wave number.

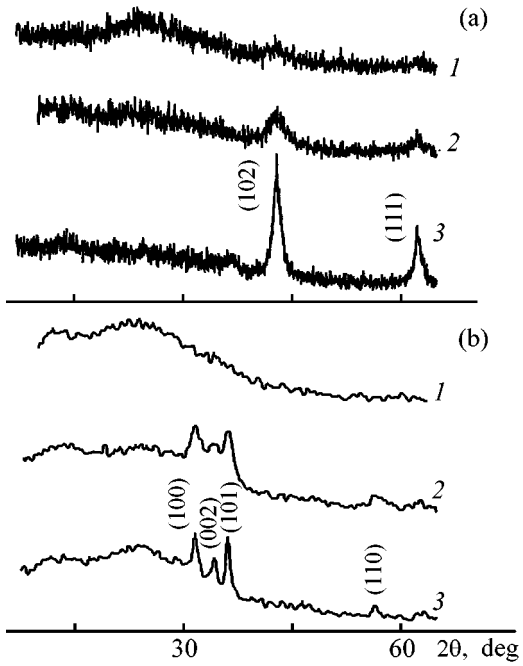

Fig. 3. Diffraction patterns of LDHs calcined at 773 K.

The IR spectra of LDH(C) contain absorption bands characteristic of double oxides [23]. The CO_3^{2-} vibrational bands disappear nearly completely, whereas the weak band around 1370 cm^{-1} is present. This indicates incomplete removal of carbonate anions, which can be occluded in the mixed oxide lattice [24].

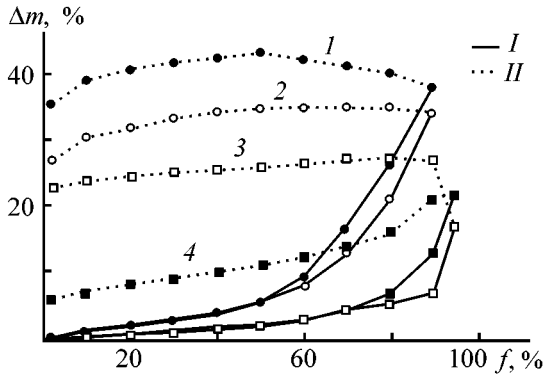

Fig. 4. Adsorption–desorption isotherms of water. (Δm) Change in sample mass and (f) relative humidity. (*I*) Adsorption and (*II*) desorption. (*1*) Mg2Al, (*2*) Mg5Al, (*3*) Zn2Al, and (*4*) Zn5l, all calcined at 773 K.

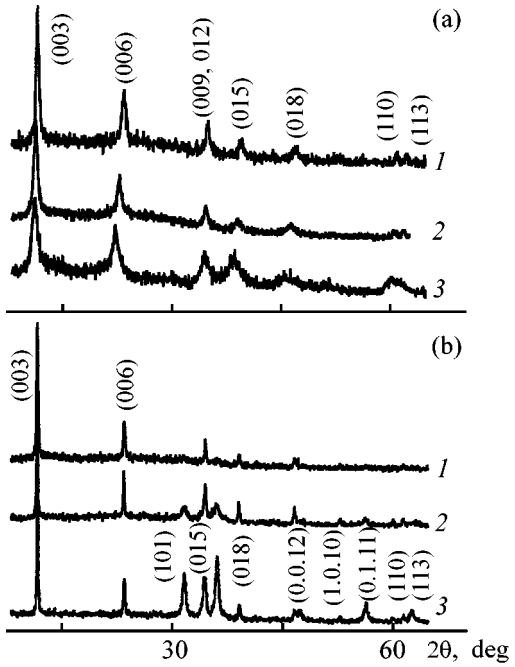

Fig. 5. Diffraction patterns of reconstructed LDHs. (a) (*1*) Mg2Al(R), (*2*) Mg3Al(R), and (*3*) Mg5Al(R); (b) (*1*) Zn2Al(R), (*2*) Zn3Al(R), and (*3*) Zn5Al(R).

The NMR revealed tetrahedrally coordinated Al^{3+} cations, Al^{3+}(tet), in the Mg–Al and Zn–Al LDHs calcined at 673–923 K [7, 17, 22]. For Zn-containing materials, the intensity of the Al^{3+}(tet) resonance is considerably higher than that for Mg–Al LDHs [7]. Double oxides prepared by calcination of Zn–Al LDHs contain Al^{3+} ions mostly in tetrahedral positions [25]. The change in partial coordination of Al^{3+} ions is caused by dehydroxylation of LDHs [17, 21]. With increasing temperature, the coordination environment of Al^{3+}(oct) cations becomes more distorted. This affects neighboring Mg^{2+} or Zn^{2+} ions [7, 21], capable of forming corresponding oxides. An analysis of the parameters of the ^{27}Al NMR line showed that the lowest ordering of Al^{3+} ions and, consequently, the most significant degradation of LDHs occur in the temperature range 723–773 K [7].

The aforesaid suggests that the Mg–Al and Zn–Al LDHs calcined at $T > 923$ K are predominantly the double oxides Mg(O)Al or Zn(O)Al. The most essential disordering of the LDH crystalline structure is observed at 723–773 K. For this reason, materials calcined at 773 K were used to study the structural reconstruction .

Hydration is the driving force of the structural reconstruction of calcined LDHs [5]. This process was studied by the method of adsorption–desorption of water vapor. As expected, it is fundamentally different from physical adsorption. Water absorption is observed even at moderate humidity (less than 40%) (Fig. 4). In the Mg–Al LDHs, the amount of sorbed water grows with increasing M^{2+}/Al^{3+} atomic ratio, whereas for Zn-containing materials, the opposite tendency is observed. The sample mass does not recover to the initial value upon water desorption (Fig. 4), i.e., the hydration is irreversible. The data obtained are consistent with the results of thermogravimetric analysis [5, 18] and show that the amount of water bound with calcined LDHs depends on the origin and concentration of a doubly charged cation. The Zn–Al samples possess lower hydrophilicity.

According to X-ray diffraction analysis, the basal reflections, typical of hydrotalcite, recover after rehydration of these materials (Fig. 5). Except in the case of the Mg5Al(R) sample, the obtained reflections are stronger and narrower than those for unheated LDHs. This result, also obtained by Prinetto *et al.* [4], can be accounted for by the increased crystallinity and (or) a more ordered orientation of LDH(R) crystallites. In the case of Mg5Al(R), in which the Mg^{2+} concentration is the highest, the lower reflection intensities indicate a lower degree of crystallinity and, probably, the presence of the oxide phase, which could not be transformed into LDH completely.

For Mg–Al(R) samples, the structural parameter a increases only slightly, compared with uncalcined LDHs (Table 2). In this case, the relation between the parameter a and the Mg^{2+}/Al^{3+} ratio is virtually similar to that for the starting materials. For Zn–Al(R) LDHs, the effect of the Zn^{2+}/Al^{3+} ratio on a is less pronounced. This may indicate that part of Zn^{2+} cations are not incorporated in brucite-like layers in reconstruction. For Zn–Al(R), the ratio Zn^{2+}/Al^{3+} approaches two, irrespective of the Zn^{2+} content in the

starting LDHs [12]. The validity of this conclusion can be confirmed by the similarity of the average *a* values for Zn–Al(R) and Zn2Al samples (Table 2). The increase in the Zn^{2+}/Al^{3+} ratio differently affects the size of LDH(R) crystallites along the *a* axis. It decreases for Mgn–Al(R) and grows somewhat for Zn–Al(R) (Table 2). This indicates that the morphologies of the reconstructed and starting LDHs are different and are affected by the type of a doubly charged cation.

The ^{27}Al NMR spectra of the reconstructed Mg–Al and Zn–Al LDHs show only a single resonance at 7.8–8.0 ppm, attributable to octahedrally coordinated Al^{3+}. The parameters of this resonance, *W* and $W_{0.1}$ (FWHM and width at one tenth of maximum, respectively), are virtually similar to those of unheated LDHs. For Zn–Al(R) LDHs, the Al^{3+}(oct) resonance is narrower and stronger than that for uncalcined materials. Apparently, in this case, reconstruction facilitates the ordering of the octahedral environment of Al^{3+} cations. It is not improbable that this results from the formation of the $Al(OH)_3$ phase characterized by the most ordered environment of Al^{3+} cations.

As in the case of unheated LDHs, the IR spectra of reconstructed materials contain a strong absorption band at 3650–3500 cm^{-1}, related to OH vibrations of the brucite-like layer [15, 18, 19]. As also in the case of the starting LDHs, the band peak shifts with growing M^{2+}/Al^{3+} ratio.

The FWHM, $I_{1/2}$, of the band in question yields information about the uniformity of the cation distribution in the brucite-like layer of LDHs [18, 19]. The additional absorption bands at around 3700 cm^{-1} indicate the presence of an oxide (hydroxide) impurity. A comparison of the starting and reconstructed LDHs shows that for Mg–Al(R) the $I_{1/2}$ parameter decreases considerably with increasing Mg^{2+}/Al^{3+} atomic ratio (Fig. 6a). Hence follows that reconstruction leads to a more uniform distribution of Mg^{2+} and Al^{3+} ions inside the brucite-like layer. At the same time, the IR spectra of these samples contain a shoulder at 3700 cm^{-1}, whose intensity grows with increasing Mg^{2+} content. Consequently, a part of these cations are not incorporated into brucite-like layers in the course of reconstruction, but form the $Mg(OH)_2$ phase instead. For this reason, Mg–Al(R) LDHs can be regarded as hydrotalcite-like materials with highly ordered structure containing an admixture of brucite.

For Zn–Al(R) samples, raising the Zn^{2+}/Al^{3+} ratio leads to a pronounced increase in the $I_{1/2}$ parameter (Fig. 6b). This indicates the less ordered distribution of Zn^{2+} and Al^{3+} structural cations in the brucite-like layer of reconstructed materials. We cannot exclude that part of them form single phases [$Zn(OH)_2$, $Al(OH)_3$, or oxides], as also indicated by the NMR data.

Table 2. Structural parameter *a* and crystallite size ε of reconstructed LDHs

Sample	*a*	ε
	nm	
Mg2Al(R)	0.3046	34.6
Mg3Al(R)	0.3063	22.7
Mg5Al(R)	0.3088	18.4
Zn2Al(R)	0.3069	21.6
Zn3Al(R)	0.3072	28.9
Zn5Al(R)	0.3075	29.7

In the wave number range 1400–200 cm^{-1}, the LDHs(R) IR spectra contain a strong absorption band near 1360 cm^{-1}, which can be attributed to bending vibrations of interlayer OH^- ions. Weakly resolved shoulders due to ν_1 and ν_2 vibrations of CO_3^{2-} are absent or shifted owing to the replacement of this ion by the hydroxide ion. For the Zn–Al (R) LDHs, the shift to higher wave numbers was observed for the 765–760 cm^{-1} absorption bands (Zn–Al–O vibrations). This can be accounted for by a change in the Zn^{2+}/Al^{3+} ratio in the brucite-like layer. Owing to the exchange

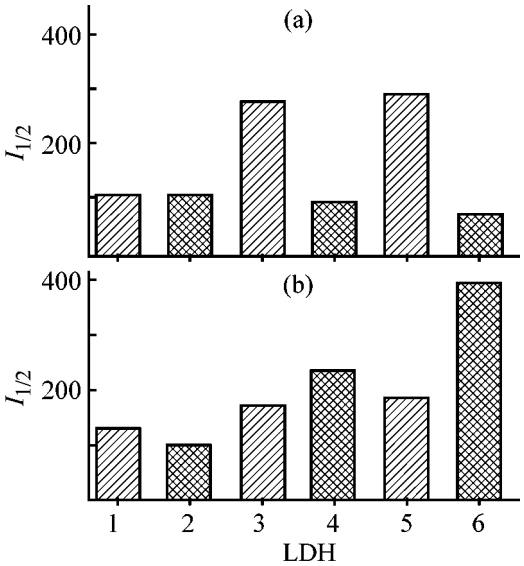

Fig. 6. The FWHM $I_{1/2}$ of the IR band related to OH vibrations (3650–3500 cm^{-1}) in a brucite-like layer for starting and reconstructed LDHs. (a) (*1*) Mg2Al, (*2*) Mg2Al(R), (*3*) Mg3Al; (*4*) Mg3Al(R), (*5*) Mg5Al, and (6) Mg5Al(R). (b) (*1*) Zn2Al, (*2*) Zn2Al(R), (*3*) Zn3Al, (*4*) Zn3Al(R), (*5*) Zn5Al, and (*6) Zn5Al(R).*

of CO_3^{2-} ions for OH^- ions, the intensities of the 688–620 cm^{-1} bands also change as compared with the starting LDHs. The IR spectra of LDH(R) show absorption bands characteristic of brucite layer vibrations at 580–560 cm^{-1} (M–O and M–O–M bonds), which indicates at least a partial reconstruction of the starting hydrotalcite structure.

CONCLUSIONS

(1) Reconstruction of calcined double layered hydroxides by hydration is a complex process resulting in a significant transformation of their structural properties, compared with the starting materials.

(2) The type of doubly charged cation and the M^{2+}/Al^{3+} atomic ratio exert the strongest influence on the extent of reconstruction of layered double hydroxides. The Mg–Al materials possess higher structural reversibility than their Zn–Al analogues.

(3) Full reconstruction of layered microstructure of the Mg–Al and Zn–Al double hydroxides is possible at calcination temperatures not exceeding 723 and 573–623 K, respectively.

(4) An analysis of the IR spectra of layered double hydroxides in the region of OH vibrations of the brucite-like layer (3600–3500 cm^{-1}) yields the most comprehensive information about the uniformity of distribution of the structural cations.

Abstract—A procedure is proposed for studying acid decomposition of solid materials with the use of ion-selective electrodes, with the experimental data recorded and processed with a personal computer. Variation of the H_3O^+, F^-, and Ca^{2+} concentrations in reaction of fluorapatite concentrate with nitric, sulfuric, and orthophosphoric acids and also the effect of particle size on the rate of solid phase decomposition were studied.

The rate of acid decomposition of mineral raw materials depends on temperature, nature of liquid and solid phases, stirring rate, and some other factors. A number of publications have been devoted to experimental studies of fluorapatite concentrate processing, aimed to reveal factors affecting the process kinetics [1–5]. The influence exerted by the composition of a phosphate substance on the rate of apatite concentrate breakdown was studied by calorimetry [6]. Changes in the density of the filtered-off fraction of nitric-phosphoric solution was found [7, 8] to be proportional to the content of reagents, and, therefore, a densitometric monitoring of the kinetics of this reaction is possible. An equation describing the time dependence of the reaction rate was obtained with the help of conductometric method [9]. However, the techniques considered rely upon the time dependence of only a single physicochemical parameter [6–9], which is apparently insufficient for describing the process mechanism most completely and reliably.

The aim of this work was to study the ionic composition of a reaction mixture in the course of acid decomposition of a fluorapatite concentrate and to develop a procedure for ionometric monitoring with simultaneous use of three ion-selective electrodes.

EXPERIMENTAL

Ionometry [10–12] enables simultaneous determination of several separate ions of starting substances and reaction products. The use of ion-selective electrodes also makes it possible to obtain an analog electric signal proportional to the activities of potential-forming ions. This signal can be recorded and processed with the help of a personal computer.

The principal element of the experimental installation is the measuring cell (reactor) with electrodes connected by means of a high-resistance interface to a personal computer equipped with a device for input and output of analog and digital information (an L-154 board). Separate units, their service characteristics, and principles of operation were described in detail in [13]. As sensors of the ionic composition of the reaction mixture were used fluoride (Kritur 09-107, electrode resistance R_{el} = 1 MΩ), calcium (EM-Ca-01, R_{el} = 0.1–3 MΩ), and glass (ESL43-07, $R_{el} = 50 \pm 40$ MΩ) electrodes. A silver chloride electrode (EVL-1M3) served as reference. Since the input resistance of the high-resistance interface ($R_{in} = 1 \times 10^9$ Ω) appeared to be insufficient in the case of the glass electrode, the input resistance of its measuring channel was raised to $R_{in} = 2 \times 10^{11}$ Ω.

To determine for the system under study the acidity range in which the EM-Ca-01 electrode potential depends linearly on the logarithm of the calcium ion concentration, we studied model systems: HNO_3–$Ca(NO_3)_2$ (I) and HNO_3–HF–$Ca(NO_3)_2$ (II) at concentrations of each component of 0.001, 0.005, 0.01, 0.05, and 0.1 M and temperatures of 298, 303, 308, 313, 318, and 323 K.

The results of potentiometric measurements in the concentration range under study show that the dependences of the potentials of calcium and fluoride

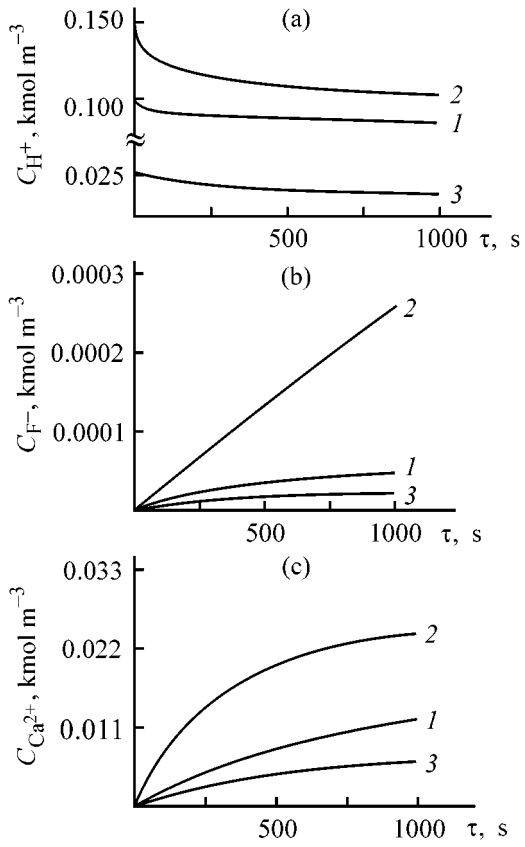

Fig. 1. Variation of concentrations of (a) H_3O^+ ion, C_{H^+}; (b) fluoride ion, C_{F^-}; and (c) Ca^{2+} ion, $C_{Ca^{2+}}$ in the reaction mixture with the time of fluorapatite decomposition τ at 30°C. (*1*) HNO_3, (*2*) H_2SO_4, (*3*) H_3PO_4.

ion-selective electrodes on the logarithm of the analytical concentrations of HF and $Ca(NO_3)_2$ are nonlinear. The reason is that complicated dissociation–association processes occur in solution, which results in a substantial difference between an analytical concentration of the electrolyte and the equilibrium concentration of a potential-determining ion.

To calculate the equilibrium compositions of model systems (I) and (II), we examined reference data [14–16] on the equilibrium constants of all the known reactions between the corresponding ionic and molecular species. The results of previous calculations [17] are in good agreement with the experimental data, which led us to conclude that the procedure used to calculate the equilibrium concentrations of potential-determining ions is reliable.

Studies of model systems (I) and (II) demonstrated that the potentials of ion-selective electrodes depend linearly on the logarithm of the calculated concentrations of ions being determined [18]. Consequently, the obtained calibration curves can be used to determine quantitatively H_3O^+, Ca^{2+}, and F^- ions in the case of their simultaneous presence in solutions with pH 1–3. As shown previously [13], the ionic strength of the reaction mixture can be taken constant during the nitric acid decomposition of a fluorapatite concentrate. Therefore, the data of potentiometric measurements, processed using calibration curves, give analytical concentrations.

We also estimated the response time of the calcium electrode for model systems (I) and (II). The concentrations of the starting solutions (0.001, 0.005, 0.01, 0.05, and 0.1 M) were varied by rapid dilution with stirring (injection procedure [19]). The time of concentration equalization (approximately 0.5 s) was found by conductometry [20]. For a calcium electrode with a solid membrane, the time in which the potential attained a steady value in the Ca^{2+} concentration range under study was from 2 to 6 s, in agreement with the known published data [11, 19]. In the course of heterogeneous reactions of acid decomposition of a fluorapatite concentrate, the content of ions being determined reached no less than 95% of their quasi-equilibrium value in 1000–1200 s. Therefore, the duration of the experiment much exceeds the time in which the potentials of the employed ion-selective electrodes attain a steady value.

Studies of the kinetics of fluorapatite acid decomposition [1–9] showed that this process is diffusion-limited, and, consequently, the rates of dissociation of the products are many times greater than the rate of the decomposition reaction itself. The proposed variant of computerized ionometric monitoring of the kinetics of acid decomposition of solid minerals allows the experiment to be carried out following a prearranged program, with the appearance of ionic forms of reaction products recorded starting from concentrations of 5×10^{-5} kmol m^{-3}.

In this study, we used the fluorapatite concentrate from the Khibiny deposit [GOST (All-Union State Standard) 3277–54], with average particle size of 26.8×10^{-5}, 18.0×10^{-5}, 13.0×10^{-5}, and 8.2×10^{-5} m, and chemically-pure grade acids. To improve the reproducibility of the kinetic data, a weighed portion of apatite was introduced into a temperature-controlled measuring cell containing 100 ml of distilled water, and the required hydrodynamic stirring mode was set. Then we introduced into the reactor 100 ml of a separately thermostated 0.2 M solution of an acid and simultaneously started measurements. The instant of mixing was taken as the reference point for the time of experiment.

The variation of the hydroxonium ion concentration with the time of fluorapatite decomposition by

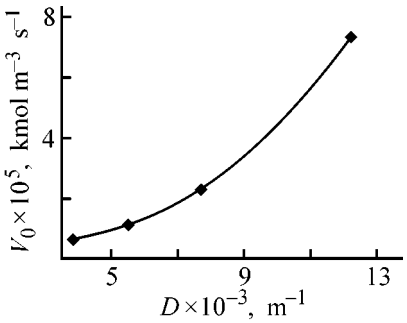

Fig. 2. Initial rate of fluorapatite decomposition, V_0, vs. the dispersity D of solid phase particles at 30°C.

0.1 M HNO_3, H_2SO_4, and H_3PO_4 at 30°C are shown in Fig. 1. It can be seen that the content of H_3O^+ ion in the reaction mixture decreases. This results from the formation of weaker, orthophosphoric and hydrofluoric, acids in the case of the nitric and sulfuric acid decomposition, and of hydrofluoric acid in the case of phosphoric acid decomposition. Experimental data on how the concentrations of F^- and Ca^2 ions vary during the fluorapatite breakdown with 0.1 M HNO_3, H_2SO_4, and H_3PO_4 at 30°C are given in Figs. 1b and 1c, respectively. It can be seen that the concentrations of fluoride anions (Fig. 1b) and calcium cations (Fig. 1c) grow in the course of decomposition. The dependence of the initial rate V_0 of fluorapatite decomposition with 0.1 M HNO_3 at 30°C on the dispersity of solid phase particles is shown in Fig. 2. The rate of heterogeneous reactions is governed by the surface area of contacting phases. Therefore, as the dispersity D (m^{-1}) of solid phase particles (and, consequently, their specific surface area) increases, the reaction rate also becomes higher (Fig. 2).

CONCLUSIONS

(1) The kinetics of fluorapatite decomposition by nitric, sulfuric, and phosphoric acids with initial concentration of 0.1 M was studied by the ionometric method. The obtained experimental data on the content of H_3O^+, Ca^{2+}, and F^- ions in the reaction mixture were interpreted using calibration curves.

(2) The variation of the concentrations of H_3O^+, Ca^{2+}, and F^- ions in decomposition was studied experimentally in relation to time, nature of decomposing agent, and specific surface area of the solid phase particles.

(3) The content of hydroxonium ion was found to decrease in the course of the decomposition, whereas the concentrations of Ca^{2+} and F^- ions increase. The dependences obtained for all the three acids under study are monotonic. Raising the dispersity of fluorapatite makes higher the rate of the acidic decomposition.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Hydrolysis of Titanium(IV) Sulfate Solutions under Hydrothermal Conditions

A. V. Tolchev, V. Yu. Pervushin, and D. G. Kleshchev

Chelyabinsk State Pedagogical University, Chelyabinsk, Russia

Received September 13, 2000; in final form, June 2001

Abstract—The structure and the phase, granulometric, and chemical composition of hydrated titanium dioxide obtained by hydrolysis of oxotitanium(IV) sulfate and ammonium titanium(IV) oxysulfate solutions under hydrothermal conditions (130–170°C) were studied by X-ray and chemical analyses, electron microscopy, and thermogravimetry. The effect of hydrolysis conditions on the formation of samples with globular shape of particles was studied.

The stage of hydrothermal hydrolysis of titanium(IV) sulfate solutions, in which hydrated titanium dioxide (HTD) is formed with anatase structure, is one of main stages in the production of pigment titanium dioxide by the sulfate method [1, 2]. According to the results of numerous studies of the hydrolysis kinetics, the chemical and granulometric compositions of HTD, including the shape of aggregates, depend on quite a number of synthesis parameters: temperature, titanium(IV) and sulfuric acid concentrations in the starting solution, rate of solution heating to a prescribed temperature, presence of seed crystals and admixtures [2–6], etc. In most of the investigations, the hydrothermal hydrolysis of titanium(IV) sulfate solutions was carried out in open reactors, which imposed limitations on the experimental temperature range (80–110°C). It is known that the hydrolysis rate constant grows with increasing temperature [7].

The aim of this work was to study the fundamental aspects of HTD synthesis by hydrothermal autoclaving of titanium(IV) solutions, which is also important for intensifying this stage in synthesis of pigment titanium dioxide.

EXPERIMENTAL

Solutions of titanium(IV) oxysulfate and ammonium titanium(IV) oxysulfate (both of chemically-pure grade) were prepared by dissolution of reagents in aqueous solutions of sulfuric acid (pure grade) at 80°C. The starting titanium(IV) oxysulfate solutions were characterized by the concentration of Ti(IV) ions (1.25 and 2.5 M) and the ratio of numbers of H_2SO_4 and $TiOSO_4$ moles taken for preparing a solution $\beta = \nu_1/\nu_2$ (1.0, 1.5, 2.0, 2.5, 3.0, and 4.0). In ammonium titanium(IV) oxysulfate solutions, $C_{Ti(IV)}$ was 1.25 M, and β, 1.0, 1.3, and 1.5. In certain experiments, seed crystals with anatase structure were added to the starting solution in amounts ranging from 0.5 to 5 wt % relative to TiO_2 contained in the solution.

We carried out hydrothermal hydrolysis of titanium(IV) sulfate solutions at 130, 150, and 170°C (heat treatment time τ = 1 h) in 0.07-dm^3 steel laboratory autoclaves lined with fluoroplastic from within. The autoclave filling factor was 0.8. Heating and stirring were done with a rotating steel frame placed in a SNOL oven. Six autoclaves were rigidly fixed on the frame and set in rotation at a speed of 50 rpm, using a gearbox. The temperature was monitored with a Chromel–Copel thermocouple connected to a KSP-3 potentiometer. The hot thermocouple junction was placed in a special pocket of an immobile autoclave of similar design, placed in the oven. The time of autoclave heating to a prescribed temperature did not exceed 1 h, the accuracy of the temperature control was ±5°C. To obtain larger samples, we used an enameled steel autoclave with volume of 3 dm^3. The precipitates obtained were separated from the mother liquor by centrifuging or filtration under pressure, washed to remove free sulfuric acid to absence of sulfate ions in the filtrate, dried to constant weight at 40°C, and crushed.

The phase and granulometric compositions of the samples studied were monitored by means of X-ray phase analysis (DRON-3 X-ray apparatus, filtered

Cu_{K_α} radiation) and transmission electron microscopy (UEVM-100K electron microscope); the chemical composition was determined by volumetric chemical analysis and thermogravimetry (Q-1000 derivatograph). The average size d of the forming crystals was calculated by Selyakov–Scherer's formula [8] from the physical broadening of diffraction peaks, $\Delta 2\theta$.

According to the X-ray phase analysis of products obtained in hydrothermal hydrolysis of titanium(IV) oxysulfate in solutions, HTD with anatase-type structure is formed in the entire range of temperatures, $C_{Ti(IV)}$ concentrations, and β values used in the study. The average size d of HTD crystals is virtually independent of $C_{Ti(IV)}$ and β, and is largely determined by the heat treatment temperature T, growing linearly with increasing temperature from 15 (T = 130°C) to 20 nm (T = 170°C). The empirical composition of HTD samples, calculated from the data of chemical analysis and thermogravimetry, is described by the formula $TiO_2 \cdot xH_2O \cdot ySO_3$, where x depends on the temperature at which the hydrolysis was carried out (see table), and decreases steadily with increasing T from 0.6 (T = 130°C) to 0.3 (T = 170°C). The y value is affected by temperature and other factors, the main of which seems to be β value. The content of sulfate ions in HTD grows with increasing β (see table). The β value also affects the degree of titanium(IV) oxysulfate hydrolysis in solutions, which decreases steadily with increasing β. Raising the hydrolysis temperature makes this dependence weaker; for example, at 170°C the degree of hydrolysis in all the experiments was no less than 99%.

It follows from the electron microscopic data that HTD samples prepared at 130°C are characterized by different shapes of aggregates, depending on the β value. For example, samples synthesized from titanium(IV) oxysulfate solutions with β = 2 mainly consist of uniform spherical aggregates (globules) (Fig. 1a) with average size D of about 0.3 μm. Comparison of the sizes of HTD aggregates and separate crystals (D >> d) shows that the globular particles contain 10^3 to 10^4 primary crystals randomly oriented relative to one another. Samples of HTD prepared from titanium(IV) oxysulfate solutions with β > 2 consist of dense aggregates of irregular shape with admixture of an amorphous phase (Fig. 1b). With increasing hydrolysis temperature, the range of β values in which HTD globular particles are formed tends to expand

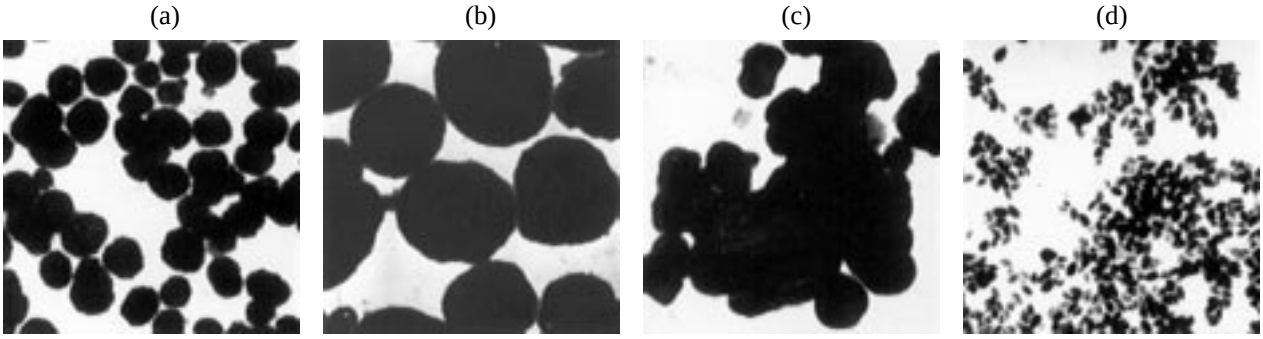

Fig. 1. Microphotographs of products of thermal hydrolysis of (a)–(c) titanium(IV) oxysulfate and (d) ammonium titanium(IV) oxysulfate. Magnification 20000. Content of seed crystals 4 wt % (c). (see table), and at β = const their average size also shows a tendency to increase to 2 μm at 170°C.

The effect of seed crystals with anatase-type structure on the HTD formation was studied for the example of hydrolysis of hydrothermal titanium(IV) oxysulfate (T = 150°C) in solutions with $C_{Ti(IV)}$ = 2.5 M and β = 1.0. We found experimentally that the introduction of seed crystals leads to an increase in the degree of titanium(IV) oxysulfate hydrolysis in solution to 99%. At weight fraction of seed crystals less than 3%, separate globular HTD particles are formed; at greater weight fractions of seed crystals, a tendency toward globule aggregation is observed (Fig. 1c).

To determine the generality of the established fundamental aspects of HTD formation in hydrothermal hydrolysis of titanium(IV) oxysulfate, we studied the hydrolysis of ammonium titanium(IV) oxysulfate under similar conditions (T = 150°C). According to X-ray phase analysis data, hydrolysis of ammonium titanium(IV) oxysulfate yields, as also in the case of titanium(IV) oxysulfate hydrolysis, HTD with anatase-type structure, with average size of crystals of about 10 nm. Raising β from 1.0 to 1.5 has only a minor effect on the average size of HTD crystals. It follows from electron-microscopic data that HTD samples obtained at different β values are monodisperse systems consisting of regular-shape aggregates, which include up to 10^3 primary crystals. The shape and size of the HTD aggregates depend on the β value. In particular, an HTD sample obtained at β = 1.0 consisted of lenticular particles with average length of about 100 nm and diameter of 50 nm (Fig. 1d), with the porous structure of these particles seen in the light-contrast areas. Raising β to 1.3 results in the formation of ellipsoidal HTD aggregates, with their average dimensions increasing to 120 and 80 nm, respectively. Spherical HTD particles with average size of about 150 nm are precipitated from ammonium titanium(IV) oxysulfate solutions with β = 1.5. When seed crystals are introduced into the starting ammonium titanium(IV) oxysulfate solution, a tendency toward aggregation of globular HTD particles is observed, which is also the case for titanium(IV) oxysulfate solutions.

Thus, our experimental data suggest that the graining rate and the chemical and granulometric composition of HTD samples formed in hydrothermal hydrolysis of titanium(IV) salts in solutions depend on the following main factors: concentration of sulfuric acid in the starting solution, acid to titanium(IV) salt molar ratio, and temperature. It is known [9] that crystals in solutions grow through incorporation of crystal-forming complexes in a nucleus of the crystalline phase, with both the nucleus and the crystal-forming complexes formed in an interaction between hydroxo aqua complexes of metal ions present in the solution. Owing to the absence of direct methods for studying the structure of such complexes and to the inconsistency of the data on their composition [10], we assume, based on the reaction of hydrolysis of M^{z+} ions in solution

$$M_{aq}^{z+} + iH_2O \rightarrow [M(OH)_i(H_2O)_{k-i}]^{(z-i)+} + iH_{aq}^{+}, \quad (1)$$

that titanium(IV) hydroxo aqua complexes have the composition $[Ti^{4+}(OH)_i(H_2O)_{k-i}]^{(4-i)+}$. Here the quantity i (depth of hydrolysis of Ti^4 ions) is determined by particular conditions of the reaction; k is the coordination number of Ti^{4+} ions in solution.[1]

With decreasing concentration of the acid in the starting solution, the depth of hydrolysis, i, of titanium(IV) ions increases, which yields not only positive-

[1] This assumption is not, on the whole, of fundamental importance and has no effect upon further reasoning.

ly charged hydroxo aqua complexes, but also neutral complexes $[Ti_m(OH)_n(H_2O)_l]^0$ ($m \geq 1$), which are the "construction material" for titanium(IV) oxide compounds [2], including hydrated compounds. The concentration of these complexes grows with increasing temperature and $C_{Ti(IV)}$ in solutions and decreases with increasing acidity of solutions (β value), which accounts for the corresponding dependences of the degree of titanium(IV) hydrolysis (see table) on the above-mentioned conditions of hydrothermal processing.

Let us consider elementary processes occurring in thermohydrolytic precipitation of HTD from titanium(IV) oxysulfate and ammonium titanium(IV) oxysulfate solutions. The whole set of experimental data on the occurrence of a latent period preceding HTD precipitation and a reduction in its duration, accompanied by a dramatic (3–5-fold) increase in the average rate of HTD precipitation, upon introduction of seed crystals into the reaction medium [2, 5] indicates that the limiting stage of HTD precipitation from solutions is the nucleation stage, rather than the hydrolysis reaction (1). Therefore, it may be assumed that by the initial instant of time the concentration of $[Ti_m(OH)_n(H_2O)_l]^0$ complexes in solution reaches the equilibrium value for given thermodynamic conditions.

During the latent period of heat treatment, two opposite processes occur in parallel in local areas of the solution [2]. The first process is the formation of HTD nuclei as a result of polycondensation of titanium(IV) hydroxo aqua complexes, which results in the formation of strong bridging oxo or hydroxo bonds between Ti^{4+} ions in a nucleus

$$p[Ti_m(OH)_n(H_2O)_l]^0 \rightarrow [Ti_{pm}O_q(OH)_{pn-2q}(H_2O)_r]^0 + (q + pl - r)H_2O, \quad (2)$$

The second process is the dissolution of nuclei through their reaction with free sulfuric acid. Nuclei of critical size, not inclined to dissolve, are formed by the end of the latent period as a result of fluctuations in local solution areas. Hydroxo aqua complexes contained in the solution start to be incorporated into these nuclei, thus forming HTD crystals. The small size of primary HTD crystals (no more than 20 nm) suggests that the growth of crystals in thermohydrolytic precipitation of HTD from solution occurs under conditions of strong supersaturation and is accompanied by irregular incorporation of hydroxo aqua complexes into the surface layer of a nucleus. We can assume that all hydroxo aqua complexes located at a distance of a diffusion jump from a critical-size nucleus are incorporated into it almost instantaneously.

This leads to a change in the ratio of activities of hydroxo aqua complexes and other solution components, in particular SO_4^{2-} or HSO_4^- ions, in a local solution region close to a primary crystal. These ions start to react with titanium(IV) ions on the crystal surface to form there a two-dimensional quasi-phase [11], which prevents further crystal growth. This may be a factor responsible for the presence of sulfate ions in HTD samples obtained by thermohydrolytic precipitation from sulfuric acid solutions (see table). The sulfate ions are rather strongly bound to HTD and can be removed on calcination of the samples in air at temperatures above 500°C [2, 11].

In the initial stage of HTD crystal formation, the solutions become heterogeneous, and, owing to an essential reduction in the work of heterogeneous nucleation as compared with homogeneous nucleation [9], nuclei are predominantly formed on the surface of the already existing HTD crystals. Because of the presence of a quasi-phase on their surface, which weakens the effect of the crystal structure of hydrated titanium dioxide on the formation and growth of the nuclei, no epitaxial growth of crystals takes place in aggregates forming in repeated events of nucleation. However, owing to the occurrence of strong chemical bonding between the quasiphase and the formed nucleus, the aggregates are rather strong formations, which retain their configuration in washing HTD to remove water-soluble salts and in mechanical treatment.

The aforesaid furnishes a consistent explanation of the observed dependence of the chemical and granulometric sion composition of HTD formed by thermohydrolytic precipitation from titanium(IV) sulfuric solutions on synthesis conditions. In particular, the increase in the average size of primary HTD crystals and the decrease in the content of crystallization water in these crystals with increasing temperature of heat treatment can be accounted for by the increase in the diffusion mobility of hydroxo aqua complexes, which results in a longer diffusion jump and more ordered incorporation of the complexes into a growing nucleus. The increase in the content of sulfate ions in HTD on raising the concentration of sulfuric acid in solution (molar ratio β) is associated with a rise in the activity of sulfate ions in solution, which results in higher weight fraction of the quasi-phase in the samples. The average size and structure of aggregated primary crystals are determined by the amount of the HTD primary crystals included in the aggregates, which grows with

increasing degree of titanium(IV) hydrolysis in sulfate solutions. Indeed, at high temperatures and α values close to 100%, the maximum concentration of titanium(IV) hydroxo complexes $[Ti_m(OH)_n(H_2O)_l]^0$ in solution is reached, which results in a shorter (down to zero) duration of the latent period of thermohydrolytic HTD precipitation from solution. In this case, the nuclei and titanium(IV) hydroxo aqua complexes are uniformly distributed over the entire volume of the reaction medium, which predetermines equal conditions for the formation of HTD crystals and manifests itself in the formation of monodisperse aggregates with globular structure. Vice versa, at low degrees of hydrolysis of titanium(IV) sulfate compounds ($T \le 150$°C, $\beta > 2$), the latent period becomes longer because of the low concentration of titanium(IV) hydroxo aqua complexes in solution. Therefore, HTD nuclei are formed by a stochastic mechanism [11] at different instants of time and, as a result, are nonuniformly distributed in the reaction medium. This results in local nonuniformity of the concentration of titanium(IV) hydroxo aqua complexes in solution and is responsible for the formation of irregularly shaped polydisperse aggregates.

CONCLUSION

The temperature required for hydrolysis of titanium(IV) in sulfate solutions under hydrothermal conditions was found to be 170°C. In this case, hydrated titanium dioxide with well-pronounced globular structure of aggregates is formed. A possible mechanism of formation of globular particles of hydrated titanium dioxide was considered.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Film-Forming Capacity of Sn(II), Zr(IV), and Hf(IV) Acetylacetonates

V. V. Dyukov, S. A. Kuznetsova, L. P. Borilo, and V. V. Kozik

Tomsk State University, Tomsk, Russia

Received March 12, 2001

Abstract—$Zr(acac)_4$, $Hf(acac)_4$, and $SnHacacCl_2 \cdot 2H_2O$ were prepared in the solid state and in enthanol solutions. The film-forming capacity and thermal stability of these compounds were studied. Films of ZrO_2, HfO_2, and SnO_2 were prepared from film-forming solutions of the corresponding acetylacetonates.

At present there is demand for thin film materials stable in corrosive media and having good optical properties. The functional and physicochemical properties of these films are mainly determined by their preparation conditions and the nature and composition of the initial film-forming compound (FFC). The promising FFCs are β-diketonates [1]. Data on the thermal stability, volatility, behavior in organic and inorganic solvents, and film-forming capacity of Group IV metal β-diketonates are scarce and often contradictory [2].

In this work, we studied the film-forming capacity of zirconium hafnium, and tin acetylaetonates. For this purpose, we prepared these complexes in the solid phase and in solution, studied their thermal stability in air, and prepared ZrO_2, HfO_2, and SnO_2 films from ethanol solutions of these acetylacetonates.

EXPERIMENTAL

Zirconium and hafnium acetylacetonates $Zr(acac)_4$ and $Hf(acac)_4$ were prepared from aqueous solutions of zirconium and hafnium oxychlorides, respectively, and acetylacetone (molar ratio 1 : 4) at pH 1.9–3.5. The resulting mixture was heated on water bath. The crystalline precipitate was washed with ice-cold water and dried in air. Tin(II) acetylacetonate was prepared from ethanol solution (96 wt % C_2H_5OH) of tin(II) chloride hydrate and acetylacetone (molar ratio 1 : 2).

The zirconium and hafnium content was determined gravimetrically. The actylacetonate ($acac^-$) content was determined by absorption of the iron(III) acetylacetonate complex at λ_{eff} = 550 nm [3].

The qualitative and quantitative composition of $SnHacacCl_2 \cdot 2H_2O$ was determined by means of X-ray spectral microanalysis (XSMA) [4] on a Camebax Microbeam device at accelerating voltage of 20 keV. Metallic tin and single-crystal sodium chloride were used as references. The presence of acetylacetone in the complex was confirmed by qualitative reaction with iron(III) [3].

The compositions of the complexes are presented in Table 1. Acetylacetone in $Zr(acac)_4$ and $Hf(acac)_4$ complexes is in the deprotonated enol form. The tin complex is coordination-unsaturated and contains hydration water and Hacac in the undissociated enol and keto forms, which were previously detected in an ethanol solution acidified with HCl [5].

The solubility of zirconium, hafnium, and tin acetylacetonates in organic and inorganic solvents was studied at room temperature. The solubility of anhydrous zirconium acetylacetonate in chloroform, aceto-

nitrile, and acetone is 30, 15, and 4–9 wt %, respectively. The solubility of hafnium acetylacetonate in these solvents is, on the average, 3 wt % lower owing to the more ionic character of the coordination bonds. $SnHacacCl_2 \cdot 2H_2O$ is insoluble in organic solvents and poorly soluble in concentrated mineral acids and water ($\sim 6 \times 10^{-4}$ M) at room and elevated temperatures.

The thermal stability of the complexes in air was studied on a Q-1500 MOM derivatograph (Hungary) in the temperature range 298–1273 K at a heating rate of 10 deg min^{-1}.

Thermal analysis data for $SnHacacCl_2 \cdot 2H_2O$ are shown in Fig. 1a. The first decomposition step is characterized by an exothermic effect in the temperature range 298–473 K and weight loss of up to 4%. As determined by X-ray spectral microanalysis, the remaining product is identical to the initial compound, which indicates that the first effect is due to the sublimation of the compound

Found, wt %: Sn 36.04, Cl 26.98.

$SnHacacCl_2 \cdot 2H_2O$.

Calculated, wt %: Sn 36.43, Cl 27.79.

In the second step (510–563 K) acetylacetone is eliminated and oxidized. As determined by X-ray phase analysis (XPA), the product is $SnCl_2 \cdot 2H_2O$, in agreement with the data of [6]. Weak exothermic peaks in the third step (563–773 K) are assigned to decomposition of $SnCl_2 \cdot 2H_2O$ to give SnO and to oxidation of this product by atmospheric oxygen to SnO_2 (Table 2).

* The data of [8] are given in parentheses.

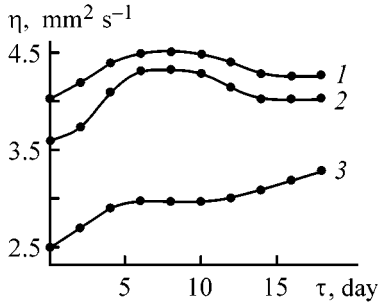

Fig. 2. FFS viscosity η vs. time τ.

The data obtained in thermal analysis of $SnHacacCl_2 \cdot 2H_2O$ and XPA of its decomposition products suggest the following scheme of its decomposition

$$SnHacacCl_2 \cdot 2H_2O \xrightarrow[-\text{Hacac} + O_2 \rightarrow \text{oxidation products}]{} SnCl_2 \cdot 2H_2O \xrightarrow[-H_2O]{} SnCl_2 \cdot H_2O \xrightarrow[-2HCl]{} SnO \xrightarrow{1/2O_2} SnO_2.$$

Decomposition of $Zr(acac)_4$ is also a three-step process (Fig. 1b). In the first step (373–473 K), one acetylacetonate ligand is liberated with an endothermic effect and 18.9% weight loss. The subsequent two steps (473–673 and 673–743 K) are due to exothermic decomposition of the complex to finally form monoclinic ZrO_2 (Table 2).

Thermolysis of $Hf(acac)_4$ is similar to that of $Zr(acac)_4$, with the temperature effects shifted by 30 K to higher temperatures. As determined by XPA, the final thermolysis product is monoclinic HfO_2 (Table 2).

Thus, ZrO_2, HfO_2, and SnO_2 can be prepared from the corresponding metal acetylacetonates at 743, 773, 773 K, respectively.

It is known that oxide films can be conveniently prepared from film-forming solutions in ethanol [8]. Since $Hf(acac)_4$, $Zr(acac)_4$ and $SnHacacCl_2 \cdot 2H_2O$ are poorly soluble in ethanol, we studied preparation of these complexes directly in ethanol without their isolation in the solid state.

Film-forming solutions were prepared from 96% ethanol, acetylacetone and Group IV metal salts [zirconium and hafnium oxychlorides, tin(II) chloride] at Zr^{4+} : acacH, Hf^{4+} : acacH, and Sn^{2+} : acacH ratios of 1 : 4, 1 : 4, and 1 : 2, respectively. The experimental results show that tin(II) acetylacetonate is stable in ethanol solution only at hydrochloric acid concentrations of no less than 0.4 M.

In practice, the stability of FFS can be estimated by their viscosity. The viscosity was measured with VPZh-2 and VPZh-4 viscometers at room temperature. The time dependences of the viscosity of solutions of zirconium and hafnium acetylacetonates are similar (Fig. 2, curves *1*, *2*, respectively). The viscosity reaches a maximum in six days (4.05–4.35 $mm^2 s^{-1}$) and then decreases to constant value by the 15th day. The increase in the viscosity is due to hydrolysis and formation of polymeric associates $-M\leftarrow O=C(CH_3)CH=C(CH_3)OM-$ (M = Zr and Hf) with acetylacetonate bridges [7]. These associates degrade (with a decrease in viscosity) to form mutually oriented coordination-saturated zirconium and hafnium chelates with coordination number of eight.

The time dependence of the viscosity of tin(II) acetylacetonate (Fig. 2, curve *3*) indicates the attainment

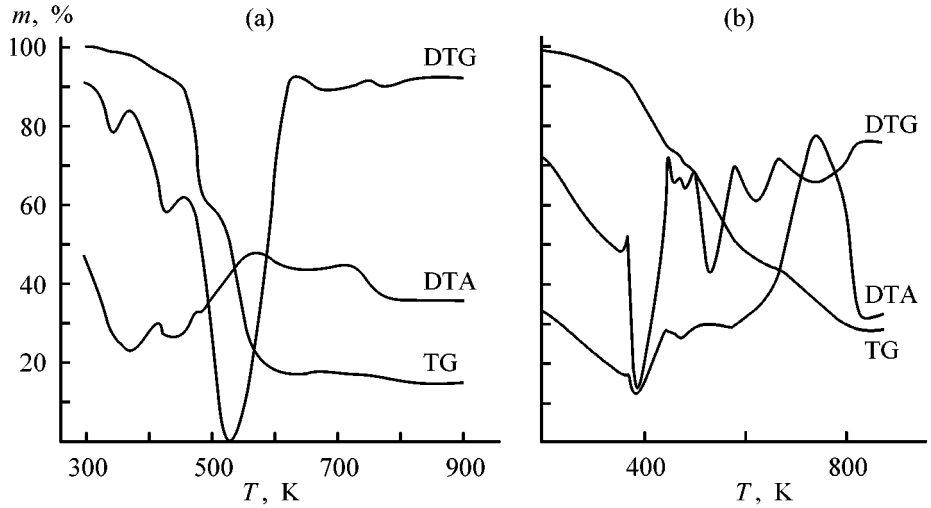

Fig. 3. TG, DTA, and DTG curves of dried FFSs of (a) tin acetylacetonate and (b) zirconium acetylacetonate.

of equilibrium in the solution in four days. The viscosity is constant during the following 6 days. This indicates that equilibrium hydrolysis and complexation of tin(II) are complete. The increase in the viscosity after 10 days is also due to the formation of polymeric associates. Since the viscosity of FFSs does not reach the critical values [8], these solutions can be used during a year after their preparation.

To study the mechanism of oxide film formation, the chemical composition of FFSs dried at 333 K was determined and thermal analysis of these products in the temperature range from 293 to 1073 K was performed.

The chemical composition of an FFS of $SnHacacCl_2 \cdot 2H_2O$ in EtOH, dried at 333 K, was determined by XSMA. The tin and chlorine concentrations in different parts of the sample indicate the presence of $SnCl_2 \cdot 2H_2O$ and $SnHacacCl_2$.

Found in FFS, wt %	Sn	Cl
$SnCl_2 \cdot 2H_2O$	52.49	34.75
$SnHacacCl_2$	43.75	24.16
Calculated, wt %:		
$SnCl_2 \cdot 2H_2O$	52.59	33.46
$SnHacacCl_2$	42.96	24.49

A quantitative XSMA of dried FFS of tin(II) acetylacetonate and $SnHacacCl_2 \cdot 2H_2O$ showed that, during drying of the sample, Hacac is evaporated with ethanol and $SnHacacCl_2 \cdot 2H_2O$ partially decomposing to form $SnCl_2 \cdot 2H_2O$.

The TG, DTA, and DTG curves of an $SnHacacCl_2$–$SnCl_2 \cdot 2H_2O$ mixture (Fig. 3a) somewhat differ from those of $SnHacacCl_2 \cdot 2H_2O$ (Fig. 1a). In the case of dried FFS, the temperature effects are shifted to higher temperatures. The first step is accompanied by two endothermic effects at 323–473 K, associated with sublimation of the complex and desorption of ethanol molecules. In the second step (exothermic effect at 473–593 K), Hacac is liberated from $SnHacacCl_2$ and then oxidized. The third step (593–873 K) involves decomposition of $SnCl_2 \cdot 2H_2O$ to SnO and oxidation of SnO by atmospheric oxygen to give SnO_2 having the rutile structure (according to XPA).

Thermolysis of dried FFS consisting of $ZrOCl_2$, Hacac, and ethanol is a complex process (Fig. 3b). Four endothermic peaks at 370, 388, 448, and 473 K and two exothermic peaks at 531 and 733 K are observed in the DTA curve, with the second exothermic peak being a sum of two effects (DTG). The endothermic effects in the temperature range 321–487 K are probably due to stepwise removal of residual ethanol and water, and to decomposition of zirconium chloride complexes. The exothermic effects in the temperature range 487–873 K are assigned to combustion of the ligand with complete oxidative degradation of FFS to form monoclinic zirconium(IV) oxide (according to XPA).

Table 3. Physicochemical properties of films*

Film composition	n	d, nm	ρ, Ω	F, kg mm^{-2}	ΔE, eV
SnO_2	1.84	41.5	10^6	0.450	3.9
ZrO_2	2.14	65.7	10^8	0.801	–
HfO_2	2.12	58.9	10^7–10^8	0.765	–

* n, F, and ΔE are the refractive index, adhesion, and the optical band gap, respectively.

The DTA curves of dried FFS containing $HfOCl_2$, Hacac, and C_2H_5OH are characterized by three endothermic peaks at 403, 448, 508 K and two exothermic peaks at 693 and 825 K, with the second of these corresponding to two effects. Monoclinic hafnium dioxide is formed at 873 K.

The results of XPA and thermal analysis of dried FFSs indicate that monoclinic zirconium and hafnium dioxides and tin dioxide with rutile stricture are formed at 873 K.

Films of zirconium, hafnium, and tin dioxides were prepared by centrifuging FFSs at 2000–5000 rpm. These films are thermally stable, chemically inert, and have good adhesion to silicon, quartz, glass, and Polikor. The physicochemical properties of high-resistivity semiconducting films of ZrO_2, HfO_2, and SnO_2 on a silicon support are summarized in Table 3. The optical properties of the films were studied with an LEF-3M ellipsometer; the electrical properties, on E7-8 and E7-12 units; and adhesion was measured with a PMT-3 microhardness gage.

CONCLUSION

The complexes $Zr(acac)_4$, $Hf(acac)_4$, $SnHacacCl_2 \cdot 2H_2O$ were prepared in the solid phase and in an ethanol solution. The film-forming capacity and thermal stability in air of these solutions were studied. High-resistivity semiconducting films of ZrO_2, HfO_2, and SnO_2 with high adhesion to different supports were prepared.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Solubility and State of Elemental Selenium in Hydrocarbons

E. I. Perov and N. V. Moshchenskaya

Altai State University, Barnaul, Russia

Received February 12, 2001

Abstract—The solubility of metallic and amorphous selenium in *n*-heptane, *n*-octane, *n*-nonane, *n*-decane, *n*-undecane, and *n*-dodecane was determined in the range 298–493 K. The effect of temperature and alkane nature is considered. The average composition of selenium molecules in alkanes was determined from ebullioscopic data.

Our study of the solubility of elemental sulfur in pure *n*-alkanes showed that at 150–200°C "low-molecular-weight" products of thermal dissociation of S_8 rings (down to S_2) exist in solution in noticeable amounts [1]. Also, a saw-tooth dependence of the sulfur solubility on the number of carbon atoms in the hydrocarbon chain was observed for the first time.

Proceeding with studies of synthesis of metal sulfides in organic solvents [2, 3], we proposed an environmentally safe method for preparing metal selenides in liquid *n*-alkanes from elemental selenium and metal carboxylates as initial reagents [4]. Hydrogen selenide formed in the reaction of selenium with hydrocarbons is then converted into a poorly soluble metal selenide. The hydrogen selenide content in the reactor was less than 0.8 mg m^{-3}.

We believe that a study of physicochemical transformations of chalcogens in nonaqueous solutions will allow development of a scientifically substantiated process for preparing semiconductor materials based on metal sulfides and selenides.

The primary stage of the interaction of selenium with *n*-alkanes is its dissolution. The state and solubility of selenium in paraffins have been poorly studied.

In this work, we studied the solubility of two selenium modifications (amorphous and crystalline; the latter is usually termed metallic selenium) in C_7–C_{12} saturated hydrocarbons in the temperature range 25–250°C by the method of immersion filtration [5, 6].

Several conical flasks with preliminarily purified solvent [7] and an immersion filter with selenium were placed in a thermostat equipped with a special vibrator. Samples of saturated solutions were taken with a sampler, and the selenium concen tration was determined gravimetrically after isothermal evaporation of the solvent. The curves of paraffin saturation with metallic and amorphous selenium are shown in Figs. 1 and 2.
