INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Hydrothermal Synthesis of Chromium Dioxide

Abstract—Two procedures for hydrothermal synthesis of chromium dioxide are compared: from chromium(VI) oxide and from chromium(VI) and chromium(III) oxides. The reaction products obtained in the presence of modifying agents such as antimony, iron, tellurium, and tin compounds are described in relation to the synthesis temperature.

Chromium dioxide, known as one of "intermediate" chromium oxides, has a rutile structure. The ferromagnetic properties of the compound distinguish CrO_2 from all other oxides of *d* elements. The quadruple-charged state of chromium, demonstrated by neutron diffraction analysis [1], is one more distinctive feature of the compound.

First syntheses of pure chromium dioxide were done by thermal decomposition of dry chromium(VI) oxide in oxygen under elevated pressure [2, 3]. The T–p_{O_2} diagram of phase transformations in the series CrO_3–$CrO_{2.67}$ (β-oxide)–$CrO_{2.44}$ (γ-oxide)–CrO_2–Cr_2O_3 was described in [4]. CrO_2 is stable in oxygen under a pressure of 10 MPa in the interval 255–280°C. At lower oxygen pressure, the limits of the narrowing range have not been determined precisely. Later investigations of ways to synthesize chromium dioxide [5–12] were aimed at obtaining powders suitable for use in magnetic recording media. These were hydrothermal syntheses in the presence of modifying additives. A distinctive feature of the powders is that their particles are small and needle-shaped. The coercive force of such a powder depends on the needle thickness.

Two main methods of hydrothermal synthesis are known: from a $CrO_3 + H_2O$ mixture (procedure A) [5–7, 11] and from $CrO_3 + Cr_2O_3 + H_2O$ mixture (procedure B) [8–10, 12]. The molar ratio Cr/H_2O is commonly within the range 0.9–1.5 in procedures A and B. The chemical aspect of these processes has been described incompletely. It is known that α-CrOOH and only trace amounts of CrO_2 are formed at 300–325°C from a dilute chromic acid solution (molar ratio $CrO_3/H_2O < 0.06$) [14]. According to [15], the hydrothermal decomposition of CrO_3 to chromium dioxide under a pressure of 50–200 MPa is preceded by stepwise formation of β and γ chromium oxides, and fast decomposition to CrO_2 occurs at above 360°C. However, at temperatures below 320°C CrO_2 is insufficiently stable in aqueous medium, chromium dioxide may decompose to give β-CrOOH even under elevated pressure of oxygen [16]. This temperature lies near the thermal stability limit of CrO_2 [4]. The common temperature of hydrothermal synthesis of CrO_2 is 350–400°C [5–11].

The hydrothermal process A is commonly described by the equation $CrO_3 \rightarrow CrO_2 + 1/2O_2$. Processes of the type B were described by the equations $Cr_2O_3 + CrO_3 \rightarrow \rightarrow 3CrO_2$ and $Cr_2O_3 + 3CrO_3 \rightarrow 5CrO_2 + O_2$ in [17], $Cr_2O_3 \cdot 3CrO_3 \cdot H_2O \rightarrow 5CrO_2 + O_2 + H_2O$ in monograph [18]; the occurrence of the process in two stages: $Cr_2O_3 + 2CrO_3 \rightarrow 3CrO_2 + CrO_3$ (250°C, nucleation) and $CrO_3 \rightarrow CrO_2 + 1/2O_2$ (75°C, growth of CrO_2 at nuclei) is reported in [10]. Apparently, the proposed schemes are tentative and contradict some facts, e.g., the good solubility of chromium(VI) oxide [19]. As modifying additives serve compounds of Sb, Te, Sb + Fe, Te + Fe, Sn + Te, and Sn + Te + Fe. Their amounts per 100 mol of chromium are in the range from 0.05 to 2.0 mol and more in the case of iron(III). A solid solution $(Cr, Fe)O_2$ and phases with the rutile structure such as $CrSbO_4$, Cr_2TeO_6, $FeSbO_4$, etc., and solid solutions on their base, e.g., $(Cr, Fe)SbO_4$, are formed in the course of the reaction [6, 20]. Already in [6], an assumption was made that these compounds can serve as nuclei in chromium dioxide formation; however, no experimental evidence in favor was presented. The proposed model of three-stage heteroepitaxial formation of CrO_2 in the presence of Sn + Te compounds [21] was based on a comparison of the finite sizes of chromium dioxide crystals with the surface area of the

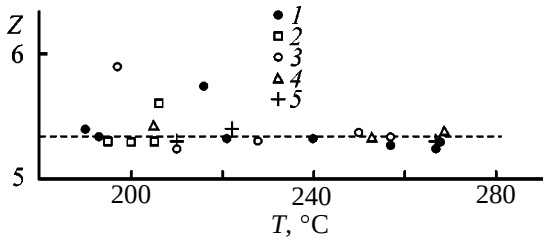

Fig. 1. Average oxidation state of chromium, *Z*, in solution vs. the synthesis temperature *T*. Synthesis procedure: (*1*–*4*) A and (*5*) B; the same for Fig. 2. (*1*, *5*) $SnO_2 \cdot nH_2O$ + $H_2TeO_4 \cdot 2H_2O$, (*2*) Sb_2O_3 + γ-Fe_2O_3, (*3*) Sb_2O_3, and (*4*) no additives; the same for Fig. 2.

modifier-matrix (hydrated tin dioxide) and the amount of the second modifier, tellurium compound. In the same communication a pathway of the hydrothermal reaction A via formation of a chromium chromate solution was reported. As noticed previously [22], this pathway is rather similar to that of reaction B. In this work, reaction A is analyzed in more detail and a reaction by pathway B is described for the first time. The obtained additional data make possible a more thorough description of the process mechanisms, including detailed description of the mechanism of modifying action of additives, and consideration of methods for control over size and composition of nanoparticles.

All experiments were performed in a 0.5-l Cr17Ni13Mo2Ti steel autoclave in which a quartz test tube with a mixture to be decomposed was placed. The experiments by procedure A were performed with the molar ratio Cr/H_2O = 0.9, and those by procedure B, with Cr(VI) : Cr(III) : H_2O = 0.41 : 0.27 : 1.0. The modifying additives were introduced in preparing the paste. In all cases the ratio of the total amount of chromium compounds to the autoclave volume (with correction for the test tube material volume) was 0.5 mol l^{-1}. The reaction product was washed out of the test tube with subsequent centrifugation in synthesizing a viscous paste or was extracted from the tube by breaking it into pieces, with subsequent grinding and drying at 110°C. The rate of mixture heating in the autoclave was 100–150 deg min^{-1}.

Table 1. Chromium oxides isolated from products of CrO_3 hydrothermal decomposition performed without modifying additives (*n* is number of moles of chromium)

Synthesis no.	*T*, °C	τ, h	Solid products	n_s/n_{in}
628	205	6.0	Not formed	0
633	253	6.8	Chromium γ-oxide	0.35
630	269	7.5	Chromium γ-oxide, CrO_2	0.45

The onset of oxygen evolution in heating of mixture A was recorded at 145–165°C in all the performed 500 runs. As a result, a chromium chromate solution with a Cr(VI) : Cr(III) ratio close to 7 : 2 (or with average oxidation state of chromium of 5.33) is formed. Apparently, this is the same Cr(VI) : Cr(III) ratio as in β chromium oxide $CrO_{2.67}$, well soluble in water [23]. An X-ray phase analysis (XPA) demonstrated the absence of β-oxide in the reaction products. In performing the reaction by procedure B, CrO_3, Cr_2O_3, and H_2O start to react in the stage of component mixing, and the mixture heats-up. At temperatures below 200°C such a mixture does not evolve oxygen (to within the experimental error). The Cr(VI) : Cr(III) ratio in the soluble part of the product is the same as in synthesis by procedure A.

Figure 1 presents the average oxidation states of chromium in centrifugates, determined for a number syntheses of types A and B at 190–270°C. The results are independent of the presence of additives or, as shown below, of whether or not CrO_2, CrO_3, or γ chromium oxide are contained in the reaction products. The mixture of products obtained at 300–400°C is a pumice-like solid mass. According to XPA, this mass is practically pure chromium dioxide. Some products of this kind were subjected to dry milling, wet grinding, and multiple washing with centrifuging. The starting portion of a powder was about 200 g; washing was terminated at a chromium content of 10 mg l^{-1} in the centrifugate. The total amount of washing water was varied within 5–8 l, and the total content of chromium in the centrifugate was in the range from 0.2 to 6.0 g. The average oxidation state of chromium in washing water varied between 5.23 and 5.44.

Thus, there exists a mother liquor from which chromium dioxide is formed. The initial concentration of chromium in the solution is as high as 10 M. This solution is the same for synthesis procedures A and B, the Cr(VI) : Cr(III) ratio in the solution is close to 7 : 2.

Data on solid products obtained by hydrothermal decomposition of pure chromium(VI) oxide (procedure A, no modifiers) are presented in Table 1. At 263°C, 35% of the initial amount of CrO_3 is converted into γ chromium oxide. This conclusion is made on the basis of gravimetric analysis and XPA of a dried precipitate. With the temperature increasing to 269°C, 45% of the starting CrO_3 is converted into oxides to give a mixture of chromium γ-oxide and

dioxide. The content of CrO_2, evaluated on the basis of the specific magnetization of the precipitate, was about 10% of the total mass of oxides (Table 1, run no. 630). The final pressure in run no. 630 was as high as 10 ± 1 MPa, and the partial pressure of oxygen, ca. 8 MPa. The latter was evaluated independently by two methods: from the residual pressure at room temperature and from the amount of gas passing through the gas meter in relieving the pressure. The obtained temperatures of formation of γ-oxide and CrO_2 under hydrothermal conditions are in good agreement with the "non-hydrothermal" phase diagram of chromium oxides [4]. Since in the synthesis procedure A oxygen starts to be evolved at about 150°C irrespective of the presence of modifiers, reduction of Cr(VI) to Cr(III) may favor formation of mixed oxides $Cr(III)Sb(V)O_4$ and $Cr(III)_2Te(VI)O_6$ already at this temperature. Indeed, the use of $H_2TeO_4 \cdot 2H_2O$ allowed isolation of Cr_2TeO_6 from the product of a reaction carried out at 150°C.

With antimony(III) oxides used as modifiers (in procedure A), mixed oxide $CrSbO_4$ is formed at a higher temperature than that observed for orthotelluric acid. This process is limited by two factors: dissolution of Sb_2O_3 and oxidation Sb(III) → Sb(V). For example, at a molar ratio Sb : Cr = 2 : 98 (with senarmontite as modifier), a precipitate was isolated after synthesis at 197°C, composed of only spindle-shaped monodisperse $CrSbO_4$ particles; the weight of the precipitate was less than 1/10 of that expected on the basis of the reaction. The rest of antimony(III) or antimony(V) was not isolated in centrifugation, but was separated from a centrifugate allowed to stand for a year in the form of an Sb_6O_{13} precipitate (ASTM 21-51). Consequently, despite the dissolution of senarmontite at 197°C, complete oxidation Sb(III) → Sb(V) did not occur. Raising the synthesis temperature to 228°C allowed complete conversion of antimony into spindle-like monodisperse $CrSbO_4$ particles. However, centrifugation was also done in two stages: immediately upon dissolving the product and a year after. The dimensions of spindles synthesized at 197 and 228°C were the same within experimental error: length 86 and 91 nm, respectively; maximum thickness (diameter) 31 nm.

XPA demonstrated a slight increase in interplanar spacings of the $CrSbO_4$ phase, compared with the data of [24]. This made necessary the refining of unit cell parameters for $CrSbO_4$ and $FeSbO_4$, for which purpose preparations synthesized by the ceramic technology were used. XPA data for the purposefully synthesized phases [20] coincided with published evidence. Simultaneously, it was found that the parameters of a $Cr_{1-x}Fe_xSbO_4$ solid solution at $x \le 0.4$ coincide with the parameters of $CrSbO_4$ [20]. The XPS spectra of a $CrSbO_4$ phase synthesized by procedure A at 197°C demonstrated the absence of iron in the compounds, which conclusively excluded from consideration the possibility that the lattice parameters of $CrSbO_4$ increase because of the iron(III) impurity in chromium(VI) oxide. XPS also revealed that the entire amount of antimony is present in the form of Sb(V), with molar ratios Cr(III)/Cr(VI) = 2.8 and Sb/Cr = 2.3. These results indicate that the surface of the $CrSbO_4$ phase is enriched with antimony atoms, presumably through their sorption from the mother liquor, and also with Cr(III) atoms. There were no thermal effects in the derivatogram of the sample. Continuous mass loss (7%) was recorded in the interval 200–800°C, presumably resulting mainly from dehydration of a preparation obtained under hydrothermal conditions. The complexity of the chemical composition of the oxide surface and the presence of water in it can serve as an additional reason for the distortion of the X-ray characteristics of the preparation, with the main reason being, presumably, the ultradispersity of the $CrSbO_4$ phase.

Table 2. Solid compounds isolated from products of CrO_3 hydrothermal decomposition performed in the presence of antimony oxides and γ-Fe_2O_3. Designations: S, Sb_2O_3, senarmontite; V, Sb_2O_3, valentinite; and G, γ-Fe_2O_3

Synthesis no.	Sb : Fe : Cr molar ratio	Type of Sb_2O_3	T, °C	Solid products
705	0.5 : 1.5 : 98	S	195	G + S + (Fe, Cr)SbO_4
704	2 : 6 : 92	S	206	G + (Fe, Cr)SbO_4
703	0.5 : 1.5 : 98	V	200	Not determined*
702	2 : 6 : 92	V	205	V + (Fe, Cr)SbO_4

* The precipitate mass was less than 2 wt % relative to modifiers, which is insufficient for XPA.

The presence of iron(III) oxide as a second additive hinders the dissolution of antimony oxides (Table 2). Synthesis by procedure A at a temperature close to 200°C is also accompanied by a structural transformation in γ-Fe_2O_3. The relative intensities of lines in the X-ray diffraction patterns of the starting γ-Fe_2O_3 were in full agreement with those in the ASTM file 25-1402, being different, and described by ASTM file 13-458, for its undissolved part. Also, a phase was formed with much larger, compared with $CrSbO_4$, unit cell parameters. In all probability, the obtained phase is a solid solution (Fe, Cr)SbO_4 whose composition cannot be interpreted using X-ray analysis

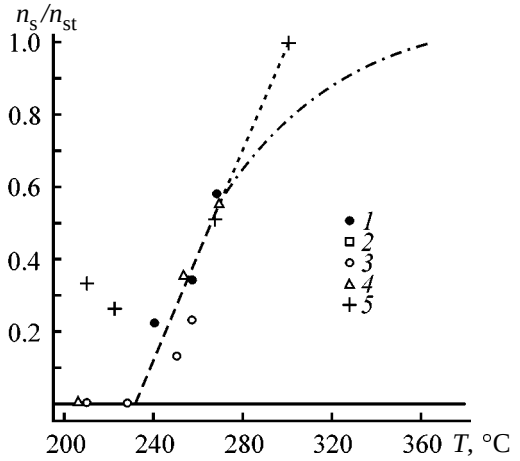

Fig. 2. Mole fraction of chromium in the oxides Cr_2O_3, $CrO_{2.44}$, and CrO_2, n_s/n_{st}, vs. temperature T of hydrothermal synthesis. (n_{st}) Number of moles of chromium in the starting compounds and (n_s) number of chromium moles in solid reaction products. Correction is made for the interaction of the starting chromium compounds with modifiers.

[20]. According to electron microscopy, the particles of the isolated precipitate had a complex star-like shape.

CrO_2 is not formed yet in the course of reaction A in the presence of senarmontite at 228°C, but at 250°C its amount is rather high. As in the case of $SnO_2 \cdot nH_2O$ + $H_2TeO_4 \cdot 2H_2O$ additives, chromium γ-oxide $CrO_{2.44}$ is not formed in the presence of antimony compounds. The temperature dependence of the degree of conversion of the starting chromium compound (CrO_3 in the given case) into oxides, n_s/n_{st}, is presented in Fig. 2. The onset temperature of the conversion is estimated to be 230–235°C.

For syntheses by procedure B, $SnO_2 \cdot nH_2O$ and $H_2TeO_4 \cdot 2H_2O$ additives were taken at a molar ratio Sn : Te : Cr = 0.2 : 0.2 : 99.4. The only solid compound found after synthesis at 210°C is chromium(III) oxide. Minor additions of tin and tellurium compounds were not detected on the background of chromium(III) oxide. The product synthesized at 222°C was CrO_2 in a mixture with Cr_2O_3. Chromium γ-oxide was not formed in this case, as also in procedure A with modifiers. Pressure buildup in the autoclave was only recorded after CrO_2 appeared.

The temperature at which the formation of chromium dioxide by pathway A was complete was determined from the coincidence of pressures in continuous heating of the autoclave at a rate of 150 deg h^{-1} to 400°C and in subsequent cooling. The poor precision of gas gages gave no way of performing the measurements with sufficient accuracy, and only an approximate value of 360 ± 10°C was determined. As indicated by experimental data, the completion temperature of the process is related to the partial pressure of oxygen and the Cr : H_2O ratio in solution. For example, in decomposition of the mixture by procedure B with additives the formation of CrO_2 is practically complete at 300°C, but in this case the partial pressure of oxygen is approximately two times lower than that in procedure A. The partial pressure release from the autoclave in procedure A also leads to completion of CrO_2 formation at 300°C: Soluble chromium compounds found in washing the product constitute only 2% of the initial amount of CrO_3.

To the point of completion of crystallization, a considerable part of water is contained in chromium chromate. For example, the partial pressure of water vapor for procedure A at 300°C was estimated to be 0.6–0.8 MPa, even though the amount of water in the autoclave was twice that necessary for reaching the equilibrium vapor density and pressure of pure water [25]: 46.2 g l^{-1} and 8.59 MPa. The final concentrations of water vapor in the autoclave for procedures A and B at complete evaporation of water are 109.6 and 133.2 g l^{-1}, respectively, which enables complete evaporation of water at 348 and 357°C [25]. Since in the latter case the formation of CrO_2 is complete at 300°C, the partial pressure of oxygen governs the reaction course.

Thus, both procedures of synthesis involve crystallization of chromium dioxide from a chromium chromate solution.

The majority of n_s/n_{st} values in Fig. 2 were determined by weighing the CrO_2 precipitate with correction made for the mass of the mixed oxide $CrSbO_4$. The strong deviation of three n_s/n_{st} values from the zero line in procedure B at 210–222°C is due to incomplete dissolution of Cr_2O_3. For the case of decomposition by procedure A without additives, calculation was based on the results of gravimetric analysis of chromium γ-oxide and its mixture with CrO_2. Apparently, the partial pressure of oxygen will be somewhat lower in obtaining chromium γ-oxide, compared with CrO_2 formation. However, the observed shift of the two indicated points does not disturb the apparent overall tendency for the partial pressure of oxygen to grow in proportion to the increasing degree of conversion and temperature. Consequently, there exists a relationship between the concentration, pressure, and temperature. As final temperatures of the process in Fig. 2 are indicated 300°C and the interval 350–370°C. In the range 240–270°C the temperature de-

pendence of the degree of conversion is nearly linear. Lowering the partial pressure of oxygen (synthesis by procedure A) leads to an increase in the amount of the solid phase in the attainment of chemical equilibrium, i.e., in fact, to complete conversion at $300 \le T \le 350$°C. In synthesis by procedure B, the occurrence of the second reaction, partial dissolution of the excess amount of chromium(III) oxide, is possible in parallel with CrO_2 crystallization, which restores the Cr(VI) : Cr(III) ratio in the solution; however, the extent of this reaction is low. Even though XPA failed to show chromium(III) oxide impurity in the product obtained at 300°C by procedure B, its presence was revealed by electron microscopy and, indirectly, by magnetic methods.

Thus, both processes, A and B, occur by the same mechanism. A more detailed study of how crystals of modifying phases and chromium dioxide itself grow can be more conveniently performed with process A in which there is no constant background of unreacted chromium(III) oxide.

As starting reagents in the syntheses served analytically pure CrO_3, Cr_2O_3 obtained by decomposition of analytically pure ammonium dichromate and having a specific surface area $S_{sp} = 27$ m^2 g^{-1}, Sb_2O_3 in the form of senarmontite ($S_{sp} = 5.7$ m^2 g^{-1}) and valentinite ($S_{sp} = 2.9$ m^2 g^{-1}), iron γ-oxide of "for ferrites" grade ($S_{sp} = 5$ m^2 g^{-1}), $H_2TeO_4 \cdot 2H_2O$ of pure grade, and hydrated tin(IV) oxide ($S_{sp} = 204$ m^2 g^{-1} in terms of anhydrous substance) obtained by treatment of tin with nitric acid. The temperature in the autoclave was measured with a Chromel–Copel thermocouple, which was inserted in a well protected from reagents by a quartz test tube 8 mm in diameter. The temperature was recorded by a KSP-4 self-recorder with an accuracy of ±5°C and maintained constant within the same limits. X-ray phase analysis was performed on DRF and DRON-3M instruments with copper- and chromium-filtered radiation. Electron micrographs were taken on a Tesla BS 613B electron microscope (100 000 magnification). Chemical analysis of solutions for the content of Cr(VI) was done by the volumetric method; the sum Cr(VI) + Cr(III) was determined upon oxidation of Cr(III) with ammonium peroxodisulfate. Minor amounts of chromium (in washing water) were determined by photocolorimetry. The error of titrimetric measurements of the average state of chromium oxidation was not greater than 0.2. Gravimetric analysis was performed by calcining chromium oxides to constant weight at 850°C.

CONCLUSIONS

(1) Hydrothermal decomposition of CrO_3 and $CrO_3 + Cr_2O_3$ mixture to give CrO_2 passes through a stage producing a chromium chromate solution with Cr(VI) : Cr(III) = 7 : 2.

(2) Crystallization of chromium oxides is governed by an unambiguous relationship between the partial pressure of oxygen and the concentration and temperature of the chromium chromate solution. Formation of $CrO_{2.44}$ in the presence of modifying additives is ruled out by the lowered temperature of CrO_2 formation.

(3) The process of CrO_2 formation ends before complete evaporation of water from the solution, below the critical point of water.

(4) Complete conversion of the modifying additive [antimony(III) compound] into the $CrSbO_4$ phase occurs at a temperature lower than the CrO_2 crystallization temperature. The isolated $CrSbO_4$ phase is composed of monodisperse nanospindles.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Nature of Contamination and Preparation of Pure Precipitates of Rh(III) and Ir(III) Ammonium Sodium Hexanitrites

S. V. Korenev, A. B. Venediktov, V. A. Nadolinnyi, and A. V. Belyaev

Abstract—Various spectroscopic methods and X-ray phase analysis were applied to study the distribution of copper(II) and lead(II) between the solution and the precipitate of $(NH_4)_2Na[Rh(NO_2)_6]$. Promising methods are proposed for fine purification of ammonium sodium hexanitrites of rhodium(III) and iridium(III) to remove contaminants, irrespective of the mechanism of their ingress into crystalline phases.

Precipitation of poorly soluble ammonium sodium hexanitrites (ASHs) $(NH_4)_2Na[M(NO_2)_6]$ (M = Rh, Ir) [1] from nitrite solutions is among methods for separating platinum metals [2], which has long been used in their refining [3, 4]. Owing to the complex elemental composition of the solutions from which ASHs are isolated in practice, these precipitates are commonly contaminated with both noble and base metals [4, 5]. The fundamental aspects of coprecipitation of impurity elements with matrices of crystalline ASHs have not been known.

The aim of this study was to obtain quantitative physicochemical data characterizing the ingress of impurities into the ASH phases of rhodium(III), to reveal on this basis the possible mechanisms of these processes, and to find ways to obtain salts with as low degree of contamination as possible. The choice of lead(II) and copper(II) as models is due to the fact that these elements are characterized by high level of coprecipitation and ASH precipitates free of Cu(II) and Pb(II) impurities can only be obtained by an exceedingly labor-consuming procedure [4, 5].

Solutions of chloride complexes of rhodium in 0.1 M HCl were prepared from reagent-grade rhodium(III) chloride. The solution concentrations were determined spectrophotometrically, by reaction with tin(II) chloride [6]. The absorption spectra were taken on a Specord M 40 instrument.

Working solutions of $Na_3[Rh(NO_2)_6]$ were prepared by treatment of standard chloride solutions with sodium nitrite of ultrapure grade at heating on a water bath for 1 h and then transferred into volumetric flasks. The starting acid solutions of rhodium(III) were partly neutralized by preliminary treatment with sodium carbonate. The nitrite : rhodium molar ratio was 10 : 1. Nitrite solutions of copper(II) and lead(II) were prepared in a similar manner.

Lead(II) nitrate of ultrapure grade and chemically pure grade copper(II) were used in the study. The concentrations of the starting Cu(II) and Pb(II) solutions were determined by EDTA titration [7]. The other reagents used were of no less than chemically pure grade.

The distribution of impurity components between the solution and the solid phase of rhodium(III) ASH was studied at 22–23°C as follows. Nitrite solutions of rhodium(III) and impurity were mixed, and a calculated amount of ammonium chloride was added to make the ammonium/rhodium ratio close to 20. The formed ASH precipitates were kept in the mother liquor for a prescribed time, separated, washed with 1% NH_4Cl and a minimum possible amount of cold water, dried in air to constant weight, and weighed. The yield of ASH in the solid phase was no less than 99% in all cases. A study of the granulometric composition of rhodium(III) ASH demonstrated that after keeping the crystals under mother liquor for 7 h the average particle size becomes ca. 21 μm and does not change further, with a normal size distribution of particles.

The impurity content in solid phases was determined by an appropriate analytical method. The amount of impurity was expressed in weight percent impurity component in the ASH phase.

Treatment with sodium nitrite of solutions containing copper(II) gave emerald-green precipitates of basic copper(II) chlorides of variable composition whose nature was studied in detail in [8]. For this reason,

1070-4272/01/7401-0007$25.00

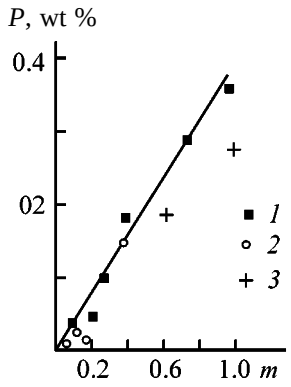

Fig. 1. Copper(II) distribution between rhodium(III) ASH precipitate and nitrite solution. (*P*) Copper content in the ASH phase and (*m*) Cu/Rh molar ratio in solution. (*1*) Set A and (*2*) set B. Time of keeping the system before precipitate isolation (h): (*1, 2*) 24 and (*3*) 12.

solutions containing copper(II) were always prepared separately. The precipitates formed were separated and the obtained copper(II) solutions were used, after determining their concentration, in sorption experiments. The content of copper in ASH phases was determined by the ESR. The ESR spectra were recorded on a Varian E-109 instrument in the X frequency range. The concentration of paramagnetic centers in ASH precipitates was determined using $CuSO_4 \cdot 5H_2O$ as reference with an accuracy of ±2%.

There is no published evidence concerning the mechanisms of impurity coprecipitation on such specific supports as ASHs of rhodium(III) and iridium(III). Previously, it has been shown that salts $(NH_4)_2Na[M(NO_2)_6]$ (M = Rh, Ir) crystallize to give an fcc unit cell with the lattice constant a = 10.517(1) (M = Rh) and 10.512(2) Å (M = Ir) [9]. In addition, it was found in [10] that rhodium(III) and indium(III) salts form a continuous series of solid solutions. As a result, all patterns obtained in studying the ASH of rhodium(III) are to the full extent applicable to its iridium analog. Moreover, the solubilities of rhodium(III) and iridium(III) salts at room temperature are the same and equal to ca. 4.0×10^{-3} M.

One of the main stages of the study consisted in obtaining quantitative data on impurity sorption on ASH precipitates. In this study, by the term "sorption" is meant the characteristic of impurity distribution between the solution and the crystalline phase, irrespective of the distribution mechanism.

In studying the sorption of copper(II), several sets of experiments were performed with varied concentrations of copper(II) and rhodium(III). Set A was carried out at $C_{Rh} = 9.66 \times 10^{-3}$ and equilibrium copper(II) concentrations of (0.95–9.5) $\times 10^{-3}$ M. The content of copper(II) in the ASH precipitates was 0.035–0.36%. Set B was performed for solutions with rhodium(III) concentration of 2.63×10^{-2} M with the equilibrium Cu(II) concentration varied within 3.1×10^{-4}–1.0×10^{-2} M, with the content of copper(II) in the precipitates equal to 0.080–0.154%. In these two sets, the ASH precipitates were separated from the mother liquor after being kept in it for 24 h. The isolated ASH precipitates had color in the range from nearly white to light green. According to X-ray diffraction analysis, all the precipitates were single-phase, with the identical unit cell parameters of salts contaminated with copper(II) and pure ASHs. In both sets the content of copper(II) in the precipitates depended linearly on its equilibrium concentration in solution. In set A, the contaminated precipitates were washed with electrolyte (2 M Na_2SO_4, 1 M HCl) solutions to desorb copper(II) impurities. However, these attempts failed. This indicates indirectly that the contamination mechanism does not have purely adsorption nature.

It can be seen from the presented data that raising the rhodium(III) concentration in a solution leads to lower content of copper(II) in the support. Two experiments performed at lowered initial concentration of rhodium(III) ($C_{Rh} = 5.50 \times 10^{-3}$ M) confirmed that precipitates obtained from solutions concentrated with respect to rhodium(III) are more pure than those in the case of dilute solutions. This effect cannot indicate a change in the sorption mechanism since the same data plotted in the coordinates Cu content in the precipitate (%)–Cu/Rh molar ratio fall on the common linear dependence shown in Fig. 1.

The fact that adsorption does not give any significant contribution to contamination of crystals with copper(II) is mainly determined by the support properties. The solubility of ASH has a narrow supersaturation region, and, therefore, a great number of crystal nuclei with approximately the same sorption capacity are formed in any precipitation technique. Shortening the precipitate aging time from 24 to 12 h (Fig. 1) makes the copper(II) content in ASH somewhat lower, and not higher, which also points to a minor contribution of occlusion to the mechanism of ASH precipitate contamination by copper(II).

Figure 2 shows a typical ESR spectrum of copper(II), observed in the ASH matrix. The spectrum is due to the Cu^{2+} ion and is described by the spin Hamiltonian

$$H = g_{xx}\beta H_x S_x + g_{yy}\beta H_y S_y + g_{zz}\beta H_z S_z + A_{xx} S_x J_x + A_{yy} S_y J_y + A_{zz} S_z J_z$$

with the following parameters: $g_{zz} = g_{\|} = 2.2218$, $g_{xx} = g_{yy} = g_{\perp} = 2.0097$, and $A_{zz} = A_{\|} = 170$ G.

The observed parameters of the ESR signal from copper(II) ions are characteristic of distorted octahedral environment of these ions formed by nitrogen atoms [11]. The resolved hyperfine structure of the signal from copper ions indicates the absence of exchange interaction between the neighboring copper ions. Thus, Cu^{2+} ions in the ASH matrix are at large distances from one another and form no isolated clusters. These data suggest that copper(II) impurity atoms are isolated and uniformly distributed over the volume of the ASH crystalline phase.

The low content of copper(II) in ASH and the lattice constant of the crystalline salt, remaining constant, give no way of confirming experimentally the formation of solid solutions in the system under consideration by methods of crystallography. Nevertheless, there exists a possibility of confirming this fact by changing the chemical form of Cu(II) in the starting solution.

For this purpose, ASH precipitation from nitrite solutions in the presence of copper(II) was effected by 2 M NH_4NO_3 + 2 M $NH_3 \cdot H_2O$ buffer solution at rhodium(III) concentration of 1.10×10^{-2} M in the range of equilibrium copper(II) concentrations 5.28×10^{-3}–1.14×10^{-2} M. The precipitate was separated from the mother liquor 2 h after the precipitation to preclude decomposition of hexanitrorhodate(III) ions in the alkaline medium. The amount of copper(II) in the precipitates was found to be much lower (0.01–0.02%) than that in sets A and B. The ASH yield varied within 99.0–99.5%. The ESR spectra of the obtained crystalline phases indicated only slight changes in the nearest environment of Cu^{2+} ions, compared with the data for sets A and B.

The pronounced decrease in the copper(II) content in the ASH phase on changing its chemical form in solution indirectly points to the mechanism by which solid solutions are formed between the main component and the impurity. The essence of the process consists in isomorphic substitution of octahedral $[Rh(NO_2)_6]^{3-}$ anions at ASH crystal lattice sites by distorted octahedral $[Cu(NO_2)_6]^{4-}$ ions. The possibility of such substitution is indicated by the closeness of the lattice constants of $K_2Pb[Cu(NO_2)_6]$ (a = 10.65 Å [12]) and $(NH_4)_2Na[Rh(NO_2)_6]$ (a = 10.52 Å).

Such a comparison is justified since the crystal lattices of the above salts are constituted by bulky complex anions, while the cations occupy tetrahedral and octahedral voids in these structures. It should also

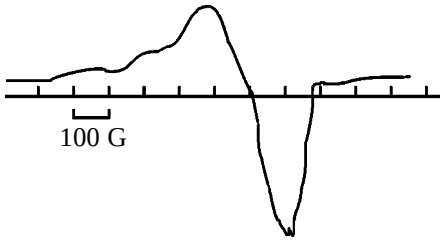

Fig. 2. Typical ESR spectrum of copper(II) in the ASH matrix.

be noted that the hexanitrocuprate(III) ion exists in aqueous solutions in very low concentrations. According to [13], copper(II) forms complexes with one and two nitro groups at 25°C in aqueous solutions, with the step instability constants pK_1 1.25 and pK_2 0.30. Presumably, copper(II) ions with one or two nitro groups in the inner sphere are adsorbed onto an ASH crystal in its formation, and in the course of crystal growth the environment of the copper ion is completed to become octahedral.

The proposed mechanism is in agreement with the entire body of experimental data and gives insight into the main reason for contamination of ASH precipitates with copper(II). With account of this mechanism and the linear isotherms of adsorption, it can be stated that if the above-mentioned solid phases of basic copper salts were not formed in the system, rhodium(III)–copper(II) solid solutions with any Cu(II) content could be obtained.

The fact of lead(II) ingress into the ASH phases in their crystallization from solutions containing Pb(II) and the complications in purification of salts to remove this impurity were noticed as far back as the early 1930s [4]. The understanding of ways of contamination by lead(II) was only gained after a detailed study of the properties of lead salts of Rh(III) and Ir(III) hexanitro complexes [14]. It was shown in [14] that treatment of solutions of complex ions $[M(NO_2)_6]^{3-}$ (M = Rh, Ir) with lead(II) salts leads to the formation of precipitates with formula $Pb_3[M \cdot (NO_2)_6]_2 \cdot 12H_2O$. The precipitates are single-phase and have a cubic lattice with lattice constants a = 10.567(3) for rhodium(III) and a = 10.604(3) Å for iridium(III). Drying the salts at 120°C leads to complete removal of crystallization water, accompanied by a practically linear decrease in the lattice constants a to 10.446(3) (M = Rh) and 10.478(3) Å (M = Ir). The solubility of lead(II) salts in water at room temperature is 1.2×10^{-4} (M = Rh) and 5.0×10^{-5} M (M = Ir).

Thus, the poorly soluble lead salts with the anions

$[M(NO_2)_6]^{3-}$ crystallize to form a cubic lattice with lattice constants close to those for ammonium sodium salts. As indicated by the presented data, the lattice constant a varies between the salts of this series by ca. 0.15 Å. Hence follows that the salts under consideration are isomorphic and form solid solutions in the entire range of concentrations, with any of these salts acting as collector for another if the latter is present in solution in a much lower concentration. Indeed, mixing of nitrite solutions of rhodium(III) and lead(II) in any proportion always gives crystalline phases with lattice constant $a \approx 10.57$ Å. However, at high concentrations of sodium nitrite in solution the forming precipitates are always colored yellow, which is due to sorption of nitrite complexes of lead on the crystals. According to [13], lead(II) forms poorly stable complexes with nitrite ions (at 25°C and ionic strength of 1 M $\log K_1 = 1.87$).

In ASH formation from chloride solutions (in agreement with actual practice) the concentration of lead(II) is determined by the equilibrium concentration of chloride ions, which is as high as 4 M. In this case, with account of the $PbCl_2$ solubility product equal to 1.6×10^{-5} [15], the concentration of lead(II) in solutions will be at the level of 1×10^{-6} M. As a result, no independent phase of lead salts with $[M(NO_2)_6]^{3-}$ can be formed and the crystallizing ASHs act as collector for microscopic amounts of lead(II). Thus, the ASH phases will be always contaminated with lead(II) if Pb(II) ions are not removed from a solution prior to ASH precipitation.

A search for ways to obtain purer ASH precipitates was carried out in several directions. It follows from the presented sorption data that lowering the concentration of copper(II) in solutions prior to ASH precipitation must decrease the contamination of the precipitate. Indeed, the ASH precipitate obtained by the standard procedure from a solution modeling, as regards the composition, an industrial solution contained 0.38% copper(II) at its concentration prior to precipitation of 9.60×10^{-3} M. Pretreatment of the solution with sodium carbonate gives an ASH containing 0.11% copper(II). To make lower the contamination with lead(II), it is advisable to treat the solution with minor amounts of salts containing, e.g., sulfate, carbonate, or phosphate anions forming poorly soluble salts with lead(II) [15]. Fundamentally different is the binding of copper(II) into stable complexes that cannot form solid solutions with ASH. As shown above, copper(II) ammines may be such complexes. It should, however, be taken into account that introduction of ammonia may lead to formation of ammine complexes of platinum, which is undesirable from the practical standpoint [16].

With account of the fact that the mechanism of contamination with copper(II) and lead(II) is associated with isomorphic crystallization, fine purification of the ASHs of rhodium(III) and iridium(III) by the above methods may be rather labor-consuming. In this study, a method was developed making it possible to obtain special-purity salts, which has little sensitivity to the mechanism of impurity ingress. On introducing a weighed portion of ASH into a sodium nitrite solution somewhat acidified with nitric acid, the salt dissolves by the reaction

$$NH_4^+ + NO_2^- \rightarrow N_2 + H_2O,$$

with the complex anions $[M(NO_2)_6]^{3-}$ (M = Rh, Ir) not involved. The optimal dissolution regimes were determined, making it possible to minimize the time and temperature of the reactions performed and to prevent loss of platinum metals in repeated precipitations of ASH. For example, in a precipitate of rhodium(III) ASH, originally containing 0.30% copper(II), the concentration of copper(II) impurity after double precipitation by the proposed technique was on the order of 0.001%. This method can be compared with the procedures proposed in [5]. One of these is the preliminary purification of nitrite solutions to remove base metals prior to ASH precipitation; however, in this case the concentration of the most difficultly separable impurities [Pb(II), Cu(II), Ni(II)] decreases only 3–5-fold. In [5], low efficiency of nitrite solution purification to remove base metals by extraction and ion exchange was revealed and salting-out of $Na_3[Rh(NO_2)_6]$ under the action of an excess of sodium nitrite after preliminary purification by a procedure mentioned above was proposed as the most suitable method for rhodium(III) recovery. In this case, 30–70% of impurity ions (Cu, Pb, Sn, Fe, Zn, etc.) remains in mother liquors. Comparison of the proposed procedures and their quantitative characteristics concerning the purification of ASH precipitates readily shows the advantages of the proposed technique.

CONCLUSIONS

(1) Quantitative data on contamination of precipitated ammonium sodium rhodium(III) hexanitrites with copper(II) and lead(II) ions were obtained and the mechanism of impurity ingress was established. The fact that the properties of ammonium sodium hexanitrites of Rh(III) and Ir(III) are close allows the

revealed relationships to be applied to the case of contamination of $(NH_4)_2Na[Ir(NO_2)_6]$.

(2) Various methods were compared and a new efficient procedure for obtaining pure $(NH_4)_2Na \cdot [M(NO_2)_6]$ (M = Rh, Ir) was developed.

ACKNOWLEDGMENTS

The authors are deeply grateful to S.A. Gromilov for X-ray phase analysis of the samples studied.

Abstract—Coprecipitated copper(II)–nickel(II) hydroxides and mechanical mixtures of these were obtained at varied metal ion ratio and time of mother liquor aging and studied by potentiometric titration, chemical and differential thermal analyses, IR spectroscopy, and X-ray phase analysis.

Hydroxide–oxide compounds are widely used as materials in various fields of science and technology, in particular, as rather inexpensive and stable catalysts [1]. For example, it has been shown that systems containing aqua and hydroxo complexes of copper(II) and nickel(II) are promising catalysts for selective oxidation of alkanes [2–5]. It is also known that some industrial processes of basic organic and petrochemical syntheses are performed with copper- and nickel-containing catalysts, including those of the oxide–hydroxide type [6–8]. Catalysts of this kind are mainly obtained by mixing of the appropriate oxides followed by thermal treatment [9, 10]. However, this method fails to always yield complex materials with sufficient reproducibility. Moreover, the ceramic synthesis technology employs high temperatures, which leads to energy losses and frequently impairs the catalytic activity of the synthesized materials. Therefore, coprecipitation of hydroxides is in some cases a more promising route to mixed copper–nickel systems containing hydroxo and oxo groups [9].

The results of previous studies established the formation of unstable heteronuclear hydroxo complexes of copper–nickel in aqueous solutions [11, 12]. It has been proposed to rely upon this fact in developing a new synthesis method based on formation in solution of unstable hydroxo complexes involving metal ions, passing subsequently into a solid phase which acts as a precursor for the target materials [13].

Apparently, to implement this idea, it is necessary to study in detail the conditions under which hydroxide precipitates can be obtained, the processes of their thermal decomposition, and products formed in these processes by various analytical methods, and just this was the purpose of the present study.

Potentiometric titration was performed with temperature control (±0.1°C) on a pH-150 pH-meter-millivoltmeter. Glass electrode of the ESL-15-11 type and silver chloride electrode of the EVL-1M4 type served as measuring and reference electrodes, respectively; the pH measurement error was ±0.02 pH units. The titration was done as follows: 1 M NaOH solution was added from a burette with scale division value of 0.02 ml to the starting mixture of 1 M Cu(II) and Ni(II) nitrates. To obtained comparable results and simplify the interpretation of the titration curves, the added NaOH volume was converted to the molar ratio $[OH^-]/[M^{2+}]$.

With account of the potentiometric titration data, solid phases were isolated by gradually adding to the starting mixture of 1 M Cu(II) and Ni(II) nitrates, with continuous stirring, 1 M NaOH solution in a stoichiometric ratio of 1 : 2, respectively. The obtained solid phases were homogenized for 5 min and filtered off under a vacuum, washed 3 or 4 times with water and then *i*-C_3H_7OH to negative reaction for NO_3^- ions [14], dried at 30–40°C in an oven, and analyzed. For comparison purposes, mechanical mixtures of Cu(II) and Ni(II) hydroxides (MMHs) were obtained under identical conditions at the same Cu(II) : Ni(II) ratios and studied in a similar way. To reveal the effect of the time of aging of the hydroxide precipitates on their properties, samples were also synthesized at Cu : Ni ratio of 1 : 1 and aging time of 24 and 72 h.

In making chemical analysis, a weighed portion of a hydroxide was dissolved in concentrated HNO_3 and analyzed. The total content of copper(II) and nickel(II) was found complexometrically with murexide; that of nickel(II), by direct titration with Na_2EDTA in ammonia buffer with murexide after masking Cu^{2+} with

1070-4272/01/7401-0012$25.00

thiosulfate ions [15, 16]; and that of copper(II), as the difference of the first two quantities. Differential thermal analysis was done on an MOM derivatograph (Hungary) at a heating rate of 10 deg min^{-1} and sensitivity of DTA and DTG galvanometers of 1/10; 0.500-g samples were heated from room temperature to 1000°C, with calcined aluminum oxide used as reference. The IR spectra (KBr pellets) were taken on a Specord 75-IR spectrophotometer in the range 4000–400 cm^{-1}. X-ray diffraction patterns of the samples were taken on a DRON-3 diffractometer with CuK_α radiation and Ni filter at a scanning rate of 2 deg min^{-1}.

Figure 1 shows the curves of titration with NaOH solution of aqueous Cu(II), Ni(II), and Cu(II)–Ni(II) nitrate solutions with varied ratio of metal ions. The titration curve of a nitrate solution of copper(II) shows two equivalence points (curve *1*). The jump in the pH range 4.3–4.9 at $[OH^-]/[M^{2+}]$ = 1.5–1.8, with the equivalence point at pH 7.0, $[OH^-]/[M^{2+}]$ = 1.7, corresponds to complete precipitation of polynuclear hydroxo complexes of copper(II) [17]. Addition of alkali to the system at pH 9.45 and $[OH^-]/[M^{2+}]$ = 1.8–2.3 does not lead to any increase in pH and corresponds to conversion of polynuclear hydroxo complexes into mononuclear hydroxides. On further introduction of OH groups into the system, the hydroxide suffers no changes, and the steep increase in pH (second jump) is presumably associated with coordination saturation of metal ions with hydroxide ligands and appearance of an excess of free OH groups in solution. In potentiometric titration of nickel nitrate (curve *2*) in the pH range 6.1–7.6 at $[OH^-]/[M^{2+}]$ = 0.0–1.5, mononuclear hydroxides are formed with minor precipitation. Intense precipitation of Ni(II) ions coincides with the onset of the jump at pH 7.6, with the equivalence point (pH 9.6, $[OH^-]/[M^{2+}] \cong$ 2.0) corresponding to complete precipitation of nickel(II) in the form of polynuclear compounds [12, 15].

The titration curves of a mixture of Cu(II) and Ni(II) nitrate solutions (Fig. 1, curves *3*–*5*) show three jumps. The first of these corresponds to precipitation of polynuclear copper(II) compounds, which is confirmed by the close pH values of the equivalence points of binary solutions and a Cu(II) nitrate solution. The second jump corresponds to precipitation of polynuclear nickel(II) compounds, and the third, presumably, to precipitation of a heteronuclear hydroxide. It can be seen that despite the similarity of the titration curves for individual and binary systems, the latter cannot be considered additive. This fact also confirms the possibility of formation, together with

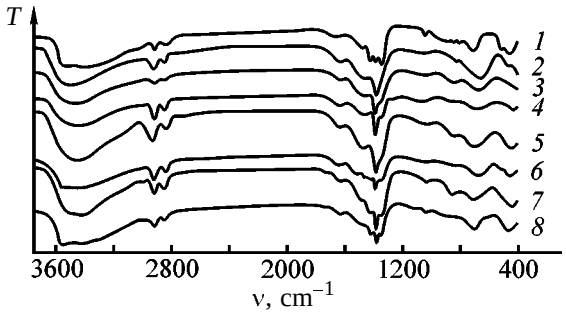

Fig. 2. IR spectra of hydroxides. (*T*) Transmission and (*ν*) wave number. Hydroxide (wt %): (*1*) 100 Cu; (*2*) 100 Ni; (*3*, *4*) 30 Cu, 70 Ni; (*5*, *6*) 50 Cu, 50 Ni; and (*7*, *8*) 70 Cu, 30 Ni. (*3*, *4*, *5*) CPH and (*4*, *6*, *8*) MMH.

two fractions of homopolymers, of a certain amount of a heteropolynuclear hydroxide precipitate [11, 12].

The results of IR spectral studies of coprecipitated hydroxides (CPHs) and MMHs (Fig. 2) indicate the presence in them of various kinds of water. The presence of a broad band of stretching vibrations of H_2O at 3650–3100 cm^{-1} points to stronger hydrogen bonds between OH^- groups. These bands are more intense and shifted to longer wavelengths in the case of CPHs (spectra *3*, *5*, *7*), which indicates an additional stability of CPHs ensured by the formation of intramolecular hydrogen bonds between aqua and hydroxo ligands [18]. Bending (1630–1625 cm^{-1}) and rocking (845–830 cm^{-1}) vibrations of H_2O indicate the presence of coordination-bound water in the compound. As shown by the IR spectra of nickel(II) and copper(II) hydroxides (Fig. 2, spectra *1*, *2*), and also by published data [19, 20], the bands peaked at 1387–1350 cm^{-1} can be attributed to bending vibrations of OH groups bonded to copper(II) and nickel(II) atoms. The absorption peaks at 1060–1035 and 700–500 cm^{-1} may belong to bending vibrations of the bridging M–O–M bonds (M = Cu or Ni), and the bands at 400–500 cm^{-1} cor-

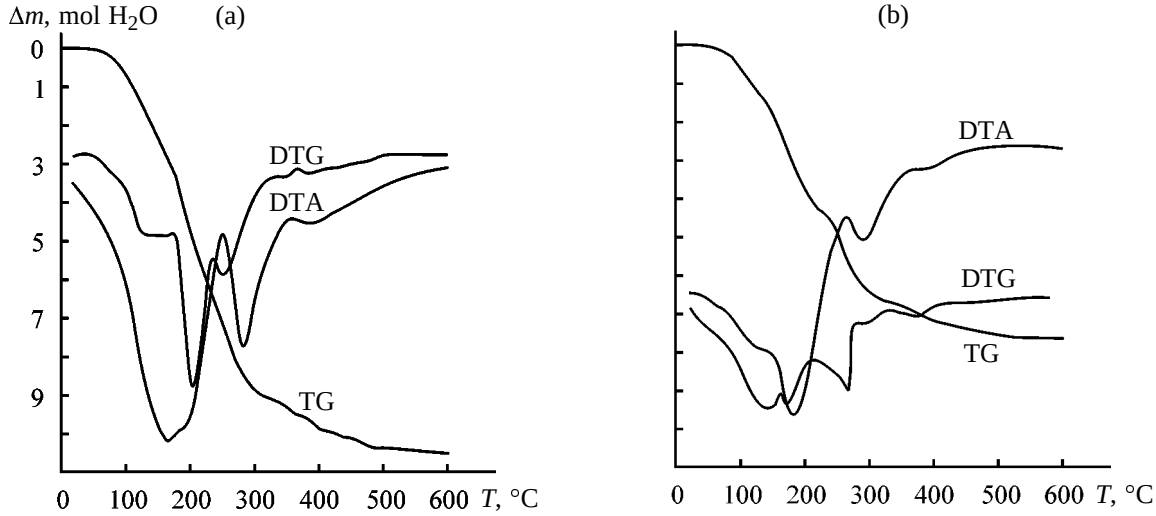

Fig. 3. Thermogravigrams of (a) CPH and (b) MMH of composition 30% Cu(II) + 70% Ni(II). (Δ*m*) Weight loss and (*T*) temperature.

respond to stretching vibrations of M–O bonds. It should be noted that the IR spectra of MMHs are more complex than those of CPHs because of the splitting of the ν(H–OH) and δ(H–OH) bands into doublets and triplets (spectra *4*, *6*, *8*). In addition, in CPHs with the Cu(II) content[1] of 30 and 50% (spectra *3*, *5*), bands of some characteristic vibrations are shifted by 10–30 cm^{-1} to smaller wave numbers, which may be due to formation of heteronuclear structures in the hydroxide precipitate [12].

To confirm this assumption and determine the content of water, the obtained CPH and MMH were subjected to thermal analysis. The weight loss curve (Fig. 3) was recalculated to moles of H_2O, which furnishes an opportunity to directly analyze the obtained thermogravigrams of decomposition of the hydroxide precipitate in terms of stoichiometry. The DTA curve of CPH of the composition 30% Cu(II) + 70% Ni(II) (Fig. 3a) shows three endothermic peaks in the intervals 40–240, 240–360, and 360–480°C. The first endothermic effect corresponds to deaquation with the loss of 7.23 mol of crystallization water, and the second and third, to liberation of 3.33 mol of bound water, equivalent to loss of 6.66 mol of OH^- groups, with a mixed oxide formed. An X-ray phase analysis of this oxide (Table 1) demonstrated the presence of approximately equal amounts of two complex oxide phases: Ni_2CuO_3 (orthorhombic crystal system, a = 2.925, b = 8.775, c = 4.336 Å) and $Cu_{0.2}Ni_{0.8}O$ (cubic crystal system, a = 4.217 Å).

A chemical analysis of the obtained hydroxides, both freshly precipitated and aged for 1 and 3 days (Table 2), demonstrated that the molar ratios of Cu(II) and Ni(II) ions in the starting solutions and the hydroxides coincide, which points to complete precipita-

[1] Here and hereinafter, molar percents.

* Peak temperature.
** Mole of H_2O.

tion of metal ions with the initial component ratio preserved in the precipitate. In this case, the following scheme of dehydration of the obtained CPH composed of 30% Cu(II) + 70% Ni(II) can be proposed:

$$CuNi_{2.33}(OH)_{6.66}\cdot 7.23H_2O \xrightarrow[-7.23H_2O]{} CuNi_{2.33}(OH)_{6.66}$$

$$\xrightarrow[-3.33H_2O]{} \sim 0.8(Ni_2CuO_3 + Cu_{0.2}Ni_{0.8}O).$$

Thermal decomposition of MMH composed of 30% Cu(II) + 70% Ni(II) (Fig. 3b) occurs in a different way. The splitting of the endothermic peak at 40–260°C in two: at 40–160°C with a peak at 140°C and at 160–260°C with a peak at 180°C, points to a more complicated nature of deaquation of a mixture of copper(II) and nickel(II) hydroxides. No similarity in amounts of removed water is observed between CPH and MMH, although the endothermic effects occur in virtually the same temperature intervals (Fig. 3). Moreover, the total loss of water is 7.66 mol, which is 2.9 mol less than in the case of CPH of the same composition. Thus, the hydroxides, the processes of their thermal decomposition, and the resulting products exhibit specific features depending on the preparation procedure (coprecipitation or mechanical mixing). An X-ray phase analysis of the products of decomposition of MMH containing 30% Cu(II) and 70% Ni(II) (Table 2) demonstrated the presence of a $Cu_{0.2}Ni_{0.8}O$ phase with minor CuO admixtures (up to 10%), with the $Cu_{0.2}Ni_{0.8}O$ phase probably formed via sintering of CuO and NiO oxides.

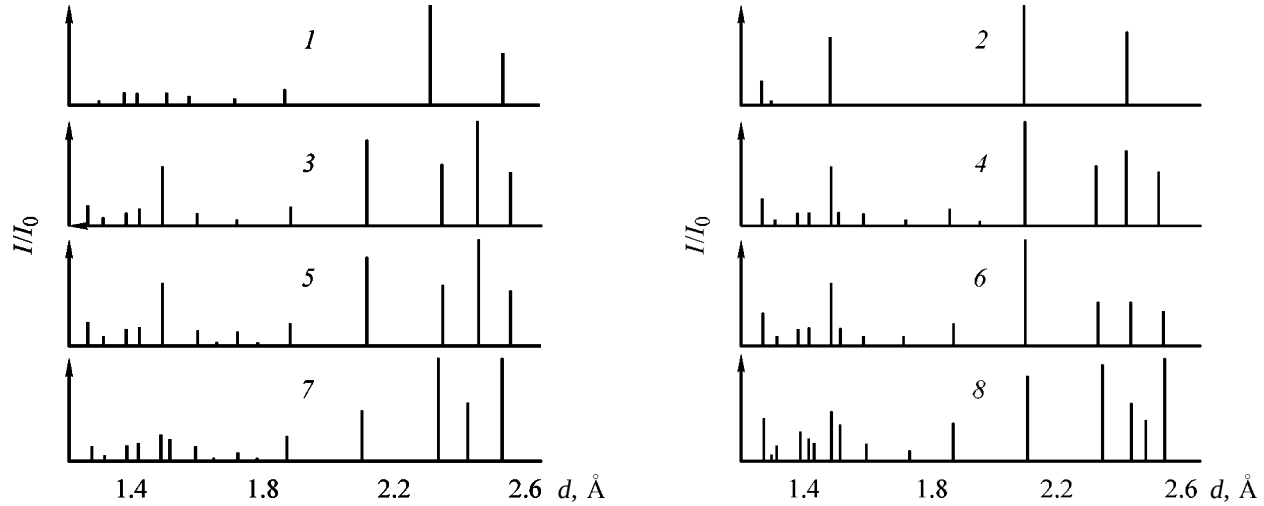

Fig. 4. X-ray diffraction patterns of the products of decomposition (T = 1000°C) of (*1*) copper(II) and (*2*) nickel(II) hydroxides, (*3*, *5*–*7*) copper(II)–nickel(II) CPHs, and (*4*, *8*) MMHs. (I/I_0) Relative intensity and (*d*) interplanar spacing. Initial content of copper(II) (wt %): (*3*–*6*) 50 and (*7*, *8*) 70; aging time (days): (*5*) 1 and (*6*) 3.

Thermogravimetric analysis of CPH and MMH containing 50% Cu(II) and 50% Ni(II) also revealed differences in their dehydration. Despite the close temperature intervals of the main endothermic effects, they differ in the amount of removed water. The total amount of water in CPH somewhat exceeds that in the corresponding MMH, increasing on passing from an unaged sample to a hydroxide isolated after 3 days of aging under mother liquor. This may be due to decomposition, in the course of precipitate aging, of a part of heteronuclear copper(II)–nickel(II) hydroxide, accompanied by disintegration of hydroxo bridges and subsequent aquation of metal ions. Thus, the longer the time of CPH aging, the smaller the amount of heteronuclear hydroxide it contains. An additional argument in favor is the amount of double oxide indicated by X-ray diffraction patterns of the products of complete decomposition (T = 1000°C) of mixed hydroxides (Fig. 4). The products of decomposition of CPH containing 50% Cu(II) and 50% Ni(II) (patterns *3*, *5*, *6*) contain phases of CuO (interplanar spacings 2.530, 2.323, 1.886, and 1.418 Å), NiO (2.088, 1.476, 1.259 Å), and $NiCuO_2$ (tetragonal crystal system, a = 4.121, c = 4.355 Å) with the main reflections at 2.427, 1.500, 1.302, 1.251, and 1.213 Å. With increasing time of aging of the initial CPH, the intensities of CuO and NiO reflections grow and the signals from $NiCuO_2$ become weaker (2.427, 1.213 Å); the reflections at 1.500, 1.302, and 1.251 Å totally disappear from the X-ray diffraction patterns of the decomposition products of CPH, subjected to aging for 1 and 3 days (Fig. 4, patterns *5*, *6*). A correlation is observed between the increasing time of CPH aging and the decreasing intensity of signals from $NiCuO_2$ in the products of its decomposition. For example, an X-ray diffraction pattern of a product of CPH decomposition (3 days of aging) shows only a single $NiCuO_2$ band (2.427 Å) with intensity of 49% (pattern *6*). It should be noted that the X-ray diffraction patterns of decomposition products of MMH containing 50% Cu(II) and 50% Ni(II) show no double oxide phase, with only the CuO and NiO phases present, which also confirms the occurrence of a chemical interaction between Cu and Ni atoms in CPH formation, just in the stage of coprecipitation, rather than in that of thermal treatment.

An X-ray phase analysis of decomposition products of CPH and MMH containing 30% Cu(II) and 70% Ni(II) (Fig. 4, patterns *7*, *8*) demonstrated the presence of only copper(II) and nickel(II) oxide phases. However, the thermal behavior of the given CPH and MMH is not additive with respect to the temperature intervals of endothermic effects and weight loss (Table 1), and the total weight loss is practically the same (31.8 and 31.4%, respectively). This can be accounted for by the different physical properties (density, porosity, specific surface area) of the hydroxides obtained by coprecipitation and mechanical mixing [21].

Thus, a technique is proposed on the basis of the investigation performed for obtaining copper(II)–nickel(II) CPH whose thermal treatment can yield new inorganic materials and, in particular, catalytic systems applicable in organic and petrochemical syntheses. The temperature intervals in which various kinds of water are removed were determined and differences were revealed between the thermal properties

of CPH and MMH whose dehydration occurs under milder conditions because of the absence of Cu–OH–Ni bridge bonds and is accompanied by liberation of a lesser amount of water. The phase composition of the products of CPH and MMH decomposition at T = 1000°C was determined; it was shown that complex oxide compounds Ni_2CuO_3, $Cu_{0.2}Ni_{0.8}O$, and $NiCuO_2$ are present together with the CuO and NiO phases. The optimal hydroxide composition [30% Cu(II) + Ni(II)] was determined at which the yield of double oxides reaches 100% (Table 1), and the efficiency of preparing these compounds from unaged CPH was confirmed.

CONCLUSIONS

(1) A procedure was developed for synthesizing coprecipitated copper(II) and nickel(II) hydroxides, ensuring formation of complex oxide catalysts with molecular distribution of the components.

(2) The optimal composition [30% Cu(II) + 70% Ni(II)] of hydroxide whose thermal decomposition gives double oxides in up to 100% yields was determined.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Physicochemical Study of Ta_2O_5 and SiO_2–Ta_2O_5 Film Formation from Film-Forming Solutions

R. V. Gryaznov, L. P. Borilo, V. V. Kozik, and A. G. Mal'chik

Tomsk State University, Tomsk, Russia

Received March 23, 2000; in final form, July 2000

Abstract—In order to study physicochemical processes of formation of Ta_2O_5 and SiO_2–Ta_2O_5 films from film-forming solutions, the properties of these solutions, and also the thermal-oxidative breakdown and the properties of the obtained films, were studied.

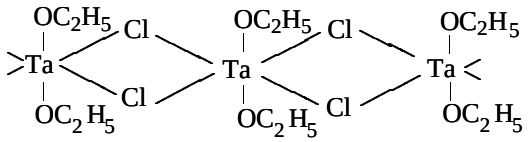
At present, particular attention is given to physicochemical properties of thin films, since the development of new fields of modern technology assigned a prominent place to the application of various materials in the thin-film state. The broadest application in various fields of electronics is characteristic of dielectric films based on complex oxides [1]. For thin-film materials to be successfully used, a relationship should be established between their physicochemical and service properties, composition, and preparation conditions.

EXPERIMENTAL

Film-forming solutions (FFSs) were prepared from tetraethoxysilane (TEOS), ethanol, and tantalum pentachloride. The viscosity was measured with a VPZh-2 or VPZh-4 glass capillary viscometer. The decomposition of deposits obtained from FFSs was studied on a Q-1500 derivatograph. The films were formed on glass or single-crystal silicon substrates with the surface area of 1–1.5 cm^2 by centrifugation and drawing, at a speed of centrifuge rotation of 1000–5000 rpm and drawing velocity of 1–5 mm s^{-1}. The uniformity of the films formed across their thickness was monitored by determining the optical thickness at 6–8 points for each sample. The film adhesion to the substrate was determined sclerometrically, and the refractive index and thickness, with an LEF-3M laser ellipsometer. Films 120–140 nm thick were obtained and studied. IR transmission spectra of the films were recorded in the 4000–400 cm^{-1} range on IR-75, M-40, and SF-20 instruments. As known, the film-forming ability is exhibited by the substances that can form macromolecules or associates in solution, which are attached to the surface when the solution is applied to a substrate and decompose to oxides upon solvent evaporation at elevated temperature [2]. The temporal stability of film-forming solutions is a factor important in technological regard, and, therefore, the relationship between the viscosity of solutions, their storage time, and the possibility of their use to obtain films was studied experimentally. When $TaCl_5$ is dissolved in ethanol, alkoxy derivatives are formed [3]:

$$TaCl_5 + 3C_2H_5OH \rightarrow TaCl_2(OC_2H_5)_3 + 3HCl.$$

A study of the film-forming ability of alcoholic $TaCl_5$ solutions demonstrated that the obtained solutions possess a viscosity (Fig. 1, curve *1*) sufficient for obtaining films, and the film-forming ability is preserved for a long time since the chloride ion, being a ligand of π-donor type, forms cluster compounds with tantalum. With account taken of published data on cluster compounds of tantalum [3], it may be assumed that chloride ions serve as bridges in the formation of stable polynuclear structures of tantalum alkoxy derivatives



Thus, the film-forming ability of an alcoholic solu-

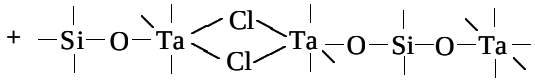
	473	3680	2935	1640	1100	800	460
	773	–	–	–	1100	800	460

tion of tantalum pentachloride is not limited to the stages of its ripening and aging.

To study the properties of film-forming solutions in the system TEOS–$TaCl_5$–C_2H_5OH, kinetic curves describing the variation of the solution viscosity were taken at different salt concentrations (Fig. 1, curves *2*–*4*). More complex processes are observed in these solutions. The solutions have no ripening range, which is probably associated with processes of tantalum pentachloride dissolution in ethanol. However, after 2 days the viscosity starts to grow steadily because of the simultaneously occurring processes of hydrolytic polycondensation of TEOS and alkoxy derivatives of tantalum:

$$Si(OC_2H_5)_3OH + TaCl_2(OC_2H_5)_3 \rightarrow C_2H_5OH$$



etc.

Therefore, the time during which stable film-forming properties are preserved decreases to 30 days. On lowering the SiO_2 concentration in a film to 10–20%, the time of FFS serviceability is again extended to 48 days. This probably occurs because the forming cluster compounds of tantalum hinder the hydrolytic polycondensation of tetraethoxysilane.

The oxide film formation consists in that the chemical composition of the starting film-forming compounds undergoes changes first in solution, then at the instant of film formation on the substrate surface, and, finally, during thermal treatment [4]. To determine the conditions of film synthesis, the main stages of formation of pure oxides and complex oxides on their base were studied. On heating a powder obtained by drying at 333 K an alcoholic solution of $TaCl_5$, the following processes occur according to thermal analysis data (Fig. 2): partial evaporation of physically adsorbed water and alcohol, reaction of $TaCl_5$ with atmospheric oxygen, and, finally, combustion of oxochlorides and alkoxy derivatives of tantalum to form the oxide.

The IR data (Table 1) confirm the presence of ethoxy groups at the oxide formation temperature of 800–840 K. At higher temperatures there are no stretching or bending vibrations of ethoxy groups.

Complex oxides SiO_2–Ta_2O_5 are formed in four stages (Fig. 3). The activation energy was calculated for all the processes involved by the Horowitz–Metzger method (Table 2) [5].

In stage I, physically adsorbed water and alcohol are removed, which is accompanied by an endothermic effect at 393 K. The second endothermic peak

(734 K) is due to evaporation of water released upon condensation of silanol groups. The activation energy calculated for this stage (Table 2) is in agreement with the value characteristic of the condensation of hydroxyl-containing organosilicon compounds [6]. In the final stage of the process (exothermic peak at 848 K) the ethoxy groups contained in the products of FFS solvation and hydrolysis are oxidized, and the formation of the SiO_2–Ta_2O_5 film is complete. The activation energy of this stage is typical of a chemical reaction.

The firmness of film attachment to the surface, and the optical and electrical properties of films, determine the possibilities of their practical use. The optical and electrophysical properties, adhesion, and porosity were studied for SiO_2–Ta_2O_5 films (120–140 nm, silicon substrate) (Table 3). It was found that the obtained films exhibit good adhesion to various substrates and contain no micropores.

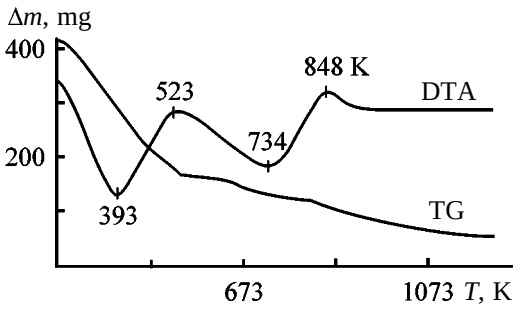

Fig. 3. Derivatogram of film formation from FFS with $TaCl_5$ and $Si(OC_2H_5)_4$.

CONCLUSION

An alcoholic solution of tantalum pentachloride possesses film-forming ability, with unlimited durability of stable film-forming properties. Gravimetry and IR spectroscopy were applied to establish the sequence of main stages of Ta_2O_5 and SiO_2–Ta_2O_5 formation from film-forming solutions. The properties of the obtained films were studied.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Precious Metals with Carbon Sorbents

Yu. E. Golodkov, V. V. Elshin, V. I. Dudarev, and L. M. Oznobikhin

Abstract—Sorption of gold and silver cyanide complexes with carbon sorbents based on composite polymeric materials and its thermodynamic characteristics were studied.

Hydrometallurgy based on carbon sorbents is one of the most efficient processes for recovery of precious metals from ores and concentrates. Such technology has advantages in the selectivity of gold and silver recovery [1–4]. The main factors hampering a wide use of this technology in the Russian gold mining industry are low mechanical resistance to wear of the industrial carbon sorbents and their short supply [5, 6]. "Carbon-in-pulp" processes are widely used in other countries in industrial production of gold [3, 7].

In this work, we studied sorption with carbon polymeric sorbents of gold and silver leached with cyanides from ores of complex composition by carbon polymeric sorbents. Data on the synthesis of wear-resistant carbon sorbents were reported in [8]. IPI-T sorbent prepared in industrial quantities from phenol–formaldehyde resins and their waste is of industrial importance. Physicochemical characteristics of IPI-T sorbent and certain known materials are compared in Table 1.

Up to now, both the mechanism of sorption of precious metals from solutions and pulps and problems of the directed synthesis of sorbents are the matter of discussions [8–10].

EXPERIMENTAL

We obtained the isotherms and kinetic curves of gold and silver sorption on IPI-T using a temperature-controlled device. To obtain sorption isotherms, variable samples of the sorbent and constant volumes of solutions with fixed initial concentrations of gold and silver cyanide complexes were used. The solutions were obtained by cyanide leaching of ores of the Kuranakh mining field. Mixers provided vigorous agitation of the sorbent in the solution. The concentrations of precious and nonferrous metals (determined by atomic absorption method) and anions were monitored.

Figure 1 shows the isotherms of gold and silver sorption from cyanide solutions with IPI-T sorbent in comparison with IGI-65, Norit, and Futamura carbon. As seen, the highest sorption power is characteristic for Norit activated carbon, while IPI-T sorbent has a slightly lower sorption power than imported carbons. Isotherms are described by the Freundlich equation

$$a = kC^{1/n}, \quad (1)$$

	20	40	60	
$[Au(CN)_2]^-$	1.172	1.508	1.886	9.62
$[Ag(CN)_2]^-$	0.753	0.967	1.250	10.19

where *a* is the equilibrium concentration of metal ion in the carbon (mg g^{-1}), *C* is the equilibrium concentration of metal ion in the solution (mg l^{-1}), and *k* and *n* are constants. Calculated *k* and *n* are listed in Table 2. The temperature dependences of *C* for IPI-T sorbent at the fixed *a* measured within the 20–60°C range are shown in Fig. 2. The differential heats of sorption of metal ions were calculated by the isosteric method [11] from linear slopes (Table 3).

The sorption kinetics was studied within the 20–60°C range (Fig. 3). The rate constant *K* of the sorption was calculated from the slope of the $\log C$–*t* straight line in accordance with the equation

$$\log C = \log C_0 - 0.434\,tK, \qquad (2)$$

where C_0 is the initial metal concentration in the solution (mg l^{-1}), *C* is the actual concentration (mg l^{-1}), and *t* is time (s).

The activation energy of sorption was calculated by the equation

$$E = -2.303R\frac{d\log K}{dT^{-1}}, \qquad (3)$$

where *T* is temperature (K). The results are listed in Table 4.

The temperature dependence of the sorption rate constant and the values of the sorption activation

energy show that in this case the internal-diffusion model of the gold and silver sorption with IPI-T sorbent is the most probable.

CONCLUSION

The efficient sorption recovery of gold and silver from cyanide solutions with the IPI-T carbon sorbent with a high wear resistance was demonstrated. This sorbent is characterized by only slightly lower sorption power with respect to these metals as compared to imported carbons. The internal-diffusion sorption is the most probable mechanism of gold and silver sorption with IPI-T.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Chromium(VI) from Aqueous Solutions on AM-2b Anion Exchanger

L. A. Voropanova and E. Yu. Getoeva

North-Caucasus State Technological University, Vladikavkaz, North Ossetia, Russia

Received June 25, 1999; in final form, March 2000

Abstract—Sorption of chromium(VI) from a solution with the initial concentration of CrO_3 of up to 30 mg dm^{-3} on a commercial macroporous AM-2b anion exchanger pretreated by various methods was studied. The optimal conditions for efficient sorption were found.

Sorption of metal ions on a number of sorbents is largely influenced by the solution acidity. Sorption of Cr(VI) from solutions with various pH was studied in [1, 2]. It was shown that sorption is governed by the state of ions in the solutions, which, in turn, depends on pH. For example, at pH < 7 chromium(VI) solutions contain the $Cr_2O_7^{2-}$, $HCrO_4^-$, and CrO_4^{2-} ions, whereas at pH > 7 they contain the $HCrO_4^-$ and CrO_4^{2-} ions. In 0.5–2.0 N solutions of H_2SO_4 the $Cr_3O_{10}^{2-}$ and $Cr_4O_{13}^{2-}$ anions are formed. Polycondensation of CrO_4^{2-} anion in acidified aqueous solutions yields chromium(VI) isopolyanions:

$$nCrO_4^{2-} + 2(n - a)H^+ = Cr_nO_{3n+a}^{2a-} + (n - a)H_2O. \quad (1)$$

The final polycondensation products are hydrated polymeric oxides with the composition $(CrO_3)_n \cdot mH_2O$. All intermediates containing polyanions have some oxygen excess in comparison with the trioxide. The composition of these intermediates can be presented by the general formula $Cr_nO_{3n+a}^{2a-}$, where n is the number of chromium(VI) atoms in the anion and a is the excess of oxygen atoms in the polyanion relative to the trioxide [3]. At the same time, CrO_2^{2+} cations are known, for which $a < 0$. It was found [3] that a and n are integer quantities varying from –4 to 1 and from zero to infinity, respectively.

For studying chromium(VI) sorption, we used macroporous bifunctional AM-2b anion exchanger containing benzyldimethylamine and benzyldimethylammonium functional groups [4].

Sorption was carried out under static conditions with continuous stirring at a constant pH as in [5, 6]. The sorbent was saturated with 0.1 N solutions of H_2SO_4 or NaOH (SO_4^{2-} and OH^- forms) for 1 h or kept in distilled water (Cl^- form).

Data on sorption from solutions with the initial concentration C_{init} = 3000, 1500, and 1500 mg dm^{-3} recalculated on CrO_3 are given in Figs. 1a–1c for the AM-2b sorbent (weight 2 g) in the SO_4^{2-}, OH^-, and Cl^- forms, respectively.

For the anion exchanger in the SO_4^{2-} form in the range pH 2–12 the dependence of the residual concentration on solution pH passes through four minima: at pH 2, 4, 6, and 9. In this case, the exchange sorption capacity (ESC) in 20 min is 160, 170, 150, and 130 mg of sorbate per gram of sorbent, respectively.

For the anion exchanger in the OH^- form in the range pH 1–11 the dependence has three minima: at pH 1, 3, and 6 (Fig. 1b). The ESC is 130, 127, and 110 mg g^{-1}, respectively.

For the anion exchanger kept in water (Cl^- form) at pH 1–11 the best results were obtained at pH 2–6 and 9 (Fig. 1c). The ESC is 144 and 90 mg g^{-1}, respectively.

As seen from Fig. 1, the sorption depends on both pH and conditions of sorbent pretreatment, because it is determined by the state of chromium(VI) ions in the solution and the state of functional groups of the anion exchanger [1]. Probably, the sorption maximum at pH ≤ 4 is due to the formation of isopolychromates and to the increased degree of protonation of the amine groups of the anion exchanger [1]. The sorption at pH < 7 is governed by the formation of $Cr_2O_7^{2-}$ ions being the product of polymerization of monomers in the solution. The sorption maximum at pH 9 results from the ion exchange with CrO_4^{2-} anions and from complexation in the resin phase. The

1070-4272/01/7401-0024$25.00

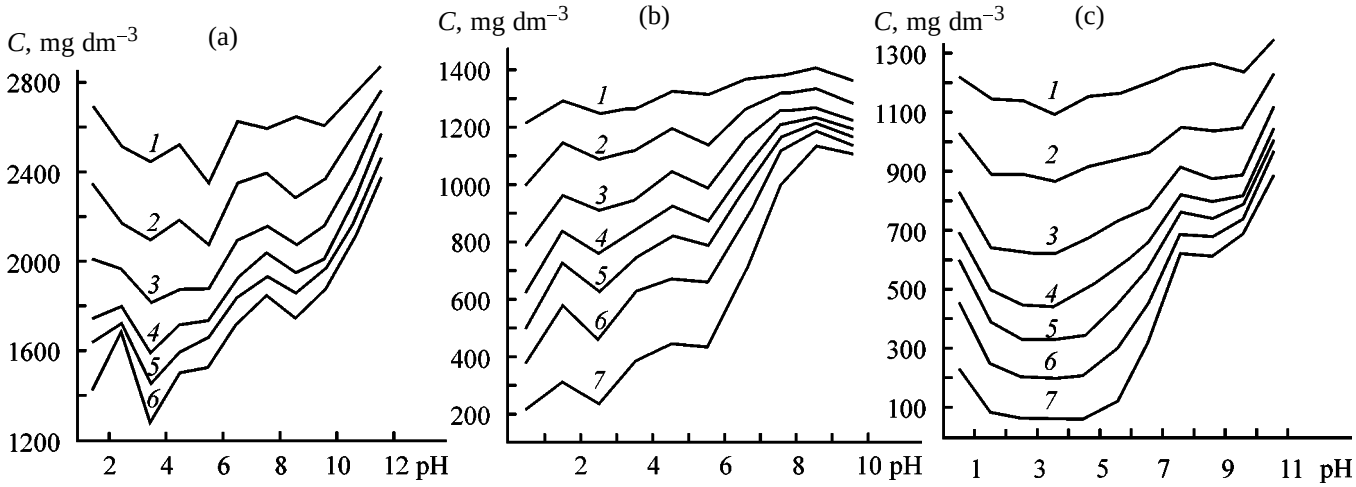

Fig. 1. Residual concentration of Cr(VI) ions C vs. solution pH at various times of sorption on AM-2b anion exchanger. Sorption time (min): (*1*) 2, (*2*) 5, (*3*) 10, (*4*) 15, (*5*) 20, (*6*) 30, and (*7*) 60. (a) SO_4^{2-} form, (b) OH^- form, and (c) preliminary treatment in water.

shift of the third maximum toward more acidic region (Fig. 1b) may be due to the fact that the low-basic groups of the AM-2b anion exchanger in the OH^- form loss virtually completely the exchange capability at pH $\geq$ 9.

The kinetic curves of Cr(VI) sorption on AM-2b anion exchanger kept in water at pH 4 are shown in Fig. 2.

Figure 3 demonstrates the isotherms of chromium(VI) sorption for the sorption time of 60 and 80 min, constructed from the data in Fig. 2.

As seen from Figs. 2 and 3, sorption increases with increasing time and initial solution concentration, which is due to polymerization.

By kinetic analysis of sorption using the substitution and graphical procedures [6], we determined the order n of the process with respect to the sorbate (n = 2):

$$-dC/d\tau = kC^n,$$

where C is the residual concentration of the sorbate in the solution, τ is the sorption time, and k is a constant.

The second order of the process suggests that the sorption process is kinetically controlled and is limited by chromium complex formation on the sorbent surface [6].

The sorption rate limited by complex formation is also governed by pH of the medium. Chromium(VI)-containing ions polymerize by polycondensation reaction (1) involving protons or hydroxide ions.

In the systems studied, the composition and struc-

ture of chromium(VI) isopolyanion of the composition Cr_nO_{3n+1} are governed by pH of the initial solution. However, reaction (1) is not in equilibrium but continues in the course of the ion-exchange process, which is confirmed experimentally by pH variations in the course of sorption.

Sorption can proceed by the reactions [7]

$$2RCl + CrO_4^{2-} = R_2CrO_4 + 2Cl^-,$$

$$mR_2CrO_4 + (n - m)CrO_4^{2-} + (n - 1)H^+ = R_{2m}Cr_nO_{3n+1}(OH)_{n-1},$$

$$2RCl + HCrO_4^- = R_2OHO_3Cr^+ + 2Cl^-, \text{ etc.}$$

* (C_0) Initial concentration of CrO_3 solution.

where R is the fixed polycation of the anion exchanger.

Further complexation may be associated with redox reactions, e.g.,

$$Cr^{6+} + 3e \rightarrow Cr^{3+} \text{ etc.}$$

The kinetic analysis of sorption was performed by kinetic equations for gel and film [8]. Table 1 shows that at a Cr(VI) concentration from 340 to 800 mg dm^{-3} the sorption is described by a kinetic equation for film, whereas at concentrations from 1000 to 4000 mg dm^{-3} it is described by a kinetic equation for gel.

The results of calculation of the diffusion coefficients D ($cm^2\ s^{-1}$) are given in Table 2 in relation to the time of contact of the anion exchanger with the solution containing different initial concentrations of Cr(VI) ions. The diffusion coefficient D is calculated by the equation

$$D = Br^2/\pi^2,$$

where r is the sorbent grain radius and B, the coefficient calculated from the tabulated data [9].

As seen from Table 2, the diffusion coefficient D decreases as the concentration C_0 of the initial solution grows. At $C_0 \geq 1000$ mg dm^{-3} D is approximately constant, irrespective of contact time.

From the equation

$$\log C_{sorb} = p\log C_s + \log(K/K_p)$$

where p is the polymerization factor, $C_{sorb} = ESC \cdot M^{-1} V_{sp}^{-1}$ is the ion concentration in the sorbent (mol dm^{-3}), V_{sp} is the specific swelling of the sorbent ($cm^3\ g^{-1}$), C_s is the ion concentration in solution (mg dm^{-3}), K is the equilibrium constant, and K_p is the polymerization constant, we determined the polymerization factors p using the procedure described in [9].

C_{init}, mg dm^{-3}	p
800–1500	0.27
1925–4200	0.14

The difference in the values of the polymerization factor p indicates that over the initial concentration range studied the chromium(VI) complexes of various compositions are sorbed. With growing initial solution concentration the degree of polymerization of the complexes increases according to Eq. (1).

CONCLUSION

(1) The calculations of the diffusion coefficient and polymerization factor, along with the kinetic analysis, indicate that at higher concentrations of the sorbate the sorption process is kinetically controlled and is limited by chromium(VI) complex formation on the sorbent surface and by chromium(VI) polymerization in the solution and on the sorbent surface.

(2) Sorption of chromium(VI) from aqueous solution is optimal at acid treatment of the sorbent and pH 4: ESC 350 mg CrO_3 per gram of sorbent at the initial solution concentration $C_{init} \leq 4000$ mg CrO_3 dm^{-3}.

SORPTION AND ION-EXCHANGE PROCESSES

The Chemical Resistance of Chabazite from Transbaikal Region

E. L. Zonkhoeva

Geological Institute, Siberian Division, Russian Academy of Sciences, Ulan-Ude, Buryatia, Russia

Received March 3, 2000

Abstract—The chemical resistance of natural chabazite of Margintui volcanic field (Transbaikal Region) in 0.01, 0.1, 1.0, and 3.0 N HCl at was studied in relation to the treatment time. The order, degree, and relative rate of cation extraction from the chabazite phase were determined.

Studying the chemical resistance of zeolites is important for understanding the mechanism of their crystallization under natural and artificial conditions. Acid treatment can be used for preparing zeolitic sorbents and catalysts with controllable properties, which significantly extends the possibilities of their application.

At treatment of zeolites with dilute acid solutions the proton of the acid first interacts with the molecules of zeolite water to form hydroxonium ions participating in cation-exchange reactions [1]. At higher concentrations of the acid the proton interacts with the oxygen of the aluminosilicate skeleton with formation of hydroxide groups. As a result, the Al–O–Si bonds break and aluminum(III) passes into the solution. In this stage, decationization and dealuminization occur simultaneously.

A majority of works is devoted to chemical resistance of zeolites, especially of mordenites. At the same time, the resistance of chabazite is studied insufficiently. For example, dealumination and amorphization of chabazite boiled in 0.12 M solution of HCl has been reported in [2]. In 2 M HCl solution the chabazite crystal structure degrades completely. Chabazite is unstable to the action of HCl vapor at 200°C [3].

The acid resistance of natural chabazite was studied by Piguzova [4]. It was found that up to 12–17% aluminum(III) is extracted from chabazite on treatment with 0.006 N HCl. As a result, the maximal pore volume increases by a factor of approximately 3 compared to the initial sample. In 3 N HCl solution, the ratio SiO_2/Al_2O_3 reaches 15, but the mineral structure remains unchanged.

Bogdanova and Belitskii [5] studied the resistance of 25 zeolite samples, including chabazite samples, to treatment for 1 h with 1 N HCl on a boiling water bath. Among the four groups, chabazite is classed with the third group of zeolites, weakly reactive with respect to dissolution. Treatment of chabazite with the concentrated acid resulted in the extraction of 97% of aluminum and total removal of Ca(II), Mg(II), and Ba(II) ions. After treatment, the residual chabazite retained the shape of the crystals.

Thus, no data are available on the chemical resistance of chabazite in relation to the treatment time.

In this work, the chemical resistance of chabazite from the Margintui volcanic field (Transbaikal Region) of the composition $Ca_{0.85}Na_{0.1}K_{0.08}Mg_{0.03} \cdot (Al_{1.7}Si_{4.2}O_{12}) \cdot H_2O$ in acid solutions of various concentrations was studied as a function of the contact time. The grain size of the mineral was 1–2 mm. Weighed portions of chabazite were placed in 0.01, 0.1, 1.0, or 3.0 N HCl for 1, 3, and 24 h at the solid-to-liquid ratio of 1 : 30. After separating the phases, chabazite was studied by X-ray phase analysis (DRON-2.0 diffractometer, CuK_α radiation) and by chemical analysis for Si, Al, K, Na, Ca, and Mg. The Al and Si concentrations were determined on an SF-46 spectrophotometer and the K, Na, Ca, and Mg concentrations, on a Saturn atomic absorption spectrophotometer (table, Fig. 1).

The samples treated with 0.01, 0.1, 1.0, and 3 M acid solutions are denoted as A, B, C, and D, respectively. The figures 1, 3, and 24 denote the treatment time (h). The degree of extraction of exchangeable cations and aluminum(III) is recalculated on oxides (Fig. 1). The rate v of passing of the ions into the solution was determined from the formula $m = vt$, and the relative rate per gram of zeolite, by the formula $\alpha = v/M$ (h^{-1}), where m is the weight (g) of the cation passed into the solution in time t (h), and M is the weighed portion of chabazite (g) [6].

The X-ray diffraction patterns of the initial sample

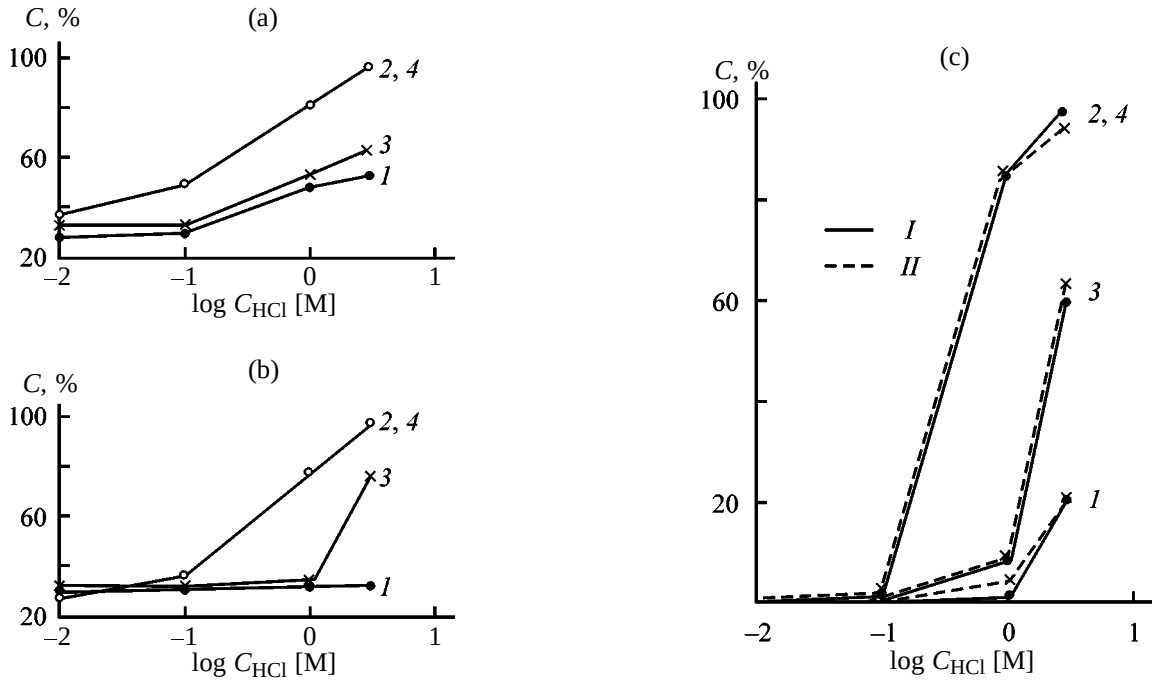

Fig. 1. Degree of extraction *C* from chabazite of (a) sodium, (b) potassium, and (c) calcium and aluminum as a function of acid concentration C_{HCl}. Treatment time (h): (*1*) 1, (*2*, *4*) 24, and (*3*) 3. Ion: (*I*) calcium and (*II*) aluminum.

agree with the reference data [7]. The crystal structure of chabazite, when treated with 1 N HCl solution for 24 h (sample C-24) and with 3 N HCl solution for 3 and 24 h (samples D-3 and D-24, respectively), degrades. The most intense reflections d_{101}, d_{211}, d_{401}, and d_{214} were retained in the diffraction pattern of the C-24 sample, but in that of the D-24 sample all reflections were absent. All other conditions of acid treatment did not affect the chabazite crystal structure.

According to chemical analysis, Na and K are the predominant exchangeable cations extracted from the chabazite solid phase into 0.01 and 0.1 N HCl (table; Figs. 1a, 1b). Upon 24-h treatment with 0.1 N HCl, only 1.11% of aluminum(III) and 2.43% of calcium(II) are extracted (table, Fig. 1c).

Magnesium(II), present in chabazite in a small amount (0.31%), is extracted to 45% as the mineral is rendered amorphous by treatment with 3 N HCl. No extraction of silicon from the chabazite occurs.

Because calcium ions in the chabazite exchangeable complex are predominant, their behavior in the systems studied is of a special interest. Figure 1c shows that on treatment of chabazite with 0.1 N HCl (sample B-24) calcium is extracted simultaneously with the start of washing-out of aluminum, but the relative extraction rate of aluminum is higher than that of calcium and other exchangeable cations (see table).

With growing acid concentration the relative rate of passing of calcium into the solution increases considerably.

ions in the chabazite have been studied in a number of works [3, 8–11]. Within the large chabazite cavity calcium ions occupy three different positions: near a six-membered ring outside the hexagonal prism, in an eight-membered ring, and inside the dihedral angle formed by the four-membered rings. The calcium coordination sphere contains water molecules separating calcium ions from the walls of the aluminosilicate skeleton and the oxygen atoms of the skeleton. Evidently, an acid proton breaks the Al–O and Ca–O bonds, which destabilizes the chabazite crystal structure and facilitates simultaneous passing of aluminum and calcium into the solution. The table clearly shows that the interaction of chabazite with an acid is a two-stage process involving ion-exchange recovery of alkali metal ions as the first stage and the dealumination combined with decalcination as the second stage.

The extent of dealumination and decationization of chabazite largely depends on the time of acid treatment. The effect produced by the treatment time on the metal ion recovery is more pronounced for sodium than for potassium (Figs. 1a and 1b, respectively). The increase in the amount of the potassium ions is due to dissolution of chabazite at treatment (1 N acid solution, 24 h and 3 N solution, 3 and 24 h). The relative rate of passing of the ions into the acid solution increases with growing acid concentration and decreases with increasing treatment time.

CONCLUSION

The study of chemical resistance of natural chabazite treated with 0.01–3 N HCl for different times showed that treatment with 0.01 and 0.1 N solutions results in the extraction of sodium and potassium ions. In 1.0 and 3.0 N acid solutions, calcium and aluminum ions are extracted along with alkali metal ions. Such a sequence of the extraction of exchangeable cations implies that calcium ions are stronger bound in the chabazite structure than alkali metal ions. Removal of aluminum(III) ion from the tetrahedral position does not affect the chabazite crystal structure, except for the case when treatment results in mineral degradation (1.0 N acid solution, 24 h and 3 N solution, 3 and 24 h). The degree of dealumination and decationization depends on the time of contact of chabazite with the acid.

SORPTION AND ION-EXCHANGE PROCESSES

Deoxygenation of Aqueous Solutions by Cathodically Polarized Copper-Containing Redox Cation Exchanger

T. A. Kravchenko, N. V. Sotskaya, and O. V. Sleptsova

Voronezh State University, Voronezh, Russia

Received June 7, 1999; in final form, January 2000

Abstract—Oxygen reduction in aqueous solutions by cathodically polarized copper-containing redox resins was studied. To provide reagent-free, continuous, and exhaustive deoxygenation, the rate of surface electroless oxidation with oxygen should be equal to the rate of electrochemical reduction (regeneration) of the redox centers.

The modern industry imposes stringent requirements on deoxygenation of water and aqueous solutions of electrolytes. There are various procedures for removing oxygen from liquid media [1]; however, copper-containing redox resins (electron and ion exchangers) are the most efficient for exhaustive deoxygenation [2, 3]. When deoxygenation is performed by reducing sorption of oxygen on a copper-containing redox cation exchanger, oxygen reacts with dispersed copper to form copper oxides or copper ions fixed as counterions in the ion-exchange matrix. The redox resins are unique substances since they have high redox capacity and developed porous structure and can be reduced or oxidized without liberation of the products of their own conversion. In addition, copper-containing redox resins have sufficient electrical conductivity and stability to electric current [4] which allows reducing sorption of oxygen on these materials under conditions of cathodic polarization [5–7], i.e., oxygen electrosorption. Previously [8, 9] we determined two consecutive and parallel pathways of electrosorption. The first occurs via redox transformations of the surface of the redox resin grains and heterogeneous chemical reactions to form chemisorbed copper–oxygen complex. The electric current regenerates the surface reaction centers of the redox resin, thus providing fast and continuous deoxygenation. The rate-determining step is heterogeneous chemical reaction (1). The subsequent electrochemical reduction of copper–oxygen compounds (2) is relatively fast:

$$\mathrm{R \cdot Cu} \xrightarrow[(1)]{\mathrm{O_2}} \mathrm{R \cdot [Cu \ldots O]} \underset{(2)}{\overset{\mathrm{e}}{\rightleftarrows}} \mathrm{R \cdot Cu},$$

where R is the polymeric matrix of the redox cation exchanger.

The second pathway is sorption and reduction of oxygen with copper of the redox resin in the depth of its grains, where the reaction centers are not affected even by the maximal cathodic polarization. At polarizing currents insufficient for regeneration of all redox centers, this pathway also provides exhaustive removal of oxygen from the solution. However, in this case the deoxygenation is slow and requires intermittent regeneration of the redox filter.

The aim of this work was to determine conditions providing constantly high rate of oxygen electrosorption from aqueous solutions on copper-containing redox resin, i.e., conditions providing continuous regeneration of the reaction surface.

We studied oxygen electrosorption on EI-21 SNU copper-containing redox resin [2] prepared from KU-23 macroporous sulfonic cation exchanger. The redox centers of this redox cation exchnager are clusters of copper atoms located around the ion groups of the resin. The diameter of resin grains is 0.5–1.0 mm. The redox capacity of the sorbent ε (the content of dispersed copper) ranged from 6.5×10^3 to 12.0×10^3 g-equiv m^{-3} of the resin. Deoxygenation with both reduced and oxidized form of the resin was studied. The degree of oxidation of the resin α was determined by microscopic examination of the concentric ring of Cu_2O clearly seen on a section of a resin grain. The oxidized form of the resin was reduced either with alkali solution of sodium dithionite $Na_2S_2O_4$ (electroless reduction) or electrochemically at $i = 0.1$ A m^{-2} and cathodic polarization $E = -0.9$ V in the absence of solution flow. Oxygen electrosorption was studied in a flow three-cell reactor of the filter-press type. The reactor consists of cathodic and two anodic cells separated by MA-40 anion-exchange

1070-4272/01/7401-0031$25.00

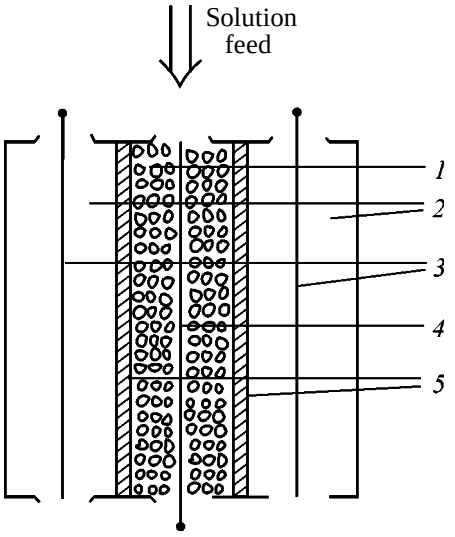

Fig. 1. Scheme of electrosorption reactor: (*1*) cathodic cell packed with the redox resin, (*2*) anodic cells, (*3*) platinum anodes, (*4*) copper cathode, and (*5*) anion-exchange membranes.

membranes (Fig. 1). The vertical electrodes were fixed along the longitudinal axis of the cells. A bed of granulated redox resin was arranged around the vertical copper wire cathode in the working cell with 1–6 cm height (h) and 1.2 cm^2 cross section. A Luggin capillary of a silver chloride reference electrode was fixed in the immediate vicinity of the cathode. A working 0.04 M solution of sodium sulfate was fed from the top with a flow velocity form 0.1 to 0.7 cm s^{-1}. The electrosorption reactor was polarized under galvanostatic conditions. The potentials were measured vs. a standard hydrogen electrode.

The rate of oxygen electrosorption $i(\Delta c)$ (A m^{-2}) was estimated from a decrease in its concentration and expressed in the units of current density:

$$i(\Delta c) = zFu\,\Delta c/s,$$

where z is the number of electrons involved in the reaction ($z = 4$); F is the Faraday number (26.8 A h mol^{-1}; u is flow rate of the oxidizing agent (l h^{-1}); Δc is difference in the oxidizing agent concentration at the inlet (c_0) and outlet (c) of the reactor, determined with the aid of a KL-215 oxygen meter (M); and s is the geometrical surface area of grains (m^2).

Table 1. Rate of oxygen electrosorption $i(\Delta c)$ and limiting current density i_{lim} for the reduced and oxidized forms of the redox resin; $\varepsilon = 10.5 \times 10^3$ g-equiv m^{-3}, c_0 = 8.6 mg l^{-1}, u = 0.46 cm s^{-1}, at i = 0.086 A m^{-2}

α, %	$i(\Delta c)$	i_{lim}	$-E$, V
	A m^{-2}		
0	1.31 ± 0.11	1.06 ± 0.07	0.2
50	0.84 ± 0.04	0.34 ± 0.03	0.9

The rate of electrochemical process was estimated from the limiting current density of the polarization curves I_{lim}, which is the limiting current of preceding chemical reaction and is described by the equation [8, 9]

$$I_{lim} = i_{react} = -zF\omega_0/\nu,$$

where ω_0 is rate of reduction of dissolved oxygen with the redox resin in the absence of the polarization, and ν is the stoichiometric number.

Let us consider the rate of oxygen electrosorption as influenced by the reactivity of the redox resin. For this purpose we studied both the reduced and oxidized forms of the resin (Table 1). The rate of oxygen electrosorption $i(\Delta c)$ and the limiting current density of polarization curves i_{lim} considerably decrease with accumulation of copper oxides in the depth of resin grains (i.e., at high oxidation degrees of the resin α). The oxidized form has a lower electrical conductivity, and hence the oxygen electrosorption on this form occurs at higher overvoltage as compared to the reduced form. Thus, the oxygen reduction on the redox resin with highly reactive reducing centers is the fastest.

The reactivity of the redox resin is determined by not only the presence of copper oxides but also the amount of reactive copper (the redox capacity of the resin ε). As seen from Fig. 2, the rate of electrosorption on the redox resins with a low content of dispersed copper is considerably higher than the limiting current density. These parameters become close starting from $\varepsilon = 10.5 \times 10^3$ g-equiv m^{-3}. The fact that $i(\Delta c)$ is higher than i_{lim} indicates that oxygen is reduced not only by the surface but also by internal reaction centers of a grain. This can decrease the reactivity of the redox resin and decelerate oxygen reduction (Table 1).

To maintain constantly high rate of the process, the rate of electroless oxidation of the redox centers with oxygen $i(\Delta c)$ should be equal to the rate of the electrochemical reduction i_{lim}. In addition, polarization currents higher than the limiting value are undesirable because of hydrogen evolution. Commercial EI-21-75 redox resin with relatively high capacity (ca. $10.5 \times$

10^3 m^{-3}) meets the indicated requirements. This sorbent can be used for oxygen electrosorption.

The redox resin after sorption or electrosorption of O_2 can be regenerated by treatment with chemical reducing agents or by cathodic polarization in a stationary solution. The regeneration procedure (chemical or electrochemical) affects the limiting current (Table 2) and does not affect the rate of oxygen sorption.

The limiting current density i_{lim} for the redox resin regenerated by chemical reduction is somewhat lower as compared to the resin regenerated by the electrochemical procedure. The constancy of the electrosorption rate indicates that the number of the reaction centers remains the same. However, the state of these centers can change owing to sorption of the reducing agent and its oxidation products, which, in turn, should affect the rate of heterogeneous chemical oxidation of these centers and hence the limiting current of their reduction. Cathodic activation of the redox centers of the resin regenerated by the chemical procedure increases the limiting current density to the value observed for the electrochemicaly regenerated redox resin. When the cathodically activated redox resin is treated with the reducing agent, the resin is converted into the initial state characterized by a low limiting current. Thus, deoxygenation on the redox resin preliminarily activated by cathodic polarization will occur via oxidation and reduction of its surface with the maximal limiting current density. In the case of the chemically regenerated redox resin the process will mainly occur via formation and accumulation of copper oxides in the depth of a grain, which will deactivate the resin, thus decelerating the O_2 electrosorption. The activity of cathodically activated redox resin and hence the rate of oxygen electrosorption of this resin remain constantly high.

Thus, the copper-containing redox resin suitable for deoxygenation of aqueous solutions should be in the reduced form, have high redox capacity, and be activated by cathodic polarization. Only in this case the rate of oxygen electrosorption at polarization with the limiting current is equal to the limiting current density of the polarization $i(\Delta c) = i_{lim}$ and the process occurs via consecutive oxidation and reduction of the surface of the resin grains, thus providing continuous regeneration of the redox centers. This can be the case only for the redox resin with definite properties and under definite conditions. Among them are, first of all, polarizing current and concentration and feeding rate of dissolved oxygen. Let us consider each of this parameters.

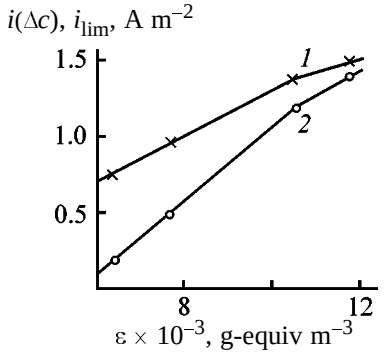

Fig. 2. (*1*) Rate of oxygen electrosorption $i(\Delta c)$ and (*2*) limiting current density i_{lim} at oxygen concentration in the solution of c_0 = 8.6 mg l^{-1}, flow velocity of the solution u = 0.46 cm s^{-1}, and height of the resin bed h = 6 cm as functions of the copper content in the redox resin ε.

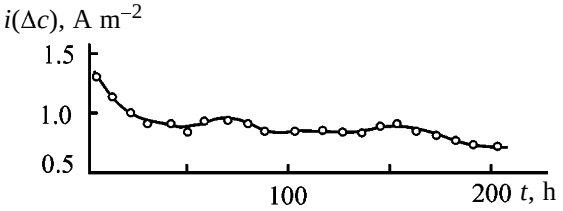

Fig. 3. Rate of oxygen electrosorption $i(\Delta c)$ by EI-21-75 redox resin at polarizing current density i = 0.86 A m^{-2}, $\varepsilon = 10.5 \times 10^3$ g-equiv m^{-3}, c_0 = 8.6 mg l^{-1}, u = 0.46 cm s^{-1}, and h = 6 cm as a function of time.

Deoxygenation with required rate can be maintained for a long time by polarization of the cathodically activated redox resin with the maximum possible current (which should depend on the limiting current) at which no hydrogen is liberated. This is indeed the case in oxygen reduction on EI-21-75 industrial copper-containing redox resin with $\varepsilon = 10.5 \times 10^3$ g-equiv m^{-3} at the equilibrium concentration c_0 = 8.6 mg l^{-1}, the flow velocity of the solution u = 0.46 cm s^{-1}, and the polarizing current density i = 0.86 A m^{-2} (Fig. 3). Negligible decrease in the reactivity of the resin in 200 h under these conditions can

Table 2. Change of the O_2 content in the solution Δc, electrosorption rate $i(\Delta c)$, and limiting current density i_{lim} for the redox resin regenerated by (I) chemical and (II) electrochemical procedure. $\varepsilon = 10.5 \times 10^3$ g-equiv m^{-3}, c_0 = 8.6 mg l^{-1}, u = 0.46 cm s^{-1}

* With sodium dithionite.

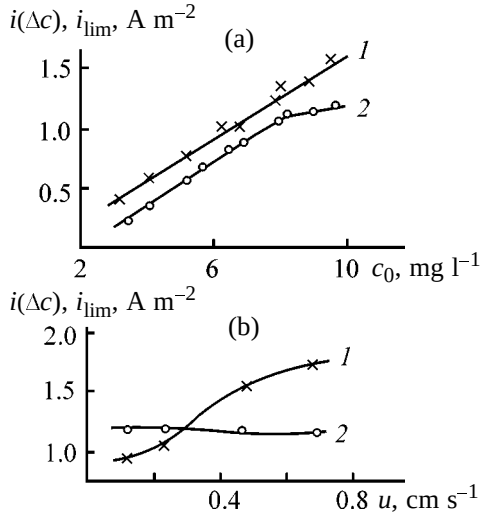

Fig. 4. (*1*) Rate of oxygen electrosorption $i(\Delta c)$ and (*2*) limiting current density i_{lim} as functions of (a) oxygen concentration in the solution c_0 ($\varepsilon = 10.5 \times 10^3$ g-equiv m^{-3}, $u = 0.46$ cm s^{-1}, and $h = 6$ cm) and (b) flow velocity of the solution u (cm s^{-1}) ($c_0 = 8.6$ mg l^{-1} and $h = 1$ cm).

be due to reducing sorption of oxygen by not only the first but also the second pathway with accumulation of Cu_2O inside a resin grain. Clearly the rate of electroless oxidation with oxygen slightly differs form that of electrochemical reduction of the resin. The equality can be attained only when the polarizing current and the rate of electroless reduction of oxygen on the resin $i(\Delta c)$ are the same. Since the polarizing current is restricted by the limiting current, the rate of oxygen reduction $i(\Delta c)$, the limiting current of the polarization curves i_{lim}, and the external polarizing current should be equal: $i = i(\Delta c) = i_{lim}$.

When the cathodically activated resin with high capacity (ε ca. 12×10^3 g-equiv m^{-3}, Fig. 2) is used, the rate of oxygen reduction $i(\Delta c)$ and the limiting current coincide at the equilibrium concentration $c_0 = 8.6$ mg l^{-1} and flow velocity of the solution $u = 0.46$ cm s^{-1}. In the case of the most frequently used industrial redox resin with $\varepsilon = 10.5 \times 10^3$ g-equiv m^{-3} these parameters slightly differ. In this connection let us consider $i(\Delta c)$ and i_{lim} for this redox resin as influenced by the oxygen concentration c_0 and flow velocity of the solution u. The electrosorption rate and the limiting current density regularly increase with increasing O_2 content in the solution (Fig. 4). At the O_2 concentration higher than 7.5 mg l^{-1} $i(\Delta c)$ exceeds the limiting current i_{lim}, suggesting oxidation of the reaction centers in the depth of a grain. The ratio of these parameters is similar at high flow rate of the solution and lower height of the resin bed (Fig. 4b).

Oxygen electrosorption on the industrial redox resin with $\varepsilon = 10.5 \times 10^3$ g-equiv m^{-3} should be performed at the flow velocity of the solution $u \le 0.23$ cm s^{-1} and the oxygen concentration $c_0 \le 7.5$ mg l^{-1}. In addition, since copper deposition on the cation exchanger involves treatment of the redox resin with a reducing agent (sodium dithionite), the sorbent should be electrochemically regenerated to increase i_{lim}.

Since in practice all parameters of the process are nonuniform throughout the resin bed of arbitrary height at large gradients of oxygen concentration in the bed, the reduction by the second pathway will occur in all cases [9]. Hence, to reach exhaustive deoxygenation, the process should be successively performed in several electrosorption reactors at the polarizing current corresponding to the rate of oxygen reduction.

Thus, continuous oxygen electrosorption on the copper-containing redox resin is provided mainly by maintaining constantly high reactivity of the resin by cathodic polarization at equal rates of electroless oxidation and electrochemical reduction of the redox centers. This is possible at definite internal and external parameters of the process (redox capacity of the resin, its oxidation degree, polarizing current density, flow velocity of the solution, and oxygen content in the solution).

CONCLUSIONS

Based on the results of this work we propose the following principles of oxygen electrosorption on the copper-containing redox resin, which provide continuous and exhaustive deoxygenation.

(1) Highly reactive cathodically activated redox resin in the reduced form with a high redox capacity should be used.

(2) To maintain high reactivity of the resin, the rate of electroless oxidation with oxygen should be equal to the rate of electrochemical reduction of the resin, which is the case when the limiting polarizing current density is equal to the rate of oxygen reduction. In the case of EI-21-75 redox resin this balance is attained at the O_2 concentrations lower than 7.5 mg l^{-1} and the flow velocity of the solution less than 0.3 cm s^{-1}.

SORPTION AND ION-EXCHANGE PROCESSES

Synthesis and Physicochemical Study of Polyfunctional Ion Exchangers Based on Dextramine Waste from Levomycetin Production

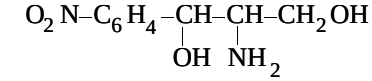
Received March 14, 2000; in final form, August 2000

Abstract—New polyfunctional anion exchangers are synthesized from dextramine (waste from levomycetin production) by condensation of its glycidyl ethers with certain polyamines. The polycondensation conditions are optimized, and physicochemical properties of the resulting ion exchangers are studied.

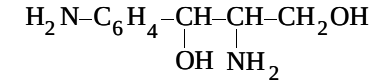
Ion-exchange materials are widely used in solving various environmental problems, in complex processing of raw materials, development of closed processes, water treatment, hydrometallurgy, and food industry [1–8]. Therefore, development of methods for synthesis of such materials from cheap and available components is an urgent problem [9–12].

EXPERIMENTAL

In this work the subject matter was *L*-1-(*p*-nitrophenyl)-2-aminopropane-1,3-diol (waste from levomycetin production)



and also its reduced form *L*-1-(*p*-aminophenyl)-2-aminopropane-1,3-diol



L-1-(*p*-Nitrophenyl)-2-aminopropane-1,3-diol diglycidyl ether (DGED) was synthesized at a molar

ratio monomer : epichlorohydrin (ECH) : NaOH = 1 : 6 : 3 [14]. As a result we obtained 311 g of a red viscous liquid (yield 96%). The epoxy group content in the product was 22% (83% of the theoretical value).

L-1-(*p*-Aminophenyl)-2-aminopropane-1,3-diol tetraglycidyl ether (TGED) was synthesized at a molar ratio monomer : ECH : NaOH = 1 : 12 : 6. 397 g of a yellow viscous liquid was obtained (yield 98%). The epoxy group content in the product, determined as in [15], was 40.3% (95.3% of the theoretical value).

The required amounts of the amine and ECH was loaded in a round-bottomed flask equipped with a reflux condenser, a drop funnel, a thermometer, and a stirrer. One mole of water was added. The reaction mixture was heated to 80°C, and 50% NaOH was gradually added over a period of 30 min. Hot water (80°C) was added until salts were dissolved. The organic phase was separated, washed with water, and volatile products were removed in a vacuum.

Found (%): C 56, H 6.3, N 8.4;
$C_{15}H_{20}N_2O_4$.
Calculated (%): C 55.5, H 6.1, N 8.6.

Found (%): C 61.5, H 7.6, N 6.4;
$C_{21}H_{30}N_2O_6$.
Calculated (%): C 62, H 7.3, N 6.8.

Polycondensation of the glycidyl ethers (GEs) with polyamines was performed at various component ratios at 80°C for 30 min, with subsequent heating at 100°C for 10 h. The polyamines were polyethylenimine (PEI), polyethylenepolyamine (PEPA), and poly-2-methyl-5-vinylpyridine (PMVP). PEI was used as a 50% aqueous solution (intrinsic viscosity 0.14, $M = 10 \times 10^3$, titrable nitrogen in an anhydrous sample 29.3%). PEPA [M = 290 (determined by cryoscopy), total nitrogen 22.6%, titrable nitrogen 19.8%] was allowed to stand over granulated KOH for 6 days. PMVP: $M = 10 \times 10^3$, 8.6% titrable nitrogen.

Solid resins were ground, converted into the OH form with 5% NaOH, and characterized as follows. Infrared spectra were registered on a UR-20 spectrophotometer using KBr technique. The potentiometric titration was carried out with an EV-74 ionometer. The thermal and chemical resistance was determined according to the GOST (State Standard) 10899–64.

Results on the effect of the reagent ratio on the ion-exchange characteristics of the resins are given in Table 1.

Study of the exchange capacity (EC), thermal and chemical resistance, and the yield of the ion exchangers allowed optimization of synthesis of the resins. The optimal proportions (mass ratio) of the components are as follows. DGED : PEI = 1 : 2, DGED : PEPA = 1 : 1.5, DGED : PMVP = 1 : 2, TGED : PEI = 1 : 3, TGED : PEPA = 1 : 2, and TGED : PMVP = 1 : 3. The resins obtained under the optimal conditions show sufficiently high thermal and chemical resistance (Table 2).

In Table 3 are summarized data on the sorption of Cu^{2+}, Ni^{2+}, and Co^{2+} from 0.05 N solutions with the resins obtained. For comparison are given data on EDE-10P commercial ion-exchange resin.

CONCLUSIONS

(1) New polyfunctional ion exchangers are synthesized by polycondensation of glycidyl ethers derived from *L*-1-(*p*-nitrophenyl)-2-aminopropane-1,3-diol or its reduced form with certain polyamines.

Table 3. Sorption characteristics of the resins

SORPTION AND ION-EXCHANGE PROCESSES

New Polymeric Sorbents Based on *N*-(Vinyloxyethyl)dithiocarbamoylethylcarbonitrile

Abstract—Homo- and copolymers based on *N*-(vinyloxyethyl)dithiocarbamoylethylcarbonitrile actively sorbing silver, gold, and mercury were prepared.

Proceeding with systematic investigations of the polymerization ability of derivatives of *N*-(2-vinyloxyethyl)dithiocarbamic acid [1, 2], we studied in this work the properties of a new monomer, *N*-(vinyloxyethyl)dithiocarbamoylethylcarbonitrile (VC):

CH_2=CH–O–CH_2–CH_2–NH–C(S)S–CH_2–CH_2–C≡N.

The synthesis of this compound was described elsewhere [3]. Bright yellow powdered polymer was prepared in a high yield by cationic homopolymerization (Table 1).

Cationic polymerization involves the vinyloxy group, whereas the dithiocarbamate group is preserved. The IR spectra of VC homopolymer contain the bands at 1400, 1490, 1580, and 3310–3400 cm^{-1} [–C(S)–NH–] and at 2250 cm^{-1} (C≡N). The bands at 244 and 364 nm in the UV spectra indicate the presence of the C=S group in the polymer. The molecular weight (weight-average) *M* is 5800–6100. Spectral data and elemental analysis confirm the linear structure of the polymer. The polymer is soluble in acetone, dioxane, and DMSO.

The VC homopolymer with maleic anhydride (MA) gives the copolymers with alternating comonomer units. The weight-average molecular weight reaches 5200–5500. The IR spectra exhibit the bands at 1850 and 1775 cm^{-1} belonging to the stretching vibrations of the MA carbonyl groups; the VC units are characterized by the main bands at 1400, 1490, 1580, 2250, and 3200–3400 cm^{-1}. The results of elemental analysis (Table 2) and spectral data suggest that, irrespective of the initial composition, copolymers are formed through the double bonds of VC and MA monomers. The copolymerization constants calculated using the Fineman–Ross procedure (r_1 = 0.05 + 0.01, r_2 = 0.09 + 0.01) suggest characteristic alternation of the units in the polymer, i.e., cross-coupling is the decisive process in the chain growth.

The VC–MA copolymers are yellow powders soluble in DMSO, DMF, chloroform, and in hot water. The radical copolymerization of MA and VC gives the copolymers with alternating comonomer units, whereas polymerization of VC and vinyl acetate (VA) yields the polymer products containing nearly 12 VA units per VC unit, irrespective of the composition of the initial reaction mixture (Table 3). The IR spectra of copolymers prepared at different initial ratios of VC and VA are similar. There are no bands of the stretching vibrations of the VA double bond and

VC vinyloxy group; the bands at 1720 and 1235 cm^{-1} belong to the –OCOCH group and that at 2250 cm^{-1}, to the nitrile groups. The UV bands at 244 and 364 nm indicate the presence of the C=S groups in the VC–VA copolymer. These copolymers (molecular weight ~4700) are yellow powders soluble in acetone, ethyl acetate, and chloroform.

The data on copolymerization of VC with styrene (ST) indicate that the composition of the resulting copolymers depends on the composition of the initial monomer mixture only at a low content of VC (5–9 mol%).

The reactivity of VC in copolymerization with ST and VA (Tables 3, 4) differs from that exhibited in copolymerization of ST and VC with simple vinyl ethers [4]. This is probably due to the fact that VC can initiate homopolymerization of ST and VA [5] under the copolymerization conditions (AIBN, 60°C). The VC–ST copolymers can be obtained as white powders or white soft fibers in the case of at least two-fold excess of VC. The resulting copolymers are soluble in DMSO, DMF, benzene, toluene, acetone, chloroform; they are well wettable with water.

It is known [6] that polymers containing the dithio-

carbamate fragment exhibit the sorption activity with respect to coordination-active metal ions. In contrast to VC–MA and VC–VA copolymers, the VC and VC–ST copolymers are rather stable in solutions of hydrochloric, sulfuric, and nitric acids at concentrations higher than 1 M, which allowed us to study the sorption properties of VC and VC–ST polymers with respect to ions of silver (in HNO_3, H_2SO_4), gold (in HCl, H_2SO_4), and mercury (in HCl, HNO_3, H_2SO_4).

The dependences of the metal recovery on the concentration and nature of the mineral acid are shown in Fig. 1. It should be noted that for the homopolymer the recovery of mercury ions from the solutions of nitric and sulfuric acid remains almost constant with increasing acid concentration from 1 to 7 M. In the case of gold and silver the recovery of metals decreases with increasing acid concentration in the above range. Such run of the recovery curves is probably due to the predominantly donor–acceptor interaction of metal ions with the active centers of the polymer. For gold occurring in a solution of hydrochloric acid as tetrachloride complex the ion-exchange interaction through the protonated nitrogen atoms is also possible. The effect of hydrochloric acid on the sorption recovery of mercury can be explained by formation of chloride complexes [7].

The data on the sorption kinetics in 1 M acid solutions indicate that both polymers recover silver with a high rate: the equilibrium is attained in 10 min. In the case of mercury the equilibrium is attained in 10 min and 2 h for VC and VC–ST copolymers, respectively. In the case of gold chloride complex the equilibrium is attained in 30 min, whereas the main fraction of the metal is recovered in 10 min.

The sorption capacity of polymers was determined from the curves of equilibrium distribution of metal ions between the solid phase and solution (Fig. 2, Table 5). As seen from Table 5, the VC homopolymer (PVC) is an efficient sorbent with respect to all three metal ions, whereas the VC copolymer is efficient with respect to mercury and gold ions. The sorption capacity of the copolymer with respect to silver and mercury ions decreases (approximately by half) with decreasing content of the active nitrogen and sulfur atoms, whereas for gold the sorption capacity increases. This is probably due to the steric factors related to the distribution of the active centers in the polymer and to the structure of the gold tetrachloride complex.

To elucidate the interaction mechanism, we studied the IR spectra of the VC copolymer and its concentrate (polymer with sorbed metal).

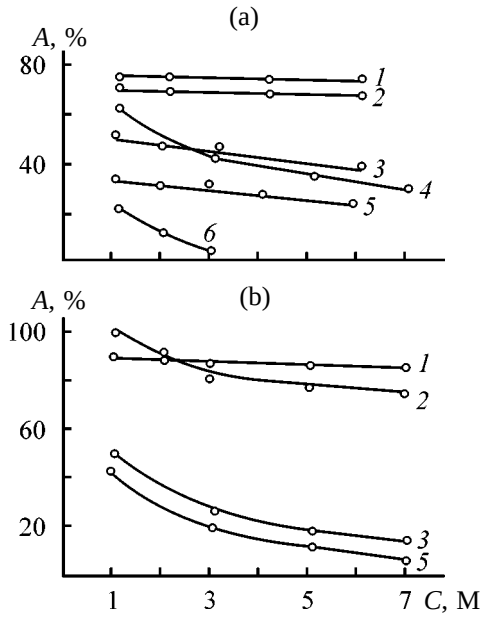

Fig. 1. Recovery A of (a) mercury and (b) silver on the (*1*, *2*, *4*) VC and (*3*, *5*, *6*) VC–ST polymers as influenced by the nature and concentration of acid C. Sorbent weight m = 10 mg, V = 20 ml, τ = 2 h. VC: m_{Hg} = 1.0, m_{Ag} = 8.0 mg; VC–ST: m_{Hg} = 3.6, m_{Ag} = 1.0 mg. Acid: (*1*, *5*) HNO_3, (*2*, *3*) H_2SO_4, and (*4*, *6*) HCl.

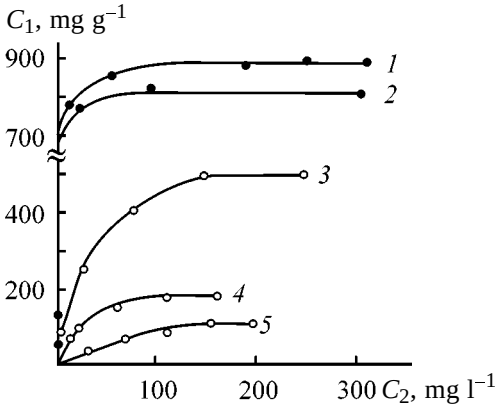

Fig. 2. Equilibrium distribution of (*1*, *2*) silver and (*3*–*5*) mercury in 1 M solutions of (*1*) nitric, (*2*–*4*) sulfuric, and (*5*) hydrochloric acids; (*1*–*3*, *5*) PVC and (*4*) VC–ST Sorbent weight m = 10 mg, V = 20 ml. Metal content (C_1) in the solid phase and (C_2) in solution.

Shift of the bands and variation of their intensity in the 1000–1250 cm^{-1} range for the concentrate indicates participation of the thioamide fragment in the coordination. Disappearance of the stretching vibration band at 1070 cm^{-1} suggests possible coordination through the C=S group. Moreover, certain changes are also observed in the 550–640 cm^{-1} range corresponding to the stretching vibrations of the C–S group. At the same time the band at 2250 cm^{-1} in the co-

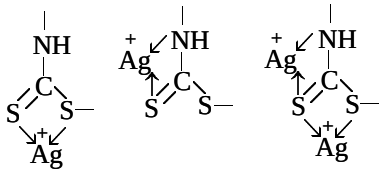
polymer spectra remains unchanged, which rules out participation of the C≡N group in the metal coordination. Thus, the above results allow us to propose the following structures of complexes formed in the sorbent phase:



1 **2** **3**

In this case, high sorption capacity of the VC homopolymer with respect to mercury and silver ions may be due to the ability of the active centers to form strong complexes with several metal ions (structure **3**).

It should be noted that the polymers in question recover mercury from 1 M hydrochloric acid solutions.

The sorption isotherms for silver (PVC), gold (PVC, VC–ST copolymer), and mercury (PVC, 1 M H_2SO_4; VC–ST copolymer, 1 M H_2SO_4, HNO_3) exhibit a large slope. The distribution coefficients of the metal ions calculated from these isotherms are very high (Table 5). These results suggest that these polymers can recover metal ions from dilute solutions.

As seen from Fig. 1, the VC–ST copolymer does not noticeable recover mercury from hydrochloric acid of concentration higher than 3 M, and this property can be used for desorption. It was found that 6 M HCl almost completely removes mercury from VC and VC–ST polymers in 1 h. The regenerated polymer can be used in further sorption–desorption cycles. The noble metals can be eluted with a 3% solution of thiourea in 1 M HCl: 10 ml of this solution completely recovers 59 μg of gold in 30 min. At 50°C the desorption period decreases to 10 min, but in this case the sorption activity of the regenerated sorbent decreases.

The sorption properties of the polymers in question were evaluated by studying sorption of iron, copper, nickel, and cobalt (C_m = 1 mg ml^{-1}) under the conditions used for recovery of noble metals.

After calcination of the polymer with the sorbed metal and dissolution of the residue the content of the metal was determined by atomic absorption spectroscopy. No sorption was observed and the content of metal in the initial solution reached 95–97%. These data show that noble metals are selectively recovered from 1 M solution of mineral acids.

The PVC sorbent and its concentrate with sorbed silver dissolve in DMF, which allows atomic absorption analysis of silver in DMF solutions after preliminary concentration. For example, a weighed portion of PVC sorbent was placed into a 1 M HNO_3 solution containing certain amounts of silver and non-noble metal ($C_{Ag} : C_M$ = 1 : 40). The concentrate was recovered and treated with DMF (10 ml). The content of silver was determined from the calibration curve plotted using the standard solutions of silver in DMF containing sorbent in the amounts required for sorption. It was found by atomic absorption spectroscopy of DMF solutions that 95–97% of silver is recovered at its initial concentration of 1.0–2.5 μg ml^{-1}. Dissolution of the concentrate in an organic solvent significantly simplifies the sample preparation.

EXPERIMENTAL

The colorless crystalline VC monomer (mp 61°C, soluble in organic solvents) was prepared in a yield of 85% by the procedure given in [3]. Maleic anhydride (mp 52.8°C) was twice recrystallized from chloroform and vacuum-sublimed over P_2O_5. ST, VA, AIBN, and solvents were purified using common procedures [8]. The IR spectra were registered on an IFS-25 spectrophotometer (KBr pellets). The radical polymerization was performed in the ampules using a high-vacuum setup, the process was controlled with an MKDP-2 isothermal microcalorimeter. Under the conditions of radical polymerization (70–90°C, 0.03% AIBN concentration) the VC homopolymerization does not proceed to a noticeable extent (yield lower than 1% at 1.3% conversion). The molecular weight of the polymer products was determined in THF on a Waters liquid chromatograph equipped with a Data Modul-730 integrator by gel-permeation chromatography. The columns were packed with ultra silica gel (10^4, 10^5, and 10^6 Å pore size). The polymer compositions were evaluated from the content of nitrogen and sulfur [9].

The sorption properties were determined under the steady-state conditions upon the contact of the required polymer sample with a solution of mineral acid of certain concentration containing required amount of metal. The residual concentration of silver and gold was determined by the atomic absorption method [10], whereas the content of mercury was determined spectrophotometrically using dithizone [11]. The content of metal in the solid phase was evaluated as the difference between the initial and residual concentrations of metal in the solution.

The solutions of silver and mercury nitrates (1.00 and 3.6 mg ml^{-1}) and hydrochloric acid solution of gold (1.62 mg ml^{-1}) were used as initial references.

CONCLUSIONS

(1) Linear homopolymer of *N*-(vinyloxyethyl)-dithiocarbamoylethylcarbonitrile (molecular weight 5200–5500) and its copolymers with maleic anhydride, vinyl acetate, and styrene were prepared by cationic polymerization. The polymer compositions are almost independent of the monomer ratio in the initial reaction mixture.

(2) Homopolymer of *N*-(vinyloxyethyl)dithiocarbamoylethylcarbonitrile and its copolymer with styrene are stable in 1–6 M solutions of hydrochloric, sulfuric, and nitric acids and effectively recover silver, gold, and mercury from multicomponent solutions in 10–30 min. The sorption–atomic absorption procedure to determine silver using DMF solutions of the concentrate was proposed.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Modeling of Gaseous Chlorine Production in a Static Electrolyzer

G. S. Zenin and A. M. Sazonov

St. Petersburg Northwest Polytechnic Institute, St. Petersburg, Russia

Received March 20, 2000

Abstract—Transfer of hydroxide and hydroxonium ions in bulk of sodium chloride solution in the course of gaseous chlorine production in a static electrolyzer was considered and a relationship was derived to determine the characteristics of a chlorinator. Principles of selecting electrolyzer currents to obtain gaseous chlorine in a static chlorinator were recommended.

Sodium hypochlorite produced by electrolysis of sodium chloride solutions is used in water treatment [1–3]. Since the resulting solutions also contain sodium chloride, it is fed into water being treated together with the hypochlorite solution, which results in increased consumption of the salt and excessive mineralization of water.

There are some data [4, 5] on the electrochemical production of gaseous chlorine for water decontamination in reactors similar in design to those used in the chlorine industry [6]. However, the implementation of this process in water-treatment stations requires complicated process schemes.

In the early stage of development of the chlorine industry, gaseous chlorine was produced in static electrolyzers, for which a qualitative theory of the electrolysis process was developed [7–9], and semiempirical relationships concerning interelectrode transfer of hydroxide and hydroxonium ions were obtained. These ions, generated in the course of electrolysis, determine the current efficiency with respect to gaseous chlorine [10]. The publications on the production of gaseous chlorine in static electrolyzers practically do not consider the effects of design characteristics of reactors on the current efficiency with respect to gaseous chlorine and on the electrolyte service life as a function of the electrolysis current.

To determine the ratio between the volumes of anodic and cathodic zones and to substantiate the optimum electrolysis conditions, we simulated in this work the operation of a chlorinator.

The relationships in gaseous chlorine formation in static electrolyzers are determined, along with the electrode current density, by the anolyte acidity, which depends on the conditions of the transfer of hydroxide ions generated on the cathode and of hydroxonium ions generated on the anode at simultaneous formation of oxygen and chlorine, and also on secondary reactions in solution involving dissolved chlorine [6]. During the electrolysis, simultaneously with the transfer of sodium ions and chlorine, hydroxide ions are transferred to the anode and hydroxonium ions, to the cathode. The ions form in the interelectrode space a neutral boundary whose width and position depend on the migration and diffusion flows in the bulk of solution:

$$j_a = j_-^m + j_-^d, \qquad j_c = j_+^m + j_+^d. \tag{1}$$

Here j_-^m, j_+^m, j_-^d, and j_+^d are the flows of the negative and positive ions driving under the action of migration and diffusion, respectively.

As the current efficiency with respect to gaseous chlorine at a constant current density is determined by the anolyte pH [11], we will consider a model of transfer of hydroxonium and hydroxide ions at a constant sodium chloride concentration (Fig. 1). Taking into consideration the condition of solution electro-

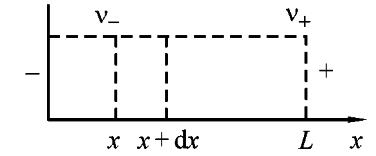

Fig. 1. Directions of ion flows in the electrolysis in a chlorinator with an immobile solution: (ν_-, ν_+) rates of the motion of hydroxide and hydroxonium ions from the cathode and anode, respectively; (L) chlorinator length; (x, $x + dx$) unit thickness of a solution layer.

neutrality, we can write the following expressions for hydroxide ions (c_-):

$$S\,dx\frac{dc}{d\tau} = Q_-^m + Q_-^d. \quad (2)$$

Here S is the area through which the amounts Q_-^m and Q_-^d of hydroxide ions are transferred in unit time $d\tau$ by migration and concentration diffusion, respectively;

$$Q_-^m = S\nu_- c_-(x) - S\nu_- c_-(x + dx),$$
$$Q_-^d = SD\,\partial c_-(x)/\partial x - SD\,\partial c_-(x + dx)/\partial x, \quad (3)$$

ν and D_- are the mobility and diffusion coefficient of hydroxide ions.

Substitution of Eq. (3) into (2) gives expression (4):

$$S\,dx\frac{\partial c_-}{\partial\tau} = S\nu_-[c_-(x + dx) - c_-(x)] - SD[\partial c_-(x + dx)/\partial x - \partial c_-(x)/\partial x], \quad (4)$$

or

$$\frac{\partial c_-}{\partial\tau} = \nu\,\partial c_-/\partial x - D_-\partial^2 c_-/\partial x^2. \quad (5)$$

For hydroxonium ions

$$\frac{\partial c_+}{\partial\tau} = -\nu\,\partial c_+/\partial x - D_+\partial^2 c_+/\partial x^2. \quad (6)$$

The right sides of Eqs. (5) and (6) represent changes in the ion flows due to migration and diffusion:

$$\frac{\partial c_\pm}{\partial\tau} = -\frac{\partial}{\partial x}(j_{a,c}), \quad (7)$$

The ion flows due to migration and diffusion in an anolyte and a catholyte, respectively, are [12]

$$j_a = \nu\,\partial c_- + D_-\partial c_-/\partial x, \qquad j_c = \nu\,\partial c_+ + D_+\partial c_+/\partial x. \quad (8)$$

Gaseous chlorine is formed with a sufficiently high current efficiency if a solution in the anodic zone is acidic or neutral [11], i.e., as long as a neutral boundary determined by condition (9) exists in solution:

$$j_a = j_c. \quad (9)$$

Expressions (7) and (8) give

$$\frac{\partial}{\partial\tau}(c_- - c_+) = 0.$$

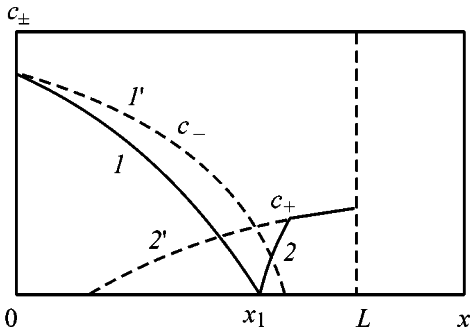

Fig. 2. Variation of the concentration of (*1, 1'*) hydroxide and (*2, 2'*) hydroxonium ions in the interelectrode space of a chlorinator (*1', 2'*) without and (*1, 2*) with the occurrence of recombination of hydroxide and hydroxonium ions.

or

$$c_- - c_+ = A. \quad (10)$$

The distribution of the concentrations in relation to the interelectrode distance is schematically presented in Fig. 2 for a hypothetical case when the chemical reactions on the boundary x_1 between the hydroxide and hydroxonium ions (curves *1'*, *2'*) are absent. The plot is based on the assumption that, because of the formation of gaseous chlorine, the current efficiency with respect to hydroxide ions is greater than the efficiency with respect to hydroxonium ions ($\eta_- > \eta_+$). Thus, for τ = const

$$c_-(x) > c_+(x), \qquad 0 < x < x_1,$$
$$c_+(x) > c_-(x), \qquad x_1 < x < L. \quad (11)$$

Actually the dependence of the concentrations of the hydroxide and hydroxonium ions on the interelectrode distance (Fig. 2) corresponds to curves *1* and *2*, which lie below curves *1* and *2* because of reduction in the concentrations of hydroxide and hydroxonium ions owing to a reaction between them, the parameter A being zero in the point x. As the migration component of the flows in Eqs. (1) is much greater than the concentration diffusion [12], we can neglect the latter in the first approximation. Then the dependence of the concentrations of the hydroxide and hydroxonium ions on the interelectrode distance and electrolysis time can be presented as

$$c_\pm = \frac{I\tau\eta_\pm}{FV_\pm} - \frac{(I_\pm l/E_\pm)_{\tau,x}}{FS\nu_\pm^0}. \quad (12)$$

Here $V_\pm$ is the volume of the alkaline or acidic zone of solution in a chlorinator; $\nu_\pm^0$ is the limiting mobility;

$\eta_\pm$ is the current efficiency with respect to hydroxide or hydroxonium ions in the electrolysis; I_+ is the fraction of current transferred by hydroxide or hydroxonium ions; $E_\pm/l$ is the electric field strength at the instant of time τ at the distance x from the electrode.

According to the data of [13],

$$(I_\pm)_{\tau,x} = I(T_\pm)_{\tau,x}, \quad (E_\pm/l)_{\tau,x} = I/S(\chi_\pm)_{\tau,x},$$

$$F\nu_\pm^0 = \lambda_\pm^0, \tag{13}$$

where $\chi_\pm$ and $\lambda_\pm^0$ are the specific and limiting equivalent conductivities of the hydroxide or hydroxonium ions, and $T_\pm$ is the transfer number of the ions.

Substituting expressions (13) in (12) and (12) in (10), in view of the relationship $A = 0$ valid under real electrolysis conditions, we obtain

$$\frac{I\tau\eta_-}{FV_-} - \frac{(T_-\chi_-)_{\tau,x}}{\lambda_-^0} - \frac{I\tau\eta_+}{FV_+} - \frac{(T_+\chi_+)_{\tau,x}}{\lambda_+^0} = 0. \tag{14}$$

Rearranging terms responsible for migration to the right side of Eq. (14), we obtain the equation describing the displacement of the neutral zone in a chlorinator in the course of electrolysis:

$$\frac{I\tau(\eta_-/V_- - \eta_+/V_+)}{F} = \frac{(T_-\chi_-)_{\tau,x}}{\lambda_-^0} - \frac{(T_+\chi_+)_{\tau,x}}{\lambda_+^0}. \tag{15}$$

Designating the chlorinator volume as V, we can express the volume of the anodic (acid) zone of a chlorinator as

$$V_+ = V - V_-. \tag{16}$$

In view of (16) we can bring expression (15) to the form

$$[\eta_-/V_- - \eta_+/(V - V_-)] = K, \tag{17}$$

$$K = \frac{F}{I\tau}\frac{(T_-\chi_-)_{\tau,x}}{\lambda_-^0} - \frac{(T_+\chi_+)_{\tau,x}}{\lambda_+^0}.$$

Equation (17) allows us to estimate the time of continuous operation of a chlorinator at a specified current.

According to Hittorf's law, it follows for the electrode balance with the neutralization of hydroxide and hydroxonium ions formed in the interelectrode space [14] that

$$\Delta c_- T_- = \Delta c_+ T_+, \tag{18}$$

where Δc_- and Δc_+ are the decreases in the concentration of hydroxide and hydroxonium ions in the catholyte and anolyte, respectively, due to their transfer to the neutral boundary where their recombination occurs.

In view of Eq. (18) and also of the expressions

$$(\chi_-)_{\tau,x}/\lambda_-^0 = \Delta c_- \text{ and } (\chi_+)_{\tau,x}/\lambda_+^0 = \Delta c_+,$$

it is evident that at $K = 0$ decreases in the concentrations of hydroxide and hydroxonium ions are in balance. Therefore, for stable operation of a chlorinator its volume should be related to the volume of its cathode zone by expression (19), which can be used to determine the design characteristics of the chlorinator.

$$V_- = V\frac{\eta_-}{\eta_- + \eta_+}. \tag{19}$$

Expression (19) is valid provided that the concentration of sodium chloride near the neutral boundary is constant, otherwise it is necessary to include in Eq. (15) additional terms responsible for the transfer of chloride and sodium ions. In practice, to maintain a constant concentration of sodium chloride in solution, it is appropriate to fill the interelectrode space with crystalline sodium chloride and to carry out the electrolysis at currents ensuring a slower decrease in the concentration of chloride ions in solution, compared to its growth due to sodium chloride dissolution. Furthermore, sodium chloride crystals, being a porous filling material, considerably reduce solution stirring [15]. As mixed solutions of sodium chloride and hydroxide have a greater density than a pure solution of sodium chloride [16], it is necessary to place the anode above the cathode, which will reduce gravitational convection of solution in a chlorinator.

The resulting relationship was used in designing and manufacturing ship plants for sewage treatment and disinfection [17], and the exploitation of the serial plants confirmed the results of our calculations [18].

CONCLUSION

A mathematical model of a chlorinator for the production of gaseous chlorine in a static electrolyzer was developed, which made it possible to deduce an expression for the calculation of design characteristics of the chlorinator.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic Dissolution of NiS in Sulfite Electrolytes

M. I. Natorkhin

St. Petersburg State Technical University, St. Petersburg, Russia

Received November 19, 1999; in final form, October 2000

Abstract—Electrochemical behavior of nickel sulfide in weakly acidic and ammonia electrolytes containing sulfite ions and also in copper sulfite electrolyte stabilized by EDTA was studied.

Since hydrometallurgical processing of copper–nickel ores is used at the majority of modern plants [1], the corresponding chemical reactions must be studied in more detail.

Laboratory modeling of complex multicomponent processes on separate samples under special conditions is regarded as promising [2, 3].

Autoclave decomposition of sulfides in aqueous medium by sulfur dioxide has been described in the literature [4]:

$$MS + 2SO_2 = MSO_4 + 2S,$$

This technique has several drawbacks. Sulfur is known [5] to dissolve readily in the presence of sulfite ion:

$$SO_3^{2-} + S = S_2O_3^{2-},$$

The SO_3^{2-} and $S_2O_3^{2-}$ ions are efficient complex-forming agents for copper [6, 7], which catalyzes the dissolution of nickel sulfide [8].

The aim of this work was to study in more detail the electrochemical behavior of pure nickel β-sulfide in sulfite-containing electrolytes.

To model the industrial process, nickel sulfide with a nickel content of 50% was synthesized from N0-grade nickel and analytically pure grade sulfur by the known procedure [9]. The working electrode was made from a nickel sulfide sample soldered to a copper current lead. The idle surface was insulated with a nitro lacquer. The operating surface (area 1 cm^2) was smoothed with emery paper no. 0 and washed with alcohol and distilled water. Cyclic voltammograms (CVA) and stationary voltammograms were recorded on a PI-50-1.1 potentiostat equipped with a PDP4-002 plane-table recorder. The experiments were carried out in a standard YaES-2 electrochemical cell (glass electrode cell). Its temperature was maintained at 90 ± 0.5°C with a UTU 2/77 thermostat. We used a three-electrode cell with nickel sulfide under study as an anode, a platinum cathode, and a saturated silver chloride auxiliary electrode (AgCl / Ag). The electrode potentials are given vs. normal hydrogen electrode. The electrolytes were prepared from analytically pure and chemically pure grade reagents.

It should be noted that the addition of Na_2SO_3 to copper sulfate in the cold results in an insignificant reduction of Cu^{2+} ions to Cu^+ ions and in formation of green complex compounds. With excess of Na_2SO_3 or on heating, brick-red Chevreul's salt is precipitated [10]:

$$3CuSO_4 + 3Na_2SO_3 + 3H_2O = CuSO_3 \cdot Cu_2SO_3 \cdot 2H_2O\downarrow + 3Na_2SO_4 + H_2SO_4.$$

Hence, simultaneous presence of $CuSO_4$ and Na_2SO_3 at 90°C is impossible. However, if a strong complexing agent L stabilizing Cu(II) ions is added to the electrolyte, Chevreul's salt is not formed and $[CuL_n]^{2+}$, a quantity of $[CuL_n]^+$, and Cu_2SO_3 (stability constant $\log\beta = 7.58$) will be present in the solution. As NiS is further dissolved at the anode and sulfur passes into the anolyte, more stable Cu(I) thiosulfate complexes $[Cu(S_2O_3)]^-$, $[Cu(S_2O_3)_2]^{3-}$, and $[Cu_2(S_2O_3)_3]^{4-}$ (stability constant $\log\beta = 10.35$) can be formed [11]. Disodium dihydrogen ethylenediaminetetraacetate (Na_2EDTA) was used as such a stabilizing agent [for Cu(II) $\log\beta = 18.86$].

The solubility of sodium sulfite decreases with increasing temperature, being 260 g l^{-1} at 90°C. However, the solubility of sodium thiosulfate, which can be formed, is approximately ten times higher. The CVA curves for nickel sulfide in Na_2SO_3 solutions

1070-4272/01/7401-0048$25.00

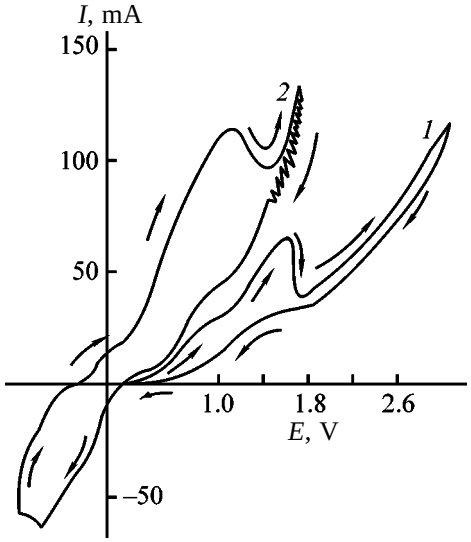

Fig. 1. Cyclic voltammograms of NiS in solutions containing (*1*) 100 and (*2*) 250 g l^{-1} Na_2SO_3. Potential sweep rate –100 mV s^{-1}, temperature 90 ± 0.5°C; the same for Figs. 2–4. (*I*) Current asnd (*E*) potential; the same for Figs. 2–4.

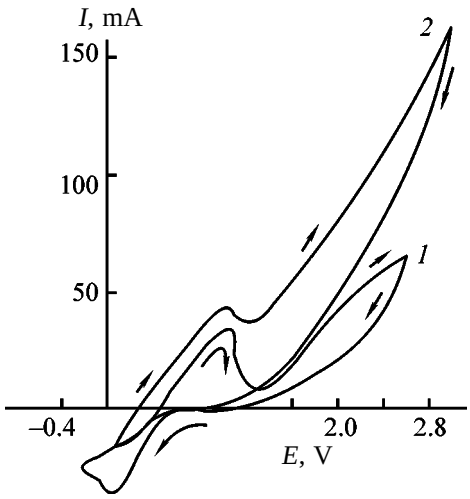

Fig. 2. Cyclic voltammograms of NiS in solutions of (*1*) 0.5 M $CuSO_4$ and (*2*) 0.5 M $CuSO_4$ + 20 g l^{-1} EDTA + 0.1 g l^{-1} Na_2SO_3.

of various concentrations (from 100 up to nearly saturated, 250 g l^{-1}) are shown in Fig. 1. An increase in the Na_2SO_3 concentration leads to a rise in the anodic current. In saturated Na_2SO_3 solution NiS actively dissolves to give loose bright green nickel hydroxide, which is precipitated on the cell bottom. A backward run of curve *2* in the potential range 1.8–1.4 V is accompanied by periodic current oscillations, which proves the presence of a semiconducting film on the electrode surface [12, 13] (possibly $NiSO_3$). The film causes a salt-type passivation.

An addition of significant amounts of Na_2SO_3 to a $CuSO_4$ solution at 90°C makes no sense because the Chevreul's salt is formed even in the presence of EDTA. A stable electrolyte containing 0.5 M $CuSO_4$, 20 g l^{-1} EDTA, and 0.1 g l^{-1} Na_2SO_3 was prepared in this work. Even such a minor addition of Na_2SO_3 results in significant changes in the electrolyte parameters. The solution becomes dark green. The CVA curves of nickel sulfide in a 0.5 M $CuSO_4$ solution and in a 0.5 M $CuSO_4$ solution containing 20 g l^{-1} Na_2EDTA and 0.1 g l^{-1} Na_2SO_3 are shown in Fig. 2.

In potentiostatic experiments at the potentials of NiS in the range 0.64–1.57 V, we observed a fast current drop (within 10–15 s) followed by current stabilization. This fact suggests formation of a film on the electrode surface which does not retard nickel sulfide dissolution (Fig. 3). In this case sulfur is deposited on the NiS surface. The intensity of green coloration of copper complexes remains almost unchanged even on a long-term electroleaching.

Oxidative leaching of sulfide raw materials with aqueous ammonia is widely used in industry [14]. At anodic polarization NiS does not dissolve in pure NH_4OH. The process course is significantly changed when sulfite ions are introduced. Two CVA curves for nickel sulfide in a solution containing 200 g l^{-1} Na_2SO_3 and 2% NH_4OH and in a solution containing 100 g l^{-1} Na_2SO_3 and 20% NH_4OH are shown in Fig. 4. In the anodic branch of curve *1* an area of insignificant electrode passivation is observed, which seems to be of a salt type.

In the case of the system containing 20% NH_4OH (curve *2*) NiS is actively dissolved without passivation. Blue-violet concentration flows of $[Ni(NH_3)_n]^{2+}$ are formed while the surface of nickel sulfide remains golden yellow. In the backward run of curve *2*, ran-

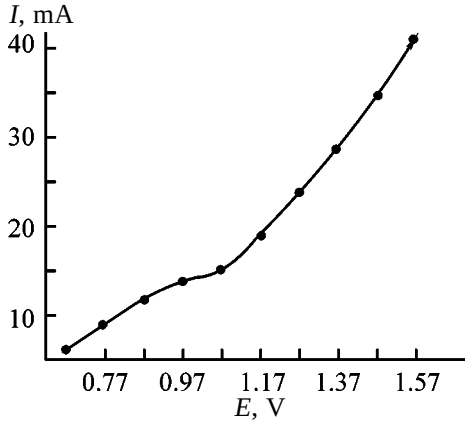

Fig. 3. Stationary polarization curve of NiS in 0.5 M $CuSO_4$ containing 20 g l^{-1} EDTA and 0.1 g l^{-1} Na_2SO_3.

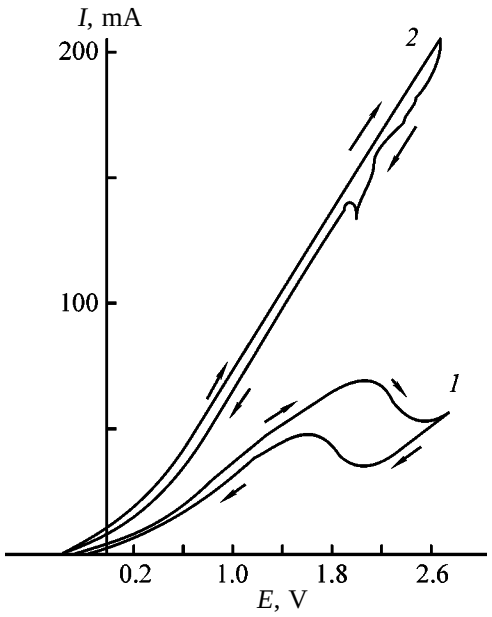

Fig. 4. Cyclic voltammograms of NiS in the solutions containing (*1*) 200 g l^{-1} Na_2SO_3 with 2% NH_4OH and (*2*) 100 g l^{-1} Na_2SO_3 with 20% NH_4OH.

dom current oscillations are observed, which seem to have the same origin as in the case of Fig. 1.

CONCLUSIONS

(1) In a pure Na_2SO_3 solution NiS actively dissolves with simultaneous formation of insoluble Ni^{2+} hydroxo compounds with a pH-dependent composition.

(2) It is possible to use Na_2SO_3 as a depolarizing addition to $CuSO_4$ in the presence of Na_2EDTA as a stabilizing complexone.

(3) Simultaneous action of NH_4OH and Na_2SO_3 results in active dissolution of NiS and formation of $[Ni(NH_3)_n]^{2+}$ complexes.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic Dissolution of Nickel Sulfide in Acidic Cu(II) Electrolytes

M. I. Natorkhin

St. Petersburg State Technical University, St. Petersburg, Russia

Received November 19, 1999; in final form, September 2000

Abstract—The effect of ligands on the anodic dissolution of NiS in copper-containing acidic electrolytes was studied.

Hydrometallurgical processing of non-ferrous metals is being actively developed at modern enterprises [1, 2]. It is known [3] that copper ions present in pressure leaching solutions have a significant catalytic effect on nickel sulfide dissolution. However, simultaneous presence of copper and sulfate ions results in passivation of the sulfide surface and, consequently, exerts an adverse effect on the process parameters.

The aim of this work was to study the effects of electrolyte anion composition and depassivating additions to sulfate electrolytes on the electrochemical behavior of nickel sulfide in copper-containing electrolytes. The origin of the catalytic action of copper ions is not fully understood. Pure copper is considered to be able to deposit at a sulfide surface [3] to form microgalvanic couples, which increase the anodic potential at certain parts of the surface. At the same time, Cu^{2+} ions in acid solutions can act as an additional oxidizing agent [4] capable of oxidizing sulfur in sulfides to the elemental form.

$$Cu^{2+} + 2e = Cu,\ E^0 = 0.334\ V;$$

$$Cu^{2+} + Cl^- + e = CuCl,\ E^0 = 0.538\ V;$$

$$Cu^{+} + e = Cu,\ E^0 = 0.521\ V.$$

It is copper which is likely to hinder further oxidation of elemental sulfur to sulfate ions, which is extremely convenient, as sulfide sulfur is removed from the process in the elemental form. We used β-NiS with a nickel content of 50 at. % as a subject of the study, because, according to [5], in the course of the oxidative dissolution of nickel sulfides Ni_3S_2 and Ni_7S_6, which occurs by the electrochemical mechanism [6], the surface is gradually enriched in a sulfide with a higher Ni content, up to NiS [7].

Nickel sulfide NiS (50 at. %) was synthesized by the known procedure [8] from equimolar amounts of cathodic N0-grade nickel and analytically pure grade sulfur in an evacuated quartz ampule. The working electrode was made from a nickel sulfide sample soldered to a copper holder. Its idle surface was insulated with a nitro lacquer. Before experiments the NiS surface under study (area 1 cm^2) was smoothed with emery paper no. 0 and washed with alcohol and distilled water. Experiments with fluorine-containing electrolytes were carried out in a fluoroplastic cell with a temperature-controlled water jacket. In the other cases a YaES-2 glass cell (glass electrode cell) temperature-controlled with a UTU 2/77 thermostat was used. Electrochemical experiments were carried out on a PI-50-1.1 potentiostat equipped with a PDP4-002 plane-table recorder. We used a three-electrode cell with nickel sulfide under study as a working electrode, a platinum auxiliary electrode, and a saturated silver chloride reference electrode (electrode potentials are given vs. normal hydrogen electrode). Electrolytes were prepared from chemically pure, ultrapure, and analytically pure grade reagents.

The following processes of oxidative dissolution of nickel sulfide in copper chloride and copper sulfate solutions were studied.

$$2CuCl_2 + NiS = NiCl_2 + 2CuCl\downarrow + S\downarrow, \quad (1)$$

$$2CuSO_4 + 2NiS = 2NiSO_4 + Cu_2S\downarrow + S\downarrow. \quad (2)$$

The processes have both advantages and drawbacks: process (1) involves high concentrations of chlorides hampering further electrolyte treatment, and process (2) requires high temperatures and pressures and also involves passivation of the NiS surface due to Cu_2S deposition. The accelerating effect of copper

1070-4272/01/7401-0051$25.00

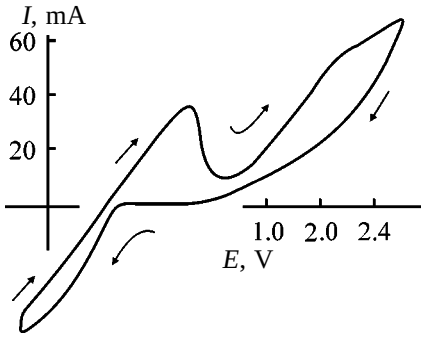

Fig. 1. Cyclic voltammogram of NiS in 0.5 M $CuSO_4$ at 90 ± 0.5°C: (*I*) current and (*E*) potential; the same for Figs. 3–5. Rate of potential scanning 100 mV s^{-1}; the same for Figs. 4 and 5.

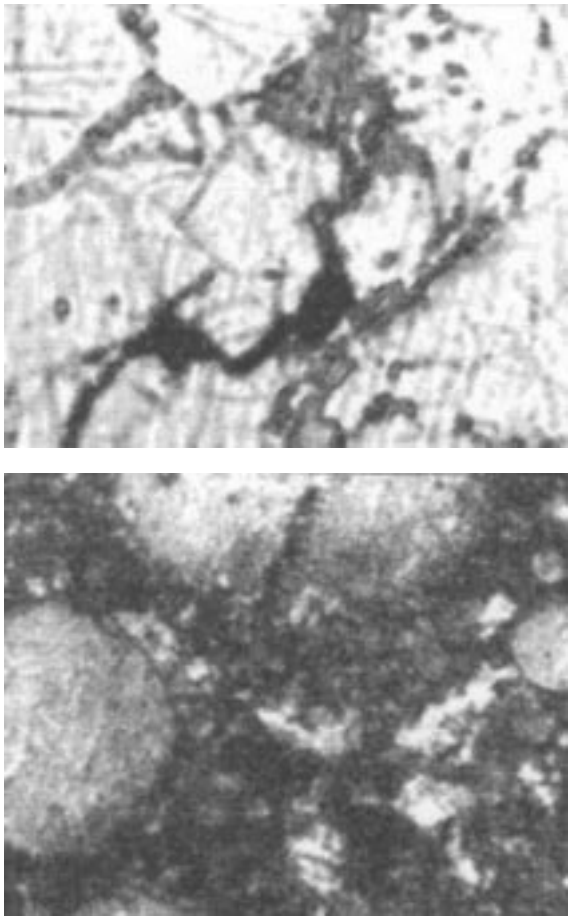

Fig. 2. Photomicrographs of NiS etched for 2 min at a potential of 1 V in (a) 0.5 M $CuSO_4$ at 20°C and (b) 0.5 M $Cu(NO_3)_2$ + 200 g l^{-1} KBr at 90°C. Magnification: (a) 800 and (b) 10.

activators on the anodic dissolution of NiS is due to the possibility of removing insoluble copper products from the nickel sulfide surface owing to the formation of copper(I) complex ions under certain conditions [9].

Sulfate ions do not form complexes with copper(I) ions under common conditions [9]; therefore, the steady-state currents of NiS dissolution are insignificant. As chloride ions form sufficiently stable complexes with Cu(I) ions, copper contained in a Cu_2S passivating film can partially pass into solution in the form of $[CuCl_2]^-$ ions, which is observed in the experiments. An increase in the concentration of chloride ions (addition of NaCl) can result in a rise of the NiS dissolution currents.

The cyclic voltammogram (CVA) obtained on NiS in 0.5 M $CuSO_4$ (pH 2.2) at 90°C is shown in Fig. 1. The anodic peak in the forward branch seems to be due to the dissolution of both NiS and copper deposited in the course of cathodic polarization.

The electroetching of an NiS sample in 0.5 M $CuSO_4$ for 2 min at a potential of 1 V results in the formation of a new phase on the nickel sulfide surface. A photomicrograph of the etched part is shown in Fig. 2a. The light-colored phase is the starting nickel sulfide. The composition of the dark-colored phase is (mol %) S 54.6–52.8 and Ni 45.4–47.3. This phase probably corresponds to Ni_3S_4 in the Ni–S phase diagram [10].

Anodic dissolution of NiS in $CuCl_2$ occurs according to Eq. (1), whereas in excess NaCl it is described by the equation

$$CuCl_2 + NiS + 2NaCl = 2NaCuCl_2 + NiCl_2 + S\downarrow. \quad (3)$$

The behavior of NiS in 0.5 M $CuCl_2$ at various rates of potential scanning is shown in Fig. 3. As known [11], in the case of diffusion control the peak current (I_p) is proportional to $V_s^{1/2}$ (V_s is the rate of potential scanning). The peak current I_p and passivation current I_{pas} as functions of potential sweep rate are given below:

V_r, mV s^{-1}	I_p, mA	I_{pas}, mA
10	32	10
100	65	20
200	91	37

Applying the linear regression approach to these data, we obtained the formula

$$I_p = 14.3 + 5.3\ V_s^{1/2}. \quad (4)$$

The effect of NaCl addition in amounts of 50–200 g l^{-1} to 0.5 M $CuCl_2$ on the forward branches of CVA is shown in Fig. 4. The anodic peak observed in the region of 0.1 V is shifted to the cathodic region,

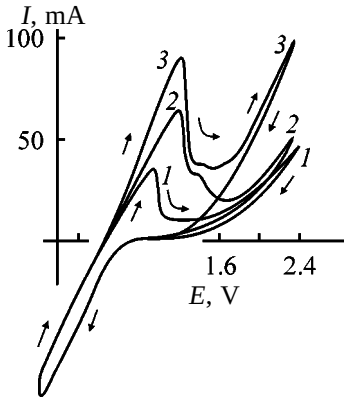

Fig. 3. Cyclic voltammogram of NiS in 0.5 M $CuCl_2$ at 90 ± 0.5°C. Potential scanning rate ($mV\ s^{-1}$): (*1*) 10, (*2*) 100, and (*3*) 200.

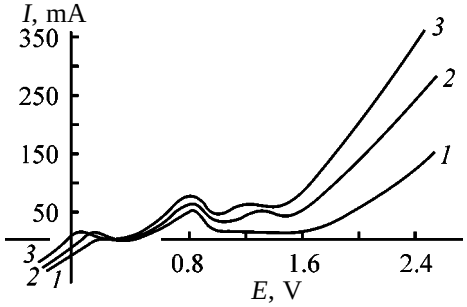

Fig. 4. Voltammograms of NiS in 0.5 M $CuCl_2$ with NaCl additions at 90 ± 0.5°C. NaCl ($g\ l^{-1}$): (*1*) 50, (*2*) 100, and (*3*) 200.

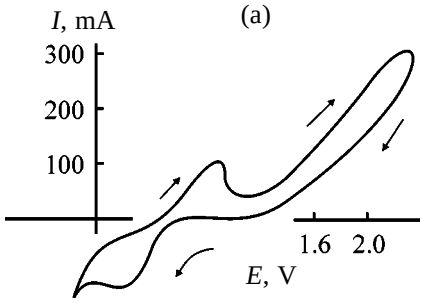

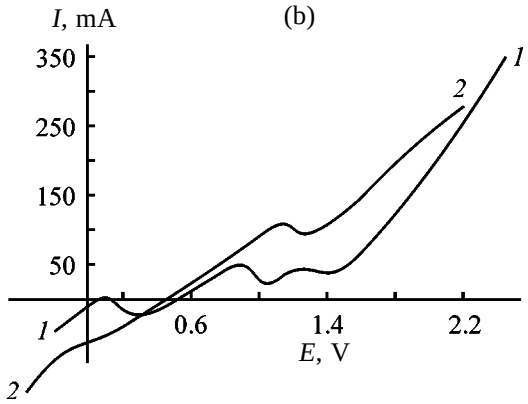

Fig. 5. Voltammograms of NiS (a) in 0.5 M $Cu(NO_3)_2$ at 90 ± 0.5°C and (b) in (*1*) 0.5 M $CuCl_2$ + 200 $g\ l^{-1}$ NaCl and (*2*) 0.5 M $Cu(NO_3)_2$ + 200 $g\ l^{-1}$ KBr.

whereas the peak current in the region of 0.8 V increases by 30–40% as the concentration of chloride ions increases. A significant increase (from 10 to 70 mA) of the current corresponding to the passivation plateau points to partial dissolution of the passivation film due to formation of $[CuCl_2]^-$ [12, 13].

The cyclic voltammetric curves of NiS dissolution in 0.5 M $Cu(NO_3)_2$ solution and in 0.5 M $Cu(NO_3)_2$ solution with addition of 200 $g\ l^{-1}$ KBr are shown in Figs. 5a and 5b, respectively.

Comparison of the anodic branches of the NiS CVAs in 0.5 M $Cu(NO_3)_2$ with addition of 200 $g\ l^{-1}$ KBr and NaCl (Fig. 5b) showed that in the case of chlorides (curve *1*) dissolution of the passivating film (convex section) occurs in the potential range 1.1–1.4 V, and in the case of nitrates (curve *2*) it occurs at 2–3 times greater passivation currents. Furthermore, the passivating film is displaced from the electrode surface by molten sulfur (Fig. 2b). At high anode potentials in the nitrate–bromide system the passivating film is absent from the electrode surface, and only the bright golden NiS surface and molten sulfur are observed. The passivating surface film is formed at low anode potentials (0.6–0.8 V) and is dissolved as the potential is increased to 1.0–1.2 V. In the course of the dissolution molten sulfur is formed (light circular parts), which tightly adheres to the sulfide surface and gradually displaces the passivating film. With 10 $g\ l^{-1}$ of KBr added to $Cu(NO_3)_2$, the rates of NiS dissolution are greater than in the case of addition of 200 $g\ l^{-1}$ NaCl to $CuCl_2$. Therefore, KBr additions are more efficient and more suitable for further processing of nickel-containing solutions.

CONCLUSIONS

(1) Anions capable of complex formation with both Cu(II) and Cu(I) ions accelerate anodic dissolution of NiS in copper-containing electrolytes.

(2) The rates of anodic dissolution are the highest in the nitrate–bromide system, as the Cu_2S film formed at low potentials is dissolved by copper bromide complexes and thus is completely displaced by molten sulfur formed on the NiS surface.

(3) A new surface phase, probably Ni_3S_4, is initially formed upon anodic dissolution of NiS in $CuSO_4$.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Discharge Characteristics of an $LaAl/C_8CrO_3$ Lithium Battery with Organic Electrolyte

L. N. Ol'shanskaya, S. S. Popova, A. G. Nichvolodin, and A. A. Ol'shanskaya

Technological Institute, Saratov State Technical University, Engels, Russia

Received December 7, 1999; in final form, March 2000

Abstract—Applicability of Paykert's equation, which relates the battery capacity to the discharge current, to prototypes of $LiAl/C_8CrO_3$ lithium batteries with an organic electrolyte (1 M $LiClO_4$ in a 1 : 1 mixture of propylene carbonate and dimethoxyethane) was examined. Pressed and rolled samples with and without modification of the C_8CrO_3 electrode with manganese dioxide were tested in the 0–50°C range.

Lithium batteries find a wide and steady demand in the market of chemical current sources. Their undoubted advantages over traditional chemical current sources are high specific energy (150–300 W h kg^{-1} and higher), wide operating temperature range (–30 to +60°C), high discharge voltage (3.0–3.5 V), hermetically sealed design, possibility of using in any position in space, tolerance for magnetic field and X-ray radiation, and the use of available and environmentally clean raw materials [1–3]. However, their high fire and explosion hazared, as well as the absence of reliable theories describing behavior of various types of batteries under such conditions, make difficult their large-scale application.

The aim of this work was to study the discharge characteristics of $LiAl/C_8CrO_3$ batteries of pressed and rolled designs with a nonaqueous organic electrolyte [1 M $LiClO_4$ in a mixture of propylene carbonate (PC) and dimethoxyethane (DME) taken in a 1 : 1 volume ratio] within the 0–50°C range and to find out whether the dependence of the capacity of such batteries on the discharge current can be described by the Paykert's equation $I^{n-1}C = K$.

On the basis of the experimental time dependences of the discharge voltage at various discharge currents [4, 5] we have simulated the discharge process and examined the relations between the battery capacity and the discharge current. It was shown that a number of internal (weight of active substances, their physicochemical properties, and design features of chemical current sources) and external (discharge current, temperature, humidity, etc.) factors affect the battery capacity, which is one of its most important electric characteristics.

Repeated efforts [4–9] were made to find a quantitative correlation between the discharge current of batteries and their actual discharge capacity, the Paykert's empirical equation being accepted as the most suitable:

$$I^n\tau = K, \tag{1}$$

whence

$$I^{n-1}C = K,$$

where n is a constant independent of capacity, which characterizes the battery type; K is a constant increasing with the weight of the active materials in the battery; C is the battery capacity (A h or mA h).

For the first time the Paykert's equation was suggested for lead batteries, but it can also be applied to chemical current sources based on the other systems [3, 4, 6, 10]. The constants n and K for a battery can be found from the experimental parameters of its operation in two different modes [10]. If the discharge time is τ_1 at the discharge current I_1, and τ_2 at I_2, then, according to Eq. (1),

$$I_1^n\tau_1 = I_2^n\tau_2 = K. \tag{2}$$

This equation in the logarithmic form for n is

$$n = \frac{\log\tau_2 - \log\tau_1}{\log I_1 - \log I_2}. \tag{3}$$

Hence, for the battery capacity C we have

$$C = KI^{1-n}. \tag{4}$$

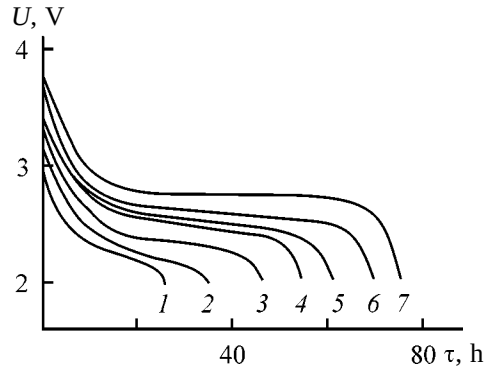

Fig. 1. Discharge curves *U*–τ (I_2 = 10 mA) of pressed and rolled lithium batteries $LiAl/LiClO_4$ + PC + DME/C_8CrO_3 at various temperatures. Temperature (°C): (*1*) 0, (*2*) 10, (*3*) 15, (*4*) 20, (*5*) 30, (*6*) 40, and (*7*) 50.

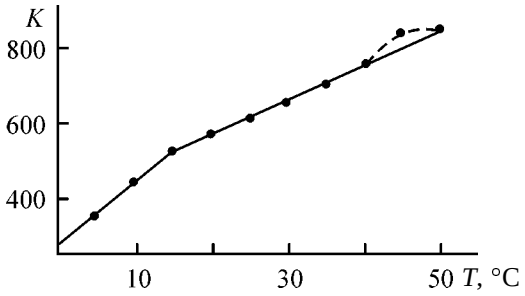

Fig. 2. Constant *K* of the Paykert's equation as a function of temperature *T* (°C).

An examination of the discharge characteristics (Fig. 1) and the determination of the constants *n* and *K* for the developed prototypes of pressed and rolled $LiAl/C_8CrO_3$ batteries of the *R*6 (316) dimension type (see table) showed that *n* varies in the range 1.02–1.13 and is almost independent of temperature, battery design, and composition of active masses of the electrodes. On the contrary, the constant *K* is a linear function of temperature, the temperature coefficient $\Delta K/\Delta T$ decreasing on passing from the 0–15°C to 15–50°C range (Fig. 2). The presence of two temperature ranges with different $\Delta K/\Delta T$ values may be due to specific features of lithium intercalation–deintercalation in active masses of the electrodes of the $LiAl/C_8CrO_3$ chemical current sources under development [11]. In the case of lead batteries the constant *K* linearly depends on temperature in the range from –20 to +20°C, and *n* varies from 1.35 to 1.72 [4, 12, 13].

Examination of the data in the table for the prototypes of $LiAl/C_8CrO_3$ lithium batteries shows that the constant *K* for the rolled batteries is higher by approximately 25% than for the pressed batteries.

Thus, the analytical dependences obtained show that the Paykert's equation can be applied to find a quantitative correlation between the actual discharge capacity of an $LiAl/C_8CrO_3$ battery and its discharge current in the I_{50}–I_{500} discharge mode (or from 0.02

to 0.002 C_{nom}) within the 0–50°C range. It follows from a formal comparison that the constants n and K calculated for lithium batteries are lower than the published characteristics of lead batteries [4, 12, 13], which can result from the fact that the discharge parameters of these systems differ by a factor of tens or even hundreds.

Abstract—Oxidation of I^- and S^{2-} anions on the silica gel surface by atmospheric oxygen was studied at room temperature. The possibility and rate of oxidation processes are determined by the content of silica gel and oxygen in the systems. Tentative interpretation of the results is based on the assumption that a highly reactive singlet $^1O_2$ species is formed in the oxygen ensemble on the silica surface.

Molecular oxygen can be transferred into an electronically excited singlet $^1\Delta_g$ state in a number of ways, including dye-sensitized photoexcitation in solutions [1–9] and zeolites [10, 11], decomposition of unstable oxygen-containing substances [1, 2, 12], laser evaporation of metal oxides [13, 14], and microwave discharge [2, 15]. The relatively long lifetime (10^{-3}–10^{-6} s in solutions), moderately high excitation energy (22.54 kcal mol^{-1}), and high chemical activity of the singlet form $^1\Delta_g$ of oxygen allow it to be considered as actual oxidizing agent in various processes, including those practically important [1–15].

It is a common knowledge that the solid substance most widely occurring in the nature, silicon dioxide, does not possess under standard conditions any redox properties, at least at the temperature of ambient air. At the same time, it cannot be positively stated that molecules with enhanced reactivity in electronically excited singlet state cannot be present in the oxygen ensemble even at room temperature under conditions of dynamic equilibrium between the SiO_2 surface and the gas phase. The excess amount and the nonuniform distribution of the surface energy may be a reason for conversion of some (presumably only a minor) part of paramagnetic $^3O_2$ molecules into the paired-spin state $^1O_2$. The energy necessary for this to occur is relatively low and, presumably, can be provided by fluctuations of the SiO_2 surface energy.

This hypothesis was the reason for undertaking the present investigation. In choosing a means of verification of the hypothesis, it was necessary to keep in mind not only the low concentration of excited oxygen molecules, but also the high probability of their impact deactivation, drastically impairing the possibility of their direct detection. In this connection, it seemed the most appropriate to assess experimentally the possibility of oxidation of a number of substances at room temperature directly on the silica surface with the aim of ensuring the involvement in the process of a finite fraction of singlet oxygen present on the surface.

Below are presented the results obtained in studying two heterogeneous reactions involving atmospheric oxygen. The first of these is oxidation of the iodide ion to molecular iodine. The choice of this reaction is governed by the reliably established fact that I^- is oxidized at room temperature neither by atmospheric nor by pure oxygen, whereas under the action of ozone [16] or singlet oxygen [17] this process occurs. The second reaction, oxidation of the sulfide ion on silica gel, is of particular interest in view of the possibility of occurrence of successive oxidative transformations and the wide variety of the involved charge states of sulfur.

EXPERIMENTAL

The study was performed on ultrapure silica gel S-157 (Fisher) with a specific surface area of 700 $m^2 g^{-1}$, giving reason to expect that analytically detectable content of oxidation products can be reached. All experiments were carried out at 25°C using a 0.1-mm sieved fraction of silica gel particles.

The rate of I^- oxidation in an aqueous suspension of a silica gel of a given type at a constant temperature is determined by the I^- and O_2 concentrations. An excess of I^- in the working solution can be used, in fact ensuring $[I^-]$ = const. The concentration of oxy-

1070-4272/01/7401-0058$25.00

gen is determined by the conditions of its supply into the system, i.e., by the intensity of bubbling and stirring. With the number of variable parameters deliberately restricted, the aim was to reveal the very possibility of oxidation and determine the fundamental conditions for its occurrence. For example, in a set of experiments, 50 ml of an aqueous KI solution was added to variable weighed portions of silica gel and stirred with a magnetic stirrer in open vessels in air, with the resulting suspension sampled at regular intervals of time, centrifuged, and analyzed for the content of molecular iodine. In order to ensure additional enrichment of the suspensions with oxygen, air was bubbled at a rate of 30 and 50 $cm^3\ min^{-1}$. In some experiments, oxidation of the iodide ion, unhindered by oxygen diffusion, was studied. For this purpose, 0.5-g portions of silica gel were impregnated with 2 ml of 1 M KI solution and exposed to air. After a prescribed time elapsed, the same solution was added to the weighed portions, with the solution volume brought to 50 ml, the suspensions were thoroughly stirred, and samples were taken for analysis.

The appearance and accumulation of molecular iodine in solution was recorded photometrically on a Shimadzu UV-2401 PC automated spectrometer in quartz cells with optical thickness of 1 cm. The enhanced solubility of iodine in solutions containing an excess of I^- ions is due to the formation of stable associates $I_2 \cdot I^-$ [17]. The electronic spectrum of I_3^- contains no broad band characteristic of an aqueous solution of iodine, whereas two peaks in the UV are close and furnish an opportunity for direct photometric determination of molecular iodine (Fig. 1). A calibration procedure demonstrated that the Bouguer–Beer law is observed at λ_{max} = 351 nm with a molar extinction coefficient $\varepsilon = 1.851 \times 10^4\ l\ mol^{-1}\ cm^{-1}$ in the concentration range 0.01–0.1 mM I_2 in a 1 M solution of KI, which well matched the goal of analytical measurements in the experiments.

The extent of oxidation of the sulfide ion on the silica gel surface and the possibility of formation, in the process, of sulfur oxides SO_2 and SO_3 were determined by Fourier ion-cyclotron resonance mass spectrometry on an IonSpec OMEGA 50 instrument. A glass ampule containing ca. 4 g of silica gel impregnated with a 1 M aqueous solution of $(NH_4)_2S$ and then kept in air was connected to the input for taking gas samples, and all components desorbed into the analyzer chamber by evacuation at room temperature were recorded. In experiments on S^{2-} oxidation in aqueous suspensions, 50 ml of 1 M $(NH_4)_2S$ solution was added to weighed portions of silica gel, and the

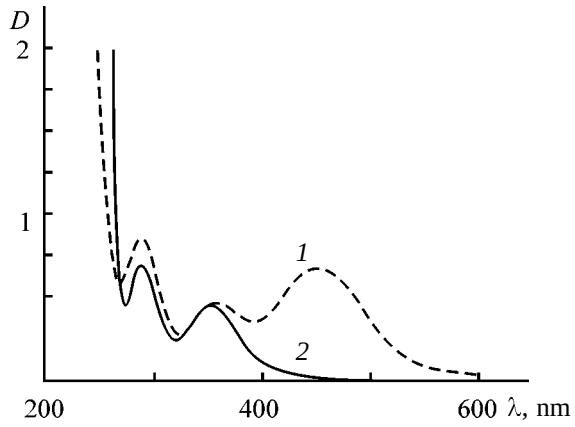

Fig. 1. Electronic spectra of iodine in (*1*) water and (*2*) 1 M solution of potassium iodide. (*D*) Optical density and (λ) wavelength; the same for Fig. 2.

mixture was stirred with a magnetic stirrer in open vessels in air.

Suspension samples taken at certain intervals of time were centrifuged and analyzed on a Dionex DX-100 liquid ion chromatograph equipped with an electrical conductivity detector and a 250-mm-long column packed with an anion-exchange resin containing bound ammonium groups. Preliminary calibration experiments demonstrated that sulfide ions are partially sorbed and/or smeared over the column in analyzing aqueous solutions containing mixtures of S^{2-}, SO_3^{2-}, and SO_4^{2-} anions in concentrations of the order of tens of ppm and, therefore, are not recorded, whereas sulfite and sulfate ions are determined together, without being separated, and are eluted as a single peak with a retention time of 3.7–3.8 min.

Formation of molecular iodine can be reliably established already during the first minutes after placing a weighed portion of silica gel in a starch-containing KI solution by the appearance of a characteristic light blue coloration. The oxidation of the iodide ion can also be observed visually in the absence of starch owing to the fast appearance of yellow coloration, particularly noticeable on the surface of silica particles and passing into solution on stirring. A typical set of spectra illustrating the accumulation of the $I_2 \cdot I^-$ form of molecular iodine are shown in Fig. 2; they completely coincide with the spectra of iodine in 1 M KI solution, taken in the course of calibration (Fig. 1). Thus, the fact of iodide ion oxidation on the silica gel surface is beyond doubt.

The essential role of the rate of oxygen supply to the silica gel surface in the course of oxidation is clearly demonstrated by the dependence in Fig. 3. The noticeable production of molecular oxygen in the ini-

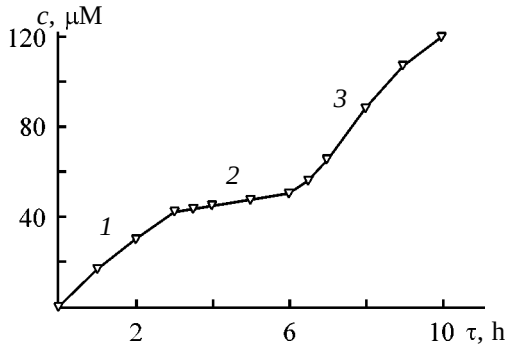

Fig. 3. Iodine concentration *c* vs. time τ of oxidation in 50 ml of 1 M KI solution containing 0.5 g of suspended silica gel. (*1*) Stirring with magnetic stirrer (150 rpm), (*2*) no stirring, and (*3*) stirring with additional bubbling of air (50 $cm^3\ min^{-1}$).

tial stage is largely ensured by the amount of oxygen present in silica gel pores and by gas supply into the system, enhanced by stirring. Switching-off the stirrer (portion *2*) lowers the content of oxygen, decelerating the oxidation. In portion *3* of the curve, the process is intensified by bubbling air through the system at a rate of 50 $cm^3\ min^{-1}$.

The kinetic curves presented in Fig. 4 furnish additional evidence in favor of the oxygen activation on the silica gel surface. The increase in silica gel mass under conditions of continuous stirring is accompanied by nearly proportional acceleration of molecular iodine formation (curves *1–3*). Air bubbling largely lifts the diffusion limitation on oxygen supply, markedly intensifying the oxidation (curves *4*, *5*). The process is accelerated to an even greater extent in the case of direct access of air to the surface of silica gel impregnated with 1 M KI solution (curve *6*).

In the aggregate, the obtained results suggest that an electronically excited $^1O_2$ species is present in the ensemble of oxygen molecules adsorbed onto the silica gel surface, ensuring the occurrence of the reaction

$$4I^- + {}^1O_2 + 2H_2O \rightarrow 2I_2 + 4OH^-, \quad (1)$$

$$2I_2 + I^- = I_3^-. \quad (2)$$

The involvement of just singlet oxygen in I^- oxidation seems to be the most likely, since formation of ozone and, the more so, of atomic oxygen requires gross energy expenditure. Appearance of charged oxygen species on the silica surface under so mild conditions is also hardly possible.

It should be emphasized that the oxidation rate is extremely low and the process can only be recorded because of the high specific surface area of silica gel. The maximum amount of molecular iodine, obtained in 12 h of experiment, is mere 10^{11}–10^{12} molecules per 1 cm^2 of SiO_2 surface, i.e., a vanishingly small fraction of a conventional monolayer.

Quantitative monitoring of the oxidation of the sulfide ion on the silica gel surface is hindered by the wide variety of products obtained, reversibility of transformations, and partial removal of gaseous substances from the reaction zone. However, even the results of preliminary qualitative experiments allow rather important conclusions. It is known that solutions containing the sulfide ion gradually become turbid in air because of the liberation of elemental sulfur; however, this process is slow and its consequences can only be observed after a long time. For example, 1 M H_2SO_4 solution remains transparent for many hours. At the same time, placing in this solution a weighed portion of silica gel causes visually observable formation of elemental sulfur on the surface of SiO_2 particles. Such a drastic acceleration of oxidation probably indicates that an active oxygen species is involved in the process:

$$2S^{2-} + {}^1O_2 + 2H_2O \rightarrow 2S + 4OH^-. \quad (3)$$

However, the oxidation in the system containing S^{2-}, O_2, H_2O, and solid SiO_2 does not terminate at this point and proceeds further with higher oxidation states of sulfur reached. Correspondingly, the mass spectrum of silica gel impregnated with 1 M solution of $(NH_4)_2S$ shows, together with the reliably recorded

components: N_2, O_2, H_2O, and H_2S, also stable weak signals with masses of 64 and 80, undoubtedly belonging to ionized oxides SO_2 and SO_3 (Fig. 5). It is possible, in principle, that SO_2 formation is a result of direct oxidation of sulfide ions by singlet oxygen on the silica gel surface:

$$2S^{2-} + 3^1O_2 + 2H_2O \rightarrow 2SO_2 + 4OH^-. \quad (4)$$

However, even in the case when oxidation proceeds in two successive stages, the occurrence of the reaction (following the liberation of elementary sulfur)

$$S + {}^1O_2 \rightarrow SO_2 \quad (5)$$

at room temperature seems to be rather uncommon and illustrative. The final stage of oxidation

$$2SO_2 + {}^1O_2 \rightarrow 2SO_3 \quad (6)$$

again indicates that highly reactive singlet oxygen is present on the silica gel surface. In all probability, along with the above reactions in the suspension, there occur equilibria and transformations typical of charged sulfur species, e.g.:

$$SO_2 + H_2O \rightleftarrows H_2SO_3 \rightleftarrows H^+ + HSO_3^- \rightleftarrows 2H^+ + SO_3^{2-}, \quad (7)$$

$$2SO_3^{2-} + {}^1O_2 \rightarrow 2SO_4^{2-}, \quad (8)$$

$$SO_2 + 2H_2S \rightarrow 3S + 2H_2O, \quad (9)$$

$$2SO_3 + S \rightarrow 3SO_2, \quad (10)$$

and also some others, including those involving unstable polythionic acids. The wide variety of possible reactions, and also partial removal of gaseous products from the system, may give rise to fluctuations in the content of sulfite and sulfate ions being formed. Indeed, these latter can be detected in the suspension soon after the onset of oxidation (Fig. 6), and their concentration changes, on the general background of growth, in a clearly nonmonotonic manner.

Thus, the above examples indirectly confirm the presence of singlet oxygen on the silica surface under standard conditions. It is the chemical activity of singlet oxygen that is presumably responsible for the oxidation on the SiO_2 surface of substances quite stable at the temperature of the ambient air. The large specific surface area of silica gel makes it possible to record oxidative transformations limited by low content of active oxygen under laboratory conditions. Consequently, there is good reason to believe that the

investigated, and many similar (which is not improbable) processes are of fundamental importance in the nature in view of the overwhelming predominance of silica on the Earth's surface and also in water basins, in suspended and precipitated states.

Finally, it should be noted that the alternative hypothetical reason for "cold" oxidative catalysis on SiO_2, based on the concepts (extensively developed in the 1970–1980s [18, 19]) assuming that coordination-unsaturated electron-acceptor centers are present on the surface of amorphous varieties of silica, is rather unlikely. It is difficult to admit of the possibility of firm adsorption and strong polarization of reagents, necessary for lowering the activation barriers of oxi-

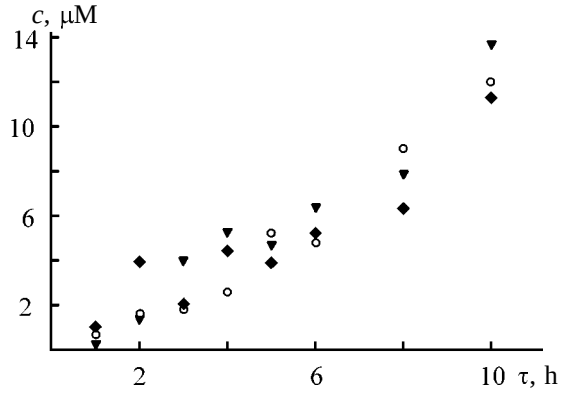

Fig. 6. Total concentration c of sulfite and sulfate ions vs. time τ of oxidation in a suspension of 1 g of SiO_2 in 50 ml of 1 M $(NH_4)_2S$ solution at a stirring rate of 100 rpm (three sets of experiments are represented).

dation processes. Moreover, the probability of reactions (1), (3), and (4) at coordination centers of silica gel is strongly limited by the action of the topochemical factor consisting in the necessity for attachment of several particles of the probable reactants in close proximity to ensure their interaction.

CONCLUSIONS

(1) The iodide ion is oxidized with oxygen at room temperature in suspensions of silica gel in aqueous KI solution to give I_3^- species.

(2) Stepwise oxidation of the sulfide ion with oxygen in suspensions of silica gel in aqueous solution of $(NH_4)_2S$, also proceeding at room temperature, gives elemental sulfur, SO_2, SO_3, and the anions SO_3^{2-} and SO_4^{2-}.

(3) The obtained results suggest that the electronically excited singlet species $^1O_2$ is involved in the oxidation reactions and serve as indirect evidence in favor of the hypothesis that oxygen can be activated on the silica surface.

Abstract—Oxide systems supported by α-Al_2O_3 and MgO were studied in oxidative dimerization of methanol. The highest selectivity is exhibited by tin oxide promoted with Na_2O and La_2O_3 supported by magnesium oxide. Reactions of partial oxidation and etherification of methanol and ethylene glycol proceed on this system to the same extent as dimerization of methanol to ethylene glycol.

Ethylene glycol, one of the most important products of petrochemical synthesis, is commonly obtained from ethylene raw materials whose price is steadily rising. A search for new routes to ethylene glycol without using ethylene is of practical interest. The most promising are techniques using as raw material directly synthesis gas or products of its processing (formaldehyde, methanol) [1, 2]. The already proposed procedures of ethylene glycol synthesis are multistage, endothermic, and economically unfeasible. A possibility was demonstrated [3, 4] of homogeneous oxidative pyrolysis of methanol to give ethylene glycol in up to 8% yield. In [5], it was proposed to synthesize dimethyl ethylene glycol ether by oxidation of dimethyl ether and to isolate ethylene glycol by subsequent hydrolysis. Heterogeneous catalytic dimerization of methanol into ethylene glycol in a flow-through reactor in a single stage may show more promise than the already proposed variations of synthesis. In addition to being practically important, this process is interesting in theoretical regard. The reactions of oxidative dimerization of methane and hydrocarbons in which a hydrogen atom in methane is replaced by an alkyl or aryl group (propylene, toluene) are well understood [6]. At the same time, reactions of dimerization of heterosubstituted methanes, e.g., CH_3OH, are little studied.

EXPERIMENTAL

Oxide supported catalysts were obtained by impregnation of α-Al_2O_3 and MgO supports with salt solutions and subsequent drying at 150°C for 4 h and calcination at 800°C for 6 h.

Experiments were done in a flow-through installation with a fixed catalyst bed. The ratio $CH_3OH : O_2 : N_2 = 4 : 1 : 4$, the time of contact was varied between 1 and 0.5 s. The reaction products were analyzed chromatographically. The reaction gases were analyzed for the content of CO_2, CO, O_2, N_2, and H_2 on an LKhM-80 chromatograph by a procedure described in [7]. The condensate was analyzed on a Khrom-5 chromatograph with a flame-ionization detector and 2.4-m-long column packed with Separon-SDA sorbent. Analysis conditions: column temperature 100°C; time 10 min, with subsequent programmed heating to 205°C at a rate of 10 deg min^{-1}; flow rate of carrier-gas helium 1.8×10^{-3} m^3 h^{-1}. The selectivity with respect to dimerization products was calculated as a total for ethylene glycol and its conversion products: glycolaldehyde, glyoxal, and di- and monomethyl ethers.

The phase composition of samples was determined on a DRON-3M diffractometer with CuK_α radiation. The specific surface area of the samples was measured chromatographically on the basis of low-temperature adsorption of argon.

The catalysts under study and their properties are characterized in Table 1. The key factor in choosing the catalytic systems was high selectivity in dimerization of methane (sample nos. 1–3, 5, 6) [6, 8, 9], toluene (sample no. 3) [6], and dimethyl ether (sample no. 4) [5].

Catalytic system nos. 1–4 promote nonselective oxidation of methanol to carbon oxides or its partial oxidation to formaldehyde, with products of dimerization found in the condensate in trace amounts. A study of the process of methanol dimerization in the batch mode on the lead–tin system, performed by

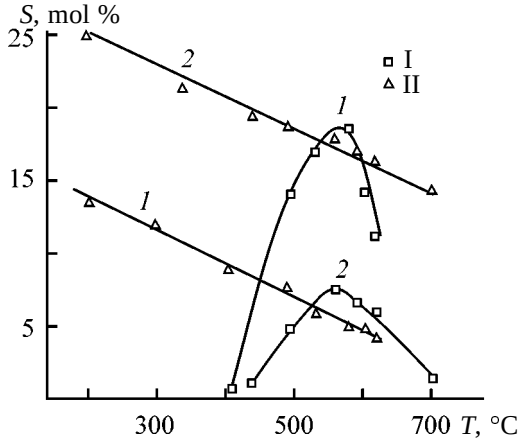
analogy with toluene dimerization [6] by alternately passing through the catalyst the oxidative mixture and methanol, also failed to give positive results since lead oxide was reduced to metal in the catalyst reduction cycle, and methanol underwent catalytic cracking with carbonization of the catalyst surface.



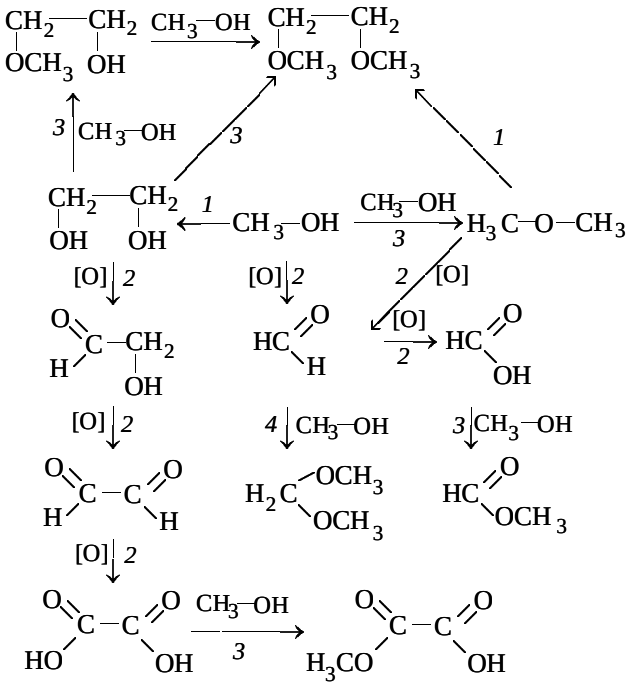
Selectivity *S* with respect to products of (I) dimerization and (II) partial oxidation of methanol vs. reaction temperature *T*. Catalyst: (*1*) 10% Na_2O–10% SnO_2/MgO and (*2–5*) 5% Na_2O–5% SnO_2/MgO.

It was found in studying the $Na_2O–SnO_2/MgO$ systems at reaction temperatures of up to 350°C that the main reactions also include partial oxidation of methanol to formaldehyde and its deep oxidation to CO_x (with mainly formaldehyde and methylal present among reaction products). The methanol conversion is about 25%. Trace amounts of ethylene glycol are detected in the condensate. Raising the temperature of the reaction on $Na_2O–SnO_2/MgO$ catalysts (nos. 4, 5) not only led to higher conversion, but also improved the selectivity with respect to the dimerization products (see figure). It should be noted that adiabatic heating-up of the catalyst bed within 30–40°C from the preset temperature was observed at temperatures of 400°C and higher.

The distribution of methane dimerization products in the condensate for magnesium–tin systems is presented in Table 2 in relation to temperature. The overall selectivity with respect to products of partial oxi-

dation and dimerization is not higher than 50% over the entire range of temperatures studied. Raising the reaction temperature to above 550°C leads to higher share of the reactions of nonselective oxidation and thermal decomposition of methanol and its conversion products to CO_x. Close temperature dependences of methanol conversion, selectivity, and distribution of dimerization products were obtained for the La_2O_3/MgO catalyst. The yield of dimerization products also increases beginning with 300°C, with the maximum yield observed at a reaction temperature of 550°C (Table 3).

According to the obtained data, the following scheme of oxidative transformations of methanol on magnesium–tin and lanthanum–magnesium systems can be suggested in the form of a set of successive and parallel reactions: dimerization (pathway *1*), partial oxidation of methanol to formaldehyde and formic acid (pathway *2*), partial oxidation of dimerization products (pathway *2*), etherification and esterification (pathway *3*), acetalization (pathway *4*), and deep oxidation and thermal decomposition of products to give CO and CO_2:



At longer time of contact and high conversion of methanol its major part is consumed for CO_x formation. The efficiency of the process can be raised by making the time of contact shorter and the methanol conversion lower; in this case, the share of undesirable reactions of partial ethylene glycol oxidation and etherification decreases. Owing to the large difference in evaporation temperature between methanol and ethylene glycol, recycling of the starting raw materials can be readily implemented.

Table 3. Effect of temperature on the yield of methanol conversion products. Catalyst La_2O_3/MgO

T, °C	Methanol conversion, %	Yield of products, mol %

Abstract—The effect of the volume of macropores (>100 nm) and pores 10–100 nm in radius in the Al–Co–Mn catalyst on its activity in hydrodesulfurization of black oil produced from West-Siberian oil was studied at varied process parameters.

The steadily growing demand for environmentally clean motor fuels can be satisfied by implementing cracking processing of heavy cuts of oil, from which heteroatoms, and in the first place sulfur, should be removed preliminarily. The growing share of sulfurous and sour oils in petroleum production [1] makes this problem even more acute. A thorough-going method for obtaining high-quality raw materials for manufacture of motor fuels satisfying modern requirements is hydrodesulfurization of petroleum residues with the use of heterogeneous catalysts. However, implementation of such a process is a rather difficult task, primarily due to the nature of heavy oil cuts, which are a complex heterogeneous system whose components are characterized by various elemental compositions, structures, and physicochemical properties. The petroleum residues constitute a colloid system of organic compounds in which asphaltenes (disperse component) are dispersed in mutually soluble oil tars and hydrocarbons.

With the fraction composition of petroleum products becoming heavier, the type of sulfurous compounds changes from thiols to sulfides and thiophenes, the degree of their aromaticity grows, and the reactivity decreases. For example, only structures containing thiophene and 2, 3, or more benzene rings are present in the narrow 425–455°C fraction [2]. About 60–80% of the entire amount of sulfur is contained in residues after oil distillation at atmospheric pressure [3], and about 20% in tars and asphaltenes [4].

The low diffusion rate of high-molecular-weight components of heavy petroleum raw material in the liquid phase and catalyst pores hinders the access of hydrogen and sulfurous compounds to the internal surface of the catalyst, making slower the rate of hydrodesulfurization. Therefore, one of the main requirements to a catalyst is that it should contain a zone of coarse pores, partly obviating the diffusion hindrance and increasing the coverage of the catalyst surface. The available relevant evidence is contradictory. The possible reason is the wide variety of raw materials used in investigations. The pore structure and physicochemical properties of catalysts should be optimized for each particular raw material and required product quality, as it was done in developing a catalyst for hydrodesulfurization of deasphalted vacuum residue produced from West-Siberian oil [5].

Previously, the advantage has been demonstrated of using coarsely porous catalysts for hydrorefining of the residue formed in distillation of products obtained in thermal cracking of vacuum residue [6]. As regards the process of black oil hydrorefining, the effect of the number of macropores (more than 100 nm in diameter) on the efficiency of the Al–Co–Mo catalyst has been studied in 24-h tests at 380°C and 10 MPa [7]. Here we report on the estimated efficiencies of heteroporous Al–Co–Mo catalysts in hydrorefining of black oil at various process parameters and during a longer time (100 and 500 h).

EXPERIMENTAL

In addition to a commercial Al–Co–Mo catalyst, test samples of varied pore structure were used. The γ-Al_2O_3 support for the test catalyst samples was synthesized by the nitrate method, with its pore structure controlled by introducing varied amounts of a 25% $NH_3 \cdot H_2O$ solution into the aluminum hydroxide paste being formed. The catalysts were prepared by successive impregnation of a support, extruded and

calcined at 550°C, with solutions of ammonium paramolybdate $(NH_4)_6Mo_7O_{24}$ and cobalt nitrate. The obtained catalyst mass was dried in air for 24 h, at 60–70°C for 2–3 h under an IR lamp with intermittent stirring, and in an oven at 120°C for 4 h. The dried samples were calcined in air at 500°C for 6 h. The concentrations of Mo(VI) and Co(II) in oxide samples were 8.5 ± 0.5 and 3.0 ± 0.2 wt %, respectively. The pore structure was studied by mercury porosimetry. The specific surface area S_{sp} was determined dynamically from thermal desorption of nitrogen. The characteristics of the prepared heteroporous samples and the commercial catalyst are listed in Table 1.

The catalysts were tested for activity in a flow-through installation with a 200-ml reactor without recirculation at hydrogen consumption of 1000 nl l^{-1}. Prior to testing, the catalysts were sulfidized at 400°C, with diesel fraction used as sulfidizing agent. Special-purpose experiments revealed that there is no external-diffusion hindrance of the process of black oil hydrodesulfurization under the adopted conditions.

To evaluate the desulfurizing activity and its dynamics in the tests, the content of sulfur in the starting black oil and periodically taken samples of the hydrogenizate was determined by the method of burning [8]. The catalyst activity was evaluated on the basis of the average apparent rate W and extent α of the process.

The starting black oil contained sulfur, asphaltenes, tars, V, and Ni in amounts of 1.7, 2.0, 2.5 wt %, 27 and 18 ppm, respectively.

Table 2 presents the estimated desulfurization efficiencies of catalysts in the course of 100-h tests at 420°C, pressure of 10 MPa, and initial degrees of desulfurization of 40–50%. The space velocities of black oil supply at a given desulfurization level were in the range from 1 to 3 h^{-1}, depending on the catalyst activity. The amount of condensation products (CPs) deposited on the catalyst surface in the course of operation was determined by the burning method, with a cooled spent catalyst preliminarily washed with diesel fraction and vacuum-treated at 100°C and 2–3 mm Hg.

As seen from Table 2, test samples surpass the commercial catalyst in every respect, which apparently indicates that there is no significant contribution of pores less than 10 nm in radius to the catalyst activity and 10–100-nm pores and macropores play an important role. According to increasing initial desulfurization rate, the test samples form the same sequence (A < B < C) as those arranged in the order of increasing macropore volume (Tables 1, 2). However, according to the retention of activity, final desulfurization rate, and amount of sulfur removed in 100 h, the catalysts are arranged in the order of increasing total volume of 10–100-nm pores and macropores (C > A > B). In the same order the catalysts are arranged according to increasing amount of removed sulfur per unit mass of formed CP. This parameter characterizes the stability of desulfurizing ability with respect to surface coking. Thus, the efficient prolonged operation of a catalyst requires the presence of a sufficient

Table 3. Results obtained in tests with coarsely porous and commercial catalysts (10 MPa)

Sample	*T*, °C	Amount of sulfur removed in 500 h		
		g/100 ml cat.	g l^{-1} cat.	g g^{-1} Mo
C	380	470	9.4	105

Commercial		515	7.8	87

number of pores 10–100 nm in diameter and macropores. Apparently, with the surface of macropores, which are the most accessible to raw material components, primarily coked and deactivated, the increasing amount of pores 10–100 nm in radius is involved in the process, and it is this fact that ensures the stability of catalyst operation at a sufficient amount of pores of both types.

The results of more prolonged tests with the most efficient sample B and a commercial sample are presented in Fig. 1 and Table 3.

Industrial hydrodesulfurization is performed at elevated temperature, which is associated with the decrease in the desulfurizing activity with time and the necessity for preservation of a prescribed content of sulfur in the product. In this connection, it was of interest to compare the efficiencies of the coarsely porous and commercial samples at temperatures of 380 and 420°C, approximately corresponding to the lower and upper temperature limits of hydrorefining of heavy oil stock. The hydrogen pressure was 10 MPa; space velocity, 2 h^{-1}; catalyst grain size, 3 mm.

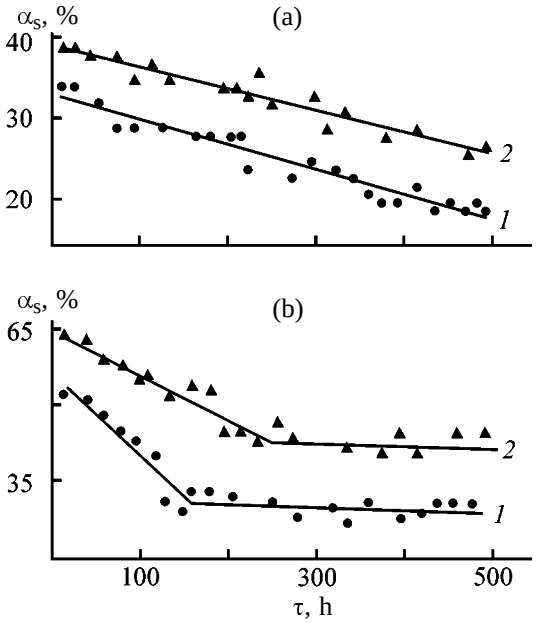

Fig. 1. Extent of black oil hydrodesulfurization, α_s, vs. the time of catalyst operation, τ. P = 10 MPa, V_s = 2 h^{-1}. Catalyst: (*1*) commercial and (*2*) coarsely porous. Temperature (°C): (a) 380 and (b) 420.

Both in the "mild" and "rigorous" temperature regimes, the coarsely porous sample surpasses the commercial catalyst in the extent of desulfurizing, output capacity of unit reactive volume and mass, and efficiency of utilization of the active component during the entire period of testing (Fig. 1, Table 3). With increasing process temperature, the above parameters grow to a greater degree for the coarsely porous sample, compared with the commercial catalyst. The fact that the difference between the catalyst efficiencies grows as the temperature is elevated can be attributed to the increasing diffusion hindrance, this being more pronounced in the case of a narrow-pore commercial sample.

At low process temperature, the activity, on the whole, changes monotonically (Fig. 1a). At high temperature, the deactivation proceeds in the initial part of a run faster than in the final stage (Fig. 1b).

The significant advantage of the coarsely porous sample in the output capacity per unit mass, compared with the value per unit reaction volume (Table 3), is due to the lower (approximately 1.4-fold) bulk density of the given catalyst.

In addition to evaluating the rate of desulfurizing, it seems appropriate to determine the effect exerted by the process parameters on the decomposition rate of asphaltenes contained in the raw material, with account of the fact that the asphaltenes contain ca. 20% sulfur and may strongly affect the course of the hydrorefining as a whole. The amount of asphaltenes in the starting black oil and hydrogenizates was determined by their precipitation in petroleum ether [8]. To solve the problem in hand, the method of mathematical experiment design was employed [9, 10]. The 2^3 design matrix of the trifactorial experiment in coded and natural values and the response functions (the rates of desulfurizing W_s and asphaltene decomposition W_a) are presented in Table 4. The duration of each test was 24 h at an extent of desulfurization in the range 20–30%. The given desulfurization level was ensured at varied temperature, pressure, and catalyst grain size by varying the space velocity of the raw material. It should also be noted that at a grain size of 0.4 mm the black oil desulfurization proceeds in a mode close to kinetic control [7].

+400	+10.0	3	2.9	2.9	6.0	6.0	1.3	1.4	3.2	3.3

The processing of the obtained experimental data gave the following equations.

For the commercial catalyst:

rate of hydrodesulfurization

$$y_1 = 3.1 + 0.5x_1 + 0.4x_2 - 1.1x_3, \quad S\{y\} = 0.17, \; S\{b_i\} = 0.06; \tag{1}$$

rate of cracking hydrogenation of asphaltenes

$$y_3 = 2.4 + 0.3x_2 - 1.6x_3 + 0.3x_1x_2, \quad S\{y\} = 0.20, \; S\{b_i\} = 0.1. \tag{2}$$

For the coarsely porous catalyst:

rate of hydrodesulfurization

$$y_2 = 4.6 + 1.0x_1 + 0.6x_2 - 0.7x_3 + 0.3x_1x_2 + 0.2x_1x_2x_3, \tag{3}$$

$$S\{y\} = 0.24, \; S\{b_i\} = 0.1;$$

rate of cracking hydrogenation of asphaltenes

$$y_4 = 2.4 + 1.1x_1 + 1.6x_2 - 0.6x_3 - 0.8x_2x_3 - 0.4x_1x_2x_3, \tag{4}$$

$$S\{y\} = 0.38, \; S\{b_i\} = 0.15.$$

All the coefficients in Eqs. (1)–(4) are significant (verified using Student's criterion at significance level of 0.05) and describe adequately the investigated range of factor variation ($F_{calc} < F_{f_1 f_2}^{0.05}$).

Analysis of Eqs. (1)–(4) suggests, in the first place, that the coarsely porous catalyst shows higher rate of black oil desulfurization both at the "zero" point (390°C, 6.25 MPa) and under "extreme" conditions (400°C, 10 MPa). The activity (rate of desulfurization) of the coarsely porous sample exceeds that of the commercial catalyst by 50 and 40 rel. %, respectively. Moreover, the sensitivity of the coarsely porous catalyst to the process conditions, i.e., the effect of the factors, much exceeds that for the industrial catalyst. This enables a more accurate adjustment of the conditions for performing the hydrodesulfurization.

The same considerations apply to the process of cracking hydrogenation of asphaltenes. In this case, the effect of the factors is even more pronounced. For example, the W_a value is practically the same for the industrial and coarsely porous catalysts at the zero point (390°C, 6.25 MPa), whereas under more severe process conditions (400°C, 10 MPa) the rate of cracking hydrogenation of asphaltenes is more than 1.8 times higher for the latter.

It is of interest to consider the kinetic aspect of the hydrorefining process. Studying the diffusion kinetics is a rather difficult task. In the given case, the complications are in the first place due to difficulties in experimental determination of the diffusion parameters for the system catalyst–raw material. The hydrorefining of the heavy oil cut consists in the interaction of two disperse systems (catalyst and raw material). All the reactions constituting the process occur on the surface of the polydisperse catalyst under conditions of its continuous deactivation. An in-depth kinetic analysis was beyond the scope of this study. Therefore, we restricted ourselves to a simplified formal approach on the assumption that models relying upon the formal kinetics can be used to find the necessary regime, e.g., to determine the flow rate of

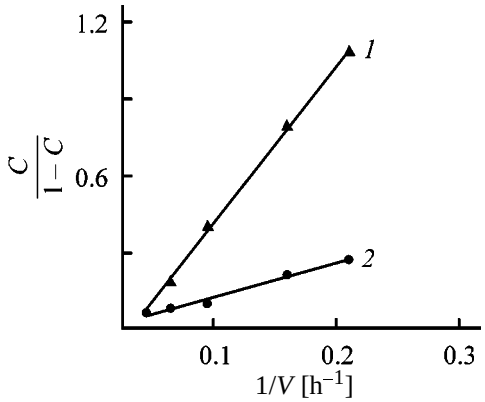

Fig. 2. (*1*) Hydrodesulfurization and (*2*) deasphalting as second-order reactions. Coarse-porous sample, T = 420°C, P = 10 MPa. (*C*) Conversion and (*V*) space velocity of the raw material.

the raw material that would ensure the necessary extent of the process.

Processing of the results of 24-h tests with heteroporous catalysts at 420°C, 10 MPa, and varied time of contact (feed rate 5–30 h^{-1}) demonstrated that, irrespective of the pore structure and grain size of a catalyst, the processes of desulfurization and asphaltene cracking are described by a second-order equation

$$\frac{C}{1-C} = k\omega\frac{1}{V}, \quad (5)$$

where C is the 24-h-average conversion (fraction units), k is the reaction rate constant, ω is the content of a component in the raw material, and V is the raw material space velocity (h^{-1}).

Figure 2 shows, as an example, data obtained for a coarsely porous sample. In all cases the correlation factors were in the range 0.96–0.99.

The revealed second order is obviously only apparent and can be accounted for by differences in reactivity between separate components. Commonly, hydrogenolysis of individual sulfurous compounds is a reaction having true or pseudo-first order with respect to sulfur concentration. Consequently, the rate constant of black oil desulfurizing is bound to decrease steadily as the most reactive compounds are converted. A similar reasoning is valid for reactions of cracking of asphalt–tar components. It is also not improbable that the observed second order is due, to some extent, to the catalyst deactivation inevitably occurring in the course of the process.

CONCLUSION

The highest efficiency in black oil desulfurization is exhibited by the catalyst whose pore structure is characterized by the presence of macropores (>100 nm) and pores 10–100 nm in radius in approximately equal amounts (0.40 ± 0.05 cm^3 g^{-1} each).

The advantage of a catalyst with the pore structure of this kind over a commercial Al–Co–Mo sample is retained at various process parameters. The process of black oil desulfurization is satisfactorily described by a second-order equation.

Abstract—The effect of structural and acid characteristics of catalysts of various nature (sulfonic cation exchangers of the KU-23 type and high-silica zeolite of the ZSM-5 type) on their activity and selectivity in production of methyl *tert*-butyl ether from isobutylene and methanol was studied.

A decrease in the toxicity of motor transport exhaust is one of the urgent environmental problems. Significant advances in this field can be reached by using environmentally safe fuel additives. In recent years, various oxygen-containing compounds, lower alcohols and ethers, found a wide use as high-octane components for production of commercial gasolines. They have high octane numbers (>100) and do not form toxic substances in combustion [1]. In addition, the use of oxygen-containing components reduces petroleum expenditure for production of the required amount of commercial gasoline.

Methyl *tert*-butyl ether (MTBE) is the component which most efficiently increases the octane number of unleaded gasolines [2]. The main raw materials for MTBE production are methanol and isobutylene. Isobutylene is the component of the butylene–butadiene fraction (BBF) of petroleum pyrolysis; its content in BBF is 16–18 wt %. Ion-exchange resins are highly efficient and selective catalysts for synthesis of MTBE. However, their use is limited owing to relatively narrow interval of operating temperatures; therefore, selection of the optimal and thermostable catalyst for this process is an urgent problem despite the existence of large-tonnage industrial equipment for MTBE production in advanced countries [3, 4].

In this connection the aim of this work was to study the effect of physicochemical characteristics of KU-23 cation exchangers on the selectivity of MTBE formation from BBF and methanol. We also studied this process in the presence of ZSM-5 zeolite catalyst having a wide range of operating temperatures.

EXPERIMENTAL

The KU-23-16/60 and KU-23-30/100 sulfonic cation exchangers and high-silica zeolite of the ZSM-5 type in H form (H-HSZ) with the silicate ratio SiO_2/Al_2O_3 = 50 were used as catalysts for synthesis of MTBE from methanol and isobutylene. The catalytic activity of the samples was determined on a laboratory flow-type setup with a fixed bed of the catalyst in the temperature range 50–120°C for sulfonic cation exchangers and 80–250°C for H-HSZ at a pressure of 1 MPa; the molar ratio methanol : isobutylene was 1 : 1. Liquid reaction products were analyzed chromatographically on a column packed with 15 wt % PEG 1500 on S-22. Gaseous reaction products were analyzed on a column packed with Al_2O_3.

The pore structure of the samples was studied on a vacuum setup equipped with a McBain quartz balance. Benzene was used as an adsorbate. The pore-volume distribution was evaluated from the isotherms of benzene desorption at 20°C with the use of the Thompson–Kelvin formula. The acidity of the samples was determined spectrophotometrically in aqueous medium with the series of Hammett indicators with pH of transition from 0.8 to 6.4 by the procedure described in [5].

The comparative characteristics of the catalytic activity of the KU-23 and HSZ cation exchangers under the same conditions of synthesis of MTBE from BBF and methanol are presented in Table 1. With selected process parameters [temperature 80°C, pressure 1 MPa, space velocity of raw materials (isobutylene of BBF) 1 h^{-1}, and molar ratio of isobutylene and meth-

* (S) Selectivity with respect to MTBE and (C) conversion.

anol 1 : 1], the degree of conversion of isobutylene does not exceed 84% and the maximal selectivity with respect to MTBE reaches 96%. The degree of conversion and the selectivity of formation of MTBE on high-silica zeolite are 17 and 70%, respectively. As a by-product only *tert*-butanol, formed owing to the presence of moisture in raw materials, was detected. At a low metanol : isobutylene ratio and higher temperature isobutylene dimerizes. With increasing temperature, at a certain concentration of reactants, intermolecular dehydration of methanol, hydration of isobutylene, and formation of methyl *sec*-butyl and metabutylene ethers take place.

The dependences of the selectivity and degree of conversion of raw materials (isobutylene of BBF) on the temperature and pressure pass through maxima. The optimal parameters of synthesis ensuring the maximal catalytic activity and selectivity of the studied samples are presented in Table 2. For the KU-23-30/100 sample, the pressure has a positive effect on the selectivity (increase from 85 to 98%) and catalytic activity (the degree of conversion of isobutylene increases from 60 to 85%). For the KU-23-16/60 sample, the similar results are observed under mild conditions of synthesis (P = 1 MPa and T = 80°C). The reaction of methanol with isobutylene on H-HSZ proceeds at 150°C and is characterized by low conversion of isobutylene.

As was shown previously [6] and in this work, the catalyst activity depends on many factors, in particular, on its structural characteristics. The studied sulfonic cation exchangers are wide-porous (16/60) and narrow-porous (30/100). The equivalent pore diameters dominating in the samples are presented in Table 3. The experimental data show that the sample of cation exchanger with wider pores, KU-23-16/60 (d > 15 nm), exhibits the highest activity in production of MTBE from BBF and methanol under the same conditions. For the narrow-porous sample, KU-23-30/100 (d = 1 mn), a significant increase in the yield of product and conversion of isobutylene is observed with increase in pressure by a factor of 1.5. Under the selected conditions of MTBE synthesis, the H-HSZ narrow-porous sample of the ZSM-5 type exhibits low catalytic activity as well. It is evident that in the case of sulfonic cation exchanger KU-23-16/60 the system of wide transition pores facilitates mass transfer in the catalyst granules, which, in turn, increases the yield of the target product and the degree of conversion of isobutylene.

The difference in the catalytic activity of the samples is also related to their acid–base characteristics caused by the acidic groups $-SO_2-OH$ in the styrene–divinylbenzene matrix of ion-exchange resins or Lewis or Brønsted acid centers in the case of H-HSZ. The measurement of the total acidity of the samples and differentiation of acid centers with respect to their strength (Table 3) showed that on the surface of the samples there are several types of acid centers different in the strength and that the strong acid centers corresponding to the pK of the indicator transition 2.5 prevail. The KU-23-16/60 sample with increased concentration of acid centers (151.7×10^{-7} mol m^{-2}) exhibits a high catalytic activity, and for low-efficient catalyst in synthesis of MTBE (KU-23-30/100 sample) the concentration of acid groups is two orders of magnitute lower (1.7×10^{-7} mol m^{-2}). The feature of distribution of acid centers on the surface of the zeolite catalyst with respect to strength is the same as in the case of sulfonic cation exchanger 30/100, and their concentration is approximately 0.4×10^{-7} mol m^{-2}. The difference in the catalytic characteristics of these two samples can be apparently caused by severe diffusion deceleration in the H-HSZ sample, which makes difficult mass transfer along the narrow zeolite pores.

CATALYSIS

Kinetics of Phase-Transfer Formation of Potassium Carbazolate, Catalyzed with 18-Crown-6

I. B. Frolova and O. I. Kachurin

Litvinenko Institute of Physical Organic Chemistry and Coal Chemistry, Ukrainian National Academy of Sciences, Donetsk, Ukraine

Received April 4, 1998; in final form, June 2000

Abstract—Kinetics of formation of potassium carbazolate in the system liquid–solid, catalyzed with 18-crown-6, was studied. Applicability of the previously proposed macrokinetic model to this process was demonstrated.

Previously [1] we showed that in the absence of catalysts the phase-transfer formation of potassium carbazolate

$$(C_{12}H_8NH)_{sol} + KOH_{solid} \underset{k_-}{\overset{k}{\rightleftarrows}} (C_{12}H_8NK)_{solid} + (H_2O)_{liq}$$

follows zero-order kinetics with respect to concentration of carbazole in the toluene solution. Based on this fact, we proposed the adequate mathematic model considering the transport of hydroxide ion to the phase boundary organic phase–aqueous interphase as the stage limiting the reaction kinetics:

$$\frac{dx}{d\tau} = k\frac{m_b^{2/3}}{w} - k_- xw, \quad (1)$$

where x and m_b are the current amounts of carbazolate and KOH (mmol), respectively, and w is the amount of "free" water given by the equilibrium

$$KOH + H_2O \underset{}{\overset{K}{\rightleftarrows}} KOH \cdot H_2O. \quad (2)$$

In this work we studied the effect on this process of 18-crown-6 (18-C-6), the commonly used phase-transfer catalyst able to transport KOH into the toluene medium [2].

The procedure was similar to that described previously [1]. The process was carried out in refluxing toluene (110°C) with powdered KOH (grain size 20 ± 10 μm) in a device equipped with a stirrer and a reflux condenser. In all runs the same amount of KOH (1.5 mmol) of the same dispersity was used and the amount of carbazole was varied from 1 to 3 mmol, which corresponded to variation of its concentration in the solution from 16.8 to 50 mM. The concentration of 18-C-6 was varied from 3 to 10 mM.

The dependence of the initial rate of the process on the catalyst concentration is presented in Table 1 and Fig. 1. This dependence is an ascending curve with saturation. In the initial portion of the curve (up to [18-C-6] ≈ 5 mM) the initial rate (mmol min^{-1}) increases approximately linearly with increasing concentration of the catalyst:

$$V_{init} \times 10^2 = (0.9 \pm 0.5) + (0.91 \pm 0.14)[18\text{-Cr-6}],$$

$$R = 0.977, \; S = 0.53.$$

It is likely that at given charges (1.5 mmol of KOH and 1 mmol of carbazole in 60 ml of toluene) the maximal catalytic effect is reached at [18-C-6] ≈ 6 mM and corresponds to the initial rate of 0.06 mmol min^{-1}.

As seen from data listed in Table 2, an increase in the carbazole concentration in the solution by a factor of 3 at a constant amount of KOH does not substantially affect the initial rate of the process; this is true for the state of the maximal catalysis efficiency reached with the given catalyst ([18-C-6] = 7.5 mM). Thus, as in the case of the noncatalyzed process, under catalysis with crown ether the process rate is limited by the transport of the reagent to the phase boundary aqueous interphase–organic phase; the reaction proceeds not in the bulk of the organic phase but at the phase boundary or in the vicinity of the phase boundary. It is well known that aqueous interphase at the surface of solid salts or alkalis (ω-phase) efficiently sorbs the phase-transfer catalyst from the organic phase [3]. It is likely that the phase-transfer catalyst dissolved in the ω-phase facilitates the reagent transport in the bulk of this phase between the solid | liquid and liquid | liquid phase boundaries. This mechanism can easily explain the saturability of the catalytic effect of the phase-transfer catalyst.

Since, as mentioned above, potassium carbazolate is formed (and also hydrolyzed) at the liquid | liquid phase boundary, the process rate, if only in view of mathematical formalism, should be described by macrokinetic model (1). This suggestion was verified by the mathematical simulation [1]. This procedure is based on simultaneous solution of differential kinetic equation (1) and algebraic equation corresponding to equilibrium (2). The calculation was carried out by numerical integration by the second-order Runge–Kutta procedure. As seen from Fig. 2, the dynamics of accumulation of carbazolate during the experiment is adequately described by this mathematical model with appropriate values of kinetic coefficients k, k_-, and K. The averages of k, k_-, and $V_{init} = k(m_b)_0^{2/3}/w_0$ (from 3–4 similar runs) are listed in Table 1. It should be noted that the numerical values of k_- and $K = 0.02$ are almost the same as in the case of the noncatalyzed process [1], which additionally suggests the identity of the mechanisms of both processes.

EXPERIMENTAL

The experimental procedure differed from that described in [1] only in the method of monitoring the course of the reaction. Potassium carbazolate formed in the catalyzed process occurs partially in the form of the complex with crown ether, slowly crystallizing from the filtered toluene solution. Therefore, the amount of unchanged carbazole was determined as the difference between the total content of carbazole in the toluene sample treated with water (spectrophotometrically, as described in [1]) and the amount of potassium ions in the aqueous extract of this sample. The content of potassium ions was determined using a pH-673m device equipped with an EM-K-01 ion-selective electrode. The potentiometric data were processed using the calibration plots.

Experiments were repeated no less than three times. The results of calculations given in this work are the averages with their root-mean-square deviations.

The initial content of water in the reaction mixtures was evaluated as the sum of the amounts of water added with alkali (~15%) and toluene (~0.03%).

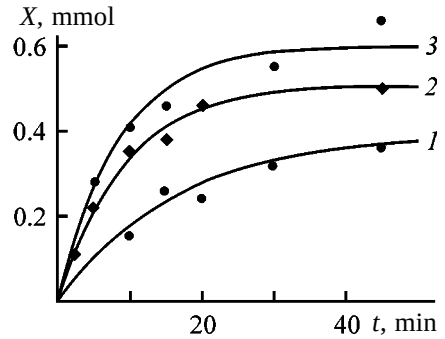

Fig. 2. Calculated (curves) and experimental (points) dynamics of accumulation of potassium carbazolate (X). (t) Reaction time. 18-C-6 concentration (mM): (*1*) 3.0, (*2*) 5.0, and (*3*) 7.5.

Table 2. Initial rates of formation of potassium carbazolate V_{init} at various concentrations of carbazole C_c^*

Carbazole amount, mmol	C_c, mM	$V_{init} \times 10^2$, mmol min^{-1}	Number of runs
1.0	16.8	6.4 ± 0.2	3
2.0	33.3	8.4 ± 0.6	3
3.0	50.0	7.7 ± 0.5	4

* Toluene volume 60 ml; KOH and H_2O amounts 1.50 and 1.69 mmol, respectively; [18-C-6] 7.5 mM; 110°C.

18-Crown-6 was added to the reaction mixtures in the form of solution with given concentration, which was prepared by dissolution in toluene of the sample recrystallized from acetonitrile.

CONCLUSIONS

(1) 18-Crown-6 catalyzes the phase-transfer formation of potassium carbazolate in the system solid KOH–toluene at 110°C, providing the maximal sixfold increase in the initial rate of the process.

(2) Under conditions of the maximal efficiency of phase-transfer catalysis with 18-crown-6, formation of potassium carabazolate follows the zero-order kinetics with respect to carbazole concentration in the toluene solution.

(3) The kinetics of the catalyzed formation of potassium carbazolate is adequately described by the macrokinetic model proposed previously for the similar noncatalyzed process, which suggests the identity of the mechanisms of these processes.

PRODUCTION AND USE OF NEW MATERIALS

Silicon Dioxide Modified with Fluorine

E. I. Mel'nichenko, M. D. Koryakova, V. M. Nikitin, G. F. Krysenko, and N. V. Speshneva

Institute of Chemistry, Far East Division, Russian Academy of Sciences, Vladivostok, Russia

Received June 3, 1999; in final form, June 2000

Abstract—IR spectroscopy and X-ray phase and chemical analyses were used to study the physicochemical properties of fluoride-containing amorphous silicon dioxide obtained by hydrolysis of $(NH_4)_2SiF_6$, and its previously unknown biocide properties were discovered. Results of biotesting are presented.

Alkaline hydrolysis of $(NH_4)_2SiF_6$ gives an amorphous porous mass with hydrated surface, which is an active silica filler and is known as "white black" [1].

A distinctive feature of silica gel obtained by hydrolysis of the SiF_6^{2-} ion (or SiF_4) is the presence of fluoride ions in it [2, 3]. The surface of the silicon dioxide prepared by this procedure is hydrophobic rather than hydrophilic [4]. However, the presence of residual fluorine in silicon dioxide has not been related to any specific physicochemical properties of silica gel and, therefore, such silicon dioxide was not classed with fluoride materials.

With account of the fact that ammonium hexafluorosilicate occupies a prominent place in developing practically all flowsheets for processing of mineral raw materials based on ammonium hydrofluoride and is involved in reagent circulation, the SiO_2 by-product is supposed to be produced in large amounts. This requires closer analysis of the effect exerted by residual fluoride ions on some properties of silicon dioxide and a search for new fields of its application.

The aim of this work was to study the chemical composition and biocide properties of hydrolytic silicon dioxide containing fluoride ions.

EXPERIMENTAL

Fluoride-containing silicon dioxide was isolated by precipitation with ammonia from saturated solution of sublimed $(NH_4)_2SiF_6$. The precipitate was washed with double-distilled water and dried at 90–105°C. Analysis for fluoride ions was made by steam distillation and titration of the distillate with a $Th(NO_3)_4$ solution. A sample obtained upon single washing of the precipitate contained 6.9% fluoride ions, and that furnished by triple washing, 3.2%. Further increase in the number of washings (to 6 or 7) lowered the residual content of fluoride ions to 0.7–0.8%.

The presence of the NH_4^+ ion was judged from the IR spectra. A conventional spectrum did not contain the characteristic bands of the ammonium ion. Only a spectrum taken in a thick layer, at the band intensities of the main substance of 200%, demonstrated the presence of ammonium in hydrolytic silicon dioxide. Chemical analysis for the ammonium ion was done by the Kjeldahl method involving evaporation with a 20% NaOH solution. The empirical formula of hydrolytic silicon dioxide containing fluoride ions and ammonium ions was established by chemical analysis:

Found, %: NH_4^+ 1.8, F^- 6.9.
$(NH_4)_{0.065}SiO_{1.915}F_{0.235}$.
Calculated, %: NH_4^+ 1.82, F^- 6.95.

The biocide activity was evaluated by standard procedures [5]. The Czapek–Dox medium was inoculated with an aqueous suspension of mold spores taken from a building wall infested by fungi. Glass tubes 1 cm high, filled with a substance under study, were placed at the center of a Petri dish inoculated with fungi, and the culture was grown for 2 days in a thermostat. The fungicide activity was determined as the radius of the zone uninfected by fungi.

The algicide activity was evaluated from the action on larvae of *Balanus* barnacles, the most common fouling organisms at the Peter the Great Bay (Sea of Japan). Fluoride ions were leached with seawater (1 l) from 1 g of hydrolytic SiO_2 in the course of 1 and 7 days, with subsequent 2-, 10-, and 100-fold dilution of the leaching solution. Larvae (100–150 specimens) were introduced into the prepared solutions, and the

deceased larvae were counted under a binocular microscope in a Bogorov chamber.

The chemistry of silicon dioxide was considered in detail in the biological respect, including its toxicity, in the monograph by Iler [4]. However, no attention was given to the behavior of various kinds of inclusions in SiO_2, especially in its amorphous forms. Depending on the preparation method and nature of inclusions, the SiO_2 properties may vary widely. For example, silicon dioxide obtained from SiF_4 has an extremely low bulk density (0.0248 g cm^{-3}) and can flow like water [4]. To evaluate the effect of fluoride ions on the properties of hydrolytic SiO_2 and determine in what form ammonium ions are incorporated, a highly sensitive method of biotesting was used together with the conventional physicochemical techniques.

According to chemical analysis data, the sample contained 1.8% ammonium ions, whereas the IR spectrum contained no corresponding bands (Fig. 1, spectrum *1*). That is why other conditions were chosen for taking an IR spectrum, which made it possible to confirm the presence of ammonium ions in the sample (Fig. 1, spectrum *2*). In addition to the main Si–O band (1100 cm^{-1}) and bands associated with the ammonium ion (3330 and 1400 cm^{-1}) and water (3400–3600 and 1630 cm^{-1}), four absorption bands were observed at 470, 720, 800, and 945 cm^{-1}. The first two of these completely coincided, as also did the absorption bands related to ammonium ion vibrations, with the spectrum of $(NH_4)_2SiF_6$ (Fig. 1, spectrum *2*) and indicated the presence of this compound in SiO_2. The band at 800 cm^{-1} was assigned to vibrations of the Si–F bond, characteristic of the $[SiX_4]$ structural unit, and the band at 945 cm^{-1} was attributed, using IR spectral tables, to vibrations of the Si–F bond in $[SiF_2]$ and $[SiF_3]$ [6].

Thus, fluoride ions contained in hydrolytic SiO_2 obtained from $(NH_4)_2SiF_6$ are present in the form of coprecipitated $(NH_4)_2SiF_6$ and, according to published data, are bound to surface silicon atoms.

Figure 2a shows a thermogram of this product. It is seen that the sample loses weight mainly in two stages: at 100 and 240°C. The total weight loss is more than 20% [$(NH_4)_2SiF_6$ 8.9% and water the rest].

The gas phase composition was determined on heating a sample in a quartz tube. It was found that only water is lost below 140°C, then, up to 230°C, water and ammonia, and above this temperature $(NH_4)_2SiF_6$ is evaporated. The release of ammonia and the temperature regime correspond to the established thermal behavior of pure $(NH_4)_2SiF_6$.

A comparison of sample spectra before and after annealing in the temperature interval 300–700°C demonstrated that, upon heating, the intensities of the bands at 800 and 945 cm^{-1} (vibrations of the Si–F bond) remained practically unchanged. Therefore, it can be stated that fluoride ions bound to surface silicon atoms are retained up to 700°C. After annealing at this temperature, the sample could absorb 6.5% moisture (Fig. 2b). In contrast to fluoride ions, ammonia was absent in the sample already upon heating to 300°C.

Since SiO_2 gel occludes $(NH_4)_2SiF_6$, it would be expected that this kind of silicon dioxide exhibits biocide activity characteristic of salts of hexafluorosilicic acid.

Biotesting for resistance to fouling organisms (larvae of *Balanus improvisus*) was performed. Table 1 lists data on larval loss in leaching solutions obtained from SiO_2 samples containing 3.2 and 6.9% fluoride ions. In contrast to copper sulfate solutions (1 g per liter of seawater), the loss of larvae was observed in 100% of cases even at 1 : 1 dilution. At stronger dilution, 15–35% of larvae died in leaching solutions, and only 5–8%, in a copper sulfate solution diluted to the

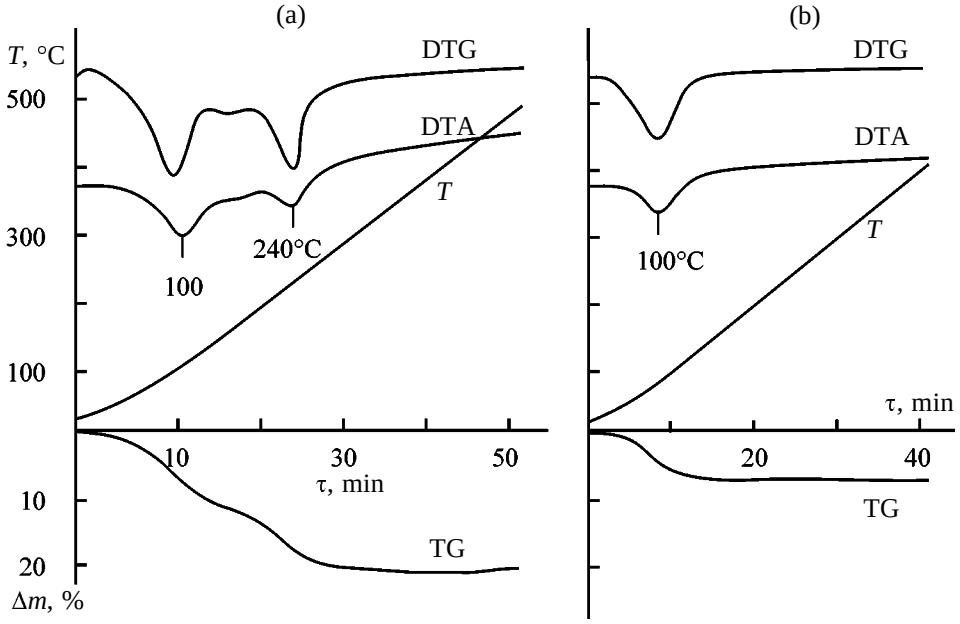

Fig. 2. Thermograms of amorphous SiO_2 precipitated from $(NH_4)_2SiF_6$. (*T*) Temperature, (τ) time, and (Δ*m*) weight loss. SiO_2: (a) freshly precipitated and (b) annealed at 700°C.

same extent, indicating the high biocide properties of SiO_2 precipitated from an $(NH_4)_2SiF_6$ solution.

It was found that, even in a multiply diluted leaching solution, the survived larvae (about 90%) lost their response to light and oxygen and did not restore these functions on being placed in pure seawater.

For comparative evaluation of the toxic properties of silicon dioxide modified with fluorine with respect to *Penicillium*, *Aspergillus*, *Mucor*, and *Cladosporium* mold fungi, biotesting was also performed for $(NH_4)_2SiF_6$, CaF_2, and fluoride-free SiO_2 obtained from rice husk. As a control substance was used copper sulfate distinguished by its fungicide and bactericide properties. Below is given the toxicity series of the substances studied, constructed on the basis of the no-fungus-growth zone radius: $(NH_4)_2SiF_6 \approx SiO_2$ (6.9% F) > $CuSO_4$ > SiO_2 (3.2% F).

Silicon dioxide obtained from rice husk and CaF_2 exhibited zero fungicide activity.

The practically equal toxicities of $(NH_4)_2SiF_6$ and SiO_2 (6.9% F) were a surprising result, as amorphous silicon dioxide is an insoluble and nonaggressive substance, and the content of fluoride ion in its sample was by a factor of 10 lower than in ammonium hexafluorosilicate. This result is very interesting and can be of practical significance.

These data were confirmed by full-scale tests. Inspection of a fungus-infected building wall treated with a lime solution with addition of $(NH_4)_2SiF_6$ (1 : 3 molar ratio) revealed a biocide effect. Table 2 lists the number of fungi at certain intervals of time after the surface treatment.

It can be seen that ammonium hexafluorosilicate, combined with calcium hydroxide, ensures a practically complete elimination of fungi and further protection of the treated surface from infestation with fungi. These data disprove the argument [2] that fluorosilicates are incompatible with CaO or $CaCO_3$ because of the formation of inactive CaF_2. The silica gel formation in the process has been disregarded.

The hydrolysis of $(NH_4)_2SiF_6$ can be described by the equations

$$(NH_4)_2SiF_6 + 4NH_3 + 2H_2O = SiO_2 + 6NH_4F,$$

$$(NH_4)_2SiF_6 + 3Ca(OH)_2 = SiO_2 + 3CaF_2 + 2NH_3 + 4H_2O.$$

Reaction of $(NH_4)_2SiF_6$ with calcium hydroxide gives no $CaSiF_6$. The SiO_2 gel precipitating from fluoride solutions occludes $(NH_4)_2SiF_6$. The assumption that the action of SiO_2 on biological objects is due to liberation of $(NH_4)_2SiF_6$ contained in its pores required experimental verification. Therefore, SiO_2 leaching with water was performed, with subsequent chemical and X-ray phase analysis of the leaching product and IR spectral study of SiO_2 after treatment.

Indeed, only $(NH_4)_2SiF_6$ was found in solution. Table 3 illustrates the dynamics of its leaching from a sample with solid to liquid phase ratio of 1 : 10.

It can be seen that only after 15 weeks $(NH_4)_2SiF_6$ completely passed into solution, which indicates low mobility of $(NH_4)_2SiF_6$ molecules entrapped in pores, associated with the structuring of the molecules [7].

On sample treatment with water, all vibration bands characteristic of the starting substance were preserved in the IR spectra of residues for 24 h. However, the intensity of the band at 720 cm^{-1}, associated with the SiF_6^{2-} ion, decreased approximately threefold in a week. This confirmed, with account of the X-ray diffraction pattern of the dry residue, the conclusion that fluoride ions are present in hydrolytic SiO_2 in two forms: as occluded mother liquor [8] and hydroxide groups on the surface, substituted by fluoride ions.

Upon prolonged contact of a sample with water, bands at 3650 cm^{-1} appeared in the SiO_2 spectrum, associated with OH groups in pores (Fig. 1, spectrum *4*). Their appearance was probably due to $(NH_4)_2SiF_6$ removal from pores.

The slow leaching of $(NH_4)_2SiF_6$ from SiO_2 ensures prolonged biocide action of a lime solution with addition of $(NH_4)_2SiF_6$, applied to a surface infested by fungi. The hydrophobic properties of SiO_2 gel, in their turn, do not favor the vital functions of fungal colonies. The antimycotic effect is also enhanced by calcium fluoride filling the pores of the treated surface, which is unfavorable for aerobic fungi.

The obtained data allow hydrolytic silicon dioxide to be regarded as silicon oxyfluoride. With account of the structure of common silica gels $SiO_2 \cdot nH_2O$ and the results of studies of residues and leaching products by chemical, X-ray phase, and IR spectral analyses, additionally confirmed by biotesting, the empirical formula $(NH_4)_{0.065}SiO_{1.915}F_{0.235}$ is more adequately represented as $SiO_{1.98}F_{0.04} \cdot n(NH_4)_2SiF_6$ with $SiO_{1.98}F_{0.04}$ matrix. The matrix formula was found from the mass of ammonium hexafluoride passed into solution. Its amount (8.7% relative to weighed portion and 5.6% in terms of fluoride ions in the starting sample) corresponded to about 1.26% firmly bound fluoride ions belonging to the SiO_2 matrix.

The fraction of surface fluoride ions can be decreased or increased only slightly, which is due to the strictly defined number of OH groups on the surface, of which no more than a half can be replaced by fluoride ions without disruption of the SiO_2 structure [4]. The content of fluoride ions in a sample can only be changed via $(NH_4)_2SiF_6$ absorption.

CONCLUSIONS

(1) IR spectral and chemical analyses demonstrated that amorphous silicon dioxide obtained by hydrolysis of $(NH_4)_2SiF_6$ contains fluoride ions imparting to it biocide properties characteristic of salts of hexafluorosilicic acid.

(2) It is shown that a part of fluoride ions are present in SiO_2 in the form of $(NH_4)_2SiF_6$ occluded in the course of precipitation, with the other part replacing the surface OH^- groups and being preserved upon heating to 700°C. In accordance with the content of

firmly bound fluoride ions (~1.26%), hydrolytic silicon dioxide is regarded as silicon oxyfluoride $SiO_{1.98} \cdot F_{0.04}$ containing up to 8.9% $(NH_4)_2SiF_6$.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Features of Cr(III) Cation-Exchange Recovery from Wash Water of Standard Chrome Plating

S. V. Plokhov, N. A. Barinova, and M. G. Mikhalenko

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received October 25, 1999; in final form April, 2000

Abstract—Features of treatment of the standard chrome plating wash water to remove Cr(III) with KU-1 cation exchanger in the H form were considered. The optimal conditions of Cr(III) recovery and ion exchanger regeneration were determined.

In [1, 2], a two-stage scheme of recovery and utilization of the main components of the standard chrome plating wash water was proposed. The scheme is based on the ion exchange followed by electrochemical treatment of chromium-containing eluates. The model and real wash waters with variable content of metal ions (g l^{-1}) were used: chromium(VI) (in the form of CrO_4^{2-} and $Cr_2O_7^{2-}$) up to 2.0, copper(II) up to 0.01, nickel(II) up to 0.01, and iron(III) up to 0.015. Along with chromium(VI) and the above foreign metal ions, wash water of standard chrome plating contains Cr(III). The chromium(VI) recovery from wash water by ion exchange was studied in [3, 4].

In this work we studied the features of Cr(III) ion-exchange recovery from wash water of standard chrome plating and determined its optimal parameters.

To recover Cr(III), we used a KU-1 cation exchanger in the H form, which was loaded into a column of 160 mm height and 18 mm inner diameter. The ratio of the cation exchanger bed height and column diameter was 9 : 1. The average diameter of ion exchanger grain was 2.5×10^{-3} m. Ion exchange was studied by both dynamic (with the concentration control at the ion-exchange column outlet) and static methods. The chromium(III) content was determined spectrophotometrically and by atomic absorption with SF-26 and S-115 spectrophotometers, respectively. The error of the above methods was 1.5–2.0%.

Ion exchange involves a series of successive stages of mass transfer over the interface controlled by hydrodynamic regime of the movement of the liquid phase [5]. Therefore, the efficiency of ion exchange should depend on the linear velocity of the flow of chromium-containing wash water. This is confirmed by ion-exchange output curves at various flow velocities (Fig. 1a) and ion-exchange characteristics (dynamic exchange capacity DEC and capacity up to breakthrough CB). DEC is the maximal mass of chromium(III) ions retained by 1 kg of swollen ion exchanger under the taken dynamic conditions of water flow. CB is the maximal mass of Cr(III) ions retained by 1 kg of ion exchanger up to appearance of Cr(III) in the eluate. The velocity of wash water flow U 3.25 m h^{-1} corresponds to the absence of CB and insignificant decrease in DEC. At this and higher flow rate, CB cannot be determined quantitatively by the above method of analysis. Hence, only linear flow velocities lower than 3.25 m h^{-1} are of practical interest. DEC and CB (Fig. 1b) are nonlinear functions of U: CB has a maximum at the flow velocity of 2.0 m h^{-1}, and DEC decreases with increasing U. The flow velocity of 2.0 m $^{-1}$ is optimal, as it corresponds to high DEC value and maximal CB (31.6 and 10.6 g per kg of the resin, respectively).

The analysis of the ion-exchange kinetics with equations of diffusion kinetics suggests existence of the limiting stage of ion exchange. It is known [5] that at the metal concentration from 0.003 to 0.1 M ion exchange proceeds under conditions of mixed kinetics. The contribution of the internal diffusion constituent increases with increasing metal concentration. Since for these conditions the theory is not developed completely, to determine the limiting stage we used equations of internal diffusion kinetics for the case of simplest models (sphere, cylinder, plate) [6], which are as follows:

$$-\ln(1 - F) = Bt - \ln A, \quad (1)$$

where A and B are coefficients depending on the

1070-4272/01/7401-0082$25.00

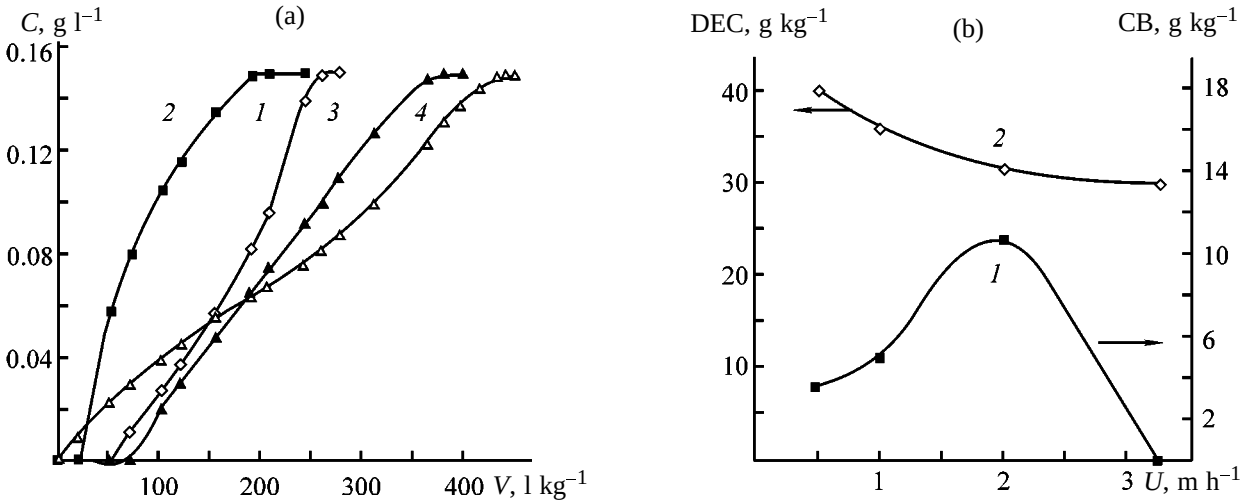

Fig. 1. Effect of (a) volume V and (b) flow velocity U of wash water on (a) the outlet concentration of Cr(III) C and (b) (*1*) CB and (*2*) DEC. Chromium(III) concentration 0.15 g l^{-1}; the same for Fig. 2. (a) Wash water flow velocity U (m h^{-1}): (*1*) 0.5, (*2*) 1.0, (*3*) 2.0, and (*4*) 3.25.

model taken, F is the exchange degree, and t is the exchange time.

The use of Eq. (1) is advisable at $F > 0.7$, because at high exchange degree the contribution of the internal diffusion constituent is very large. Coefficient A is the criterion of adequacy of the model taken and is 0.61, 0.69, and 0.81 for sphere, cylinder, and plate, respectively. In this case, the sphere model is the most acceptable. At high F, coefficient B can be determined from the slope of the $-\ln(1 - F)$–t dependences. Then, the apparent diffusion coefficient D can be calculated:

$$B = D\pi^2 / R^2, \quad (2)$$

where R is the ion exchanger grain radius.

The value of D is 1.5×10^{-8} cm^2 s^{-1}. This value corresponds to the prevalence of the internal diffusion constituent and small contribution of the external diffusion. This allows explanation of the dependence of DEC on the velocity of wash water flow (Fig. 1b, curve *2*). At increased velocity, the contact time in the ion exchanger grain–liquid phase system becomes shorter, and hence, DEC decreases (especially strongly at the velocities higher than 3.25 m h^{-1}).

The effect of chromium(III) concentration in the wash water on the ion exchange dynamics was found at the wash water flow velocity of 2.0 m h^{-1} (Fig. 3a). With increasing metal ion concentration from 0.1 to 0.3 g l^{-1}, CB and DEC change (Fig. 3b), and their maxima are observed at a Cr(III) concentration of 0.15 g l^{-1}. Probably, such dependences are due to Cr(III) complexation in sulfate solutions. At the Cr(III) concentration increased to 0.15 g l^{-1} transfer of metal ion from the solution to the surface of the ion exchanger grain accelerates, and DEC and CB increase. At Cr(III) concentration higher than 0.15 g l^{-1}, the internal diffusion constituent becomes prevailing, and DEC and CB decrease. The apparent diffusion coefficient D was 3.5×10^{-8} $cm^2 s^{-1}$. The effect of Cr(III) concentration was studied also for other velocities of wash water flow within the 0.1–6.25 m h^{-1} range. It was found that the shape of the DEC and CB dependences and the location of curve maxima are independent of the chromium(III) concentration. This is caused by a fairly narrow range in variation of the Cr(III) concentrations studied.

The above data on chromium(III) recovery show that fairly high wash water volume to breakthrough, maximal capacity to breakthrough (it amounts to 7.3, 10.6, 2.1, and 1.0 g per kg of the resin for concentra-

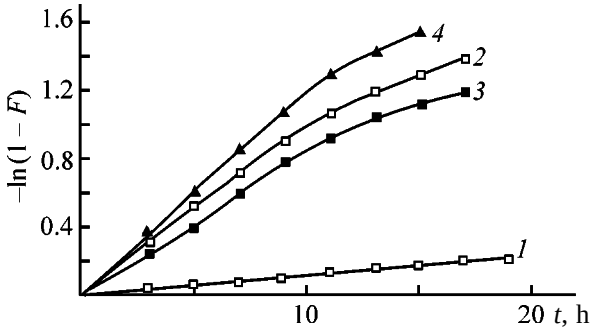

Fig. 2. Kinetics of Cr(III) sorption with KU-1 cation exchanger in the H form: (F) exchange degree and (t) time. Wash water flow rate U (m h^{-1}): (*1*) 0.5, (*2*) 1.0, (*3*) 2.0, and (*4*) 3.25.

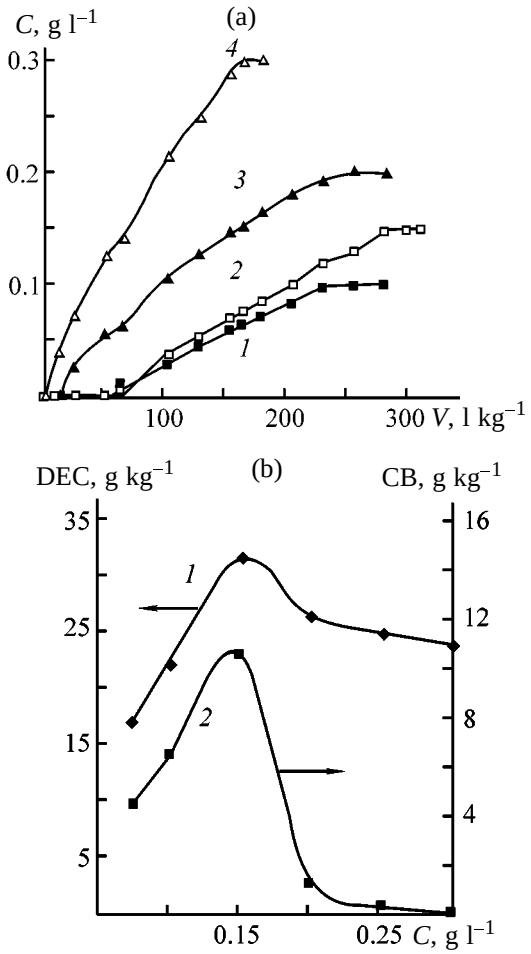

Fig. 3. Influence of wash water volume V and Cr(III) concentration C on (a) the outlet concentration of Cr(III) C and (b) (*1*) DEC and (*2*) CB. Wash water flow velocity 2.0 m h^{-1}. (a) Cr(III) concentration (g l^{-1}): (*1*) 0.1, (*2*) 0.15, (*3*) 0.2, and (*4*) 0.3.

tions of 0.1, 0.15, 0.2, and 0.3 g l^{-1}, respectively), and maximal DEC (31.6 g kg^{-1}) correspond to the Cr(III) concentration of 0.15 g l^{-1}.

Ion exchanger regeneration was performed with sulfuric acid solutions. We considered the effect of acid concentration and flow velocity of the solution on this process. The effect of acid concentration was studied by the static method. Cation exchanger was saturated with Cr(III) ions under the optimal conditions (0.15 g l^{-1}, 2 m h^{-1}) and then washed up to absence of trace amounts of Cr(III) in the eluate. Then, the resin was dried to the constant weight. The samples of solutions containing the same amount of H_2SO_4 and various amounts of water were added to the equal samples of the ion exchanger (4.0 g). The ratio of the cation exchanger to H_2SO_4 was 1 : 6.25 (by weight). The amount of Cr(III) recovered was determined by chemical analysis as a function of the time of cation exchanger contact with the solution. The data obtained are listed in the table.

Amount of chromium(III) recovered in regeneration

H_2SO_4, g l^{-1}	Amount of Cr(III), g, in indicated time, h				
	1	3	22	24	47
25.0	0.015	0.023	0.052	0.067	0.084
50.0	0.031	0.049	0.080	0.104	0.116
100.0	0.027	0.034	0.066	0.083	0.099
150.0	0.022	0.031	0.062	0.080	0.102
200.0	0.021	0.032	0.063	0.083	0.104
250.0	0.022	0.033	0.064	0.083	0.105

As seen, the best recovery is reached with 50.0 g l^{-1} H_2SO_4, which was used in the subsequent experiments.

We found that the maximal amount of the metal recovered corresponds to the flow velocity of sulfuric acid of 1.0 m h^{-1} (Fig. 4). This follows from comparison of the areas under the corresponding curves. At any volume of the sulfuric acid solution, the velocity of 1.0 m h^{-1} corresponds to the maximal amount of Cr(III) in the eluate, which is important for the further processing of the eluates into the commercial product. This result can be explained as follows. At the flow velocity of the H_2SO_4 solution below 1.0 m h^{-1}, the regeneration of the resin is controlled by mixed kinetics and at higher velocities, it is controlled by internal diffusion kinetics, which decreases the amount of recovered Cr(III).

The dependences of the recovery degree on the amount of sulfuric acid solution show that the maximal recovery is reached at a flow velocity of 1.0 m h^{-1} (98%), while for the velocities of 0.25, 0.5, and 2.0 m h^{-1} it was 64.4, 80.1, and 78.3%, respectively.

The volume of the acid solution required for complete regeneration was 43.12 l per kg of the resin [98% of chromium(III) recovery]. The 80% recovery of Cr(III) is reached on passing 7.2 l per kg of the resin. It is reasonable to maintain this level of the resin regeneration, because the additional volume of the acid required to reach the 98% recovery is unduly large. On the other hand, the incomplete regeneration degree should lower DEC and CB in the further use of the ion exchanger, which should be taken into consideration when designing the equipment for treatment of industrial wastewater.

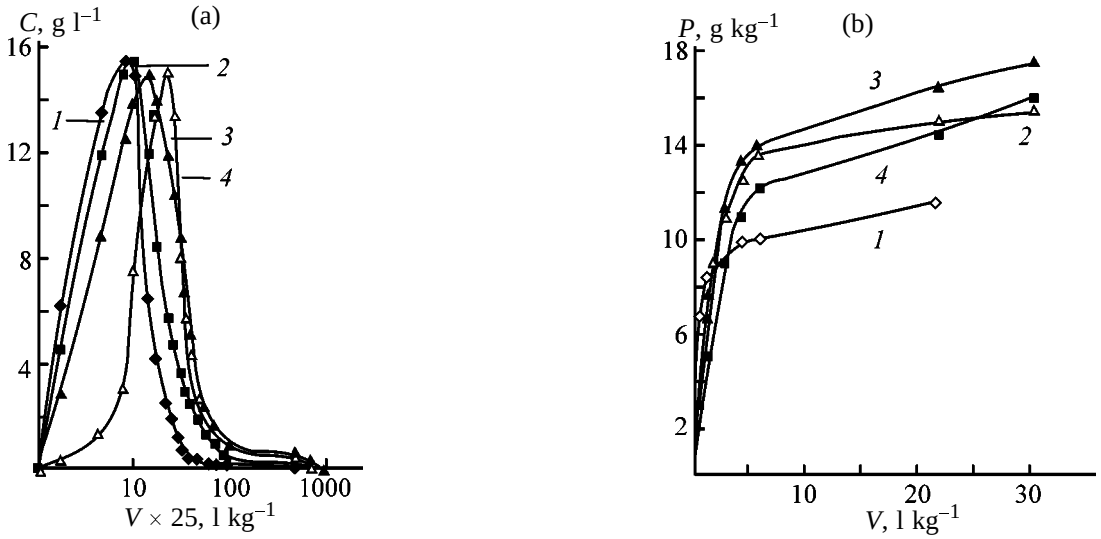

Fig. 4. Effect of the volume of the regenerating solution V on (a) the outlet concentration of Cr(III) C and (b) the amount of Cr(III) recovered P. Concentration of H_2SO_4 50 g l^{-1}. H_2SO_4 flow velocity (m h^{-1}): (*1*) 0.25, (*2*) 0.5, (*3*) 1.0, and (*4*) 2.0.

CONCLUSIONS

(1) Optimal parameters of Cr(III) cation exchange recovery from wash water of the standard chrome plating were determined: Cr(III) content in wash water 0.15 g l^{-1} and wash water flow velocity 2.0 m h^{-1}. Under these conditions, the dynamic exchange capacity and the cation exchanger capacity to breakthrough were 31.6 and 10.6 g per kg of the resin, respectively.

(2) It is advisable to regenerate the ion exchanger with 50 g l^{-1} sulfuric acid at the flow velocity of 1.0 m h^{-1} to recovery degree of 80%.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Color Removal from Aqueous Solutions of Humic Substances in the Presence of Praestol and Aluminum Sulfate

V. F. Kurenkov, S. V. Snigirev, and L. S. Kogdanina

Kazan State Technological University, Kazan, Tatarstan, Russia

Received September 5, 2000

Abstract—Color removal from aqueous solutions of humic substances by introducing Praestol (cationic coagulant) in combination with aluminum sulfate (flocculant) was studied as a function of the coagulant and flocculant concentrations, chemical composition of flocculant, its molecular weight, macromolecule conformation in solutions, pH, and the order and time of coagulant and flocculant introduction.

Numerous problems of the natural and wastewater decontamination can be successfully solved by the use of flocculant (F) in combination with coagulant (C) [1, 2]. The promising approach to solution of these problems is based on the use of macromolecular flocculants Praestols[1] of cationic type belonging to widely used polyacrylamide flocculants. These compounds are copolymers of acrylamide (AA) and dimethylaminopropylacrylamide methylene chloride (DMAPA MC). It was found previously that cationic Praestols in combination with aluminum sulfate as a coagulant can be used for color removal from water [3]. It was shown also that the mixtures of cationic and anionic Praestols promote sedimentation of kaolin–water suspensions [4]. For efficient use of Praestols for color removal from water, data are required on the influence of molecular characteristics of flocculants and features of dispersed systems on flocculation. This matter is poorly studied by now. In this work we studied the effect of chemical composition, molecular weight, and conformation in solution of cationic Praestol on color removal from model solutions of humic substances. This process was studied also as influenced by pH of the medium and the order and time of the flocculant and coagulant $[Al_2(SO_4]_3$ introduction.

EXPERIMENTAL

The characteristics of the cationic Praestol samples used in our experiments are listed in the table. The Praestol samples A, B, C, and D were prepared at the Moscow–Stockhausen–Perm Russian–German Private Company; F, G, H and I samples were prepared by chemical degradation of Praestol C. Aluminum sulfate $Al_2(SO_4)_3 \cdot 18H_2O$, pure grade [GOST (State Standard) 3758–65], and distilled water were used. Other reagents were of chemically pure grade.

The content of the DMAPA MC ionic units in the Praestol macromolecules was evaluated from the content of chloride anions determined mercurimetrically [5].

The molecular weight of Praestol M was evaluated by measuring the intrinsic viscosity of its aqueous

solutions [η], since according to Mark–Kuhn–Houwink equation, $M \sim [\eta]$. The [η] values of Praestol solutions in 0.5 M NaCl were determined with an Ubbelohde viscometer (d_c = 0.54 mm) at 25°C.

The effective size of Praestol macromolecule in solution was evaluated from the reduced viscosity of its aqueous solution η_{sp}/C_p at a fixed copolymer concentration C_p [6–8]. The reduced viscosity was measured with a VPZh-3 viscometer (C_p 0.002%, d_c = 0.54 mm) at 25°C.

The pH of solutions was measured on a pH-121 pH meter with ESL-63-07 glass and chloride (EVL-1M3) silver electrodes.

Praestol B sample (see table) was subjected to degradation in 0.1% aqueous solition at 50°C in the presence of 0.008% potassium persulfate as a radical-generating agent. The degradation of Praestol was monitored viscometrically [9]. This reaction was performed in a cylindrical reaction vessel equipped with a thermostated water jacket, a magnetic stirrer, a control thermometer, and a sampling tube. In the course of degradation at certain intervals a portion of Praestol solution was sampled and both [η] and the efficiency of the color removal were determined. The table shows that the Praestol F, G, H and I samples prepared by chemical degradation of Praestol B are characterized by different [η] but identical chemical composition.

In our experiments we studied color removal from aqueous solutions of humic substances with a color index equal to 226° (cobalt bichromate scale). These solutions were prepared by dilution of biohumus [TU (Technical Specifications) 9891-007-111580–98] with water with stirring. The mixture was settled for 2 days, the precipitate and suspension were separated by filtration, and the resulting filtrate was diluted so as to achieve the above-indicated color index which varies in direct proportion with the optical density [4]. Color removal from a humus solution was carried out as follows. In the first stage a coagulant was introduced into a solution of humic substances and then, after 1 min, a flocculant was added. The mixture was stirred, kept for 1 h, and filtered through a Schott filter. The filtrate was poured into a 5-cm quartz optical cell, and the reference cell was filled with distilled water. The optical density was determined on a KFK-2 photocolorimeter at 400 nm. The color removal efficiency was evaluated by the expression

$$E = (n_0 - n)/n,$$

where n_0 and n are the optical densities of the initial aqueous solution of humic substances and that after introduction of the coagulant and flocculant, respectively.

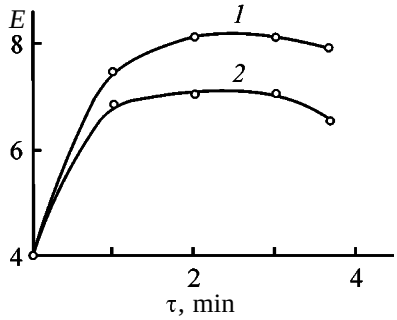

Fig. 1. Dependence of color removal efficiency E on time (τ) of introduction of the second component of the C + F mixture. C_p = 0.5 mg l^{-1}, C_c = 40 mg l^{-1}. Order of reagent introduction: (*1*) C + F and (*2*) F + C.

In the first experiments we studied the dependence of the color removal from solutions of humic substances on the order and time of introduction of a flocculant (Praestol C) in combination with a coagulant (C). Two series of experiments were performed which differ by the order of introduction of flocculant and coagulant. In the both series of experiments the coagulant (C_c) and flocculant (C_p) concentrations were constant and the second reagent was introduced at different intervals after introduction of the first reagent. Figure 1 shows the results of these experiments. It is seen that at simultaneous introduction of the flocculant and coagulant mixture F + C (τ = 0) the color removal efficiency is lower than that at separate introduction of the reagents ($\tau > 0$). The mutual arrangement of curves *1* and *2* in Fig. 1 shows that introduction of the flocculant after the coagulant (C + F) increases the color removal efficiency to a larger extent than introduction of the coagulant after the flocculant (F + C) at the same intervals. This result shows that irreversible sorption of flocculant macromolecules depends on the order of the reagent introduction. The maximum color removal efficiency E was observed when the flocculant was added 1 min after introducing the coagulant (Fig. 1, curve *1*). This is due to the fact that under these conditions the coagulant has time to be hydrolyzed to sufficient extent to form positively charged particles capable of associating with the negatively charged particles of humic acids. The resulting coagulant–humic acid aggregates rapidly coagulate. In further adding a flocculant the more complicated aggregates containing coagulant and humic acid particles and flocculant molecules can be formed. The humic acid–flocculant units in these aggregates are the interpolymeric complexes [10] formed by interaction of

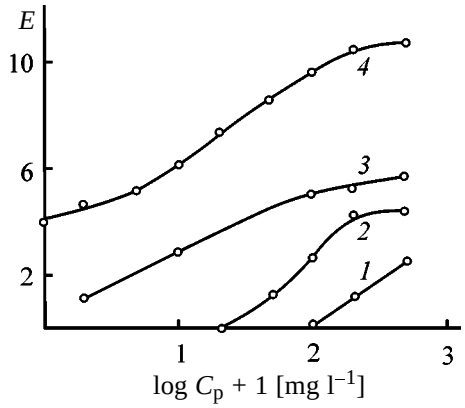

Fig. 2. Dependence of color removal efficiency E on flocculant concentration (Praestol C) C_p at varied coagulant concentrations. Order of reagent introduction C + F, the flocculant was added 1 min after introducing the coagulant.

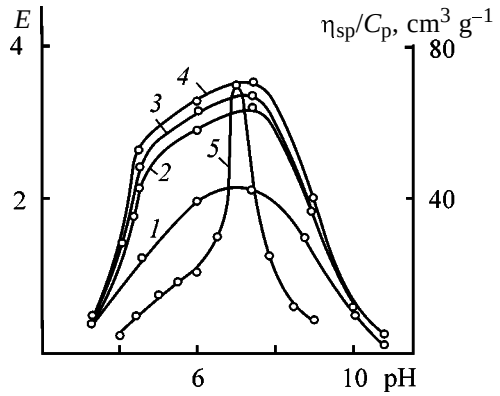

Fig. 3. Dependence of (*1–4*) color removal efficiency E and (*5*) parameter η_{sp}/C_p of flocculant (Praestol C) solutions on pH. (*1–4*) C_p = 0.5 mg l^{-1}; C_c = 16 mg l^{-1}. The parameter η_{sp}/C_p was determined at C_p = 0.1% at 50°C; the same for Fig. 5. Content of ionic groups in flocculant, mol %: (*1*) 9, (*2*) 33; (*3*) 20, and (*4, 5*) 27.

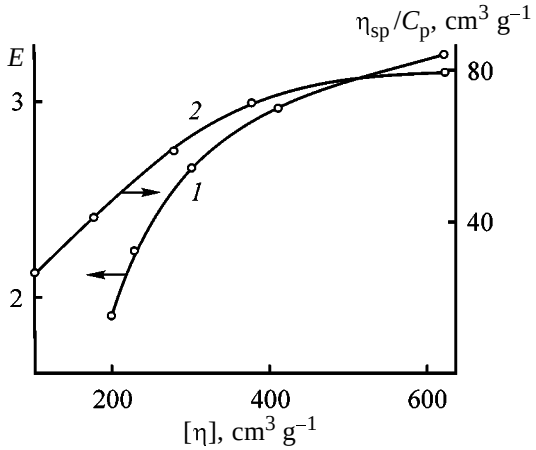

Fig. 4. Dependence of (*1*) color removal efficiency E and (*2*) parameter η_{sp}/C_p on [η] of flocculant (Praestol C) solutions. C_p = 0.5 mg l^{-1}, C_c = 24 mg l^{-1}.

the free carboxy and phenolic groups of humic acids with the amino groups of the flocculant. Due to this cooperative interaction between the coagulant and flocculant, coarse floccules are formed which precipitate, facilitating color removal from water. Based on these results, in further experiments we added flocculant 1 min after introducing the coagulant.

The efficiency of removal of colored humic substances from aqueous solutions at different flocculant concentrations was studied with the use of Praestol C. Figure 2 shows that the color removal efficiency increases with increasing C_p both in the absence of the coagulant (curve *1*) and in its presence in varied amounts (curves *2–4*). Comparison of these curves at constant C_p shows also that introduction of the coagulant and increase of its concentration (passing from curve *1* to curve *4*) improve the color removal. In accordance with the above-considered mechanisms, this effect is due to formation of bridging bonds connecting particles of coagulant and humic acids and flocculant macromolecules. These processes result in formation of coarse floccules capable of fast sedimentation.

The color removal from solutions of humic substances as influenced by pH was studied for Praestols A, B, C, and E of different chemical composition and close molecular weight (see table) at constant concentrations of both flocculant and coagulant. The required pH was adjusted by adding HCl and NaOH aqueous solutions. As seen from Fig. 3, the plots of E vs. pH show maximum for all flocculant samples irrespective of their chemical composition. The maximal E in these plots is observed at pH ~7. The similar maximum occurs in the plot of η_{sp}/C_p vs. pH (Fig. 3, curve *5*) which characterizes the pH dependence of the effective size of macromolecular globules of the flocculant. This fact is indicative of the correlation between the color removal efficiency of the flocculant and its conformational state in solution. At pH < 11 the dissociation degree of the ionic groups of the flocculant increases, the electrostatic repulsion between the positively charged sites along a polymeric chain increases, and, as a result, the flocculant macromolecules lengthen and the flocculant globules become larger. This effect is manifested as increase in η_{sp}/C_p. At pH < ~7 the concentration of counterions increases, compensating the fixed positive charges of the macromolecular chains and weakening the electrostatic repulsion along them. Therefore, the flocculant globules become more compact, which is manifested as the decrease in η_{sp}/C_p (Fig. 3, curve *5*). Figure 3 shows that the maximum color removal is observed for Pra-

estol C containing 27% ionic groups. This flocculant is characterized by the maximal η_{sp}/C_p parameter and, therefore, by the largest effective size of macromolecules. These results show that in the case of Praestol C the largest floccules are formed at pH 7. These floccules, due to their low aggregative stability in solution and fast sedimentation, facilitate color removal from water (Fig. 3).

The dependence of the color removal efficiency on $[\eta]$ of the flocculant solutions was studied for Praestols F, G, H, and I with the similar chemical composition of the macromolecules (see table) at constant C_p and C_c. These results show (Fig. 4, curve *1*) that with increasing $[\eta]$ the color removal efficiency increases. The dependence of η_{sp}/C_p on $[\eta]$ (Fig. 4, curve *2*) is similar, i.e., the increase in the color removal efficiency correlates with the increase in the macromolecule effective size. As a result, coarser floccules are formed incorporating larger amount of humic acids and accelerating the sedimentation.

CONCLUSIONS

(1) In introduction of flocculant in combination with coagulant into humic acid aqueous solutions the color removal efficiency increases with increasing $[\eta]$ of flocculant and coagulant and flocculant concentrations, in passing from simultaneous to successive introduction of reagents, and when changing the order of the reagent introduction from (coagulant after flocculant) to (flocculant after coagulant).

(2) The most efficient color removal from solutions of humic substances is provided by Praestol flocculant containing 27 mol % of ionic groups at pH 7 when the largest macromolecular globules are formed.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Raising the Coefficient of Turbulent Diffusion in the Reaction Zone as Means To Improve Technical and Economical Parameters of Polymer Production

Abstract—Use of a new type of apparatus, high-output small-size tubular turbulent reactors of mainly diffuser–confuser design, in very fast processes, including polymerization, is considered. The turbulent diffusion coefficient D_t and its distribution over the apparatus volume were calculated as functions of the confuser divergence angle α. The calculations were confirmed by experimental data. New reactor designs for a number of processes of large-tonnage polymer production were proposed and put into practice.

One of the most important problems of chemical industry in performing both chemical and physical processes consists in organizing fast and high-quality mixing of fluid–fluid and gas–fluid flows, which requires intensification of mass-transfer processes. This problem is particularly topical in developing technologies for fast, primarily polymerization, processes in which mixing flows have strongly different densities and viscosities. This is clearly seen even in mixing infinitely soluble fluids, e.g., sulfuric acid or glycerol with water, when a phase boundary is preserved for a long time [1].

In industry, basic processes are commonly performed in volume mixing apparatus equipped with mechanical devices for vigorous stirring. However, in conducting fast exothermic processes in solution, e.g., cationic polymerization of isobutylene, copolymerization of isobutylene with isoprene or styrene, interaction of sulfuric acid with water, etc., volume mixing reactors have low efficiency, similarly to tubular plug-flow apparatus with laminar flows.

An ovel solution to the problem of developing technologies for fast chemical processes and improving the technical and economical parameters of the production process as a whole was to use reactors of new type. These were high-output small-size tubular apparatus operating in a quasi-plug-flow mode with turbulent flows and combining advantages of tubular plug-flow and volume mixing apparatus. These reactors also exhibited novel fundamental properties untypical of the conventional industrial apparatus [2–4]. The problems of achieving a vigorous stirring of the reaction medium, at which homogeneous reactant concentration fields are created in this kind of apparatus, are solved in a simpler and more efficient way.

The aims of this work were to analyze theoretically the turbulent mixing of fluid flows in tubular jet apparatus particularly efficient in fast chemical reactions (with characteristic reaction time $\tau_{ch} < 10^{-2}$ s) and physical mass-exchange processes, to provide recommendations for the reactor design on the basis of the analysis, and to discuss some examples of their industrial use.

As is known, the efficiency of mixing largely depends on the relative variation of the coefficient of turbulent diffusion along the reactor axis [2, 3]. The efficiency of mixing can be improved not only by raising the linear flow velocity u_0, but also by maintaining D_t at a certain high level along the direction of flow motion. This can be achieved by generating recirculation zones in a tubular apparatus, in particular, by changing the design (geometric arrangement) of the reactor [5]. Rather efficient in this regard are small-size tubular turbulent apparatus with identical repeating geometric units of diffuser–confuser design (Fig. 1b) ensuring a noticeable (by an order of magnitude and more) increase in D_t and maintaining con-

stant flow turbulence along the apparatus at arbitrary length [6].

The theoretical description is based on the following main model assumptions: The medium is Newtonian and incompressible; the flow is axially symmetrical and nonswirling; the turbulent flow can be described in terms of the so-called standard model [7] whose parameters are the specific kinetic energy of turbulence, *K*, and its dissipation ε; it is assumed that the coefficient of turbulent diffusion is equal to the kinematic coefficient of turbulent viscosity $D_t = K_t = \mu_t/\rho$. Let us write the mathematical model equations within the framework of these assumptions in the cylindrical system of coordinates: the continuity equation expressing the mass conservation law

$$\frac{1}{r}\frac{\partial(ru)}{\partial r} + \frac{\partial v}{\partial z} = 0; \quad (1)$$

the momentum transfer equation

$$\frac{\rho}{r}\frac{\partial(ruu)}{\partial r} + \rho\frac{\partial(uv)}{\partial z} = -\frac{\partial p}{\partial r} - \left[\frac{1}{r}\frac{\partial(r\tau_{11})}{\partial r} - \frac{\tau_{33}}{r} + \frac{\partial\tau_{21}}{\partial z}\right], \quad (2)$$

$$\frac{\rho}{r}\frac{\partial(ruv)}{\partial r} + \rho\frac{\partial(vv)}{\partial z} = -\frac{\partial p}{\partial r} - \left[\frac{1}{r}\frac{\partial(r\tau_{12})}{\partial r} + \frac{\partial\tau_{22}}{\partial z}\right], \quad (3)$$

with the components of the stress tensor given by

$$\tau_{11} = -2\mu\partial u/\partial r, \quad \tau_{22} = -2\mu\partial v/\partial z, \quad \tau_{33} = -2\mu u/r, \quad (4)$$

$$\tau_{12} = \tau_{21} = -\mu(\partial v/\partial r + \partial u/\partial z); \quad (5)$$

and the equations describing the transfer of specific kinetic energy of turbulence and its dissipation

$$\frac{\rho}{r}\frac{\partial(ruK)}{\partial r} + \rho\frac{\partial(vK)}{\partial z} = -\frac{1}{r}\frac{\partial}{\partial r}\left(\frac{\mu}{\sigma_K}\frac{r\partial K}{\partial r}\right) + \frac{\partial}{\partial z}\left(\frac{\mu}{\sigma_K}\frac{\partial K}{\partial z}\right) + \mu_t G - \rho\varepsilon, \quad (6)$$

$$\frac{\rho}{r}\frac{\partial(ru\varepsilon)}{\partial r} + \rho\frac{\partial(v\varepsilon)}{\partial z} = -\frac{1}{r}\frac{\partial}{\partial r}\left(\frac{\mu}{\sigma_E}\frac{r\partial\varepsilon}{\partial r}\right) + \frac{\partial}{\partial z}\left(\frac{\mu}{\sigma_E}\frac{\partial\varepsilon}{\partial z}\right) + \mu_t C_1 G\varepsilon/K - C_2\rho\varepsilon^2/K, \quad (7)$$

$$G = [(\tau_{11}^2 + \tau_{22}^2 + \tau_{33}^2)/2 + \tau_{12}^2]/\mu^2, \quad (8)$$

$$\mu_t = \rho\frac{C_\mu K^2}{\varepsilon}, \quad (9)$$

where *p* is pressure, *r* is the radial coordinate, *u* is the axial velocity component, *v* is the radial velocity component, *z* is the longitudinal component, μ is the effective dynamic viscosity coefficient, μ_t is the dynamic coefficient of turbulent viscosity, and ρ is density.

The following standard constants of the turbulence model were used:

$$C_1 = 1.44,\ C_2 = 1.92,\ C_\mu = 0.09,\ \sigma_K = 1.0,\ \sigma_E = 1.3. \quad (10)$$

The flow of a fluid with dynamic viscosity coefficient $\mu_m = 0.001$ Pa s and density $\rho = 1000$ kg m^{-3} is considered. The boundary conditions are conditions of symmetry along the *z* axis and condition of fluid adhesion to the solid wall surface. The pressure was set at the apparatus outlet (along the CD line), and the linear flow velocity $u_0 = 5$ m s^{-1}, at the inlet (AB line) along the symmetry axis. The lengths of the inlet and outlet orifices of the tubular apparatus exceeded its diameter manyfold ($L \gg d$). This ruled out any influence of the input and output turbulence parameters on the characteristics of turbulent flow in the diffuser–confuser part of the apparatus, which is the object of study. It was also taken that $D_t = V_t = \mu_t/\rho$.

To confirm the adequacy of the calculations performed, the obtained theoretical results were compared with the available experimental data for a cylindrical channel of constant diameter (Fig. 1a) at $\mathrm{Re} = 2 \times 10^5$ [8], with the obtained results also in agreement with the calculations done in [9]. In particular, Table 1 lists the lengths of the circulation zone appearing in the peripheral part of the tube, immedi-

ately downstream from the flow inlet into the diverging channel. A satisfactory agreement is observed (within 15%) between the calculated and experimental circulation zone lengths.

It was also shown experimentally that the quality of the forming emulsion (its homogeneity) strictly depends on the level of turbulence in the diffuser–confuser channel of the tubular jet apparatus (Fig. 2).

The agreement of the results is also observed for the axial velocity profiles and specific kinetic energy of turbulence (Fig. 3). The obtained results make it possible to calculate with confidence the characteristics of turbulent flow for analogous conditions and geometrically similar channels.

Calculations demonstrated that the best efficiency of fluid flow mixing is provided by tubular turbulent apparatus of diffuser–confuser design (Fig. 1b) with divergence angle α exceeding 20°–30°, with the convective velocity in the peripheral part of the apparatus much lower than that in its central part (Fig. 3). The transfer processes occur via turbulent exchange. This makes τ_m markedly shorter, which is rather important in performing fast chemical and mass-exchange processes. As a result, a tubular apparatus of diffuser–confuser design ensures, and this should always be kept in mind, a sufficiently homogeneous field of the turbulent diffusion coefficient D_t, with average D_t values in the central and peripheral parts of the tubular apparatus being only slightly different. The volume-averaged turbulent diffusion coefficients D_t are given in Table 2 for different parts of the apparatus and diffuser–confuser sections with different confuser divergence angles α. Noteworthy is the preservation of high numerical values of D_t at divergence angles α in the range 30°–85°.

The calculations performed allow apparatus of new type, not mentioned in the classification of apparatus for chemical industry [3, 4], to be recommended for use in fast chemical and mass-exchange physical processes. These are small-size tubular (0.03–0.3 m in diameter) apparatus of diffuser–confuser design, comprising several sections with divergence angles α ranging from 20° to 85°. Presently, apparatus of this kind are rather widely used in industry, including the manufacture of polymeric products. They are also highly efficient in the case of combined flows of fluids having strongly different densities and viscosities and in processing high-viscosity fluids. This results from the fact that a self-similar regime of fluid flow with viscosity-independent average character-

istics of the turbulent flow can be created in tubular turbulent jet apparatus [10].

Tubular turbulent apparatus of diffuser–confuser design show good performance in commercial production of elastomers based on binary and ternary copolymers of ethylene and propylene (preparation of gas–liquid mixtures, catalyst decomposition, introduction of stabilizers) [11–13], halobutyl rubber (chlorination of butyl rubber and also neutralization and washing of chlorobutyl rubber solutions) [14], and butadiene–styrene (emulsification, termination of the copolymerization reaction) [15], stereoregular *cis*-1,4-isoprene (prereactor, neutralization and washing of return solvent) [16, 17], stereoregular *cis*-1,4-butadiene (prereactor) rubbers, etc.

In all cases, the efficiency of reagent mixing increases markedly, which makes higher the sensitivity of the process to the action of various agents and improves the uniformity of the obtained polymeric products, including that between batches, and their technological, operational, and molecular characteristics. A quality level completely corresponding to the theoretical predictions could be achieved for a number of polymers. On the whole, all the processes are distinguished by pronounced energy and resource saving.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Prediction of the Quality of Mixing of Disperse Materials

A. N. Verigin, V. G. Dzhangiryan, M. V. Emel'yanov, and V. G. Petrov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received June 1, 1998; in final form, July 2000

Abstract—An expression is derived allowing evaluation of the maximum achievable quality of mixing on the assumption that the key component particles are randomly distributed over the mixture volume.

Mixing of disperse materials, considered in a number of papers and monographs [1–9], is widely used in chemical industry. It is the stage of mixing that governs the quality of quite a number of final products, which determines the interest of a wide circle of researchers and engineers in this process.

Mixing consists in spatial distribution of components in order to obtain a mixture with uniform composition and physicochemical and chemical properties of the mixture [1]. The quality of a mixture is commonly assessed after its preparation by analysis of sample statistics, based on the distribution laws of their numerical characteristics or combinations of these. One of the most widely used criteria for assessment of the quality of a prepared mixture is the coefficient of heterogeneity (variation) or the variance of the key component distribution over its volume, calculated by analyzing samples of certain size. It is commonly believed that the practically achievable minimum variance corresponds to a random distribution of key component particles over the mixture bulk, except in the case when the variance is zero [1].

In practice, a problem is frequently encountered when it is necessary to assess, without performing the actual mixing, what is the achievable quality of the mixture and whether it can be improved in further operation of a mixer, i.e., the problem of quality prediction. Presently, there is no theoretically substantiated and experimentally verified technique for predicting the achievable quality of a mixture, i.e., finding the minimum variance of the key component distribution over its volume. Such a technique should take into account the size (volume) v_0 of particles of the key component, their volume-average content $c_0 = N_0 v_0 / V$, the mixer volume V, and, necessarily, the sample volume $V^* = \alpha V$, where $0 \le \alpha \le 1$. This problem has been commonly solved using statistical equations or empirically [1, 5, 7].

In the absence of segregation, the best mixture quality can be obtained on attainment of an equilibrium dynamic state, when the quality cannot be improved by random particle redistribution and the variance of the key component distribution over the mixture volume remains constant [5]. Thus, prediction of the quality of a mixture of disperse materials involves construction of a model of its equilibrium dynamic state. It is necessary to determine the possible deviation of the content of key component particles in an arbitrary volume (sample) from its mean value for a mixture with random particle distribution.

As an acceptable numerical characteristic of the equilibrium dynamic state of a system of disperse materials can serve the fractal dimension of a set of discrete objects (particles) [10]. The dimension of a point set can be determined in a number of ways [11–13]. Let us use its information dimension [14]. In analyzing the state of a mixture, measurement assumes its being partitioned into separate boxes of equal size. The measurement is done with a uniform scale with division value ε (resolving capacity). If we are interested in the number of key component particles in a box, then the mixture is divided into $1/\varepsilon$ boxes and the measurement is performed in one of these. Let $n(\varepsilon)$ be the number of boxes covering the mixture with nonzero probability (i.e., containing at least one particle of the key component). Some boxes will contain a greater number of particles than the others. The "natural measure" of the given partition is proportional to the frequency at which a key component particle is found within it. Following [14], we define $p_i(\varepsilon)$ as "probability density" of finding a particle in the ith box. The set of probabilities $\{p_i(\varepsilon)\}$ is termed "rough" or "coarse-grained" probability distribution at resolving capacity ε. Let N_0 be the total number of key component particles in the mixture (number of points in the set). To calculate the infor-

1070-4272/01/7401-0095$25.00

mation dimension, we find the number of particles N_i in each box $n(\varepsilon)$ of the partition and evaluate the probability $p_i(\varepsilon)$ of finding a particle in the ith box:

$$p_i(\varepsilon) = N_i/N_0, \qquad \sum_{i=1}^{N} p_i(\varepsilon) = 1. \tag{1}$$

We emphasize that $N_0 \neq n(\varepsilon)$. The average amount of information furnished by a single measurement with resolving capacity ε is given by

$$I(\varepsilon) = -\sum_{i=1}^{n(\varepsilon)} p_i(\varepsilon) \ln p_i(\varepsilon). \tag{2}$$

With decreasing ε (increasing resolving capacity), the number of boxes grows and we obtain a sequence of increasingly "fine-grained" probability distributions.

The information dimension d_I is the rate at which the amount of information grows with increasing measurement accuracy:

$$d_I = \lim_{\varepsilon \to 0} \frac{I(\varepsilon)}{\ln(1/\varepsilon)}. \tag{3}$$

It can be seen from formula (3) that d_I is determined by the asymptotic value of the slope of the plot of $I(\varepsilon)$ against $\ln(1/\varepsilon)$.

If the probabilities of all boxes in the partition are the same, then $I(\varepsilon) = \ln n(\varepsilon)$, and the information dimension reaches its maximum and coincides with the fractal dimension [14]:

$$d = \lim_{\varepsilon \to 0} \frac{\ln n(\varepsilon)}{\ln(1/\varepsilon)}. \tag{4}$$

The limit (4) may not always exist [15]. In the case when it does not, the notions of lower and upper information dimensions are introduced.

We can pass from a multicomponent mixture of volume V to analyzing a system uniting the set of coordinates of key component particles [8]. Provided that the particle sizes and, consequently, the ε value are finite, the fractal dimension of such a set (4) is given by the expression

$$d = \ln N/\ln(1/\varepsilon). \tag{5}$$

If the particle size is taken as the measure ε of the set (measurement accuracy), the latter can be written as

$$\varepsilon = (v_0/V)^{1/3}.$$

The number N of elements in a mixture having key component concentration c_0 and particle volume v_0 is given by

$$N = c_0 V/v_0 = N_0.$$

The expression for the fractal dimension of the mixture is written as

$$d = 3\ln N_0/\ln(V/v_0). \tag{6}$$

Correspondingly, we have for a sample

$$d^* = 3\ln(\alpha N_0)l/\ln(\alpha V/v_0). \tag{7}$$

Apparently, the condition $d^* < d$ must be fulfilled for $\alpha < 1$.

At sufficiently large mixture volume, when the number of particles of the key component is great, the concentrations at specific points can be considered a continuous source of information. It this case it seems natural to relate the uncertainty in the choice of a value of a random continuous variable to the density of probability distribution $p(c)$ of these values. If we assume that the mixture volume is unlimited, the expression for the entropy $I(C)$ of a continuous source of information has the form [16]

$$I(C) = -\int_{-\infty}^{\infty} p(c) \ln p(c) \mathrm{d}c - \lim_{\Delta c \to 0} \Delta c. \tag{8}$$

The second term in the right-hand side of relation (8) tends to infinity when the difference between the neighboring values of the random variable approaches zero: $\Delta c \to 0$, and it may be concluded that the entropy of the continuous distribution is infinitely large. There is nothing paradoxical in this conclusion; moreover, it would have been drawn beforehand. The uncertainty in the choice from an infinitely large number of possible values of the number of key component particles at specific points is infinitely large.

The first term in the right-hand side of relation (8) has a finite value depending on the distribution of the random variable C and independent of the accuracy of its determination Δc. It has the same structure as the entropy of the discrete source (2). The second term of the same relation, conversely, depends solely on the quantization step Δc (accuracy of determination) of

the random variable C. It is this term that is reason why $I(C)$ becomes infinite.

The finite characteristic of the information properties of a continuous source can be obtained using two known approaches.

On the one hand, the first term in relation (8) is taken as uncertainty. The entropy determined in this way, the so-called differential entropy, can be interpreted as mean uncertainty in the choice of a random variable C with arbitrary distribution with respect to the mean uncertainty in the choice of a random quantity varying within the range from zero to unity and having uniform distribution.

Let us assume that the domain of variation of a random continuous variable C with mean value c_0 is unbounded but its variance is known to be bounded. Then the maximum differential entropy will be observed for a normal distribution of the variable C with mean value c_0. For a mixture of two disperse materials, the first assumption follows from the assumption of a continuous distribution of the key component over the mixture volume, and the second, from the very formulation of the problem. To furnish proof [16], it is necessary to solve the problem of finding a function $p(c)$ ensuring the maximum value of the functional (9) under the following constraints:

$$\int_{-\infty}^{\infty} p(c)\mathrm{d}c = 1, \qquad \int_{-\infty}^{\infty} c^2 p(c)\mathrm{d}c = \sigma^2.$$

The sought-for distribution density $p(c)$ can be determined by the Lagrange multiplier method in the form of a Gaussian distribution

$$p(c) = \frac{1}{\sigma(2\pi)^{1/2}} \exp[-(c - c_0)^2/(2\sigma^2)]. \qquad (9)$$

Having calculated the functional (8) for this distribution, we obtain the maximum differential entropy I_c^*

$$I_c^* = -\int p(c) \ln p(c)\mathrm{d}c = \ln[(2\pi e)^{1/2}\sigma/c_0]. \qquad (10)$$

On the other hand, as applied to the problem in question, the concentration can be only determined at a sufficiently large sample volume, when the probability of finding in it at least one particle of the key component is close to unity. Therefore, the possible number of C values within the prescribed measurement accuracy (sample volume) is to be considered as a single value. It is necessary to subtract from the mean uncertainty of the choice by the source of a certain value (unit sample) the mean uncertainty of the same source, obtained under the condition that C is determined with a certain accuracy. Such a difference is the measure of eliminated uncertainty or amount of information. With a sample taken from the mixture at random, the average amount of information contained in any particular sample with respect to the amount of information contained in the mixture as a whole is equal to the difference of the *a priori* and *a posteriori* entropies of the source of information (mixture). The information entropy depends on the accuracy with which V^*, i.e., the sample volume, is measured. With account of (2) and (4), the expression for evaluating the maximum entropy of a mixture (source) becomes

$$I(\alpha) = -\sum_{i=1}^{n(\alpha)} d \ln \alpha = (d - d^*) + \ln(d - d^*). \qquad (11)$$

In this case, account was taken of the fact that there is no scaling invariance for the mixture and the fractal dimension depends on the sample volume. Comparison of expressions (10) and (11) gives

$$\ln[(2\pi e)^{1/2}\sigma/c_0] = (d - d^*) + \ln(d - d^*).$$

Simple transformations give the sought-for expression for evaluating the mixture quality

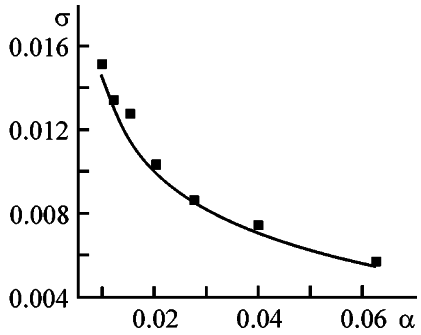
$$\sigma = \frac{c_0}{(2\pi e)^{1/2}}(d - d^*)\exp(d - d^*). \qquad (12)$$

where σ is the limiting minimal variance of the distribution of the key component over the volume of a mixture with prescribed properties, independent of the type of a mixer employed.

With account of expressions (7) and (8) allowing calculation of the fractal dimensions of the mixture, d, and sample, d^*, we get

$$d - d^* = \frac{3\ln\alpha \ln c_0}{\ln(V/v)\ln(\alpha V/v_0)}.$$

The possibility of using Eq. (12) was verified experimentally. Investigations were carried out on 5-l mixers with planetary stirring device [9]. To rule out the possible influence of physicochemical effects and gravity forces on the mixture quality, stirring experiments were done with particles of the same size and density (polystyrene, ca. 3 mm in size), differing only in color. The distribution of tracer particles over the mixer volume was studied. After the mixing process



Variance σ of the key component distribution over the mixture volume vs. the relative sample volume α. (Line) calculation by Eq. (12); (points) experiment.

was complete, the mixture volume was divided into a certain number of samples. The number of tracer particles in a sample was determined by counting. Then the mixture variance was calculated. The experimental data are compared with results of calculations by Eq. (12) in the figure where the mixture variance is plotted against the sample volume determined as a fraction of the volume mixture. The observed discrepancy is accounted for by the fact that expression (12) is derived under the condition of a random distribution of the key component over the mixture volume. This condition can be only met if each dispersion particle can independently execute a certain finite motion in any direction during a finite interval of time. Such conditions cannot be provided in experiment. The character of motion of dispersion particles depends on specific features of the mixer operation, and the intensity of this motion depends on the energy expended in mixing.

CONCLUSION

Analysis of a mixture with random distribution of components gave an expression for calculating the limiting minimum variance of the key component distribution in the mixture volume in relation to the component properties, sample size, and mixer volume. The results of theoretical investigations are confirmed by the experiment.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of a High-Energy-Capacity Compound, Tetrammine-*cis*-bis(nitro-2*H*-tetrazolato-N^2)cobalt(III) Perchlorate

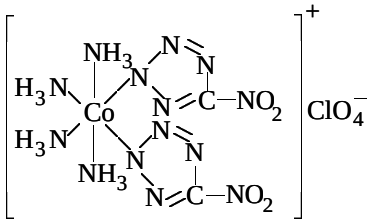
Abstract—The conditions for preparing tetrammine-*cis*-bis(nitro-2*H*-tetrazolato-N^2)cobalt(III) perchlorate and the nature of impurities affecting the yield and purity of the target product were studied. The compound can be efficiently prepared using microwave heating.

To meet the requirements to the process, service, and environmental safety of explosives, which become more and more stringent, efforts are made to find new high-energy-capacity compounds to be used as primers among *d*-metal coordination compounds [1–3]. Tetrammine-*cis*-bis(nitro-2*H*-tetrazolato-N^2)cobalt(III) perchlorate (**I**), according to [4, 5], is one of the most promising explosives for safe primers (including laser initiation):



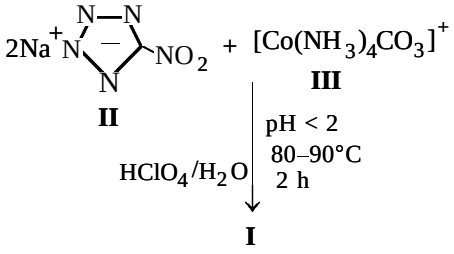
1

Some physicochemical and explosive properties of **I** are given below:

Density of single crystal, g cm^{-3}	2.05	[6]
Detonation rate at a single crystal density of 1.97 g cm^{-3}(calculation), km s^{-1}	8.1	[5]
Temperature of the onset of intense decomposition, °C (at heating rate of 20 deg min^{-1})	269	[7]
Sensitivity to the fire beam of fuse, cm	3–5*	[5]
Minimal charge for hexogen, g (KD8)	0.05	[5]
Time of transition from combustion to detonation, μs	~10	[4]

* Sensitivity limit: upper 3 cm, lower 5 cm.

In this work we studied the influence of the synthesis conditions on the yield and quality of **I**. Compound **I** can be prepared by the following scheme [7]:



(1)

We found that the yield of the target product was 50–70%. The synthesis conditions were optimized by fractional factorial experiment (FFE) of the 2^{3-1} type with the generating ratio $X_3 = X_1X_2$. Analysis of the mathematical description revealed the effect on the process of the following factors: reaction (or exposure) time, x_1 (h); acidity of the medium, expressed through the perchloric acid concentration, x_2 (%); and reaction temperature, x_3 (°C). As the response function we chose the yield of the target product y (%). The *a priori* information suggested that the interaction effect X_1X_2 is insignificant; therefore, it was replaced in the design matrix by the factor X_3.

Main characteristics of the FFE of the 2^{3-1} type

Plan parameter	x_1	x_2	x_3
Zero level	2.0	7.5	80
Variation interval	1.0	2.5	10

The experimental results are given in the table.

The determining contrast and the system of simultaneous estimates of the coefficients have the form

$$1 = X_1X_2X_3;$$

$$b_1 \rightarrow \beta_1 + \beta_{23},$$

1070-4272/01/7401-0099$25.00

Fractional factorial experiment of the 2^{3-1} type

Run no.	Planning matrix			Response function	
	x_1	x_2	x_3	y_{ej}	y_{cj}
1	+1	–1	–1	23.1	23.85
2	–1	+1	–1	32.2	31.45
3	–1	–1	+1	60.3	60.85
4	+1	+1	+1	69.5	69.35

$$b_2 \rightarrow \beta_2 + \beta_{13},$$

$$b_3 \rightarrow \beta_3 + \beta_{12}.$$

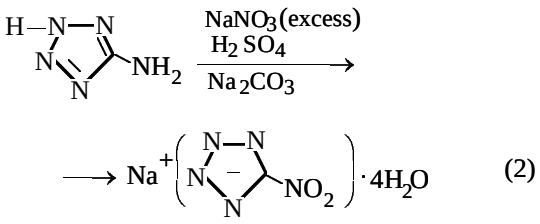
By statistical processing of the experimental data, we obtained a regression equation adequately (acoording to the Student and Fisher tests [8]) describing the reaction:

$$y = 46.3 + 4.6x_1 + 4.5x_2 + 18.6x_3.$$

Analysis of the regression equation shows that the reaction temperature is the most significant factor of the process.

Further experiments on synthesis of **I** were performed with microwave heating (MWH). Recently there has been an increased interest in MWH as an alternative way of thermal activation of chemical reactions [9]. A chemical system containing polar molecules or ions can actively take up the energy of a UHF electromagnetic field, transform it to thermal energy, and thus warm up (in our case to ~102°C). The MWH accelerates anation in Co(III) ammine complexes [10]. By substitution of coordinated water with the 5-nitrotetrazole anion under MWH conditions (1 h), we prepared compound **I** in a 78% yield, which practically coincides with the value predicted by the mathematical description. Thus, microwave heating of the reactants ensures a high yield of **I** within a considerably shorter time.

In synthesis of **I**, we used sodium 5-nitrotetrazolate (**II**) prepared by the noncatalytic Sandmeyer reaction from 5-aminotetrazole [11]:

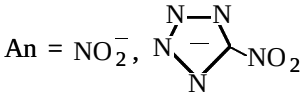


(2)

Salt **II** can contain sodium nitrite $NaNO_2$ as a natural impurity if the crude product is purified insufficiently. The NO_2^- ion competes with the nitrotetrazolate ion for the position in the inner sphere in the anation reaction [12]:

$$[Co(NH_3)_4(H_2O)_2]^{3+} + 2An \xrightarrow{H^+} [Co(NH_3)_4(An)_2]^+ + 2H_2O, \quad (3)$$

where



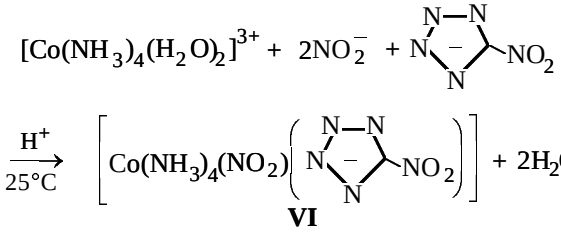
Therefore, it is very important to elucidate the influence of nitrite ion on formation of **I**. At +25°C, nitrite ion substituted both water molecules in **IV** within 170 h.

$$[Co(NH_3)_4(H_2O)_2]^{3+} + 2NO_2^- \xrightarrow{H^+} [Co(NH_3)_4(NO_2)_2]^+ + 2H_2O. \quad (4)$$

IV **V**

Complexes **IV** and **V** were isolated as sulfates: $[Co(NH_3)_4(H_2O)_2]_2(SO_4)_3$ (**IVa**) and $[Co(NH_3)_4 \cdot (NO_2)_2]_2SO_4$ (**Va**).

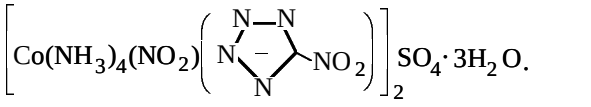
At the same temperature, simultaneous action of an excess of nitrite and nitrotetrazolate ions on cation **IV** for 170 h results in complete substitution of inner-sphere water and formation of complex **VI**:



(5)

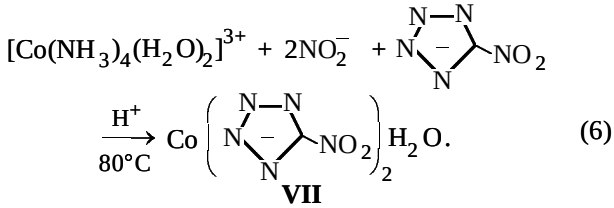
VI

Compound **VI** was isolated as crystal hydrate:



VIa

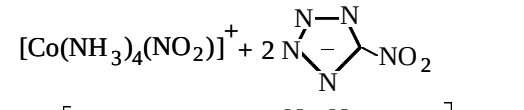
At the temperature increased to 80°C, instead of the expected product **I** we isolated from the reaction mixture salt **VII**:



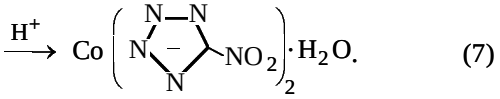
(6)

VII

Salt **VII** is very sensitive to mechanical actions and decomposes on heating with explosion. Hence, it is a primer [13]. Its impurity in **I** is inadmissible. Formation of **VII** involves breakdown of the inner sphere of **I** with reduction of Co(III) to Co(II). This process is probably due to possible combination of redox reactions initiated by the nitrite ion and to an appreciable *trans* effect of the nitrotetrazolate anion in the inner coordination sphere [14]. To confirm this assumption, we studied the reaction between **V** and 5-nitrotetrazolate anion in acid solution at 50–70°C. We found that the product composition depends on time. For example, 2 h after the start of the reaction the major product is complex **VIII**, but then its content decreases as compound **VII** is accumulated:



VIII



VII

Formation of complex **VIII** confirmed the assumption that in the course of synthesis of **I** in the presence of nitrite ions the ammine ligands become labile and can be substituted by other ligands.

Our experimental results show that the synthesis of **I** in aqueous solution should be performed at a temperature as high as possible and that the reactants should be thoroughly purified to remove sodium nitrite.

EXPERIMENTAL

The IR spectra were recorded on a Specord M-80 spectrophotometer from thin-film samples between KBr plates. The ^{1}H NMR spectra were taken on a Perkin–Elmer R-12 spectrometer operating at 60 MHz, with HMDS as internal reference. The reaction progress was monitored by TLC on Silufol UV-254 plates (eluent 3% aqueous $NaClO_4$).

The UHF heating device was a short-circuited waveguide of 9×4.5 cm cross section, connected to a UHF generator with the output capacity of 600 W and working frequency of 2450 MHz. The reaction vessel (a glass test tube 35 mm in diameter, equipped with a thermometer with an organic working liquid and a reflux condenser) was placed in the waveguide through a special hole.

Carbonatotetramminecobalt(III) perchlorate (IIIa) was prepared by the procedure in [15]. The yield of **IIIa** after drying was 77%. IR spectrum, ν, cm^{-1}: 1596 s, 1560 m (C=O, NH_3), 1084 s (ClO_4). ^{1}H NMR spectrum (DMSO-d_6), δ, ppm: 4.40 (12H, NH_3).

Found, %: C 4.6, H 4.7, N 20.1.
$CH_{12}ClCoN_4O_7$.
Calculated, %: C 4.2, H 4.2, N 19.6.

Tetrammine-*cis*-bis(nitro-2*H*-tetrazolato-N^2)cobalt(III) perchlorate (I). A 1-g portion of carbonatotetramminecobalt(III) perchlorate (**IIIa**) was dissolved in 10 ml of 10% perchloric acid until the CO_2 evolution ceased. The solution was filtered, and 34 ml of a 4.4% solution of sodium 5-nitrotetrazolate (**II**) was added. The reaction mixture was heated on a boiling water bath for 4 h and then cooled to 15°C; the precipitate was filtered off, washed with ethanol (2 ± 0.5 ml), and recrystallized from 1% $HClO_4$. Yield of **I** 0.92 g. IR spectrum, ν, cm^{-1}: 1588 m, 1316 m (NH_3, tetrazole), 1076 m (ClO_4), 1540 m (NO_2). ^{1}H NMR spectrum (DMSO-d_6), δ, ppm: 3.79, 4.29 (12H, NH_3).

Found, %: C 4.8, H 2.3, N 42.6.
$C_2H_{12}ClCoN_{14}O_8$.
Calculated, %: C 5.3, H 2.7, N 43.1.

Dinitritotetramminecobalt(III) sulfate (Va) was prepared according to [16]. Yield after drying 57%. IR spectrum, ν, cm^{-1}: 3120 m, 1620 m (NH_3), 1388 m, 1304 m (NO_2), 1120 m (SO_4).

Found, %: H 4.1, N 31.4.
$H_{24}Co_2N_{12}O_{12}S$.
Calculated, %: H 4.5, N 31.4.

Nitrito(nitrotetrazolato)tetramminecobalt(III) sulfate trihydrate (VIa). To a mixture of 16 ml of an aqueous solution containing 3.3 g of sodium nitrite and 60 ml of a 4.4% solution of sodium 5-nitrotetrazolate (**II**), we added 10 ml of a 1.5% sulfuric acid solution containing 1 g of diaquatetramminecobalt(III) sulfate (**IVa**) prepared according to [16]. The mixture was allowed to stand for 7 days. After drying, the yield of **VIa** was 70%. IR spectrum, ν, cm^{-1}: 1552 w (C–NO_2), 1400 m (NO_2), 1280 m (NH_3), 1052 m (SO_4).

Found, %: C 3.3, H 3.8, N 38.3.
$C_2H_{30}Co_2N_{20}S$.
Calculated, %: C 3.3, H 4.2, N 38.6.

Cobalt(II) nitrotetrazolate monohydrate (VII). To a mixture of 16 ml of an aqueous solution containing 3.3 g of sodium nitrite and 60 ml of a 4.4% solution of sodium 5-nitrotetrazolate (**II**), we added 10 ml of a 1.5% sulfuric acid solution containing 1 g of diaquatetramminecobalt(III) sulfate (**IVa**) prepared according to [16]. The mixture was heated to 80°C and kept at this temperature for 3 h. Yield of **VII** after drying 62%. IR spectrum, ν, cm^{-1}: 3544 w, 1616 m (H_2O), 1560 s, 1320 m (NO_2), 1440 m (tetrazole).

Found, %: C 7.8, H 0.6, N 45.6.
$C_2H_2CoN_{10}O_5$.
Calculated, %: C 7.9, H 0.7, N 45.9.

Triamminebis(5-nitrotetrazolato)nitritocobalt(III) hydrate (VIII). To a mixture of 16 ml of an aqueous solution containing 3.3 g of sodium nitrite and 60 ml of a 4.4% solution of sodium 5-nitrotetrazolate (**II**), we added 10 ml of a 1.5% sulfuric acid solution containing 1 g of diaquatetramminecobalt(III) sulfate (**IVa**) prepared according to [16]. The mixture was heated to 60°C and kept at this temperature for 2 h. Compound **VIII** precipitated on cooling. Yield after drying 39%. IR spectrum, ν, cm^{-1}: 3200 m (NH_3), 1544 s, 1332 m (C–NO_2), 1416 m, 1312 (NO_2).

Found, %: C 5.4, H 2.8, N 48.5.
$C_2H_{11}CoN_{14}O_7$.
Calculated, %: C 5.9, H 2.7, N 48.7.

The mother liquor was kept for 1 h at 60–70°C. An additional crop of **VII** was obtained; yield after filtration, washing, and drying 25%.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Efficient Procedure for Preparing Salicyl Alcohols

M. L. Belyanin, V. D. Filimonov, and E. A. Krasnov

Siberian State Medical University, Tomsk, Russia
Tomsk Polytechnic Institute, Tomsk, Russia

Received February 21, 2000

Abstract—A new convenient procedure was developed for selective *ortho*-hydroxymethylation of phenols by reaction of paraformaldehyde with a mixture of phenol and orthoboric acid. The method is general for phenols containing no strong electron-withdrawing substituents; it allows preparation of *o*-hydroxybenzyl alcohols of high purity in a high yield.

Salicyl (*o*-hydroxybenzyl) alcohol and its derivatives are of interest as intermediates in synthesis of many organic compounds: phenylchromones [1], isoflavones [2], etc.

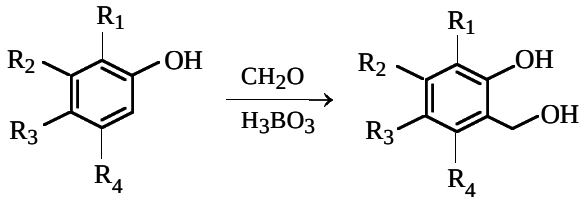
Salicyl alcohol is an aglycone of a number of glycosides found in Salicaceae. Some of them exhibit antihelminth [3] and antiviral [4] activity.

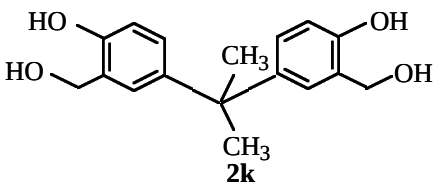
One of the most widely used routes to salicyl alcohol is hydroxymethylation with formaldehyde or compounds generating it of phenyl metaborate PhOB=O (exists as trimers [5]). The initial metaborate is prepared by refluxing equimolar amounts of phenol and boric acid in aprotic aromatic solvents (toluene, xylene) with azeotropic distillation of the released water [5–9]. The yield of the crude target product, according to patents [6–8], depends on the initial phenol and does not exceed 65%; attempts to reproduce the synthesis of salicyl alcohol described in the patent resulted in a yield as low as 35% [5]. The conversion of phenol was incomplete, and polycondensation products formed, complicating purification of the target product [5].

Another route is hydroxymethylation of phenol in the presence of a 1.5-fold excess of arylboronic acids $ArB(OH)_2$. The reaction involves intermediate formation of cyclic esters of hydroxybenzyl alcohol and arylboronic acid. The desired alcohol is released by treatment of these esters with propylene glycol or hydrogen peroxide [10].

A simpler route to salicyl alcohols is reaction of paraformaldehyde with a mixture of phenol and excess boric acid in benzene under conditions of continuous azeotropic distillation of water, without preparing phenyl metaborate in advance. By this method we successfully performed selective *o*-hydroxymethylation of a series of phenols **1a**–**1k** and obtained the corresponding salicyl alcohols **2a**–**2k** (Table 1).

The structures of **2a**–**2k** were proved by the ^1H NMR (Table 2) and IR spectra and by comparison with the authentic samples. The IR spectra of **2a**–**2k** contain two strong absorption bands at 3475–3440 and 3240–3165 cm^{-1} characteristic of the intramolecular hydrogen bond and of O–H stretching vibrations, and also characteristic absorption bands ν(C–O) at 1015–1045 cm^{-1}:





2k

where $R^1 = R^2 = R^3 = R^4 = H$ (**a**); $R^2 = R^3 = R^4 = H$, $R^1 = CH_3$ (**b**); $R^1 = R^2 = R^4 = H$, $R^3 = CH_3$ (**c**); $R^2 = R^3 = H$, $R^1 = CH(CH_3)_2$, $R^4 = CH_3$ (**d**); $R^1 = R^2 = R^4 = H$, $R^3 = OCH_3$ (**e**); $R^1 = R^2 = R^4 = H$, $R^3 = Cl$ (**f**); $R^1 = R^2 = R^4 = H$, $R^3 = F$ (**g**); $R^1 = R^2 = R^4 = H$, $R^3 = Ph$ (**h**); $R^1 = R^2 = R^4 = H$, $R^3 = OCOPh$ (**i**); $R^1 = R^3 = R^4 = H$, $R^2 = OCOPh$ (**j**).

ortho-Hydroxymethylation of phenols **1a**–**1k** by the suggested procedure occurs at lower temperature (up to 81°C), takes longer time, and requires a larger

2k	49	56	144–145 (water)

* In parentheses are published data.

excess of boric acid (up to 1.5 mol) than hydroxymethylation of aryl metaborates [5–9]. Also, fresh portions of paraform should be added at regular intervals to compensate for its removal with the distillate. Nevertheless, there are important advantages: complete conversion of the initial phenol, absence of oligomeric products, and higher yield and purity of the target alcohols **2a**–**2k**.

It is important for practice that in hydroxymethylation of phenyl metaborate the resulting salicyl alcohol, as a rule, is isolated by treatment of the reaction mixture with alkali [5–7, 9], which makes this procedure unsuitable for preparing salicyl alcohols with substituents sensitive to bases. It was found that the boric acid esters formed under conditions of our procedure can be successfully saponified by keeping the reaction mixture in water without adding alkali. This approach allowed us to perform for the first time direct selective hydroxymethylation of phenols **1i** and **1j** containing phenyl benzoate moieties. The resulting alcohols **2i** and **2j** (Table 1) are synthetic equivalents of difficultly accessible dihydroxybenzyl alcohols.

The relatively low yield of **2j** is due to the fact that reaction of phenol **1j** with paraform yields, according to the ^{1}H NMR spectrum, a mixture of **2j** and its isomer, 2-hydroxymethyl-3-benzoyloxyphenol, inseparable by chromatography. In other words, hydroxymethylation occurs at both *o*-positions of the phenolic hydroxyl in **1j**. We were able to isolate only a portion of **2j** by single recrystallization of the mixture from benzene.

It should be noted that pyrocatechol monobenzoate appeared to be almost inert in hydroxymethylation (110 h). This is probably due to a strong intramolecular hydrogen bond blocking the phenolic hydroxyl in the *o*-position relative to the benzoate group.

Reaction of bisphenol **1k** containing two equivalent phenolic hydroxyls with paraform yields bis(hydroxymethyl) derivative **2k** within 49 h. At a shorter reaction time, the reaction mixture contained, according to TLC, unchanged **1k**, the monohydroxymethylation product, and alcohol **2k**; the latter is formed even in early stages of the reaction. Thus, hydroxymethylation of phenol **1k** occurs nonselectively at both phenyl rings.

Table 2. ^{1}H NMR spectra of salicyl alcohols **2a**–**2k** in DMSO-d_6

Compound	δ, ppm
2a	4.70 (s, 3H, CH_2OH), 6.70–7.18 (m, 4H, Ar), 8.80 (s, 1H, ArOH)

* In $CDCl_3$. ** In pyridine-d_5.

Phenols with electron-withdrawing substituents in the ring (NO_2, CHO, COOH) remain inert under the reaction conditions and do not give the corresponding salicyl alcohols.

The positive effect reached in hydroxymethylation of phenols in the presence of excess boric acid can be explained as follows. In the case of equimolar amounts of phenol and boric acid [5–9], the presumable precursors of salicyl alcohol are cyclic borates [5]. We can assume with confidence that under the reaction conditions these cyclic borates are in equilibrium with free alcohol **2a** which enters further side transformations (dehydration, condensation with formaldehyde, etc.). Then excess boric acid under the suggested conditions decreases the concentration of free salicyl alcohol owing to shift of the equilibrium. Also, it is significant that the reaction is performed at a lower temperature (81°C) than suggested in the literature (90–95°C) [5–9]. It is known that salicyl alcohol is thermally unstable, and at temperatures above 100°C it rapidly forms polymeric products [14].

EXPERIMENTAL

The IR specrtra were taken on a Specord M-80 spectrophotometer in KBr pellets, and the ^{1}H NMR spectra, on a Bruker AC 200 spectrometer (200 MHz, DMSO-d_6, internal reference HMDS).

The reaction progress was monitored and the product purity checked by TLC on Silufol UV-254 plates, eluent benzene–ethanol (9 : 1). The plates were developed using filtered UV radiation, diazotized sulfanilic acid, or 5% $FeCl_3$ solution.

The typical procedure of hydroxymethylation of phenols **1a**–**1k** with paraform in the presence of boric acid was as follows. A mixture of 40 mmol of appropriate phenol, 3.72 g (60 mmol) of boric acid, and 1.8 g (60 mmol) of paraform in 70 ml of benzene was refluxed in a flask equipped with a Dean–Stark trap with continuous azeotropic distillation of water until the initial phenol was completely converted (TLC). Every 4 h, a fresh 0.45-g (15-mmol) portion of paraform was added. After reaction completion, excess benzene was distilled off under reduced pressure. To the residue 30 ml of water was added, and the mixture was allowed to stand for 5 h to ensure hydrolysis of the intermediate boric acid ester of the salicyl alcohol. The product was extracted with ether (three 40-ml portions), and the combined ether extracts were washed with watedr (20 ml). The solvent was removed, and alcohols **2a**–**2k** were purified by recrystallization.

CONCLUSIONS

(1) Reaction of paraform with phenols in the presence of excess boric acid under conditions of continuous azeotropic distillation of water results in selective *o*-hydroxymethylation of the substrates with complete conversion of the initial phenols and formation of salicyl alcohols.

(2) A general procedure was developed for preparing salicyl alcohols from phenols containing no strong electron-withdrawing substituents.

(3) The suggested procedure allowed for the first time preparation of the synthetic equivalents of dihydroxybenzyl alcohols.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of Aryl-Substituted Propanols, Pentanediols, and Tetrahydropyran

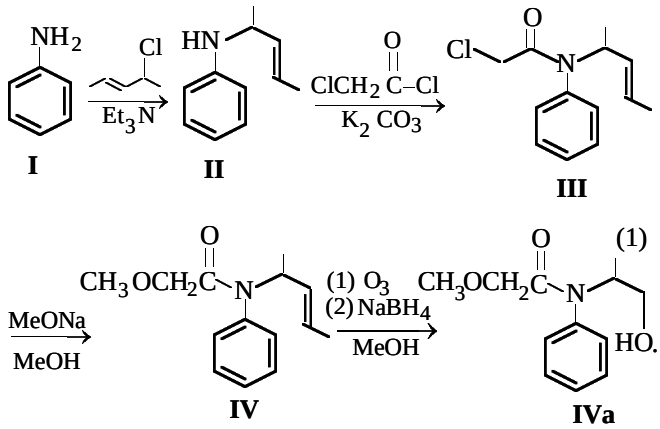
Abstract—Oxidation of *N*- and *C*-alkenylanilines with ozone under conditions of alcohol formation was studied. Depending on the structure of the alkenyl moiety, the reaction yields aryl-substituted propanols, pentanediols, or tetrahydropyran.

Since early 1960s, when the feasibility was demonstrated for preparative synthesis of Claisen rearrangement products from *N*-allylaniline [1, 2], there has been a great deal of interest in the chemistry of alkenylanilines. These compounds find extending use in organic synthesis, including preparation of practically useful substances. It is known that some *N*- and *C*-alkenylanilines exhibit activity as potato growth regulators and fungicides against potato phytophthora infection, inhibit biosynthesis of chitin of flour moth [3], show a pronounced local anesthetic effect [4], and are successfully used in synthesis of some valuable alkaloids [5]. Proceeding with studies [6–8] on transformations of *o*-alkenylarylamines, we studied oxidation of *N*- and *C*-alkenylanilines with ozone.

For example, from aniline (**I**) by a series of condensations we prepared *N*-methoxyacetyl-*N*-(2-penten-4-yl)aniline (**IV**) in a 68% yield:



Previously field tests of the *N*-ethoxyacetyl analog of this compound demonstrated its efficiency against potato phytophthora infection, which was level with the known antiphytophthora agent Ridomil [ethyl *N*-methoxyacetyl-*N*-(2-methyl-6-ethylphenyl)aminobutyrate]; the productivity increased by 30%. Presumably, under the testing conditions involving the impact of soil, atmospheric oxygen, and sunlight, this compound could undergo transformations with participation of the unsaturated C=C bond of the pentenyl unit. Oxidation of amine **IV** with ozone is one of possible routes to hydroxy derivatives of this substance. We found that ozonation of **IV** followed by treatment with $NaBH_4$ gives *N*-methoxyacetyl-*N*-(1-hydroxyprop-2-yl)aniline in a 35–45% yield.

When an equimolar amount of ozone is passed through a solution of **IV** in cyclohexane–methanol, the reaction does not go to completion, and the ratio of the initial amine **IV** and product **IVa** is 1.5 : 1. When the similar reaction is performed in methanol, the ratio of these compounds [scheme (1)], according to the ^1H NMR data, varies from 1 : 1 to 1 : 0.7.

In contrast to *N*-alkenylaniline **IV**, ozonation in methanol of pentenylanilines **VIa** and **VIb** exhibiting local anesthetic activity [4] goes to completion; subsequent treatment of the reaction mixture with $NaBH_4$ gives propanols **VIIa** and **VIIb** in 50–60% yields [scheme (2)]. Oxidation of 2-cyclopentenylanilines **VIIIa**–**VIIIc** under these conditions yields pentanediols **IXa**–**IXc** in a 60–70% yield [scheme (3)].

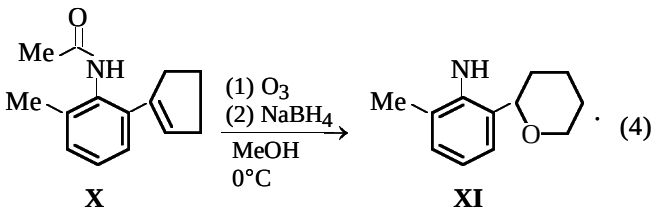
where R^1 = R^2 = R^3 = H (**a**); R^1 = Me, R^2 = R^3 = H (**b**); R^1 = H, R^2 = R^3 = F (**c**).

Reagents and conditions: A, $ClCH_2C(O)Cl$, K_2CO_3, 20°C; B, excess piperidine; C, O_3, MeOH, 0–5°C; D, $NaBH_4$, MeOH, 0–5°C.

Oxidation of *N*-acetyl-2-methyl-6-(cyclopent-1-enyl)aniline (**X**) [9] unexpectedly gave tetrahydropyran **XI** (yield 70%):



X **XI**

The structure of the products was proved by the IR and ^1H, ^{13}C NMR spectra and also by elemental analysis. The IR spectra of all the products contain a characteristic absorption band of the OH group at ν 3400–3600 cm^{-1}. In the ^1H NMR spectrum of amine **IVa**, the methyl protons of the propanol moiety give a doublet at δ 0.96 ppm (J 6.99 Hz). In the ^{13}C NMR spectrum, the signal of the methyl carbon of the propanol moiety is shifted upfield ($\delta_{C_{1'}}$ 14.73 ppm) as compared fo **IV**. The signals of the $C^{1'}$ and $C^{2'}$ atoms in **IVa** are observed at 64.45 and 53.62 ppm, respectively.

In the ^1H NMR specrta of amino alcohols **VIIa** and **VIIb**, the methyl groups give a doublet at 1.16 ppm (J 7.07 Hz). The methine proton $H^{2''}$ and the methylene protons $H^{1'}$ give multiplets at 4.33 and 3.64 ppm. The signals of the $C^{1''}$, $C^{2''}$, and $C^{3''}$ atoms of **VIIa** and **VIIb** in the ^{13}C NMR spectra are observed at 68, 35–37, and 17–18 ppm, respectively.

In the ^1H NMR spectra of diols **IXa**–**IXc**, the $H^{1''}$ and $H^{5''}$ protons of the pentanediol moiety give signals at 3.70 and 3.45 ppm, and the signal of OH protons is observed at 4.80 ppm. In the ^{13}C NMR spectra of **IXa**–**IXc**, the $C^{1''}$ and $C^{5''}$ signals are observed at 67 and 62 ppm, respectively. The signals of the $C^{2''}$, $C^{3''}$, and $C^{4''}$ atoms are observed at 41 and 28–29 ppm. The signals of the benzene carbon atoms in the ^{13}C NMR spectrum of **IXc** are split owing to coupling with F and give doublets with the coupling constants of 17–20 (for $C^{1'}$, $C^{2'}$, $C^{3'}$, and $C^{6'}$) and 216–223 Hz (for the $C^{4'}$ and $C^{5'}$ atoms directly bound to F).

The mass spectrum of the tetrahydropyranyl derivative **XI** contains a molecular peak M^+ (*m/z* 191).

EXPERIMENTAL

The ^1H and ^{13}C NMR spectra were taken on a Bruker AM-300 spectrometer (working frequency 300 and 75 MHz, respectively; solvent $CDCl_3$; internal reference TMS), and the IR spectra, on a UR-20 spectrometer. The product purity was checked by TLC (Silufol UV-254 plates). The mass spectrum was obtained with an MKh-1320 spectrometer (70 eV). The physicochemical characteristics of **VIb** and **VIIa**–**VIIc** are given in [10, 11].

***N*-(2-Methoxyacetyl)-*N*-(3-penten-2-yl)aniline (IV)** was prepared according to [1]. Yield 90%. R_f 0.48 (CH_2Cl_2–CH_3OH, 95 : 5), bp 123°C (1 mm Hg).

Found, %: C 70.41, H 8.35, N 6.07.
$C_{13}H_{19}NO_2$.
Calculated, %: C 70.59, H 8.60, N 6.33.

^{1}H NMR spectrum ($CDCl_3$, δ, ppm): 0.98 d (3H, *J* 6.61 Hz, CH_3), 1.50 d (3H, *J* 6.35 Hz, CH_3), 3.19 s (3H, OCH_3), 3.50 m (2H, CH_2), 5.25–5.45 m (3H, CH, HC=CH), 6.96–7.29 m (5H, ArH). ^{13}C NMR spectrum ($CDCl_3$, δ, ppm): 17.46, 17.63 (CH_3); 51.39 ($C^{1'}$); 56.76 (CH_3); 70.58 (CH_2); 127.21, 128.28, 128.92, 129.81, 130.59, 136.83 (C_{arom}, C=C); 167.77 (C=O).

***N*-Chloroacetyl-2-(3-penten-2-yl)-4-methylaniline (Va).** A three-necked flask equipped with a power-driven stirrer, a reflux condenser, and a dropping funnel was charged with dry K_2CO_3 and 17.1 g (0.1 mol) of 2-(3-penten-2-yl)-4-methylaniline in methylene chloride. A solution of 0.2 mol of freshly distilled chloroacetyl chloride in 80 ml of CH_2Cl_2 was slowly added dropwise with stirring. After reaction completion, the precipitate was filtered off, 100 ml of water was added, and the organic layer was washed with a 10% solution of $NaHCO_3$ until the CO_2 evolution ceased and then with two 100-ml portions of water. The organic solution was dried over $MgSO_4$. The solvent was vacuum-evaporated, and the residue was recrystallized from benzene. Yield of **Va** 15.4 g (90%), mp 109°C. IR spectrum, ν, cm^{-1}: 3275 (NH). ^{1}H NMR spectrum, δ, ppm (*J*, Hz): 1.35 d (3H, *J* 7.15, CH_3), 1.66 d (3H, *J* 7.05, CH_3), 2.35 s (3H, CH_3), 3.60 m (1H, $H^{1'}$), 4.28 s (2H, CH_2), 5.59 m (2H, HC=CH), 6.90 (1H, ArH), 6.87 (1H, ArH), 7.85 br.s (1H, NH). ^{13}C NMR spectrum ($CDCl_3$), δ, ppm (*J*, Hz): 20.25 (**Ia**), 35.80 ($C^{1'}$), 42.79 (C–Cl), 165.50 (C=O), 136.70 (C^1), 141.80 (C^2), 125.55 (C^3), 124.49 (C^5), 128.53 (C^4), 134.79 (C^6), 135.60 ($C^{2'}$), 130.45 ($C^{3'}$).

***N*-[(2-(3-propen-2-yl)-4-methylphenyl)aminocarbonylmethyl]piperidine (VIa).** Chloroacetylated aniline **Va** (2.3 g, 10 mmol) was dissolved in hot toluene (20 ml), and 5 ml of piperidine was added. The mixture was refluxed for 4 h. The amine hydrochloride precipitate was filtered off and washed with 5 ml of toluene. The filtrate was vacuum-evaporated, and the residue was recrystallized from a minimal amount of toluene. Yield of **VIa** 2.3 g (68%). R_f 0.48 (CH_2Cl_2).

Found, %: C 75.56, H 9.28, N 9.27.
$C_{19}H_{28}N_{20}$.
Calculated, %: C 76.00, H 9.33, N 9.33.

IR spectrum, ν, cm^{-1}: 3280 (NH). ^{1}H NMR spectrum ($CDCl_3$), δ, ppm (*J*, Hz): 1.49 d (3H, *J* 6.97, CH_3); 1.70 d (3H, *J* 6.46, CH_3); 2.30 s (3H, CH_3); 1.50, 1.60, 2.55 (m, 10H, H_{pip}); 3.08 s (2H, CH_2); 3.50 m (1H, CH); 5.35–5.65 m (2H, HC=CH); 7.00 s (1H, H^3); 7.05 d (1H, *J* 8.79, H^6); 7.90 d (1H, H^5); 9.25 s (1H, NH). ^{13}C NMR spectrum ($CDCl_3$, δ, ppm): 17.78, 20.03, 21.01 (C_{methyl}); 23.52, 26.08, 54.97 (C_{pip}); 63.03 ($C^{2''}$); 168.78 (C=O); 36.63 ($C^{1'}$); 134.75 (C^2); 122.62 ($C^{3'}$); 132.22 (C^1); 134.11 (C^2); 127.21 (C^3); 135.22 (C^4); 127.20 (C^5); 137.24 (C^6).

The general procedure of oxidation was as follows. Through a solution of 10 mmol of **IV**, **IVa**, **IVb**, **VIIIa**, **VIIIb**, or **X** in 10 ml of methanol at 0–5°C we passed a calculated amount of an ozone–oxygen mixture (controlled with a stopwatch). The mixture was kept for 5 min at this temperaturem after which 0.6 g of $NaBH_4$ was added at the temperature maintained no higher than 10–15°C. The mixture was allowed to stand at 20°C for 18 h and then diluted with a 10 : 1 mixture of H_2O and CH_3COOH. The product was extracted with CH_2Cl_2, washed with 5% $NaHCO_3$ and saturated NH_4Cl solution, and dried over Na_2SO_4. The solvent was evaporated, and alcohols **IVa**, **VIIa**, **VIIb**, and **IXa**–**IXc** or pyran **XI** was obtained.

***N*-(2-Methoxyacetyl)-*N*-(1-hydroxy-2-propyl)aniline (IVa).** Yield 91%. R_f = 0.27 (CH_2Cl_2–CH_3OH, 95 : 5).

Abstract—The mechanism of acetol formation in two-stage process of sulfuric acid cleavage of cumyl hydroperoxide was studied and confirmed by comparison with related reaction systems.

One of undesirable by-products in production of phenol and acetone by cleavage of cumyl hydroperoxide is hydroxyacetone (acetol). This impurity in commercial phenol dramatically deteriorates its color index. Acetol is removed from crude phenol catalytically by treatment with sulfonic cation-exchange resins. On an acid catalyst acetol partially reacts with phenol to form 2-methylbenzofuran (2-MBF). The amount of the forming 2-MBF is directly related to the content of acetol in the product to be catalytically purified. Separation of 2-methylbenzofuran from phenol is very difficult and is possible only by fractional azeotropic distillation with water. At the same time, 2-MBF, even when present in concentrations as low as 0.001 wt %, also dramatically impairs the color index of the commercial phenol.

The simplest way to improve the color index of commercial phenol is to prevent formation of acetol or sharply decrease its content in products fed to distillation. It is known that acetol is formed in the stage of sulfuric acid decomposition of cumyl hydroperoxide (CHP) into phenol and acetone; its concentration in the reaction mixture reaches 0.2 wt %. The mechanism of acetol formation and ways to decrease its concentration in CHP decomposition products were not elucidated. It was suggested that acetol forms with participation of acetone and CHP [1]. It was assumed that CHP directly reacts with acetone, or that CHP reacts with mesityl oxide formed by condensation of two acetone molecules in the presence of sulfuric acid. The mechanism of the direct reeaction was not described, and the second pathway was presented as a series of consecutive reactions:

$$2CH_3{-}\underset{\underset{O}{\|}}{C}{-}CH_3 \longrightarrow CH_3{-}\underset{\underset{O}{\|}}{C}{-}CH_2C(OH)(CH_3)_2$$

$$\longrightarrow CH_3{-}\underset{\underset{O}{\|}}{C}{-}CH{=}C(CH_3)_2,$$

$$CH_3{-}\underset{\underset{O}{\|}}{C}{-}CH{=}C(CH_3)_2$$

$$\xrightarrow[-R]{ROOH + H^+} CH_3{-}\underset{\underset{O}{\|}}{C}{-}CH_2(CH_3)_2COOH,$$

$$CH_3{-}\underset{\underset{O}{\|}}{C}{-}CH_2(CH_3)_2COOH$$

$$\xrightarrow[-(CH_3)_2CO]{H^+} CH_3{-}\underset{\underset{O}{\|}}{C}{-}CH_2OH.$$

It was also suggested [2] that acetol can form by reaction of acetone with hydrogen peroxide present in a small amount in the reaction mixture from cleavage of CHP.

EXPERIMENTAL

Acetol formation was studied under conditions of two-stage CHP decomposition into phenol and acetone in the presence of catalytic amounts of sulfuric acid [3]. The first stage, according to the adopted process scheme, was performed under conditions of almost complete decomposition of technical-grade CHP into target products, phenol and acetone, with simultaneous transformation of dimethylphenylcarbinol (DMPC) impurity into dicumyl peroxide (DCP). The experiment was performed in a glass flow-circulation system. The second stage, in which decomposition of CHP was completed and DCP was converted into α-methylstyrene, was performed in an autoclave equipped with a stirrer and a sampler. The composition of the products was determined by GLC [4].

concentrations C_{CHP}, we studied the dependence of the acetol concentration C_A in the reaction mixture on the main process parameters: temperature T, sulfuric acid concentration C_{acid}, and residence time τ.

The results show that the concentration of acetol in the reaction mixture in the circulation conduit depends on all the above-mentioned parameters; the concentration decreases with decreasing temperature, sulfuric acid concentration, and residence time.

To elucidate the specific features of acetol accumulation in the second stage of the process, we studied the dependence of its concentration in the reaction mixture on the sulfuric acid concentration and temperature at various residence times.

We found that the acid concentration has no appreciable efect on the rate of acetol accumulation, and the decisive factor affecting the reaction rate is the temperature. Data on variation of the acetol concentration in the reaction mixture with time at various temperatures are given in Tables 1 and 2.

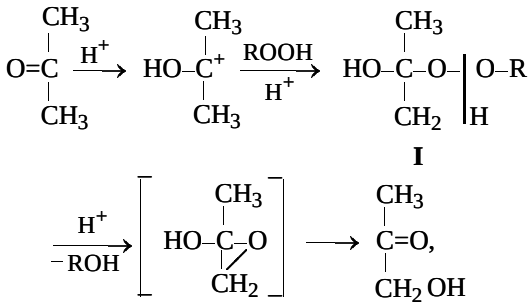
In the course of studying accumulation of acetol in the second stage of CHP decomposition, we revealed some experimental trends. First, when we used as the feed the products obtained in the circulation unit, the acetol concentration in the reaction mixture considerably increased. Second, when the feed for the second stage was prepared in the first stage at the same sulfuric acid concentrations, temperatures, and circulation multiplicities, the final acetol concentrations after completion of the second stage were equal irrespective of its conditions. Third, when we used as the feed for the second stage a model mixture identical in the composition (according to GLC analysis) to the product of the first stage, the increase in the acetol concentration in the reaction mixture did not exceed 0.005 wt %.

These facts give some insight into possible pathways of acetol formation in the course of sulfuric acid decomposition of CHP. Apparently, the necessary condiiton for acetol formation is simultaneous presence in solution of acetone, hydroperoxide (HP), and catalytic amounts of sulfuric acid. The nature of HP and the presence of phenol are of no significance; additional experiments showed that acetol is efficiently formed in acetone solution in the presence of other HPs, in particular, hydrogen peroxide and *tert*-butyl hydroperoxide (TBHP). Data on acetol accumulation in the second stage of CHP decomposition are consistent with this conclusion; the only specific feature is that with the products from the first stage used as the feed the amount of the forming acetol, according to GLC data, exceeds several times that obtained with the model mixture of the same composition. This fact can be explained only by assuming that formation of acetol from acetone in the presence of CHP and acid occurs via formation of intermediate(s) undetectable by GLC. It is assumed that in the first stage of CHP decomposition this intermediate transforms into acetol only partially, and the reaction is completed in the second stage.

Possible intermediates that cannot be isolated and identified are 2-hydroxy-2-cumylperoxypropane **I** and 2,2-bis(cumylperoxy)propane **II**. It is known that compound **I** and related α-hydroxy peroxides derived from other HPs are formed reversibly in reactions of ketones with HPs at low temperatures [5]. These compounds are extremely labile, and their formation was

confirmed only by IR spectroscopy. Compound **II** was not described in the literature, but data are available on its analog prepared from acetone and TBHP [6].

Based on the above assumption and taking into account published data, we suggest the following scheme of acetol formation from acetone and CHP:



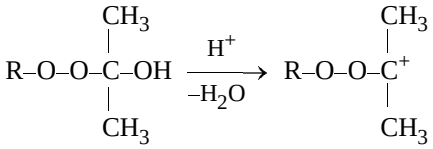
I

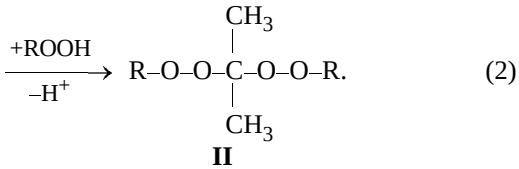
(1)

where R is the cumyl radical.

Decomposition of **I** with intermediate formation of the oxide is shown arbitrarily; most probably, decomposition with carbinol elimination and intramolecular rearrangement occur simultaneously.

The above hypothetical scheme can explain the pathway of acetol formation in the first stage of CHP decomposition, but, because of the low stability of α-hydroxy peroxides, in the second stage this pathway is improbable. The acetol precursor in the second stage should be a relatively stable compound. Presumably, along with the reactions shown in scheme (1), compound **I** reacts with CHP with formation of more stable compound **II** by the scheme

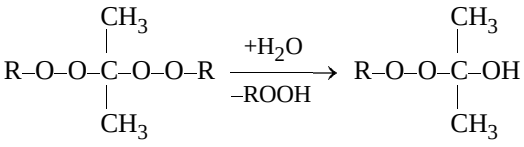




(2)

II

Compound **II**, presumably formed in the course of CHP decomposition in the first stage, in the second stage at elevated temperature decomposes to form CHP, DMPC, and acetol:



Since it is extremely difficult to confirm experimentally formation of acetol by pathway (1) because of the low stability of α-hydroxy peroxides, we examined the possibility of occurrence of reaction (2). An evidence in favor of this process could be formation of CHP, DMPC, and acetol in a stoichiometric ratio from specially prepared compound **II**. Since this compound does not exist in the neat form and since CHP formed from **II** by reaction (2) rapidly decomposes into phenol and acetone under conditions of acid catalysis, our proof of this mechanism was based on chemical analogies. To simulate formation of acetol in the second stage of CHP decomposition, we used an analog of **II**, which was specially prepared from acetone and TBHP according to [6]. This compound was subjected to decomposition in the presence of sulfuric acid in a solution of phenol in acetone. The GLC analysis showed that decomposition of this diperoxide yields equimolar amounts of TBHP, trimethylcarbinol, and acetol, which is an indirect evidence in favor of the suggested mechanism. In this process, acetol is formed via intermediate carbocations, as indicated by the absence of acetol in the products of thermal decomposition of the model hydroperoxide in aprotic CCl_4 without acid.

CONCLUSIONS

Formation of acetol in the course of sulfuric acid decomposition of cumyl hydroperoxide into phenol and acetone occurs by the carbocationic mechanism via intermediate formation of 2-hydroxy-2-cumylperoxypropane and 2,2-bis(cumylperoxy)propane.

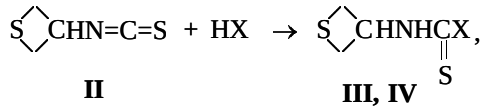
Abstract—3-Substituted thietanes were prepared by reaction of 1,2-epithio-3-chloropropane with various nucleophiles in aqueous solutions and were characterized. The inhibiting power of these compounds in cumene oxidation was studied.

Previously we studied antioxidant activity of various thiiranes and thietanes. It was shown that the inhibiting mechanism involves both termination of an oxidation chain by reaction with peroxy radicals with oxidation of the inhibitors by cumyl hydroperoxide (CHP) and formation of substances catalyzing hydroperoxide degradation into molecular products and readily reacting with peroxy radicals.

In this work we synthesized 3-substituted thietanes and studied their antioxidant activity in cumene oxidation.

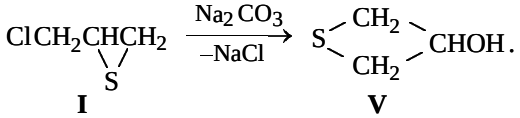
1,2-Epithio-3-chloropropane (**I**) was prepared by reaction of epichlorohydrin with thiourea in the presence of methanol [7]. Reaction of **I** with ammonium thiocyanate in an aqueous solution to form 3-thietanyl isothiocyanate (**II**) was studied in [8]. 3-Thietanyl-substituted thioureas **III** and **IV** were prepared by addition of 3-thietanyl isothiocyanate to benzylamine and morpholine, respectively:



II **III, IV**

where X = $NHCH_2$– (**III**), –N⟨⟩O (**IV**).

3-Thietanol (V) was prepared by reaction of 1,2-epithio-3-chloropropane with sodium carbonate [9]:



I **V**

The structure of the resulting compounds was confirmed by IR and 1H NMR spectroscopy and the purity, by elemental analysis and thin-layer and gas–liquid chromatography (GLC).

The IR spectra of 3-thietanyl-substituted thioureas **III** and **IV** contain the bands in the range 670–680, 720–730, and 1420–1435 cm^{-1}, which are typical for stretching vibrations of the four-membered thietane ring. The band in the range 1500–1520 cm^{-1} is assigned to stretching vibrations of the thiourea NHC(S) fragment.

In the range 2.65–3.65 ppm the ^1H NMR spectra of 3-thietanyl-substituted thioureas **III** and **IV** contain a quintet of four protons of two equivalent methylene groups of the thietane ring with the intensity ratio of 1 : 4 : 6 : 4 : 1. The signal of the single methine proton of the thietane ring appears as a quintet in the range 4.25–4.75 ppm. The broad strong signal of the NH protons of the thiourea skeleton is observed at 7.05–7.65 ppm. The signals of CH_2 protons of the benzyl fragment are observed in the range 2.5–2.9 ppm. The singlet in the range 6.61–6.89 ppm is assigned to five aromatic protons.

Reactions of **II**–**V** with CHP were performed in chlorobenzene under nitrogen at 110°C in a temperature-controlled glass reactor. The CHP content in the samples taken at regular intervals was determined by iodometric titration.

To determine the reaction stoichiometry, CHP was taken in excess. The stoichiometric coefficients calculated by the equation

1070-4272/01/7401-0114$25.00

$$\nu = \frac{[CHP]_0 - [CHP]_\infty}{[InH]_0},$$

(where $[CHP]_0$ and $[CHP]_\infty$ are the initial and final CHP concentrations, respectively, $[InH]_0$ is the initial concentration of the inhibitor) show that products formed from a single molecule of the inhibitors cause several thousand CHP molecules to decompose.

The kinetic parameters of the catalytic decomposition of CHP in the presence of **II**–**V** are presented in the table. High stoichiometric coefficients ν indicate the catalytic nature of CHP decomposition.

Analysis of the kinetic parameters of reaction of the tested compounds with CHP shows that their activity in this reaction appreciably depends on the nature of the substituent in a thietane molecule.

As in the case of the reaction with cumylperoxy radicals, compound **IV** is the most active in reaction with CHP. The rate constant K and the stoichiometic coefficient ν for this compound are higher by an order of magnitude than those for the other compounds.

The study of cumene autooxidation at 110°C in the presence of compounds **II**–**V** showed (Fig. 1) that all these thietanes inhibit the oxidation. To determine their antioxidant power in elementary reactions responsible for inhibition of cumene oxidation, we studied reactions of these compounds with cumylperoxy radicals and CHP. All the tested compounds (Fig. 2) inhibit initiated oxidation of cumene. The stoichiometric coefficient of inhibition equal to the number of oxidation chains terminated on single inhibitor molecule and products of its conversion was calculated from the induction period τ by the equation

$$f = \frac{\tau w_i}{[InH]_0},$$

where τ is the induction period (s), w_i is the initiation rate (under the conditions studied it is equal to 2×10^{-7} mol l^{-1} s^{-1}) [10].

The rate constant of the reaction of the tested inhibitors with peroxy radicals K was calculated form the rate of oxygen uptake. For this purpose the kinetic curves of oxygen uptake in the $\Delta[O_2]$ vs. t coordinates were transformed into the $\Delta[O_2]^{-1}$ vs. t^{-1} coordinates. From the slope of the straight line

$$\tan\alpha = \frac{fK_7[InH]_0}{K_2[RH]w_i}$$

the constant K_7 was calculated by the equation

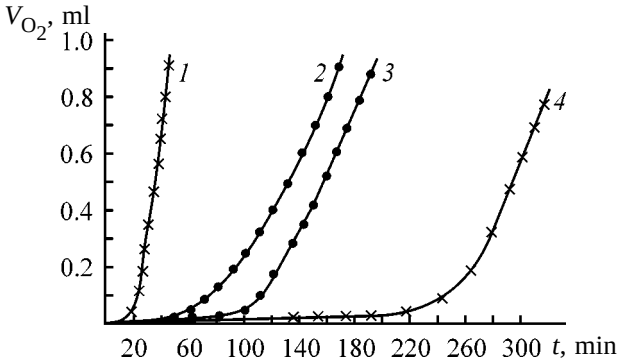


Fig. 1. Kinetic curves of cumene autooxidation at T = 110°C in the presence of the tested inhibitors with the concentration [InH] = (*1*) 0, (*2*, *3*) 5×10^{-5}, and (*4*) 5×10^{-6} M. (V_{O_2}) Oxygen volume and (t) time; the same for Fig. 2.

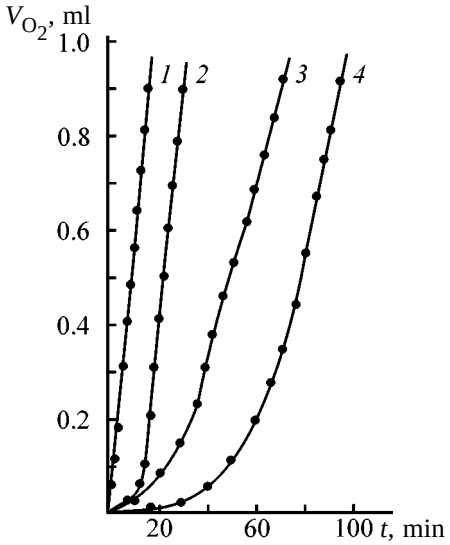

Fig. 2. Kinetic curves of initiated oxidation of cumene at [AIBN] = 2×10^{-2}, $w_i = 2 \times 10^7$ M, and T = 60°C: Inhibitor and concentration, M: (*1*) none; (*2*) **II**, 1×10^{-4} (*3*) **III**, 3×10^{-4}, and (*4*) **IV**, $5\ 10^{-6}$ M.

$$K_7 = \frac{\tan\alpha K_2[RH]w_i}{f[InH]_0},$$

where K = 1.51 l mol^{-1} s^{-1} [12], [RH] = 6.9 M.

As seen from the kinetic curves of initiated oxidation of cumene, the oxidation rate in the presence of the inhibitors after the induction period (Fig. 2, curves *2*–*4*) is lower than that in their absence (Fig. 2, curve *1*). This indicates that products of reaction of **II**–**V** with cumylperoxy radicals are also inhibitors. The kinetic parameters of reaction of **II**–**V** with cumylperoxy radicals are presented in the table.

As seen from the table, the stoichiometric coefficient f and the rate constant K_7 for **II**–**V** range from

Kinetic parameters* of reaction of 3-substituted thietanes with cumylperoxy radicals (60°C, [AIBN] = 2×10^{-2} M) and CHP (110°C)

Compound	f	$K_7 \times 10^{-4}$	K	ν
		l mol^{-1} s^{-1}		
II	0.96	2.23	20	53800
III	1.86	2.4	24	68600
IV	34	7.05	225	586000
V	0.24	2.0	12	23500

* AIBN is azobis(isobutyrolnitrile), f is the stoichiometric coefficient of inhibition, K_7 is the rate constant of reaction of the inhibitors with peroxy radicals, K is the rate constant of the reaction with CHP, and ν is the catalytic factor.

0.24 to 34 and from 2.0 to 7.05×10^{-4} l mol^{-1} s^{-1}, respectively. Analysis of the kinetic parameters of reaction of **II**–**V** with cumylperoxy radicals shows that the reactivity of these compounds strongly depends on the nature of the substituents at the thietane ring. Compound **IV**, unlike the other inhibitors, repeatedly terminates the oxidation chains (f = 34) and exhibits very high reactivity with respect to cumylperoxy radicals ($K_7 = 7.05 \times 10^{-4}$ l mol^{-1} s^{-1}).

Thus, all the tested inhibitors actively decompose CHP in three steps (Fig. 3): the first step is very slow (the induction period), the second is fast and autocatalytic, and the third is the final step of CHP degradation. The first two steps last different times depending on initial concentrations of hydroxperoxide and inhibitor. The induction period shortens with increasing the hydroperoxide concentration. The shape of the curves of CHP autocatalytic decomposition indicates that CHP decomposes under the action of products formed in the first slow step of the reaction

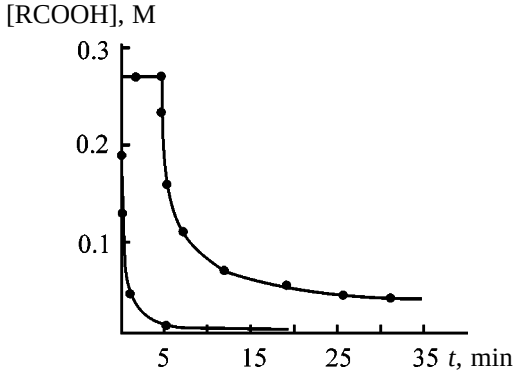

Fig. 3. Kinetic curves of CHP decomposition at T = 110°C under the action of **V**. [InH] 5×10^{-5} M. ([ROOH]) Concentration and (t) time.

of the inhibitors with CHP, but not under the action of the initial inhibitors.

EXPERIMENTAL

The IR spectra were recorded in a thin layer on a Specord 75-IR spectrometer. The ^{1}H NMR spectra were recorded on a Varian T-60 spectrometer operating at 60 MHz, with tetramethylsilane as the internal reference.

Thin-layer chromatography of **I**–**V** was performed on Silufol-254 plates using an ethanol–hexane mixture (1 : 5) as the eluent. In all case a single spot was observed after development with iodine.

1-Benzyl-3-(3'-thietanyl)thiourea (III). Benzylamine [10.7 g (0.1 mol)] was mixed with 3-thietanyl isocyanate [13.1 g (0.1 mol)]. The reaction mixture slightly warmed up. Crystalline target product was isolated after the reaction mixture was cooled to room temperature and diluted with benzene. The reaction course was monitored by TLC and IR spectroscopy. The yield of **III** was 24 g (87%), mp 165°C, R_f = 0.86.

Found, %: C 55.25, H 5.67, N 11.92, S 27.16.
$C_{11}H_{44}N_2S_2$.
Calculated, %: C 55.42, H 5.92, N 11.75, S 26.90.

Compound **IV** was prepared similarly in a 17.7 g (81%) yield from morpholine [8.7 g (0.1 mol)] and 3-thietanyl isothiocyanate [13.1 (0.1 mol)]; mp 165–166°C, R_f = 0.80.

Found, %: C 51.21, H 7.75, N 14.85, S 17.37.
$C_8H_{14}N_2OS_2$.
Calculated, %: C 51.58, H 7.58, N 15.04, S 17.21.

Cumyl hydroperoxide was purified by the known procedure [13] with subsequent distillation. Chlorobenzene and cumene were treated with concentrated sulfuric acid [14] to remove impurities. The CHP concentration was determined by iodometric titration [15]. Decomposition of CHP at 110°C in a chlorobenzene solution was studied in glass bubbling reactor under an inert atmosphere. The concentration of CHP and the tested compounds was varied from 0.23 to 0.45 and from 0.5×10^{-4} to 5×10^{-6} M, respectively. Cumene oxidation initiated by AIBN was studied on a manometric unit [10]. The rate constant of the initiation at 60°C is $K = 1.0 \times 10^{-5}$ s^{-1} [11]. The initiator concentration in all experiments was constant (2×10^{-2} M). The concentration of the inhibitors ranged from 1×10^{-4} to 5×10^{-6} M.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Preparation of Amino Derivatives from Industrial Mixtures of Polychlorobiphenyls

Received June 21, 2000

Abstract—Chemical utilization (conversion) of polychlorobiphenyls by nitration of their industrial mixture was studied. Reduction of the nitro derivatives gave mixtures of aminopolychlorobiphenyls.

One of the main sources of environmental pollution with highly toxic compounds, polychlorodibenzodioxins (PCDDs) and polychlorodibenzofurans (PCDFs), is continuing use of polychlorobiphenyls (PCBs) as liquid dielectrics. The first step to stop environmental pollution with PCDDs and PCDFs was made in early 1990s and implied total cessation of production of PCBs.

Today active efforts are made throughout the world to develop processes for utilization (conversion) of PCBs accumulated in large amounts, and state regulations are being adopted on determination and analysis of noxious impurities in air, water, and soil. Much attention is given to development and implementation of various projects aimed at normalization of the environment. A new program, Protection of the Environment and Population from Dioxins and Dioxin-Like Toxicants in 2000–2005, is to be adopted in Russia [1].

Procedures for utilization (conversion) of PCBs are summarized in [2]. Methods based on combustion of PCBs followed by trapping of off-gases seem to be economically unfeasible. Conversion of PCBs into useful nontoxic materials would be more acceptable.

Previously procedures were proposed for chemical processing of PCBs by substitution of two chlorine atoms in the initial industrial mixtures by alkoxy groups in the presence of alkali metal hydroxides [3].

In this work we continue a search for alternative chemical methods of conversion (utilization) of PCBs.

The goal of this study was development of procedures for preparing amino derivatives from the industrial PCB mixture. Such derivatives show promise in synthesis of polymeric compositions [4], dyes [5], analytical reagents [6–8], etc. The main precursors of aromatic amino derivatives are aromatic nitro compounds [5]. Both mono- [5, 9] and dinitro [10] derivatives of biphenyl are known. Mononitrobiphenyls are usually prepared by indirect procedures from various mononuclear derivatives [9], rather than by direct nitration of biphenyl. Treatment of biphenyl with nitrating mixture gives 4,4'-dinitrobiphenyl [10]. The by-product is 3,5,4'-trinitro-4-hydroxybiphenyl (less than 2%) [11]. In treatment of biphenyl with nitrating mixture, compounds with a greater degree of nitration were not detected. Other dinitro derivatives of biphenyl are also prepared by indirect procedures.

* After sampling, an additional portion of oleum was introduced.
** After sampling, a portion of nitrating mixture was added.

A procedure was developed for nitration of a mixture of pentachlorobiphenyls PCB-5 (**I**), which are the main components of industrial PCBs. The isomeric composition of the industrial mixture of PCBs used in enterprises of the Ural region was determined by GLC; the results are reported elsewhere [3].

Nitration of PCB-5 (**I**) was performed by treatment with a mixture of nitric acid and oleum (20% SO_3) (see scheme). The reaction parameters (amount of the nitrating mixture, time, temperature) were determined (Table 1). The progress of nitration and the extent of PCB-5 conversion were monitored qualitatively by the Yanovskii reaction [6–8, 13] (see Experimental; Table 2).

Analysis of the nitration products **IIb** shows that under the reaction conditions two nitro groups are

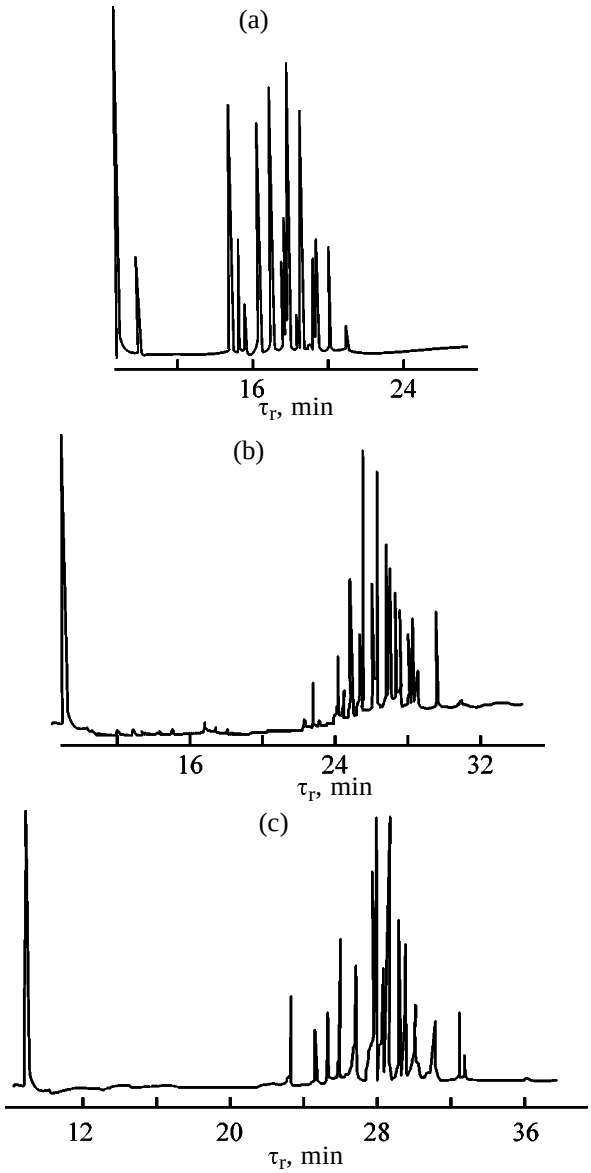

Fig. 1. Chromatograms of 5% solutions in toluene of (a) industrial PCB-5 mixture **I**, (b) mixture of dinitropentachlorobiphenyls **II**, and (c) mixture of diaminopentachlorobiphenyls **III**. (τ_r) Retention time.

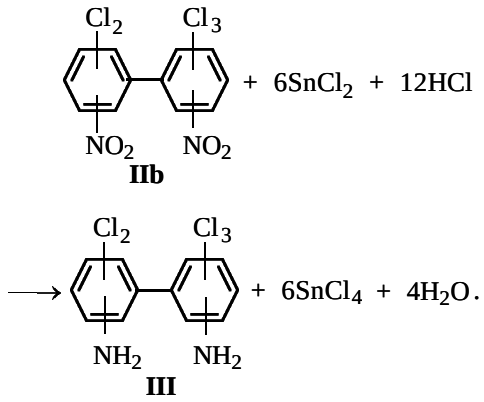
introduced into the moleculees of the initial PCB-5. The presence of chlorine atoms in PCB-5 should favor deeper nitration. However, analysis of the isomeric composition of **I** [3] shows that accumulation of substituents (chlorine atoms) in positions 2 and 2' in the eleven major components distorts the coplanarity of the PCB-5 structure [10]. Furthermore, in six isomers of eleven both 4- and 4'-positions are occupied, and in the remaining five isomers one of these positions is occupied. All these factors prevent deep nitration of PCB-5 (**I**).

Figure 1 shows the GLC data proving complete conversion of the initial mixture **I** in the course of nitration.

Diamino derivatives **III** are prepared by reduction of nitro groups in mixture **IIb**. The most efficient laboratory procedure for reduction of dinitro derivatives **IIb** is their treatment with a solution of $SnCl_2$ in HCl (see scheme). The reaction occurs within 2 h and gives the crude product in a good yield (86%). After additional purification, the yield of target compounds **III** is 68–72% (Table 3):



It should be noted that the temperature conditions of reduction of mixture **IIb** (about 100°C) exclude formation of dioxin-like structures from the initial substance [14]. This reduction procedure has significant advantages over the procedures used in industry and involving in most cases elevated temperatures and pressures [15].

Diaminopentachlorobiphenyls **III** can be used as starting compounds in production of dyes [5] and as components in polycondensation for preparing epoxy resins, polyamides, polymer blends [4], etc.

EXPERIMENTAL

The IR spectra were taken on a Specord 75-IR spectrophotometer from films of toluene solutions. The product purity was checked with a Shimadzu GC-14A gas–liquid chromatograph (Chromatopac C-RGA data processing system) equipped with a flame-ionization detector (HP-5 quartz capillary column, 30 m long, 0.2 mm i.d., carrier gas nitrogen). Compounds were injected as 10% solutions in hexane or methanol. The column temperature was kept at 100°C for 3 min with subsequent heating to 280°C at a rate of 10 deg min^{-1}. The vaporizer temperature was 280°C, and the detector temperature, 300°C.

The procedure of the Yanovskii reaction is described in detail elsewhere [16]. The blank experiment

* (N/d) The yield was not determined, because the isolated product contained **IIb** along with **III**.

(mixture of PCB-5, acetone, and NaOH solution) gives a three-layer system of immiscible initial reactants [from bottom to top: PCB-5 (**I**), colorless NaOH solution, and colorless acetone phase].

The control sample (a mixture of dinitropentachlorobiphenyls **IIb**, acetone, and NaOH solution) is a uniform liquid of intense reddish brown color, nontransparent in transmitted light.

A three-necked reactor equipped with a power-driven stirrer, a water-cooled reflux condenser, and a dropping funnel was placed on a boiling water bath and was charged with 195.9 g (0.6 mol) of pentachlorobiphenyl **I**. Then the nitrating mixture (120 ml of concd. HNO_3 and 144 ml of H_2SO_4 + 20% SO_3) was added dropwise with vigorous stirring. After addition completion, the mixture was stirred for 8 h, and 20 ml of oleum was added. The stirring was continued for 6 h, and a new portion of the nitrating mixture, similar to the first portion, was added. The stirring was continued for an additional 9 h, after which the nitration product was washed with hot water to pH 7. After drying, 247.4 g (99%) of dinitropentachlorobiphenyl **IIb** was obtained as a yellow solid, mp 72–75°C. IR spectrum, ν, cm^{-1}: 1550, 1335 (antisymmetrical and symmetrical stretching vibrations of the NO_2 groups).

Found, %: C 34.19, H 0.76, Cl 42.68, N 6.77.

$C_{12}H_3Cl_5N_2O_4$.
Calculated, %: C 34.61, H 0.73, Cl 42.57, N 6.73.

A three-necked vessel equipped with a power-driven stirrer, a water-cooled reflux condenser, and a dropping funnel was placed on a boiling water bath, 41.6 g (0.1 mol) of **IIb** was added, and a mixture of 162.7 g (0.72 mol) of $SnCl_2 \cdot 2H_2O$ and 146 ml of concd. HCl was added dropwise. After addition completion, the mixture was stirred for 2 h and washed with water, Na_2CO_3 solution, and again water until the medium became weakly acidic. The solid product was collected and dried. Then the dry substance was dissolved in toluene, and the $SnCl_4$ precipitate was washed by decanting. The solvent was distilled off, and the residue was kept in a vacuum. Yield of crude diaminopentachlorobiphenyl **III** 30.6 g (86%). Product **III** was distilled in a roughing-pump vacuum, bp 249–256°C/6 mm Hg. Yield of purified **III** 25.3 g (71%). IR spectrum, ν, cm^{-1}: 3460, 3365 (NH stretching vibrations), 1600 (NH bending vibrations).

Found, %: C 40.57, H 1.89, Cl 49.76, N 7.74.

$C_{12}H_7Cl_5N_2$.
Calculated, %: C 40.43, H 1.98, Cl 49.73, N 7.86.

CONCLUSIONS

(1) A procedure was developed for preparing dinitro derivatives from industrial mixture of polychlorobiphenyls.

(2) Reduction of dinitro derivatives of polychlorobiphenyls gave a mixture of diaminopolychlorobiphenyls in a yield of up to 72%.

(3) Diaminopolychlorobiphenyls can be valuable intermediates in production of polymers, dyes, etc.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Viscosity of Melts of H Complexes Based on Acidic Diesters of Benzophenonetetracarboxylic Acid and Diaminodiphenylmethane or *m*-Phenylenediamine

T. A. Kosterova, V. N. Artem'eva, N. V. Kukarkina, V. P. Samarin, V. E. Yudin, Yu. N. Panov, and V. V. Kudryavtsev

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received July 10, 2000

Abstract—The time dependences of the viscosity of melts of H complexes formed by dimethyl or diethyl dihydrogen 3,3',4,4'-benzophenonetetracarboxylate and 4,4'-diaminodiphenylmethane, *m*-phenylenediamine, or equimolar mixture of these diamines at 95 and 105°C were studied.

It is known that thermal imidization of H complexes formed by dimethyl dihydrogen 3,3',4,4'-benzophenonetetracarboxylate and aromatic diamines is the key step in preparation of light-weight polyimide foam composites containing felts and fabrics based on organic thermally stable fibers (including polyimide felt) as a reinforcing filler. Due to their low density along with high cryo- and thermal stability, refractoriness, and high thermal and sound insulation properties, these composites show promise for ship-building and aircraft industry [1].

In preparation of polyimide foam composites H complexes are used as prepolymers of polyimide binders. In the process, relatively low melting point (mp) of H complexes (from 70 to 130°C depending on the composition [2]) is a decisive factor. However, thermal imidization of H complexes also starts at low temperatures (100–120°C [3]). Thus, separation of melting and further intensive imidization of H complexes during prepreg preparation is of particular importance. This problem can be solved by preparing the prepreg at lower temperature (95–105°C) when the required H complexes occur in the molten state, but imidization is yet very slow.

To optimize the prepreg preparation the viscosity of the melt of the H complex (binder) and the kinetics of its variation should be determined. In this work we studied H complexes of dimethyl or diethyl dihydrogen benzophenonetetracarboxylate with aromatic diamine (diaminodiphenylmethane, *m*-phenylenediamine, or their mixture) under various preparation conditions.

EXPERIMENTAL

The initial H complexes were prepared as follows. 3,3',4,4'-Benzophenonetetracarboxylic dianhydride (0.03 mol) was dissolved with stirring in 15 ml of boiling methanol or ethanol (absolute or with addition 10 vol % water). The solution of dialkyl dihydrogen benzophenonetetracarboxylate was cooled to room temperature and the equimolar amount of the corresponding diamine (or diamines) was added dropwise with stirring. After solution homogenization the resulting solid H complexes were recovered by removing the solvent in a vacuum at room temperature. The abbreviations of the H complexes studied (depending on diamine and esterifying agent) are presented in the table.

Before use 3,3',4,4'-benzophenonetetracarboxylic dianhydride [BZP; TU (Technical Specifications) TSR 2159–69] was purified by refluxing in acetone (mp 225°C); 4,4'-diaminodiphenylmethane (DADPM) was distilled in a vacuum (1–3 mm Hg, mp 90–92°C); and *m*-phenylenediamine (*m*-PDA) was sublimed from zinc dust in a vacuum (mp 63°C).

The viscosity of the melts of H complexes was measured at 95 and 105°C on a PIRSP rheometer with a cone–plane working unit (1° angle at the cone apex, 40 mm cone diameter) [4].

The kinetic dependences of the viscosity of the melts of H complexes based on dimethyl dihydrogen benzophenonetetracarboxylates (BZPMe) prepared under various conditions are shown in Figs. 1a and 1b (in absolute methanol and in the mixture of methanol

with 10 vol % water, respectively). As expected, with increasing temperature from 95 to 105°C the viscosity of melts increases more rapidly. The decrease in the viscosity, most pronounced at 105°C (Fig. 1a, curves *2*, *3*; Fig. 1b, curve *3*), is probably due to foaming of the molten sample and weight loss occurring in this case, because the foaming melt partially escapes from the rheometer cell (observed visually). The viscosity decrease is the more pronounced, the greater the melt foaming.

The time dependences of the viscosity of the melts of H complexes based on diethyl dihydrogen benzophenonetetracarboxylate (BZPEt) prepared under various experimental conditions are shown in Figs. 1c and 1d. With substitution of BZPEt for BZPMe in the H complex the life period of the melt increases,

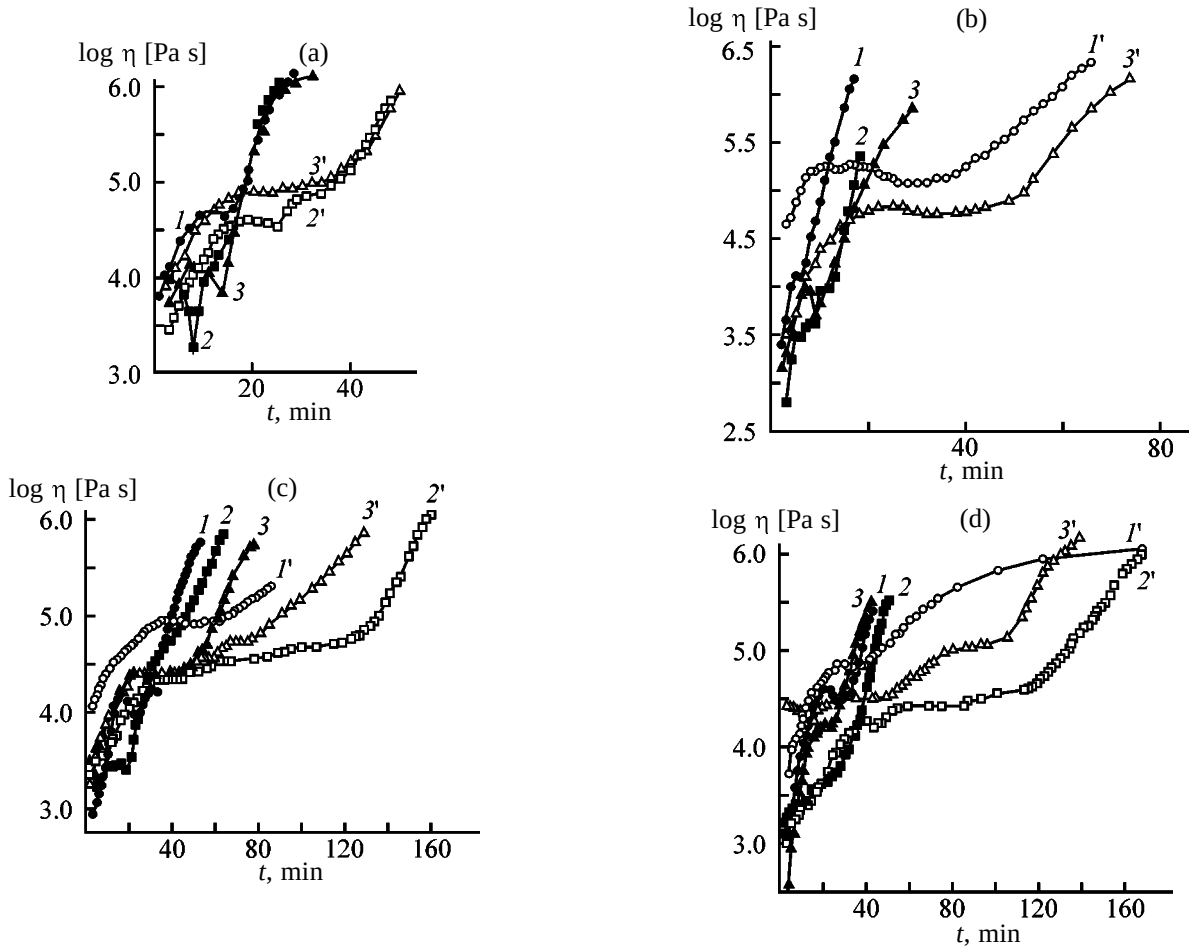

Fig. 1. Viscosity η of the melts of H complexes as a function of time *t*. (a): (*1*) BZPMe–DADPM, (*2*, *2*′) BZPMe–*m*-PDA, and (*3*, *3*′) BZPMe–(DADPM + *m*-PDA); (b): (*1*, *1*′) BZPMe–DADPM(H_2O), (*2*) BZPMe–*m*-PDA(H_2O), and (*3*, *3*′) BZPMe–(DADPM + *m*-PDA)(H_2O); (c) (*1*, *1*′) BZPEt–DADPM, (*2*, *2*′) BZPEt–*m*-PDA, and (*3*, *3*′) BZPEt–(DADPM–*m*-PDA); (d) (*1*, *1*′) BZPEt–DADPM(H_2O), (*2*, *2*′) BZPEt–*m*-PDA(H_2O), and (*3*, *3*′) BZPEt–(DADPM + *m*-PDA)(H_2O).

whereas the intensity of foaming significantly decreases.

Now, we consider the effect of the diamine nature in the H complex on the melt viscosity. As seen from Figs. 1a–1d, H complexes based on DADPM possess the greatest viscosity (curves *1*, *1*'). It should be noted that the temperature of 95°C is insufficient to melt the BZPMe-DADPM H complex prepared in absolute methanol (curve *1*' in Fig. 1a is absent). As a rule, H complexes based on *m*-PDA exhibit the lowest viscosity (Figs. 1a–1d, curves *2*, *2*'). The melts of H complexes based on the mixture of diamines (curves *3*, *3*') exhibit the intermediate viscosities.

Next, we analyze the effect of water present in the solvent used for esterification of BZP dianhydride and preparation of H complex on the melt viscosity. At 95°C the life period of the melts of H complexes prepared in aqueous alcohol (Figs. 1b, 1d, curves *1*'–*3*') is greater as compared with H complexes prepared in absolute solvents (Figs. 1a, 1b, curves *1*'–*3*'). However, at 105°C the relation is reverse: the life period of the melts of H complexes prepared in absolute alcohols (Figs. 1a, 1c, curves *1*–*3*) is greater than that of the complexes prepared in aqueous solvents (Figs. 1b, 1d, curves *1*–*3*).

Let us analyze how the structure of the H complex and the temperature of the experiment affect the rate of the increase in the melt viscosity at the final stage of the process, which is usually regarded as cross-linking and polymerization [5]. In our case it involves thermal imidization of H complexes. In all the cases the rate of the increase in the viscosity of the melt of the H complex based on BZPEt is significantly lower as compared with the H complex based on BZPMe. The rate constant of the increase of the melt viscosity of the H complex based on BZPEt–DADPM at 105°C is two times lower as compared with the H complex based on BZPMe–DADPM (2.7×10^{-3} and 5.2×10^{-3} s^{-1}, respectively). For H complexes based on the mixture of the diamines this difference is still greater (2.0×10^{-3} and 9.0×10^{-3} s^{-1}, respectively). Actually, the rate constant of imidization of the H complexes based on BZPEt is several times lower as compared with the H complexes based on BZPMe [3].

As for water present in the solvent during preparation of H complexes, it decelerates or accelerates the growth of the melt viscosity for H complexes based on BZPMe and BZPEt, respectively.

The dependence of the melt viscosity η on the shear rate $\dot{\gamma}$ was studied for the H complex based on BZPEt–(DADPM-*m*-PDA) (Fig. 2). This dependence can be approximated by the following expression:

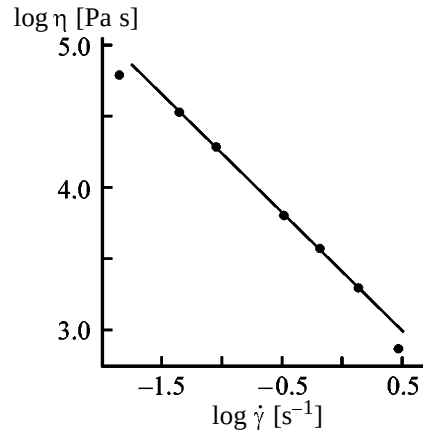

Fig. 2. Viscosity η of the melt of H complex based on BZPEt–(DADPM + *m*-PDA) as a function of the shear rate $\dot{\gamma}$ 40 min after the start of the experiment ($\log\dot{\gamma}$ = –1.88, T = 95°C); $n = \log\eta/\log\dot{\gamma}$ = 0.8.

$$\eta \sim \dot{\gamma}^{-n}.$$

For high-molecular-weight flexible-chain polymers n varies within 0.5–0.7 [5, 6]. In the case of structural ordering of the melt, e.g., typical for liquid-crystalline polymers, application of the shear stress breaks the melt structure and, as a result, n increases. In our case n = 0.8 (Fig. 2), which suggests formation of the mesomorphic rather than the liquid-crystalline structure in the melts of H complexes.

Our data allow some conclusions on the selection of the chemical composition of the binder for polyimide foam composites and conditions for preparing the corresponding precursors.

CONCLUSIONS

(1) Taking into account high viscosity of H complexes based on 4,4'-diaminodiphenylmethane, the use of binders based on the mixture of two diamines (4,4'-diaminodiphenylmethane and *m*-phenylenediamine) is the most promising.

(2) Preparation of binders in aqueous alcohols is advisable.

(3) Since curing of H complexes based on diethyl dihydrogen benzophenonetetracarboxylate at 95°C to prepare precursors is very slow, higher temperatures are recommended as compared with curing of H complexes based on dimethyl dihydrogen benzophenonetetracarboxylate.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Study of Polymerization of Ammonium Salts of *N,N*-Dimethylaminoethyl Methacrylate by Differential Scanning Calorimetry

D. Yu. Efimova, V. G. Shibalovich, and A. F. Nikolaev

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received February 9, 2000; in final form, June 2000

Abstract—The kinetics of thermal polymerization of ammonium salts of *N,N*-dimethylaminoethyl methacrylate and mineral acids (HCl, HNO_3, H_2SO_4, and H_3PO_4) were studied by dynamic differential scanning calorimetry. The apparent rate constants, reaction orders, and thermal effect of polymerization of the salts were determined.

Water-soluble cationic polyelectrolytes based on aminoalkyl esters of (meth)acrylic acids and their derivatives, tertiary and quaternary salts, attract considerable interest, which is due, on the one hand, to the possibility of widely varying their chemical nature and physicochemical characteristics and, on the other hand, to their wide use in various branches of national economy, industry, technology, and medicine [1–5].

The most used procedure of their production is the liquid-phase polymerization in the presence of various initiators [1–4]. Of special interest are studies of solid-phase polymerization of ammonium salts using thermal methods, in particular, differential scanning calorimetry (DSC) and differential thermal analysis (DTA), allowing monitoring of the reaction kinetics, qualitative transformations of reactants, and the effect of various conditions on the reaction pathways [6–9].

In this work we studied solid-phase polymerization of ammonium salts of *N,N*-dimethylaminoethylmethacrylate (AS DM) and mineral acids by DSC in air.

AS DMs were synthesized by the reaction of equimolar amounts of DM and mineral acid in an organic solvent according to the scheme [10]

$$CH_2=C(CH_3)C(O)OCH_2CH_2N(CH_3)_2 + H^+A^-$$

$$\rightarrow [CH_2=C(CH_3)C(O)OCH_2CH_2N(CH_3)_2H^+]A^-,$$

where A^- is Cl^- (**I**), NO_3^- (**II**), HSO_4^- (**III**), and $H_2PO_4^-$ (**IV**).

The synthesized ammonium salts are white crystalline products, readily soluble in water and polar solvents.

Previously [11], when studying thermal transformations of AS DMs by DTA and TG in air, for all the studied salts we observed the endothermic peaks with maxima at 50–120°C and exothermic peaks with maxima at 105–210°C without weight loss, caused by melting of the crystalline phase of AS DMs and their polymerization, respectively. For salt **I**, polymerization and degradation proceed simultaneously.

The use of DSC, furnishing rich information on behavior of polymer systems under nonisothermal conditions, allows study of chemical and physical transformations in a wide temperature range, estimation of qualitative and quantitative characteristics of these transformations, and calculation of the kinetic parameters of the process [7–9].

In Fig. 1 are presented the DSC curves for salts **I**–**IV**. These curves reveal clearly pronounced endothermic and exothermic effects caused by melting and

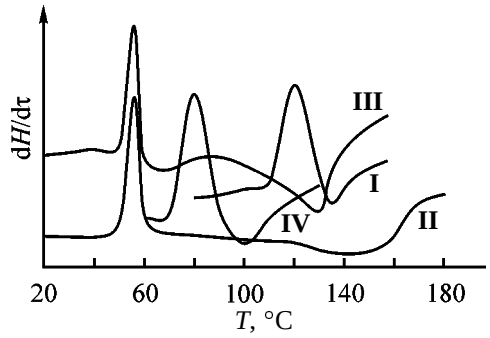

Fig. 1. DSC curves for ammonium salts **I**–**IV**. (d*H*/dτ) Rate of heat evolution, and (*T*) temperature (°C); the same for Fig. 2. Numbers at curves are numbers of compounds in Table 1.

Table 1. Temperature ranges of melting and polymerization of AS DMs from DSC data

Salt	Temperature, °C			
	melting		polymerization	
	t_{init}	t_{fin}	t_{init}	t_{fin}
I	102	130	193	203
II	42	65	71	180
III	47	67	86	147
IV	75	83	92	123

polymerization of these salts, respectively. The temperature ranges of these processes are presented in Table 1.

Analysis of the DSC curves for salts **II**–**IV** (Fig. 2) registered at various heating rates (2.5, 5.0, and 10.0 deg min^{-1}) allowed unambiguous conclusion that the observed thermal effects correspond to polymerization; additional (concurrent) reactions were not found. For salt **I**, as mentioned above, the quantitative estimation of the polymerization parameters was not carried out owing to parallel polymerization and degradation processes.

The heat of polymerization for salts **II**–**IV**, determined by comparison of the peak areas of the sample and reference [6, 8], varies from 43 to 48 kJ mol^{-1}

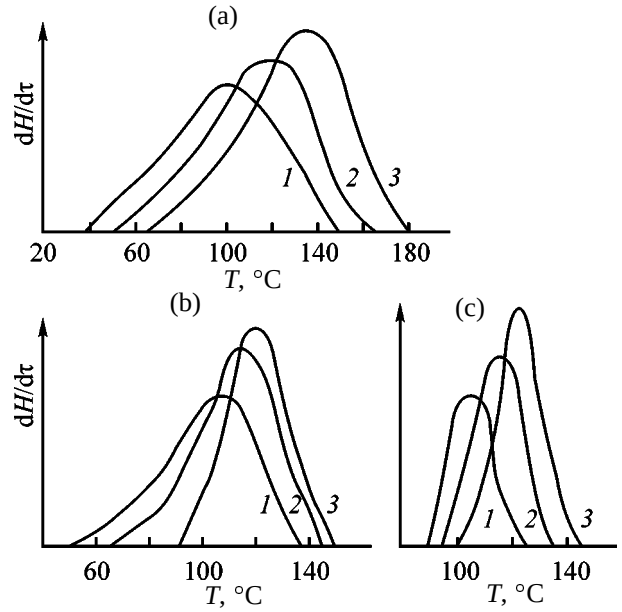

Fig. 2. DSC curves for polymerization of salts (a) **II**, (b) **III**, and (c) **IV**. Heating rate (deg min^{-1}): (*1*) 2.5, (*2*) 5.0, and (*3*) 10.0.

(Table 2). The relatively low enthalpies of polymerization of AS DMs (independent of the nature of the anion) are probably due to the effect of bulky substituent on the reactivity of the double bond in comparison with methacrylic acid.

To evaluate the apparent kinetic parameters of thermal polymerization of AS DMs, we used the methods of mathematical treatment of data [6–9, 12–14].

The apparent reaction orders, obtained by the Freeman–Carroll method [12], are in a good agreement with those evaluated by the Kissenger method [13] (deviation does not exceed 3%) (Table 2). Hence, considering the experimental errors, we can assume with sufficient accuracy that the reaction is second-order regardless of the salt nature.

The apparent total activation energy E_a of polymerization of salts varies from 23.0 to 83.0 kJ mol^{-1} depending on the nature of the anion (Table 2). For comparison, in Table 2 are presented the values of E_a for thermal polymerization of AS DMs, evaluated for the reactions performed under traditional isothermal conditions [15]. As seen from data listed in Table 2, the values of E_a obtained under isothermal and dynamic conditions are in a good agreement (deviation 6%), which suggests a possibility of using dynamic DSC for studying thermal polymerization of salts.

The comparative analysis of the kinetic parameters of thermal polymerization of AS DMs (Table 2) showed that these salts are fairly reactive; their polymerization proceeds at a high rate increasing in the order **IV** < **III** < **II**.

EXPERIMENTAL

AS DMs were synthesized by the procedure described in [10].

The DSC curves were recorded on a Perkin–Elmer DSC-2 scanning calorimeter with a heating rate of 1.5, 2.5, 5.0, 10.0, and 20.0 deg min^{-1}; the weighed portion was varied from 0.500 ± 0.001 to 1.500 ± 0.001 mg. Indium was used as a reference. Sealed small platinum crucibles were used. When studying thermal polymerization of salts **II**–**IV** by the dynamic DSC, we followed the main principles of thermal analysis [7–9].

To evaluate the kinetic and thermodynamic parameters of the process, we assumed that [7–9] (1) the heat Q_1, determined at a given time interval from the DSC curve, is in direct proportion to the degree of poly-

Table 2. Apparent kinetic parameters of polymerization of AS DMs from DSC data

Parameter	Salt		
	II	**III**	**IV**
Enthalpy $-\Delta H$, kJ mol^{-1}	48.28 ± 0.96	44.01 ± 0.88	43.03 ± 0.86
Entropy $-\Delta S$, J mol^{-1} K^{-1}	117.18 ± 2.34	109.48 ± 2.19	113.84 ± 2.28

1	4.67	1.94	1.13
2	4.73	1.98	1.09
3	4.05	1.81	0.93
4	4.71	1.92	1.10

Note: Method: (1) Freeman–Carroll, (2) Piloyan, (3) Kissenger, (4) Borchardt–Daniels, and (5) isothermal.

merization α throughout the process duration and (2) the total heat of polymerization Q_0, corresponding to the total area of the DSC peak, exactly corresponds to the process as a whole from the initial to final stage; $\alpha = 1 - (Q_1 Q_0)$.

These assumptions are true for chemical reactions with clearly pronounced initial and final stage, which is observed for salts **II**–**IV**.

The apparent kinetic parameters (reaction order, activation energy, and reaction rate constant) of polymerization of AS DMs were determined by the Freeman–Carroll [12], Kissenger [13], and Borchardt–Daniels [14] methods.

CONCLUSIONS

(1) Thermal polymerization of ammonium salts of *N*,*N*-dimethylaminoethyl methacrylate was qualitatively and quantitatively studied by the dynamic differential scanning calorimetry.

(2) The calculated main kinetic and thermodynamic characteristics of polymerization of these ammonium salts (enthalpy, entropy, apparent activation energy, order and rate constant of polymerization) suggest that the process parameters depend on the nature of anion; the reactivity varies in the order **II** > **III** > **IV**.

Abstract—The IR MATIR spectra in the 1535–1680 cm^{-1} range were studied for epoxy–DPP resins (M_N = 1650–3400) in coatings on germanium substrate obtained from oligomer solutions in methylene chloride and Cellosolve with the concentration c = 10–50%. The concentration dependences of the relative viscosity of narrow-MWD fractions of epoxy oligomers (M_N = 1500–5300) in chloroform and Cellosolve solutions were studied. The structure of the network of cross-linked polymers based on epoxy (M_N = 2100–3400) and phenol–formaldehyde (M_N = 860) resins was studied by the electron-microscopic silver chloride decoration method. Based on the cluster lattice model, the optimal molecular weight and the concentration regimes were determined for epoxy oligomers in the lacquer composition for can protection.

Kurmakova *et al.* [1] found that the chemical stability of cross-linked polymer coatings obtained from solutions of epoxy-4,4'-isopropylidenediphenol (DPP) and phenol–formaldehyde resins [2] depends on the molecular weight M, functionality, and the density of cross-linking of epoxy oligomers [3–5]. It is believed [1] that the differences in the chemical stability of cured epoxy–phenol coatings on metal substrates [2] formed from narrow-MWD fractions of epoxy–DPP resins with close average molecular weights M and close amounts of epoxy and hydroxy groups [1] are due to nonlinear structure of the oligomers with M_N = 2000–5300 [4]. The fractions of epoxy resins containing branched macromolecules are more prone to aggregation in Cellosolve solution than linear macromolecules [1], and the corresponding coatings exhibit low chemical resistance to organic acids.

It is known [6] that the orientation ordering in the boundary layers of epoxy oligomers on the surface of optical crystals can be studied by IR MATIR spectroscopy [7]. This approach implies the use of Fresnel's and Kramers–Kronig formulas and takes into account the intermolecular interaction potential [6, 9]. This yields correct absorption æ(ν) and refraction $n(\nu)$ spectra, as well as complex polarizability $\alpha'(\nu)$ spectra of oligomers in their intrinsic absorption region and the orientation and polarizability anisotropy parameters of the macromolecules on the solid surface [7, 10].

As shown previously [10, 11], the orientation of the macromolecules on the surface of optical crystals of germanium and KRS-5 depends on the molecular weight M and concentration c of polymers in solution. In particular, the orientation parameter Σ of the macromolecules on the KRS-5 surface as calculated from the $\alpha'(\nu)$ spectra of epoxy oligomers (M_N = 450–3400) in chloroform solution takes a minimal value in the vicinity of a certain critical value c^*, and the maximal concentration excess of the molecules on the surface is observed at $c < c^*$ [7].

Dilute solutions of epoxy oligomers with a finite number of Kuhn segments N = 1–3 contain rod-like macromolecules which are self-associated at moderate concentrations in chloroform and Cellosolve solutions [4, 12]. The change in the slope of the concentration dependences of the relative viscosity of the narrow-MWD fractions of epoxy resin E-05 in Cellosolve solution is due to the difference in the hydrodynamic behavior of linear and branched macromolecules [1]. According to the Rayleigh scattering data [11, 12], DER-663 epoxy resin (N = 2) in chloroform solution in the vicinity of the critical concentration c^* exhibits a decrease in the light scattering intensity relative to

** Low-molecular-weight sample of E-05 resin.

the $c < c^*$ region corresponding to formation of discrete aggregates of macromolecules [7].

The cluster model [13] distinguishes two stages of aggregation of macromolecules in solutions. In dilute solutions, the probability p of formation of aggregates is determined by pair collisions of the molecules, and the degree of aggregation of macromolecules tends to slowly increase with increasing concentration c at $[\eta]c < 1$, where $[\eta]$ is the intrinsic viscosity. Indefinite growth of s at $[\eta]c > 1$ is due to aggregation of macromolecules by the cluster–cluster mechanism [13]. The concentration of the aggregates $c_s = c/s$ [14] is maximal at the probability $0.31 < p < 0.69$, where 0.69 is the threshold value of p_c for simple cubic lattice and Euclidean dimensionality $E = 3$ [13]. With growing molecular weight M of the macromolecules, p approaches the threshold value p_c, and in the case of the flexible-chain macromolecules in a thermodynamically good solvent the fractal dimension of the globules in the entangled state is $D = 5/3$ [15].

A transition from discrete clusters to infinite cluster on the surface of polymer films and coatings involves a change in the fractal dimension D appearing in the expression describing the density of the cluster cross-linking sites as a function of the radius R of the circumference incorporating the cluster of macromolecules [16]. The density of the points of the physical network of engagements on the polymer surface represented as a function of the cluster radius R asymptotically approaches a power funciton at $R > \zeta$, where ζ is the correlation radius [13], the fractal dimension D of the clusters of macromolecules being approximately equal to 5/3 at $R < \zeta$.

Densely cross-linked coatings based on epoxy–phenol resins experience internal stresses and degrade at a high rate, which decreses their protecting efficiency [4, 5]. It should be noted that loosely cross-linked networks based on epoxy oligomers with low molecular weight are permeable [17], and the corresponding coatings also have low protecting efficiency. The optimal protecting efficiency of epoxy–phenol resin-based coatings on metal substrates is achieved at the molecular weight M of the epoxy oligomers in the region of M_N = 2100–5000 [1, 4].

In this work, we studied the IR MATIR spectra in the 1535–1680 cm^{-1} range for epoxy resins (M_N = 1650 and M_N = 3400) in coatings on germanium substrates obtained from solutions of oligomers in methylene chloride and Cellosolve. Based on the spectra of absorption æ(ν) and reflection $n(\nu)$ indices, the concentration dependences were calculated for the orientation and polarizability anisotropy parameters for oligomers on the surface. The viscosity data obtained were used for determining the optimal concentration regimes of oligomers in solutions in terms of the cluster model. The structure of the surface of the cross-linked epoxy–phenol resins for epoxy oligomers with M_N = 2100–3400 was investigated by the electron-microscopic silver chloride decoration method.

The aim of the work is to study the aggregation of macromolecules in solutions and the orientation ordering of the macromolecules on the coating surface, as well as the structural parameters of the network of cross-linked epoxy–phenol resins, as influenced by the molecular weight and concentration of epoxy oligomers. It should be noted that these factors govern the physicochemical principles of designing oligomeric compositions, as well as the choice of the optimal concentration regimes of oligomers in lacquer compositions intended for can protection [2].

EXPERIMENTAL

We studied samples of DER-664 and DER-668 (Dow Corporation) and E-05 (Pigment Research and Production Association, Joint-Stock Company) epoxy resins, as well as narrow-MWD fractions of the E-05 resin whose characteristics are presented in Table 1. The latter fractions were prepared by precipitating with water from 10% solutions in acetone followed by distilling off the solvent. The concentration dependences of the relative viscosity η_{rel} of oligomeric samples in chloroform and Cellosolve solutions were obtained on an Ubbelohde capillary viscometer at 298 K in the concentration range c = 3–55 wt % (shear rate 110 s^{-1}, flow time of chloroform 86 s). The intrinsic viscosity [η] was determined by the conventional procedure [18], and the molecular weight of the samples, by liquid chromatography [19].

The IR MATIR spectra of the oligomers in coatings on the germainum surface under *s* and *p* polarization of the incident light were recorded on a Specord IR-75 double-beam spectrophotometer and a Perkin–Elmer 1720 X single-beam Fourier spectrometer using three- and four-mirror MATIR accessories and MATIR elements made of single-crystalline germanium ($N = 2 \times 14$, $\theta = 45°$) [6]. The spectra were recorded in the 1535–1680 cm^{-1} range with a resolution of 1 cm^{-1} (Fig. 1). In the single-beam procedure, the IR MATIR spectra of the oligomers on the substrate surface were recorded in the signal accumulation mode (10–100 scans) by subtracting from the IR spectrum of the sample the absorption of the MATIR element (germanium) in the reflection coefficient R (%) vs. wave number ν (cm^{-1}) coordinates with the relative error of ≤0.05%. The RPI-4 replica served as polarizer [6].

The absorption æ(ν) and refraction n(ν) indices were calculated by computer processing, according to Fresnel's and Kramers–Kronig procedures [8, 9], of the IR MATIR spectra of epoxy oligomers in coatings in the 1535–1680 cm^{-1} region corresponding to ν(C=C) vibrations of the double bonds in the aromatic fragments of the macrochain [7] (Fig. 2).

The 4–6-mm-thick coatings on germanium substrate were obtained from solutions of sample nos. 1–4 in methylene chloride and Cellosolve at c = 5–50% and dried in air at 373 K. The refraction index n(ν) at the reference points [8] was determined by extrapolation of the n_D values (16980 cm^{-1}) to the 1535–1665 cm^{-1} range [20]. The corresponding values for sample nos. 1 and 2 (Table 1) at the reference points

Spectra of (a) (*1*–*3*) absorption indices æ(ν) and (b) refraction indices n(ν) in (*4*) *p*- and (*5*) *s*-polarized incident light in the 1550–1650 cm^{-1} range and decomposition of the ν(C=C) doublet into individual bands at (*1*) 1583 and (*2*) 1608 cm^{-1} [(*3*) aggregate curve)]. Coating on germanium from solution of sample no. 3 in Cellosolve, c = 31%, N = 28. (ν) Wave number.

[8] were estimated as follows: 1535 cm^{-1}, n_1 = 1.5336 and n_1' = 1.5366, and 1665 cm^{-1}, n_2 = 1.5338 and n_2' = 1.5368. The parameter æ at the reference points was calculated from the IR absorption spectra of oligomers in chloroform solutions using the values of the absorption coefficient $a = 4\pi\nu æ$ [6]. The corresponding values for sample nos. 1 and 2 were estimated at $æ_1(1535\ cm^{-1}) = æ_2(1665\ cm^{-1}) = 4 \times 10^3$.

The æ(ν) spectra were decomposed into individual components, 1583 and 1608 cm^{-1}, of the doublet due to the stretching vibrations of C=C double bonds in the aromatic fragments of the oligomer chain in the 1535–1665 cm^{-1} range, and the intensity æ and the integral intensity A(æ) of the band at 1608 cm^{-1} were calculated similarly to [7] (Fig. 2). The band

* Local maximum of orientation of the macromolecules on the surface.
** Local minimum of orientation of the macromolecules.

shape was approximated by superposing the Lorentz and Gauss functions, the former with the contribution of 0.8. The parameter æ was determined accurately to within less than 7%.

The polarizability spectra $\alpha'(\nu)$ were calculated by the expression [8]

$$\alpha'_{p(s)} = 3[(n^2_{p(s)} - 1)/(n^2 + 2)]/4\pi N_A, \quad (1)$$

where $n = (2n_p + n_s)/3$, $\alpha = (2\alpha'_p + \alpha'_s)/3$, and N_A is the Avogadro number [9].

The dichroic ratios $D_{p,s}(æ) = A_p/A_s$ (where A_p and A_s are the integral intensities of the band at 1608 cm^{-1} for *s*- and *p*- polarized incident light, respectively) and $D_{p,s}(\alpha') = \alpha'_p/\alpha'_s$ were calculated from the æ(ν) and $\alpha'(\nu)$ spectra, respectively (Table 2).

The second-order orientation parameter Σ was determined by the expression

$$\Sigma = (gD_{p,s} - 1)(1 - 3/2\sin^2\beta)(gD_{p,s} + 2). \quad (2)$$

Here, the factor g takes into account the light wave field effects and is approximately equal to the n_p/n_s ratio [9], and β is the angle between the direction of the dipole moment of transition M (1608 cm^{-1}) and the long axis of the oligomer molecule [7].

The parameter Σ was calculated from the dichroic ratios $D_{p,s}$ of the band at 1608 cm^{-1} in the æ(ν) and $\alpha'(\nu)$ spectra under assumption that β = 0° [7].

The orientation order was characterized by the polarizability anisotropy $\alpha'_s - \alpha'_p$ and the parameter $S = 1/2(3\langle\cos^2\varphi\rangle - 1)$, where φ is the angle between the transition moment M (1608 cm^{-1}) and the 0X axis of the XYZ larobatory coordinate system [9]. The effective depth of penetration of the light into oligomeric coatings on germanium substrate was calculated by the expression $d_{eff} = \ln(R_0/R)/4\pi\nu æ$ [6] as ≈1 μm.

Coatings with a thickness of 4–6 μm on electrolytically tin-plated sheet metal were prepared as prescribed for the EP-547 lacquer formulation [2] and formed from solution of epoxy and FPF-1 (M_N = 860) phenol–formaldehyde resins in Cellosolve at the epoxy resin concentration in the solution c = 31 wt % and the mass ratio of the components of 4 : 1. The coatings were cured at 473 K for 10 min and cooled in air at a rate of 20 deg min^{-1}. The preparations were produced by AgCl sputtering onto the external surface of the coatings in the 1.33×10^{-3} Pa vacuum to effective thickness of 0.4 nm and dissolved in hot chloroform. The carbon replicas were prepared by the standard procedure [16]. The AgCl molecules are accepted by hydroxy groups of epoxy and phenol–formaldehyde resins which are the AgCl nucleation centers [21]. The photomicrographs of the coatings were obtained with an EVM 100 L electron microscope; the

magnification in the computer processing of the decorograms was 100000 (Fig. 3).

Using the decorograms of the coating surface (Table 1, sample nos. 2–4), we determined the density ρ of the decorating AgCl particles corresponding to macromolecular clusters [22]. We used the model of percolation along the bound circumferences centered at particles [16]. With increasing radius $\langle R\rangle$, the circumferences overlap and get bound into clusters to form a percolation cluster. The lattice density ρ_l was calculated by the expression $\rho_l = \rho(\langle R\rangle)/\rho'$, where $\rho(\langle R\rangle)$ is the particle distribution density; ρ' is the density of the points of a two-dimensional lattice equivalent in the spatial distribution pattern of the particles and in the coordination number m corresponding to the area enclosed by the first maximum of the function $2\pi\rho\langle R\rangle g(\langle R\rangle)$, $g(\langle R\rangle)$ is the radial distribution function [23]. For $m = 3$, the relation $\rho' = 0.77/r^2$ [23] holds, where r is the most probable distance between the particles. The density of the cross-linking sites of the network of the cross-linked epoxy–phenol resin was calculated by the expression [21]

$$\rho(\langle R\rangle) = [1 + 2\pi\rho\int_0^R g(\langle R\rangle)\langle R\rangle d\langle R\rangle]/\pi\langle R\rangle^2. \qquad (3)$$

In the æ(ν) spectra of epoxy–DPP resins (Table 1, sample nos. 1 and 2) in coatings on germanium substrate, the intensity of the band at 1608 cm^{-1} for s polarization of the incident light exceeds that for p polarization [11]. Therefore, the dichroic ratio $D_{p,s}$ is under unity (Fig. 2, Table 2). The data obtained suggest that the orientation parameters $D_{p,s}$ and Σ of the oligomer molecules on the surface depend on the concentration c of the oligomers in the methylene chloride solution (Fig. 4). For sample no. 2, the parameter S takes a minimal value at the critical concentration c^* of 28±1%. In this case, the long axis of the macromolecules makes with the XY plane of the XYZ laboratory coordinate system an angle φ of about 54°, which corresponds to complete disordering of the

* Concentration c^* corresponding to the fractal-D_1–fractal-D_2 transition.
** Maximal concentration of the aggregates c_s.

molecules on the surface [6]. In the $c < c^*$ and $c > c^*$ regions, the increase in the orientation parameters of oligomer molecules on the substrate surface is due to a decrease in the angle φ. For example, at c = 18.7 and c = 31.7% the angle φ is about 40°, and the polarizability anisotropy $\alpha'_s - \alpha'_p$ of the oligomer molecules on the surface increases relative to the concentration regime at $c = c^*$ (Table 2).

For sample no. 1, virtually complete disordering of

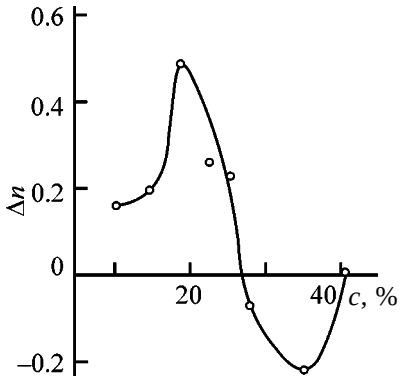

Fig. 5. $\Delta n = n_s - n_p$ parameter as a function of the concentration c of the oligomer in Cellosolve solution. Coating on germanium, sample no. 2.

the macromolecules in coatings on germanium obtained from oligomer solutions in methylene chloride is observed at c = 40%, which significantly exceeds the critical concentration for sample no. 2 (Fig. 4b, Table 2). Growth of the parameters S and $\alpha'_s - \alpha'_p$ at $c > c^*$ and $c < c^*$ is due to a decrease in the angle φ relative to the value of 54° corresponding to $c = c^*$.

In coatings obtained from Cellosolve solution of sample no. 2, the dependence of the anisotropy of the refraction index $\Delta n = n_s - n_p$ on the concentration c is nonmonotonic. The dichroism $D_{p,s}$ of the band at 1608 cm^{-1} is close to unity, and $\Delta n = 0$, which is due to disordering of the molecules on the surface at $c = 28 \pm 1\%$ (Fig. 5, Table 2). The inversion of the sign for Δn is observed at $c < c^*$ ($\Delta n > 0$) and $c > c^*$ ($\Delta n < 0$). The analogous inversion of the dichroism $D_{p,s}$ and the sign of Δn was revealed for coatings obtained for sample nos. 2–4 at c = 31%. With growing molecular weight of the samples, the orientation of the oligomers on the surface becomes less ordered, and, consequently, $\Delta n > 0$ (sample nos. 3 and 4) and $\Delta n < 0$ (sample no. 2).

As known [9], the Kerr constant describes the anisotropy of the polarizability of molecules in the

visible range of the spectrum. In solution of benzyl alcohol (or aniline) in CCl_4 the Kerr constant exhibits inversion of the sign [9]: positive values correspond to dilute solutions, and negative, to formation of aggregates of molecules in concentrated solutions. Therefore, virtually complete disordering of the macromolecules on the surface corresponds to minimal values of parameters S and $\alpha'_s - \alpha'_p$ (Δn) at the critical concentration c^* of oligomers in solution, and the growth of the parameters at $c < c^*$ and $c > c^*$ is due to the change in the degree of aggregation of macromolecules in solutions (Tables 2, 3). With growing molecular weight of oligomers, the orientation and optical anisotropy of macromolecules on the surface decrease at the concentration of epoxy resin in Cellosolve solution of 31%, which corresponds to the value prescribed for the composition based on epoxy and phenol–formaldehyde resins [2].

As known [13], the density ρ of the cross-linking sites of fractal aggregate tends to decrease with increasing degree of aggregation s or hydrodynamic volume $\langle V \rangle$ of the aggregate of macromolecules by the law valid for $E = 3$

$$\rho = Vs/\langle V \rangle = s^{(D-E)/D}, \quad (4)$$

where V is the hydrodynamic volume of the macromolecule.

In the case of fractal-D_1–fractal-D_2 transitions, the density ρ depends on the fractal dimension D of the aggregates [24]. In the first approximation, the relative viscosity η_{rel} in solution is described by the expression [14]

$$\ln \eta_{rel} = [\eta] c_s s^{(3-D)/D} = [\eta]_c c_s, \quad (5)$$

where $[\eta]_c$ is the current value of the intrinsic viscosity whose absolute analog is, as known [18], the parameter $(\eta_{rel} - 1)/c$.

As $Vs/\langle V \rangle = [\eta]/[\eta]_c$ [18], expressions (4) and (5) can easily be combined into the relation for the density ρ of the aggregates

$$\rho(s) = [\eta]/[\eta]c_s = s^{(D-3)/D}, \quad (6)$$

where $s = [\eta]_c c / \ln \eta_{rel}$ [14].

Expression (6) suggests that the slope of the $\rho(s)$ plot on the logarithmic scale is equal to $(D - 3)/D$, and $\rho(s)$ at $s \gg 1$ asymptotically approaches a power function [13, 15], which for polystyrene in bromoform solution at $[\eta]c > 3$ corresponds to $D \sim 5/3$.

For sample nos. 1 and 2 the dependences of the relative viscosity η_{rel} on the concentration c of oligomers in chloroform solution differ in the nature of

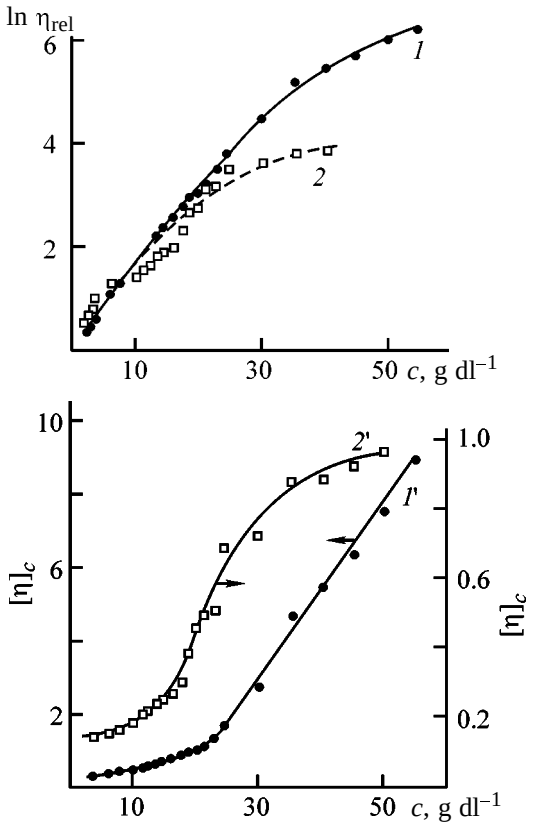

Fig. 6. (*1*, *2*) Relative η_{rel} and (*1'*, *2'*) current intrinsic $[\eta]_c$ viscosities as functions of the concentration c of oligomers in chloroform solution. Sample (*1*, *1'*) no. 1 and (*2*, *2'*) no. 2, 298 K.

variation of $[\eta]_c$ with c (Fig. 6). For low-molecular-weight sample no. 1, the parameter $[\eta]_c$ attains saturation at $c > 35$ g dl^{-1}. For narrow-MWD fractions of epoxy resin E-05 (Tables 1, 3), $[\eta]_c$ varies with the oligomer concentration in Cellosolve solution by a power law. The shape of the curves $\rho(s)$ calculated from the $\eta_{rel}(c)$ dependences for solutions of oligomers in chloroform and Cellosolve (Figs. 6, 7) is in

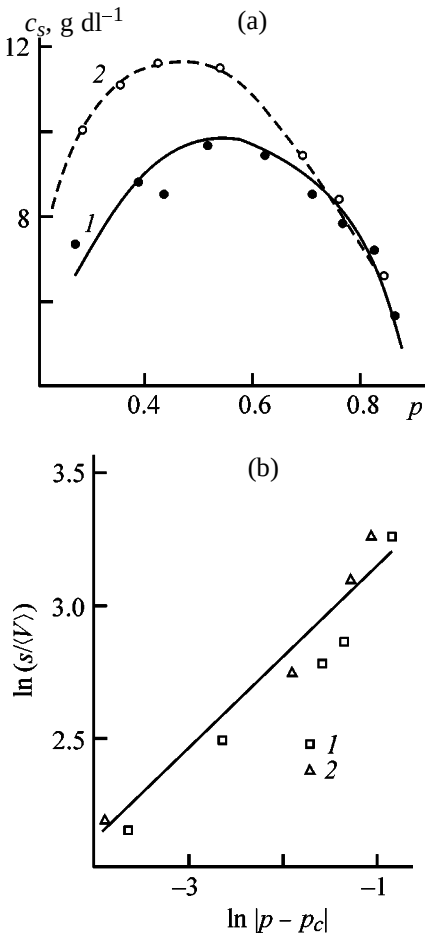

Fig. 9. (a) Concentration of the aggregates c_S of macromolecules in Cellosolve solution as a function of the flow probability *p* and (b) lattice density $s/\langle V\rangle$ as a function of the parameter $\Delta p = |p - p_c|$. Sample (*1*) no. 5 and (*2*) no. 6.

agreement with expression (6), these curves in the logarithmic coordinates consisting of two linear sections (Fig. 8).

It was found that the slope of the ρ(*s*) curves in the ln*p*–ln*s* coordinates for wide-MWD sample nos. 1 and 2 in chloroform solution changes at the critical concentration *c** corresponding to the flow probabilty $p > 0.69$ (Fig. 8a). At $c > c^*$, the aggregates of macromolecules forming in the case of sample no. 1 are more compact than for sample no. 2, the degree of aggregation *s* increasing with increasing molecular weight *M* (Table 3).

In solutions of narrow-MWD fractions of the E-05 resin (Table 3, sample nos. 5, 6) in Cellosolve, fractal-D_1–fractal-D_2 transitions occur at $c^* \sim 30\%$ and the flow probability $p_c = 0.69$. The resulting aggregates are looser than aggregates of the oligomer in chloroform. The concentration of the aggregates c_S varies nonmonotonically with increasing flow probability $p = 1 - 1/s$ [14] (Fig. 9). It is maximal in the region of $0.31 < p < 0.69$ and sharply decreases at $p > 0.69$. The appearance of the $c_S(p)$ curves suggests a transition to a continuous fluctuation network of engagements in solutions of oligomers in the vicinity of *c** [14], as the lattice density $\rho = s/\langle V\rangle$ of aggregates in the vicinity of the flow threshold $p_c = 0.69$ ($E = 3$) satisfies the expression $\rho \sim (\rho - 0.69)^a$, where $a = 0.4$ [13, 24].

The density ρ of the aggregates of macromolecules decreases with increasing molecular weight of the aggregates $M_S = Ms$ and the flow probability *p* (Table 3, Fig. 10). As follows from the dependence of the density of aggregates of macromolecules ρ on the parameter $\Delta p = p - 0.69$ obtained for nine fractions of the E-05 resin ($M_N = 1500$–5300, $M_w/M_N = 1.4$) in Cel-

Table 4. Cluster structure parameters for cross-linked epoxy–phenol polymers in coatings on sheet metal as estimated by electron microscopy

2	0.88	33	1.66	1.89	3	0.62	0.79	36	24
3	0.69	28	1.57	1.89	>3	0.70	0.77	26	18
4*	0.63	18	1.15	1.87	<3	0.74	0.53	19	11
4**	1.35	126	1.89	2.00	4	–	–	363***	116

Note: The density ρ of the aggregates of macromolecules was calculated for $E = 3$ and $E = 2$ using the viscosity data for sample nos. 2–4 in Cellosolve solution at $c = 30\%$. The ζ_p parameter was calculated from the average hydrodynamic radius of the aggregates $\langle R \rangle = 0.512(\langle V \rangle/\Phi)^{1/3}$, where Φ is the Flory constant [13, 18].

* For the first section of the network of small AgCl particles.

*** Maximal radius of aggregates of macromolecules [13].

losolve solutions at $c = 30\%$, for the threshold value $p_c = 0.69$ the density ρ is equal to 0.62 and $M_N = 3500 \pm 200$, which corresponds to the hexagonal ($m = 3$) planar lattice [25]. Thus, the most uniform network ($m = 3$, $E = 2$) of the cross-linked epoxy–phenol polymer can be expected for epoxy oligomer with $M_N = 3400$ (Table 4).

We found that the most uniform network of the decorating AgCl nanoparticles representing the chemical network of cross-linked epoxy–phenol polymer is characteristic of the oligomer sample no. 2 (Fig. 3a). The distribution pattern for small AgCl particles corresponds to the network of cross-linked epoxy oligomer, and larger AgCl particles correspond to aggregates of the high-modulus component (FPF-1 resin) uniformly distributed over the epoxy polymer matrix. The most probable distance r between the points of the small-scale network composed of regular hexahedrons ($m = 3$, $E = 2$) [23] is equal to 15 nm, and that for large-scale network, 150 nm.

The correlation radius ζ and the fractal dimension D of the clusters of macromolecules was determined by the expression for the lattice density [13]

$$\rho_l(\langle R \rangle) \sim \langle R \rangle^{D-2}, \quad (7)$$

where $\langle R \rangle = \zeta$ at the flow threshold $pD_c = 0.5$ ($E = 2$) [15, 21, 25].

The uniform network of macromolecules of the cross-linked polymer corresponds to $D_1 = 1.66$ and $D_2 = 1.89$ calculated from the slope of the $\rho_l(\langle R \rangle)$ dependence in the logarithmic coordinates (Fig. 11). The inflection point in the $\rho_l(\langle R \rangle)$ curve plotted in these coordinates corresponds to ζ [13, 22] equal to 33 nm (Table 4, sample no. 2). For sample no. 3 we found a marked decrease in the lattice density $\rho_l(\zeta)$, correlation radius ζ, and fractal dimension D_1 compared to sample no. 2.

In sample no. 4 the network containing units of epoxy and phenol–formaldehyde resins breaks into

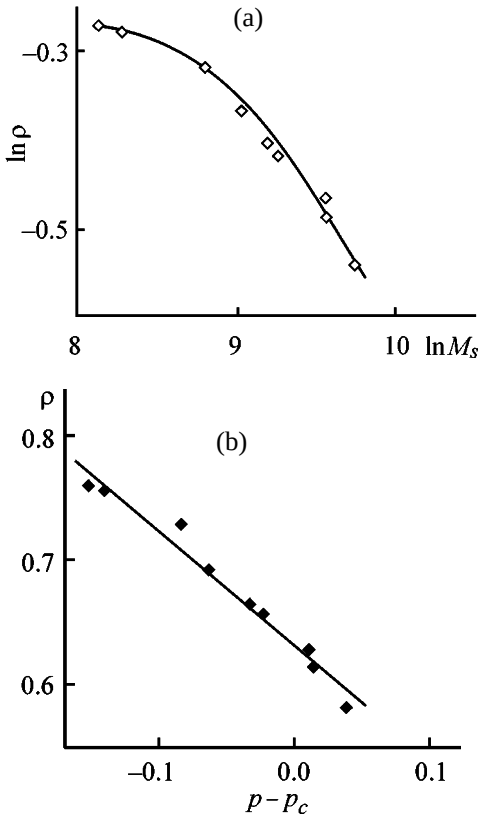

Fig. 10. Density of aggregates of macromolecules ρ in Cellosolve solution as a function of (a) molecular weight of aggregates M_s and (b) parameter $\Delta p = p - p_c$. $c = 30\%$, fractions of the E-05 resin, $M_N = 1500$–5300.

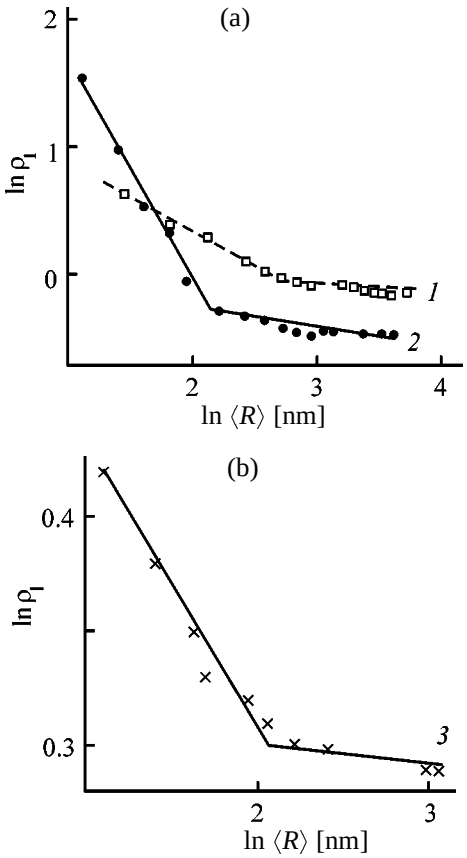

Fig. 11. Lattice density ρ_l of the decorating particles as a function of the radius $\langle R\rangle$, nm, of the circumference incorporating the cluster, as plotted in the logarithmic coordinates. Sample (*1*) no. 2 and (*2*) no. 4; (*3*) "lattice animals" fragment of sample no. 4. Radius dimension, nm: (a) with coefficient 2 and (b) with coefficient 15.

discrete clusters (Figs. 3b, 3c). In this case the decorogram of the polymer surface consists of sections lean (ρ_l = 0.63) and rich (ρ_l = 1.35) in small AgCl particles representing various fragments of the network of the epoxy resin. The discontinuity boundaries are the sites of localization of large AgCl particles attributed to FPF-1 resin, which suggests phase separation of the components [16, 17]. The average distance r between large AgCl particles is equal to 200 nm, and that between small particles, to 10 μm.

The values ρ_l = 0.63, D_1 = 1.15, and $m > 3$ (Table 4, sample no. 4) obtained for the first fragment of the network of small AgCl nanoparticles (Fig. 3b) support the conclusion concerning low local density of clusters of macromolecules. For the second fragment of the decorogram characterized by high local density of distribution of small AgCl nanoparticles (Fig. 3c) the values ρ_l = 1.36, D = 1.89, and m = 4 suggest formation of closely packed clusters of the "lattice animals" type [24]. For such clusters the correlation radius is by an order of magnitude greater than ζ corresponding to the first fragment of the network with a low density of AgCl particles (Fig. 11).

In accordance with the cluster approach [13], the density ρ of the aggregates as calculated from the viscosity data for narrow-MWD fractions of oligomers for three-dimensional (E = 3) and two-dimensional (E = 2) space increases with decreasing molecular weight M of the oligomers relative to the value M_N = 3400, as the concentration regime of the macromolecules in solution varies from $c = c^*$ to $c < c^*$ (Table 3, Fig. 10). For wide-MWD sample nos. 2–4, the density ρ of aggregates on the surface (E = 2) substantially decreases with decreasing M of the oligomers owing to a decrease in the fractal dimension D_1 of the aggregates (Table 4). This causes optical anisotropy to increase (Table 2), the network of the cross-linked epoxy–phenol resin to break down into discrete clusters, and the chemical resistance of the coatings to deteriorate.

CONCLUSIONS

(1) The orientation ordering in oligomer coatings on germanium substrate can be determined by IR MATIR spectroscopy. The ordering depends on the molecular weight and concentration of the oligomers in solutions. Complete disordering of the macromolecules on the surface is observed at the critical concentration c^* of epoxy oligomer (M_N = 3400) in Cellosolve solution of 28±1%. The increases of the orientation and polarizability anisotropy parameters of macromolecules on the surface are due to formation of discrete aggregates in solution at $c < c^*$.

(2) Based on the cluster lattice model, expressions were obtained for the density ρ(s) of the aggregates of macromolecules suitable for calculating, from the viscosity data, the critical concentrations c^* of oligomers in solutions. For narrow-MWD fractions of the E-05 resin (M_N = 1500–5300) in Cellosolve solution the density ρ(s) of aggregates of the macromolecules decreases with increasing molecular weight of epoxy oligomers and the flow probability p. For the threshold probability p_c = 0.69 and c^* = 30%, the value M_N = 3500±200 was obtained which is an optimal one. With decreasing molecular weight the average density of aggregates ρ(s) in solution and on the surface tends to increase. The value ρ = 0.62 for M_N = 3500 and c = 30% corresponds to a hexagonal planar lattice or the most uniform network of macromolecules on the surface.

(3) According to electron-microscopic data, epoxy oligomer with M_N = 3400 is characterized by the most uniform network of cross-linked epoxy–phenol polymer on the coating surface. A decrease in the molecular weight of epoxy resin from 3400 to 2100 causes breaking down of the continuous network of the cross-linked epoxy–phenol polymer into fragments with low and high local densities of discrete clusters of macromolecules, as well as a sharp decrease in the chemical stability of lacquer protecting coatings on sheet metal.

Abstract—The fruit body composition of the cultivated wood rotting fungi *Phanerochaete sanguinea* 16–65, *Ganoderma applanatum* 4–94, and *Ganoderma applanatum* 40–90 and their sorption characteristics with respect to Cr(III) and Methylene Blue are studied.

The existing processes for cellulose bleaching with chlorine-containing reagents are necessarily accompanied by contamination of both the environment and the target product (bleached cellulose) with toxic chlorinated organic compounds (dioxins). In this connection searching for environmentally safe processes for cellulose bleaching using biological agents is a pressing problem. As known, it is possible to remove lignin from cellulose and thus increase its whiteness by direct treatment with white-rot fungus mycelium, pure hemicellulase (cleavage of ligno-carbohydrate bonds) and ligninase preparations (lignin degradation), and also with an enzymatic system from a mycelial culture. The latter case requires cultivation of lignin-degrading fungi having low cellulolytic activity. Efficient cellulose bleaching processes based on the use of lignin-degrading enzymes from various strains of wood-rotting fungi is under development at the St. Petersburg Academy of Forestry Engineering [1, 2]. Wastes from such processes represent fungal fruit bodies containing chitin, cellulose, melanin, and other components which can be used in various branches of industry and in medicine.

The goal of this work is to study the chemical composition of the cultivated wood-rotting fungi *Phanerochaete sanguinea* 16–65, *Ganoderma applanatum* 4–94, and *Ganoderma applanatum* 40–90 and to evaluate the sorption capacity of the fungal material and prospects for its utilization.

† Deceased.

EXPERIMENTAL

Three fungal strains *Ph. sanguinea* 16–65, *G. applanatum* 4–94, and *G. applanatum* 40–90 were grown by surface cultivation in 500-ml Erlenmeyer flasks at 26°C in a culture medium (175 ml) developed by Gavrilova [3]. Its composition was as follows ($g\ l^{-1}$): glucose 10.0, pentone 2.5, K_2HPO_4 0.4, $MgSO_4$ 0.5, $ZnSO_4$ 0.001, NaCl 0.3, $FeSO_4$ 0.005, and $CaCl_2$ 0.05. The culture medium was sterilized before use in an autoclave under pressure, cooled to room temperature, and inoculated with mycelial disks (0.5 mm) in Petri dishes on a pure culture agar. As the mycelium grew, the activity of oxidative enzymes in the culture medium was monitored. After reaching the peak activity the cultural liquors from different flasks, in which a given fungus was cultivated, were combined, filtered through a capron filter, and tested as cellulose bleaching agents.

The residual fungal fruit bodies were analyzed by successive extraction with hot water for 8 h, alcohol–benzene (1 : 2) mixture at bp for 8 h, and 6% NaOH at 100°C for 12 h. The residual insoluble chitin–glucan complex (CGC) was then hydrolyzed in concentrated HCl at 70°C for 7 h. The nonhydrolyzed fraction was additionally treated with a mixture of hydrogen peroxide and ammonia (1 : 10), and hydrolyzed again under the same conditions. The resulting hydrolyzates were combined and analyzed for glucose and glucosamine spectrophotometrically using color reactions of glucose with anthrone and of glucosamine with salicylaldehyde. The results are given in Tables 1 and 2.

1070-4272/01/7401-0142$25.00

Table 1. Fraction composition of fungi *Ph. sanguinea* 16–65, *G. applanatum* 4–94, and *G. applanatum* 40–90

Strain	Moisture, %	Fraction, %, soluble in indicated solvent			Insoluble residue, %
		hot water	alcohol–benzene mixture	6% NaOH	
Ph. sanguinea, 16–65	87.9	18.1	15.4	49.8	16.7
G. applanatum, 4–94	91.0	19.0	12.9	55.9	12.2
G. applanatum, 40–90	89.4	9.4	9.5	61.1	20.0

Note: Fraction composition is expressed in per cents from dry sample weight.

Infrared spectra were registered on a Specord 80/85 instrument (Carl Zeiss, Jena) using KBr technique.

Sorption experiments were conducted as follows. To a weighed portion of the sorbent (0.1 g recalculated to dry sample) we added 20 ml of a buffer solution and 10 ml of 0.01 M $CrCl_3$. After a lapse of time the sorbent was filtered off, and the residual Cr(III) was determined in the filtrate by chelatometric titration [4]. Sorption of Methylene Blue was performed as follows. To a 0.3-g sample 20 ml of 0.5% Methylene Blue and 80 ml of distilled water were added. After a lapse of time the sorbent was filtered off, and the filtrate was analyzed spectrophotometrically for Methylene Blue. The sorption capacity for *Esherichia coli* was estimated from the amount of adsorbed Methylene Blue (0.016 g of adsorbed Methylene Blue corresponds to 176×10^6 bacteria).

Table 1 shows that the highest moisture is observed for the fungus *G. applanatum* 4–94 and the least, for *Ph. sanguinea* 16–65, both growing on hardwood. Under natural conditions (in air, but not in aqueous medium as in this work) fruit bodied of these fungi are characterized by considerably lower moisture. The water-soluble fraction consisting of mineral salts and soluble hemicelluloses varies from strain to strain. The least content is found in *G. applanatum* 40–90 growing on softwood. The same strain contains the least amount of fats and resins representing the fraction soluble in the alcohol–benzene mixture. Hot aqueous NaOH dissolves proteins and melanin (partly). The percentage of this fraction is the highest (50–60%). The CGC content ranges from 12 to 20%, which is considerably lower than that in the mold fungus *Aspergillus niger* (50%), but comparable with that in the yeast *Saccharomycetes cerevisae* (12%) [5].

It was demonstrated by the IR spectra that the insoluble residue is represented by chitin–glucan complex. The spectra show the adsorption bands at 1203 and 1376 cm^{-1} (CH and CH_2 groups) typical of cellulose and other glucans [6] and also at 1652, 1555, and 1310 cm^{-1} (amide I, II, and III, respectively) [7] characteristic of chitin of various origins. The spectra are nearly identical with those obtained for CGC from mycelium of the fungus *Aspergillus niger*.

The elemental analysis data (Table 2) of the fungi after removal of the three soluble fractions demonstrate the presence of nitrogen, which is indicative of chitin.

Data on the composition of the insoluble fraction, obtained after it was totally hydrolyzed, confirmed the conclusion that this residue is represented by chitin–glucan complex. The hydrolyzed forms were demonstrated to be glucose, formed in cleavage of the glucan component of CGC, and glucosamine formed in hydrolysis of the chitin component to *N*-acetylglucosamine with simultaneous deacetylation. From these data we determined the composition of CGC isolated from the fungal fruit bodies (Table 3).

Table 3 shows that the chitin content in CGC is high in fruit bodies of all the strains studied, especial-

Table 2. Elemental composition of insoluble residue of fungi *Ph. sanguinea* 16–65, *G. applanatum* 4–94, and *G. applanatum* 40–90

Strain	Composition, %			
	C	H	N	ash
Ph. sanguinea, 16–65	41.5	6.5	2.2	0.7
G. applanatum, 4–94	42.8	7.0	2.2	0
G. applanatum, 40–90	42.0	6.6	1.6	0.9

Table 3. Composition of CGC isolated from *Ph. sanguinea* 16–65, *G. applanatum* 4–94, and *G. applanatum* 40–90

Strain	Content, %	
	chitin	glucan
Ph. sanguinea, 16–65	59.0	41.0
G. applanatum, 4–94	74.0	26.0
G. applanatum, 40–90	64.0	36.0

Table 4. Sorption characteristics of fungi *Ph. sanguinea* 16–65, *G. applanatum* 4–94, and *G. applanatum* 40–90 after treatment with hot water

Strain	Sorbed Cr(III), mg, at indicated pH and sorption time					SEC, mg-equiv g^{-1}, at pH 6.86
	1.68	4.60	6.86			
	t, min					
	1440	1440	10	60	1440	
Ph. sanguinea, 16–65	1.42	0.95	1.73	1.67	1.66	0.62
G. applanatum, 4–94	1.23	0.90	1.69	1.90	1.87	0.41
G. applanatum, 40–90	1.08	0.98	1.73	1.69	1.69	1.11

ly in *G. applanatum* 4–94 for which it is comparable with that in the wood rotting fungus *Fomes fomentarius* (71%) [5]. However, in contrast to the fungi studied, CGC from *F. fomentarius* additionally contains 10% intracellular melanin.

Such a high chitin content in CGC of the fungi studied and also the fact that their fruit bodies contain proteins suggest that these strains can be efficient ion exchangers for heavy metal ions. We studied the sorption properties of the fungi after treatment with hot water with an example of Cr(III). Sorption was performed over the pH range from 1.68 to 6.86. For all the fungi studied the maximal sorption in 24 h was observed at pH 6.86. The major fraction of Cr(III) was demonstrated to be sorbed in the first 10 min. The highest static exchange capacity (SEC) was shown by the strain *G. applanatum* 40–90 containing 61.1% proteins (Table 1) capable of fixing heavy metal ions.

Comparative analysis shows that CGC from the fungus *Aspergillus niger* demonstrates better sorption characteristics in strongly acidic solutions (depending on the composition, SEC for Cr(III) at pH 1.68 is 1.81–2.01 mg-equiv g^{-1} [8]). The strains studies in this work show better sorption from neutral solutions, and, although SEC obtained for these strains is lower, it should be taken into account that it refers not to CGC, but to fruit bodies only treated to remove the water-soluble fraction.

Finally, the fungal strains studied demonstrate high exchange capacity for Methylene Blue: recalculated to the sorbed amount of *Esherichia coli* it was found to be 176×10^6, 118×10^6, and 317×10^6 for *Ph. sanguinea* 16–65, *G. applanatum* 4–94, and *G. applanatum* 40–90, respectively.

CONCLUSIONS

(1) Fruit bodies of the cultivated fungi *Ph. sanguinea* 16–65, *G. applanatum* 4–94, and *G. applanatum* 40–90 contain up to 20% chitin–glucan complex, the relative content of chitin and glucan in CGC being dependent on the strain.

(2) The fungal strains studied show high sorption capacity for Cr(III), Methylene Blue, and *Esherichia coli*.

ACKNOWLEDGMENTS

The authors are grateful to V.A. Solov'ev and O.N. Malysheva for help in cultivating the wood-rotting fungi.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Comparative Study of Reactivity of Cellulose, Chitosan, and Chitin–Glucan Complex in Sulfoethylation

L. A. Nud'ga, V. A. Petrova, A. D. Ben'kovich, and G. A. Petropavlovskii†

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received July 20, 2000

Abstract—Sulfoethylation of the chitin–glucan complex, isolated from mycelium of the mold fungus *Aspergillus niger*, by substitution with sodium β-chloroethylsulfonate or addition of sodium vinylsulfonate is examined. A comparative study is made of the reactivity of the chitin–glucan complex, chitosan, and cellulose in the both reactions. The sorption characteristics of the sulfoethylated products with respect to Cu(II) and Cr(III) are determined.

It is known that introduction of sulfo groups in cellulose and some other polysaccharides makes them water-soluble. Solutions of the resulting sulfo derivatives are stable in polymineral media, which is important in view of their use in metallurgy and oil production. Also sulfo derivatives can be used as cation exchangers and blood anticoagulants. Thus, chitin was sulfonated to synthesize a full analog of heparin [1].

The sulfoethyl group imparts the same properties to polysaccharides as the sulfo group, but additionally makes the resulting ether more resistant to hydrolysis in acid and alkaline solutions, since it is bound to the skeleton chain of the polysaccharide by an ether bond. It was reported also that sulfoalkyl derivatives of polysaccharides can exhibit biological, particularly anti-AID activity [2].

It is known [3–5] that sulfoethyl derivatives of cellulose and chitosan can be obtained, having a degree of substitution (DS) sufficiently high to make them water-soluble. At the same time, despite the fact that chitin–glucan complexes (CGCs) show promise as a source of chitin (utilization of various biochemical work wastes), there is only limited information on preparation of sulfoethyl derivatives of CGC [6]. The fact that chitin–glucan complexes contain both chitin and glucan fragments makes it possible to compare the CGC reactivity with that of cellulose and chitin in the same reactions.

Depending on an alkylating agent, sulfoalkylation can proceed either as substitution (with haloalkylsulfonates) or addition (with vinylsulfonate or alkane sultones). For alkylation of cellulose all the three types of reagents were used; selection of a reagent was governed by the length of the alkyl residue. Thus, for synthesis of sulfomethyl and sulfoethyl cellulose ethers haloalkylsulfonates were used [7]. Sulfoethyl cellulose was also obtained by addition of sodium vinylsulfonate [8] (this reaction is also known as sulfovinylation, despite the fact the product is a saturated sulfoethyl ether). In the case of higher homologs alkane sultones were also used [9].

Study of cellulose sulfoethylation by reaction of the first type showed that the yield increases when the reaction is performed in a diluent [7]. Additionally, this reduces the degradation of the macromolecules and improves the uniformity of the substituent distribution along the polysaccharide chain. Also the use of a diluent improves the product solubility and the quality of its solutions. It was demonstrated that the best suited diluents are branched alcohols or their mixtures with xylene. The optimal temperature of the reaction is 80°C from the viewpoint of competition of hydrolysis of sodium β-chloroethylsulfonate (β-NaCES) and substitution of the cellulose hydroxyls. The degree of substitution attained in this reaction was no more that 0.8, whereas in reaction of the second type [with sodium vinylsulfonate (NaVS)] products were obtained with SD of about 2.0.

In this work for CGC sulfoethylation we used substitution with β-NaCES and addition of NaVS.

In the case of substitution the reaction is written as

$$R(OH) + ClR_1SO_3Na + NaOH \rightarrow R\text{–}OR_1SO_3Na + NaCl + H_2O.$$

† Deceased.

1070-4272/01/7401-0145$25.00

Table 1. Results on substitution sulfoethylation of chitin–glucan complex in isopropanol (T = 80°C; N_2; CGC: β-NaCES : NaOH = 1 : 3 : 6)

Run no.*	τ, h	DD	Sulfur content, %	DS	*S*, %	[η]**
1	1	–	0.63	0.04	4.8	–
2	2	–	0.87	0.05	7.0	–
3	3	–	1.27	0.08	32.7	–
4	3	–	1.66	0.11	32.0	–
5	1	0	6.20	0.50	66.0	1.2

7	3	0.15	8.90	0.75	97.0	1.7
8	3	–	7.40	0.52	99.5	3.8
9	1.5	0.87	5.32	0.35	72.5	–

* (4) Reagent was added in portions at 30-min intervals; (5–7) initial CGC was included with isopropanol; and (8, 9) β-NaCES : NaOH = 1 : 1 : 3, the starting materials were, respectively, wood cellulose and chitosan from crab shells, the reagent was added in portions at 30-min intervals.

** Determined in 2% NaOH (for the soluble fraction).

Addition by the Michael reaction is written as

$$ClCH_2CH_2SO_3Na + NaOH \xrightarrow{-5^\circ C} CH_2{=}CHSO_3Na + NaCl + H_2O,$$

$$R(OH) + CH_2{=}CHSO_3Na \longrightarrow ROCH_2CH_2SO_3Na.$$

Finally, addition of alkane sultones is written as

$$ROH + \underset{\backslash\ /}{O{-}R_2}\ \underset{SO_2}{} \longrightarrow R{-}OR_2SO_3Na.$$

In these reactions R = Cell, Chit, CGC; $R_1 = CH_2$, C_2H_4; and $R_2 = C_3H_6$, C_4H_8, C_5H_{10}.

The sulfoethylated derivatives of CGC were examined as sorbents for Cu(II) and Cr(III), and their sorption characteristics were compared with those of chitosan and CGC.

EXPERIMENTAL

In experiments we used CGC isolated from mycelium of the mold fungus *Aspergillius niger*. The chitin and glucan contents in the product were 81.6 and 15.6%, respectively. In the reactions we used as-isolated CGC with a moisture content of 72.5%, or preliminary inclusion was performed with the same alcohol as was then taken as a diluent.

Chitosan was prepared from crab shells by alkaline deacetylation. The degree of deacetylation (DD) of the product was 0.88 and the molecular mass, M_v = 1.88×10^5. In the work we used TsA wood cellulose ($M_v = 1.1 \times 10^5$). β-NaCES was recrystallized from ethanol.

Sodium vinylsulfonate was preparad from β-NaCES by reaction with 28% NaOH at –5°C for 1 h. In sulfovinylation we used both crude vinylsulfonate containing NaCl and the product recrystallized from isopropanol or *tert*-butanol.

Sulfoethylation was carried out in isopropanol at 80°C under nitrogen with stirring. A calculated portion of β-NaCES was introduced either as one portion just at the beginning of the reaction or in equal portions at 0.5-h intervals.

The product was filtered off, washed to remove NaCl and residual alkali with 80% methanol, dehydrated with acetone, and, finally, dried at 60°C in a vacuum drier. All the products were analyzed for sulfur by Schoeniger. The solubility in water (*S*) was determined by conductometric titration. The intrinsic viscosity was determined in 0.5 M NaOH.

The sorption capacity of the products was determined in static experiments [10]. Sorption was performed from 0.01 M copper acetate or $CrCl_3$. The experiment time was 24 h. pH was adjusted by adding an appropriate buffer solution.

The kinetics of sulfoethylation with β-NaCES was studied as influenced by the alkylating agent concentration, procedure of its introduction, and CGC pretreatment procedure. The results are summarized in Table 1. As should be expected, with increasing reaction time (all other conditions being equal) the sulfur content in sulfoethylated CGC (SECGK) and, there-

fore, DS increase (see run nos. 1–3), though remaining at a low level. Introduction of β-NaCES in several portions somewhat increases DS (run no. 4) as a result of decreasing consumption of the reagent in hydrolysis. However, significant increase in DS was observed only when preliminary inclusion with isopropanol was used, providing replacement of water without deterioration of the highly developed inner surface of CGC. In experiment nos. 5–7 DS is above 0.50, and the products become substantially water-soluble. Alkaline conditions initiate partial deacetylation of the chitin fraction of CGC. Although DD increases with time in this case, it remains small (0.05–0.15). Therefore, the reaction products cannot be regarded as polyampholytes, in contrast to CGC carboxymethylation products in which DD reached 0.20–0.37 at DS of 0.16–0.81 [11].

The results obtained show that sulfoethylation proceeds to a greater degree with cellulose; in this case neither inclusion nor portionwise introduction of β-NaCES is needed. With chitosan DS 0.35 was obtained without inclusion, but with portionwise introduction of β-NaCES. It should be pointed out that with cellulose and chitosan higher solubility in water is attained at lower DS as compared to CGC. Similar result was obtained previously in carboxymethylation of CGC [11]. Evidently, in sulfoethylation also the substituent is nonuniformly distributed throughout the amorphous and ordered regions of the CGC supramolecular structure.

Addition sulfoethylation with NaVS was studied as influenced by the reaction medium and time and also by the quality of the alkylating agent and pretreatment of the starting material (Table 2). The results show that *tert*-butanol is the most suited diluent for the reaction. This is true for all the starting materials studied: CGC, chitosan, and cellulose. Evidently, the reason is that the accessibility of reaction centers of polysaccharides increases in diluents with bulky molecules.

The figure demonstrates the kinetic curves of sulfovinylation with cellulose, chitosan, and CGC, obtained under identical conditions without inclusion. The degree of substitution increases with time. The effect increases in the order CGC < chitosan < cellulose. Such a difference in the reaction rate for polysaccharides having the same reaction centers can be attributed to different supramolecular structure.

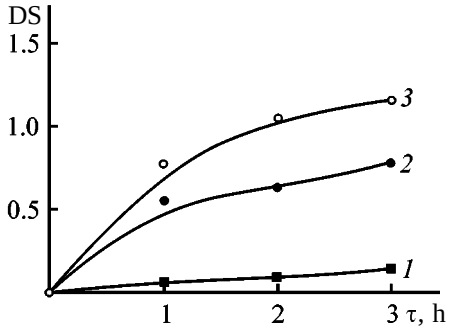
Purification of NaVS to remove NaCl somewhat increases DS, but to a lesser extent than preliminary inclusion of CGC, as in substitution sulfoethylation. Therefore, of primary importance in these reactions is a highly developed inner surface of CGC. In the case of addition sulfoethylation the reaction proceeds to a greater degree, providing higher DS and totally water-soluble products. Furthermore, in the addition NaOH acts only as a promoter; the consumption of this reagent is lower, eliminating deacetylation of the chitin fraction of CGC.

Table 2. Addition sulfoethylation of chitin–glucan complex (T = 80°C; N_2; CGC : NaVS : NaOH = 1 : 6 : 3)

Run no.*	Diluent	τ, h	Sulfur content, %	DS	*S*, %
1	Isopropanol	1	1.02	0.06	5.4
2	″	2	1.42	0.09	14.2
3	″	3	2.13	0.14	21.5
4	″	3	9.07	0.85	100
5	″	3	9.67	0.95	100
6	*tert*-Butanol	3	2.70	0.18	32.3
7	″	3	3.27	0.22	35.0
8	Isopropanol	3	11.30	1.05	100
9	*tert*-Butanol	3	12.08	1.21	100
10	Isopropanol	3	8.77	0.76	100
11	*tert*-Butanol	3	10.19	0.98	100

* (4) Inclusion with isopropanol; (5) CGC was included with isopropanol, NaVS was purified to remove NaCl; (7) NaVS was purified to remove NaCl by treatment with *tert*-butanol; (8, 9) cellulose was a starting material; and (10, 11) chitosan was a starting material.

Finally, despite the fact that one more stage (preparation of NaVS from β-NaCES) is needed, addition sulfoethylation is more preferable, as providing uniform highly substituted water-soluble products. Sodium vinyl sulfonate can be prepared from crude β-NaCES (the presence of NaCl only slightly influences DS in the product). It should be pointed out also that if preliminarily included CGC is used, the reactivity of CGC, chitosan, and cellulose in the reaction with NaVS is leveled.



Kinetic curves of sulfovinylation of (*1*) CGC, (*2*) crab shell chitosan, and (*3*) wood cellulose in isopropanol at 80°C and polysaccharide : NaVS : NaOH = 1 : 6 : 3. (DS) Degree of substitution and (τ) time.

Table 3. Static exchange capacity of CGC and its derivatives

Sample	DD	DS	pH*	SEC, mg-equiv g^{-1}, for indicated ions	
				Cr^{3+}	Cu^{2+}
CGC	0	0	1.68	1.81	–
CANGC	0.31	0	1.68	1.90	–
CANGC	0.70	0	1.68	2.44	–
SECGC	0	0.18	1.68	–	7.60
			6.80	–	11.90
SECGC	0	0.74	1.68	1.30	10.80
			6.80	6.70	11.60
CAN	0.15	0	6.80	2.20	–
CAN	0.80	0	6.80	–	4.50

The sorption experiments were carried out with the iniital CGC, SECGC with DS of 0.18 and 0.74, partially deacetylated CGC (CANGC), and crab chitosan. The static exchange capacity (SEC) at various pHs is given in Table 3. The general trends are as follows. (1) All the sorbents studied better sorb Cu(II) than Cr(III). (2) The metals are better sorbed from neutral solutions than from acid solutions. (3) The greater the amount of adsorption centers in sorbents (amino groups in CAN and CANGC, sulfoethyl groups in SECGC), the higher SEC, regardless of the sorption mechanism on these groups. In the case of SECGC the ion-exchange sorption dominates, and the contribution of complexation with aminoacetyl group cannot be higher than SEC of CGC (free primary amino groups were not found in the CGC samples studied). In CAN and CANGC samples bearing primary amino groups sorption proceeds through complexation. Comparison of SEC obtained at pH 1.68 suggests that the ion-exchange mechanism is more favorable for the both cations.

CONCLUSIONS

(1) Sulfoethylation of the chitin–glucan complex, isolated from mycelium of the mold fungus *Aspergillius niger*, by substitution with sodium β-chloroethylsulfonate or addition of sodium vinylsulfonate is examined. The addition proceeds to a greater degree than the substitution. The addition products demonstrate more uniform distribution of substituents along the chain, which provides total solubility of sulfoethylated derivatives in water.

(2) In the both reactions the reactivity of the polysaccharides decreases in the order cellulose > chitosan > chitin–glucan complex.

(3) Preliminary activation of CGC by inclusion and sulfoethylation by the addition mechanism allow preparation of highly substituted CGC derivatives.

(4) The maximal sorption of Cu(II) and Cr(III) with sulfoethylated CGC was observed from neutral solutions.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Urethane Formation in the Presence of Stabilizers

M. M. Nazipov, A. A. Tabachkov, A. D. Elchueva, and A. G. Liakumovich

Kazan State Technological University, Kazan, Tatarstan, Russia

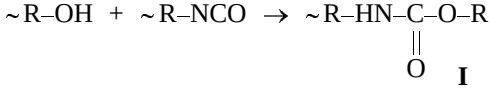
Received March 7, 2000

Abstract—The kinetics of urethane formation was studied in relation to the stabilizer type. A series of urethane elastomers (sealants, coatings, adhesives), derived from stabilized prepolymers and polyoxyalkylene-polyols of various molecular weights, were developed.

In production of cold-curable urethane elastomers [1–3], block copolymers of ethylene and propylene oxides with terminal hydroxy goroups (Laprols[1]) are widely used as polyether components. As compared to any polyester analogs, polyethers ensure higher frost and hydrolysis resistance of the composite materials.

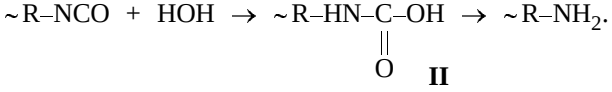
Polyoxyalkylenepolyols readily react with toluene diisocyanate (TDI) to form reactive oligomers, prepolymers, which are intermediates in production of castable polyurethanes, sealants, corrosion-protective coatings, adhesives, etc.

The urethane formation processes are based on polycondensation of a polyol with the prepolymer, yielding urethane units:



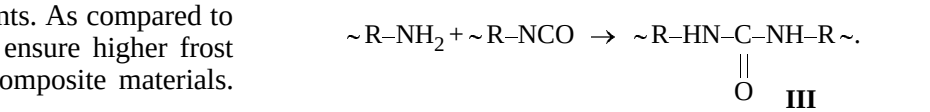
I

The main urethane formation reaction is always complicated by various side reactions somewhat distorting the structure of the final polymer, i.e., macromolecules of a highly elastic polyurethane consist of segments with different thermodynamic flexibility. "Soft" segments with weak intermolecular interaction and low glass-transition point are formed by oligomeric chains, and "hard" segments consist of products of reaction of the isocyanate group with low-molecular-weight compounds. Despite thorough drying of the polyol, amino groups **II** are formed in certain amounts; they very rapidly react with isocyanate groups to give urea units **III** in the macromolecules:



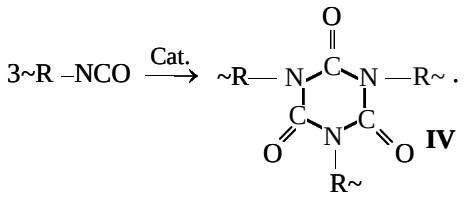
II

Urea groups are also formed by reaction of the isocyanate-containing prepolymer with amine-type curing agents:



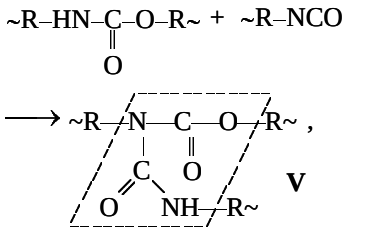
III

At the same time, curing of the prepolymer can occur by trimerization (**IV**) of the terminal isocyanate groups under the action of a catalyst:



IV

Urethane and urea units in polymeric chains, owing to the presence of labile hydrogen atoms, react with isocyanate groups to form a three-dimensional cross-linked structure containing allophane (**V**) and biuret (**VI**) moieties:



V

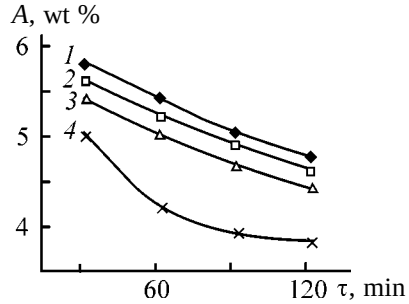

Fig. 2. Kinetic curves of synthesis of prepolymers from various TDI samples stabilized with HCl: (*1*) T-65/35, (*2*) T-80/20, (*3*) T-102T, and (*4*) nonstabilized TDI.

The presence of polar groups of different nature, randomly or regularly distributed in a relatively low-polar matrix of flexible oligomeric chains, is a specific feature of urethane elastomers, largely determining their supramolecular structure and chemical and physical properties. Owing to these groups, all types of urethane elastomers are characterized by fairly intense intermolecular interactions, mainly of the hydrogen bond type. The developed three-dimensional network of physical cross-links in network structures supplements the chemical cross-linking. The longer the chain of the hydroxyl-containing component, the lower the concentration of labile hydrogen atoms in urethane groups and hence the weaker the intermolecular interactions and the more flexible the polymeric chain. High rate of chain growth in reaction of a polyol with the prepolymer favors preparation of highly elastic materials, and high cross-linking rate results in preparation of stronger composites, up to formation of "glassy" polyuretyhane.

The main goal in urethane formation is to preserve the reactivity of the prepolymer and enhance its stability in storage. The effect of acetylacetone as a stabilizer in reaction of an ester polyol with TDI was studied in [4]. It is known that acetylacetone forms chelates with many metal ions occurring in the forms of salts, oxides, hydroxides, etc. Its reactivity toward isocyanates is very low; hence, in systems containing isocyanates and metal ions acetylacetone will form practically exclusively metal acetylacetonates, which catalyze the reaction between the NCO and OH groups and do not promote side reactions in the course of urethane formation.

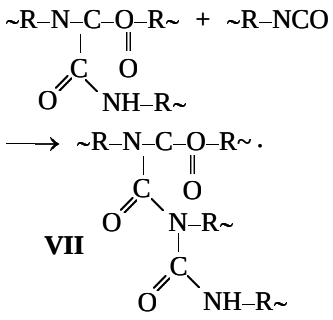
In this work we examined for the first time the stabilizing effect of readily available hydrochloric acid on prepolymers based on polyoxyalkylenepolyols. The polyether is prepared in the presence of a base catalyst. Base impurities are strong catalysts of trimerization of prepolymers (**IV**), reducing their storage life and reactivity and even causing gelation. Addition of acid compounds into the reaction mixture in synthesis of prepolymers favors neutralization of alkali and more complete reaction between the NCO and OH groups.

EXPERIMENTAL

The polyether was placed in a vessel equipped with a stirrer and a jacket for heating or cooling and dried in a vacuum to a moisture content of about 0.05%; after that, a stabilizer (0.05 wt %) was added, the mixture was stirred for 5–10 min, and TDI was added in an amount required for preparing a prepolymer of a specified molecular weight. Urethane formation is exothermic; therefore, TDI was added in portions and the reactor was cooled through the jacket, so as to maintain the temperature at 70–75°C.

The process of sealant preparation includes the following stages: (a) preparation of a sealing paste (paste A) by mixing a reactive oligomer (thiokol or polyol), a filler, a catalyst, and the other additives; (b) preparation of a curing paste (paste B) by synthesis of a stabilized prepolymer from polyoxyalkylenepolyol with addition of a hydrophobic filler if required; (c) mixing of pastes A and B directly before application to a working surface. We used polyoxyalkylenepolyols of molecular weight 3000–5000 [TU (Technical Specifications) 2226-023-10488057–95) and a polysulfide oligomer (brand I thiokol). As curing catalysts we used dimethylaminomethylphenols (OM-1, OM-2, OM-3) of Agidol 51, 52, and 53 brands (TU 38-30356–86) in amount of 1.5–3.5 wt parts per 100 wt parts of polyol; the filler was P-803 industrial carbon [GOST (State Standard) 7885–77] in amount of 60–80 wt parts per 100 wt parts of polyol. The composites were tested on an RMI-250 tensile testing machine according to GOST 7762–74.

Figure 1 shows the kinetic curves of the synthesis of prepolymers from polyoxyalkylenepolyol of molecular weight 5000 and TDI (T-80/20) in the presence of HCl and acetylacetone and from the active polyether. In reactions of TDI with active polyols, side formation of allophanes **V** is possible. In storage, these prepolymers often undergo gelation due to formation of a three-dimensional cross-linked structure through side allophane bonds:



VII

By aminolysis, we detected in the prepolymer allophane groups in amount of 0.5–1.2 wt %, which are practically absent in the prepolymer based on stabilized polyols. IR examination revealed the presence of triisocyanurate structures in the prepolymer from active polyethers, which results in cross-linking of polyurethane macromolecules. In this process, the viscosity increases and the content of isocyanate groups decreases. It is known [5] that the rate of allophanate formation considerably exceeds the rate of trimerization of isocyanate groups. A sharp decrease in the content of NCO groups is particularly noticeable with the polyether of a lower molecular weight (Fig. 2, curve *4*). The brand of the TDI used does not play a significant role.

In the case of the stabilized prepolymer, urethane formation is characterized by occurrence of the main reaction [reaction (1)]. The type of the stabilizer has no significant effect on the kinetics of prepolymer synthesis; the content of the NCO groups becomes approximately constant within 90 min and does not change further (Fig. 3).

A process was suggested for preparation of polyurethane (TU 38.3 030 098–95, 38.4 030 103–95, 38.4 030 104–95, 222 600 201-3 013 487–95) and thiourethane sealants containing a stabilized prepolymer based on polyoxyalkylenepolyol of molecular weight 5000. The composite materials as compared to the industrial analogs are characterized by increased strength, elasticity, and water resistance and by good adhesion to various substrates. The use of a catalytic

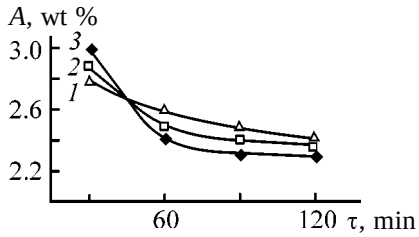


Fig. 3. Kinetic curves of synthesis of prepolymers in the presence of various stabilizers: (*1*) diisopropyl hydrogen phosphite, (*2*) diisooctyl hydrogen phosphite, and (*3*) phosphorochloridite.

curing coagent of reactive oligomers with various functional groups allows practically complete chemical binding with simultaneous improvement of physicomechanical parameters. The advantage of these sealants is that the sealing and curing pastes are taken in comparable amounts (ratio A : B varies from 2 : 1 to 1 : 1), which favors good mixing of the components under industrial conditions.

The physicomechanical parameters of polyurethane sealants determined in extended tests are listed in Table 1. The advantages of our formulations are simpler process and lower power consumption due to decreased amount of the components and curing at room temperature. Also, there are vast prospects for production of colored composites.

Polyoxyalkylenepolyols of molecular weight from 500 to 6000 are commercially available. Experiments showed (Table 2) that the best combination of elasticity and strength is attained when the molecular weight of the polyol is 3000–5000. With lower-molecular-weight polyethers, denser cross-linked materials are formed, which exhibit increased cohesion strength but low elasticity. With the molecular weight of the polyethers above 5000, the strength of the composites decreases. Introduction of a stabilizer (0.05 wt % HCl) into the prepolymer levels its reactivity toward polyols and suppresses side reactions. Formation of urethane elastomers occurs as a chain growth reaction. When the polymer contains no allophane cross-links, its reaction with polyol yields linear macromolecules, which is favorable for microphase segregation; such composites exhibit higher elasticity.

Phenol Mannich bases (PMBs), dimethylaminomethylphenols, are widely used catalysts of reactions of oligothiols and polyols with isocyanate-containing prepolymers. It was found previously [6] that the activity of these catalysts varies in parallel with their basicity. When the amount of the catalyst is low, the oligomers react slowly, which favors formation of a

low-defective network, and the resulting composites exhibit increased cohesion strength and elasticity (Table 3).

The increased content of the catalyst favors faster reaction of the oligomers, but the resulting network can become defective. Furthermore, at larger amounts of the catalysts formation of isocyanurates **IV**, which do not react with the polyether at room temperature, becomes more probable. As a result, the strength and adhesion characteristics of the product decrease.

Table 3. Influence of the catalyst amount on the physicomechanical characteristics of composites

Relative elongation at break, %	350–400	280–340

We also examined the possibility of using Schiff bases derived from aliphatic diamines and various aldehydes as catalysts for curing of single-component sealants of the polyurethane and thiourethane nature. With aldimines it is possible to avoid a drawback characteristic of traditional single-component urethane systems: release of CO_2 at curing of isocyanate prepolymers with moisture present, as a rule, in fillers. We studied the reaction of mono- and diisocyanates with Schiff bases and hydrolysis of Schiff bases at various ratios of the components, curing temperatures, and pH values of the medium. With decreasing pH the hydrolysis of Schiff bases accelerates and the reaction of isocyanate groups with water decelerates. Electron-

donor substituents in aldimines accelerate with reaction with isocyanates.

CONCLUSION

Addition of an acid stabilizer to a prepolymer levels its reactivity toward a polyol or oligothiol and suppresses side reactions in the course of urethane formation. The use of the stabilized prepolymer opens prospects for preparation of a wide assortment of urethane elastomers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Boric Acid Esters as Fungicide Additives and Heat Stabilizers of Elastomers Based on Siloxane Rubber

V. I. Grachek, N. N. Bukanova, A. V. Smolyakov, and A. N. Lukashik

Institute of Physical Organic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received August 4, 2000

Abstract—New boric acid esters with an azomethine bond were prepared. These compounds exhibit an efficient fungicide and heat-stabilizing effect on elastomers based on SKTV-1 rubber.

Aging and stabilization of polymers is still an urgent problem. There is a growing interest in multifunctional stabilizers containing in the same molecule a number of functional groups acting by different mechanisms [1]. It is known that organoboron compounds exert a fungicide [2, 3] and heat-stabilizing effect [4–6] on polymeric materials. With the aim to develop promising fungicide additives and heat stabilizers for siloxane rubber, we prepared new boric acid esters containing azomethine groups, in view of the fact that compounds containing C=N groups are efficient heat-stabilizing agents for polysiloxanes [7].

Borates were prepared by heating of a mixture of boric acid with pyrocatechol and hydroxy compounds containing azomethine groups at 70–80°C in benzene with heteroazeotropic distillation of the released water.

The structure of the products was proved by IR and ^{1}H NMR spectroscopy, mass spectrometry, and elemental analysis.

The IR spectra of the compounds contain bands at 1040 ± 10 and 1350 ± 10 cm^{-1} characteristic of the symmetrical and antisymmetrical vibrations of the B–O group and at 1090 ± 10 and 1240 ± 10 cm^{-1} characteristic of the symmetrical and antisymmetrical vibrations of the C–O group. The band at 1640 ± 5 cm^{-1} is due to the CH=N vibrations, and that at 1754 cm^{-1}, to the stretching vibrations of the ester carbonyl (in **III** and **IV**).

The ^{1}H NMR spectra of the compounds are given in Table 1. The proton signals of the pyrocatechol ring are observed at 6.20 ± 0.04 and 5.60 ± 0.02 ppm. The azomethine proton gives a signal at 8.15 ± 0.03 ppm. The chemical shifts of protons of the substituents are also given in Table 1. In addition, the spectra of **III** and **IV** contain signals at 1.23 and 3.58 ppm, belonging to the methyl and methylene protons of the ethoxy group.

The mass spectra of the boric acid esters contain molecular peaks (Table 1), but their intensity is relatively low. The molecular peaks of all the compounds have a close intensity. Apparently, the extent and character of electron density delocalization in substituents, affecting the stability of the compounds to electron impact, yield of molecular ions, and formation of stable radicals, are similar in all the compounds.

The most characteristic and intense peaks in the mass spectra of the borates are those at *m/z* 135, 108, 92, and 65. They presumably originate from the $C_6H_4BO_3$ moiety, common for all the compounds.

All the compounds contain a strong peak at *m/z* 65, corresponding to the $C_5H_5^+$ ion, which can form only by rearrangement with hydrogen transfer from one part of the molecule to another.

The physicochemical characteristics of the compounds are listed in Table 2.

The synthesized esters were added to rubber stocks based on SKTV-1 siloxane rubber. The optimal content of the additives was 1 wt part per 100 wt parts of rubber. With larger amounts of the additives, the physicomechanical properties of the rubbers get worse. The rubber stocks were prepare on rollers using standard formulations. Boric acid esters do not exude to the surface of siloxane rubber and do not affect the peroxide curing of rubbers.

Rubbers with triaryl borate additives were tested for fouling with mold fungi. The fungus resistance of rubbers (extent of fungus growth on rubber samples) was evaluated in a six-point scale [GOST (State Standard) 9049–75]. The results are listed in Table 3. It is seen that the borate-containing rubbers are fouled

with mold fungi to a considerably lesser extent than the rubbers with no additives. For example, the rubbers with the suggested additives remained fungus-resistant for 84 days, whereas the rubbers with no additives are intensely fouled in this period (5 points). Of the four examined triaryl borates, three are efficient fungicide additives to siloxane rubbers: **I**, **III**, and **IV**. Compound **II** showed a weak fungicide activity. This compound differs from **I** only in position of linking of the 2-naphthyliminomethyl group to the phenyl ring. It may be assumed that the more rigid molecule of **II** containing a substituent in the *o*-position of the phenyl ring diffuses to the rubber surface considerably more slowly, so that its surface concentration appears to be insufficient to suppress the fungus growth.

The heat resistance of the rubbers was evaluated from variation of their main physicomechanical properties: modulus of elasticity at 100% elongation M_{100}, nominal strength P, relative elongation at break L, and elongation set I. The inhibiting effect of the suggested additives was evaluated in comparison with the rubber containing no additives. The characteristics of rubbers at thermal aging, determined according to GOST 270–75, are listed in Table 4. It is seen that the synthesized triaryl borates inhibit thermal aging of rub-

IV	0	0–1	1	1–2
No additive	4	4	5	5

Table 4. Thermal aging of vulcanized siloxane rubbers in the presence of triaryl borates

Compound	Before aging				After aging							
	M_{100}	P	L	l	250°C, 5 days				300°C, 1 days			
	MPa		%		M_{100}, MPa	K_P	K_L	l, %	M_{100}, MPa	K_P	K_L	l, %
I	1.8	7.0	390	4	2.0	0.60	0.51	8	2.5	0.56	0.50	9
II	2.2	6.8	330	5	3.4	0.75	0.42	7	Brittle			
III	2.4	7.2	320	6	3.0	0.68	0.56	5	2.5	0.58	0.62	6
IV	2.1	7.1	360	9	3.2	0.70	0.72	3	2.5	0.65	0.67	8
No additive	2.2	5.9	240	0	4.8	0.51	0.52	5	3.8	0.44	0.50	0

Note: $K_P = P/P_0$, $K_L = L/L_0$.

bers. For example, after keeping for 5 days at 250°C the modulus of elasticity of the rubbers with the additives increases to a lesser extent (by a factor of 1.5–2) than that of the rubber with no additives. This means that in the presence of the additives the cross-linking of the siloxane rubber occurs to a considerably lesser extent. The loss of the rubber strength in the presence of the additives is 10–20% smaller than in their absence. At a higher temperature (300°C), the changes in the modulus of elasticity and strength are also considerably less pronounced in the rubber samples containing additives (except **II**).

Compound **IV** is the most efficient heat stabilizer. This is due to the presence of the following atoms and groups: (1) boron atoms scavenging radicals owing to pronounced tendency to add groups containing free electrons; (2) nitrogen atoms capable of chain termination; (3) hydroxy groups enhancing the stabilizing effect owing to easy reaction of phenol radicals with peroxy radicals; and (4) ester group.

Our study showed than the synthesized triaryl borates exert a fungicide and heat-stabilizing effect on siloxane rubber. It is known [8] that siloxane rubber has a poor fungus resistance, and microorganisms accelerate degradation of rubbers.

Recently the requirements to environmental safety of additives to elastomer formulations became more stringent [9].

The synthesized triaryl borates meet the requirements imposed on fungicide additives: they are sufficiently toxic for mold fungi and nontoxic for humans (LD_{50} 590–640 mg kg^{-1}); they are well compatible with the rubber, do not prevent peroxide vulcanization, do not give rise to process complications, and enhance the heat resistance of the rubbers. With these additives, the service life of siloxane rubbers increases, and it becomes possible to use them in warm and humid climate at elevated temperatures without additional heat stabilizers.

CONCLUSION

New triaryl borates containing azomethine groups were prepared. The borates are heat stabilizers for vulcanized SKTV-1 rubbers and simultaneously protect them from fouling with mold fungi.

CHEMISTRY OF FOSSIL FUEL

Distribution of Varius Forms of Organic Nitrogen in a Lignite Macromolecule

Received July 26, 1999

Abstract—The chemical composition of organic bases from tars of stepwise semicoking of lignite was studied. The features of distribution of organic nitrogen in a coal macromolecule and the most probable pathways of thermal degradation of the nitrogen-containing fragments were examined.

Up to now, fossil fuel is one of the sources of diverse nitrogen organic compounds (NOCs). Data on structural types of organic nitrogen and its distribution in a coal macromolecule are necessary for determining the chemical structure of coal and recovering in maximal yield the NOCs of the given structural-group and qualitative composition. Nitrogen organic compounds are valuable raw materials for preparing a wide set of pesticides, pharmaceuticals, dyes, heat-resistant fibers, special-purpose rubbers, ion-exchange resins, flotation agents for rare and rare-earth metals, surfactants, and vitamins. Recovery of NOCs from coals in high yield is hampered by the lack of detailed information on the chemical composition of the semicoking tars, which, in turn, does not allow scientifically substantiated selection of the initial brown coals and optimization of their processing.

The goals of this work were to study in detail the chemical composition of organic bases from tars of stepwise semicoking of lignite,[1] determine the features of distribution of organic nitrogen in the lignite macromolecule, and reveal the most probable pathways of thermal degradation of the nitrogen-containing fragments.

Semicoking was performed in a retort so as to minimize the pyrolysis of "primary" vapor–gas products [1]. Therefore, the major components of these products can be fairly reliably assigned to certain native fragments of the organic matter of lignite (OML). The tar was collected in three temperature ranges (°C): (I) <350, (II) 350–450, and (III) 450–500°C, corresponding, according to DTA, to the maximal yield of the tar. The tar yield (wt % based on OML) in stages I, II, and III was 1.5, 4.9, and 3.4, respectively.

The tars were subjected to total chemical group analysis [2]. The yield of organic bases in stages I, II, and III, wt % based on anhydrous tar (wt % based on OML), was 0.85 (0.013), 1.85 (0.091), and 1.17 (0.040), respectively.

The general characterization of the molecular structure of nitrogen organic compounds was based on data of IR, UV, ^{1}H and ^{13}C NMR spectroscopy, cryoscopy, elemental and quantitative functional analysis, and capillary gas–liquid chromatography (CGLC) [3–6].

The structural-group composition of organic bases from tars of stepwise semicoking of Near-Moscow lignite, calculated from the CGLC data, is listed in the table. It is seen that the organic bases recovered in different temperature ranges of OML degradation significantly differ in the structural-group composition.

For example, the tars recovered in the temperature range 350–450°C have a high content of picolines, lutidines, ethyl-, *n*-propyl-, isopropyl-, *n*-butyl-, and isobutylpyridines, and aliphatic and aromatic amines. The content of pyridine, quinoline, isoquinolines, benzoquinolines, benzoisoquinolines, indoles, carbazoles, hydrogenated quinolines and benzopyrroles, and polycyclic NOCs is the highest in the tars recovered in the range 450–550°C.

The distribution of NOCs in the coal macromolecule can be estimated more descriptively from the yield of separate groups of NOCs (see table). It is seen that the tar recovered in the second stage of

[1] Lignite from the Near-Moscow fields was studied (Kimovsk open pit).

2	Picolines	6.82	11.65	7.92	8.87	106.02	31.68
3	Lutidines	8.51	13.95	9.45	11.06	126.95	37.80
4	Ethylpyridines	0.90	1.65	0.92	1.17	15.02	3.68
5	C_3-Pyridines	7.91	9.45	6.65	10.28	86.00	26.60
6	$>C_4$-Pyridines	6.42	8.52	5.00	8.35	77.53	20.00
7	Quinolines	1.95	4.65	8.45	2.54	42.32	33.80
8	Isoquinolines	0.95	2.30	4.45	1.24	20.93	17.80
9	Benzoquinolines	0.65	1.82	5.55	0.85	16.57	22.20
10	Aromatic amines	1.95	2.50	1.25	2.54	22.75	5.00
11	Indoles	2.45	4.35	6.25	3.19	39.60	25.00
12	Carbazoles	0.65	1.50	2.85	0.85	13.65	11.40
13	Polycyclic NOCs	0.95	2.45	5.62	1.24	22.00	22.50
14	Aliphatic amines	1.65	1.90	0.85	2.15	17.30	3.40
15	Hydrogenated quinolines	8.90	10.50	13.45	11.57	95.60	53.80
16	Hydrogenated benzopyrroles	9.30	12.80	15.35	12.09	116.48	61.40

semicoking (350–450°C) is characterized by the highest content of NOCs. The major organic bases (content $A \times 10^4$, wt % based on OML) are picolines (106.02), lutidines (126.95), hydrogenated quinolines (95.60) and benzopyrroles (116.48), propyl- (86.00) and butylpyridines (77.53), quinolines (42.32), and indoles (39.60).

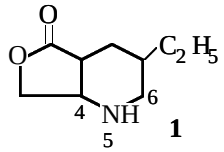
The table shows that the fragments of the molecular (or bituminous) fraction and the periphery of the macromolecular network of the lignite macromolecule contain pyridine and its alkyl derivatives (methyl-, dimethyl-, trimethyl-, ethyl-, *n*-propyl-, isopropyl, *n*-butyl-, isobutylpyridines). Also present in small amounts are aliphatic and aromatic amines. The macromolecular network of the lignite molecule is built of fragments of quinoline, isoquinoline, benzoquinolines, indole, carbazole, hydrogenated quinolines amd benzopyrroles, and polycyclic NOCs whose relative content in the organic bases increases with increasing temperature of OML degradation.

The scheme of the distribution of various nitrogen-containing fragments in the lignite macromolecule suggests ways to optimize semicoking of lignites to obtain tars enriched in given groups of NOCs or even in individual components.

Since ammonia is the main nitrogen-containing gaseous product of semicoking and, the more so, high-temperature coking of coals, it is important to elucidate the nature of its precursors.

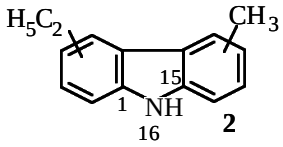
To solve this problem, we calculated the structural and energy characteristics of separate components of organic bases. The calculation was based on data on the lengths of the C–N bonds and on the assumption that the bond length is inversely proportional to the bond dissociation energy.

The structures of separate representatives of lignite organic bases, identified in the tar, and the C–N bond lengths are given below:



1

l_{4-5} 1.440 Å
l_{5-6} 1.4502 Å



2

l_{1-16} 1.339 Å
l_{15-16} 1.325 Å

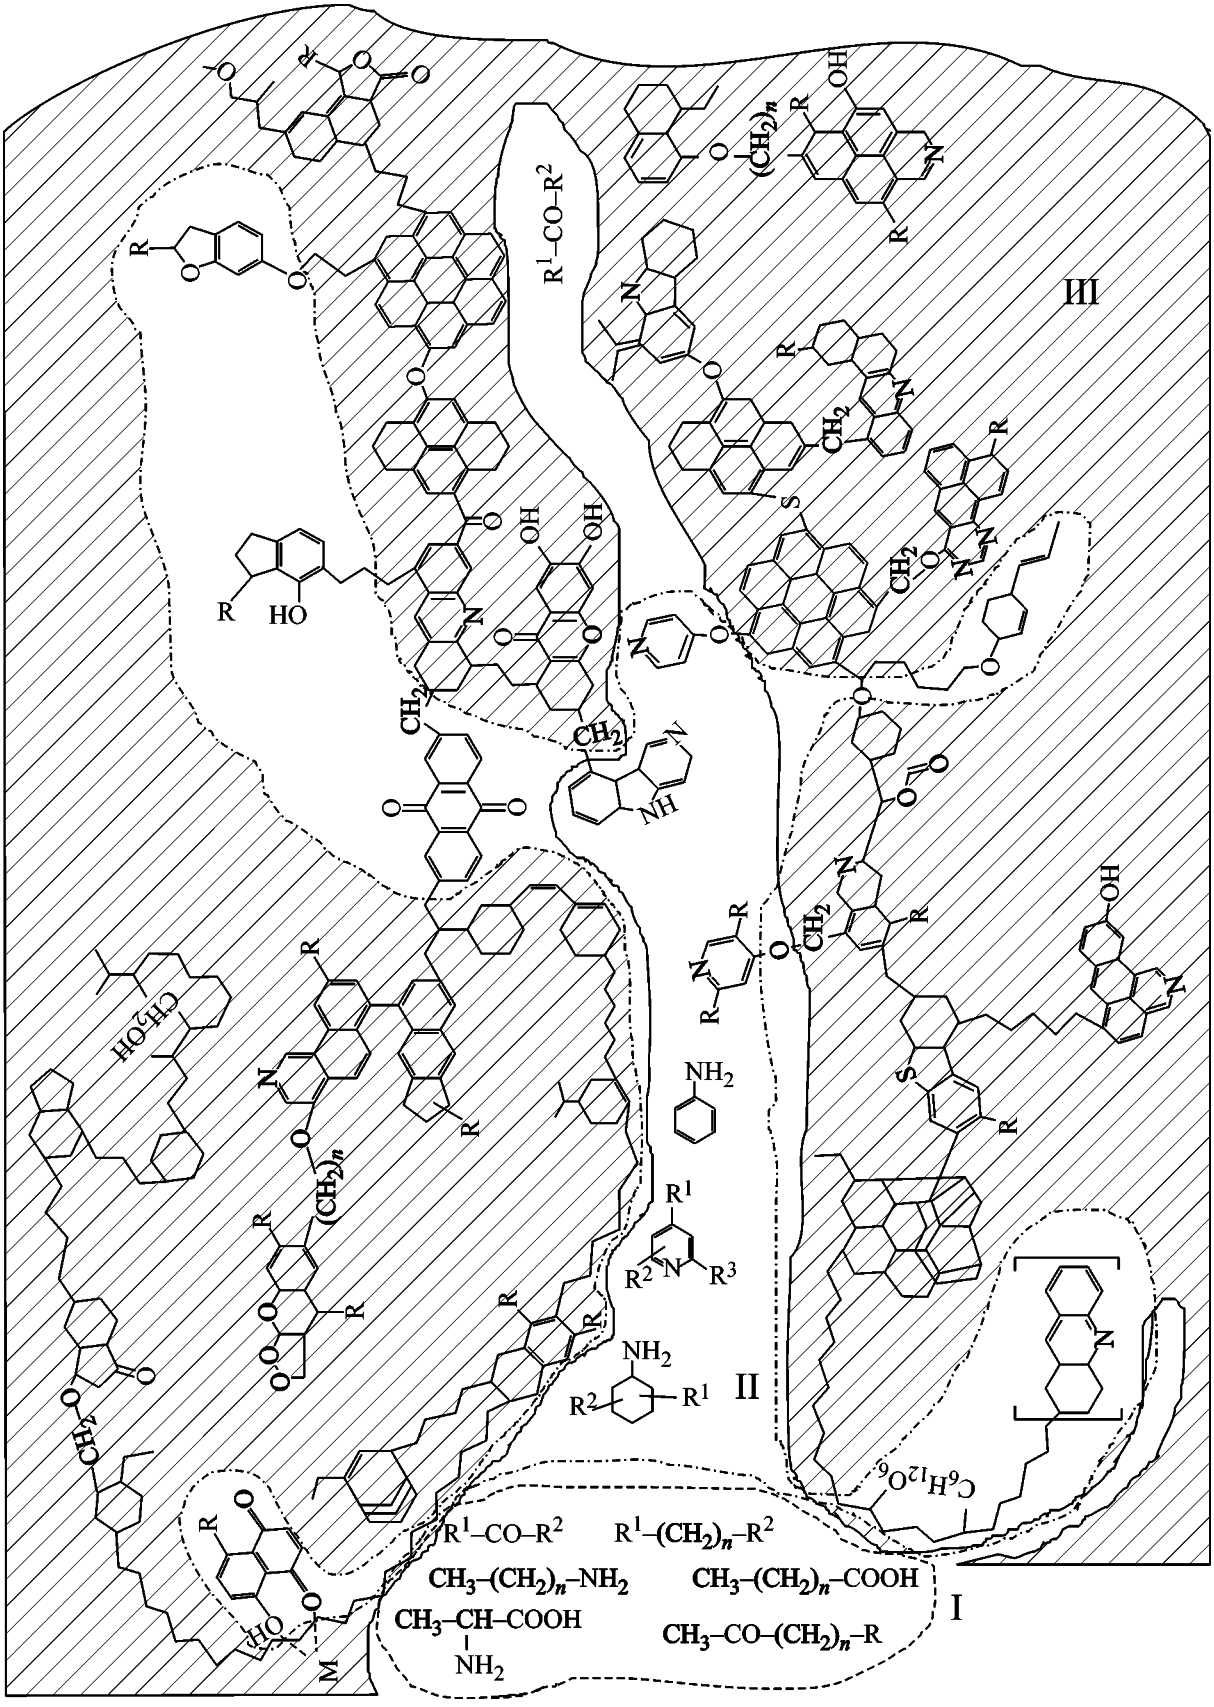
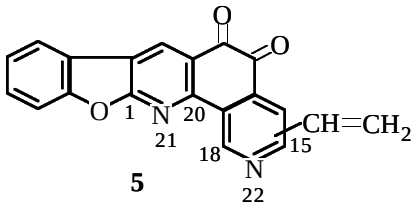
l_{6-14} 1.343 Å l_{1-13} 1.265 Å
l_{8-15} 1.343 Å l_{12-13} 1.2640 Å

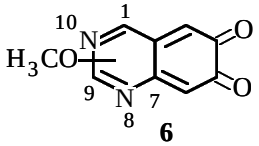
Scheme of distribution of various nitrogen-containing fragments in a lignite macromolecule





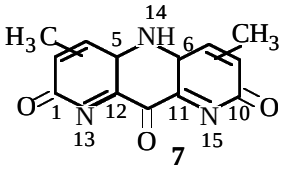
5

$l_{1–21}$ 1.261 Å $l_{18–22}$ 1.263 Å
$l_{20–21}$ 1.267 Å $l_{15–22}$ 1.266 Å



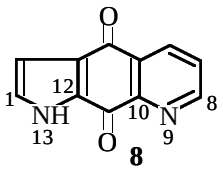
6

$l_{7–8}$ 1.265 Å $l_{1–10}$ 1.263 Å
$l_{8–9}$ 1.265 Å $l_{9–10}$ 1.266 Å



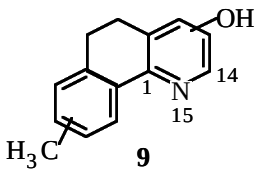
7

$l_{1–13}$ 1.398 Å
$l_{12–13}$ 1.322 Å
$l_{5–14}$ 1.473 Å
$l_{6–14}$ 1.472 Å
$l_{11–15}$ 1.321 Å
$l_{10–15}$ 1.400 Å



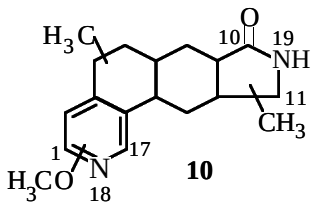
8

$l_{1–13}$ 1.330 Å
$l_{12–13}$ 1.325 Å
$l_{8–9}$ 1.343 Å
$l_{9–10}$ 1.325 Å



9

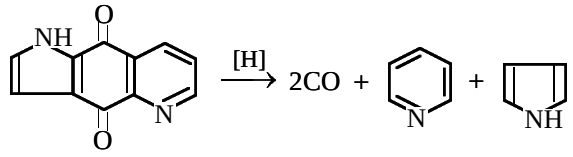
$l_{1–15}$ 1.265 Å
$l_{14–15}$ 1.265 Å

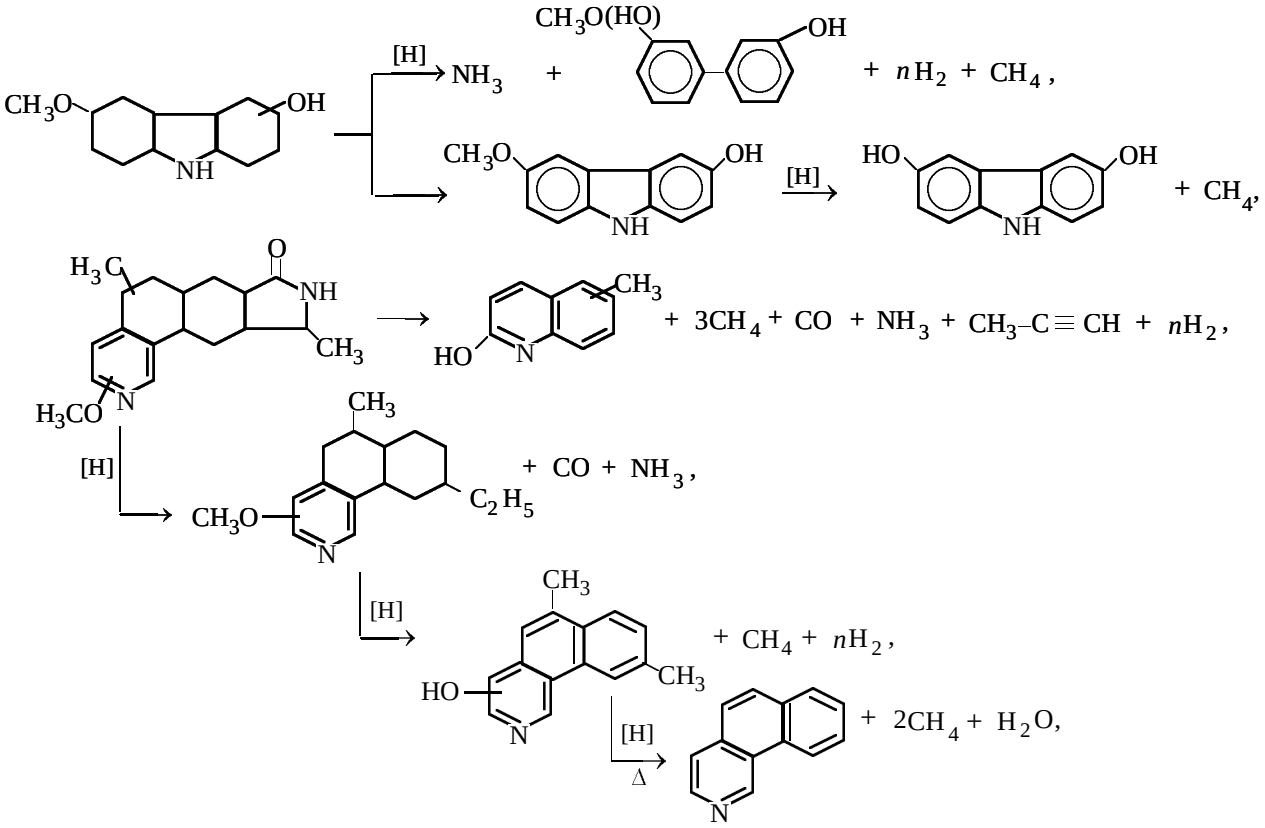


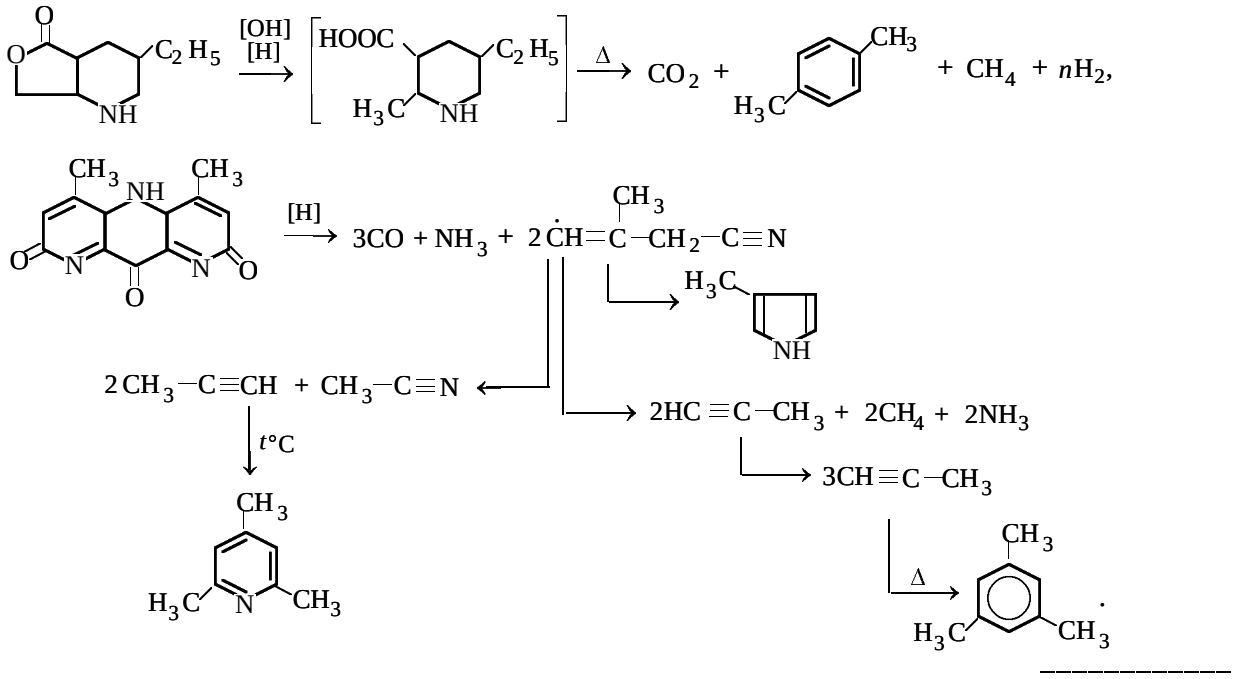
10

$l_{1–18}$ 1.264 Å
$l_{17–18}$ 1.462 Å
$l_{10–19}$ 1.371 Å
$l_{11–19}$ 1.443 Å

The bond lengths suggest that compounds **1, 3, 7, 8**, and **10** will decompose first, and compounds **4**–**6** and **9** will be more heat-resistant. Therefore, the following pathways of thermal degradation of components with formation of ammonia were suggested:







The lack of published data on the lengths and dissociation energies of the C–N bonds in complex molecules did not allow us to confirm the suggested degradation pathways by calculation of the activation energy for each process, e.g., by the Moin's method [7, 8]. However, it can be definitely concluded that the major sources of ammonia in high-temperature coking of lignites are structures containing pyrrole, pyrimidine, and piperidine rings, purine bases, five- and six-membered lactams, aliphatic and aromatic amines, and diamines.

CONCLUSIONS

(1) The chemical composition of organic bases from tars of stepwise semicoking of lignite from the Near-Moscow fields was studied.

(2) The dynamics of distribution of various nitrogen-containing fragments in the lignite macromolecule was elucidated, and the feasibility was demonstrated for thermal degradation of lignites to obtain tars enriched in a definite set of organic bases.

(3) Possible pathways of thermal degradation of separate organic bases with formation of ammonia were suggested. The main sources of ammonia are pyrrole, piperidine, pyrimidine, and lactam fragments of the coal macromolecule, and also purine bases, aliphatic and aromatic amines, and diamines.

BRIEF COMMUNICATIONS

Thermodynamic Characteristics of Vaporization of Diethylarsine and Triethylmethoxystannane

A. K. Baev

Belarussian State Technological University, Minsk, Belarus

Received March 1, 2000; in final form, June 2000

Abstract—Saturated vapor pressures of diethylarsine and triethylmethoxystannane were measured in a wide temperature range. Thermodynamic characteristics of their vaporization and temperatures of the decomposition onset were determined.

The use of arsine in the synthesis of submicrometer structures of gallium arsenide by organometallic gas-phase epitaxy provides a high quality of the resulting products. However, from the environmental viewpoint, it is urgent to look for organoarsenic compounds with reduced toxicity and stability. The use of organotin compounds in the synthesis of thin-film articles enables their contact soldering and preparation of conductive oxide layers. Diethylarsine and triethylmethoxystannane are of interest in this connection, but published data on these compounds are limited to their spectra. Therefore, the goal of this work was to measure the vapor pressure of these compounds and to determine their thermal stability and thermodynamic characteristics of their vaporization.

The experiments were carried out under static conditions by a membrane method for samples containing 99.9 mol % main substance. A sample was introduced into a membrane chamber by distillation in vacuum using an all-glass sealed system, which was preliminarily heated under evacuation with a zeolite pump to remove moisture adsorbed on glass. Vapor pressures were measured with an MChR-3 manometer accurate to 0.1 mm Hg at fixed temperatures controlled by a liquid thermostat. A silicone liquid was used for the temperature control above 313 K and water, at lower temperatures. The accuracy of the temperature control in this temperature range was ± 0.05 K. Prior to and after the completion of an experiment the membrane chamber was cooled to the temperature of liquid nitrogen, and the residual vapor pressure was an evidence of side processes occurring in the system on heating. Experimental vapor pressures were treated by the least-squares method at a confidence level of 0.95.

The temperature dependences of the experimental saturated vapor pressures (Table 1) fit characteristic exponential curves. They are well reproduced on heating and cooling the systems. The semilogarithmic plots of vapor pressure against temperature are linear within the limits of experimental errors, which indicates that only vaporization processes occur in the temperature range under study.

* Diethylarsine: T = 281–366 K; triethylmethoxystannane: T = 312–435 K. ** Antoine's equation.

The data on the vapor pressure P (mm Hg) were treated by the equation $\log P = -A/T + B$ and by the Antoine's equation. The calculated constants of the equations and enthalpies and entropies of vaporization are given in Table 2. The enthalpies of diethylarsine and triethylmethoxystannane vaporization found by the Antoine's equation are 35.15 (273.15 K), 34.24 (298.15 K), and 32.49 and 49.91 (273.15 K), 48.71 (298.15 K), and 42.61, respectively.

The average molecular weights of diethylarsine and triethylmethoxystannane, calculated using the experimental pressures of unsaturated vapors of diethylarsine and triethylmethoxystannane, well agree with the weights calculated from their formulas, which proves that monomeric molecules are present in the vapors. The pressures of unsaturated vapors obey the Gay–Lussac's law within a wide temperature range. Heating unsaturated vapors in steps of 1 K with sufficient in time thermostatic control at each fixed temperature allowed us to detect the temperatures of the onset of noticeable irreversible decomposition of diethylarsine (497.5 K) and triethylmethoxystannane (493.3 K).

As the enthalpies of vaporization of triethylarsine (38.52 ± 0.74 kJ mol^{-1}) [1] and diethylarsine (32.96 ± 0.15 kJ mol^{-1}) were obtained from the data on the vapor pressure in the same temperature range, their difference of 5.56 kJ mol^{-1} should be attributed to the change in the intermolecular interaction on the replacement of one C_2H_5 group by hydrogen. In view of the fact that the integral enthalpy of vaporization [2] is determined by the number and energy of bonds existing in solution, we can deduce $D(\mathrm{As}\cdot C_2H_5\text{–As})$ = 6.42 kJ mol^{-1}. This is a limiting value, as dispersion interactions in solution were not taken into account [3, 4]. With this value taken unchanged in liquid diethylarsine, we obtain $D(\mathrm{As–}C_2H_5\cdot\mathrm{As})$ equal to 3.64 kJ mol^{-1}, which can be used to estimate the enthalpies of vaporization of arsenic dialkyl derivatives.

The replacement of an ethyl group in $Sn(C_2H_5)_4$, having $\Delta H^0(T)$ = 46.6 ± 0.6 kJ mol^{-1} and $\Delta S^0(T)$ = 102.4 ± 1.7 J mol^{-1} K^{-1}, by a methoxy group in triethylmethoxystannane reduces the enthalpy of vaporization to 45.45 ± 0.36 kJ mol^{-1}, i.e., it only slightly affects the intermolecular interaction energy.

CONCLUSION

The obtained experimental data on the vapor pressure and thermodynamic properties can be used in the development of procedures for exhaustive purification of substances and in the gas-phase synthesis of semiconductor materials by decomposition of alkyl compounds.

Microdosing on Evaporation from the Surface of a Porous Solid

S. I. Krichmar and Yu. N. Bardachev

Kherson State Technical University, Kherson, Ukraine

Received May 4, 2000

Abstract—The processes are examined that occur when dilute gas mixtures are prepared by the evaporation of a solution of impurities in an indifferent liquid solvent from the surface of a porous solid. Relationships between the concentrations of the impurities in the liquid and gas phases are given.

A procedure for dosing small amounts of volatile impurities in gases was suggested in [1]. This procedure enhances the capabilities of the known technique [2, 3] by increasing the surface area for the evaporation on a liquid–vapor interface owing to the use of a capillary-porous solid. The technique can be used on a larger scale if highly volatile components are dissolved in an indifferent liquid solvent with a vapor pressure lower than the vapor pressure of the impurities under study [4].

The aim of this work was to describe in more detail the possibilities of the suggested dosing procedure. We emphasize that this procedure can be used for the preparation of gas mixtures of pollutants with a given composition not only for calibration of gas sensors, but also in modern technologies of obtaining pure gases.

The operation of the leak device is the following. A solution of impurities in a liquid solvent is placed in narrow glass tube *2* with a widening in its top end filled with capillary-porous solid *3* (Fig. 1). Its bottom contacts the solution, and flat upper interface *4* is directed to the space through which a diluent gas is continuously flowing. The diameter of the glass tube is chosen in such a manner that the liquid does not flow out via its open lower end. The position of the liquid meniscus in the lower part of the tube is detected at regular time intervals with a cathetometer. In a conventional case the limitations in the choice of the tube diameter prevent measuring evaporation rates of poorly volatile liquids. The evaporation rate is proportional to the evaporation surface, all other factors being equal. The surface of a finely porous solid impregnated with a liquid is the most suitable for technical use of this property. A fine liquid film distributed over this solid evaporates evenly with a rate considerably higher than the rate of the liquid transport along the pores. Therefore, the process is almost independent of the equilibrium vapor pressures of the components.

In a steady-state mode the evaporation from the surface of a porous solid and from the meniscus in the tube results in changes in the position of the liquid level. The rate of its migration along the measuring tube (Fig. 1) is dl/dt, where l is the capillary length and t is the time. If the capillary cross section is S and the liquid density is ρ, the weight of substance evaporating in unit time is $S\rho(\Delta l/\Delta t)$. When the space velocity of the gaseous diluent is ϑ_p, the relative weight concentration of the ith component in the liquid containing several components will correspond

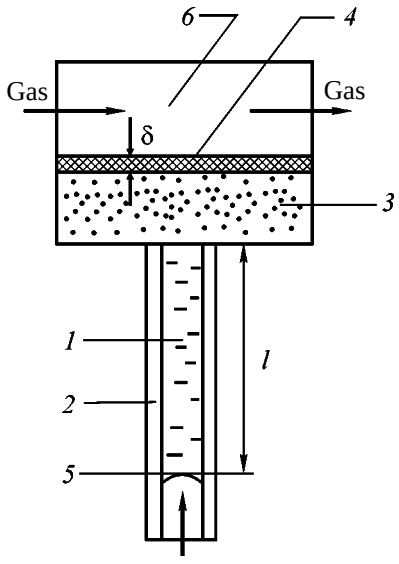

Fig. 1. Scheme of the leaking device: (*1*) liquid solution, (*2*) transparent tube, (*3*) porous solid, (*4*) evaporation surface (liquid–gas interface), (*5*) meniscus, and (*6*) gas space; (σ) effective diffusion layer and (l) capillary length (mm).

1070-4272/01/7401-0164$25.00

to the concentration X_i (g/cm^3) in the resulting gas:

$$X_i = x_i \frac{\rho S(\Delta l/\Delta t)}{\vartheta_p}. \quad (1)$$

With regard to the dependence of the volume of the vapor of the liquid on the absolute temperature T, the volume concentration of the ith component C_i (vol %) is calculated by the formula

$$C = 8.20 \times 10^3 \frac{S\rho T N_i(\Delta l/\Delta t)}{\vartheta_p \Sigma M_i N_i}, \quad (2)$$

where M_i and N_i are the molecular weights and mole fractions of the components of an evaporated liquid.

This relationship is similar to the relationship for the conventional installation [1].

At a constant cross section of a porous solid under steady-state conditions the flows of impurities J and of liquid solvent J_L are constant throughout the length (the averaged cross section of the pores is constant); hence,

$$J = Scu, \; J_L = S c_L u_L, \quad (3)$$

where u and u_L are linear migration rates of the components.

The starting nonstationary transfer process includes several stages, the diffusion being the limiting stage in the liquid layer adjacent to the interface. In the steady-state regime (operation) the transfer of an impurity component is described by the equation of linear convection–diffusion transfer in pores

$$D\frac{\partial^2 c}{\partial y^2} + u\frac{\partial c}{\partial y} = 0, \quad (4)$$

where D is the coefficient of impurity diffusion, C is its concentration, and y is a coordinate.

The limiting conditions are:

$$C_0 = C, \; y_0 = 0 \text{ at the interface,}$$
$$C = C^0, \; y = \infty \text{ far from the interface.} \quad (5)$$

The integration of Eq. (4) with regard to (5) gives

$$\frac{c - c_0}{c_i^0 - c_0} = 1 - e^{-uy/D}. \quad (6)$$

The diffusion density of the flow at the interface $y = 0$

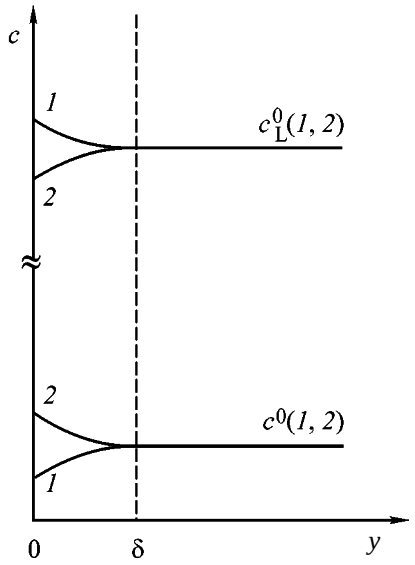

Fig. 2. Scheme of concentration distribution in the porous solid: (*1*) the impurity is more volatile than the diluent and (*2*) the impurity is less volatile; c^0 and c_L^0 are the same for both cases.

$$j_0 = D(\partial c/\partial y)_{y=0} = (c^0 - c_0)u = D\frac{c^0 - c_0}{\delta}, \quad (7)$$

where the effective diffusion layer is

$$\delta = D/u. \quad (8)$$

The time of attaining the steady-state regime is described in detail in [5]. We estimate the critical time of its setting τ as

$$\tau \approx \delta^2/D = D/u^2. \quad (9)$$

The ratio between the flows J/J_L and the section S along the whole length of the porous solid are constant, hence

$$J/J_L = \frac{uc - D(\partial c/\partial y)_{y=0}}{uc_L - D(\partial c/\partial y)_{y=0}} = c^0/c_L^0. \quad (10)$$

It is impossible to find from Eqs. (7) and (10) the concentrations in any point and, in particular, at the interface where $y = 0$. They can be found using the Raoult's equations by comparing the flows in the gas phase. Let the pressures of an impurity and solvent vapor in the gas phase be p and p_L, and p_0 and p_L^0 be their vapor pressures above the pure components,

respectively, at a given temperature. Then in the gas

$$J_L/J = \frac{p_L^0(1 - N)}{p^0 N} = \frac{p_L^0(1/N - 1)}{p^0}. \quad (11)$$

Therefore,

$$N = (J_L p^0/J p_L^0 + 1)^{-1}, \quad (12)$$

or, with regard to the fact that the amount of impurities is noticeably smaller than that of the liquid solvent,

$$c_0 \approx \frac{p_L(J_L p^0/J p_L^0 + 1)}{M_L} = \frac{p_L(c_L^0/c^0 p_L^0 + 1)}{M_L}. \quad (13)$$

If $(c_L^0 p^0/c_0 p_L^0) \to 0$ on condition that $p^0/p_L^0 < c_L^0/c^0$ (vapor pressure of the impurity is very small), $c^0 \approx p_L/M_L$, which corresponds to the concentration of the pure solvent. If $c_L^0 p^0/c^0 p_L^0 \gg 1$, $c_0 \approx c^0 p_L^0/p^0$, i.e., the concentration of the impurity at the interface is lower than the starting concentration. The both situations are illustrated in Fig. 2.

The data of experimental tests of the procedure (see table) are taken from [5]. The drawing of the dosing unit is shown in Fig. 3.

As seen from the given experimental data, the dosing unit is able to operate with impurities whose partial pressure can be both lower and higher than the pressure of the diluent.

BRIEF COMMUNICATIONS

Hydrolysis of Nitrosylsulfuric Acid

P. P. Kim, G. V. Pastukhova, and A. A. Peretrutov

Dzerzhinsk Branch, Nizhni Novgorod State Technical University, Dzerzhinsk, Russia

Received May 21, 1998; in final form, March 1999

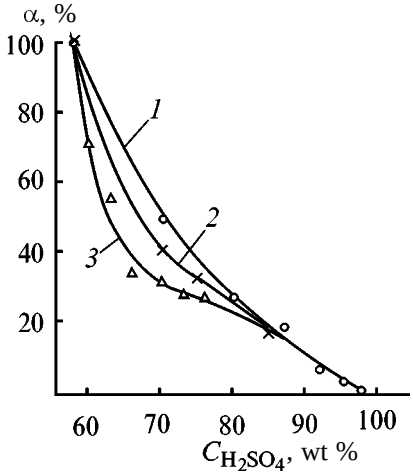
Abstract—The statics and kinetics of hydrolysis of nitrosylsulfuric acid were studied at the initial sulfuric acid concentrations in the range 60–76 wt % and temperatures in the range 20–100°C or 30–130°C. The results were compared with the published data.

The reactivity of nitrosylsulfuric acid (NSA) depends on the degree of its hydrolysis and is determined by the concentration of nitrogen compounds formed in the solution in the free state in the course of hydrolysis. The NSA hydrolysis is an important industrial process, which has been little studied so far because of experimental difficultes. Data for diluted (60–70%) sulfuric acid are lacking.

In this work, the statics of NSA hydrolysis was studied with an SF-46 spectrophotometer. A cell with the nitrose sample and a reference cell were maintained at constant temperature using a special attachment in the form of a 1-mm-thick brass plate containing pockets for two cells and light-transmitting holes. Silicone oil delivered from a UH-8 thermostat through a heat-resistant pipe was circulated within the attachment. It was found that in the concentration range 0–5% N_2O_3 and 57.5–100% H_2SO_4 the Lambert–Beer law is fulfilled. The degree of NSA hydrolysis was calculated from the residual NSA concentration of the nitrose sample, as determined from comparison of its optical density with that of the nitrose sample containing 57.7 wt % of the initial sulfuric acid (assuming 100% hydrolysis of NSA).

The degrees of NSA hydrolysis are given in Table 1, and the dependences of the hydrolysis degree α on the initial sulfuric acid concentration $C_{H_2SO_4}$ at about 20°C are shown in the figure. The Shperling's data [1] for nitroses with about 0.2% N_2O_3 (curve *1*), the data of [2] for nitroses with 0.19% N_2O_3 (curve *2*), and experimental data obtained in this study (curve *3*) were compared. As seen, for the H_2SO_4 concentration exceeding 80% the data of [1, 2] are similar, whereas at concentrations less than 80% the hydrolysis degree is lower than that found in [1]. Our results are underestimated compared to [2]. The degree of NSA hydrolysis decreases considerably as the sulfuric acid concentration grows from 57.5 to 75 wt % (concave curve), passes through an inflection point at 73 wt % H_2SO_4, and then decreases more slowly (convex curve). Such behavior is observed over the entire studied range of N_2O_3 concentrations. The increase in the N_2O_3 concentration facilitates the NSA hydrolysis. The lower the sulfuric acid concentration, the wider the N_2O_3 concentration range corresponding to a drastic growth of the hydrolysis degree. For the H_2SO_4 concentrations up to 66 wt %, this range is 0–0.55%. At a further increase in the N_2O_3 concentration, the degree of NSA hydrolysis increases to a considerably lesser extent. At N_2O_3 concentrations above 1.2–1.6% the hydrolysis degree increases virtually linearly for temperatures within 20–100°C, depending on the decrease in the sulfuric acid concentration.

The experimental data obtained confirm once again that the hot regime is efficient for operation of sulfuric



Degree α of NSA hydrolysis vs. the initial sulfuric acid concentration $C_{H_2SO_4}$. Temperature 20°C; N_2O_3 concentration 0.2%. (*1–3*) For comments, see text.

acid system and NSA denitration. The high efficiency of utilization of high-nitrose solution was also confirmed. In the process, the nitrose activity increases not only owing to the increase in the N_2O_3 concentration, but also owing to the fact that the equilibrium in the nitrose is shifted toward the products of NSA hydrolysis.

The kinetics of NSA hydrolysis was studied on an Impul's KL-2 conductometer. The nitrose studied was charged into two cells of the conductometer and cooled to 0°C. Then, the cells were rapidly transported into a thermostat preheated to a specified temperature. After that, the time and the conductometer readings were recorded. In the course of the NSA hydrolysis the nitrose conductivity increased and then remained constant after the lapse of some time. This time was assumed as the time of complete hydrolysis. The second cell served for measuring temperature.

Table 2. Rate constants *k* of NSA hydrolysis

T, °C	*k*, l mol^{-1} min^{-1}, at indicated $HNSO_5$ concentration, wt %		
	4 (1.2% N_2O_3)	10 (3.0% N_2O_3)	15.2 (4.5% N_2O_3)
30	9.61×10^{-4}	5.52×10^{-3}	0.095
50	3.36×10^{-3}	1.43×10^{-2}	0.184
60	4.56×10^{-3}	1.69×10^{-2}	0.238
80	7.68×10^{-3}	3.24×10^{-2}	0.314
100	1.18×10^{-2}	5.90×10^{-2}	0.455
120	1.66×10^{-2}	7.58×10^{-2}	0.520
130	2.19×10^{-2}	9.72×10^{-2}	0.780

The reaction of NSA hydrolysis is of the overall second order and of the first order with respect to each component. The rate constant was calculated by the formula [3]

$$k = \frac{1}{\tau(C_{10} - C_{20})} \ln \frac{C_{20}(C_{10} - X_1)}{C_{10}(C_{20} - X_2)},$$

where C_{10} and C_{20} are the initial concentrations of $HNSO_5$ and H_2O (M), respectively, and X_1 and X_2, the concentrations of unchanged components (M).

The experimental data treated in the τ–$\ln[C_{20}(C_{10} - X_1)/C_{10}(C_{20} - X_2)]$ coordinates fall on a straight line, which confirms the value of 2 for the overall reaction order.

Table 2 shows how the kinetic parameters of NSA hydrolysis at the initial sulfuric acid concentration of 72.3 wt % change with temperature. As seen, the rate constant of the hydrolysis increases with N_2O_3 concentration and temperature. Depending on temperature, the increase in the N_2O_3 concentration from 1.2 to 3.0 and 4.5% increases the rate constant by a factor of 5.7–4.4 and 99–36, and the increase from 3.0 to 4.5%, by a factor of 17–8. At the temperature increased from 30 to 50 and 130°C at the N_2O_3 concentration of 1.2, 3.0, and 4.5% the rate constant of NSA hydrolysis increases by a factor of 3.5 and 22.8, 2.6 and 17.6, and 1.9 and 8.2, respectively, and the temperature coefficient increases from 0.57 to 1.75.

The obtained data on the statics and kinetics of NSA hydrolysis will be useful for intensifying the nitrose process.

CONCLUSIONS

(1) The degree of hydrolysis increases with increasing temperature and N_2O_3 concentration in solution and with decreasing sulfuric acid concentration.

(2) The hydrolysis rate is comparable with the rates of the other stages of the nitrose process.

Synthesis of Hexafluoroacetone by Catalytic Oxidation of Hexafluoropropylene

S. M. Igumnov, G. I. Lekontseva, A. A. Shipigusev, O. D. Gomzyakova, and V. A. Soshin

Perm Branch, Prikladnaya Khimiya Russian Scientific Center, Perm, Russia

Received May 17, 1999; in final form, August 2000

Abstract—Oxidation of hexafluoropropylene with molecular oxygen in a fixed bed of a catalyst (activated carbon promoted with alkali metal fluorides) was studied.

Catalytic oxidation of hexafluoropropylene (HFP) is a most promising route to hexafluoroacetone (HFA). In known procedures oxidation is carried out using as catalysts oxides of tin, iron, and indium [1] or fluorinated aluminum oxide [2], which in some cases is activated with water (0.001–0.003 mol per mole HFP [3]). Catalytic oxidation of HFP in the presence of palladium, platinum, rhodium, ruthenium, and iridium deposited on activated carbon was studied in [4].

In this work we found that the oxidation of HFP to HFA proceeds on a catalyst (activated carbon promoted with alkali metal fluorides NaF, KF, CsF, or RbF) at 50–300°C and the HFP : O_2 molar ratio of 1 : (0.1–10.0):

$$CF_3CF{=}CF_2 + 1/2\,O_2 \xrightarrow{C_{act}/MF,\ \Delta} (CF_3)_2C{=}O. \quad (1)$$

The reaction probably proceeds with intermediate formation of a carbanion generated by reaction with fluoride ion on the catalyst surface:

$$CF_3CF{=}CF_2 + F^- \rightarrow (CF_3)_2\bar{C}F + O_2 \rightarrow (CF_3)_2C{=}O + F^-.$$

Appearance of COF_2 in the reaction products is due to more profound oxidation:

$$CF_3CF{=}CF_2 + 1.5O_2 \rightarrow 3COF_2. \quad (2)$$

Formation of 1,1,1,2,3,3,3-heptafluoropropane is probably due to partial hydrolysis of COF_2 with residual moisture on the catalyst and further addition of hydrogen fluoride to HFP:

$$COF_2 + H_2O \rightarrow CO_2 + 2HF, \quad (3)$$

$$CF_3CF{=}CF_2 + HF \rightarrow CF_3CFHCF_3. \quad (4)$$

The required catalysts were prepared using a BAU-A brand crushed activated carbon with a particle size of 1.5–2.0 mm. In the tests the content of alkali metal fluorides was varied within 5–60 wt %; in this range the yield of HFA was almost constant. It was found that at the content of alkali metal fluoride smaller than 5 wt % the yield of HFA decreases, whereas the increase to more than 60 wt % is practically unfeasible. Oxidation at temperatures higher than 300°C and the HFP : O_2 molar ratio greater than 1 : 10 causes more profound oxidation of HFP yielding predominantly COF_2.

The catalyst activity remains stable for 1500 h. During this period the particle size also remains constant (1.5–2.0 mm). At longer operation the catalysts in question partially lose their activity because of changes in the grain-size distribution. The conditions of catalytic oxidation and experimental results are listed in the table.

EXPERIMENTAL

A tubular reactor (0.3 dm^3) equipped with an electrical heater, a thermocouple, and pipes to supply the initial components and O_2 and remove the oxidation products was filled with a catalyst (0.25 dm^3). The catalyst was activated carbon with 1.0–1.5 mm particle size, promoted with alkali metal fluorides. The catalyst was preliminarily activated by heating in a flow of dry nitrogen at 180–200°C for 4 h. Then the catalyst was cooled to the required temperature and HFP and O_2 were supplied at a rate of 1.0–3.0 l h^{-1} in the required molar ratio.

The gas mixture from the reactor was condensed in a trap cooled to –90°C and analyzed by gas–liquid

chromatography. The individual components were recovered by low-temperature fractional distillation.

The components were identified by IR and NMR spectroscopy. The yield of HFA was 55–62%, and conversion, 90%.

CONCLUSIONS

(1) Procedure was developed for preparing hexafluoroacetone by catalytic oxidation of hexafluoropropylene using activated carbon promoted with alkali metal fluorides.

(2) The main reaction is accompanied by side oxidation of hexafluoropropylene to CO_2 and 1,1,1,2,3,-3,3-heptafluoropropane.

Abstract—Differential high-temperature mass spectrometry was applied to study evaporation in sulfur-lean melts of the systems Cu–S and Cu–Ni–S at 1500 K. Data on partial pressures and activities of melt components were obtained.

Presently, a new autogenous technology for processing of a nickel-containing copper concentrate obtained in converter matte separation is being developed and put into practice. This technology has to produce copper with the minimum possible (for this process) impurity content.[1] The behavior of basic impurities (nickel and sulfur) in this process is governed by the thermodynamic properties of the Cu–Ni–S system at Ni content in the range 0.5–50% and up to 21.0% sulfur.

Here we report the results obtained in studying evaporation processes in sulfur-lean melts of the system Cu–Ni–S at a temperature of 1500 K by differential high-temperature mass spectrometry.

The investigation was performed on an MS-1301 mass spectrometer which, including apparatus units for measurements by the Knudsen effusion method and mass-spectrometric analysis of the vapor phase, allows experimental determination of partial vapor pressures of melt components. In this work, the evaporation occurred from a double effusion cell made of molybdenum and calibrated by the calcium fluoride vapor pressure [1].

The set of studies of evaporation from Cu–Ni–S melts also included investigations of evaporation from sulfur-lean Cu–S melts and measurements of partial vapor component pressures over the Cu_2S melt. The latter was necessary since Cu_2S was used as pressure standard in studying Cu–S and Cu–Ni–S melts.

The system Cu–S has more than once been the object of study by various methods in varied temperature ranges [2–10].

A previously described technique [10, 11] was applied to measure the partial pressures of copper and sulfur over Cu_2S (pure grade) melt in the temperature range 1359–1500 K. As standard substance was used copper of M00k brand, with partial vapor pressure at 1500 K P^0_{Cu} = 0.364 Pa. The copper and sulfur vapor pressures over Cu_2S melt were measured in [10]. It was found that at 1500 K the vapor over a Cu_2S melt contains only atomic copper and diatomic sulfur molecules, whose partial pressures are practically constant (0.043 ± 0.02 and 0.15 ± 0.02 Pa, respectively), being in sufficiently good agreement with published data [12–14].

The temperature dependences of the partial pressures (Pa) of copper and sulfur in the temperature range 1390–1550 K are described by

$$\log p_{Cu} = 12.40 \pm 0.05 - (19\,300 \pm 730)/T, \qquad (1)$$

Table 1. Partials pressures of copper and sulfur over Cu–S melt at 1500 K

$$\log p_{S_2} = 10.71 \pm 0.12 - (17\,300 \pm 530)/T. \quad (2)$$

A Cu_2S preparation was used as pressure standard in measuring the partial pressures of copper and sulfur over a copper melt containing in the initial state 2.2 at. % sulfur at 1500 K. The partial pressures measured in the course of evaporation of this sample are presented in Table 1.

Table 1 shows that in the course of evaporation the partial pressure of copper is virtually constant and equal to the partial pressure over Cu_2S, and the partial pressure of sulfur falls from 0.047 to 0.007 Pa with decreasing content of sulfur in the melt.

The dependence of the partial pressure of sulfur on the content of sulfur in the melt at 1500 K is shown in the figure.

Published data on the partial pressure of sulfur in the given range of compositions and temperatures are diverse. For example, a value of 0.001 Pa was presented in [14]. Schuhmann and Moles obtained for compositions in this range at a temperature of 1523 K a partial pressure of sulfur equal to 0.025 Pa [15].

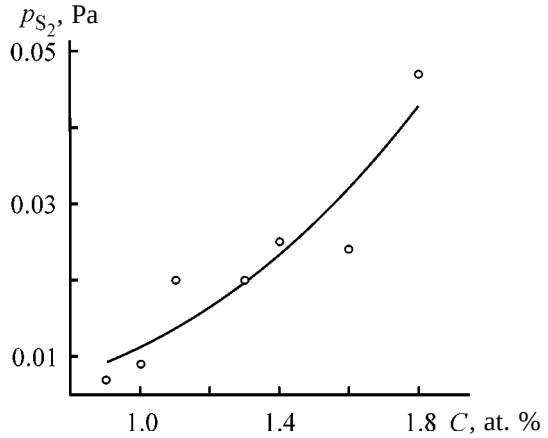
High-temperature mass spectrometry can be used as a variety of the classical "vapor pressure method" in determining the thermodynamic activity. The basic equation of the method $a_i = p_i/p_i^0$ gives directly the a_i value as a ratio of ion currents. Since $p_i = bI_iT$ and $p_i^0 = bI_i^0T$, then

$$a_i = I_i/I_i^0, \quad (3)$$

where p_i and p_i^0 are the partial pressures of ith component, measured over a composition under study and pure component, and I_i and I_i^0 are the respective ion currents.

If pure copper (p_{Cu}^0 = 0.364 Pa) at the same temperature is taken as the standard state of copper, then the activity of copper in molten Cu_2S and Cu–S melt containing ca. 2 at. % S is approximately unity. If the state of sulfur in the Cu_2S melt is taken as standard, then the activity of sulfur in a Cu–S melt containing ca. 2 at. % S is 0.31 and falls to 0.05 with its content in the melt decreasing to 0.09 at. % S. It is noteworthy that, in going from melts containing ca. 30 at. % S to melts with ~2 at. % S, the activity of sulfur decreases from 1 to 0.3 and the activity coefficient of sulfur increases from 0.03 to 0.15.

The evaporation from Cu–Ni–S melts was studied on preparations containing (at. %) copper 92.7 and 90.6, nickel 4.9 and 4.8, and sulfur 2.4 and 4.6. The working temperature was 1500 K. The experimental results are presented in Table 2.



Partial pressure of sulfur p_{S_2} vs. content C of sulfur in the Cu–S melt.

Table 2 shows that the partial pressure of copper over melts is virtually constant, as also is the content of copper in the melt. The partial pressure of nickel over the melt at this temperature is $(0.4-0.5) \times 10^{-3}$ Pa, which is close to the detection limit of the

88.6	11.1	0.3	0.330	~0.5	0.025

measuring instrument. The partial pressure of sulfur depends on the content of sulfur in the melt, with this dependence expressed by the equation

$$p_{S_2} = -0.019[S]^2 + 0.12[S] - 0.0046. \quad (4)$$

The activity of copper in Cu–Ni–S melts is close to unity with the state of copper in Cu_2S ($p_{Cu\ in\ Cu_2S}$ = 0.34 Pa) as the standard state and somewhat less than unity if its state in metallic copper ($p_{Cu\ in\ Cu}$ = 0.364 Pa) is taken as the standard.

If the state of sulfur in Cu_2S (p_{S_2} = 0.15 Pa) is taken to be its standard state, then the activity of sulfur in the Cu–Ni–S melt decreases from about 1 to 0.1–0.2 with the content of sulfur in the melt decreasing from 4.5 to 0.3 at. %. In this case, the content of copper in the melt remains virtually constant, and that of nickel increases from 5.0 to 11.1 at. %.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

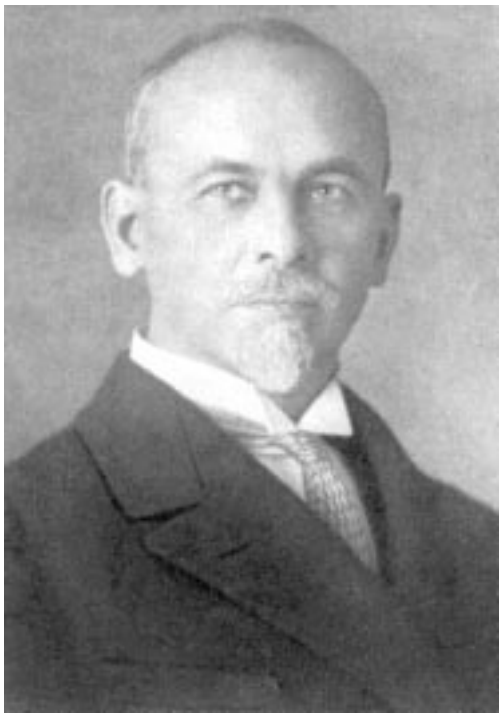
First Studies in the Field of Fixation of Atmospheric Nitrogen in Russia (Experiments of A.I. Gorbov and V.F. Mitkevich in 1906–1912)

The only sources of fixed nitrogen in the late XIX–early XX century were natural Chile saltpeter (sodium nitrate) and ammonia obtained in very limited amounts as a by-product of coal carbonization. Chile, a relatively small state, supplied saltpeter to, in fact, all the world's countries. No major deposits of saltpeter were known in any other region.

Chile saltpeter was used to manufacture nitric acid and served as fertilizer. A steady production of nitric acid in Russia was of interest for the Russian military. The agriculture needed fertilizers. The agrarian reforms started in 1906 gave rise to higher demand for fertilizers. For example, during the period from 1906 till 1912, the overall consumption of mineral fertilizers in Russia increased from 7.6 to 35.3 million poods (1 pood = 16 kg). The use of nitric fertilizers (Chile saltpeter) increased during the same period from 1.0 to 3.1 million poods, i.e., more than threefold [1]. The Russian–Japanese war demonstrated that, without domestic sources of fixed nitrogen, it is rather difficult to supply a sufficient amount of nitric acid to the industry of explosives.

It should be noted that, in addition to the gross expenditure for import of saltpeter, there were other factors stimulating the work aimed at obtaining nitric acid directly from atmospheric nitrogen. Russia received the whole amount of Chile saltpeter through its western boundary and Baltic ports. In case of military action in this region, a complete termination of saltpeter supply would be expected, which could deprive the armaments industry of the most important source of raw materials.

In December 1905, an interdepartmental Commission on the Problem of Obtaining Nitric Acid by Oxidation of Atmospheric Nitrogen was created at the Chief Engineering Department of the Ministry of Defense. The commission included staff members of the Artillery department: professors of the Mikhailovskaya Artillery Academy lieutenant-general G.A. Zabudskii (Chairman) and V.N. Ipat'ev, and colonels A.V. Sapozhnikov and N.M. Vittorf; Naval Department: P.P. Rubtsov and professor S.P. Vukolov,



Vladimir Fedorovich Mitkevich

a known specialist in explosives; Ministry of Trade and Industry: professors N.S. Kurnakov and I.F. Shreder, prominent physical chemists, and professor V.F. Mitkevich, a specialist in electrical engineering; Chief Engineering Department: professor A.I. Gorbov, a chemist and initiator of commission's creation and its secretary [2, 3]. In its first meeting on February 14, 1906, the commission stated that "the Empire has no major deposits of saltpeter and, therefore, only manufacture of nitric acid from air is to be considered." Gorbov and Mitkevich were assigned to perform preliminary experiments in this direction.

Aleksandr Ivanovich Gorbov (1859–1939) graduated from the Natural Department of the Physicomathematical Faculty at St. Petersburg University in 1883. He was a pupil of A.M. Butlerov (1828–1886), who created the theory of structure of organic compounds, and a close friend of D.I. Mendeleev (1834–

1070-4272/01/7401-0175$25.00

1907). In 1883–1885, he worked at the University, and in 1885–1894, at the chemical laboratory of the St. Petersburg Academy of Sciences. Beginning in 1894, he taught at the Military Engineering Academy. Gorbov was a well-educated chemist and an active member of the Russian Physicochemical Society. His main scientific investigations were concerned with various problems of military technology. He also was one of the best-known popularizers of chemical science in the country [4–6]. Since 1926 and till the end of his life he had been Editor-in-Chief of *Zhurnal Prikladnoi Khimii* (Soviet Journal of Applied Chemistry) [7].

Vladimir Fedorovich Mitkevich (1872–1951), having graduated from the Physicomathematical Faculty of St. Petersburg University in 1895, taught electrical engineering and physics at higher school institutions in St. Petersburg and at the Electromechanical Department of the Polytechnic Institute beginning in 1902. He laid the groundwork of the course Theoretical Foundations of Electrical Engineering. In 1906, having backed his adjunct's dissertation, Mitkevich was elected a professor. During many years he held the chair of the fundamentals of electrical engineering, in 1927, he became a corresponding member, and in 1929, a full member of the Academy of Sciences of the USSR. Of exceptional importance are Mitkevich's studies concerned with the nature of electric arc, summarized in the monograph *O vol'tovoi duge* (On the Electric Arc). In 1907, he was awarded Popov Prize for these classical investigations [8–12].

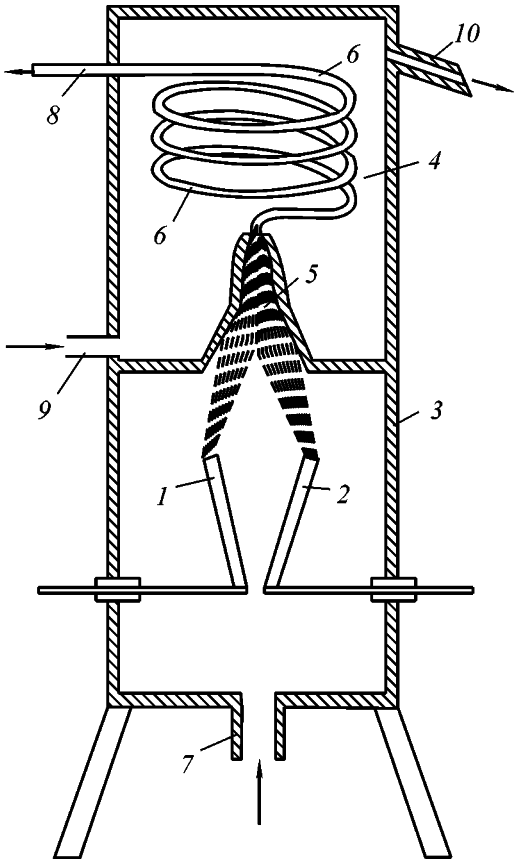
At the end of the XIX century, William Crookes, the known English physicist and chemist, demonstrated experimentally that strong electric discharge in air may lead to oxidation of nitrogen to give nitric and nitrous acids. Further experiments revealed that 43.5 g of nitric acid per 1 kW h can be obtained in the oxidation of atmospheric nitrogen [2, 3]. Later, a yield of 60–75 g of HNO_3 per 1 kW h was achieved. In 1906, the first commercial installation for nitric acid production was constructed in Norway, a country rich in low-cost hydroelectric power. It is this method that Gorbov and Mitkevich became interested in.

Gorbov and Mitkevich studied the conditions for efficient production of nitrogen oxides and, in the end, nitric acid during several years. However, already in May 1906 the authors presented an original design of an arc furnace for fixing atmospheric nitrogen. The furnace design was patented in Russia, Norway, and Germany. Experiments were first done at the Mining Institute; later, M.A. Shatelen (1866–1957), the dean of the electromechanical department of the Polytechnic Institute, proposed to construct a pilot installation at the St. Petersburg Polytechnic Institute. Based on a vast experimental evidence, the authors established a clear dependence "...between the percentage of nitrogen oxide formed in burning of air under the action of an electric arc, volume of air introduced into the furnace during 1 h per kilowatt of electric arc power, and grams of nitric acid into which the nitrogen oxides can be converted..." In the authors' opinion, the equation had general character, being not related to any furnace design feature [13, 14].

Gorbov and Mitkevich established the influence of various factors on the efficiency of nitrogen fixing. In particular, it was found that the specific yield of the product per unit electric power expenditure decreases with increasing total power of the furnace. The possible reason was that zones with lower temperature appear in the furnaces, with reverse reactions occurring therein. The authors noted [14] that "...it is impossible to apply arbitrarily high power to a given furnace, and a power exists for this furnace of the maximum energy efficiency." Thus, it is necessary to find its own optimal process regimes for each furnace design. However, "it is important to have furnaces with as high power as possible, this making much simpler the monitoring of their correct operation" [14].

Eight furnaces were constructed for experiments, differing in the arrangement of electrodes, method of air supply, and design of condenser and combustion chamber. Two furnaces were single-phase, and the remaining six, three-phase. The power of seven furnaces was varied within 10–30 kW, and the eighth, three-phase furnace had power ranging from 60 to 220 kW. Special apparatus developed by the authors allowed monitoring of the process and variation of the experimental conditions.

Large-scale experiments were conducted under plant conditions at Sestroretsk, near St. Petersburg. The NO content of gases was on the average 2.44%, and the yield of nitric acid, 70.5 g per 1 kW h. In 1916, Gorbov and Mitkevich designed a 3000-kW furnace, and a plant started to be constructed at Kondopoga, on the northwestern bank of Lake Onega in Karelia. The site was chosen with account of the hydropower of River Suna flowing into Lake Onega. In 1918, the construction of the plant was suspended.



Gorbov and Mitkevich's furnace: (*1, 2*) electrodes creating the electric arc, (*3*) cylindrical furnace, (*4*) space for cooling water, (*5*) electric arc, (*6*) cooling coil for nitrogen oxides, (*7*) air inlet, (*8*) outlet for cooled nitrogen oxides, (*9*) pipe for supply of coil-cooling water, and (*10*) water outlet pipe.

Received July 26, 2000

Abstract—The formation of nickel–tantalum compounds in halide fluorotantalate melts was studied at 750°C. The mechanism of electroless tantalum plating onto nickel is considered and it is suggested that disproportionation underlies the spontaneous transfer.

In electrolytic recovery of tantalum in a nickel crucible-cathode, the nickel impurity completely passes into the cathode deposit to form acid-resistant compounds [1]. Previously [2, 3], the behavior of nickel has been studied in salt mixtures containing 2.5 mol% K_2TaF_7, commonly used in electrolysis, and it has been found that electroless deposition of tantalum ions to form mainly the compound Ni_3Ta occurs at its surface. In view of the use of nickel in apparatus for metal-thermal production of high-capacity tantalum powders [4], it is of interest to study the interaction of nickel with a NaCl–K_2TaF_7 (14 mol %) melt having practical importance [5].

The aim of this study was to elucidate the mechanism of electroless tantalum plating onto nickel from halide melts containing K_2TaF_7, analyze the composition of nickel–tantalum intermetallic compounds in relation to their formation conditions, and obtain protective coatings on the nickel crucible walls directly in the process of obtaining sodium-reduced tantalum powders.

EXPERIMENTAL

The investigation was performed in a hermetically sealed steel retort in helium at 750°C. As a container for the melt served nickel or glassy carbon (SU 2000) crucible. Sodium chloride of special-purity grade was calcined in air at 600°C and melted in an atmosphere of pure helium. Potassium heptafluorotantalate was obtained from HF solutions and dehydrated by heating in a vacuum at 400°C. Working samples were cut-out from rolled nickel of 99.99% purity, treated with a mixture of HNO_3, H_2SO_4, and CH_3COOH acids, and washed with water and alcohol. The potential of the nickel plate was measured relative to a polished tantalum rod. Fusion cakes of salt mixtures were analyzed on an IK 20 IR spectrophotometer. X-ray patterns of the samples were taken on a DRON-2 diffractometer with graphite monochromator (Cu_{K_α} radiation, scan rate 2 deg min^{-1}, analysis depth ca. 1 μm). The highest peak in Figs. 1 and 2 is taken to be 100 on the relative intensity scale. Tantalum was determined in melts by X-ray fluorescence analysis with a SpaRK X-ray spectrometer (Ag anode, threshold sensitivity C_{th} = 0.001%, relative error 5–10%).

According to experimental data, the corrosion of nickel in chloride–fluorotantalate mixtures at 750°C was 2–5 g m^{-2} h^{-1}, depending on the sample exposure time, which contradicts the conclusions made in [6] about high corrosion resistance of the metal in a chloride melt with 4 mol % K_2TaF_7. The corrosion of nickel terminates when tantalum metal is introduced into a melt in the form of plates or a powder. Five intermetallic compounds exist in the Ni–Ta system: Ni_8Ta, Ni_3Ta, Ni_2Ta, NiTa, and $NiTa_2$ [7]. The compound Ni_3Ta, possessing the minimum Gibbs energy and having the highest growth rate constant as compared with the other phases, is the most stable [8]. It is this compound that was unambiguously identified on 350–400-μm-thick rolled nickel in melts containing 2.5 mol % K_2TaF_7 in those cases when two plates, of tantalum and nickel, were placed in the melt si-

multaneously. The compound Ni_8Ta could not be detected in any of the numerous experiments. The pair—tantalum plate–50-μm-thick nickel foil—was used to obtain, at experiment duration of 4 h, coatings in which X-ray phase analysis (XPA) revealed, in addition to Ni_3Ta, two tantalum-richer intermetallic compounds, Ni_2Ta and $NiTa_2$ (Fig. 1, X-ray pattern no. *2*). Five hours after the beginning of an experiment, tantalum starts to be co-deposited together with the intermetallic compounds (Fig. 1, X-ray diffraction pattern no. *3*).

To obtain high-purity tantalum powders by the metal-thermal method, the time of formation of a protective coating on the nickel reactor walls should be the minimum possible. The metal loss from rolled tantalum about 500 μm thick at 750°C in a salt mixture NaCl–K_2TaF_7 (14 mol %) is approximately 380 g m^{-2} h^{-1} in the absence of nickel and becomes higher for the nickel–tantalum pair. Simultaneously, the concentration of tantalum in the melt grows. For example, introduction of a tantalum metal powder into the melt in amount of 5 or 10 wt % makes the tantalum concentration in the melt grow from 23.1 to, respectively, 24.1 or 25.4 wt % in 3 h. The rate of formation of surface diffusion alloys-coatings markedly increases since the introduction of a tantalum metal powder into the salt mixture immediately before an experiment rules out the possibility that the overall rate of electroless transfer of tantalum onto nickel is controlled by the first stage of the process—tantalum corrosion [9]. In NaCl–K_2TaF_7 (14 mol %) with 0.8 wt % dissolved tantalum powder, the mass of nickel samples increases already in the course of melting, and formation of intermetallic layers starts on their surface. During the time of experiments, including heating, melting, and keeping at 750°C for 15 min, protective layers are formed, composed, according to XPA, of a mixture of Ni_3Ta and tantalum-richer compound Ni_2Ta. This indicates that conditions more favorable for formation of protective coatings are created by the higher concentration of K_2TaF_7 in the melt and introduction of tantalum into the bath in the form of a metal powder. The maximum thickness of the obtained coatings was about 25 μm. On the whole, the process is controlled by the dynamic equilibrium

$$2Ni_3Ta + [Ta] \rightleftarrows 3Ni_2Ta, \quad \Delta G = -86.6 \text{ kJ g-at.}^{-1} \text{ Ta.} \quad (1)$$

However, no $NiTa_2$ compound or tantalum (foil thickness 50 μm) could be detected in dilute melts with 2.5 mol % K_2TaF_7 by XPA. The results of an analysis performed on an MS-46 Cameca X-ray microanalyzer of three samples with electroless coatings 18 to 23 μm thick demonstrate the same total content of tantalum in the range from 51.665 to 53.706 wt %, in agreement with XPA data. The phenomenon of electroless transfer is commonly associated with the presence in the melt of two charged species of a deposited metal [9]. In other words, disproportionation of tantalum ions underlies the spontaneous transfer of tantalum onto nickel.

Several studies of the mechanism of electrochemical reduction in the NaCl–KCl–K_2TaF_7 melt have been reported in the literature. Lantelme *et al.* [10] demonstrated that reduction of tantalum proceeds in a single reversible stage Ta(V) + 5e $\rightleftarrows$ Ta(0). The single-stage mechanism of tantalum discharge was confirmed by Kuznetsov [11] and Polyakova [12], but was identified as irreversible. The authors of [13, 14] allow for the presence of low-charge tantalum species in the molten mixtures and explain the formation of

carbides of high-melting metals by the disproportionation reaction.

The electrochemical behavior of tantalum was studied by linear and stationary voltammetry [10, 12] in chloride melts with low K_2TaF_7 concentration (0.04–0.25 mol %).

Chloride-fluorotantalate melts with high K_2TaF_7 content were chosen by the authors of the present study in view of the fact that salt melts with 2.5 and 14 mol % are of practical importance for obtaining tantalum powders by electrolysis and sodium-reduction. In addition, to make the formation of surface diffusion alloys-coatings faster, tantalum metal powder was added, directly in the course of the experiment, to the salt mixture before its being charged into the reactor, i.e., formation of low-charge compounds was promoted. When the content of tantalum powder introduced into the salt mixture prior to melting was raised to 5 wt % and more, XPA revealed the compound K_2TaCl_6 (Fig. 2), which points to the existence in the melt of two kinds of charged species in comparable amounts.

An IR spectral study demonstrated that the dissociation by the scheme

$$K_2TaF_7 \rightarrow KF + KTaF_6 \qquad (2)$$

becomes stronger with increasing content of tantalum metal in the chloride-fluorotantalate melt. The spectrum clearly shows a shift of the Ta–F absorption band from 535 (K_2TaF_7) to 545 cm^{-1} ($KTaF_6$), which is due to the fact that the Ta–F bond in the hexacoordinate complex becomes stronger because of the decreasing coordination number of tantalum ions (Fig. 3). This leads to the appearance of K^+ and F^- ions in the melt.

From the standpoint of the "autocomplex" model of the structure of molten alkali metal halides [15], the melting of an ionic crystal is accompanied by symmetry breakdown in the mutual arrangement of particles, resulting in that ion–dipole interaction is superimposed on the ion–ion interaction to give complexes. The role of a complexing agent in sodium chloride is played by the cation whose binding energy in the complex exceeds the cation energy in the second coordination sphere by 78 kJ mol^{-1}, i.e., complex ions $NaCl_4^{3-}$ are present in the starting chloride-fluorotantalate melt. The tendency of anions to form complexes becomes more pronounced with their increasing ionic moment and polarizability. The formal ionic moment ($1/r$, $Å^{-1}$) decreases in going from F^- to Cl^- (0.75–0.52), and the polarizability ($Å^3$) increases

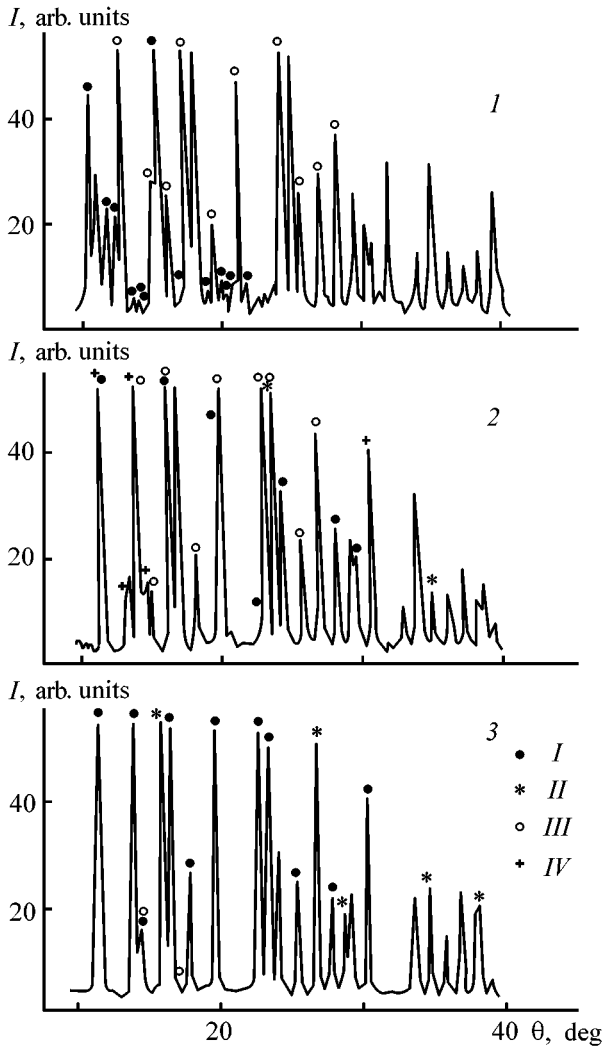

Fig. 2. X-ray pattern of a frozen melt. Background: NaCl–K_2TaF_7 (14 mol %) and tantalum metal (wt %): (*1*) 1.0, (*2*) 5.0, and (*3*) 10.0. (*I*) K_2TaF_7, (*II*) K_2TaCl_6, (*III*) K_3TaClF_7, and (*IV*) $KTaF_6$ (14 mol %).

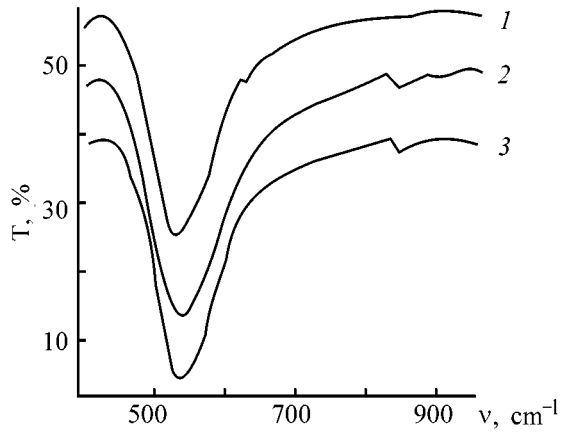

Fig. 3. IR spectra of potassium fluorotantalate in NaCl–K_2TaF_7 melt (14 mol %). (T) Transmission and (ν) wave number. Content of Ta metal powder (wt %): (*1*) 1.0, (*2*) 5.0, and (*3*) 10.0.

(0.64–2.96). As a result, the binding energy grows in passing from chloride to fluoride complexes because of a pronounced increase in their ionic momentum. Fluoride ions gradually replace chloride ions in autocomplexes, which leads to the appearance of free Cl^- ions in the melt. Fluoride complex compounds are formed in mixed chloride-fluoride melts at a relative excess of fluoride ions [16]. It is noteworthy that the amount of fluoride ions formed by reaction (2) in salt mixtures NaCl–K_2TaF_7 is negligible, compared with the content of chloride ions in the melt. Hence, the detection of just the chloride complex of a low-charge tantalum compound, K_2TaCl_6, by XPA in chloride-fluorotantalate melts with addition of up to 5 wt % tantalum metal and more is a well-established fact. The presence of potassium ions in the second coordination sphere of the tantalum(IV) complex K_2TaCl_6 cannot be accounted for in terms of the ion–ion interaction, since the ionic moment of K(I) is less than that of K(I). However, from the standpoint of the ion–dipole interaction, the potassium cation is more competitive since its polarizability exceeds that of the sodium cation [17]: $\alpha \times 10^{24}$ is 1.012 for K(I) at 800°C and 0.281 for Na(I). Probably, the ion–dipole interaction plays a key role in the case of formation of the K_2TaCl_6 compound.

The chemical reaction of tantalum(IV) compound formation can be written as follows

$$4K_2TaF_7 + Ta + 30NaCl + 2KF \rightarrow 5K_2TaCl_6 + 30NaF. \quad (3)$$

A calculation of the Gibbs energy of reaction (3) from reference data by the first Kireev method [18] demonstrated that the occurrence of this reaction is unlikely (ΔG_{298} = +853 kJ mol^{-1}). It becomes possible only in the simultaneous presence in the melt of the pair tantalum–nickel, when intermetallic compounds are formed on the nickel surface; ΔG = –118 kJ mol^{-1} for Ni_3Ta and –107.7 kJ mol^{-1} for Ni_2Ta [8]. This conclusion is confirmed by experiment: the compound K_2TaCl_6 (XPA data) and a shift of the equilibrium (2) (IR spectral data) are only observed on raising the content of tantalum metal powder to more than 5 wt % in the presence of a nickel plate. It is noteworthy that the reduction of tantalum pentachloride to tetrachloride $TaCl_4$ by tantalum foil has long been known [19].

The tantalum oxidation level was calculated using the corrosion current densities i (A cm^{-2}) obtained on shorting the external circuit of the electrodes with small resistances [3], by the formula [20]

$$i = \frac{K\bar{m}nF}{1000A} = Km\frac{n}{A}2.68 \times 10^{-3}, \quad (4)$$

where $K\bar{m}$ is the loss of Ta (g m^{-2} h^{-1}), n is the Ta oxidation level, F is the Faraday constant (A h g-equiv^{-1}), and A is the atomic weight of Ta.

At a current density of 0.003 A cm^{-2} and one-hour Ta loss of 50 g m^{-2} h^{-1} in a melt with 2.5 mol % K_2TaF_7, the lowest oxidation level of Ta was approximately +4.

The concentration gradient of potential-determining ions in various states of oxidation are the driving forces of the ion transfer occurring via diffusion at the electrodes and convection in the electrolyte bulk. Ions of the reduced form diffuse (j_{red}) from pure tantalum, where their concentration is higher, toward the alloy, where their concentration is lower, and disturb the equilibrium ratio of ions $[Ta^{4+}]/[Ta^{5+}]$ at the alloy surface. For the equilibrium to be restored, a reaction must occur, lowering the Ta^{4+} concentration at the surface of the positive nickel electrode. Nickel reacts with tantalum to give a surface alloy

$$3Ni + 2Ta^{4+} \rightarrow Ta^{5+} + Ni_3Ta. \quad (5)$$

Ta^{5+} ions with higher oxidation level, formed by reaction (5), diffuse toward the electrode made of pure tantalum, which, in turn, disturbs the equilibrium ratio of tantalum ions $[Ta^{4+}]/[Ta^{5+}]$ at its surface, creating an excess of Ta^{5+} ions. The response of the Ta/$[Ta^{4+}]$ system to the disturbing action of the j_{ox} flow has the form of the tantalum dissolution reaction to give ions of the reduced form Ta^{4+}, after which these ions again start their motion along the gradient toward the alloy. Thus, the transfer process is closed into the cycle occurring by the scheme [9].

$$Ta \left| \begin{array}{c} \nearrow [Ta^{4+}] \xrightarrow{j_{red}} [Ta^{4+}] \searrow \\ [Ta^{5+}] \xleftarrow{j_{ox}} [Ta^{5+}] \end{array} \right| Ni_3Ta \left| Ni \right.$$

CONCLUSIONS

(1) The composition of nickel–tantalum intermetallic compounds in chloride-fluorotantalate melts depends on the K_2TaF_7 concentration in the melt, amount of tantalum metal added to the melt, thickness of the nickel substrate, and experiment duration. In melts with high content of K_2TaF_7 (14 mol %), introduction of tantalum powder in amounts of ca. 1 wt % and more leads to faster formation of protective coatings on nickel. It follows from experiments that the nickel reactor walls are covered with Ni_3Ta and Ni_2Ta compounds.

(2) The compound K_2TaCl_6 was found in NaCl–K_2TaF_7 melts (14 wt %) upon introduction of tantalum powder in amounts of 5 wt % and more. A conclusion is made that the formation of surface intermetallic compounds is due to the disproportionation reaction. IR spectroscopy reveals the growing share of dissociation by scheme (2).

(3) The surface alloy is formed by reaction (5).

(4) The results of the study made it possible to obtain directly in the course of sodium-reduction tantalum powders with low content of nickel impurity.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A New Technique for Synthesis of Nordstrandite

V. A. Lipin

All-Russia Aluminum-Magnesium Institute, St. Petersburg, Russia

Received June 19, 2000; in final form, November 2000

Abstract—Basic physicochemical characteristics of aluminum trihydroxide prepared for the first time by carbonization in the form of nordstrandite are described. Silicon-containing complexes present in the solution being carbonized act as stabilizers of the nordstrandite structure in the course of hydroxide precipitation from aluminate solutions.

Nordstrandite, synthesized in 1956 by Robert van Nordstrand, a known chemist, and named after him, is, together with bayerite, gibbsite, and doyleite, a polymorphic modification of aluminum hydroxide $Al(OH)_3$ [1–3]. Nordstrandite occurs in nature in eroded rocks, in association with carbonates, and in a number of bauxite ores [2–6].

A specific feature of thermal dehydration of nordstrandite is the formation of η-Al_2O_3 possessing a special type of crystal lattice defects and exhibiting thermal stability, which allows its use as a starting material in production of supports of catalysts for dehydration, isomerization, reforming, and some other catalytic processes [6, 7].

Synthesizing artificial nordstrandite involves certain technological difficulties. It can be obtained from X-ray-amorphous aluminum hydroxide by keeping ("aging") it in the presence of chelate-forming agents (ethylenediamine, ethylene glycol) under the conditions in which bayerite would be produced in the absence of these reagents. Also, nordstrandite mixed with bayerite can be obtained in reaction of aqueous solutions of aluminum with ammonium hydroxide, with subsequent many-day keeping at pH 7.5–13.0 [7, 8]. The complexity and long duration of synthesis hinder large-tonnage production of nordstrandite by conventional methods and restrain its practical use.

Nordstrandite described in this communication was for the first time obtained by carbonization from aluminate solutions produced in manufacture of alumina. The mechanism of the carbonization process is not completely clear despite numerous investigations. The reaction of aluminate solutions with carbon dioxide onsets at pH > 13 because of the excess of alkali in solution. Then, on introducing CO_2 into the solution, the pH decreases. With account of the modern concepts, the occurring reactions can be represented as

$$CO_2 + 2OH^- = CO_3^{2-} + H_2O, \quad (1)$$

$$[Al(OH)_4]^- + H_3O^+ = AlOOH + 3H_2O, \quad (2)$$

$$AlOOH + OH^- + H_2O = [Al(OH)_4]^-, \quad (3)$$

$$[Al(OH)_4]^- = Al(OH)_3 + OH^-, \quad (4)$$

$$CO_2 + 2H_2O = H_3O^+ + HCO_3^-, \quad (5)$$

$$2AlOOH + 2(Na, K)^+ + 2HCO_3^- = (Na, K)_2O \cdot Al_2O_3 \cdot 2CO_2 \cdot 2H_2O. \quad (6)$$

In processing aluminum-containing raw materials into alumina and other products, aluminum hydroxide is prepared in such a way that it should be obtained in the form of gibbsite. In addition, bayerite, pseudoboehmite, hydroaluminocarbonates of alkali metals (HAC), and X-ray-amorphous modification of these materials can be obtained under certain carbonization conditions [1]. Theoretical prerequisites for obtaining nordstrandite by carbonization of aluminate solutions had existed before [9], but have not been confirmed by practice.

The carbonization conditions were chosen in view of the specific features of nordstrandite formation in nature. A condition favoring nordstrandite formation is, as a rule, decomposition of basalt by weakly alkaline solutions via the compounds aluminohy-

drocalcite $CaO \cdot Al_2O_3 \cdot 2CO_2 \cdot 5H_2O$ or dawsonite $(Na, K)_2O \cdot Al_2O_3 \cdot 2CO_2 \cdot 2H_2O$. Since nordstrandite is mainly formed in the presence of silicon-containing mineral compounds, aluminate solutions with increased, with respect to that in alumina production solutions, content of silicon were subjected to carbonization.

Nondesiliconized aluminate solutions produced in leaching of nepheline cake were used in experiments [10]. The carbonization was done with diluted carbon dioxide (16–25% CO_2) to pH 11.0–11.3. The formed solid phases and filtrates were separated on a Schott filter, with the precipitates washed with water at 30°C and analyzed for the content of main component gravimetrically and by the volumetric and photometric methods. The concentration of the "carbonate alkali" (R_2O_{cb}) in aluminate solutions, stoichiometrically proportional to the amount of CO_3^{2-} ions present in solution, was calculated in terms of sodium oxide as the difference between the "total" (R_2O_t) and "caustic" (R_2O_c) alkalis. The total and caustic alkalis were determined using titration by conventional techniques adopted in the alumina industry.

The granulometric composition of the obtained phases was determined with a SILAS laser granulometer. Crystal-optical measurements and microphotography were done with a COMIBAX microscope. The phase composition of the precipitates was determined by X-ray phase analysis and IR spectroscopy. X-ray patterns were taken on a Philips automated powder diffractometer with Cu_{K_α} radiation and graphite monochromator. IR spectra were obtained with a Perkin–Elmer spectrometer in the wave number range 400–3800 cm^{-1}. Samples for measurements were prepared by compaction of pellets with KBr. The solution pH was determined with an EV-74 ion meter.

The results obtained in carbonization of nondesiliconized aluminate solutions are presented in Table 1.

It follows from the data in Table 1 that a number of conditions is to be met for aluminum hydroxide to be formed as nordstrandite, including a temperature of 60–75°C and presence of a silica-containing phase in a solution being carbonized. In all probability, it is silica that stabilizes nordstrandite in the course of carbonization in a transition from metastable to crystalline phases. In the absence of silica in a solution being carbonized, all other conditions being the same, there occurs precipitation of the following phases conventional for the alumina production: gibbsite, bayerite, or aluminocarbonates of alkali metals [1].

Crystal-optical studies demonstrated the presence of finely crystalline aggregates of nearly radial-beam structure (Fig. 1). Inside the aggregates, there are point inclusions of the silicate phase. Nordstrandite has the following refractive indices of the crystalline phase: $\alpha = 1.582(1)$, $\beta = 1.582(1)$, $\gamma = 1.586(1)$.

An IR spectrum of nordstrandite obtained by carbonization of a nondesiliconized solution is shown in Fig. 2. In the positions of the main bands, the spectrum is close to the spectra of both the natural mineral [2, 3] and synthetic nordstrandite samples prepared by other methods [7, 8]. The spectrum shows high intensity of stretching vibrations of OH^- groups in water molecules (3300–3700 cm^{-1}), deformation vibrations

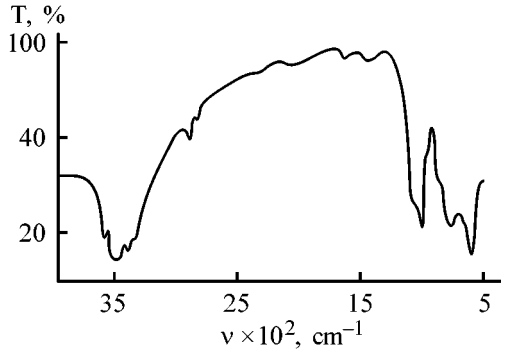

Fig. 2. IR spectrum of nordstrandite obtained by carbonization of an aluminate solution. (T) Transmission and (ν) wave number.

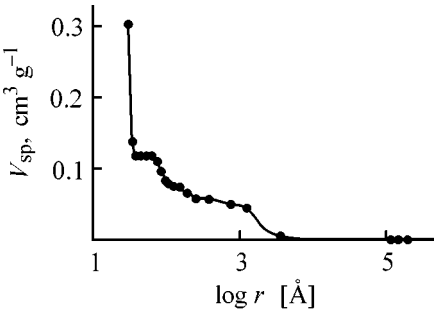

Fig 3. Integral porogram of aluminum oxide obtained by nordstrandite calcination at 550°C. (V_{sp}) Specific pore volume and (r) equivalent pore radius.

of OH^- groups (700–1100 cm^{-1}) and vibrations of the Al–O group (around 500 cm^{-1}).

An X-ray phase analysis of samples obtained by carbonization revealed virtual coincidence of the interplanar spacings and relative intensities of the obtained nordstrandite with the respective reference parameters in the ASTM file (Table 2).

The granulometric composition of nordstrandite was as follows:

d_{av}, μm	N, %
0–6	1.0–3.5
+6–12	0.7–4.9
+12–16	3.6–6.1
+16–24	36.7–44.7
+24–32	25.8–30.9
+32–48	15.4–29.7
+48	1.3–2.6

The average particle diameter is 24.6 μm. A specific feature of the obtained nordstrandite is that it has a monogranulometric composition and 80–95% of the material is constituted by particles 16–48 μm in size.

The porous structure of aluminum oxide prepared from nordstrandite produced by carbonization was studied by mercury porosimetry. A nordstrandite sample was heated at 550°C for 6 h. The measurements were done on a mercury porosimetric setup comprising high- and low-pressure porosimeters [11].

It follows from the obtained integral porogram, plotted in the coordinates pore volume–logarithm of equivalent pore radius (Fig. 3), that mesopores are predominant in the material under study. This is in agreement with the data of [6]. The high values of the average pore volume (0.60–0.67 $cm^3\ g^{-1}$), obtained in [7], were not observed in aluminum oxides prepared from nordstrandite.

CONCLUSIONS

(1) Nordstrandite was for the first time synthesized by carbonization and its basic characteristics are described. No significant difference in physicochemical properties between this kind of nordstrandite and that obtained by the conventional techniques was revealed.

(2) The experimentally confirmed possibility of obtaining nordstrandite by carbonization allows a substantial reduction in the price of the product and thereby expands the range of its practical use.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Polymorphism of Micelles in Aqueous Cetyltrimethylammonium Bromide Solutions

Chunsheng Mo and N. N. Kochurova

Research Institute of Chemistry, St. Petersburg State University, St. Petersburg, Russia

Received August 9, 1999; in final form, January 2000

Abstract—A viscometric study was made of the polymorphous transformation of micelles in an aqueous solution of cetyltrimethylammonium bromide in the presence of NaBr and sodium methylbenzenesulfonate. The effects of temperature and nature and concentration of additives on the second critical micelle concentration were studied. The thermodynamic characteristics of the micellar transition are estimated.

It is well known that inorganic electrolytes and polar organic compounds have a considerable effect on the physicochemical characteristics of aqueous solutions of ionic surfactants. Most clearly this effect is reflected in the viscosity of a micellar solution [1]. It has been demonstrated experimentally that small spherical micelles formed at the first critical micelle concentration (CMC_1) may transform into cylindrical micelles with increasing surfactant concentration or as a result of addition of polar compounds. Such a transformation results in higher viscosity of the solution and changes other thermodynamic characteristics. The use of certain organic electrolytes, such as benzenesulfonates, salicylates, etc., as additives to an aqueous surfactant solution allows preparation of highly viscous fluids, semisolid pastes, or gels. This phenomenon is widely used in pharmaceutical, food, and cosmetics industries, environmental protection, etc. Therefore, studying the indicated polymorphism is of considerable practical importance.

The asymmetrization of spherical micelles and the viscoelastic properties of aqueous solutions of cetyltrimethylammonium bromide (CTAB) in the presence of various additives have been studied extensively [2–13]. However, systems with low additive concentrations were considered in most of these works. Data on the thermodynamic characteristics of such systems are very scarce.

In this communication, we report the effects of the CTAB concentration and temperature on the polymorphism in dilute aqueous solutions of CTAB at relatively high NaBr concentrations (0.2 and 0.4 M) and in the presence of an organic additive, sodium methylbenzenesulfonate (NaMBS). The activation energy of viscous flow is estimated.

EXPERIMENTAL

As a surfactant we used CTAB (analytically pure grade) multiply recrystallized from a mixture of acetone and methanol (19 : 1). As the criterion of high quality served the absence of a minimum in the surface tension isotherm.

Sodium bromide and *p*-methylbenzenesulfonate (both of analytically pure grade) were used without further purification.

The viscosities at 30, 35, 40, 45, and 50°C were measured by capillary viscometry with an Ubbelohde viscometer on an experimental setup described in [14]. The dynamic viscosity η (Pa s) was determined from the outflow time of water and the solutions, using reference data on the viscosity of water.

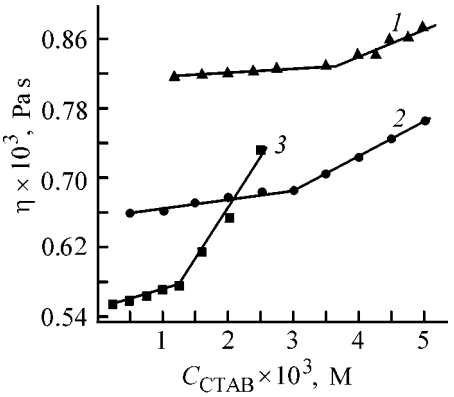

Fig. 1. Dynamic viscosity η of CTAB micellar solutions vs. the CTAB concentration $C_{CTAB} \times 10^3$ in the presence of various additives. Additive (M): (*1*) 0.2 NaBr, (*2*) 0.4 NaBr, and (*3*) 0.025 NaMBS. Temperature (°C): (*1*) 30, (*2*) 40, and (*3*) 50.

The densities of the tested fluids were measured pycnometrically.

The CMC_1 of CTAB in aqueous salt solutions was determined from the dependence of the surface tension on the surfactant concentration at a fixed temperature by the drop volume method [15]. In the measurements, the temperature was controlled to within 0.1°C. Doubly distilled water was used for solution preparation.

The dynamic viscosity η in water–CTAB–salt ternary systems, measured at various CTAB concentrations and temperatures, is given in Table 1 and Fig. 1. Table 1 also includes the relative viscosity η_r determined as the ratio of the outflow times of a solution tested and water.

The resulting dependences are broken straight lines consisting of two portions, which is consistent with the results reported in [16, 17]. The break point corresponds to the second critical micelle concentration CMC_2. CMC_2 values are given in Table 2 along with CMC_1 data obtained previously [15]. The results show that the viscosity gradually grows with the con-

centration incresing above CMC_1. Evidently, the shape of micelles is not changed between CMC_1 and CMC_2. Above CMC_2 the viscosity increases more rapidly with concentration.

Figure 1 illustrates the effects of the nature and concentration of additives on the sphere–cylinder micellar transition. It is seen that at 50°C the CTAB concentration at which transition occurs in 0.025 M NaMBS is lower than that for 0.4 and 0.2 M NaBr.

In micellar solutions, CMC_2 increases with temperature at a constant electrolyte concentration and decreases with increasing electrolyte concentration at constant temperature (Table 2). It is known that the temperature effect is about the same in the absence of additives [18]. Addition of NaMBS favors formation of cylindrical CTAB micelles at lower salt concentration as compared with the other salts. All these facts indicate that the nature and concentration of the additives play an important role in the asymmetrization of spherical CTAB micelles.

The mechanism of the electrolyte effect on the shape of micelles of ionic surfactants is associated to a considerable extent with the salting-out effect leading to closer packing of polar groups on a cylindrical micelle surface, which cannot be realized on a spherical surface [19].

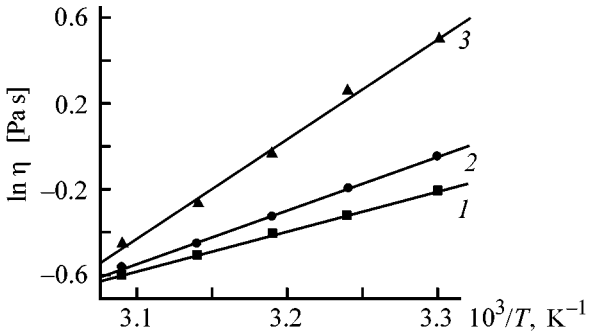

Fig. 2. Arrhenius plots for determining the enthalpy of activation. (η) Viscosity and (*T*) temperature. Solution composition: (*1*) H_2O + 1.17×10^{-3} M CTAB + 0.2 M NaBr, (*2*) H_2O + 4×10^{-3} M CTAB + 0.4 M NaBr, and (*3*) H_2O + 2×10^{-3} M CTAB + 0.025 M NaMBS.

According to Eyring's theory [20], the viscosity η is related to temperature *T* by

$$\eta = \frac{N_A h}{V} \exp\left(\frac{\Delta G^{\#}}{RT}\right), \quad (1)$$

where $\Delta G^{\neq}$ is the Gibbs activation energy of viscous flow in the solution (J mol^{-1}), *V* is the molar volume (m^3 mol^{-1}), η is the dynamic viscosity of the solution (Pa s), *T* is temperature (K), N_A is the Avogadro number, *h* is the Planck constant, and *R* is the gas constant.

The molar volume of surfactant in the equilibrium micellar solution, *V*, can be calculated by

$$V = \frac{100}{(100\rho - W)/M_0 + W/M}, \quad (2)$$

where *W* is the surfactant concentration (g/100 ml solution), M_0 and *M* are the molecular weights of water and surfactant, respectively, and ρ is the density of the micellar solution (g cm^{-3}).

Using Eq. (1) and taking into account that the standard enthalpy $\Delta H^{\neq}$, entropy $\Delta S^{\neq}$, and Gibbs energy $\Delta G^{\neq}$ of viscous flow activation are related by $\Delta G^{\neq} = \Delta H^{\neq} - T\Delta S^{\neq}$, we can write

$$\eta = \left(\frac{N_A h}{V}\right) \exp\left(\frac{-\Delta S^{\neq}}{R}\right) \exp\left(\frac{\Delta H^{\neq}}{RT}\right), \quad \eta = \exp\left(\frac{\Delta H^{\neq}}{RT}\right), \quad (3)$$

$$A = \left(\frac{N_A h}{V}\right) \exp\left(\frac{-\Delta S^{\neq}}{R}\right), \quad \ln \eta = \ln A + \frac{\Delta H^{\neq}}{RT}. \quad (4)$$

The dependence $\ln \eta = f(1/T)$ is expressed graphically as a straight line intersecting the ordinate axis. Examples of the Arrhenius plots for our experimental data (Table 1) are given in Fig. 2. The slope of the

straight line gives $\Delta H^{\neq}$, and then $\Delta S^{\neq}$ is determined to be $(\Delta H^{\neq} - \Delta G^{\neq})/T$.

The activation energy $\Delta G^{\neq}$ of viscous flow in aqueous-salt CTAB solutions at 30–50°C, calculated by Eq. (1) using the experimental values of η and ρ, and also $\Delta H^{\neq}$ and $\Delta S^{\neq}$, are given in Table 3. The results show that $\Delta G^{\neq}$ decreases with increasing temperature at constant CTAB concentration; the enthalpy and entropy of activation are practically independent of temperature. At constant temperature, $\Delta G^{\neq}$, $\Delta H^{\neq}$, and $\Delta S^{\neq}$ grow with increasing CTAB concentration. At constant CTAB concentration and constant temperature, $\Delta G^{\neq}$, $\Delta H^{\neq}$, and $\Delta S^{\neq}$ grow with increasing NaBr concentration. At constant CTAB concentration and any temperature from the experimental range, $\Delta G^{\neq}$, $\Delta H^{\neq}$, and $\Delta S^{\neq}$ are higher in aqueous NaMBS solutions, compared with the values in the presence of NaBr, indicating the significance of the counterion nature.

CONCLUSIONS

(1) The second critical micelle concentration was determined at 30–50°C in micellar aqueous solutions of cetyltrimethylammonium bromide in the presence of sodium bromide and methylbenzenesulfonate.

(2) The activation energy of viscous flow of the investigated aqueous solutions was estimated. The high positive $\Delta S^{\neq}$ compensates for the high enthalpy of activation $\Delta H^{\neq}$.

SORPTION AND ION-EXCHANGE PROCESSES

Cation Exchange in Oxohydroxide Matrices of Niobium(V)

Abstract—Exchange of lithium, sodium, and potassium cations for hydrogen ions in oxohydroxide matrices of niobium(V), with alkali metal to niobium ratio of 1, was studied potentiometricaly. The possibility is considered of predicting the content of various singly charged cations in the case of their simultaneous presence in a complex hydrated oxide based on niobium(V).

Inorganic materials based on metaniobates of alkali metals possess specific electrical and optical properties, which enables their wide use in various fields of technology [1, 2]. However, the presence of impurity phases and deviations from a prescribed composition impairs the quality of the produced articles. In solid phase synthesis of metaniobates of alkali metals [2–4], low degree of homogenization gives rise to difficulties in obtaining a monophase product. The physicochemical properties of complex oxides of niobium and an alkali metal are substantially improved by creating alcoholate-based precursors and their subsequent hydrolysis [2, 5–7] and also direct reaction between hydroxides in aqueous solutions [8]. The quality of the obtained product depends on the composition and formation conditions of solid phases containing niobium(V) and an alkali metal.

To develop efficient approaches to manufacture of high-quality materials based on complex oxides, a knowledge is necessary of the formation conditions and composition of compounds obtained in aqueous solutions and thermodynamic characteristics of processes involving these compounds. The behavior of oxohydroxide forms of niobium(V) in aqueous electrolyte solutions is still a matter of discussion. Niobium(V), possessing high ionic potential, exhibits a strong tendency toward hydrolysis to give various oxygen- and hydroxide-containing complexes, including polynuclear complexes [9–20]. The compounds formed in the process can act as inorganic ion-exchangers. The authors of [12, 21] pointed to the formation of oxide compounds containing niobium(V) and an alkali metal in aqueous solutions; however, these data give no way of making an unambiguous conclusion about processes of solid phase formation.

The aim of this study was to analyze processes of competitive exchange of singly charged cations in oxohydroxide matrices of niobium(V).

EXPERIMENTAL

The processes of cation exchange were studied in aqueous chloride solutions. The electrolyte was chosen in view of the fact that chloride ions are characterized by a weak tendency toward association with polyvalent metals in the pH range studied (3–12) [17, 20], ruling out any influence of the anion background. In studying the exchange of alkali metal cations present in solution with the solid phase, a difficulty is encountered in monitoring the variation of their concentration. The most convenient and appropriate is an analysis of the exchange of an alkali metal cation for hydrogen ion. Therefore, the study was based on an analysis of curves of potentiometric titration of hydrated lithium, sodium, and potassium niobates with a 0.1 M solution of hydrochloric acid at constant ionic strength μ of a solution containing chloride of the respective alkali metal.

The starting hydrated amorphous lithium and sodium niobates of composition $Li_3NbO_4 \cdot 3.5H_2O$ and $Na_6Nb_4O_{13} \cdot 11.4H_2O$, and also water-soluble crystalline potassium niobate of composition $K_8Nb_6O_{19} \cdot 9H_2O$ were synthesized using freshly precipitated niobium(V) hydroxide. In preparing niobium(V) hydroxide [22], in the first stage, ammonium niobate was precipitated by gradually adding a hot acid fluoride solution of niobium ($C_{Nb(V)}$ = 1.13, C_{F^-} = 7.26 g-ion l^{-1}) to a concentrated solution of ammonia, taken in about 130% excess with respect to the stoichiometry, to pH > 9

Initial conditions; temperature 20°C; (a) LiCl solution, $C_{Nb(V)} = 6.2 \times 10^{-2}$ M, $C_{OH^-}/C_{Nb(V)} = 0.96$; (b) NaCl solution, $C_{Nb(V)} = 5.6 \times 10^{-2}$ M, $C_{OH^-}/C_{Nb(V)} = 0.52$; (c) KCl solution, $C_{Nb(V)} = 4.9 \times 10^{-2}$ M, $C_{OH^-}/C_{Nb(V)} = 2.62$. Ionic strength, μ: (*1*) 0.1, (*2*) 0.2, (*3*) 0.4, and (*4*) 0.8.

with continuous stirring. After filtration, the obtained precipitate was "washed" to remove fluoride ions by triple repulpation in a 5% solution of ammonia. In the second stage, ammonium cations were exchange for hydrogen ions by adding hydrochloric acid to pH 4. The absence of ammonium ions was judged from IR spectra of a sample, taken on a UR-20 spectrophotometer. The sample was prepared in the form of a pellet with KBr. The thus obtained freshly precipitated niobium(V) hydroxide was repulped in a 0.5–1.0 M chloride solution of an alkali cation at pH ~12–13. After that, the solid phase was filtered off, washed with alcohol, and dried in air.

To prevent the possible hydrolysis, weighed portions of the starting samples were repulped in an alkaline solution with a prescribed $C_{OH^-}/C_{Nb(V)}$ ratio and then titration with HCl solution was carried out. The pH values were measured to within ±0.02 on an I-130 ion meter with an ESL-43-07 or ESL-63-07 glass electrode in a thermostated (±0.25°C) cell with continuous stirring.

Solid phases to be studied were isolated upon repulpation of the starting hydrated lithium, sodium, or potassium niobates in 0.2–0.4 M lithium, sodium, or potassium solutions, respectively, at pH values corresponding to the equivalence points found in potentiometric titration. The solutions were prepared from the above salts of chemically pure or special-purity grades in distilled water. The obtained suspensions were kept with stirring for 0.5 h. Further, the forming precipitates were filtered off with a vacuum filter, washed with alcohol on the filter, and dried in air. The content of alkali metal in hydrated and calcined at 700°C niobate samples taken from aqueous suspensions was determined by atomic-emission spectrophotometry with induction-coupled plasma and gravimetrically. The phase composition of compounds obtained upon thermal treatment was analyzed on a DRON-2 diffractometer with graphite monochromator (Cu_{K_α} radiation, counter velocity 2 deg min^{-1}). The total exchange capacity Γ^0 of a sample and the content of alkali metal cations, Γ_M, and hydrogen ions, Γ_H, in the solid phase were determined by comparing potentiometric data with the results of chemical and X-ray phase analyses with an accuracy of 3%.

Figures 1a–1c present the equilibrium pH values of the solution in relation to the ratio of concentrations of the acid introduced in titration and niobium(V). The first equivalence point at $C_{H^+}/C_{Nb(V)}$ ratios of 1, 0.5, and 2.5 (Figs. 1a, 1b, and 1c, respectively) is due to neutralization of free hydroxide ions in solution. The ratio of the content of alkali metal ions to that of

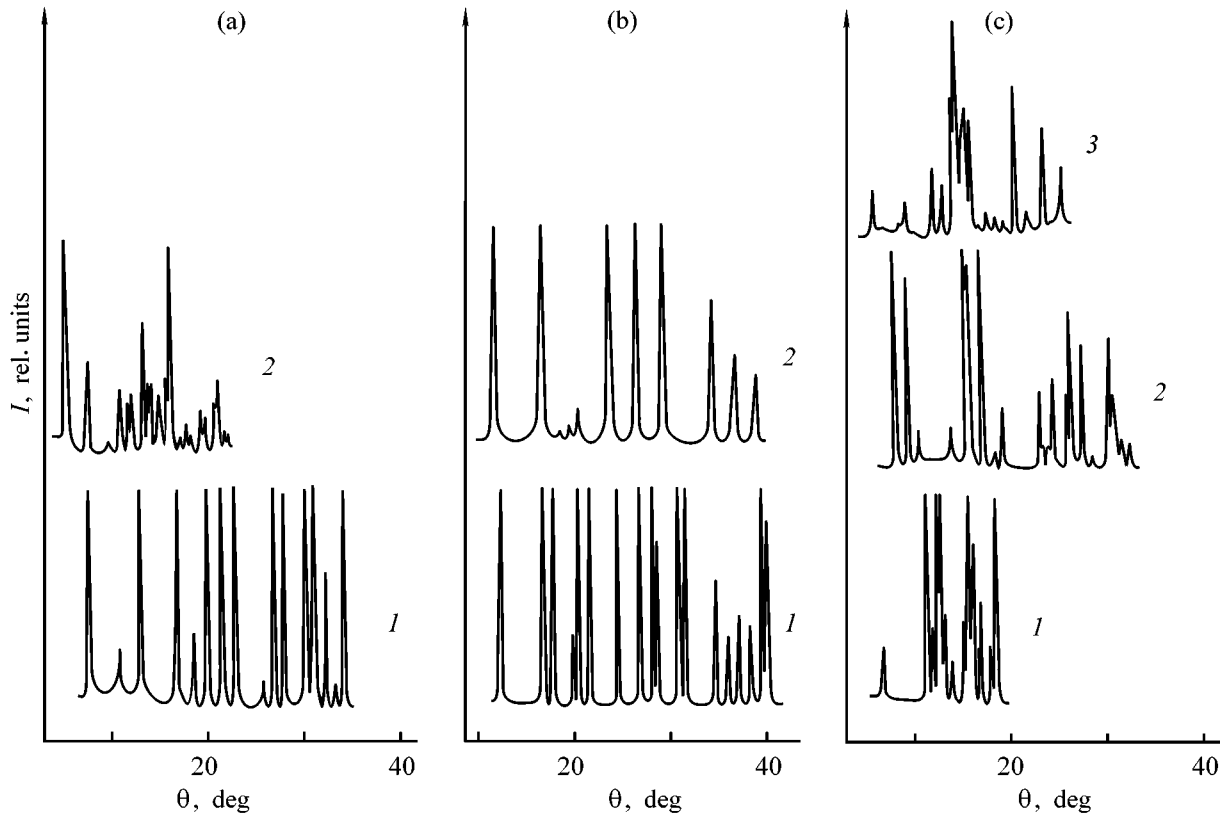

Fig. 2. X-ray diffraction patterns of lithium, sodium, and potassium niobate samples isolated from aqueous suspensions. (*I*) Intensity and (θ) Bragg angle. All the samples except crystalline $K_8Nb_6O_{19} \cdot 9H_2O$ were calcined at 700°C. (a) (*1*) Li_3NbO_4 and (*2*) $K_8Nb_6O_{19} \times 9H_2O$; (b) (*1*) $LiNbO_3$ and (*2*) $NaNbO_3$; (c) (*1*) $LiNb_3O_8$, (*2*) $Na_2Nb_4O_{11}$, and (*3*) K_4NbO_{17}.

niobium(V) in the niobate under study corresponds to the value in the starting sample. Further titration leads to the formation of, first, a hydrated metaniobate of the alkali metal M with M/Nb(V) = 1 ($C_{H^+}/C_{Nb(V)}$ = 3, 1, or 3; Figs. 1a, 1b, or 1c, respectively) and then niobium(V) hydroxide. Chemical and X-ray phase analyses of the solid phases formed confirmed the results of potentiometric measurements (Table 1; Figs. 2a and 2b).

Raising the ionic strength μ of the solution (Figs. 1a–1c), and, correspondingly, making higher the concentration of alkali metal ions in it, shifts the existence range of niobates to lower pH values and may strongly hinder the hydroxide formation. With the concentration of alkali metal in the solution raised substantially ($C_{M^+} > 0.8$ g-ion l^{-1}), two titration waves are observed instead of a single wave corresponding to niobium(V) hydroxide formation. The equivalence point of the first wave indicates the formation of niobates with the following alkali metal ion to niobium(V) ratios: Li : Nb = 1 : 3, Na : Nb = 1 : 2, K : Nb = 2 : 3. The results of chemical and X-ray phase analyses (Table 1; Fig. 2c) correlate well with the potentiometric data and indicate the formation of hydrated compounds of composition $LiNb_3O_8$, $Na_2Nb_4O_{11}$, and $K_4Nb_6O_{17}$, respectively, which are transformed into niobium(V) hydroxide upon further titration.

Table 1. Composition of alkali metal niobates isolated from aqueous suspensions

Solid phase	Composition, wt %, of a sample				
	air-dry			calcined	
	M_2O	Nb_2O_5	H_2O	M_2O	Nb_2O_5
Li_3NbO_4	19.6	55.2	26.1	26.9	72.7
$Na_6Nb_4O_{13}$	19.3	57.6	22.3	25.3	75.9
$K_8Nb_6O_{19}$	25.8	54.2	19.7	32.4	67.6

	60	6.65		

Potentiometric studies revealed a rather wide range of hydrogen ion concentrations at which there exist hydrated forms of lithium, sodium, and potassium metaniobates with alkali metal ion to niobium(V) ratio of 1.

The formation of the disordered structure of the niobium(V) amorphous matrix via hydrogen bonds gives rise to high mobility of solution ions within the matrix and their free access to the solid phase, which results in that the process of heterogeneous cation exchange has bulk nature.

The ion exchange of alkali metal cations for hydrogen ions in hydrated metaniobate can be represented as

$$MR + H^+ \rightleftarrows HR + M^+, \qquad (1)$$

where R is the oxohydroxide matrix of niobium(V).

In the case when two solid phases are formed simultaneously, the constant of ion exchange by scheme (1) will be only controlled by the ratio of alkali metal ion and hydrogen ion activities in solution. Then, at constant ionic strength of the solution and equilibrium conditions, constant pH values would be expected at different degrees of exchange. Analysis of the obtained experimental data suggests that the cation exchange by scheme (1) involves only a single solid phase having the form of a hydrated oxohydroxide matrix of niobium(V) in which alkali metal cations are gradually replaced by hydrogen ions.

The content of alkali metal cations (MR) and hydrogen ions (HR) in the solid phase can be represented as a fraction of the total exchange capacity of the metaniobate sample. Since $\Gamma_M + \Gamma_H = \Gamma^0$, then $N_M = \Gamma_M/\Gamma^0$ and $N_H = \Gamma_H/\Gamma^0$. Then the expression for the cation exchange constant has the form

$$K_p = \frac{N_H a_{M^+}}{N_M a_{H^+}}.$$

At the same time, the apparent cation exchange constant, found from experimental data, is given by

$$K_H = \frac{N_H [M^+]}{N_M a_{H^+}}.$$

Analysis of the results of potentiometric titration (Figs. 1a–1c) shows that, despite μ = const, K_H has no constant value and its logarithm depends linearly on the degree of exchange of alkali metal cations for hydrogen ions. Since

$$\log K_H = \log K_p - \log f_{M^+}, \qquad (2)$$

the $\log K_p$ value must also linearly depend on Γ_H/Γ^0 at constant activity coefficient of the alkali metal in solution, f_{M^+}. The possible reason for such a dependence is the gradual change in the activity of cations in the solid phase from the value corresponding to a hydrate metaniobate of alkali metal to that characteristic of niobium(V) hydroxide. The true value of the thermodynamic constant K_p^t can be determined from the expression [23]

$$\log K_p^t = \int_0^1 \log K_p \, d(\Gamma_H/\Gamma^0).$$

With account of the linear dependence of $\log K_p$ on Γ_H/Γ^0, the $\log K_p^t$ value will correspond to $\log K_p$ at 50% substitution, i.e. at $\Gamma_H = \Gamma_M$. Substitution into (2) of the activity coefficient of alkali metal in solution yields

$$\log K_H = \log K_p^t + \frac{Az^2\sqrt{\mu}}{1 + aB\sqrt{\mu}}, \qquad (3)$$

$$\log K_H = \log [M^+] + pH,$$

where the solution pH corresponds to a value at 50% exchange of alkali metal cations for hydrogen ions in the oxohydroxide matrix of niobium(V).

The dependence of $\log K_H$ on the ionic strength of the solution is linear in the coordinates of Eq. (3). An extrapolation of this dependence to $\mu = 0$ gave the corresponding values of the logarithm of the thermodynamic constant at various temperatures and $\Gamma_H = \Gamma_M$ (Table 2).

The K_p^t values for exchange of alkali metal cations for hydrogen ions in hydrated metaniobates of sodium and potassium grow with increasing temperature, which shifts the existence region of niobium(V) hydroxide to higher pH values. In a similar exchange of cations in hydrated lithium metaniobate, the K_p^t value decreases with increasing temperature and the existence region of niobium(V) hydroxide is shifted to lower pH.

The thermodynamic exchange constant is determined from

$$\Delta G^0 = -2.3RT \log K_p^t, \quad (4)$$

where ΔG^0 is the change in the free Gibbs energy in ion exchange by scheme (1) and in the accompanying sorption and desorption of the solvent and dissolved electrolyte.

Substitution of $\Delta G^0 = \Delta H^0 - T\Delta S^0$ into expression (4) gives

$$\log K_p^t = \frac{\Delta S^0}{2.3R} - \frac{\Delta H^0}{2.3R}\frac{1}{T}. \quad (5)$$

An analysis of the dependence of $\log K_p^t$ on $1/T$ in the coordinates of Eq. (5) allowed a calculation of changes in the enthalpy, ΔH^0, and entropy, ΔS^0, in heterogeneous cation exchange (Table 2).

As it can be seen from Table 2, the affinity of the alkali metal cation for the oxohydroxide matrix of niobium(V) grows in order $K^+ < Na^+ < Li^+$. Decreasing ion radius and increasing size of the hydration shell favor firmer capture of cations into the solid phase. The course of the heterogeneous exchange process is presumably primarily determined by the difference between the degrees of hydration of the exchanging ions in the solid phase and in solution.

The parameter characterizing the degree of hydration of an alkali metal is the ratio between the radius of the hydrated ion, r_h, and the crystallographic radius r_c. Linear dependences of ΔH^0 and ΔS^0 on the degree of hydration of the cation being exchanged were obtained using the r_h and r_c values reported in [24, 25]. The destruction of the hydration shell in the course of sorption and the change in the coordination of bonds within the solid phase determine the ΔH^0 and ΔS^0 values. The change in entropy is the stronger, the lower the degree of hydration of the exchanged ion.

The results obtained in studying the heterogeneous cation exchange in oxohydroxides matrices of niobium(V) allow a choice of conditions under which hydrated compounds are formed with alkali metal cation to niobium(V) content ratio of 1 and high degree of homogenization with respect to singly charged cations. The isolation of the solid phase of this composition from aqueous suspensions with subsequent thermal treatment yields monophase metaniobate of alkali metal. On the basis of the investigations performed, a method was developed for synthesizing lithium metaniobate of stoichiometric composition in aqueous solutions [26, 27].

In synthesizing metaniobate, it is sometimes necessary to introduce simultaneously two or more cations of alkali metals into the oxohydroxide matrix of the solid phase. An important factor in this case is the relationship determining the exchange of several ions. Since the reactions

$$M_1R + H^+ \rightleftarrows HR + M_1^+,$$

$$M_2R + H^+ \rightleftarrows HR + M_2^+$$

are characterized by the constants

$$K_p^{(1)} = \frac{\Gamma_H[M_1^+]}{\Gamma_{M_1}a_{H^+}} \text{ and } K_p^{(2)} = \frac{\Gamma_H[M_2^+]}{\Gamma_{M_2}a_{H^+}},$$

$$K_p^{(1-2)} = \frac{\Gamma_{M_2}[M_1^+]}{\Gamma_{M_1}[M_2^+]} = \frac{K_p^{(1)}}{K_p^{(2)}}$$

corresponds to the constant of ion exchange by the scheme

$$M_1R + M_2^+ \rightleftarrows M_2R + M_1^+.$$

In the general case of a heterogeneous exchange process involving n singly charged cations

$$\Gamma = K_p^{(i-m)}\frac{[M_m^+]}{[M_i^+]}\Gamma_i,$$

where $m \neq i$. With account taken of the fact that $\Gamma_1 + \Gamma_2 + \ldots + \Gamma_n = \Gamma^0$, it can be written

$$K_p^{(i-1)}\frac{[M_m^+]}{[M_i^+]}\Gamma_i + \ldots + \Gamma_i + \ldots + K_p^{(i-n)}\frac{[M_n^+]}{[M_i^+]}\Gamma_i = \Gamma^0.$$

Therefore, the following expression is valid for calculating the solid phase composition

$$\Gamma = \frac{\Gamma}{1 + \sum\limits_{\substack{m=1,\\ m\neq i}}^{m=n} K_p^{(i-m)}\frac{[M_m^+]}{[M_i^+]}},$$

where i is the ion being exchanged and n is the number of ions involved in the exchange.

Thus, the obtained results make it possible to prognosticate the conditions necessary for synthesizing a solid phase containing various alkali metals in a prescribed ratio.

CONCLUSIONS

(1) The concentration and temperature limits of existence of hydrated lithium, sodium, and potassium metaniobates were determined. The thermodynamic characteristics of the heterogeneous exchange of al-

kali metal cations in these compounds for hydrogen ions were calculated.

(2) It is established that the affinity of alkali metal cations for the oxohydroxide matrix of niobium(V) grows in the order $K^+ < Na^+ < Li^+$ with increasing degree of their hydration.

(3) The possibility of synthesizing monophase metaniobates of alkali metals of prescribed composition in aqueous solutions is demonstrated.

(4) A model is proposed for calculating the content of various singly charged cations in their simultaneous incorporation into a complex niobium(V)-based hydrated oxide.

SORPTION AND ION-EXCHANGE PROCESSES

A Sensitive Piezoelectric Crystal Sensor for Analyzing Phenols in Air

Received December 15, 1999; in final form, June 2000

Abstract—A method was developed for analyzing volatile phehols in gaseous media by means of piezoelectric crystal sensors. The efficiency of the modifiers applied to the piezoelectric-crystal surface to improve the sensitivity and selectivity of analysis of toxic compounds was assessed. The choice of the conditions under which phenols are analyzed (nature and flow rate of carrier gas, mass of modifier film) is substantiated.

Monitoring of the atmosphere and air in the working area of industrial enterprises makes wide use of sensors of varied nature [1–3]. The subjects of the most active recent investigations have been mass-change-sensitive sensors with changing frequency of quartz crystal oscillations, operating on surface or volume acoustic waves [4–9]. Such sensors are easily incorporated into computer-based data acquisition and processing systems; they have low inertia and are suitable for remote detection of toxic compounds. The selectivity of the sensors is improved by their surface modification with sensitive sorbents of varied nature or specific biopolymers, as well as by incorporation into neutral polymers of compounds capable of reacting selectively with toxicants being analyzed. Among the most widely distributed organic toxicants to be monitored in air are phenol and its derivatives. The maximum permissible concentration (MPC) of volatile phenols in air in working areas is 5 mg m^{-3} [10].

The aim of this study was to assess the efficiency of various modifiers for piezoelectric crystal sensors (PECSs) and to develop a method for analyzing volatile phenols in air.

EXPERIMENTAL

Our studies were carried out on a setup comprising [11, 12] (Fig. 1) probe injection (*1a*) and gas mixture preparation (*1b*) units, detection cell *2*, quartz-crystal oscillation excitation circuit *3*, gas meter *4*, and data acquisition and processing unit *5*.

The analysis was carried out as follows. The gas mixture containing a compound to be analyzed was injected into a flow of dried carrier gas supplied from a gas cylinder and passed through the detection cell. The instrument was calibrated using standard gas mixtures prepared by passing carrier gas through a thermostated diffusion cell containing the compound to be analyzed. The carrier gas flow rate was measured with float rotameters. The passed volume of the gas was monitored with a rotary gas meter accurate within 0.0001 m^3.

The detection cell can incorporate 1–12 mass-sensitive AT-cut-off PECSs with a resonance oscillation frequency of 8–9 MHz, operating on the volume acoustic wave principle. The changes in the oscillation frequency of the PECS are recorded with a frequency meter or is transmitted with a 12-channel analog-digital converter to a Pentium 166 PC.

As analytical signal serves the change Δf in the oscillation frequency of PECS during sorption of a compound of interest with modifier films applied to the sensor surface. Both the mass of the film coatings applied and the mass of the compound sorbed by the PECS surface were determined using the Sauerbrey equation [13]

$$\Delta f = -2.3 \times 10^6 f_0^2 \Delta m/S.$$

Here, Δf is the change in the resonance oscillation frequency of the PECS owing to film application ($f_0 - f_f$) or sorption of the compound being analyzed ($f_f - f_a$), Hz; f_0 is the resonance (basic) oscillation

frequency of the PECS, MHz; Δm is the mass of the coating applied or the sorbate in the film, g; and S is the PECS surface area, cm^2.

The PECS were modified with low- and high-molecular-weight compounds (analytically pure) which can be conventionally classified into three groups [14]: (i) nonpolar saturated compounds (polymethylsiloxane liquid PMS-100, polymethylphenylsiloxane PMPS); (ii) polar compounds with locally concentrated negative charges, π bonds, and lone electron pairs at N and O atoms [1,2,3-tris(2-cyanoethoxy)propane TCEP, polyvinylpyrrolidone PVP, polyethylene glycol phthalate PEGP, polyethylene glycol adipate P-400, bis(2-ethylhexyl) sebacate BEC, pentaerythritol tetrabenzoate TBPE, polyphenyl ether PPE]; and (iii) polar compounds with surface-localized positive and negative charges (polyethylene glycols PEG-2000, PEG-3000; monoethanolamine MEA; polyvinyl alcohol PVA).

Using a microsyringe, 0.2–3.0 μl of the solution of the modifier with a concentration of 10 mg ml^{-1} was applied to the PECS surface. The solvents were double-distilled water, acetone (pure), ethanol (chemically pure), and dimethylformamide (chemically pure). The film was dried in a desiccator to constant weight at T = 65°C. After sorption of a compound being analyzed, the film was regenerated by passing pure carrier gas (argon, extra pure) through the detection cell.

The choice of the PECS modifier was based not only on the sorption properties of the coating but also on its elasticity ensuring adequate transfer of the signal from the piezoelectric crystal sensor. The efficiency of the modifiers was assessed using to the data obtained: sensitivity A calculated as the ratio between the change in the oscillation frequency of the PECS, Δf, and the concentration of the aromatic compound; dynamic sorption capacity (SC), i. e., sensitivity per unit mass of a modifier film; and the half-sorption and half-desorption times $t_{1/2}$ and $t'_{1/2}$, respectively.

The carrier gas flow rate was chosen on the basis of the rates of external and internal diffusion of volatile phenols to the PECS film surface and the sorption rate, taking into account the fact that at high rates of the carrier gas the pressure on the PECS increases and, therefore, the experimental error grows. The only optimal flow rate of the carrier gas was $(3.5–4.0) \times 10^{-5}$ $m^3 s^{-1}$ for virtually all the modifiers (Fig. 2). The only exception is the MEA-based coating for which sorption is almost instantaneous, and the PECS sensitivity is the greatest at a rate of 6.5×10^{-5} $m^3 s^{-1}$. An inert gas as carrier gas improves the kinetic parameters of analysis (the time of a single measurement decreases by 15 min relative to that in previous analyses in air [15, 16]).

The sensitivity of analyzing phenols in air, using sensors with coatings of varied nature, depends on the film modifier mass affecting the concentration of active functional groups on its surface. Therefore, the optimal mass of the film is estimated at (μg): 4.5 for low-molecular-weight MEA; 10–13 for linear polymers PMS-100, TCEP, PEG-2000, PEF-3000, P-400; and 17–20 for high-molecular-weight polymers PEGP, PVP, and PPE. A decrease in the modifier film mass to 3 μg and below impairs the film surface, which substantially decreases the sensitivity and reproducibility of the results of phenol determination.

The analytical response of PECS is governed both by the structure of a compound analyzed and the nature of modifier (Table 1). With increasing number of active functional groups in the phenol molecule,

both the sensitivity of analysis A and the sorption–desorption time grow. The sensitivity of determining all the phenols studied is at a maximum for PECS modified with polyols and polylactams. The sensitivity A increases in the series of polyols as follows: P-400 < PEG-3000 < PVA < PEG-2000 < PEGP. For coatings with high sensitivity, the sorption–desorption time is typically greater. The exception are substrates based on polyethylene glycols, capable of efficient rapid sorption and desorption of phenols. High sorption activity of the films based on PEG-2000 (compared to PEG-3000) can be accounted for by the increase in the flexibility of the polymer chain because of the smaller number of functional groups.

The sorption–desorption kinetic parameters are determined by the nature and amount of the functional groups in the polymer molecule. For example, hydroxy groups in the PVA molecule, bound by intramolecular hydrogen bonds, sterically hinder sorption of phenol and prolong the sorption–desorption cycle, and bulky aromatic radicals in the PEGP molecule substantially retard sorption of phenols owing to the shielding of the ester oxygen atoms. The set of sorption and kinetic characteristics is optimal for PVP-based coatings which exhibit the maximal sensitivity and rate of sorption and desorption of phenols. The efficiency of the PVP-based coatings is due not only to the active centers present in its molecule but also to its arrangement favoring phenol sorption. Piezoelectric crystal sensors modified with PVP and PEGP can be recommended for monitoring of phenol in air at the working areas, in particular, for automated monitoring.

The kinetics of sorption of phenol on modifier films obtained by solvent evaporation were studied by IR spectroscopy [the spectra were recorded on an

IKS-40 spectrophotometer (CaF_2 cell) after exposing the coatings to phenol vapor for 1–3, 5, 7, and 10 min. A comparison of the IR spectra showed that the substances being analyzed are sorbed by the TCEP-based film via hydrogen bonding with nitrile (Fig. 3a) and ether (Fig. 3b) groups of the modifier

$$CH_3-CH_2-C(-O-CH_2-CH_2-C\equiv N)_3.$$

The interaction is intensified on increasing the exposure time: the bands corresponding to the stretching vibrations of the nitrile (2252 cm^{-1}) and ether (1179 cm^{-1}) groups grow in intensity and broaden. Sorption of phenols by the support based on P-400

$$[-OC_2H_4-O-C(=O)-C_2H_4-C(=O)-]_n$$

initially involves interaction with only carbonyl oxygen atom (already after 3-min exposure) and then with the carbonyl (1609 cm^{-1}) and ester (1160 cm^{-1}) oxygen atoms. This is accompanied by broadening of the bands of the stretching vibrations of the functional groups and their shift to lower frequencies. Thus, all the reactive functional groups of the modifiers participate in hydrogen bonding during phenol sorption. The order in which functional groups interact with phenol depends not only on the reactivity of the complexing atoms, but also on the easiness of access to a group of interest.

To increase the sensitivity, the PECS supports were modified with chemical reagents that reacted quantitatively and selectively with phenols: 4-aminoantipyrine (4-AP), $FeCl_3 \cdot 6H_2O$ [15], and amidopyrine (AP) (Table 2). The maximal growth of the sensitivity observed in sorption of phenol by films containing up to 5 wt % 4-AP is accounted for by the formation of strong complexes between the reagent and phenol. Further increase of the 4-AP concentration decreases the sorption activity of the modifier owing to the growth of the film weight and mutual shielding of the functional group. Phenol desorption by the carrier gas is hindered as well, and PECS regeneration requires that heated air should be used or the modified sensor kept in a thermostat at 65°C. With piezoelectric crystal sensors coated with impregnated polymers (PEG-2000 with 4-AP, 5 wt % PVP with 4-AP, 5 wt %) it is possible to determine phenol in air of the working area in amounts of 0.3 and 0.08

* $K_{A/B} = \Delta m_A C_B/(\Delta m_B C_A)$, where Δm_A and Δm_B are the masses of the compounds sorbed and C_A and C_B are their concentrations.

MPC, respectively. However, inexhaustive desorption (≤90 %) reduces the service life of PECS and makes necessary additional calibration at regular intervals (Fig. 4).

When PECS is used in serial analysis, stable analytical response is important. After the first sorption–desorption cycle for phenol, all the coatings studied exhibit hysteresis depending on the nature and mass of the modifier film (Fig. 4). This is due to the structural changes in the film during its formation, as well as to the partial irreversibility of the sorption process. Repeatedly used PECSs modified with individual polymers (Figs. 4a, 4b) exhibit stable analytical signal (more than 10 sorption–desorption cycles for one film). The hysteresis is the most pronounced for films based on polyethylene glycol phthalate with its rigid polymer chain.

Piezoelectric crystal sensors modified with both individual polymers (PVP, PEG-2000, PEGP) and films containing specific reagents are characterized by low selectivity and are primarily intended for group analysis of volatile phenols in the presence of nonpolar substances (benzene, naphthalene, etc.). Comparison of the selectivity coefficients in determining individual phenols in gas mixtures (Table 3) suggests suitability of TCEP-based coatings for determining chlorophenols (2,4,6-trichlorophenol, TCP) and aromatic aldehydes in the presence of phenol and its alkyl derivatives, and phenol in the presence of certain *ortho* isomers. The gas mixture components can be separately analyzed using multisensor systems comprising a group of sensors arranged in the detection cell. This approach was described in detail for a set of nonspecific sensors employed in water monitoring [18].

We developed a procedure for determining volatile phenols in air, using PECS modified with a film based on polyvinylpyrrolidone and 4-AP (5 wt % solution in acetone) suitable for detecting phenols in 0.40 mg m^{-3} concentration (carrier-gas flow rate 3.7×10^{-5} m^3 s^{-1}). Each analytical run, including PECS regeneration, is complete within 10–15 min. The procedure based on the use of PECS, proposed in this work, compares favorably with the standard gas-chromatographic method [19] in simplicity, economic efficiency, and promptness. It can be used for determining phenols in remote or autonomous, including automated, regimes, which is of special importance for the environmental monitoring.

CONCLUSIONS

(1) The conditions for determining phenols using piezoelectric crystal sensors modified with macromolecular compounds of different nature were elucidated. The optimal experimental conditions are the carrier-gas flow rate of $(3.5–4.0) \times 10^{-5}$ m^3 s^{-1} and the modifier film mass of 10–13 μg.

(2) The efficiency of the modifiers was estimated by the piezoelectric-crystal microweighing. The most efficient coatings for piezoelectric crystal sensors employed for analyzing phenol in air are those based on polyols and polylactams. The kinetics of phenol sorption on various modifiers was studied by IR spectroscopy.

(3) A procedure was developed for determining volatile phenols by means of a modified piezoelectric-crystal sensor for which the detection limit is 0.40 mg m^{-3}.

SORPTION AND ION-EXCHANGE PROCESSES

Effect of Chemical Modification of Walnut Shell on the Yield and Pore Structure of Activated Carbon

A. A. Bagreev, A. P. Broshnik, V. V. Strelko, and Yu. A. Tarasenko

Institute of Sorption and Endoecology, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received July 5, 1999; in final form, September 2000

Abstract—The effect of walnut shell treatment with solutions of inorganic salts prior to carbonization on the yield and properties of the obtained activated carbon was studied. The possibility of controlling the pore structure of the products in thermal treatment is demonstrated.

Recently, interest has again aroused in carbon sorbents prepared from fruit kernels and shells of various nuts [1–5]. This is due to their having much lower cost, compared with the traditional precursors (synthetic polymers and coals) used to produce activated carbons (ACs). However, a search for ways to increase the yield of the resulting product and to improve the structural-sorption characteristics of ACs prepared from fruit-kernel raw materials and, in particular, walnut shells (WS) is still urgent [6].

It has been noted [7–10] that, to improve ACs properties, make higher the yield, and obtain a more developed pore structure, the initial cellulose materials are treated with solutions of inorganic salts, which play the role of fire retardants and catalysts for carbonization and dehydration, ensuring a high yield of the products.

The character of WS dehydration in carbonization strongly affects all stages of ACs preparation. For example, intensifying the dehydration makes higher the ACs yield and hinders formation of resinous substances produced in cellulose degradation reactions competing with dehydration [7]. The choice of appropriate additives and dehydration conditions limiting the side processes resulting in carbon loss is an important problem in AC preparation. For example, the conventional thermal treatment of WSs (carbonization with subsequent activation) fails to yield high-quality AC for some reasons [11, 12].

Firstly, precursor is a macroporous material (the volume of macropores in the carbonization product is about 95% of the total pore volume. At the same time, to prepare highly porous ACs, it is necessary that the carbonization product should have some initial microporosity [9]. Secondly, WSs containing poorly structured components (lignin, hemicellulose, pectin, and proteins), and also mineral impurities, are carbonized to give a large amount of an amorphous coke residue impeding the evolution of pyrolysis gases. As a result, the forming "imperfect" carbon skeleton is contaminated with an amorphous coke residue.

Mineral impurities present in the initial WSs affect adversely the AC quality [9]. Mainly represented by carbonates, chlorides, sulfates, and nitrates of alkali and alkaline-earth metals, the impurities, on the one hand, make lower the onset temperature of carbonization, and, on the other, facilitate degradation of polymeric chains in cellulose, being catalysts for carbon oxidation.

At the same time, preliminary treatment of cellulose materials with phosphate-containing solutions increases the yield of raw carbon [7, 10]. In this case, three-substituted esters may be formed, along with one- and two-substituted esters, owing to the cross-linking of cellulose fragments [13]. Undoubtedly, the cross-linked fragments in the modified cellulose material subjected to pyrolysis strongly affect the structure and properties of raw carbon and ACs produced from this material.

The presence in cellulose-containing materials of phosphate groups, efficient catalysts of both intra- and intermolecular dehydration, accelerates these processes and makes slower the rate of the competing depolymerization reaction [7], which affects the yield and properties of carbonized residues. This concept sub-

stantiates the necessity for preliminary treatment of cellulose raw materials (i.e., for WS modification).

In this connection, the aim of this study was to analyze how impregnation (modification) of the initial WS with solutions of inorganic salts affects the yield and pore structure of carbonized products and activated carbons.

EXPERIMENTAL

As raw material served WSs. The method of shell preparation was described in [6]. The initial WS was impregnated with concentrated solutions of inorganic salts (chlorides, phosphates, sulfates, borates, or mixtures of these) so that the modifier content in the samples was 5–15 wt % (in terms of dry residue). After being separated from the solution, the nutshell was dried at 110°C.

The modified WS was subjected to thermolysis in argon at 800°C for 1 h on an installation described in [6]. To obtain AC samples with combustion loss from 6 to 50%, the thermolysis products were activated with steam at 750°C for varied time.

The mass change X (%) and yield R (%) of samples after each stage of thermal treatment, as well as the sorption volume of the pores V_s ($cm^3\ g^{-1}$) with respect to benzene, were estimated. The pore structure parameters of the materials—the micropore volume V_{mi} ($cm^3\ g^{-1}$); volume of sorbing pores V_t ($cm^3\ g^{-1}$), found from the isotherm of nitrogen adsorption at $P/P_0 = 0.95$; and the specific surface area S_{BET} ($m^2\ g^{-1}$), measured in different stages of thermolysis—were determined from sorption isotherms of carbon dioxide and nitrogen at 0°C and –196°C, respectively. The obtained isotherms were processed using modern methods of the adsorption theory [14, 15].

As noted in [16], the type and amount of introduced salt affect the thermal degradation of cellulose. The amount of salt required for WS modification is considerably lower than that commonly used for chemical activation [9]. This enables estimation of the true contribution of the salt additive and makes unnecessary washing of the final product.

The influence exerted by the nature of anion, salt concentration, and degree of exchange of the protons of phosphoric acid for ammonium ions on the yield and pore volume of ACs was studied. The results obtained are listed in Table 1. It can be seen that modification strongly affects the properties of the carbonization products and AC. In particular, the AC yield increases from 5.2% (unmodified WS) to 18.4–27.7% (modified samples). The activated carbons prepared from preliminarily modified WS possess higher pore volume than those prepared from unmodified WS (0.23 and 0.24–0.45 $cm^3\ g^{-1}$, respectively).

An estimate of the influence exerted by the amount of introduced salt (for the example of ammonium hydro- and dihydrophosphates) showed that AC samples prepared from WS with 5% of salts have the highest yield (22.2%) and the largest pore volume ($V_s \approx 0.39$–0.45 $cm^3\ g^{-1}$). For AC samples synthesized from WS with 15% ammonium phosphate, the yield is 18–20% and the pore volume, about 0.44 $cm^3\ g^{-1}$. It should be noted that the optimal concentration of ammonium orthophosphate in WS is 5%. Further increase in the amount of salt does not virtually affect the AC yield and pore volume.

It was found with various ammonium salts (chloride, sulfate, and phosphate) that the highest yield (27.7%) is observed for an AC sample prepared from WS modified with ammonium sulfate, and the largest pore volume (0.45 $cm^3\ g^{-1}$), for that prepared from WS preliminarily impregnated with ammonium ortho-

Table 2. Yield and parameters of pore structure of the carbonization products and ACs

Parameter	Carbonization product	AC	Parameter	Carbonization product	AC
R, %	35.6	20.1	V_{mi} (CO_2), $cm^3\ g^{-1}$	0.26	0.27
V_s, $cm^3\ g^{-1}$	0.12	0.44	V_t (N_2), $cm^3\ g^{-1}$	0.03	0.47
V_{mi} (N_2), $cm^3\ g^{-1}$	0.03	0.42	S_{BET} (N_2), $m^2\ g^{-1}$	50	850

phosphate. The yield and the pore volume for an AC sample prepared from WS impregnated with ammonium chloride solution are 23.4% and 0.43 $cm^3\ g^{-1}$.

The influence exerted by the degree of proton exchange in H_3PO_4 for ammonium ions was analyzed for samples modified with 5% solutions of $(NH_4)_3PO_4$, $(NH_4)_2HPO_4$, $(NH_4)H_2PO_4$, and H_3PO_4 to reveal the following tendency: the highest yield (24.3%) is observed for an AC sample based on phosphoric acid-impregnated WS and the largest pore volume (0.45 $cm^3\ g^{-1}$) for that prepared from WS impregnated with ammonium orthophosphate.

Borax taken alone and that with addition of boric acid or ammonium hydrophosphate give AC samples in 25.5–26.7% yield. For these AC samples, as well as for the AC samples synthesized from WS modified with ammonium phosphate, the highest yield corresponds to 5 wt % modifier. The pore volume in the ACs prepared from WS impregnated with borates is about 0.33 $cm^3\ g^{-1}$.

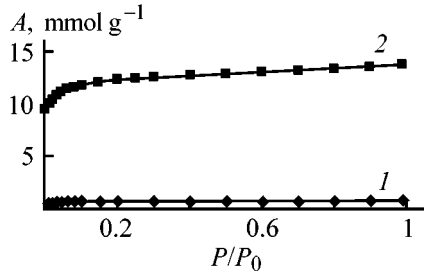
The treatment of WS with ammonium chloride, ammonium phosphate, boric acid, or its salts leads to a substantially larger pore volume in carbonized and activated materials, with the AC yield increasing nearly 2-fold.

Data on the formation and development of the pore structure in carbonized products and ACs were obtained from the results of an adsorption experiment. The figure shows, as an example, the nitrogen adsorption isotherms taken on carbonized samples and ACs prepared from WS containing 5 wt % ammonium hydrophosphate. The estimated yields R (%) and calculated pore structure parameters are listed in Table 2. For the carbonization product obtained from WS treated with ammonium hydrophosphate, the adsorption isotherm shows low slope and small adsorption of nitrogen over a wide range of pressures (curve *1* in the figure). This indicates that only a microporosity is present in the carbonized sample (Table 2), which is confirmed by the fact that the volume of sorbing pores V_t and that of micropores V_{mi} (N_2) coincide. As seen from the data on CO_2 sorption, this sample has a considerable volume of narrow micropores V_{mi} (CO_2).

The adsorption of nitrogen on AC prepared from WS pretreated with phosphates is 15 times that for the product of carbonization (curve *2* in the figure). As in the case of the carbonization products, these samples are characterized by low slope of the isotherms, which is typical of microporosity. The fact that the volume V_t of sorption pores and that of micropores V_{mi} (N_2) (Table 2) coincide also confirms the absence of mesoporosity in the prepared ACs.

Activation of a carbonized sample prepared from WS treated with ammonium hydrophosphate to 44% combustion loss (Table 2) leads to larger micropore volume determined from nitrogen sorption, whereas the pore volume found from CO_2 sorption does not virtually change. This suggests the formation of coarse micropores, which is confirmed by changes in the specific surface area and pore volume (Table 2). As a result of activation, S_{BET} increases 17-fold and V_s grows from 0.12 to 0.44 $cm^3\ g^{-1}$.

Thus, among all the salt additives used for preliminary impregnation of WSs, the highest AC yield is ensured by borates and ammonium sulfate, and the largest pore volume, by phosphates and ammonium chloride. Modification of WS with phosphates allows preparation of ACs with developed pore structure and



Isotherms of nitrogen adsorption on thermolysis products prepared from WS modified with ammonium hydrophosphate. (A) Adsorption and (P/P_0) relative pressure. (*1*) Carbonization product and (*2*) AC with a 44% combustion loss.

makes it possible to control the pore structure of the thermolysis products (i.e., to synthesize microporous sorbents).

CONCLUSION

Modification of walnut shell with inorganic salts prior to carbonization raises the yield of activated carbon and allows control of its structural-sorption characteristics. The activated carbons obtained in this process have reasonable operation characteristics.

Received July 26, 2000

Abstract—The results obtained in a study of the electrochemical separation of multicomponent tin-based alloys in salt melts are presented. The influence exerted by electrolysis conditions on the discharge at the auxiliary electrode of a number of metals accompanying lead and tin was determined.

Manufacture and purification of non-ferrous metals from polymetallic raw materials yield a great amount of polymetallic alloys [1, 2]. The qualitative and quantitative compositions of such alloys vary widely, depending both on the composition of starting raw materials and on the method of their processing. For example, purification of tin by vacuum refining yields alloys of the following composition (wt %): tin 30–40, bismuth up to 10, antimony up to 5–6, copper up to 3–5, silver up to 0.1–0.2, arsenic up to 0.3–1.5, iron up to 0.1–0.3, and lead the rest. The known methods for separation of such alloys into components are rather labor-consuming, involve large amounts of recirculated products, and are characterized by low recovery of the metals [2]. Silver and gold, accompanying non-ferrous metals, are, as a rule, distributed among the processing products and lost with them. It has been shown [2–4] that electrolysis in salt solutions, ensuring concentration of noble metals at the cathode, is an efficient method for processing alloys of this kind. A considerable progress in separation of multicomponent alloys by electrolysis in melts can be made with an auxiliary electrode hindering transfer of metals with more positive electrode potential from anode to cathode, thus favoring a higher degree of separation into components. This communication presents the results obtained in studying the electrochemical separation of tin-based multicomponent alloys in high-temperature electrochemical reactors of various kinds, including those with a porous electrode.

EXPERIMENTAL

A schematic of the electrochemical reactor for separation of multicomponent alloys is shown in Fig. 1. The experiments were done at current loads of 50 to 200 A. The developed electrolyzer design allows work in two modes: with and without auxiliary electrode mounted between the anode and cathode. Figure 1 shows an electrolyzer variant with an auxiliary electrode. A vessel *1* of arbitrary shape, made of an electrically conducting material and lined with graphite from inside, serves as cathode and receiver of metal deposited onto the cathode. Inside, this vessel contains a vessel *2* for anodic metal. The base of the anodic vessel *2* is made of a porous dielectric material *3*. The porosity of this material is chosen so as to rule out mechanical seepage of the anodic metal. Common-

ly, heat-resistant silica fabrics of various brands are used as porous diaphragm. Owing to the surface tension forces, the molten metal is contained within the anodic vessel and comes into contact with molten electrolyte through the pores. On passing a direct current, the metal dissolves at the anode and, after being transferred through the electrolyte layer, is deposited onto the cathode.

As molten electrolyte served salt mixtures based on zinc chloride. Zinc chloride and mixtures on its basis occupy a distinctive position among molten salts. They have low melting point and allow work in the interval 230–550°C. Zinc has more negative potential, compared with many non-ferrous metals, and, therefore, its compounds may be present in the electrolyte mixture, taking no part in the mass exchange between the electrodes. In molten state, zinc chloride forms associates of the type $(–Zn–Cl–)_n$, decomposing in the presence of weakly polarizing cations of alkali metals. The decomposition to give $[ZnCl_4]^{2–}$ anions is the stronger, the larger the cation of an alkali metal [7]. These anions can coordinate in the outer sphere cations of many non-ferrous metals, thus exerting influence on their discharge potential, and stabilize compounds with lower oxidation level. In addition, it has been established [8] that the electrical conductivity of mixtures based on zinc chloride also depends on the cation composition. Mixtures of this kind tend to segregate, with salts of heavy metals (e.g., lead) accumulated in the lower layers of the melt [9]. Thus, by controlling the composition of the electrolyte mixtures based on zinc chloride, one can change in a desirable direction the degree of metal separation, resistance of the electrolysis bath, and, consequently, the specific power consumption.

Table 1 lists the potentials of cathodic reduction half-waves for some non-ferrous metals relative to a chlorine reference electrode in molten zinc chloride–based electrolyte mixtures.

Current–voltage measurements were carried out in potentiodynamic mode on glassy carbon electrodes at potential sweep rate of 2 mV s^{-1}. It can be seen from the presented data that, in the mixtures under study, lead and tin have more negative potentials relative to such metals as copper, silver, antimony, and bismuth. Consequently, a lead–tin alloy must be deposited at the cathode in electrochemical separation of tin-based polymetallic alloys in the molten mixtures of the indicated composition, with metals having more positive potential—antimony, bismuth, silver, and copper—concentrated at the anode. The discharge–ionization potentials of metals have different values in mixtures of different compositions. In the ternary mixture, they are shifted to a more negative range. The order of ion discharge at the cathode is preserved, but the difference between the reduction potentials of some metals, e.g., lead and copper, lead and silver, etc., increases. This is apparently due to the nature of interaction between these ions and electrolyte components, which is poorly understood. It follows from the obtained data (Table 1) that, in mixtures ensuring a greater difference between the discharge–ionization potentials of lead and tin ions and those of accompanying metal ions with more positive potential (copper, silver, antimony, bismuth), these latter must pass into the salt phase in lesser amount. This must be promoted, to a certain extent, by the reducing action of lead and tin on cations of the above metals that have passed into the salt phase

$$2M^{n+} + nPb^0(Sn^0) \rightarrow nPb^{2+}(Sn^{2+}) + 2M^0, \quad (1)$$

where M^{n+} = Ag^+, Sb^{3+}, Bi^{3+}, and Cu^{2+}.

Table 2. Amount of accompanying elements passing into the salt phase in anodic dissolution of a multicomponent alloy containing (wt %): Pb 35.8, Ag 16.8, Cu 1.20, Bi 0.24, Sn 22.5, and Zn the rest

Electrolysis conditions		Melt-electrolyte	Concentration of metals in the salt phase, wt %			Electrolysis conditions		Melt-electrolyte	Concentration of metals in the salt phase, wt %		
$i \times 10^{-3}$, A m^{-2}	Q, A h		Cu	Ag	Bi	$i \times 10^{-3}$, A m^{-2}	Q, A h		Cu	Ag	Bi
10.0	18	Binary	0.0017	0.0026	0.0038	8.0	35	Binary	0.179	0.035	0.0060
	18	Ternary	0.0012	0.0020	0.0033		35	Ternary	0.151	0.026	0.0052

The investigations performed confirm this conclusion. Indeed, a lower degree of dissolution of electropositive components is observed in anodic polarization of polymetallic alloys in a ternary electrolyte (Table 2).

This fact is very important in those cases when the purified metal or alloy is obtained at the cathode. In this connection, a three-component mixture of zinc, sodium, and potassium chlorides, containing lead chloride for ensuring mass exchange between the electrodes, was used as molten electrolyte. In order to achieve more complete recovery of lead and tin by shifting the potential of the anodic alloy to more negative values, no tin chloride was introduced into the mixture. Owing to the close values of the electrode potentials of lead and tin, this component inevitably appears in the electrolyte on passing direct current. In the course of electrolysis, a certain component ratio is attained in the electrolyte, reflecting the mass exchange between the electrodes with account of changes in the alloy composition at the anode. The change in the concentrations of lead and tin chlorides in the course of electrolysis is presented in Fig. 2.

It can be seen from Fig. 2 that tin chloride is accumulated in the course of electrolysis. In the course of lead and tin recovery from the anodic alloy, the concentration of lead chloride in the electrolyte decreases. It was noticed that the concentration of zinc chloride changes somewhat only in the initial stage of electrolysis and remains virtually unchanged afterwards.

An alloy containing (wt %): Pb 39.6, Sn 50.1, Bi 7.5, Sb 2.2, Ag 0.12, and In 0.073 was subjected to electrochemical separation. The amount of metal charged into the anode chamber was 14.2 kg, and the electrolyte mass, 71 kg. The electrolysis was conducted at 400 ± 10°C, current of 50 A (current density of 0.125 A cm^{-2}), and average voltage drop of 2.5 V. As the anodic alloy gradually dissolved, its additional amounts (3 kg per 24 h) were introduced into the anode chamber. The quantity of electricity passed through the electrolyzer was 17 050 A h, and the total amount of alloy charged into the anode chamber, 53 kg. After passing 15 225 A h of electricity, the addition of the alloy into the anode chamber was terminated and additional amounts of lead and tin were recovered at the cathode. As a result, an alloy of the following composition was obtained at the anode (wt %): Pb 1.4, Sn 6.2, Bi 65.7, Sb 24.2, In not detected.

A typical dependence of the composition at the electrodes on the quantity of passed electricity is presented in Fig. 3. The dashed line denotes the instant when additional charging of the starting alloy into the anode chamber was terminated. In the initial stage of electrolysis, dissolution of metals having the most negative electrode potentials (In, Pb, Sn) was observed. This is indicated by the manner in which the content of lead and tin in alloys at the electrodes changes. With recovery of lead from the anodic alloy,

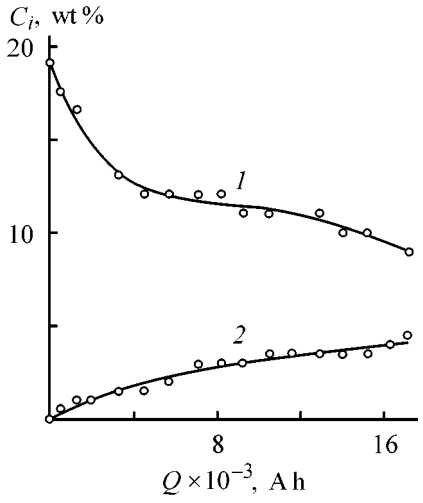

Fig. 2. Concentration C_i of (*1*) lead and (*2*) tin in electrolyte vs. the quantity Q of passed electricity. I = 60 A, j = 1500 A m^{-2}, T = 400°C.

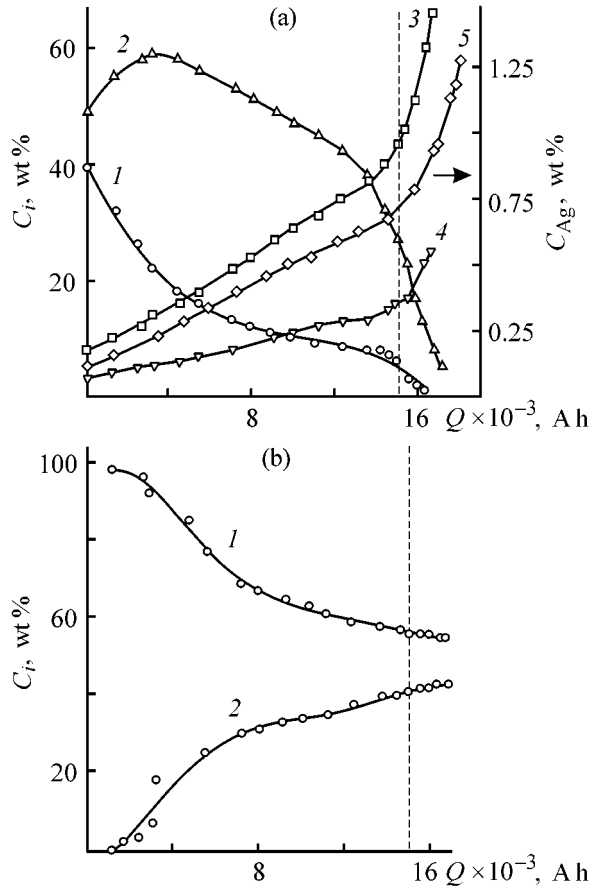

Fig. 3. (a) Anodic and (b) cathodic composition C_i vs. the quantity Q of passed electricity. (*1*) Lead, (*2*) tin, (*3*) bismuth, (*4*) antimony, and (*5*) silver. I = 60 A, j = 1500 A m^{-2}, U = 3 V, T = 400°C.

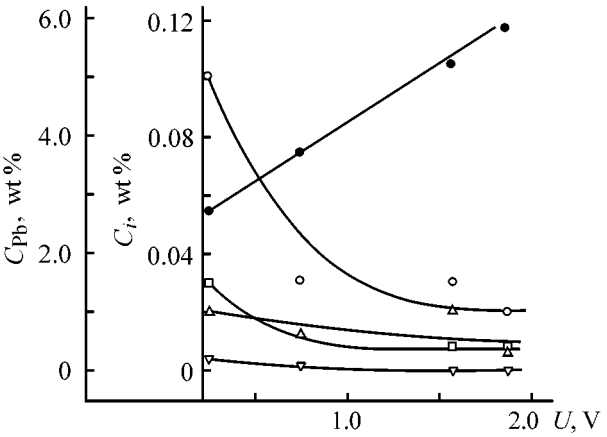

Fig. 4. Alloy composition C_i at the auxiliary electrode vs. the total voltage drop U across the electrolyzer. Q = 10 A h, T = 400°C. (*1*) Lead, (*2*) antimony, (*3*) silver, (*4*) bismuth, and (*5*) copper.

the concentration of tin in it grows. The alloy acquires a more positive potential, which favors simultaneous dissolution of lead and tin. Beginning in this instant of time (after passing 4000 A h of electricity in the given case), the content of both lead and tin in the anodic alloy starts to decrease, this occurring faster after the charging of additional amounts of the starting alloy is terminated. After passing 9350 A h of electricity, the concentration of indium in the anodic alloy was not higher than 5×10^{-3}%; further, virtually no indium was detected. Since the starting melt contained no tin ions, mainly lead was deposited at the cathode in the initial stage of electrolysis, and lead–tin alloy, in later stages, with accumulation of tin in the electrolyte. The concentration of silver in the cathodic alloy was not higher than 5×10^{-3}%, and that of Bi, 2×10^{-2}% during the entire course of electrolysis.

Generalization of the results of electrochemical separation of lead–tin alloys of varied composition demonstrates that at 95% recovery of Pb and Sn at the cathode, the anodic alloy contains 92–95% of the initial amount of Ag, 98–99% of Bi, and 93–96% of Sb.

If the anodic dissolution of the obtained alloy, enriched with Ag, Sb, and Bi, is continued, the concentration of Pb in it can be reduced to 0.04%, and that of Sn, to 0.01%. In doing so, the concentration of Ag decreases from 1.3 to 0.2% and an antimony–bismuth alloy containing up to 70% Bi remains at the anode.

In order to diminish the transfer of metals with more positive potential (Ag, Bi, Sb) from the anode to the cathode, electrolysis was studied in reactors with a porous auxiliary electrode made of graphitized carbon and placed between the anode and cathode.

It has been found [5, 6] that such an electrode hinders transfer of metals with more positive potential from the anode to the cathode. For example, the concentration of Ag in the cathodic metal was 5×10^{-3}% without the auxiliary electrode, whereas the use of a porous auxiliary electrode made it possible to reduce this concentration to 1×10^{-3}% under the same electrolysis conditions. The concentration of Sb and Bi decreased from 2×10^{-3}% to 1×10^{-3}%. The conditions of metal discharge on a porous auxiliary electrode of this kind were analyzed in detail in [5, 6]. It was shown that the discharge of metal ions at the porous electrode depends on the voltage drop across the electrolyzer, being only observed in those cases when the voltage drop across the porous electrode is greater than, or equal to, the decomposition voltage of a metal salt in a given molten electrolyte. In this connection, it is of practical interest to study how the composition of the alloy deposited at the auxiliary electrode depends on the total voltage drop across the electrolyzer. It follows from the data in Fig. 4 that the at small voltage drops and, consequently, at low electrode current densities the alloy

deposited at the auxiliary electrode contains a greater amount of metals with more positive potential (copper, bismuth, antimony, silver) and a lesser amount of lead. The main component of the alloy is tin.

The observed dependence is in qualitative agreement with the conclusions of [5, 6] and also with the general pattern of the cathodic deposition of impurity metals in refining of non-ferrous metals in salt melts [10], according to which their content N_i in the cathodic alloy is proportional to the electrode current density j

$$N_i = K_g(C_i/j^{i-n}), \quad (2)$$

where K_g is the mass-transfer constant, C_i is the impurity concentration in the salt phase, and n = 0.5–1.0, depending on the electrolysis mode.

The porous auxiliary electrode markedly diminishes the transfer of impurity metals with more positive potential from the anode to the cathode at small voltage drops across the electrolyzer, which are, however, sufficient for their discharge.

CONCLUSIONS

(1) A method was developed for electrochemical separation of tin-based multicomponent alloys, ensuring high recovery of pure lead and tin at the cathode, with 92–95% of the initial amount of silver, 98–99% of bismuth, and 93–96% of antimony remaining at the anode. The variation of the alloy composition at the electrodes with electrolysis time was determined.

(2) In order to diminish the transfer of accompanying impurity metals from the anode to the cathode, an electrolysis scheme is proposed with a porous auxiliary electrode made of graphitized carbon. The effect of electrolysis conditions on the recovery efficiency of metals accompanying lead and tin at the auxiliary electrode was determined.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodeposition of Nickel–Chromium Coatings from Chromium(III) Sulfate Electrolytes

B. A. Spiridonov and A. I. Falicheva

Voronezh State Technical University, Voronezh, Russia

Received March 14, 2000

Abstract—The kinetics of electrodeposition of nickel–chromium alloys from chromium(III) sulfate electrolytes containing succinic and malonic acids was studied. The effect exerted by the electrolysis mode and the pH of the electrolyte on the composition and quality of the obtained coatings was investigated. The possibility of obtaining protective and decorative nickel–chromium coatings containing 20–55% chromium is established.

In electroplating, chromium is deposited from chromic acid electrolytes [1–3]. However, this technique of obtaining chromium coatings has a number of essential drawbacks: very high toxicity of electrolytes, low cathode current efficiency by chromium ($CE_{Cr} \approx$ 10–15%), low electrochemical equivalent, and low throwing power [4]. To improve the process of chromium plating, modified electrolytes have been created on the basis of chromium(VI), and also new electrolytes containing chromium(III) have been developed [5–7]. Chromium(III)-based electrolytes are promising: they are harmless, their electrochemical equivalent is twice that in chromic acid solutions, and the current efficiency by chromium is greater (up to 40%) [8]. However, these electrolytes have not found wide application to the present day, which is in the first place associated with their instability caused by strong tendency of chromium toward complexation. The composition of chromium(III) complexes depends on a number of factors: chromium(III) concentration, temperature, nature of ligands, pH, etc. [9]. For example, on being dissolved in water, violet chromium(III) sulfate forms hexaaqua cations $[Cr(H_2O)_6]^{3+}$ [10] which are hydrolyzed to give $[Cr(OH)(H_2O)_5]^{2+}$ in concentrated solutions and $[Cr(OH)_2(H_2O)_4]^{+}$ in dilute solutions [11]. The hydrolysis is accelerated on heating, and the solution becomes blue-green at 40–45°C, and green [green chromium(III) sulfate, GCS] at 80–90°C [8]. The conversion of violet chromium(III) sulfate to GCS is accompanied by a shift of the peaks in their absorption spectra from λ_1 = 407 and λ_2 = 570 nm to λ_1 = 424–425 and λ_2 = 590–592 nm, respectively (λ_1 and λ_2 are the wavelengths of the absorption peaks), which confirms the occurrence of complexation [12].

It was shown in [9, 11] that GCS forms polynuclear anion complexes in moderately diluted and concentrated solutions. In these complexes Cr^{3+} ions are bound by hydroxo or oxo bridging groups and by SO_4^{2-} ions. The number of ligands in the complexes depends on the GCS concentration and the solution pH. The violet modification is converted to GCS on sufficiently fast heating (within several minutes), and the reverse transition is very slow (virtually occurring within a year) and involves transformation of bridging hydroxo groups into water molecules, and oxo groups into OH^--ions. This is accompanied by a gradual shift of the absorption peaks to shorter wave-lengths.

Chromium is known to be difficultly deposited from violet solutions [4] and deposited with very low current efficiency (CE_{Cr} 5–7%) from GCS solutions. The best results (with CE_{Cr} of up to 40%) have been achieved in chromium plating from solutions obtained by "aging" of GCS (keeping at 20–25°C for 20–25 days). The thus obtained chromium(III) sulfate was named "modified" GCS [4]. Unlike the violet and green solutions, modified GCS is rather stable: it retains its composition for a long time (within 6 months), as indicated by spectral measurements. The absorption peaks (λ_1 = 415 and λ_2 = 582 nm) occupy an intermediate position between the peaks for the violet solution and GCS [12].

However, chromium plating from solutions of modified GCS has an essential drawback: CE_{Cr} decreases with increasing electrolysis duration τ_{el} and cathode current density D_c. It was found by thermography [13] that the electrolyte temperature in the near-cathode lay-

1070-4272/01/7402-0214 $25.00 © 2001 MAIK "Nauka/Interperiodica"

er increases to 50°C and more, as τ_{el} and D_c increase. This is accompanied by fast conversion of modified GCS to GCS, which does not allow thick chromium coatings (more than 40 microns) to be obtained.

The use of pulsed current makes it possible to slow down the formation of GCS and to increase the thickness of chromium coatings to 50 μm [14].

Recently, new electrolytes based on chromium(III) salts have been developed, allowing the thickness of chromium coatings to be considerably increased (to 300 μm) and yielding hard chromium coatings [15]. However, despite this apparent progress, new chromium plating electrolytes have not found wide application.

In some cases, coatings with alloys of chromium and iron-group metals, e.g., nickel, can serve as an alternative to the coatings obtained from chromium(III) compounds [16, 17]. Solutions for depositing Ni–Cr alloy coatings are prepared from nickel plating electrolytes by addition of chromium(III) salts [3]. It is impossible to obtain Ni–Cr coatings using an electrolyte with chromic acid.

Nickel plating electrolytes are stable, and nickel is deposited with high current efficiency. Acid electrolytes for nickel plating have found the widest application. The deposition from these electrolytes involves two conjugated processes at the cathode: discharge of nickel(II) and discharge of hydrogen ions. The decrease in the concentration of the latter in the course of electrolysis results in a higher pH in the near-cathode layer (pH_s) and leads to the formation of nickel hydroxide and its basic compounds, which, being incorporated into the cathode precipitate, make higher the defectiveness of its crystalline structure. To stabilize the pH_s and obtain coatings with improved physicochemical properties, buffer components are introduced into nickel plating electrolytes, boric acid being the most widely used additive [3, 18]. However, it only exerts a buffer effect in a narrow pH range (5–6). The acid cannot be used as a buffer component in the electrolytes for deposition of Ni–Cr alloys, since chromium hydroxide is formed at much lower pH than nickel hydroxide (the solubility products $SP_{Ni(OH)_2}$ and $SP_{Cr(OH)_3}$ are 3.2×10^{-6} and 6.3×10^{-31}, respectively). More effective buffer components for plating of both nickel and Ni–Cr alloys are aminoacetic acid [19] and oxo- and dicarboxylic acids: tartaric H_2Tart, citric H_3Cit, malonic H_2Mal, succinic H_2Suc, glutaric H_2Glut, etc. [18, 20, 21].

Aqua complexes $[Ni(H_2O)_6]SO_4$, i.e. outer-orbital $4sp^3d^2$ octahedral ions, are formed in aqueous solutions of nickel(II) sulfate [9]. The introduction of oxo- and dicarboxylic acids into a nickel(II) sulfate solution is accompanied by complexation, which is confirmed by absorption spectra [20]. For example, the complex $[NiH_2Cit]^+$ is formed with citric acid. It has been found that the stability of the forming complexes with respect to a ligand decreases in the order: $Tart^{2-} > Cit^{3-} > Glut^{2-} > Suc^{2-} > Mal^{2-}$.

These results are in agreement with published data [22]. For example, in the series of acids H_2Mal–H_3Cit–H_2Tart the least stable complex is formed with malonic acid ($K_i = 7.3 \times 10^{-5}$), and the most stable, with tartaric acid ($K_i = 3.8 \times 10^{-6}$). The same buffer additives have been recommended for deposition of Ni–Cr alloys. For example, to obtain mirror-bright Ni–Cr coatings up to 3 μm thick with chromium content of 10–16%, aminoacetic acid is introduced into the sulfate electrolyte [19].

A preliminary study has shown that nickel–chromium coatings can be obtained from sulfate electrolytes (based on modified GCS) containing both succinic [23] and malonic acids as buffer and complexing additives. In the present study, we continued investigation of the electrodeposition of Ni–Cr alloys from sulfate electrolytes containing succinic and malonic acids.

EXPERIMENTAL

For the electrodeposition of Ni–Cr alloys we prepared a solution containing a brightener and nickel and chromium sulfates (modified GCS) (M): $NiSO_4 \times 7H_2O$ 1.0, $Cr_2(SO_4)_3$ 0.5; butyne-1,4-diol 1.5 ml l^{-1}. From this solution we obtained electrolytes containing succinic and malonic acids (M): electrolyte I H_2Suc 0.5, electrolyte II H_2Mal 0.1, and electrolyte III H_2Mal 0.5. For comparative studies we prepared electrolyte IV for chromium plating (0.5 M modified GCS and 0.2 M monoethanolamine) and electrolyte V for nickel plating (1.5 M $NiSO_4$, 30 g l^{-1} H_3BO_3, and 1.5 ml l^{-1} butyne-1,4-diol).

The current efficiency by the alloy (CE_{al}) was determined gravimetrically using a copper coulometer, with account taken of the alloy composition. The nickel content of the alloy was determined spectrophotometrically with dimethylglyoxime, and that of chromium, by the persulfate-silver method. The cathodic polarization was studied potentiodynamically (4 mV s^{-1}) on a P-5827 M potentiostat with a KSP self-recording potentiometer. All the potentials are given relative to a silver chloride electrode which served as a reference; platinum was used as an auxiliary electrode. Partial polarization curves were obtained by decomposition of the overall experimental curves on the basis

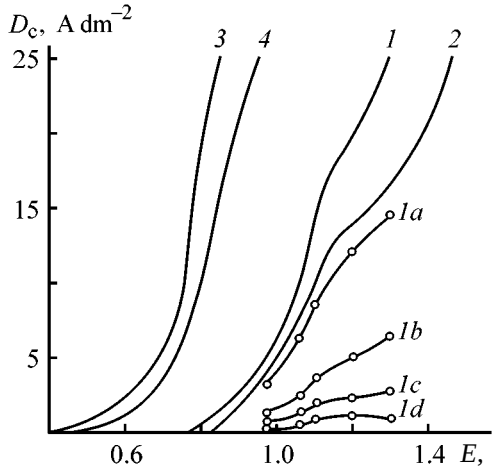

Fig. 1. Cathodic polarization curves obtained in deposition of nickel–chromium alloys from electrolytes with (*1*, *2*) succinic and (*3*, *4*) malonic acids at 50°C. D_c Current density and E potential; the same for Fig. 2. pH: (*1*, *3*, *4*) 1.0, (*2*) 1.5. H_2Mal concentration (M): (*3*) 0.1, (*4*) 0.5. of data on the current efficiencies by hydrogen, nickel, and chromium. The quality of the cathode deposits was judged from the outward appearance of the coatings; their reflectivity was studied with an FM-58 P photometer, and the morphology, with an MIM-7 microscope.

Analysis of the partial polarization curves derived from the overall curve of Ni–Cr alloy deposition from electrolyte I with succinic acid (Fig. 1) shows that chromium(III) is reduced to chromium(II) ($E^0_{Cr^{3+}/Cr^{2+}}$ = –0.41 V) simultaneously with the formation of hydrogen ($E^0_{H^+/H^0}$ = 0 V), nickel ($E^0_{Ni^{2+}/Ni^0}$ = –0.25 V), and chromium ($E^0_{Cr^{3+}/Cr^0}$ = –0.71 V). The rate of the last process (curve *1b*) exceeds that of nickel deposition (curve *1c*). One of the reasons why nickel formation is hindered is the adsorption of colloid surface-active $Cr(OH)_3$ on active sites of the cathode. The formation of chromium(III) hydroxide becomes possible at pH_s 2.9, a value that can be reached during the electrolysis [24].

With pH increasing from 1 to 1.5, the polarization curve shifts to the negative region, e.g., by 0.15 V at D_c = 15 A dm^{-2} (Fig. 1, curve *2*), which is accompanied by a decrease in the rate of hydrogen formation (Table 1). In the process, CE_{al} grows from 20 to 36%. The rate of nickel formation increases insignificantly (by a factor of ~1.2). Mention should be made of a decrease in the rate of the formation of Cr(II) ions. For example, at D_c = 25 A dm^{-2} the partial current density of chromium(II) ion formations decreases from 6.57 to 5.73 A dm^{-2}. Simultaneously, the partial current density of chromium formation increases from 1.05 to 2.91 A dm^{-2}, i.e., almost by a factor of three, and the alloy is enriched with chromium (from 32 to 51%).

It follows from these data that chromium(II) ions are formed at stronger polarization than chromium ions. It may be assumed that the process Cr^{3+} + 3e $\rightarrow$ Cr^0 is more probable, compared with $Cr^{3+} \rightarrow Cr^{2+} \rightarrow Cr^0$. A similar conclusion was made in [25]. Studies of the mechanism of chromium deposition from ammonium chromic alum have shown that the joint reduction of Cr^{3+} and Cr^{2+} ions to the metal is only possible when the fraction of Cr^{2+} ions in solution is no less than 50% of the total chromium (III) concentration in the electrolyte, which is impossible under the actual electrolysis conditions.

When pH exceeds 1.5, the rate of chromium deposition and CE_{al} decrease, the quality of the coatings is impaired, the coatings become dull, and burning appears along the cathode contour.

With D_c increasing to above 20 A dm^{-2}, the rate of chromium formation decreases (Table 1) and the alloy is enriched with nickel. Making the electrolysis duration longer has a similar effect. For example,

Table 1. Partial current densities of hydrogen, chromium(II), nickel, and chromium formation at T = 50°C

D_c, A dm^{-2}	i_{H^2}		$i_{Cr^{2+}}$		i_{Ni^0}		i_{Cr^0}	
	A dm^{-2}, at electrolyte pH							
	1.0	1.5	1.0	1.5	1.0	1.5	1.0	1.5
5	3.12	3.03	1.23	0.97	0.61	0.66	0.04	0.34
10	6.15	5.12	2.25	2.04	1.32	1.62	0.28	1.22
15	8.44	6.64	3.56	2.92	2.04	2.63	0.96	2.81
20	11.86	9.13	4.69	4.43	2.43	3.31	1.02	3.13
25	14.67	12.21	6.57	5.73	2.71	4.15	1.05	2.91

with τ_{el} increasing from 20 to 30 min, the content of chromium in the alloy decreases by approximately 20%. The hindrance to chromium deposition is due to a rise in pH_s with increasing τ_{el}, and it becomes more pronounced with growing D_c. With increasing pH_s, not only chromium(III) hydroxide is formed, but also the ionic composition of the electrolyte changes, which is accompanied by an increase in the concentration of green chromium(III) complexes whose reduction proceeds at higher cathode polarization [8].

It is evident from Fig. 1 that the overall polarization curves of Ni–Cr alloy deposition from electrolytes with malonic acid lie at more positive potentials (Fig. 1, curves *3* and *4*) than those for an electrolyte with succinic acid (curves *1* and *2*). This is apparently due to the lower stability of nickel complexes with H_2Mal.

Comparison of *E*–*i* curves for electrolytes II and III shows that the alloy is deposited with greater polarization from the electrolyte with higher H_2Mal concentration (curve *4*), which is attributable to the complexation involving not only nickel, but also chromium.

The overall polarization curve of joint deposition of nickel and chromium at room temperature lies between the curves of chromium deposition from electrolyte IV (Fig. 2, curve *2*) and nickel deposition from electrolyte V (Fig. 2, curve *1*).

The pH of electrolyte noticeably affects the position of the overall *E*–*D* curves. It is seen from Fig. 2 that the polarization curves are shifted to the negative region with pH increasing from 1 to 1.5. For example, at D_c = 15 A dm^{-2} the shift of the potential in electrolyte IV is 0.18 V (curve *2*'), and that in electrolyte V, 0.12 V (curve *1*').

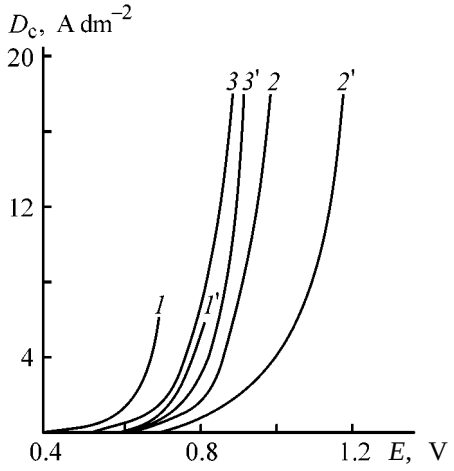

Fig. 2. Cathodic polarization curves of deposition of (*1*, *1*') nickel, (*2*, *2*') chromium, and (*3*, *3*') nickel–chromium alloy from sulfate electrolytes with H_2Mal (0.5 M) at 25°C. pH: (*1*–*3*) 1.0 and (*1*'–*3*') 1.5.

Comparison of curves *3* (Fig. 2) and *4* (Fig. 1) shows that, with temperature increasing from 25 to 50°C, the polarization of alloy deposition decreases, which is obviously due to an increase in the overvoltage of hydrogen evolution and higher solubility of chromium(III) hydroxide.

Table 2. Nickel content C_{Ni} of the alloy, CE_{al}, thickness δ, and outward appearance of coatings deposited from sulfate electrolytes with H_2Mal at *T*=50°C, τ_{el} = 20 min

	20	21.7	76.4	17.7 (D)		20	7.4	58.1	8.1 (D)
						30	9.8	60.2	14.2 (D)

Note: L lustrous, SL semilustrous, D dull.

The effect of the electrolysis modes on the nickel content of an alloy, CE_{al}, and thickness and quality of coatings is illustrated in Table 2. It is evident that CE_{al} does not exceed 22% at the maximum thickness of 25 μm, and the deposited coatings are dull. Mirror-bright coatings have a thickness of 4–6 μm. With increasing D_c, the current efficiency by the alloy grows for both the electrolytes, CE_{al} being higher in all electrolysis modes for the electrolyte with lower H_2Mal concentration. Electrolyte III has a wider D_c range for obtaining bright coatings, but in this case the deposit has smaller thickness.

CONCLUSIONS

(1) It was found that joint electrodeposition of chromium and nickel is possible from electrolytes containing nickel and chromium sulfates [modified green chromium(III) sulfate] and succinic or malonic acid as buffer and complexing additives.

(2) Analysis of the partial curves shows that chromium(II) ions are formed in electrolysis; however, they do not exert any significant influence on the formation of metallic chromium, the process $Cr^{3+} + 3e \rightarrow Cr^0$ being, therefore, more probable.

(3) Sulfate electrolytes with succinic and malonic acids were developed for depositing protective and decorative nickel–chromium alloy coatings (20–55% Cr) at D_c 5–20 A dm^{-2}, T = 50°C, and pH 1–1.5; the current efficiency by the alloy is 20–35%.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrochemical Decomposition of Phenylhydrazine on a Fibrous Carbon Electrode

O. S. Zhukova, L. P. Lazareva, and V. Yu. Glushchenko

Institute of Chemistry, Far Eastern Division, Russian Academy of Sciences, Vladivostok, Russia

Received July 13, 2000

Abstract—Oxidation of phenylhydrazine by atmospheric oxygen in aqueous solution, its catalytic breakdown in the presence of Aktilen A carbon fiber, and electrochemical decomposition on a polarized carbon fiber were studied. Formation of various organic products of phenylhydrazine breakdown, remaining in solution after oxidation with air and catalytic decomposition on a carbon fiber, was studied by spectroscopy and chromatography. Feasibility of electrochemical decomposition on a carbon fiber for wastewater treatment to remove hydrazine derivatives was examined.

Hydrazine derivatives are a class of organic compounds widely used in various industries and in pharmacology. Hydrazines being highly toxic, various methods are used to remove hydrazine derivatives from wastewater. These methods are predominantly based on decomposition of the hydrazine group by various oxidants, such as chlorine, ozone, and oxygen [1].

At present, a process for oxidative decomposition of hydrazines on the electrode surface is being developed. However, the data on this process are scarce and mainly concern the mechanism of oxidation of hydrazine and its low-molecular-weight derivatives on a charged surface. Data on electrochemical oxidation of complex aromatic hydrazine derivatives are lacking.

In most works, the electrodes are built of various carbon materials, especially carbon fibers with excellent kinetic properties in sorption and electrochemical processes, ensured by the mobility of fibrils in the fiber structure [2, 3]. These fibrous carbon materials are used as matrices for preparing modified electrodes catalytically active with respect to hydrazine decomposition. Their surface is modified with noble metals [4–7] or metal complexes [8]. In all the cases, the electrolysis of hydrazine solution at controlled oxidation potential causes electrolytic oxidation of hydrazine to nitrogen. As shown in the above papers, no electrolytic oxidation of hydrazine is observed in the case of unmodified fibrous carbon electrodes in the range of potentials extending up to the potential of oxygen evolution from water.

It should be noted that data on electrochemical decomposition of hydrazine and its organic derivatives on unmodified fibrous carbon electrodes are almost lacking. As found in [9], electrolytic oxidation of phenylhydrazine on the surface of unmodified pyrographite yields benzene, nitrogen, and a number of complex organic compounds. Since carbon materials are suitable for hydrazine oxidation, investigating the electrochemical oxidation of more complex hydrazine derivatives on a carbon fiber for their removal from wastewater is of practical importance.

Published data [10, 11] indicate that hydrazines are unstable in aqueous solutions; they are oxidized by atmospheric oxygen and decompose in the presence of various catalysts. Hence, electrochemical oxidation of hydrazine derivatives in real wastewater on fibrous carbon electrodes will be accompanied by the above processes.

In this study, we analyzed the interaction of phenylhydrazine with the surface of a carbon electrode charged from an external electric current source and the feasibility of electrochemical decomposition on fibrous carbon electrodes for wastewater treatment to remove phenylhydrazine.

EXPERIMENTAL

In this study, we used Aktilen A brand carbon fiber with specific surface area S_{sp} 1000 $m^2 g^{-1}$ and average pore radius r_{av} 2.5 nm.

1070-4272/01/7402-0219 $25.00 © 2001 MAIK "Nauka/Interperiodica"

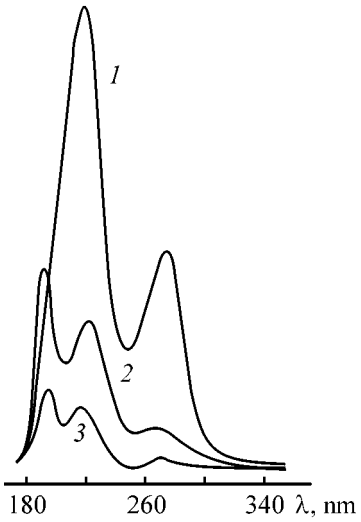

Fig. 1. UV spectra of a phenylhydrazine solution: (*1*) initial, (*2*) after contact with atmospheric oxygen, and (*3*) after contact with carbon fiber. (λ) Wavelength; the same for Fig. 6. Phenylhydrazine concentration C_0 7×10^{-3} M; the same for Figs. 2, 4–6.

Phenylhydrazine was prepared from crystalline phenylhydrazine hydrochloride [12]. Phenylhydrazine hydrochloride (200 g) was treated with a 30% solution of sodium hydroxide (100 ml), and phenylhydrazine was extracted with two 50-ml portions of benzene. The benzene extract was dried over potassium hydroxide and the solvent was removed on a rotary evaporator. Phenylhydrazine was purified by distillation in a vacuum; fraction with bp 120°C/12 mm Hg was collected.

The supporting electrolyte was a 0.1 N solution of chemically pure grade Na_2SO_4; the initial solutions of phenylhydrazine (0.2 M) were prepared in this electrolyte solution.

The electrochemical tests were carried out using a P-5827-M potentiostat and a three-electrode cell with cathode and anode volumes separated by an MB-2 bipolar membrane. The experimental procedure is presented elsewhere [13].

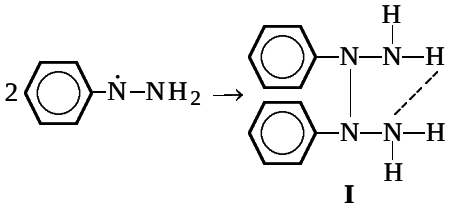
The spectral characteristics of the products of phenylhydrazine decomposition were registered on a Hitachi-220A spectrophotometer with the supporting electrolyte as reference. A chromatographic analysis of the products was performed on a Shimadzu LC 9A chromatograph equipped with a 250 × 4.6-mm Zorbax C18 column (ODS). Gradient elution was carried out with the concentration of isopropanol in the eluent varied between 0 and 100% in a single separation run; the elution rate was 0.6 ml min^{-1}. A UV detector was used; the analysis time was 1 h.

As seen from published data, the decomposition of hydrazine on the surface of a charged fibrous carbon electrode proceeds simultaneously with the oxidation of hydrazines by atmospheric oxygen and their catalytic oxidation on the fibrous carbon surface. Thus, to assess the feasibility of using carbon fibers as electrodes for electrolytic oxidation of phenylhydrazine it is necessary to elucidate the role of the above processes in the phenylhydrazine decomposition.

It is known that the oxidation of hydrazine derivatives involves formation of a diimide intermediate [14, 15]. The typical reaction is as follows:

(1)

This phenyldiimide can participate in several reactions yielding various oxidation products, such as benzene and nitrogen (main products) and hydrazobenzene, azobenzene, etc. [16]. Moreover, it was found that phenyldiimide radical participates in the radical dimerization yielding dimer **I** by the following reaction [9, 17]:



(2)

I

To elucidate the contribution of each reaction proceeding in phenylhydrazine solutions, we studied freshly prepared model solutions and phenylhydrazine solutions after their contact with air for 1–5 days. After contact with air, the model solution acquired an intense yellow-brown color, and a crystalline brown precipitate was formed and accumulated . This is probably due to the formation of product **I** by reaction (2).

The resulting solution was filtered, and a significant decrease in the phenylhydrazine concentration was found. The UV spectra (Fig. 1) show that the intensity of the peak at λ 272 nm, typical of phenylhydrazine, significantly decreases for solution brought in contact with air as compared with the freshly prepared solution. This result is confirmed by a chromatographic analysis of phenylhydrazine solutions, indicating that the concentration of phenylhydrazine in solution significantly decreases after its contact with air; moreover, additional peaks are observed in the chromatogram

(Fig. 2). One of these peaks was assigned to benzene, which was confirmed by the chromatogram of a reference benzene sample registered under the same conditions. Two other peaks belong to unidentified compounds. The decrease in the concentration of phenylhydrazine, evaluated from the peak areas, is 70%. The main pathway of phenylhydrazine consumption during contact of its solutions with air is probably precipitation of compound **I**.

Our data show that, after the oxidation of solutions with initial phenylhydrazine concentration of 300 mg l^{-1}, the residual content of phenylhydrazine in solution is as high as 36 mg l^{-1}, which significantly exceeds the maximal permissible concentration (MPC), 0.01 mg l^{-1}.

Thus, oxidation of phenylhydrazine solutions by air is characterized by insufficient conversion of phenylhydrazine, formation of significant amounts of compound **I**, and intense coloring of the solution.

Decomposition of hydrazine and its derivatives in the presence of catalysts proceeds more readily as compared with oxidation by air [18]. Published data show that hydrazine decomposes faster in the presence of such catalytically active materials as *d* metals [19], modified carbons [20, 21], and carbon fibers [22]. We studied the decomposition of phenylhydrazine in the presence of Aktilen A carbon fiber. The decrease in the concentration of phenylhydrazine is predominantly observed during its sorption on the fiber surface (Fig. 1). It should be noted that this process is accompanied by significant gas evolution associated with partial degradation of phenylhydrazine on the fiber, which is catalytically active in the phenylhydrazine oxidation. The gas evolution observed is probably due to catalytic decomposition of phenylhydrazine, which, by analogy with the case of hydrazine [18], can be described by the following equations:

$$2Ph{-}NHNH_2 + [O] \rightarrow 2Ph{-}NH_2 + N_2 + H_2O, \quad (3)$$

$$Ph{-}NHNH_2 + [O] \rightarrow C_6H_6 + N_2 + H_2O. \quad (4)$$

The chromatographic data (Fig. 2) show that, after 5-h contact with carbon fiber, the decrease in the phenylhydrazine concentration in solutions, calculated from the areas of the chromatographic peaks, reaches 70%. The decrease in the phenylhydrazine concentration after solution contact with carbon fiber for 4 days reaches 90%. All the chromatograms exhibit peaks belonging to various oxidation products. The main oxidation product is benzene. It should be noted that the content of these products in solution remains almost constant even after 4-day contact with carbon fiber.

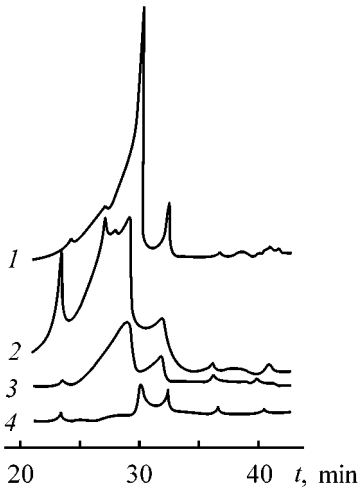


Fig. 2. Chromatograms of phenylhydrazine solution: (*1*) initial, (*2*) after contact with atmospheric oxygen for 5 days, and after contact with carbon fiber for (*3*) 5 h and (*4*) 5 days. (*t*) Time; the same for Figs. 3–5.

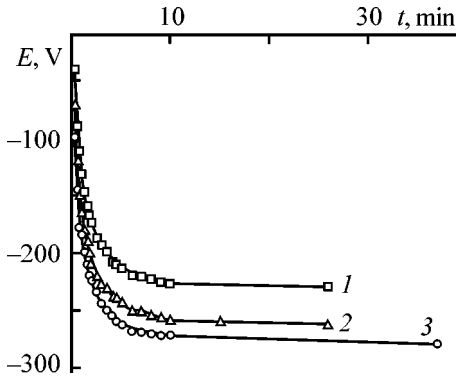

Fig. 3. Shift of the potential of Aktilen A fiber from the initial value upon addition of phenylhydrazine to 0.1 N Na_2SO_4 solution. (*E*) Potential. Phenylhydrazine concentration C_0 (mM): (*1*) 1, (*2*) 5, and (*3*) 7.

Our experimental data suggest that the decomposition of phenylhydrazine in solution in the presence of carbon fiber yields predominantly nitrogen and organic oxidation products, which are retained in solution and on the fiber surface. Thus, the catalytic decomposition of phenylhydrazine on the carbon fiber surface is unsuitable for wastewater treatment to remove phenylhydrazine. Although the catalytic conversion of phenylhydrazine is rather high, it takes too long time.

During our experiments on catalytic oxidation of phenylhydrazine on a fibrous carbon electrode with controlled potential, we found that the stationary electrode potential strongly shifts toward the cathodic region upon addition of phenylhydrazine to the solution (Fig. 3).

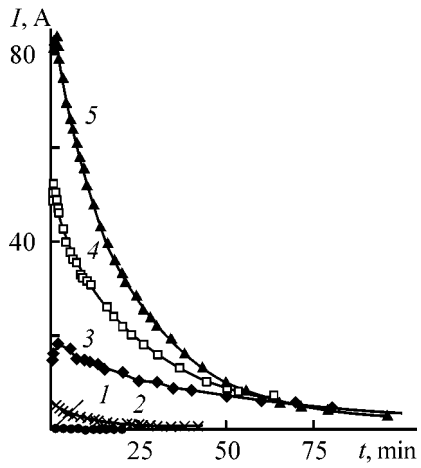

Fig. 4. Anodic current *I* on (*1, 2*) platinum gauze electrode and (*3–5*) Aktilen A fibrous carbon electrode in (*1*) 0.1 N Na_2SO_4 solution and (*2–5*) phenylhydrazine solutions. Potential *E* (V): (*1, 2, 4*) +0.25, (*3*) +0.15, and (*5*) +0.40.

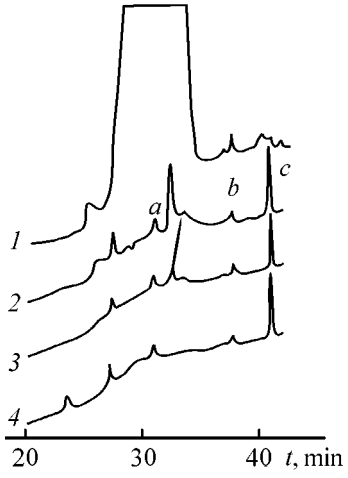

Fig. 5. Chromatograms of phenylhydrazine solutions: (*1*) initial and (*2–4*) that after contact with Aktilen A carbon fiber at various polarization potentials. Potential *E* (V): (*2*) +0.15, (*3*) +0.40, and (*4*) +0.60.

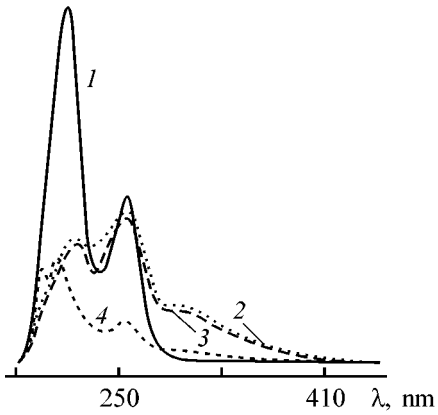

Fig. 6. UV spectra of (*1*) initial phenylhydrazine solution and (*2–4*) that after its contact with Aktilen A carbon fiber. Potential *E* (V): (*2*) +0.15, (*3*) +0.25, and (*4*) +0.40.

To study the effect of the carbon fiber potential on the oxidation efficiency, we measured the dependences of the current of anodic oxidation of phenylhydrazine carbon fiber surface at potentials of +0.15, +0.25, +0.40 (Fig. 4, curves *3–5*), and +0.60 V. All the curves have the same shape. Upon addition of phenylhydrazine the current first sharply increases and then decreases, which suggests intensive oxidation of phenylhydrazine on the charged fiber surface in the initial period. Then the oxidation current gradually decreases, which is due to the decrease in the phenylhydrazine concentration in solution, and reaches a certain constant value corresponding to the current of the Faraday reaction on the carbon fiber surface in the electrolyte solution in the absence of phenylhydrazine. This indicates that the decomposition of phenylhydrazine is practically complete at all the potentials studied.

With increasing potential of the carbon electrode, the initial current jump increases, i.e., the reaction rate depends on the polarization potential: the higher the polarization potential, the shorter the time in which the Faraday reaction current is attained.

It should be noted that the contribution from electrochemical decomposition of phenylhydrazine on the platinum current lead is insignificant. The currents of phenylhydrazine oxidation on the platinum electrode (Fig. 4, curve *2*) are significantly smaller than the total reaction current and thus the entire effect of electrocatalytic oxidation is due to the carbon fiber activity [23].

A chromatographic analysis of phenylhydrazine solutions brought in contact with polarized carbon fiber (Fig. 5) showed that the composition and content of the products of electrochemical oxidation of phenylhydrazine correlate with the electrode potential. As seen from the chromatogram of the phenylhydrazine solution after contact with the fibrous electrode at *E* +0.15 V, nearly 1% of phenylhydrazine is retained in solution along with various oxidation products (peaks *a–c*, peak *b* is assigned to benzene). Some of the oxidation products are colored, probably of aromatic nature, with a system of conjugated bonds requiring additional identification. The presence of the colored compound is manifested in the UV spectra of solutions as the band at λ 328 nm (Fig. 6).

At increased polarization potential of the carbon electrode, removal of the oxidation products from the solution is almost complete. The phenylhydrazine solutions obtained after oxidation at *E* +0.40 and +0.60 V are colorless; the oxidation of phenylhydra-

zine at these potentials is accompanied by vigorous gas evolution. The chromatograms of the resulting solutions are similar and contain peaks belonging to traces of organic compounds. Thus, the electrochemical decomposition of phenylhydrazine is almost complete even at +0.40 V. Our experimental results suggest that the unmodified carbon fiber is also active in electrochemical oxidation of phenylhydrazine and provides its almost complete decomposition and removal from solution.

Thus, the electrochemical decomposition of phenylhydrazine involves two simultaneous processes: oxidation of phenylhydrazine on the catalytic centers of carbon fibers and electrochemical oxidation in contact with the charged fiber surface. This suggests that the electrochemical decomposition of phenylhydrazine on the carbon fiber is an electrocatalytic process.

However, it should be noted that in some papers low activity of carbon fibers in the oxidation of hydrazine derivatives was observed, and it was recommended to modify the electrode surface to improve the oxidation efficiency [20–23].

CONCLUSIONS

(1) Even unmodified carbon fiber exhibits high electrocatalytic activity in electrochemical oxidation of phenylhydrazine and ensures its almost complete decomposition and removal from solution.

(2) The method of electrochemical decomposition can be recommended for wastewater treatment to remove phenylhydrazine, because the oxidation proceeds at low potentials and no additional contaminants are formed; as a result, phenylhydrazine is decomposed into environmentally safe products.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Protective Properties of Lead Coating with Tin Sublayer for Copper Current Leads of Negative Electrodes in Lead-acid Batteries

Abstract—The possibility of using a two-layer coating consisting of a tin sublayer and a lead layer for protection of copper current leads of negative electrodes in lead batteries was studied. The processes occurring on reflowing of the tin coating were investigated. The dependence of the protective characteristics of the tin coating on the heat treatment mode was shown to have extrema.

High per-unit-weight electrical characteristics and improved current distribution being of special importance for high-power lead-acid batteries, the cutting-through current leads of their negative electrodes are made of copper [1–3].

The use of copper current leads is due to the lower specific density of copper and its higher electrical conductivity, compared with that of lead, and also to the fact that copper has sufficient mechanical strength and is easily processed.

However, copper current leads can partially dissolve in sulfuric acid solutions, which is accompanied by oxygen depolarization. The subsequent electrodeposition of copper onto the paste surface in the negative electrode results in stronger gas evolution and self-discharge, lower capacity of the negative electrode, and lower efficiency of the charging current.

From the thermodynamic point of view, almost any quantity of copper ions in solution is sufficient for copper deposition onto lead surface. The minimum equilibrium concentration of copper in solution, $\alpha_{Cu^{2+}}$, at which this process begins, is 10^{-23} mol dm^{-3} as determined from the equation

$$\alpha_{Cu^{2+}} = \exp[nF(E_{Pb} - E^0_{Cu})/RT]. \quad (1)$$

Here n is the number of electrons involved in the reaction, F is the Faraday number, R is the gas constant, T is temperature, E_{Pb} is the potential of the lead electrode, and E^0_{Cu} is the standard potential of copper.

It is evident that there is no safe concentration of copper in solution, and, therefore, we can consider only its critical or practically insignificant level. It was shown in [4] that gas evolution is considerably enhanced at copper concentrations of about 4.8×10^{-4} mol dm^{-3}. Therefore, copper current leads should be protected with a coating from coming in contact with the electrolyte. The working conditions (strongly corrosive medium and cathodic-anodic polarization) impose very stringent requirements on the quality and stability of such a coating.

At present, electrodes with copper current lead protected by a galvanic lead coating are used in high-power lead-acid batteries [1–3]. The passivation of lead makes it stable in solutions of sulfuric acid, and, thus, continuous lead coatings are expected to have high protective characteristics. However, under conditions of cathodic-anodic polarization, typical of the operation of lead batteries, the surface of a lead coating is gradually loosened through $Pb \rightleftarrows PbSO_4$ transitions associated with considerable changes in the volume and morphology of the electrode material, giving rise to pores in the originally almost pore-free coatings. Simultaneously, the adhesion of the coating may deteriorate. This results in stronger self-discharge and gas evolution because of the lower overvoltage of hydrogen evolution on copper, compared with that on lead.

The protective properties of the lead coating can be improved by depositing a sublayer [3, 5]. In the present study, we analyzed the possibility of using a tin

1070-4272/01/7402-0224 $25.00 © 2001 MAIK "Nauka/Interperiodica"

sublayer deposited from a chloride-fluoride electrolyte [6].

The microstructure of electroplated coatings was studied by electron microscopy and X-ray microanalysis on a JEOL JSM-840A scanning electron microscope (Japan). When compiling X-ray images, we used a LINK ANALYTICAL AN10/85S energy-dispersion analyzer (UK). As samples were used 5×5-mm plates cut from middle parts of larger copper laminas with electrolytic coatings. Micrographs were taken at the same magnification of 2000. The mapped surface area was 5×10^3 μm^2.

The corrosion resistance of the coatings was studied in a sulfuric acid solution with density of 1.100 g cm^{-3}. The corrosion resistance was judged from the outward appearance of the coatings and from changes in their weight upon testing. After the tests, we determined the porosity of the coatings, and also the strength of coating adhesion to the copper base, by the method of marking a grid of scratches. The content of copper and tin in sulfuric acid solutions was determined by the atomic absorption method.

As shown by a microstructural study, electroplated tin coatings have a coarsely crystalline structure and are porous at layer thickness less than 25 μm. That is why we made an attempt to improve the protective properties of porous coatings by their reflowing.

To study the dependence of the structure of electroplated coatings on the reflowing duration, we used samples in the form of $105 \times 75 \times 0.2$ mm copper laminas with tin layer 5 μm thick. The samples were placed in a muffle furnace heated to 250°C and kept at this temperature for 5, 10, 20, 30, 45, and 60 s. A microstructural study demonstrated that a tin coating, subjected to reflowing for 10 s is uneven. With increasing duration of reflowing, the surface relief is smoothed out. Apparently, in the beginning of heating, a thin layer of tin covers copper at the bottom of through pores. On further heating, the thickness of the layer decreases with simultaneous relief leveling, to the point of formation of a mirror-like surface. For example, a tin coating subjected to reflowing for 30 s is a finegrained deposit.

Corrosion tests performed for three days demonstrated that the tin coating is completely absent on a sample not subjected to heat treatment. A sample heat-treated for 10 s retained a tin layer without visible imperfections. After 20 s of heat treatment, the tin layer on the sample was lost to a considerable extent, especially in those parts where tin had bright tint. Tin heat-treated for 45 s was almost completely dissolved.

Thus, with the duration of reflowing increasing to 30 s, on the one hand, the porosity of a tin coating becomes lower and, on the other, its corrosion is accelerated. The dependence of the protective characteristics of a tin coating on the duration of heat treatment shows an extremum, which points to the occurrence of at least two processes oppositely affecting the corrosion resistance of a tin layer on copper. In the absence of reflowing, tin has a certain through porosity, which ensures a contact of copper with solution. Therefore a copper–tin contact corrosion pair arises, in which tin is the anode, and copper, the cathode. Since a high hydrogen overvoltage is characteristic of tin, its corrosion takes place mainly with oxygen depolarization and depends on the rate of oxygen supply to the tin surface.

The rate of tin corrosion in a 0.1 N solution of sulfuric acid in the presence and absence of oxygen is 600 and 100–150 g m^{-2} day^{-1}, respectively [6]. Taking into account the known fact that tin corrosion occurs with oxygen depolarization, we can approximately calculate the corrosion rate V_{cor} in battery acid (density 1.280 g cm^{-3}). The weight of tin dissolved in a time τ is given by

$$M_{Sn} = Kj_{Sn}S\tau. \quad (2)$$

Here K is the electrochemical equivalent, j_{Sn} is the current density of tin dissolution, and S is the surface area of the electrode.

Under steady-state conditions

$$j_{Sn} = j_{O_2}, \quad (3)$$

$$j_{O_2} = 4FD_{O_2}C_{O_2}\delta^{-1}. \quad (4)$$

Here j_{O_2} is the current density of oxygen reduction, D_{O_2} and C_{O_2} are the diffusion coefficient and the concentration of dissolved oxygen, respectively, and δ is the diffusion layer width. Then

$$M_{Sn} = Kj_{O_2}S\tau = 4KFD_{O_2}C_{O_2}S\tau\delta^{-1}, \quad (5)$$

$$V_{cor} = M_{Sn}/S\tau = 4KFD_{O_2}C_{O_2}\delta^{-1}. \quad (6)$$

Substitution of $K = 2.1$ g A^{-1} h^{-1}, $F = 96500$ C mol^{-1}, $D_{O_2} = 2.5 \times 10^{-5}$ cm^2 c^{-1}, $C_{O_2} = 6.5 \times 10^{-7}$ mol cm^{-3}, $\delta = 10^{-2}$ cm, $S = 10^4$ cm^2, and $\tau = 24$ h [7] gives V_{cor} equal to 327 g m^{-2} day^{-1}. The corrosion rate must be much lower under real conditions, when 20 μm of lead, strongly hindering oxygen transfer, is deposited onto the tin sublayer. However, under the conditions when tin is in contact with a more noble metal (copper), which in addition

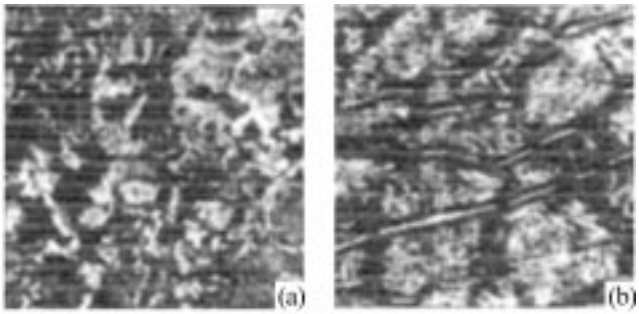

Fig. 1. Microstructure of surface layers of tin-plated samples subjected to reflowing for varied time. Reflowing duration (s): (a) 10 and (b) 30.

has hydrogen overvoltage much lower than that in tin, the mechanism of tin depolarization changes and the rate of its corrosion increases. This increase is also promoted by loosening of the lead layer in charging–discharge cycling of the battery. Thus, the absence of pores in the tin coating is a necessary condition for achieving its high protective properties. Therefore, reflowing of the tin sublayer is a necessary stage.

However, the reflowing of tin involves processes at the tin–copper interface, which strongly affect the protective characteristics of the tin coating. The distribution of copper and tin in the protective coatings on copper bases was determined by X-ray microanalysis. An analysis of such a distribution for a 5-μm-thick tin layer subjected to reflowing at 250°C for 10 s revealed the existence of a 2.5–3.0-μm-thick copper–tin transition layer on the copper side. A low-melting η-phase (Cu_6Sn_5) is formed at the tin–copper interface in the initial stage of tin reflowing as a result of copper dissolution in liquid tin. With increasing duration of reflowing, the thickness of the layer of intermetallic compounds grows noticeably. Raising the reflowing temperature also favors an increase in the thickness of this layer. Thus, the interaction of copper with molten tin results in the formation and growth of a layer of intermetallic compounds. This complicated process includes a reaction between copper and tin and the subsequent propagation of acicular crystals of intermetallic compounds across the thickness of the tin layer. It was found that the intermetallic compounds grow at a maximum rate within the first 5 s of reflowing. The intermetallic compounds of copper and tin are always of the cathodic nature with respect to tin, and, therefore, their emergence on the surface of the tin coating accelerates tin corrosion.

The microstructure of tin-plated samples subjected to reflowing in various modes is shown in Fig. 1. The structure of a coating subjected to reflowing in the optimum regime (10 s) has an appearance characteristic of electroplated tin—without acicular crystals (Fig. 1a). An X-ray analysis demonstrated the absence of copper on the surface. A coating subjected to reflowing for 30 s (Fig. 1b) has a structure of tin whose spherical crystals are pierced by acicular crystals of intermetallic compounds. An X-ray analysis demonstrated the presence of copper over the entire field under study. It is the presence of intermetallic compounds on the surface of such a coating that is responsible for its low corrosion resistance. The whole set of our experimental data confirms once more that the absence of copper in the surface layers of a nonporous coating is the condition for the high corrosion resistance of a tin coating on copper.

It follows from the aforesaid that an increase in the duration of reflowing of a tin sublayer may impair its protective characteristics, and, therefore, the choice of the duration of reflowing of the tin sublayer is one of key factors in preparing a two-layer coating.

To study the possibility of using a tin coating as a sublayer in lead-plating of copper current leads, we studied the corrosion resistance of the two-layer coating. The copper bases protected by a two-layer coating (a tin sublayer and a lead layer) were subjected to corrosion tests in sulfuric acid (density 1.100 g cm^{-3}) for 8 months. Samples with lead coating were used as reference. The results of the corrosion tests are presented in the table.

It may be safely suggested on the basis of these data that the processes occurring in a two-layer coating with tin sublayer, placed in a sulfuric acid solution, have the following mechanism. A coating without tin sublayer (sample no. 1) had good adhesion to the copper base after 5 months of tests, but the content of copper in solution was 145 mg l^{-1}, which points to rather poor protective characteristics of the coating. The accumulation of copper in solution results from the fact that the surface of lead is covered with a sulfate layer precluding contact deposition of copper from the solution.

The lead coating on a sublayer of tin not subjected to reflowing (sample no. 2), flaked away from the copper base after 5 months of tests. In this case, the content of copper in solution was 45 mg l^{-1}, which points to better protective properties of two-layer coating as compared with the coating without tin sublayer. However, the decrease in the content of copper in solution was accompanied by high content of tin (1286 mg l^{-1}). The initial weight of the tin sublayer and the concentration of tin in solution were used to determine that approximately 70–80% of the tin sub-

* τ is the duration of reflowing.

layer was dissolved in 5 months. Thus, on the one hand, tin protects copper from dissolution by the protection mechanism and, on the other, the high dissolution rate of tin not subjected to reflowing results in the loss of the coating adhesion to the base, with the resulting strong flaking, higher contact resistance, and uncovering of the copper base. An X-ray microanalysis of the copper base surface under a flaked away lead coating and of the surface of this coating from the copper base side for sample no. 2 demonstrated that, without reflowing, tin was almost completely dissolved at the copper–tin interface, as indicated by the absence of tin on the copper base surface. At the same time, the inner surface of the flaked-off lead coating consists of tin. These data indicate that in the case in question the corrosion of the two-layer coating is accompanied by a local (crevice) dissolution of the tin sublayer from the copper side. This mechanism of tin dissolution is responsible for the loss of adhesion of the protective layer to the copper base.

The lead coating deposited onto a sublayer of tin subjected to the optimal reflowing (sample no. 3, reflowing time 10 s) exhibited good adhesion to the base. After five months, the copper content in solution was 5.6 mg l^{-1}, and that of tin, less than 3 mg l^{-1}. All these facts point to a rather high corrosion resistance of tin subjected to the optimal reflowing. In this case, the corrosion of tin is accompanied by oxygen depolarization resulting from the high overvoltage of hydrogen evolution on tin under the conditions when the oxygen flow toward the tin surface is hindered by the lead layer. If a continuous layer of tin is disrupted either through the appearance of through pores (tin not subjected to reflowing) or because of the emergence of intermetallic compounds on its outer surface (on exceeding the permissible reflowing time), the mechanism of tin depolarization will change. Since copper and the intermetallic compounds have low overvoltage of hydrogen evolution, the oxidation of tin will occur with hydrogen depolarization, with the rate of hydrogen flow not limited by the layer of lead sulfate. All these factors will make higher the corrosion rate of the tin sublayer.

The lead coating deposited on a sublayer of tin subjected to reflowing in a non-optimal regime (sample no. 4, reflowing time 20 s) exhibited unsatisfactory adhesion to the base and strong flaking. The content of copper in sulfuric acid solution after five months was 6.5 mg l^{-1}, and that of tin, 1156 mg l^{-1}, which corresponds to dissolution of 65–70% of the tin sublayer. The aforesaid suggests that the increase in the reflowing time, resulting in disruption of a continuous tin sublayer through emergence of intermetallic compounds on the surface, makes higher the rate of its dissolution and, hence, leads to loss of adhesion of the protective coating to the copper base. An X-ray microanalysis demonstrated that the surface of the cop-

per base under the flaked-off coating contains 50–60% copper, and the inner side of the flaked-off coating consists of tin. The coatings with tin sublayer subjected to reflowing for 30, 45, and 60 s had similar characteristics. The data of corrosion tests performed during the subsequent three months confirmed this mechanism of the behavior of a two-layer coating with tin sublayer in sulfuric acid solutions.

Thus, our data demonstrate the exceptional importance of observing the regime of tin sublayer reflowing.

CONCLUSIONS

(1) A tin coating on a copper base, deposited from a chloride-fluoride electrolyte, is porous and shows rather poor anticorrosive characteristics. The fact that these characteristic are impaired in comparison with the corrosion rate of a compact tin is due to the accelerating effect of a $Cu/H_2SO_4/Sn$ contact pair, in which copper is cathode, on the corrosion rate.

(2) The range of heat treatment duration providing high-quality coatings was established. It was shown that making the reflowing longer results in a decrease in the corrosion resistance of a tin coating.

(3) Non-observance of the optimum regime of sublayer reflowing in fabricating a two-layer coating results in a considerable dissolution of the sublayer and loss of adhesion of the main lead layer to the copper base.

CATALYSIS

Fe_2O_3–Li_2O Catalysts for Ammonia Oxidation

N. I. Zakharchenko

Zhukovskii State Aerospace University, Kharkov, Ukraine

Received June 13, 2000; in final form, October 2000

Abstract—The catalytic properties of the Fe_2O_3–Li_2O system in ammonia oxidation were studied in the high-temperature region. The influence of the phase composition of the system on the physicochemical and catalytic properties of the catalysts were revealed. The catalytic properties of lithium ferrite, which is the most active and selective component of the Fe_2O_3–Li_2O system, were studied. The mechanism of lithium ferrite deactivation at 1273 K is considered.

Catalytic oxidation of ammonia to nitrogen(II) oxide is the basic reaction for industrial production of nitric acid [1]. Owing to the high cost, deficiency, and irrecoverable loss of industrial catalysts (platinum, rhodium, and palladium alloys) in technological processes, a search for new efficient non-platinum catalysts (NPC) is urgent. Iron(III) oxide is a promising support for NPC, used industrially as a component in the second stage of a combined system for ammonia oxidation [1, 2]. To preserve the high activity and selectivity with respect to nitrogen(II) oxide and to enhance the thermal and chemical resistance of iron(III) oxide, various modifying additives are used, and metal oxides in particular [1–6]. The available data on catalysts for ammonia oxidation are empirical, because the modern theory of catalysis allows no unambiguous prediction of a set of properties for catalysts with various compositions, preparation procedures, and chemical prehistories. Accumulation of data on the catalytic properties of the systems is of practical and theoretical interest for the development of scientifically substantiated methods for creating catalysts with prescribed properties.

Lithium oxide (Li_2O) is used as modifying additive to iron oxide–containing catalysts, but the system Fe_2O_3–Li_2O has not been studied in a wide composition range [1, 3, 5–6]. The present work is concerned with the catalytic and physicochemical properties of the Fe_2O_3–Li_2O system in ammonia oxidation.

The catalyst was prepared by thermal decomposition in air of ferric nitrate hydrate $Fe(NO_3)_3 \cdot 9H_2O$ and lithium nitrate hydrate $Li(NO_3) \cdot 3H_2O$ (both analytically pure) mixed in a calculated ratio [7]. An X-ray phase analysis was performed on a URS-50I diffractometer in Fe_{K_α}-radiation. The phase composition of the Fe_2O_3–Li_2O catalytic system is presented in Table 1.

Table 1. Phase composition of the Fe_2O_3–Li_2O catalytic system

C_{Li_2O}, wt %	Phase composition	Properties of system components	
		crystal structure	unit cell parameter *a*, nm
0	α-Fe_2O_3	Trigonal α-Al_2O_3	0.5430
0–3.5	α-Fe_2O_3 + α-$Li_{0.5}Fe_{2.5}O_4$	–	–
3.6	α-$Li_{0.5}Fe_{2.5}O_4$	Cubic $MgAl_2O_4$	0.8330

Note: X is the limiting AAM load, Y is ammonia breakthrough under the critical process conditions, and S_{NO} is selectivity by NO.

The specific surface area S_{sp} of the catalysts was measured by low-temperature adsorption of nitrogen and calculated by the BET equation (Table 2).

The catalyst selectivity by NO was determined on a flow-through installation with a quartz reactor 2×10^{-2} m in diameter [8]. The catalyst bed $(4–12) \times 10^{-2}$ m in height was composed of $(2 \times 3) \times 10^{-3}$-m granules; the ammonia concentration in the ammonia–air mixture (AAM) was about 10 vol %; the time of contact was 6.77×10^{-2} s, and the optimal pressure, according to previously obtained data [4], was 0.101 MPa. The test temperature corresponded to the maximum selectivity of a single-component iron oxide catalyst (1053 K) [7]. The compositions of the products of ammonia oxidation and thermal decomposition of nitrogen(II) oxide on the catalysts were determined by chromatographic analysis of the gas mixture for NH_3, O_2, N_2, NO, and N_2O before and after catalyst introduction, as in [9]. The sensitivity of analysis was (in 10^{-3} vol %): 3.0 for NH_3, 3.5 for NO, and 5.0 for O_2, N_2, and N_2O.

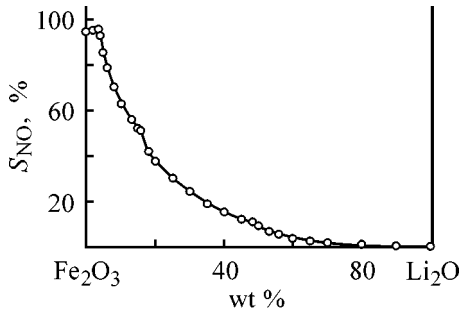

Fig. 1. Catalyst selectivity S_{NO} vs. composition of the Fe_2O_3–Li_2O system.

The limiting AAM load was determined by a procedure [3] consisting in that the catalyst is loaded to a critical state (dying), with the heat balance of a catalyst disturbed when the reaction passes from the diffusion to the kinetic region.

The results obtained in studying the catalytic properties of the Fe_2O_3–Li_2O system are presented in the Fig. 1 and Table 2.

Only two nitrogen compounds, N_2 and NO, were found among the reaction products of ammonia oxidation on the catalysts studied; under conditions far from critical no ammonia "breakthrough" occurred. Thus, the overall conversion of the initial substance is 100% and the only variable parameter of the catalytic process is the ratio between nitrogen(II) oxide and molecular nitrogen, i.e., the selectivity by NO (or by nitrogen). Thermal dissociation of NO may diminish the observed selectivity by nitrogen(II) oxide:

$$2NO = N_2 + O_2. \quad (1)$$

Experimental data on the degree of thermal dissociation of nitrogen(II) oxide on the catalysts of the system studied are presented in Table 3.

At the testing temperature and the optimal time of contact (6.77×10^{-2} s), nitrogen(II) oxide undergoes thermal dissociation in trace amounts (Li_2O and a mixture of Li_5FeO_4 with Li_2O) to 1.2% (on $Li_{0.5}Fe_{2.5}O_4$). The thermal dissociation of NO on lithium oxide does not virtually occur. At higher reagent flow velocities, i.e., with the time of contact decreasing to 1.2×10^{-3} s (critical conditions of catalyst dying), no thermal dissociation of nitrogen(II) oxide occurs, which is consistent with data on other NPC catalysts for ammonia oxidation [1, 10].

At lithium oxide concentrations of up to 3.6%, iron(III) oxide with a structure of α-Fe_2O_3 hematite (reflections with interplanar spacings of 0.3680, 0.2690, 0.2510, 0.2204, 0.1844, 0.1693, 0.1482, and 0.1452 nm) coexists with lithium ferrite α-$Li_{0.5}Fe_{2.5}O_4$ (main reflections with interplanar spacings of 0.589, 0.478, 0.374, 0.340, 0.2946, 0.2769, 0.2514, 0.2084, 0.1703, 0.1605, 0.1474, 0.1273, 0.1204, and 0.1115 nm) as a binary mixture. At the stoichiometric ratio $Li_2O : Fe_2O_3 = 1 : 5$ (3.6 wt % Li_2O) lithium ferrite is formed with a structure of the $Fe^{3+}[Li^{+}_{0.5}Fe^{3+}_{1.5}]O_4$ inverted spinel. The specific surface area of lithium ferrite (7.1 $m^2\ g^{-1}$) slightly exceeds that of iron(III) oxide (5.9 $m^2\ g^{-1}$). The selectivity of lithium ferrite by nitrogen(II) oxide is 95.5, i.e., exceeds the similar characteristic for α-Fe_2O_3 (94.7%). When the concentration of lithium ferrite, possessing the higher selectivity and specific surface area, is raised, the selectivity of catalysts of the α-Fe_2O_3–α-$Li_{0.5}Fe_{2.5}O_4$ system grows.

In the lithium oxide concentration range 3.7–15.7%, the ferrite phase α-$Li_{0.5}Fe_{2.5}O_4$ coexists with the α-modification of lithium metaferrite α-$LiFeO_2$ (main reflections with interplanar spacings of 0.239, 0.2073, 0.1467, 0.1252, 0.1200, 0.1089, 0.0925, 0.0845, 0.0640, and 0.0657 nm) as a binary mixture. The selectivity and the specific surface area of lithium metaferrite (51.0% and 3.5 $m^2\ g^{-1}$) are considerably lower than the similar characteristics for α-$Li_{0.5}Fe_{2.5}O_4$. The increase in the concentration of the low-active phase of lithium metaferrite in the α-$Li_{0.5}Fe_{2.5}O_4$–α-$LiFeO_2$ system leads to an abrupt monotonic decrease in the selectivity of catalysts by nitrogen(II) oxide.

X-ray phase analysis shows that, at lithium oxide concentrations of 15.9–48.2%, lithium metaferrite α-$LiFeO_2$ coexists with the Li_5FeO_4 phase as a binary mixture. Li_5FeO_4 ranks far below α-$LiFeO_2$, and especially α-$Li_{0.5}Fe_{2.5}O_4$, in selectivity and specific surface area (11.2% and 1.5 $m^2\ g^{-1}$). Raising the concentration of the low-active Li_5FeO_4 phase in the α-$LiFeO_2$–Li_5FeO_4 system drastically decreases the selectivity of catalysts by NO.

Table 3. Degree of NO decomposition on Fe_2O_3–Li_2O catalysts at 1053 K [Gas mixture composition (vol %): 9.5 NO, 71.3 N_2, 4.6 O_2, and 14.6 H_2O (vapor) ($\tau = 6.77 \times 10^{-2}$)]

70.0	Li_5FeO_4 + Li_2O	<0.1
100.0	Li_2O	<<0.1**

* Degree of NO decomposition.
** Virtually absent.

At lithium oxide concentrations exceeding 48.3%, Li_5FeO_4 coexists with the phase of lithium oxide as a mixture of two compounds. The selectivity and the specific surface area of lithium oxide (0.4% and 0.4 $m^2\ g^{-1}$) are lower than those of Li_5FeO_4 and all other system components. Raising the lithium oxide concentration in the Li_5FeO_4–Li_2O system leads to a monotonic decrease in the selectivity of catalysts by nitrogen(II) oxide. Thus, the selectivity of the system depends on its composition, in particular, on the ratio of phases in the two-component catalyst.

In the Fe_2O_3–Li_2O catalytic system, the only component of practical interest is lithium ferrite α-$Li_{0.5}Fe_{2.5}O_4$, the most active and selective compound surpassing even α-Fe_2O_3 in its characteristics. The other system components are low-active (α-$LiFeO_2$ and Li_5FeO_4) or virtually inactive (Li_2O).

The high-temperature oxidation of ammonia on catalysts occurs by two parallel reactions [1, 11]:

$$4NH_3 + 5O_2 = 4NO + 6H_2O, \quad (2)$$

$$4NH_3 + 3O_2 = 2N_2 + 6H_2O. \quad (3)$$

The redox mechanism of the reactions [11] is responsible for the correlation between the selectivity and strength of binding of chemisorbed oxygen to the catalysts [12]. The measure of the strength of oxygen binding to the catalyst is the heat of its chemisorption [11, 12]. For catalysts of certain nature (metals and

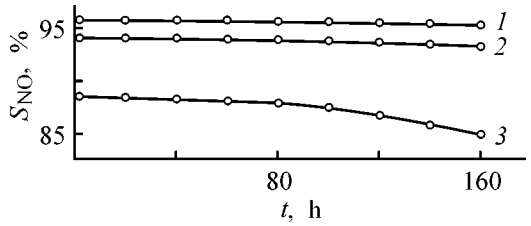

Fig. 2. Selectivity S_{NO} of lithium ferrite vs. operation time t. The linear velocity of AAM flow is 0.8 m s^{-1} (operation conditions). Temperature (K): (*1*) 1073, (*2*) 1173, and (*3*) 1273.

metal oxides) there exists an optimal energy of oxygen binding to the compound surface, ensuring the maximum selectivity by nitrogen(II) oxide [11–14]. The deviation of the binding energy from the optimal value impairs the NO selectivity and improves the selectivity by N_2. The binding energies of the surface oxygen to the individual components of the catalytic system in the oxidized state were determined from the temperature dependence of the pressure of oxygen in thermodynamic equilibrium with the surface oxygen of the compounds [15] (kJ mol^{-1} O_2): α-Fe_2O_3 143.5, α-$Li_{0.5}Fe_{2.5}O_4$ 138.2, α-$LiFeO_2$ 179.8, Li_5FeO_4 224.3, and Li_2O 242.5.

For hematite and lithium ferrite, the energies of oxygen binding to the surface are close and the selectivities differ only slightly. The energy of oxygen binding to the surface of α-$LiFeO_2$, and especially to the Li_5FeO_4 and Li_2O surfaces, much exceeds that for α-Fe_2O_3 and lithium ferrite. The product of stronger ammonia oxidation (i.e., nitrogen(II) oxide) is formed with breaking of a greater number of oxygen–catalyst bonds, compared with molecular nitrogen. This means that the selectivity by NO decreases with increasing binding energy of adsorbed oxygen [11, 13, 14], and it is this phenomenon that is observed for α-$LiFeO_2$, Li_5FeO_4, and Li_2O.

The limiting ammonia load grows with increasing specific surface area of the catalyst: it is the highest for lithium ferrite [7.82×10^3 m^3 NH_3 h^{-1} m^{-2}] and the lowest for lithium oxide (0.44×10^3 m^3 NH_3 h^{-1} m^{-2}] (Table 2). The limiting load for iron(III) oxide (6.50×10^3 m^3 NH_3 h^{-1} m^{-2}] is slightly lower than that for lithium ferrite. This parameter depends on the rate of the chemical reaction on the surface, which is, in turn, determined by the chemical composition of the catalyst. Under the critical process conditions ($\tau = 1.2 \times 10^{-3}$ s), no decomposition of nitrogen(II) oxide by pathway (1) is observed, but part of unreacted ammonia is found after the catalyst (breakthrough) (Table 2). With increasing specific surface area of the catalysts, the ammonia breakthrough decreases, which is consistent with the higher activity of such catalysts. The ammonia breakthrough is the highest for lithium oxide (1.97%) and the lowest for lithium ferrite (0.21%). In this respect, α-Fe_2O_3 is close to lithium ferrite (0.30%), their specific surface areas differing insignificantly.

The kinetic characteristics of the reaction on lithium ferrite, which is the most active and selective component of the Fe_2O_3–Li_2O system, were determined using the "burning" and "dying" temperatures of a lithium ferrite pellet, i.e., the temperatures at the critical points. The reaction rate was calculated by the method in which the temperature limits of the external diffusion region were determined using the "dying" of a catalyst pellet on lowering the AAM temperature [16]. The temperature of the catalyst surface was measured with a TPP-2 thermocouple inserted into the pellet from the side of AAM flow. A layer of lithium ferrite granules $(2.0–3.0) \times 10^{-3}$ m in size was placed between the pellet and the reactor walls to eliminate the heat loss. The kinetic parameters of the process were calculated by the Buben equation [17] solved for two reaction rates at a constant oxygen concentration. The equation has the form

$$(1 + a)\left[1 + (m - 1)\frac{a}{b}\right] - \frac{a}{\varepsilon}\left(1 - \frac{a}{b}\right) = 0, \quad (4)$$

$$a = T/T_0 - 1, \quad b = Q\beta C_0/(\alpha T_0), \quad \varepsilon = RT_0/E,$$

where m is the reaction order by ammonia, T is the catalyst surface temperature at the critical point (K), T_0 is the AAM temperature, C_0 is the ammonia concentration in the flow, α and β are the mass- and heat-transfer coefficients, Q is the heat effect of the reaction, and E is its activation energy.

The coefficients α and β were calculated from the known equations [18].

The kinetic parameters of ammonia oxidation on lithium ferrite are as follows: temperature of catalyst "burning," 527 K; ammonia concentration in AAM, 10 vol %; activation energy of the reaction, 9.54 kJ mol^{-1} NH_3; reaction order by ammonia, 0.19; and catalyst selectivity by NO (at 1053 K), 95.5%.

A study of the dependence of catalyst selectivity on operation time confirmed the high stability of lithium ferrite at 1073–1173 K (Fig. 2).

The selectivity of lithium ferrite at 1073 and 1173 K decreases by 0.4 and 0.7%, respectively, after 160 h of operation. The iron(III) oxide selectivity at

1073 K decreases by 3.5% after the same period of time [7]. With the process temperature raised to 1273 K, lithium ferrite undergoes deactivation under the influence of the elevated temperature and the reaction medium: the catalyst selectivity after 160 h of operation decreases by 3.5%. To elucidate the deactivation mechanism, the chemical and phase composition of the catalyst were studied along with its structure. X-ray diffraction patterns of the surface layer of a catalyst that operated at 1273 K contain lithium ferrite reflections and reflections with interplanar spacings of 0.485, 0.297, 0.253, 0.242, 0.2101, 0.1712, 0.1614, and 0.1485 nm, characteristic of magnetite Fe_3O_4 [19]. This conclusion is confirmed by IR spectral data. The IR spectra of the surface layer of a catalyst after operation contain the magnetite absorption peaks at 407, 427, 480, 557, 673, and 980 cm^{-1} [20]. Magnetite suppresses the catalyst selectivity, i.e., it is the low-active phase [7] (the magnetite selectivity at 1073 K is 7%). The intensity of the phase transformations occurring in the catalyst grows with increasing reaction temperature, as shown by X-ray diffraction analysis and IR spectroscopy. The increase in the concentration of the low-active phase with growing temperature results in a more abrupt decrease in the catalyst selectivity. In addition, the catalyst operated at 1273 K contains a new, relatively low-active phase—α-modification of lithium metaferrite α-$LiFeO_2$. The selectivity of α-$LiFeO_2$ at 1053 K is 51%. The appearance of the new, low-active phases of magnetite and α-$LiFeO_2$ at elevated temperatures is associated with the redox mechanism of ammonia oxidation [1, 5, 11] and is in good agreement with the results of thermodynamic calculations [21]. According to these data the high probability of lithium ferrite transformation at $T \geq 1273$ K (P_{O_2} = 0.021 MPa, air) by the reaction

$$6Li_{0.5}Fe_{2.5}O_4 = 3LiFeO_2 + 4Fe_3O_4 + O_2 \quad (5)$$

results in the formation of new phases, found in experimental studies. Similar transformations during heat treatment of lithium ferrite were observed in [22].

Under the influence of high temperature, the catalyst recrystallizes, with the specific surface area decreasing (Table 4). After 160 h of operation the size of lithium ferrite granules increases from 200 to 340 nm. The reaction conditions being far from critical, i.e., the reaction being limited by ammonia diffusion toward the catalyst surface, the specific surface area does not exert decisive influence on the selectivity of lithium ferrite [1, 3, 6]. This means that the drop in selectivity at 1273 K is mainly due to phase and chemical transformations of the catalyst. Under the critical conditions of the reaction (catalyst dying) the activity of lithium ferrite decreases and the limiting load falls from 7.49×10^3 to 2.97×10^3 m^3 NH_3 h^{-1} m^{-2}) as a result of recrystallization and a decrease in the specific surface area of the catalyst.

Table 4. Changes in selected structural and catalytic properties of lithium ferrite α-$Li_{0.5}Fe_{2.5}O_4$ during operation at 1273 K

t, h	S_{sp}, $m^2 g^{-1}$	Root-mean-square granule size, nm	Limiting load by ammonia, $A \times 10^{-3}$, $m^3 h^{-1} m^{-2}$
4	6.8	200	7.49
40	6.6	207	7.27
60	6.4	218	7.05
80	5.8	240	6.39
100	4.9	265	5.40
140	3.3	308	3.63
160	2.7	340	2.97

Thus, a set of chemical and phase transformations of the catalyst, yielding low-active and low-selective components (Fe_3O_4 and α-$LiFeO_2$) with rearranged structure is the reason for lithium ferrite deactivation. In the temperature range 1073–1173 K, lithium ferrite is a highly selective and stable catalyst for ammonia oxidation.

CONCLUSIONS

(1) The catalytic properties of the $Fe_2O_3Λi_2O$ system in ammonia oxidation were studied in the component concentration range 0–100 wt %.

(2) The catalytic properties of the individual components (α-Fe_2O_3, Li_2O, α-$Li_{0.5}Fe_{2.5}O_4$, α-$LiFeO_2$, and Li_5FeO_4) of the system were determined.

(3) The influence of the phase composition of the system on the physicochemical and catalytic properties of the catalysts, including the activity and selectivity by nitrogen(II) oxide, was revealed. The activity and the selectivity of the system depends on composition and, in particular, on the ratio of the amount of α-Fe_2O_3 phase to that of the α-$Li_{0.5}Fe_{2.5}O_4$ phase of a two-component catalyst. The same is true for the $Li_{0.5}Fe_{2.5}O_4$ and α-$LiFeO_2$, α-$LiFeO_2$ and Li_5FeO_4, and Li_5FeO_4 and Li_2O phases.

(4) The process parameters were determined on the ferrite catalyst, which is the most active and selective component of the Fe_2O_3–Li_2O system.

(5) A set of chemical and phase transformations of the $Li_{0.5}Fe_{2.5}O_4$ catalyst, resulting in the formation of low-active and low-selective components (Fe_3O_4 and α-$LiFeO_2$) with rearranged structure, is responsible for the deactivation of lithium ferrite at 1273 K.

(6) The obtained data on the catalytic properties of the Fe_2O_3–Li_2O system can be used in developing highly efficient modified catalysts for ammonia oxidation.

CATALYSIS

Pyrolysis of Straight-Run Naphtha on ZSM-5 Zeolites Modified with Alkaline-Earth Metal Cations

V. I. Erofeev, L. V. Adyaeva, and Yu. V. Ryabov

Direction of Scientific and Technical Development, Tomsk Petrochemical Combine Joint-Stock Company, Tomsk, Russia

Received September 20, 2000

Abstract—The acid and catalytic properties of high-silica zeolites of ZSM-5 type, modified with alkaline-earth metal cations in pyrolysis of straight-run naphtha, were studied.

Until recently, lower C_2–C_4 olefins, which are important raw materials for petroleum chemical processes, have been prepared predominantly by pyrolysis of various hydrocarbons at high temperatures (800–850°C). Further intensification of the process by improving the design of tubular furnace pyrocoils or using more rigorous conditions is largely hindered by the chemical features of the process and technological factors. Therefore, pyrolysis of hydrocarbons in the presence of catalysts [1–6], allowing preparation of lower olefins at lower temperatures and with higher selectivity, is rather promising.

Although numerous oxide catalysts for pyrolysis of hydrocarbons are known, search for highly efficient systems for preparing C_2–C_4 olefins is still urgent.

Extensive studies of thermal pyrolysis and pyrolysis in the presence of oxide catalysts have shown that these processes are largely similar. It has been found that the catalyst does not affect the pathway of hydrocarbon pyrolysis, which predominantly proceeds by the heterogeneous–homogeneous radical-chain mechanism, and only makes higher the concentration of free radicals in the system [4]. However, only few reports are known of the use of zeolite catalysts for hydrocarbon pyrolysis [7, 8]. In this work, we studied the acid and catalytic properties of high-silica zeolites (HSZs) of ZSM-5 type, modified with alkaline-earth metal (AEM) cations in pyrolysis of straight-run naphtha.

The initial HSZs with silicate modulus of 30 were prepared by hydrothermal synthesis from alkaline aluminosilicates [9]. The zeolites were impregnated with AEM cations using appropriate metal nitrate solutions, and the resulting catalysts were dried at 110 and calcined at 600°C for 8 h. The content of AEM cations (M^{n+}) in HSZ was 1 wt % in terms of metal. The catalytic properties of zeolite-containing catalysts were studied on a flow-type setup in the 500–700°C range under atmospheric pressure at space velocity of 3 h^{-1}. The reagents and pyrolysis products were analyzed by gas chromatography [10]. As initial hydrocarbon raw material served straight-run naphtha (Surgut Gas Processing Plant) of the following composition, wt %: 56.89 paraffinic, 32.76 naphthenic, and 8.54 aromatic hydrocarbons.

The acid properties of catalysts were studied by thermal desorption of ammonia. A catalyst sample (0.7 g) was placed in a quartz reactor, the reactor was purged with helium (130 $cm^3\ min^{-1}$) at 600°C for 2 h and then cooled to 100°C, and the sample was saturated with ammonia. The thermal desorption of ammonia was carried out on heating at a rate of 10 deg min^{-1} to 650°C [11].

The curve of thermal desorption from HSZ-30 exhibits two forms of ammonia desorption: low-temperature form I with a peak at T_{max} 203°C, typical predominantly of Lewis acid centers, namely, coordination-unsaturated aluminum cations in H-HSZ-5, and high-temperature form II with T_{max} 400°C corresponding to stronger Brønsted centers, namely, hydrogen ions of the bridging hydroxy groups in HSZ (Fig. 1, curve *1*).

Incorporation of AEM cations into HSZ affects the strength and concentration of the acid centers in zeolite-containing catalysts. Modification of H-HSZ-30 with strontium and barium cations shifts their low-temperature forms I to higher temperatures: T_{max} 213 and 212°C, respectively (Fig. 1, curves *4*, *5*). At the same time, modification of HSZ-30 with any AEM cation strongly shifts T_{max} of the high-

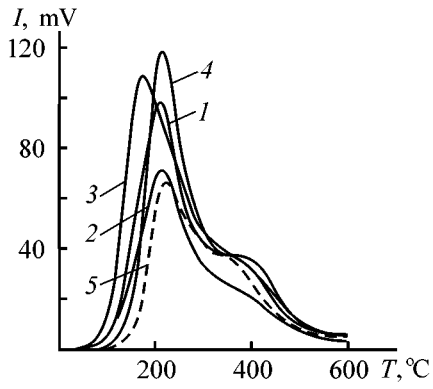

Fig. 1. Thermal desorption of ammonia from the HSZ surface as influenced by temperature. (*I*) Intensity and (*T*) temperature. Catalysts: (*1*) HSZ, (*2*) Mg-HSZ, (*3*) Ca-HSZ, (*4*) Sr-HSZ, and (*5*) Ba-HSZ; the same for Fig. 2.

temperature form II to lower temperatures, i.e., it strongly decreases the acidity of the corresponding centers. The greatest shift in T_{max} of the high-temperature form II to lower temperatures (335 and 350°C) is observed for HSZ modified with magnesium and barium, respectively (Fig. 1, curves *2* and *5*). Modification of HSZ-30 with magnesium and barium cations significantly decreases their total acidity to 610 and 525 μmol g^{-1}, respectively (Table 1) with respect to unmodified H-HSZ-30 (754 μmol g^{-1}). It should be noted that the concentration of the Lewis acid centers in the modified zeolite catalysts is 1.8–2.5 times greater than the concentration of the Brønsted acid centers, except in Ba-HSZ having close concentrations of the Lewis and Brønsted acid centers: 296 and 229 μmol g^{-1}, respectively. The common feature of all the zeolite-containing catalysts is that the addition of the AEM cations affects predominantly the strongly acidic Brønsted centers and causes their weakening, which is especially typical of Mg- and Ba-HSZs.

A study of the pyrolysis of straight-run naphtha, using zeolite catalysts modified with AEM cations, revealed a correlation between their acid and catalytic properties. In the 500–650°C range, the conversion of straight-run naphtha on HSZ-30 reaches 86–90%, which is three times the thermal conversion of naphtha on quartz powder in the same temperature range. With the temperature increasing from 500 to 650°C, the selectivity of formation of C_2–C_4 olefins increases to become 27% (11.95 and 10.52% ethylene and propylene, respectively), whereas the relative yield of aromatic hydrocarbons is 39.58% at 650°C.

Modification of HSZs with AEM cations lowers the total yield of pyrolysis products, with the relative yield of lower olefins increasing to 54.06% (Table 2, Fig. 2). With the temperature increasing from 550 to 700°C, the conversion and yield of C_2–C_4 alkenes grow for all the samples in question. The ef-

Ba-HSZ	212	350	296	229	525

Table 2. Composition of the products of straight-run naphtha pyrolysis in the presence of HSZs modified with various AEM cations

Sample	*T*, °C	Conversion, %	Yield based on initial naphtha			Content, %	
			gas	alkenes C_2–C_4	arenes	alkenes in the gas phase	arenes in catalyzate
HSZ	700	88	58.49	26.01	35.81	44.46	86.29
Mg-HSZ	700	81	66.61	44.08	19.39	66.17	58.07
	750	89	70.4	45.81	24.41	65.06	92.59
Ca-HSZ	700	83	61.27	40.26	28.15	65.7	72.68
Sr-HSZ	700	77	59.86	40.41	21.50	67.5	53.31
Ba-HSZ	700	83	67.41	48.74	21.87	72.32	67.11

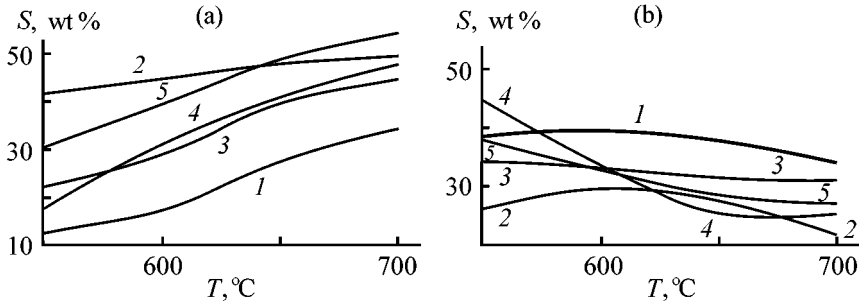

Fig. 2. Yield S of (a) C_2–C_4 alkenes and (b) arenes in conversion of straight-run naphtha. (T) Temperature.

fect of modification on the product composition is the most pronounced at lower temperatures of straight-run naphtha pyrolysis. Addition of Mg, Ca, and Ba to the zeolite increases the gas liberation from 58.5 (H-HSZ) to 67.4% (Ba-HSZ), with the content of alkenes simultaneously increasing from 44.5 to 72.3%. Addition of 1% strontium(II) to H-HSZ decreases the conversion of straight-run naphtha from 88 to 77 wt %. As compared with the initial H-HSZ, the gas evolution on the Sr-HSZ sample remains almost the same, whereas the content of alkenes in the gas phase increases from 44.5 to 67.5%.

Modification of HSZs with AEM cations by impregnation with solutions of the respective metal nitrates with subsequent calcination at 600°C leads to absorption and deposition of AEM cations in the HSZ pores and channels, decreasing the effective channel diameter, changing the diffusion and absorption characteristics, and lowering the activity and acidity of modified zeolite catalysts [12]. Modification of zeolites with AEM cations decreases not only the amount of the strongly acidic Brønsted centers (Table 1), but also the ratio between the Lewis and Brønsted acid centers, which affects the activity and selectivity of the catalysts. Dehydroxylation of the surface of zeolite-containing catalysts in the course of high-temperatures catalytic pyrolysis makes higher the concentration of the Lewis acid centers and Al^{3+} cations that escaped from the zeolite skeleton to form acid–base pairs $Al^{+}O^{-}$, which can activate hydrogen and saturated hydrocarbons yielding hydrocarbon radicals (the stage of heterogeneous generation of hydrocarbon radical). Then, during pyrolysis the hydrocarbon radical weakly bound to the surface passes into the bulk and the reaction proceeds in the homogeneous phase by the radical-chain mechanism [13, 14].

CONCLUSION

Modification of ZSM-5 high-silica zeolite with alkaline-earth metal cations increases the yield of lower C_2–C_4 olefins in pyrolysis of straight-run naphtha. High-silica zeolites modified with magnesium and barium cations exhibit the highest selectivity with respect to lower olefins in conversion of straightrun naphtha, which correlates with their acid properties.

CATALYSIS

Catalytic Activity of Homogeneous Mixtures of Metal Chelates of Polyfluorinated β-Keto Esters with Tertiary Amines in Urethane Formation

M. S. Fedoseev and T. S. Vshivkova

Institute of Technical Chemistry, Ural Division, Russian Academy of Sciences, Perm, Russia

Received August 1, 2000

Abstract—A series of Cu(II), Co(II), Mn(II), Fe(III), and La(III) chelates with unsymmetrical fluorinated β-keto esters, taken separately and in mixtures with tertiary amines, were tested as catalysts in urethane formation and in synthesis of network elastomers.

Homogeneous catalysis in the liquid phase is widely used to effect oligomerization and dimerization of olefins, polymerization of acrylates and α-oximes, and oxidation, hydroxylation, and hydrogenation of oligomers. As for synthesis of polyurethanes, data on homogeneous catalysis of this process are much less extensive as compared, e.g., with those for synthesis of olefin oligomers. At the same time, significant rise in the industrial production of polyurethane materials by reactive injection molding (RIM) is impossible without using homogeneous catalytic systems. The process is based on the pseudo-prepolymer principle of formulating monomer–oligomer compositions to provide reliable compatibility of the reactants with active catalysts and fast curing of the mixture after molding.

The following catalysts are used in RIM processes: dibutyltin dilaurate, 1-methyl-3,5-diethylphenyl-2,4- and 2,6-diamines, 2,3-dimethyl-3,4,5,6-tetrahydropyrimidine, and their molecular complexes [1].

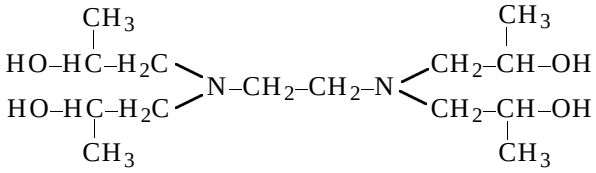
Studies of the newest RIM formulations show that the catalysts employed, such as dibutyltin dilaurate and tertiary amines, facilitate thermal oxidative degradation of the polymer [1]. Therefore, search for new catalytic systems free of these drawbacks is an urgent problem.

Previous studies of polyfluorinated copper β-diketonates have shown [2] that these compounds not only exhibit catalytic activity but also improve the structural organization of elastomers owing to donor–acceptor interaction with the polymer matrix. As a result, the properties of the materials become stable upon aging.

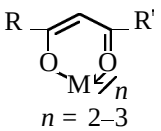
It is interesting to use this valuable property of fluorinated chelates in development of catalytic systems for RIM formulations. However, fluorinated copper chelates are less catalytically active than the existing catalysts [2], and the required curing rate cannot be ensured without adding cocatalysts with a synergistic effect. As such cocatalysts we chose tertiary amines whose synergistic effect on the catalysts is well known [3].

Here we report on a study of homogeneous catalysis with mixtures of Cu(II), Co(II), Mn(II), Fe(III), and La(III) chelates of fluorinated β-keto esters with an oligomeric tertiary amine, Lapromol-294.

Lapromol-294, a product of reaction of methyloxirane with ethylenediamine, has terminal functional hydroxy groups and is a reactive component of polyurethane compounds (chain-lengthening agent).



The rate constants of the reaction of phenyl isocyanate with *n*-butanol in cyclohexanone at 40°C in the presence of metal chelates of fluorinated β-keto esters (0.05 M) of the general formula

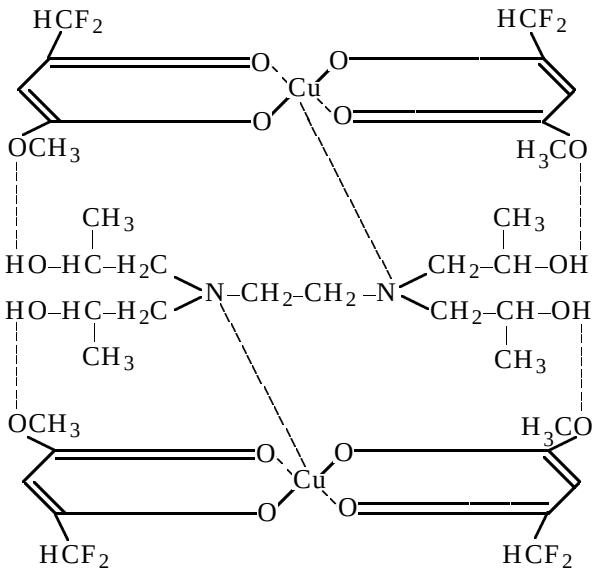


n = 2–3

are listed in Table 1. It is seen that all the chelates tested are homogeneous catalysts of urethane formation. Their catalytic activity increases in the order Co < Cu < La < Mn < Fe.

1070-4272/01/7402-0238 $25.00 © 2001 MAIK "Nauka/Interperiodica"

As seen from Table 2, addition of Lapromol-294 produces a pronounced synergistic effect. To understand its mechanism, special studies are required. The significant acceleration of urethane formation is probably due to the formation of molecular complexes of the fluorinated chelates with Lapromol-294:



The interaction of the fluorinated chelates with Lapromol is manifested in the IR spectra as changes in the carbonyl absorption bands at 1640 and 1610 cm^{-1} and as a shift of the band of the Lapromol hydroxy groups at 3300 cm^{-1} because of the formation of a hydrogen bond with the oxygen atom of the alkoxy group in the coordinated β-keto ester anion.

Then we examined the influence of the homogeneous catalysts studied in the model reaction on the processing and physicomechanical properties of castable network polyurethanes.

The network polyurethanes were prepared and tested as described in [2]. Additionally, 20 wt % Lapromol-294 was added. The processing and physicomechanical properties of the stocks and catalytically cured elastomers are listed in Table 3.

It is seen that the examined catalyst mixtures substantially accelerate the polyurethane formation, which allows them to be recommended for production of polyurethane articles by the RIM process. It should also be noted that the polyurethanes exhibit highly stable properties in thermal aging.

Thus, Cu(II), Fe(III), Mn(II), Co(II), and La(III) chelates with florinated β-keto esters are homogeneous catalysts of urethane formation; their catalytic action is considerably enhanced in the presence of the synergistic additive Lapromol-294.

EXPERIMENTAL

Chelates of Cu(II), Fe(III), Mn(II), Co(II), and La(III) with fluorinated β-keto esters were prepared at the Institute of Organic Synthesis, Ural Division, Russian Academy of Sciences, by the procedures described in [4–6]. The procedures for calculating and determining experimentally the rate constant of the reaction of phenyl isocyanate with *n*-butanol and preparing network polyurethanes were described in [2].

CONCLUSIONS

(1) A series of Cu(II), Fe(III), Mn(II), Co(II), and La(III) chelates with fluorinated β-keto esters were studied as catalysts of urethane formation (both taken separately and as mixtures with amine oligomer Lapromol-294). All the chelates exhibit catalytic activity, which is enhanced in the presence of Lapromol-294.

(2) The catalytic mixtures are active in synthesis of network polyurethanes. The processing and physicomechanical properties of the resulting castable polyurethanes were determined. These materials are highly stable in aging.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Measurement of the Solubility of Volatile Substances by Vapor-Phase Gas-Chromatographic Analysis

A. G. Vitenberg

Research Institute of Chemistry, St. Petersburg State University, St. Petersburg, Russia

Received January 27, 2000

Abstract—A new procedure is proposed for vapor-phase gas-chromatographic determination of the solubility of partly soluble volatile compounds in liquids. The method is based on successive pneumatic sampling to take small and equal portions of the equilibrium gas from the gas-liquid system containing an excess of the volatile component forming the second liquid phase. The gas-chromatographic determination of this component in the samples of the equilibrium gas makes it possible to find the slope of the isotherm describing the distribution of the substance between the liquid and gas phases near the saturation point, estimate the nonlinear portion of the isotherm, and calculate the substance content in the saturated solution.

Data on the solubility of volatile substances that are partly soluble and extremely poorly soluble in aqueous media are required to control the content of toxic impurities in industrial waste and in natural and drinking water. The shape of the distribution isotherm and, in particular, the interval of linearity and deviation from it in the region close to saturation are of interest for studying the thermodynamic properties of solutions and gas-liquid equilibrium in binary and more complex systems.

In the reference literature, data on the solubility of volatile compounds are scarce [1]. This is caused, on the one hand, by the reduced demand for such data and, on the other, by the lack of reliable methods for determining the solubility of volatile substances with an error of 0.1 wt% and less. At the same time, the development of sanitary-chemical and environmental monitoring requires reliable information on the content of volatile noxious impurities in dilute aqueous solutions at a level of 10^{-3}% and less, e.g., traces of aromatic and halogen-containing hydrocarbons in natural, drinking, and tap water. *A priori* calculation allows only approximate estimation of the content of volatile organic substances in saturated solutions.

Traditional methods for determining the solubility of partly or poorly soluble substances usually include measuring the maximal solubility of a volatile substance in a homogeneous solution; the excess soluble substance gives a second liquid phase. Such a state of the system is characterized by the practically constant concentration of the volatile component in the gas phase over the solution, independent of its amount in the liquid.

The content of the volatile substance in the saturated homogeneous solution is measured after thorough separation of two liquid phases. Fairly complex procedures using various devices are required for this purpose [2]. Their main drawback is the difficulty and sometimes impossibility of preparing and sampling a saturated homogeneous solution because of the formation of a supersaturated solution or an emulsion and evaporation of volatile components: it is very difficult to attain saturation of both phases without phase separation.

Substantial progress in determining the solubility of volatile substances in liquids is associated with the use of vapor-phase gas-chromatographic analysis (VPA) [3, 4]. This method includes measuring the content of volatile substances in the condensed phase by gas chromatography of the equilibrium gas phase. In this method, not a solution being studied but the vapor phase equilibrated with this solution at given temperature is introduced into the gas-chromatographic column. The vapor-phase analysis procedure is best adapted to analysis of a volatile component of a condensed matrix. One of the first publications on quantitative VPA is devoted to determining the solubility of hydrocarbons in water [5].

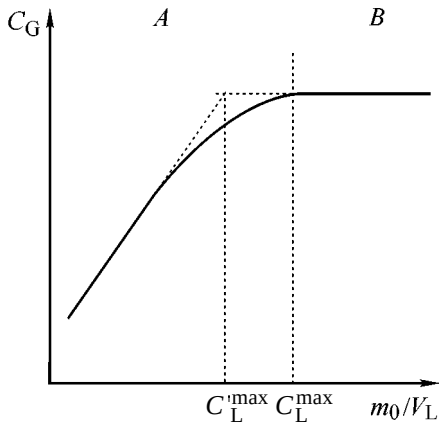

Fig. 1. Solubility of volatile substances in liquids, measured by VPA of a series of solutions with substance concentrations close to the saturation limit. (C_G) Concentration of volatile substance in the equilibrium gas; (m_0/V_L) substance concentration in the liquid phase. (*A*) Region of unsaturated homogeneous solutions and (*B*) region of phase separation of the liquid solution.

The use of VPA in measuring the solubility of volatile substances in liquids is based on the pattern of distribution of the solution components between the condensed and gas phases. The concentration dependence of the partial pressure of the volatile components of the liquid phase is described by the activity coefficients.

In dilute solutions with concentrations of volatile substances less than 0.01 wt %, the activity coefficient γ_i^∞ is practically constant [4, 6] and coincides with the activity coefficient for infinitely dilute solution:

$$\gamma_i^\infty = \lim_{x_i \to 0} \gamma_i. \quad (1)$$

In this case, Henry's law is fulfilled

$$P_i = H_i x_i. \quad (2)$$

According to this law the partial pressure P_i of the *i*th component over the solution is the product of its mole fraction x_i in the solution and Henry's constant H_i related to the saturated vapor pressure of this component P_i^0 by

$$H_i = P_i^0 \gamma_i^\infty. \quad (3)$$

At $\gamma_i \approx \gamma_i^\infty = \text{const}$ the system is characterized by a linear isotherm of distribution of the *i*th component between the liquid and gas phases. In such cases, the numerical value of the distribution coefficient

$$K = C_L/C_G, \quad (4)$$

equal to the ratio of the equilibrium weight concentrations of the substance in the liquid (C_L) and gas (C_G) phases, is practically independent of x_i.

In real solutions, at concentrations of volatile substances exceeding 0.1 wt %, the activity coefficient is usually a function of the mole fraction of the substance in the solution, i.e., $\gamma_i = f(x_i)$, and the system is characterized by a nonlinear distribution isotherm, with K depending on x_i.

In the region of liquid phase separation, the partial pressure of the *i*th component is independent of its amount in the system. In this case, the distribution isotherm is a straight line parallel to the concentration axis.

Based on such relations, the vapor-phase method for determining the solubility of the volatile substances was proposed as far back as the early 1980s [6]. The method involved preparation of a series of aqueous solutions with varied, and close to the saturation limit, concentrations of the components to be determined. The distribution isotherm $C_G = f(C_L)$ was derived from the data on the content of the component studied in the gas phase. The maximal solubility of the substance in the solution was determined by linear extrapolation of the sloping and horizontal sections of the isotherm, as shown in Fig. 1. The abscissa of the intersection point of these straight lines was taken as the maximal solubility of the substance. The method was tested by determining the solubility of chlorinated aromatic and saturated hydrocarbons in water.

Along with evident advantages, this method has a major constraint consisting in that it assumes a linear isotherm within the entire range of concentrations of unsaturated solutions up to the solubility limit. In other words, the method is based on the assumption that the activity coefficient is constant in the entire range of homogeneous solutions. When deviations of the isotherm from the linearity become substantial, the differences between the actual (C_L^{max}) and apparent extrapolated ($C_L^{'max}$) values (Fig. 1) may exceed the permissible value.

Another disadvantage of the above method is that it is labor-consuming, since it is necessary to prepare a great number of solution samples with the concentrations of volatiles less than 0.01–0.1 wt %.

We can avoid these difficulties by successively taking small and equal portions of the equilibrium gas from the gas–liquid system containing an excess of the volatile substance (i.e., in the case when a second

liquid phase exists). In the VPA method with pneumatic sample dosing into a chromatograph [7, 8], it is possible to take from the vessel containing the mass m_G of a volatile substance strictly specified mass fractions

$$m_g^i/m_G = (p' - p)/p' \quad (5)$$

(m_g^i is the weight of the substance sampled from the gas phase) and to vary them in a wide range by changing the pressures in the thermostated vessel with the solution studied, p', and in the chromatograph evaporator, p.

Repeated vapor-phase dosing of the samples into the chromatograph with a strictly fixed pressure jump from p' to p gives a series of chromatograms shown schematically in Fig. 2. The range of the phase separation of the liquid (even if it is not found visually) is characterized by chromatograms with constant height and area of peaks (section *I*) and, hence, constant weight of the substance taken. As the volatile substance is removed from the heterogeneous system, its amount decreases until the second liquid phase disappears, or, in other words, until the nonvariant equilibrium transforms into a monovariant one. This instant corresponds to the last chromatogram with the maximal peak height. Further vapor sampling decreases the concentration of the volatile substance in the solution, and the chromatograms of the equal portions of the equilibrium gas have the form of a series of peaks with decreasing height (sections *II* and *III*). The range of the constant ratios of peak heights (or areas) in the chromatograms of successive portions of the gas phase (section *III*) corresponds to the linear part of the distribution isotherm or to the region of infinite dilution, in which the distribution coefficient K is practically independent of the solute concentration. The range of the nonlinear isotherm (section *II*) is characterized by variable, and lower than unity, ratio of masses of the substance sampled from the system.

It should be noted that, in accordance with the features of VPA with pneumatic sampling [7, 8], the ratio of the gas (V_G) to liquid (V_L) phase volumes

$$r = V_G/V_L \quad (6)$$

in the vessel is the fundamental parameter determining the conditions of the experiment. The conditions for the use of the method with tolerable error can be expressed by the inequality

$$K \le r \le (p'/p). \quad (7)$$

These simple criteria allow, within the scope of the above method, determination of the boundaries of each portion of the distribution isotherm in the case

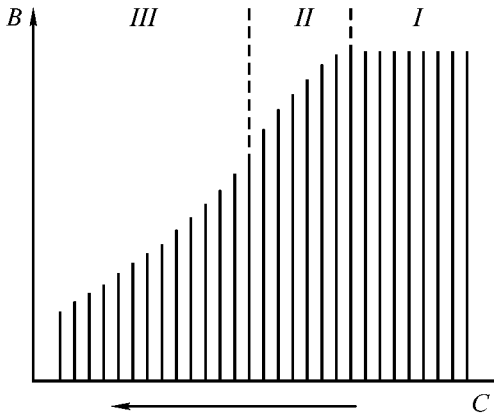

Fig. 2. Successive dosing of the equilibrium vapor into a chromatograph from a liquid–gas system with phase separation of the liquid phase: (*B*) detector signal and (*C*) successive dosing of the liquid phase. (*I*) Region of phase separation of the liquid phase, A_G^{n+1}/A_G^n = const; (*II*) nonlinear portion of the distribution isotherm, $A_G^{n+1}/A_G^n < 1$; and (*III*) linear portion of the distribution isotherm, $A_G^{n+1}/A_G^n = 1$. (A_G) Area of the chromatogram peak; (n) chromatogram ordinal number. Each vertical line is the amplitude of the detector signal or the peak height in the chromatogram.

of partly or poorly soluble volatile liquids with the distribution coefficient not exceeding several tens.

The thus obtained data can be used to calculate the substance solubility. One of the possible, and the simplest calculation procedures is as follows. In the case of a known saturated vapor pressure P_0 of the pure substance whose solubility is measured its concentration in the saturated solution C_L^0 can be calculated by the equation

$$C_L^0 = \frac{m_0 - m_g - m_0^n}{V_L}, \quad (8)$$

where m_0 is the mass of the substance introduced into the system before sampling, m_g is the calculated mass of the substance in the gas phase over the saturated solution, and m_g^n is found from VPA as the mass of the substance forming the second liquid phase and removed from the system in the first portion of the distribution isotherm (Fig. 2).

m_g is calculated with regard to the saturated vapor pressure of the volatile substance at the experiment temperature by the formula following from the fundamental gas equation of state:

$$m_g = \frac{P^0 \alpha_w V_G}{RT} M, \quad (9)$$

where R is the universal gas constant, M is the molecular mass of the volatile substance whose solubility

Fig. 3. (*I*) Producing elevated pressure in the vessel with a sample and (*II*) dosing the gas phase into the chromatograph.

is measured, and α_w is the coefficient reflecting the solubility of water in the organic phase.

When this solubility can be neglected, $\alpha_w = 1$. In other cases, α_w can be calculated by the formula

$$\alpha_w = \frac{P_i'}{P_i^0} = \frac{A_G''}{A_G^0} \quad (10)$$

from the saturated vapor pressure over pure (dry) organic substance, P_i^0, which is determined as the peak area A_G^0 in the chromatogram and that over the water-saturated organic phase, P_i'', also found as the peak area A_G'' in the chromatogram obtained under standard conditions.

The mass of the second organic phase can be calculated as the sum of masses of the volatile substance, m_g', sampled in each of n dosings into the chromatograph in the first portion of the distribution isotherm:

$$m_g^n = \sum_1^n m_g^i. \quad (11)$$

Since m_g'/m_g is the fraction of the substance sampled from the gas phase in each dosing of the saturated vapor into the chromatograph, we can write, in accordance with Eq. (5),

$$m_g^n = m_g^i n = m_g \frac{p' - p}{p'} n. \quad (12)$$

Then

$$C_L^0 = \frac{m_0 - m_g\{1 - n[(p' - p)/p']\}}{V_G}. \quad (13)$$

The condition for attaining the maximal accuracy of measurements is

$$(m_0 + m_g) >> m_g^n. \quad (14)$$

The inequality

$$n\frac{p' - p}{p'} \le \frac{\Delta C_L^0}{C_L^0}, \quad (15)$$

which relates the analysis conditions to the relative error of C_L^0 measurements, can serve as the criterion of the fulfillment of inequality (14). In practice, this condition is attained when no more than 3–5 samplings are performed on the horizontal portion of the distribution isotherm. In this case, the error of substance solubility measurement is determined by the procedure and the accuracy of introducing the mass m_0 and may be no worse than several percents.

EXPERIMENTAL

Measurements were performed on a Tsvet-500M chromatograph with a flame-ionization detector and a 200 × 0.4-cm glass column packed with 10% OV-101 as a stationary phase on Chromosorb W-AW (0.16–0.2 mm). The temperatures of the column, evaporator, and detector were 60, 120, and 180°C, respectively. The carrier gas flow rate in the chromatographic column was 20 ml min^{-1}, the detector signal was recorded by a TZ-4620 recording potentiometer and processed using Multikhrom package for Windows B.1.38 (IBM-486).

The equilibrium gas phase was dosed into the chromatographic column pneumatically by a special attachment for vapor-phase dosing of samples [8] heated to 150°C (Fig. 3). This attachment is installed on the evaporator of a standard chromatograph and provides introduction of a known volume (0.5–2.0 ml) of a gas phase from a vessel (in which the equilibrium is reached) into a chromatographic column through a short (5–7 cm) hot line.

Aqueous solutions with a given microcontent of benzene, toluene, chlorobenzene, chlorodibromomethane, dichlorobromomethane, 1,1-dichloroethane, and 1,2-dichloropropane were prepared using precisely weighed samples of the respective chemically pure grade substances under conditions excluding their loss.

The analysis procedure was as follows. Into a 15-ml standard vessel *1* for medical preparations (“penicil-

lin") was introduced 3–5 ml of water preliminarily checked for the absence of volatile organic substances. The vessel was plugged with elastic rubber plug *2* and hermetically sealed in a screw chuck *3*. To avoid sorption, the surface of the rubber stopper was protected with a Teflon film or aluminum foil. Then, 2–10 μl (accurate sample) of aromatic or halogenated hydrocarbon were introduced into the vessel with preliminarily calibrated Hamilton glass microsyringe by puncturing the rubber plug with the syringe needle. The vessel with the water sample was kept at 20, 25, and 30°C for 15 min with intermittent agitation of the liquid to reach the equilibrium. The sample temperature was controlled by water flow through screw chuck nipples *3* from a liquid thermostat. Then, the vessel with the sample in the temperature-controlled screw chuck was punctured with the needle *5* of a batcher through the elastic rubber plug to a length of 5–10 mm so that the needle end was in the gas phase. At this time, the cock *6* should be in position *I*, when the pressure p' in the vessel exceeds the pressure p in the chromatographic column. In this case, the standard manometer *7* shows the pressure of the carrier gas in the chromatograph evaporator *8*. By reversing the cock in position *II*, the gas space of the vessel *1* is connected with the chromatograph evaporator *8*. In this position, the sample of the equilibrium gas passes in pulsed mode into the chromatographic column owing to the pressure difference. At this time, manometer *7* shows the pressure p' in the auxiliary line. After a chromatogram was recorded, the stopcock *6* was returned to position *I*. The repeated dosing of the equilibrium gas into the chromatographic column was performed by reversing the cock *6* to position *II*. The pneumatic dosing of the gas into the chromatograph and the methods of the quantitative vapor-phase analysis were described in detail in [3, 7, 8].

The possibility of measuring the solubility of volatile substances in liquids by the above-described method was checked with aqueous solutions of the simplest aromatic and halogenated hydrocarbons. The choice of these compounds was governed by the availability of reliable reference data on their solubility in water and also by their high volatility and low VPA detection limit in solution (10^{-6}–10^{-8}%).

The measurement procedure is illustrated by an example of repeated pneumatic sampling of the equilibrium gas from a vessel with saturated aqueous solution of benzene with a minor (~1 mg) excess of pure benzene forming the second liquid phase. Data in Table 1 shows that the first eight chromatograms reflect the phase separation portion of the distribution isotherm, the ratio of the peak areas A_G^{n+1}/A_G^n being virtually unity. This isotherm portion is completed by a peak with the area of 9019 μV s^{-1}. Then, the system becomes two-phase (the liquid becomes homogeneous), and the portion of a nonlinear isotherm starts, which is completed with the 12th chromatogram with peak area of 7963 μV s^{-1}, giving way to the linear portion of the distribution isotherm. It should be noted that the upper limit of concentrations bounding the linear portion of the isotherm is only 15% less than the concentration of the maximal benzene solubility in water.

Similar series of chromatograms for toluene, chlorobenzene, 1,1-dichloroethane, and 1,2-dichloropropane allowed calculation of the solubility of these compounds in water. Data of Tables 2 and 3 show that our method provides acceptable accuracy in measuring the solubility of such volatile substances. Deviations from the reference data obtained by traditional methods [6, 9] do not exceed 10% and are within the error limits for the methods compared. However, differences between the results of the vapor phase extrapolation method [6] and our vapor-phase analysis

with manifold sampling of the equilibrium vapor from the same vessel (Table 3) are somewhat greater. These deviations are systematical and probably associated with the above-noted features of the extrapolation calculation of the maximal solubility of volatile substances in liquids, which can give underestimated results.

CONCLUSION

The method was developed for determining the solubility of volatile substances, based on the principles and technique of vapor-phase gas-chromatographic analysis with repeated pneumatic sampling of the equilibrium vapor from the system and its dosing into a chromatographic column. Within the 0.1–10 g l^{-1} concentration range, the error of this method does not exceed 10%.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Diffusion, Osmotic, and Electroosmotic Permeability of Reverse-Osmosis Membranes

V. B. Korobov and S. I. Lazarev

Tambov State Technical University, Tambov, Russia

Received October 4, 1999; in final form, February 2000

Abstract—The diffusion, osmotic, and electroosmotic permeabilities of MGA-100 and OPM-K membranes in aniline- and morpholine-containing aqueous solutions were studied in the concentration range 0.4–12.5 kg m^{-3} at 20–45°C. The behavior of the permeabilities with solution concentration and temperature is analyzed and accounted for.

In [1–3] were presented results obtained in studying by the methods of reverse osmosis and electroosmofiltration the purification of wastewater produced at plants manufacturing chemicals-additives for polymeric materials. As objects of study served aniline- and morpholine-containing kinds of wastewater (both model and real) and polymeric reverse-osmosis membranes MGA-100 and OPM-K. It was shown that the baromembrane methods are promising for wastewater purification.

The present communication reports the results obtained in studying the diffusion, osmotic, and electroosmotic permeabilities to aniline and morpholine of reverse-osmosis membranes MGA-100 and OPM-K.

These data are necessary for analyzing transport phenomena and performing engineering calculations of membrane processes [4–5].

EXPERIMENTAL

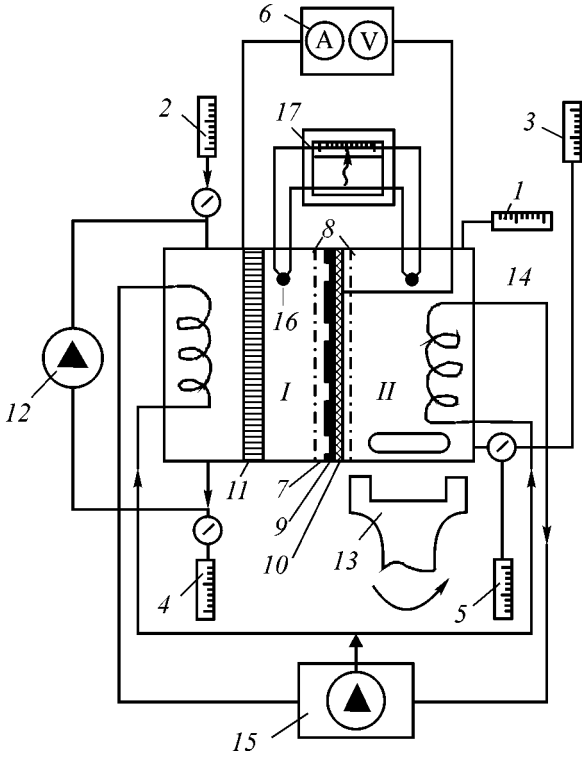
A schematic of the experimental setup for studying the diffusion, osmotic, and electroosmotic permeabilities is presented in the figure.

The setup comprises a thermostated cell *I–II*, measuring capillary *1*, vessels for the starting (*2*, *3*) and spent (*4*, *5*) solutions, and a dc power source *6*.

The main unit of the setup is the *I–II* cell. It consists of two chambers, *I* and *II*, separated by a membrane *7* under study.

In analyzing the diffusion and osmotic permeabilities, a membrane is pressed between grids *8* made of acrylic resin in order to prevent its bending under the action of hydrostatic pressure and temperature stresses.

In studying the electroosmotic permeability, the membrane is fixed between chambers *I* and *II* in another way. A membrane under study is placed on a piece of Whatman paper, in its turn laid on the po-



Schematic of the experimental setup. For explanations see the text.

rous electrode (cathode) *10*. The membrane, Whatman paper, and the porous electrode are pressed between the acrylic resin grids. In addition, one more porous electrode (anode) *11* is placed in chamber *I*.

The solution in chamber *I* is stirred by means of its continuous circulation effected by a centrifugal pump *12*, and that in chamber *II*, by a magnetic stirrer *13*. The necessary solution temperature in the cell chambers is maintained by heat-exchangers *14* in the cell chambers, through which water from thermostat *15* is circulated. The temperature in chambers *I* and *II* is monitored with Chromel-Copel thermocouples 16 connected to a potentiometer *17*. Constant temperature within the chambers is maintained automatically. The volume of the cell chambers is 0.6×10^{-3} m^3, and the working area of the membranes, 2.275×10^{-3} m^2. Chambers *I* and *II* are made of acrylic resin.

The diffusion and osmotic permeabilities were studied as follows. Preliminarily, a membrane to be studied was inspected and placed in a vessel with regularly renewed distilled water for 24 h and then used to assemble a measuring cell (figure). Chamber *I* was filled with a solution of certain concentration, and chamber *II*, with distilled water. To attain steady diffusion and osmotic flows, the solutions were kept in the chambers for a long time (11–13 h) and then discharged. After that the cell chambers were washed with distilled water for 15 min. Then the chambers were filled as in the preceding experiment: chamber *I*, with a solution of the same concentration, and chamber *II*, with distilled water. The content of the chambers was sampled through spent-solution vessels *4* and *5* and replenished through the starting-solution chambers *2* and *3*. Further, an experiment was performed to determine the diffusion and osmotic permeabilities. The experiment duration was 3 h.

The amount of water that passed across the membrane and the intensity of its osmotic transfer into chamber *I* were determined from the decrease in volume in the measuring capillary *1*. The amount of solute that passed across the membrane in the direction opposite to that of the osmotic transport as a result of diffusion was determined after an experiment was complete and the solutions were discharged into spent solution vessels *4* and *5*. The content of solutes in the samples was determined by photocolorimetry for aniline and by titrimetry for morpholine.

The coefficients of diffusion P_d (m^2 s^{-1}) and osmotic P_{os} (m^5 kg^{-1} s^{-1}) permeabilities were calculated under assumption of independent flows of solute and solvent (water) across the membrane by the formulas

$$P_d = \frac{C_2 V_2 X}{(C_1 - C_2) S \tau}, \quad (1)$$

$$P_{os} = \frac{\Delta V X}{(C_1 - C_2) S \tau}, \quad (2)$$

where V_1 and V_2 are volumes of chambers *I* and *II* (m^3); C_1 and C_2 are the concentrations of diffusate in, respectively, chambers *I* and *II* at the final instant of time (kg m^3); ΔV is the amount of solvent transferred across the membrane (m^2); S is the membrane surface area (m^2); X is the membrane thickness (m); and τ is the experiment duration (s).

The electroosmotic permeability was determined as follows. The cell was assembled and preliminary operations were performed: the chambers were filled with working solution and the solution allowed to stay until a steady state was attained, chambers *I* and *II* were washed with distilled water and again filled with the working solution, and a necessary temperature regime was estallished. After that, first a trial and then the main experiments were carried out. For this purpose, a voltage was applied to the electrodes and a necessary current density was set. In view of the intensive solvent transfer, the duration of the preliminary and main experiments was 30 min. The amount of solvent (water) that passed across the membrane and the intensity of its electroosmotic transfer into chamber *II* were determined from the increase in volume, ΔV, in the measuring capillary *1*.

The electroosmotic permeability coefficient P_{eos} (m^3 A^{-1} s^{-1}) was calculated by the formula

$$P_{eos} = \frac{\Delta V}{Si\tau}, \quad (3)$$

where i is the current density (A m^{-2}).

Tables 1 and 2 give the coefficients of diffusion and osmotic permeabilities of MGA-100 and OPM-K membranes in relation to the concentrations and temperatures of aqueous aniline and morpholine solutions. It follows from the presented data that the diffusion permeability to aniline changes with its concentration in solution in opposite directions for the MGA100 and OPM-K membranes: for the former, the diffusion permeability first grows with increasing concentration, passes through a maximum, and then starts to fall, whereas for the latter it first falls, passes through a minimum, and then starts to grow.

The dependences of the permeability on the morpholine concentration in solution are more complex, but also antibate for the MGA-100 and OPM-K membranes.

Let us analyze the behavior of the diffusion permeability with the solution concentration in more detail.

It is known that the diffusion permeability depends on quite a number of factors: types of membranes and solutions [6]; nature of interaction between the solute and membrane, solvent and membrane [7]; etc. When passing across the membrane, the solute may diffuse both through the pore space filled with the solution and through amorphous regions of a swollen membrane. With increasing concentration of the solutions under study, molecules of aniline or morpholine, being incorporated into the matrix of cellulose acetate membrane, probably plasticize it [8–10], with the result that the diffusion permeability coefficient grows with increasing solute content of the solutions in the low-concentration range (Table 1).

Simultaneously with membrane plasticization, there possibly occurs the process of narrowing and even complete volume filling of pores, caused by solute sorption onto the membrane [11]. With this phenomenon dominating, the diffusion permeability coefficient decreases (Table 1).

However, for solutions of morpholine in water, the process of membrane "loosening" probably dominates, with the result that the diffusion permeability increases in this case (Table 1).

As mentioned above, the runs of the dependences of the diffusion permeability coefficients are the opposite for the OPM-K and MGA-100 membranes.

In addition, the diffusion permeability is somewhat lower for OPM-K membranes, compared with those of the MGA100 type. Apparently, the magnitude and the type of dependence of the diffusion permeability on the solution concentration are mainly affected by the membrane nature and the radius distribution of pores in the selective layer of membranes. Unfortunately, published data on the pore characteristics of reverse-osmosis polyamide membranes are extremely scarce and mostly unspecific [12, 13].

Sorption factors probably predominate for OPM-K membranes at low concentrations. With increasing solution concentration, the pore space decreases, as also does the diffusion permeability. With the solution concentration solution increasing further, the solute penetrates into the polymer matrix and the diffusion permeability coefficient starts to increase. However, for morpholine solutions, the diffusion permeability coefficient reaches a maximum after a certain increase and then (with the concentration growing futher) again falls, if only slightly (Table 1). This is probably due to the overall dehydration of the membrane.

In addition to the already mentioned reasons for a change in the diffusion permeability coefficients, there presumably are also other factors affecting this parameter: nonlinear concentration dependence of the distribution coefficients of the solute [11], possibility of associate formation, membrane charge, etc. With increasing temperature, the diffusion permeability always grows for the investigated types of membranes (Table 1), in agreement with the commonly accepted concepts [8].

Let us consider the behavior of the osmotic permeability of membranes. Table 2 presents the osmotic permeability coefficient in relation to the solution concentration and temperature. It can be seen that the osmotic permeability of OPM-K membranes much exceeds that of MGA-100 membranes. This is probably due to differences in the nature of the membrane materials, their structural characteristics, and sign of charge on the membranes.

With increasing solution concentration, the sorption of solutes by membranes leads to their dehydration, to changes in their porous structure (because of membrane swelling and pore narrowing), and, as a result, to a dramatic decrease in osmotic permeability (Table 2). A similar pattern has been observed in studying the osmotic permeability of heterogeneous and homogeneous ion-exchange membranes [14, 15].

With increasing temperature, the osmotic permeability of the membranes grows (Table 2). This is in agreement with the commonly accepted concepts concerning the effect of temperature on the coefficients of water diffusion in polymers [8].

To conclude, it should be noted that the coefficients of osmotic permeability to aniline and morpholine solutions of the reverse-osmosis membranes studied are rather low, which also agrees with the commonly accepted concept of a rather low osmotic pressure of aqueous solutions of low-molecular organic substances [6].

Table 3 presents the electroosmotic permeability coefficients in relation to solution concentration and temperature. It follows from Table 3 that the electroosmotic permeability coefficients depend on the type

of membrane (being higher for the OPM-K membrane, compared with MGA-100) and solution concentration (also falling with increasing concentration).

It is known [14, 16] that the electroosmotic flow of liquids depends on a number of factors, the most important of which are the solution viscosity, ion hydrability, nature of membrane matrix, its moisture content, degree of homogeneity, adsorption capacity, etc.

With increasing concentration of the solutions, their viscosity and electrical conductivity increase somewhat. Consequently, the electroosmotic permeability coefficient must decrease with increasing solution concentration. This is confirmed by the investigation performed (Table 3).

With increasing temperature, the viscosity of the solutions decreases somewhat, but their electrical conductivity grows to a greater extent. This suggests that the behavior of the electroosmotic permeability with temperature may vary. In the case in question, the key factor is, probably, the fast rise in electrical conductivity with increasing temperature, which leads to a substantial decrease in electroosmotic permeability with increasing solution temperature (Table 3).

As shown by experimental studies (Table 3), the electroosmotic permeability coefficient is independent of current density for the systems studied. The experiments were mainly performed at a current density of 13.5 A m^{-2}, and, in part, at 20°C and current densities of 8.8 and 19.8 A m^{-2}.

The difference between the electroosmotic permeability coefficients of the MGA-100 and OPM-K membranes is presumably due to the difference in the nature of the membrane materials, in their porosities, charge, etc.

CONCLUSIONS

(1) The diffusion, osmotic, and electroosmotic permeabilities of MGA-100 and OPM-K membranes strongly depend on the nature of solute and its concentration and temperature.

(2) The diffusion permeability of MGA-100 membranes exceeds that of OPM-K membranes. The dependences of the diffusion permeabilities on the concentration of aniline or morpholine are rather complex and show opposite kinds of behavior for these membranes.

(3) The osmotic permeability of MGA-100 membranes much exceeds that of OPM-K membranes. For all kinds of membranes and solutions studied, the osmotic permeability decreases dramatically with increasing solution concentration.

(4) Over a wide range of concentrations studied the electroosmotic permeability of MGA-100 membranes is lower than that of OPM-K membranes. With increasing concentration, the electroosmotic permeability falls.

(5) With increasing temperature, the diffusion and osmotic permeabilities increase, and the electroosmotic permeability falls.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Deironing of Water with Natural Carbonate-containing Tripoli

Received September 15, 1998; in final form, March 2000

Abstract—The possibility of using natural carbonate-containing tripoli for water deironing was studied. Factors are considered determining the efficiency of tripoli in Fe(III) absorption.

Siliceous rocks constituted by various finely disperse opal-crystobalite formations (opokas, diatomites, tripolis) occur in nature either in pure form or with varied content of an associated component—most frequently of the carbonate-clay type [1]. The content of calcium carbonate in rocks of this kind is 0–60%, and that of clay, 0–15%, for different deposits.

In contrast to purely siliceous rocks, which are raw materials serving for various purposes and having their traditional areas of application (e.g., in manufacture of construction cement [1, 2]), carbonate-clay materials have not found wide use.

Large deposits of carbonate tripoli have been discovered in many regions of Belarus, Lithuania, and Russia. In this connection, it is of current interest to reveal the possibility of their use in the national economy.

With account of the ability of the carbonate component to absorb ions of heavy and non-ferrous metals from aqueous solutions [3–11], carbonate tripolis show ecological promise.

Compared with carbonates, carbonate-containing silicas are characterized by more developed porous structure and lower solubility [12], and also by ability to form strong granules [10], and, therefore, their use in water purification seems to be more promising than that of carbonates.

Previously, the high efficiency of carbonate-containing tripolis in recovery of a number of heavy metal ions: Cr(III), Pb(II), Zn(II), and Cu(II), has been demonstrated [9, 10]. The present communication reports the results obtained in studying their efficiency in deironing. A search for new high-efficiency materials for deironing of ground water and wastewater is an important task [13].

EXPERIMENTAL

The experiments were done with a tripoli containing 43.5% calcium carbonate, with its aqueous extract characterized by pH 8.6.[1] A representative sample of a natural carbonate tripoli and four its thermal modifications obtained by calcination in air at 500, 600, 700, and 800°C (designated as tripoli-500, tripoli-600, etc.) were used in the study.

The absorption of Fe(III) ions under static conditions from 0.001–0.1 N nitrate solutions with pH 1.7–2.3 was studied at 15–20°C at liquor ratio M = 1 : 125 [M = s : l, where s denotes the mass of solid sorbent (g), and l, the volume of liquid phase (ml)].

The experimental procedure was as follows: 25 ml of a solution was poured over 0.2 g of sorbent (0.09–0.25-mm fraction) and the mixture was kept for 1 day with periodic stirring. In studying the kinetics of the process, the experimental technique was similar, but the time of contact between the solution and the solid phase was varied between 10 min and several days. The solution was separated from the solid phase and the residual content of iron in the filtered solution was determined by complexometric titration or atomic-absorption spectrometry.

The solid phase was washed with water, dried in air, and subjected to X-ray phase analysis (DRON-2.0 diffractometer, Cu_{K_α} radiation).

The variation of the solution pH during sorption was monitored with an EV-74 ion meter.

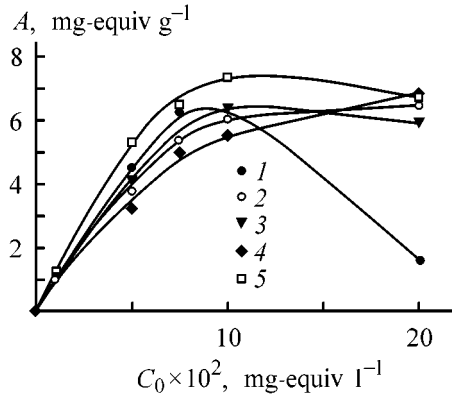

Fig. 1. Curves of Fe(III) ion absorption by natural tripoli and its thermal modifications. (*A*) Absorption and (C_0) initial concentration of $Fe(NO_3)_3$ solutions. (*1*) Starting tripoli, (*2*) tripoli-500, (*3*) tripoli-600, (*4*) tripoli-700, and (*5*) tripoli-800.

The experiments on deironing of real ground water under dynamic conditions were performed as described below.

Curves of Fe(III) ion absorption from $Fe(NO_3)_3$ of varied concentration by a carbonate-containing tripoli not subjected to thermal treatment and by samples calcined for 2 h at temperatures in the range from 500 to 800°C are shown in Fig. 1. It can be seen that the maximum amount of absorbed Fe(III) A_{Fe} is 7.5 mg-equiv g^{-1} [tripoli-800, $C_{Fe(NO_3)_3} = 10^{-1}$ g-equiv l^{-1}].

The absorption curves plotted in the coordinates A_{Fe}–$C_{0\,\{Fe(NO_3)_3\}}$ [$C_{0\,\{Fe(NO_3)_3\}}$ is the initial concentration of the iron(III) nitrate solution] for some of the samples pass through a maximum at $C_{0\,\{Fe(NO_3)_3\}} = 10^{-1}$ g-equiv l^{-1}, the most pronounced for the sample not subjected to thermal treatment.

According to published data [5–8, 14], calcium carbonate absorbs cations of doubly charged metals from acid and neutral solutions through formation of less soluble M(II) carbonates or hydrocarbonates. Carbonates of triply charged metal ions [Fe(III), Al(III)] cannot be obtained in aqueous solutions because of their hydrolytic decomposition [15]. When brought in contact with carbonates, these metals form hydroxides by the reaction

$$Fe(NO_3)_3 + CaCO_3 + HOH \rightarrow Fe(OH)_3 + CO_2 + Ca(NO_3)_2. \quad (1)$$

According to reference data, the pH of the onset of iron hydroxide precipitation depends on the Fe(III) concentration, being equal to 1.5 and 2.3 for solutions with concentrations of, respectively, 0.03 and 3 g-equiv l^{-1} [16]. Complete deironing of solutions of concentration 0.15 g-equiv l^{-1} with a calcium carbonate sorbent is observed at equilibrium solution pH 3.5 [14]. In deironing of solution with Fe(III) concentrations in the range $(5.4–43.0) \times 10^{-3}$ g-equiv l^{-1} with calcite, complete precipitation of iron hydroxide was observed in [17] at equilibrium solution pH exceeding 7.

The results obtained in deironing of aqueous solutions with the use of carbonate tripolis (Fig. 1, Table 1) also indicate that the amount of absorbed iron(III) and also the peak in the A_{Fe}–$C_{0\,\{Fe(NO_3)_3\}}$ curves (Fig. 1) correlate with how pH varies in the system under study. Table 1 lists the concentrations and pH values of the starting and equilibrium (brought in contact with the sorbent) $Fe(NO_3)_3$ solutions, and also the calculated degree of purification to remove iron(III) from solutions of various concentrations.

It can be seen from Table 1 that the pH of iron nitrate solutions with concentration lower than 10^{-1} g-equiv l^{-1} (Fig. 1, region before the peak in the curve) is 1.86–2.34 before the contact with the sorbent. After purification, i.e. after bringing the solution in contact with carbonate tripoli, the pH values increase to become 1.9–11.04. The degree of purification of such solutions to remove iron(III) is very high, but, nevertheless, it approaches 100% only in those cases when the pH of the equilibrium iron(III) solution exceeds 7, in agreement with the results of [17].

The pH of iron(III) nitrate solutions with concentrations exceeding 10^{-1} g-equiv l^{-1} (Fig. 1, region after the peak in the A_{Fe}–$C_{0\,\{Fe(NO_3)_3\}}$ curve) is 1.7–1.8 before and 1.6–1.8 after sorption. The absorption of iron(III) from these solutions is not accompanied by any significant change in pH. The extent of iron hydroxide precipitation in this region decreases, which is the reason for the appearance of the peak in the absorption curve.

For calcined tripoli modifications, the peak in the A_{Fe}–$C_{0\,\{Fe(NO_3)_3\}}$ curve is less pronounced. According to previously obtained data [9], thermal treatment of a carbonate tripoli in the range 500–800°C does not change significantly its phase composition, but is accompanied by a decrease in the intensity of calcite peaks. The alkaline properties of the tripoli are not

changed significantly in the process. Table 2 lists the pH values of an aqueous extract and solubilities of carbonate tripoli before and after thermal treatment. It can be seen that the pH of the aqueous extract is three units higher for tripoli-800, compared with the starting carbonate tripoli, being equal to 11.99. The solubility of the carbonate-containing tripoli [calcium(II) content in solution] also grows. The thermal treatment is accompanied by partial decomposition of calcite to give a more soluble and more alkaline component—calcium oxide, and by an increase in the pH of the aqueous extract. The increase in the sorbent alkalinity levels out the peak in the absorption curves.

Table 2. Solubility in water and pH value of an aqueous extract of a carbonate tripoli before and after thermal treatment; pH of starting distilled water 5.1

Parameter	Starting tripoli	Tripoli-500	Tripoli-800
pH of aqueous extract	8.05	8.22	11.99
Ca(II) concentration in aqueous extract, mg-equiv l^{-1}	1.1	1.6	10.7

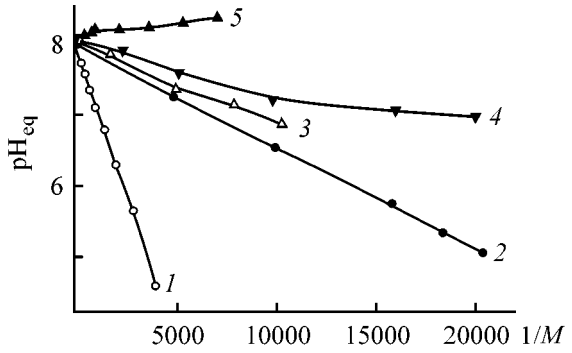

Fig. 2. pH of equilibrium solution vs. ratio of the tripoli mass to the volume of the starting aqueous solution. (*M*) Liquor ratio. pH of the starting solution: (*1*) 2.6, (*2*) 3.5, (*3*) 4.6, (*4*) 6.5, and (*5*) 7.5.

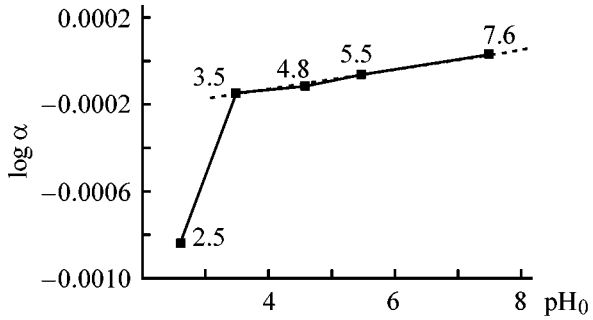

Fig. 3. Slope α of pH_{eq}–1/*M* straight lines vs. the pH_0 of the starting solution.

Thus, it is clear that the efficiency of iron(III) absorption from aqueous solutions by natural carbonate-containing tripoli is governed by the pH of equilibrium solution, pH_{eq}. This parameter is, in turn, a function of the pH of the starting solution and the liquor ratio used in purification, equal to the ratio of the solid sorbent mass to the volume of a solution being purified.

Table 3. Physicochemical characteristics of artesian water

Characteristic	Average value of parameter
Chromaticity	<20
pH	8.0
Chloride ions, mg l^{-1}	9.2
Sulfate ions, mg l^{-1}	15.1
NH_4^+, mg l^{-1}	0.52
Nitrate ions, mg l^{-1}	4.7
Nitrite ions, mg l^{-1}	Trace
Total iron, mg l^{-1}	3.65
Mn(II), mg l^{-1}	0.01
Fe(II), mg l^{-1}	3.31
Oxidizability by permanganate ions, mg l^{-1}	5.35
Alkalinity, mg-equiv l^{-1}	4.35
Temperature, °C	9.2

To determine the relationship between these parameters, the variation of the pH value in the system tripoli–water was studied in a wide range of s : l ratios and pH_0 values. A weighed portion of a sample was placed in distilled water with different pH_0 values adjusted using nitric acid or sodium hydroxide, kept for 1 day, and then the pH of the equilibrium liquid phase was determined. The obtained results are presented in Fig. 2 in the form of a set of pH_{eq}–1/*M* curves for solutions with different pH_0 values. As it can be seen from the figure, the value $pH_{eq} > 7$, necessary for complete purification to remove iron(III), is achieved for $Fe(NO_3)_3$ solutions with pH_0 in the range from 2.6 to 3.5 at 1/*M* of 1500–7000. For less acid solutions, this value is 20000 and more.

The initial portions of the pH_{eq}–1/*M* curves (Fig. 2) are approximated by a straight line with small standard deviation and are described by equations calculated by the least-squares method. All the approximated curves converge to a single point with sufficient accuracy. Hence follows that the existing system of five equations describing the dependence of pH_{eq} on 1/*M* at different pH_0 values can be combined into a single equation by determining the relationship between the slope of an experimental curve and the pH_0 value (Fig. 3). The data in Fig. 3 indicate the existence of a linear relation between tan α and pH_0 in the pH_0 range 3.5–7.5, expressed by the equation

$$\tan\alpha = -(-31.372 - 4.1627pH_0) \times 10^{-5}. \quad (2)$$

Thus, the relationship between pH_{eq}, pH_0, and liquor ratio M = s : l for solutions with pH falling within the above interval can be expressed as a linear equation

$$pH_{eq} = 7.98 - (31.372 - 4.1627pH_0) \times 10^{-5} M. \quad (3)$$

Relation (3) can be used to evaluate fast the efficiency of carbonate-containing materials in purification of real solutions. For example, at a weighed tripoli portion of 1 kg and prescribed pH_0 6, the solution volume V_l (l) that can be neutralized to pH 7 can be readily calculated using Eq. (3):

$$V_l = \frac{(31.37 - 4.16\,pH_0) \times 10^{-5} T}{7.98 - pH_{eq}} = 6.5 \times 10^5. \quad (4)$$

Equation (3) and its variations can also be helpful in evaluating the efficiency of a material in water pu-

Table 4. Efficiency of Fe_{tot} removal

rification under dynamic conditions. In doing so, account should be taken of the kinetics of attainment of acid-base equilibria under dynamic conditions and the physical form of a sorbent.

The efficiency of carbonate-containing tripoli in deironing was confirmed in purification of artesian water.[1] The physicochemical characteristics of the water are presented in Table 3. It can be seen that, for this water source, the content of iron ions exceeds manyfold the maximum permissible concentration (MPC) of 0.3 mg l^{-1}.

As indicated by chemical analysis data, iron is present in the water of this source mainly in the form of Fe(II). According to published data, deironing is the most efficient in solutions of triply charged iron. The oxidation process Fe(II) $\rightarrow$ Fe(III) occurs in air under the action of atmospheric oxygen. Under the dynamic purification conditions, the process of saturation with oxygen of the solutions being purified is frequently intensified by additional aeration [13].

Water purification was performed in dynamic filtration mode with simplified aeration [13] on a column charged with granulated tripoli (column diameter 35 mm, charge bed height 600–650 mm, grain diameter 3 mm at 3-mm length). To obtain a granulated form of the sorbent, a humid mixture of carbonate tripoli with 10% addition of bentonite clay as binder was formed in an FP-015 granulator into cylindrical grains dried in air and then calcined at 650°C.

As it can be seen from the data in Table 4, water is purified to remove iron ions to the MPC standard. The rate of filtration is 10–12 m h^{-1} at sorbent bed height in the column of no less than 60–70 cm.

[1] Strumen' water intake (Pinsk).

CONCLUSIONS

(1) Carbonate-containing tripoli exhibit high efficiency in Fe(III) removal from aqueous solutions and are of interest as promising material for deironing of ground water and wastewater.

(2) Deironing is the most efficient under conditions when the relation between the tripoli mass and the starting solution volume ensures a pH value of the equilibrium solution higher than 7. The tripoli capacity with respect to iron reaches in this case the maximum value of 7.5 mg-equiv l^{-1}.

Received November 13, 1999; in final form, June 2000

Abstract—The mineralization of the products of detoxification (neutralization) of yperite–lewisite mixture by electrochemical oxidation was studied. A procedure for separation of potassium salts and arsenic compounds by electrocoagulation was developed. A possibility of using the resulting potassium salts as fertilizers for agriculture was discussed.

Russia's stock of chemical warfare includes nerve gases (sarin, soman, and VX) and blister gases [yperite, lewisite, yperite–lewisite mixtures (YLMs)]. The universally adopted concept of their disposal envisages two stages. In the first stage, war gases are neutralized to give reaction masses unsuitable for further use for military purposes. The second stage involves combustion or processing of the reaction mass into a commercial product.

The procedures for chemical detoxification of blister gases are rather well developed and tested at pilot plants; they can be used for practical purposes. It has been found that the detoxification products, excluding arsenic compounds, belong to compounds of hazard grade III [1].

It has been proposed to utilize the reaction masses by combustion. However, an analysis of the approaches to the development of processes based on the combustion of reaction masses showed that their realization results in the formation of large amounts of environmentally hazardous wastes [2]. This, in turn, caused counteraction of environmentalists and the public. In addition, the combustion of the reaction masses is highly expensive: the construction cost of gas-cleaning systems reaches 30% of the total expenditure [3].

The aim of this study was to develop a procedure for enviromentally safe conversion of detoxification products of YLMs into mineral fertilizers for agriculture and arsenic compounds serving as secondary raw materials for the reprocessing indusrtry.

As the object of study served a process solution from detoxification of YLM obtained by its alkaline treatment in the presence of monoethanolamine.[1] The process solution from YLM detoxification (so-called neutralizate) is a turbid brown-green liquid with black flakes.

The organic components of 300 ml of the YLM neutralizate were mineralized using a universal laboratory pilot setup (Fig. 1).

The electrolyzer parameters were as follows: operating volume 100 ml, anode (graphite) surface area 300 cm^2, voltage 6 V, and anodic current density 0.01 A cm^{-2}. The electrocoagulator parameters were as follows: operating volume 300 ml, surface area of aluminum electrodes 1040 cm^2, ac current density 0.01 A cm^{-2}, and voltage 6 V.

The electrolysis process and the composition and amount of organic products were monitored by high-resolution ^1H NMR spectroscopy [4].

The ^1H NMR spectra were recorded on a WP80SY NMR spectrometer (Bruker, Germany) under the standard conditions with compensation of ^1H signals from

residual water, which were used as internal reference in determining the chemical shifts (δ = 5.00 ppm at pH > 2).

The arsenic content in the solutions was determined on an AAS-5100 Zeeman atomic-absorption spectrometer (Perkin–Elmer, US).

During electrolysis, the composition of the gas phase was determined on an MM8-80 mass spectrometer (VG, UK). Samples for mass-spectrometric analysis were withdrawn from the gas phase of the mixer (Fig. 1). Before the experiments, the reactor was purged with argon.

The total content of salts and organic substances in the solutions was determined gravimetrically from the weight of the dry residue after extraction separation of organic and inorganic fractions from the solid phase with chloroform.

The contents of sulfates, chlorides, nitrates, and carbonates in the YLM neutralizate and products of its processing were determined by the procedures described in [5, 6].

The pH in aqueous solutions was monitored with Lachema universal indicator paper (Czech Republic). The pH of ^1H_2O and ^2H_2O solutions was determined on an I-155 pH meter (Armenia). Potassium chloride, potassium hydroxide, nitric acid, and chloroform used in the experiments were of chemically pure grade.

From data presented in [1], the main products of alkaline detoxification of yperite, a YLM component, in the presence of monoethanolamine are *N*-(2-hydroxyethyl)thiomorpholine and monoethanolamine hydrochloride [Eq. (1)]. The main products of alkaline detoxification of lewisite [7], a YLM component, are acetylene, sodium arsenate, and sodium chloride [Eq. (2)]:

$$S(C_2H_4Cl)_2 + 2H_2NC_2H_4OH = [S{=}C_4H_8{=}NHC_2H_4OH]Cl + [HOC_2H_4NH_2]Cl, \quad (1)$$

$$ClCH{=}CHAsCl_2 + 4NaOH = CH{\equiv}CH + NaAsO_2 + 3NaCl + 2H_2O. \quad (2)$$

Thus, *N*-(2-hydroxyethyl)thiomorphine, monoethanolamine, sodium chloride, and sodium arsenate would be expected to be the main components of YLM neutralizate.

The ^{1}H NMR spectrum of the organic phase of YLM neutralizate, extracted with chloroform, contains three multiplets at δ 4.0, 3.0, and 1.5 ppm (Fig. 2).

The multplets at 4.0 and 3.0 ppm can be assigned to protons of free monoethanolamine (Fig. 3c) and *N*-(2-hydroxyethyl)thiomorpholine. In addition, ^{1}H signals from S–CH_2 groups of the thiomorpholine fragment may appear at 3.0 ppm [8].

The position of the ^{1}H NMR signals of N–NH_2 groups of the thiomorpholine fragment can be predicted by comparing the ^{1}H NMR spectral char-

acteristics of the organic fraction of the YLM neutralizate with those of the morpholine derivative 2-methylene-*N*-hydroxyethylmorpholine, for which the ^{1}H signals of the N–CH_2 groups are observed at 2.5 ppm [9]. In passing from morpholine to thiomorpholine, it is quite reasonable that the ^{1}H signals of thiomorpholine are shifted upfield by 0.3–0.4 ppm owing to the lower electronegativity of sulfur in comparison with oxygen. The additional upfield shift of the ^{1}H signals of the N–CH_2 groups of thiomorpholine by approximately 0.7 ppm can be attributed to the effect of the unshared electron pair of nitrogen atom, as was observed for festuclavine [10].

Thus, the multiplet at 1.5 ppm can be assigned to protons of the N–CH_2 group of *N*-(2-hydroxyethyl)-thiomorpholine. The spin–spin coupling of all the three multiplets observed in the ^{1}H NMR spectrum (Fig. 2) confirms this suggestion.

The fact that the main organic product of YLM neutralization is a thiomorpholine derivative is additionally confirmed by the ^{1}H NMR titration of the neutralizate (Figs. 3a, 3b), indicating a downfield shift of all the signals of the spectrum in passing from alkaline to acid medium. A similar shift is observed for the ^{1}H NMR signals of monoethanolamine (Figs. 3c, 3d). The pH ranges of the shift observed for the neutralizate and monoethanolamine are the same (pK 7.2), which is characteristic of the conversion of monoethanolamine and *N*-(2-hydroxyethyl)thiomorpholine into the corresponding hydrochlorides.

With account of the accumulated experience on degradation of some toxins and pollutants [8, 11–13], we selected electrolysis as the most universal and efficient technique and the method of electrocoagulation with the use of soluble aluminum electrodes, since arsenic salts that are formed in electrocoagulation as stable aluminum arsenates difficultly soluble in water.

The YLM neutralizate was subjected to electrolysis in the presence of potassium hydroxide on the laboratory pilot setup described above. The relation between the components of the starting reaction mixture to be used in electrolysis was evaluated using overall chemical equations (3) and (4) from the neutralizate composition, assuming that the electrolysis of organic components proceeds to complete mineralization with conversion of organic nitrogen into molecular form.

$$2C_6H_{13}ONS + 28KOH + 20.5O_2 = 12K_2CO_3 + 2K_2SO_3 + N_2 + 27H_2O, \quad (3)$$

$$2H_2NC_2H_4OH + 8KOH + 6.5O_2 = 4K_2CO_3 + N_2 + 11H_2O. \quad (4)$$

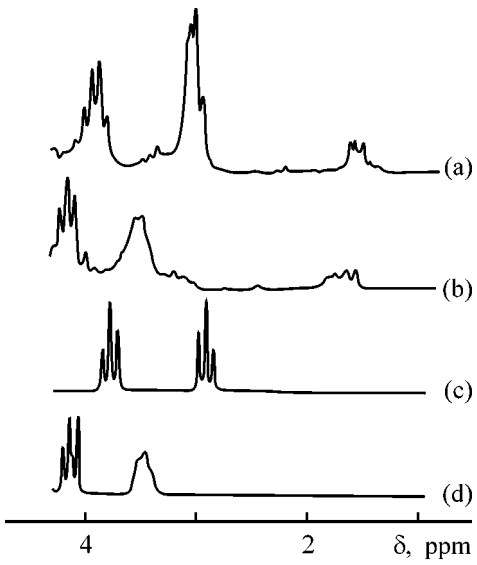

Fig. 3. ^{1}H NMR spectra of (a, b) the organic phase of YLM neutralizate and (c, d) monoethanolamine. pH: (a, c) 12 and (b, d) 5.5.

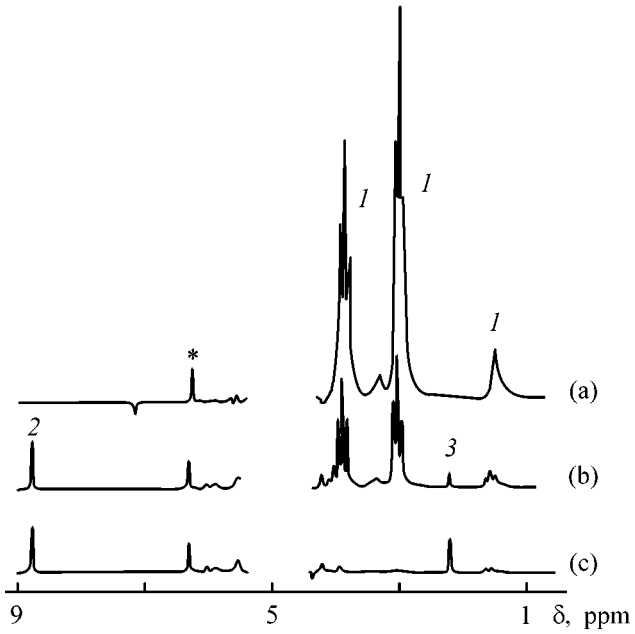

Fig. 4. ^{1}H NMR spectra of YLM neutralizate, taken during electrolysis. Neutralizate: (a) initial, (b) after 8 h, and (c) after 20 h of electrolysis. (*1*) Protons of organic compounds of neutralizate, (*2*) formate proton, and (*3*) protons of the methyl group of acetate. The ^{1}H signal of maleic acid used as internal reference is marked with an asteric.

Monitoring of the electrolysis of YLM neutralizate by the ^{1}H NMR (Fig. 4) showed that the intensities of all the signals decrease simultaneously and ^{1}H signals of acetate and formate appear. Analysis of the dynamics of consumption of the organic fraction

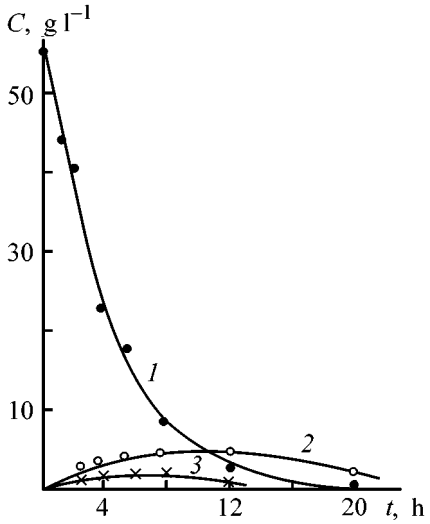

Fig. 5. Dynamics of variation of the content of organic components during electrolysis of YLM neutralizate. (*C*) Component concentration and (*t*) time. (*1*) Organic phase of neutralizate, (*2*) formate, and (*3*) acetate.

and accumulation of acetate and formate (Fig. 5) suggests exhaustive degradation of the organic fraction of YLM neutralizate during electrolysis. The relatively low content of acetate and formate in the reaction mixture during electrolysis indicates that these components are intermediates.

Comparison of the composition of YLM neutralizate before and after complete electrolysis (Table 1) confirms that the organic phase is for the most part mineralized to carbonates and sulfates. The relatively low content of nitrates in the electrolyzate (0.9 against calculated 9.7 g l^{-1}) suggests oxidation of organic nitrogen to the elemental state.

An analysis of the composition of the gas phase during electrolysis of a YLM neutralizate (Table 2) showed that the main components of the gas evolved during electrolysis are oxygen and nitrogen. The relatively high content of nitrogen in the gas phase confirms the conclusion that organic nitrogen is oxidized to elemental nitrogen.

The content of carbon oxides in the gas phase is relatively low, which can be attributed to their absorption by alkaline medium to give potassium and sodium carbonates.

In addition, the content of arsenic in the neutralizate decreases during electrolysis from 14.1 to 2.2 g l^{-1} (Table 1). Further purification of the electrolyzate to remove arsenic salts by electrocoagulation is impossible, because the medium is alkaline owing to a high content of sodium and potassium carbonates (Table 1). To decrease the arsenic concentration in the solution, the reaction mixture should be neutralized. The electrolyzate was neutralized with concentrated nitric acid to produce potassium nitrate as a target product. The resulting mixture was subjected to electrocoagulation, which decreased the arsenic content to 0.4 mg l^{-1} (Table 1).

The precipitates obtained after filtration of the reaction masses formed in electrolysis and electrocoagulation were combined, dried to constant weight, and weighed. The arsenic content was determined. As a result, 6.6 g of dry substance containing 67% arsenic was obtained from 300 ml of the initial neutralizate.

The purified electrolyzate and the solution of potassium carbonate, produced in the stage of treatment with HNO_3, were combined and evaporated with subsequent drying of the precipitate to constant weight (Table 1). As a result, 286 g of the salt product was obtained from 300 ml of the initial neutralizate. The composition of the product was as follows (wt %): potassium 40.6, sodium 4.2, carbonate 16.4, nitrate 34.0, chloride 3.2, and sulfate 1.6. The content of potassium and sodium was evaluated from the amount

Table 1. Composition of YLM neutralizate during processing

of sodium and potassium hydroxides used in neutralization and mineralization.

Thus, the possibility of complete YLM mineralization was demonstrated. The process includes two main stages: (i) detoxification of war gases with alkali in the presence of monoethanolamine or a mixture of monoethanolamine with ethylene glycol and (ii) mineralization of the organic products of YLM detoxification by wet electrolytic combustion in the presence of alkalis with the use of electrocoagulation for purifying the reaction masses to remove arsenic and its salts.

As mentioned above, the first stage (stage of chemical weapon disposal proper) has been developed, tested on a semicommercial scale, and is ready to use [1].

In this work, we showed experimentally that, with potassium hydroxide used in all stages of the process, mineralization of the YLM neutralizate gives mixtures of potassium carbonates and nitrates with admixture of chlorides and sulfates.

Arsenic compounds contained in wastes formed in processing of YLM detoxification products are a mixture of metallic arsenic and aluminum arsenates with mechanical impurities. The amount of these waste products with arsenic content of 67% is 22% of the total amount of processed YLM. This conglomerate is a powder-like substance suitable for prolonged storage, transportation, and use as a raw material in industry, medicine, and agriculture.

Gases evolved in electrolysis of YLM detoxification products mostly contain oxygen and nitrogen, with relatively low content of hydrogen and without admixture of noxious components. They are not fire- and explosion-hazardous since the ratios of oxygen and hydrogen concentrations are far from those corresponding to the detonating mixture.

The main product of YLM neutralizate processing (potassium salts) was analyzed for the content of arsenic salts, which are enviromentally detrimental impurities in the case when this product is used as fertilizer in agriculture. The content of arsenic compounds (in terms of arsenic) in the final product of war gase processing is 0.4 mg per 1 kg of the product (Table 1), which is 5 times less than the maximum permissible concentration of arsenic in soil [7]. This means that the use of the final product as potassium fertilizer in agriculture will be enviromentally safe.

Further inprovement of the procedure of processing of YLM detoxification products could be aimed at reducing the expenditure of electrical energy and reagents (acids and alkalis). A promising approach to decreasing this expenditure is complex chemical biological processing of YLM detoxification products, including separation of the reaction mass formed in detoxification into organic and inorganic fractions, conversion of the residual organic substances in the inorganic fraction to mineral fertilizers by wet combustion, and biological utilization of the organic fraction with the use of microbes.

CONCLUSIONS

(1) Electrolysis of the products of alkaline detoxification of yprite-lewisite mixture in the presence of potassium hydroxide in a diaphragmless electrolyzer results in complete mineralization of the organic fraction of the neutralizate to potassium carbonates with admixture of chlorides and sulfates and partial reduction of arsenic to the elementary state. The waste gases formed are mixtures of nitrogen and oxygen with minor admixture of hydrogen.

(2) The use of electrocoagulation after treatment of the reaction mass with HNO_3 allows decontamination of potassium salts to remove arsenic and its compounds to a residual content below the maximum permissible concentration for soil, which makes possible their use as fertilizers in agriculture. The expected yield of potassium salts in mineralization is approximately 15 per ton of yperite–lewisite mixture. In this case, the yield of arsenic-containing wastes does not exceed 0.3.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Flocculating Efficiency of Polyelectrolytes Prepared from Wastes of Nitron Fiber Production

V. I. Grachek, A. A. Shunkevich, and O. P. Popova

Institute of Physical and Organic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received December 18, 1998; in final form, August 1999

Abstract—Water-soluble cationic, amphoteric, and anionic polyelectrolytes were prepared from wastes of the Nitron fiber production. The extent to which the polyelectrolytes reduce the turbidity, content of petroleum products, and chemical oxygen demand was studied as a function of polyelectrolyte type and its concentration.

The cationic and anionic polyelectrolytes are widely used to intensify the separation of natural dispersed matter and decontamination of industrial wastewater [1–3]. In these processes, both separate polyelectrolytes of certain ionic type and their mixtures are used. Data on the acceleration of sedimentation with a flocculant mixture were reported in [4]. Amphoteric polyelectrolytes containing both cationic and anionic functional groups are the most promising for decontamination of aqueous solutions to remove suspended particles.

It is known [5–7] that derivatives of polyacrylamide are commonly used for wastewater decontamination. The flocculating efficiency of these reagents is mainly due to their ionic functional groups.

The aim of this study was to synthesize water-soluble polyelectrolytes with different charges of functional groups from wastes of production and reprocessing of acrylic polymers and analyze their flocculating characteristics. The wastes from Nitron fiber production (WNF)[1] containing 92.5% acrylonitrile were used as a raw material.

EXPERIMENTAL

In the experiments, we used an anionic polyelectrolyte prepared by alkaline hydrolysis of wet wastes from Nitron-C and Nitron-D fiber [8] production. Cationic polyelectrolyte was prepared by amination of WNF with ethylenediamine [9]. The amphoteric polyelectrolyte was prepared by two-stage synthesis. In the first stage, the fiber was aminated with ethylenediamine to reach an ion-exchange capacity of 4–6 mg-equiv g^{-1}. This product was hydrolyzed with 5% NaOH at 100°C for 2–3 h until a uniform mixture was formed.

In IR spectrum of amphoteric polyelectrolyte, a broad band at 3350 cm^{-1} due to the N–H stretching vibrations appears instead of the nitrile band at 2240 cm^{-1}. The spectrum also contains a strong absorption band at 1650 cm^{-1} due to C=O stretching vibrations and bands at 1550 and 1400 cm^{-1} associated with the symmetrical and antisymmetrical vibrations of the hydroxy groups.

The polyelectrolyte samples prepared by us were purified to remove oligomeric impurities and converted to the required form, and their exchange capacity was determined.

The exchange capacity of carboxy groups of the anionic flocculants was determined as follows. A commercial flocculant sample was acidified with 1 M HCl to pH 2. Under these conditions the polyelectrolyte was precipitated. This precipitate was washed with ten 20-ml portions of 0.1 M HCl and then with distilled water to pH 3. The washed precipitate was dissolved by treating it with 0.1 NaOH to pH 5. The resulting solution was acidified with 0.1 M HCl to reprecipitate the polyelectrolyte. The precipitate formed was washed to pH 3–3.5 and dried at 85 ± 5°C. A weighed sample of polyelectrolyte (50–100 mg) was dissolved in water and titrated potentiometrically with 0.1 N NaOH with stirring. pH value was monitored with a I-130 M ionometer. The exchange capacity of the polyelectrolyte was calculated from the titrant volume at the inflection point in the titration curve.

* (SEC) Static exchange capacity.

Prior to determining the exchange capacity of the cationic polyelectrolyte, an aqueous solution of the commercial product was passed through a hollow-fiber filtering unit to remove impurities with molecular weight higher than 20 000. This purification procedure was performed at continuous washing with distilled water for 8 h to neutral reaction of the eluate. The concentration of the cationic polyelectrolyte in the eluate was determined gravimetrically. The exchange capacity of amino groups was calculated from the inflection point in the curve of the potentiometric titration of a weighed polyelectrolyte sample with 0.1 M HCl.

A commercial amphoteric polyelectrolyte containing Na-carboxylate groups and free amino groups was acidified with 0.1 M HCl to pH 2–2.1 and precipitated with a tenfold excess of acetone. The precipitate was kept in acetone for 15 min, filtered off, twice washed with acetone, and then dissolved in the minimal volume of distilled water. The polyelectrolyte obtained was again precipitated with acetone, dried in a vacuum to constant weight, and its 2 wt % aqueous solution was prepared. A 25-ml portion of this solution was titrated potentiometrically with 0.1 M NaOH. The amount of 0.1 M NaOH spent for reaction with a sum of amino groups combined with HCl and carboxy groups was determined from the inflection point in the curve of potentiometric titration. Separate determination of the amino groups associated with HCl molecules was carried out mercurimetrically [10]. The content of the carboxy groups in the amphoteric polyelectrolyte was calculated as the difference between the total amount of the functional groups and the amount of the amino groups.

The content of the functional groups in the anionic, cationic, and amphoteric polyelectrolytes is given in Table 1.

The flocculating efficiency of polyelectrolytes prepared by us was tested both with a model kaolin suspension in distilled water and with industrial wastewater. In these experiments, flocculant was introduced in combination with $Al_2(SO_4)_3$ as coagulant.

The flocculating efficiency of the polyelectrolytes was measured in a volumetric cylinder (50 cm^3) as the velocity of motion of the visible boundary between the columns of the calrified liquid and concentrated aqueous-kaolin suspension. In these experiments, we used the kaolin fraction with size no less than 0.1 mm [GOST (State Standard) 21 285]. In all experiments, the kaolin concentration in the suspension was 4 wt %. The samples were taken at a depth of 3 cm below the surface of the liquid and their optical density was measured on a KFK-2 photocolorimeter at 490 nm.

The flocculating efficiency of polyelectrolytes under consideration was also tested with industrial wastewater from the Naftan Production Association, Novopolotsk. In these experiments, the tested polyelectrolytes and commercial $Al_2(SO_4)_3$ were used as flocculants and coagulant, respectively. The degree of water decontamination was determined from its optical density at 440 nm. The chemical oxygen demand (COD) and the content of petroleum products was determined too. These tests were carried out as follows. A wastewater sample was poured into a 100-ml volumetric cylinder, and the flocculant and coagulant were added. This mixture was stirred for 30 s and allowed to stand for 60 min. Water samples were taken at a depth of 5 cm below the liquid surface, and their optical density was measured with a KFK-2 photocolorimeter. We also determined the chemical oxygen demand (COD) by the technique reported in [11] and the content of petroleum product with a Flyuorat-02 liquid analyzer.

In the first stage, the flocculating efficiency was studied as influenced by the type and concentration of a flocculant.

The curves of sedimentation of a kaolin suspension in the presence of anionic and amphoteric polyelectrolytes are given in Fig. 1. These curves show that the rate of sedimentation of the suspension depends on the type of polyelectrolyte and its concen-

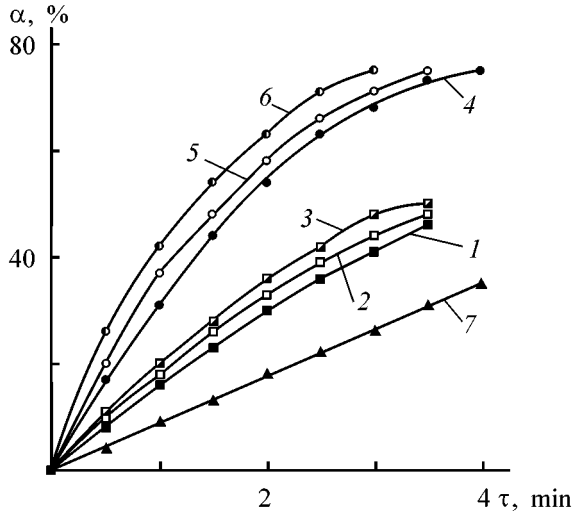

Fig. 1. Degree of clarification of the aqueous-kaolin suspension α vs. the sedimentation time τ. Type and concentration (mg l^{-1}) of polyelectrolyte: amphoteric, (*1*) 10, (*2*) 15, and (*3*) 20; cationic, (*4*) 10, (*5*) 15, and (*6*) 20; (*7*) with no flocculant.

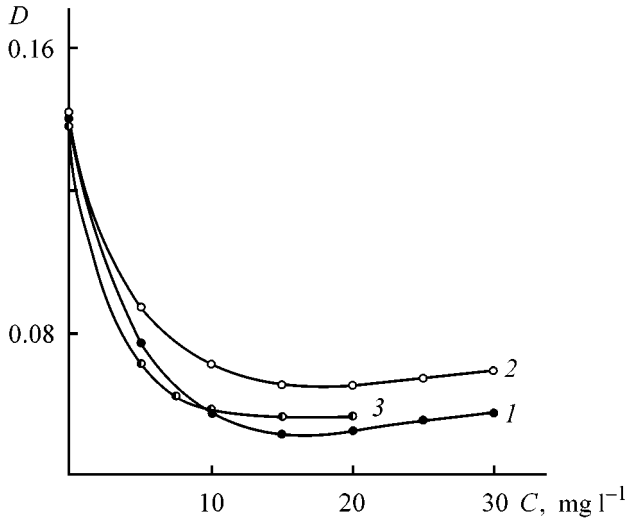

Fig. 2. Clarification of the aqueous-kaolin suspension vs. the polyelectrolyte concentration *C*. (*D*) Optical density; the same for Figs. 3, 4. Polyelectrolyte: (*1*) cationic, (*2*) amphoteric, and (*3*) commercial VA-2.

tration. Introduction of polyelectrolyte considerably increases the rate of sedimentation as compared with the system without flocculant. These curves also show that the cationic polyelectrolyte increases both the flocculation rate and the degree of clarification to a considerably larger extent than the amphoteric flocculant does. Introduction of anionic polyelectrolyte stabilizes the aque-on ous-kaolin suspension. We found that even an amount of the anionic polyelectrolyte as small as 5 mg l^{-1} stabilizes the aqueous-kaolin suspension to some extent and, as a result, decelerates the sedimentation. With increasing polyelectrolyte concentration, the suspension is further stabilized and the sedimentation stops.

Figure 2 shows the optical density of the aqueous-kaolin suspension as influenced by varied amounts of the cationic and amphoteric polyelectrolytes prepared by us and the commercial cationic flocculant VA-2. As seen from these results, the polyelectrolytes prepared by us provide the most efficient clarification at a concentration of 15–20 mg l^{-1}. According to [12], at these concentrations the globules of the flocculant macromolecules have the largest size and, therefore, provide the most efficient aggregation of particles of the aqueous-kaolin suspension. With the polyelectrolyte concentration increasing further, the flocculating efficiency decreases somewhat. Figure 2 shows that at polyelectrolyte content higher than 10 mg l^{-1} the polyelectrolyte synthesized by us becomes more efficient, whereas at low concentration of polyelectrolyte (5–10 mg l^{-1}) the flocculating efficiency of VA-2 flocculant slightly exceeds that of the cationic polyelectrolyte prepared in this work.

Since the optimal flocculant concentration C_{fl} required to clarity industrial wastewater may differ from that for the model aqueous-kaolin suspension, we studied the clarification of wastewater from the Naftan Production Association as influenced by the flocculant concentration. In these experiments, the flocculant was added in combination with a coagulant, because fast flocculation only occurred under these conditions.

Figure 3 shows that settling of the suspension for 1 h after simultaneous introduction of an flocculant and coagulant into the wastewater ensures an acceptable degree of clarification. Therefore, in further experiments, the flocculating efficiency of the polyelectrolytes was determined after settling of the suspension for 1 h after simultaneous introduction of the polyelectrolyte and coagulant.

Figure 4 shows the effect exerted by the concentration of the synthesized polyelectrolytes on the clarification of wastewater from the Naftan Production Association. According to these results, with increasing polyelectrolyte concentration, their flocculating efficiency first increases and then, after passing through a maximum, starts to decrease somewhat. These clarification curves are similar to those for the case of clarification of the aqueous-kaolin suspension (Fig. 2). The only difference is that in the clarification of wastewater the anionic polyelectrolyte in combination with the coagulant shows a slight flocculating effect.

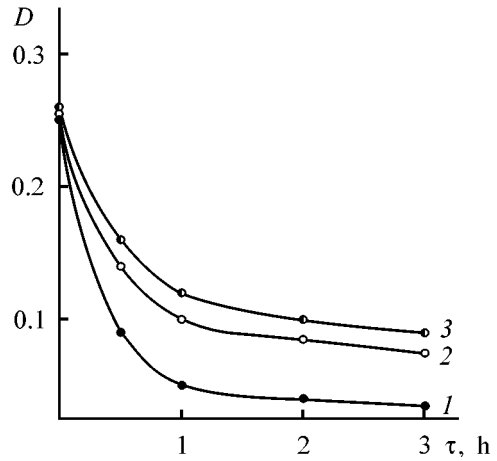

Fig. 3 Dependence of water clarification on the settling time τ. Coagulant concentration 100 mg l^{-1}, polyelectrolyte concentration 20 mg l^{-1}. Polyelectrolyte: (*1*) cationic, (*2*) amphoteric, and (*3*) anionic; the same for Fig. 4.

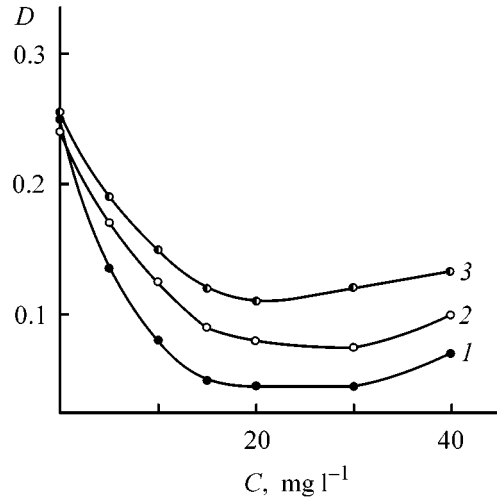

Fig. 4. Clarification of wastewater vs. polyelectrolyte concentration *C*. Coagulant concentration 100 mg l^{-1}.

Data on decontamination of wastewater from the Naftan Production Association are summarized in Table 2. The initial wastewater had the following characteristics: petroleum product concentration 34.48 mg l^{-1}, chemical oxygen demand (COD) 339 mg l^{-1}, and pH 7.8. Table 2 shows that all the polyelectrolytes tested improve the decontamination of the wastewater owing to their flocculating effect. The maximum degree of wastewater decontamination to remove petroleum products decreases in the order: cationic polyelectrolyte (68%), amphoteric polyelectrolyte (59%), and anionic polyelectrolyte (17%). For the same series of flocculants the maximum degree of wastewater decontamination evaluated from the COD decreases in the order: cationic (60%), amphoteric (45%), and anionic (40%). These data show that the cationic flocculant is preferable for decontamination of wastewater from petrochemical plants. Macromolecules of this polyelectrolyte are characterized by the optimal relation between of the sign and density of electric charge and flexibility of chains, ensuring the largest effective size of the flocculant globules and, as a result, the most efficient aggregation of dispersed particles in the wastewater.

Table 2. Characteristics of wastewater decontamination with flocculants prepared in this work

Flocculant	*C*, mg l^{-1}	pH	Content of petroleum products in wastewater before decontamination, mg l^{-1}	Degree of wastewater decontamination to remove petroleum products, %	COD, mg O_2 l^{-1}	Degree of decontamination, determined from COD, %
Cationic	10	7.9	21.4	38	188	45
	15	7.9	11.7	66	147	57
	20	8.0	11.0	68	136	60
Amphoteric	10	7.8	28.6	17	231	32
	15	7.9	16.4	52	199	41
	20	7.9	14.1	59	187	45
Anionic	10	7.8	29.8	13	260	23
	15	7.7	29.1	15	210	38
	20	7.6	28.4	17	203	40
Coagulant	50	7.7	29.9	13	261	23

CONCLUSION

Water-soluble cationic, amphoteric, and anionic polyelectrolytes were prepared from wastes of Nitron fiber production. It was found that the flocculating efficiency of these polyelectrolytes in clarification of the aqueous-kaolin suspension and wastewater from a petroleum processing plant decreases in the order: cationic, amphoteric, and anionic.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Tribological Characteristics of Oligoorganosiloxanes with Higher n-Alkyl Substituents

State Research Institute for Chemistry and Technology of Organoelement Compounds, State Scientific Center of the Russian Federation, Moscow, Russia

Received August 9, 2000

Abstract—A procedure was developed for hydrosilylation of α-olefins with oligohydrosiloxanes, and a series of comb-shaped organosiloxanes of the general formula $R_3SiO(R_2SiO)_m(RR'SiO)_nSiR_3$ (where R is CH_3, C_2H_5; R' is *n*-alkyl C_8–C_{18}) with random distribution of dimethylsiloxane (or diethylsiloxane) and methylalkylsiloxane (or ethylalkylsiloxane) units were obtained. The physicochemical characteristics of these oligomers were studied, with particular attention given to their lubricating properties (diameter of the wear spot and critical jamming load), which were compared to those of lubricating oils based on organosilicon compounds (PMS-100, KhS-2-1) and hydrocarbon-based MS-20 oil.

The presently available lubricating materials are inefficient in friction units of modern machines and mechanisms working under extreme conditions (boundary friction, high loads, temperature range from –60 to 250°C). The previously developed lubricants based on organosilicon liquids, in particular, polydimethyl- (PMS), polydiethyl- (PES), and polydimethylhaloorganosiloxanes (e.g., oligomethyldichlorophenylsiloxane KhS-2-1), have certain advantages over petroleum oils. Their heat resistance and chemical stability are fairly high; they remain liquid in a very wide temperature range, and their viscosity depends on temperature to a considerably lesser extent than that of mineral oils. These properties of the lubricants make them applicable at both high and low temperatures in the hydrodynamic friction mode. However, these materials are inefficient in the boundary friction mode because of the low carrying power of the boundary layer. This is due to the specific structure of the boundary phase of organosilicon liquids and to its lower viscosity as compared to the bulk phase [1]. At high loads the boundary layer is broken down, and the friction surfaces come in direct contact.

At the same time, mineral oils based on the hydrocarbons show high adhesion and cohesion characteristics, high carrying power of the boundary layer, and good lubricating properties in both friction modes; however, they have relatively narrow range of working temperatures, high temperature coefficient of viscosity, and low heat resistance.

It would be expected that replacement of a part of methyl (or ethyl) groups at the silicon atoms in a PMS (or PES) molecule by *n*-alkyl groups with 8 to 18 carbon atoms could give a lubricant combining the advantages of organosilicon liquids and mineral oils (a sort of "hybrid" of silicones with hydrocarbons).

Here, we report on synthesis of oligoorganosiloxanes with higher *n*-alkyl substituents and present their tribological characteristics.

One of simple and widely used routes to organosilanes and organosiloxanes with higher substituents at silicon atoms is hydrosilylation of α-olefins in the presence of a catalyst [2, 3].

However, the procedure developed in this work is not a simple interaction of a Si–H bond with an α-C=C bond. The oligomer molecule contains several Si–H bonds which successively react with olefin molecules. The reaction occurs in steps, with the rates of these steps being different. The growing steric hindrance can prevent completion of the reaction. It would be more adequate to consider hydrosilylation in systems of this kind as polyaddition of α-olefins to oligoorganohydrosiloxanes.

20	CH_3	CH_3	$C_{18}H_{37}$	7.2	6.3	1.448	–	180	31	–

First, we studied the reaction of oligoorganohydrosiloxanes (with a known length of the siloxane chain and prescribed content of Si–H groups) with α-octene and α-octadecene. The overall reaction scheme can be represented as

$$R_3SiO(RRSiO)_m(RHSiO)_nSiR_3 + nCH_2{=}CH(CH_2)_pCH_3 \rightarrow R_3SiO(RRSiO)_m[R(CH_2(CH_2)_{p+1}CH_3)SiO]_nSiR_3.$$

Apparently, the structure and properties of the products must depend on the chemical nature and ratio of the diorganosiloxane units, length of the *n*-alkyl substituent, and molecular weight of the compound as a whole.

It was necessary to determine first the optimal conditions (temperature, time, reactant concentrations, stirring conditions) for preparing oligoorganosiloxanes with higher substituents.

We started from commercial hydrosiloxane samples differing in structure and content of hydride hydrogen. The purity of the initial olefins (octene and octadecene) was 98.3–99%.

The synthesis was performed in an inert atmosphere in the presence of the Speier catalyst (0.1% solution of H_2PtCl_6 in isopropyl alcohol).

The degree of conversion was judged from the consumption of Si–H groups, monitored by ^1H NMR. The results are given in Tables 1 and 2.

The experiments reflected in Table 1 were aimed at revealing conditions for maximal conversion of Si–H bonds in the reaction of octene with GKZh-94 com-

mercial oligoethylhydrosiloxane built of $–SiH(C_2H_5)O–$ units. The molar ratio of α-olefin to GKZf-94 was 1.0–1.1 in all experiments.

The results of experiments (Table 1) show that at temperature varied in the range 110–150°C, the amount of catalyst was within the range from 0.8×10^{-7} to 1.2×10^{-7} mol, and the reaction time, from 5 to 7 h, with the conversion not exceeding 40%. On raising the temperature to 170°C, α-olefin did not react with the hydrosiloxane because of the decomposition of the catalyst. The maximal conversion of 99.2% was attained with bubbling of an inert gas (activation by stirring), catalyst amount of 1.1×10^{-7} mol, temperature of 120–140°C, and reaction time of 6 h (run no. 14). The subsequent experiments were performed under these optimal conditions.

Oligoorganosiloxanes with *n*-alkyl radicals C_8H_{17} and $C_{18}H_{37}$ were prepared by reaction of oligomethyl-(ethyl-)hydrosiloxanes with octene and octadecene at molar ratios of 1 : 1.1 and 1 : 1, respectively. The composition and some physicochemical properties of the products are listed in Table 2.

Table 4. Critical jamming load at various temperatures

Sample	P_c (kg) at indicated temperature, °C	
	20	150
no. 14	126	63
no. 15	100	–
MS-20	63	24
PMS-100	<20	–
KhS-2-1	<20	–

Experimental results show that the high conversion (90–99.8%, residual concentration of hydride hydrogen 0.06–0.0016 wt %, respectively) was attained irrespective of the nature of alkyl groups at terminal and internal silicon atoms (methyl or ethyl), initial content of hydride hydrogen, and length of the hydrosiloxane and olefin chains.

At room temperature, oligosiloxanes with octyl radicals are uniform colorless transparent viscous liquids not solidifying on cooling to at least –50 (sample no. 14) or –60°C (sample no. 15). The kinematic viscosity of these liquids at these temperatures was 0.1193 and 0.0767 $m^2 s^{-1}$, respectively. At the same time, their analogs with octadecyl radicals are nontransparent pasty substances even at room temperature and become transparent viscous liquids only when heated to 34–35°C.

The tribological characteristics of the products were evaluated on a four-ball friction machine at various temperatures and loads on the friction couple in comparison with polymethylsiloxane liquids of linear (PMS-100) and branched (PMS-1.5r) structure, oligodimethyldichlorophenylsiloxane (KhS-2-1), and MS-20 lubricating oil on a hydrocarbon base. The obtained results are listed in Table 3.

As expected, partial replacement of methyl or ethyl groups by higher *n*-alkyl substituents (C_8H_{17} or $C_{18}H_{37}$) substantially improved the lubricating properties of oligoalkylsiloxanes, bringing them to the level characteristic of petroleum oils (Table 3).

Thus, the wear spot diameter D_2 and the friction coefficient k_f of oligodiethyl- (sample no. 15) and oligodimethylmethyloctylsiloxane (no. 17), oligodiethylethyloctadecylsiloxane (no. 19), and its methyl analog (no. 20) are close to those of MS-20 oil and are considerably smaller than those of PMS-100 and KhS-2-1.

The excellent lubricating properties of oligoalkylsiloxanes with higher alkyl substituents are manifested especially clearly when comparing the critical jamming loads P_c, determined by a standard procedure [GOST (State Standard) 9490–75] at 1500 min^{-1} in the course of 10 s. The results are listed in Table 4.

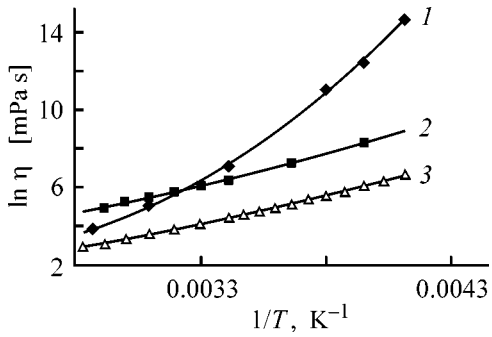
As seen from Table 4, in the case of oligodiethylethyloctylsiloxanes the load at friction destroying the lubricant layer is almost twice that with MS-20 hydrocarbon oil and considerably higher than that with PMS-100 and KhS-2-1. This means that oligoethyloctylsiloxanes form on friction surfaces a strong film with high carrying power and good adhesion and cohesion characteristics.

The temperature dependences (in Arrhenius coordinates) of the viscosities of MS-20 oil and oligoorganosiloxane nos. 15 and 17 are shown in the figure. The smaller, as compared with the case of MS-20, slope of the $\ln\eta$–$1/T$ curves for sample nos. 15 and 17 shows that the viscosity of these oligoorganosiloxanes is considerably less temperature-dependent, which extends the field of their possible application.

Thus, we developed a general route to a new class of liquid organosilicon oligomers with higher *n*-alkyl substituents. The optimal reaction conditions were found, and a series of compounds were prepared. Their lubricating properties are level with the case of MS-20 hydrocarbon oil, with the critical jamming load being higher and the temperature dependence of the viscosity being more favorable as compared with those of MS-20 oil.

EXPERIMENTAL

A five-necked flask equipped with a stirrer, a reflux condenser, a thermometer, a dropping funnel, and a tube for inert gas bubbling was charged with 82 g of alkylhydrosiloxane (GKZh-94, content of hydride



Temperature dependence of the viscosity η (in Arrhenius coordinates) of (*1*) MS-20 lubricating oil, (*2*) oligoorganosiloxane sample no. 15, and (*3*) sample no. 17.

hydrogen 1.22%), and nitrogen was passed for 20 min at a rate of 3 $l\,h^{-1}$ with continuous stirring to remove atmospheric oxygen. After the completion of purging, the reactor was heated to 120°C, and 123.2 g of octene containing the required amount of the catalyst was added from a dropping funnel at a rate at which the temperature of the reaction mixture could be kept below 140°C (initially the reaction is fast and is accompanied by considerable heat release). After adding the whole amount of octene, the mixture was stirred for 2 h, the unchanged octene was distilled off, the mixture was cooled to room temperature, and the product was unloaded.

The conversion of hydride groups was 98%. The ^{1}H NMR spectrum of the oligomer contained signals (ppm) from α-CH_2 (0.53–0.56), β-CH_2 (0.9–1.0), and more remote (1.3) protons.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Photochemical Chlorination of α,α-Difluoroanisole

A. I. Shipilov and L. A. Kolpashchikova

Perm Branch, Prikladnaya Khimiya Russian Scientific Center, Perm, Russia

Received July 26, 2000

Abstract—Chlorination of α,α-difluoroanisole was performed. The yield of chlorodifluoromethoxybenzene was studied in relation to the mode of reaction initiation.

Trufluoromethoxy benzene derivatives are valuable intermediates in production of effective drugs [1].

One of synthetic routes to trifluoromethoxybenzenes is as follows:

$$ArOH + CHClF_2 \xrightarrow{\text{NaOH solution}} ArOCF_2H \xrightarrow{Cl_2} ArOCF_2Cl \xrightarrow{HF/SbCl_5} ArOCF_3.$$

In this work, we studied one of the stages of this scheme, namely, chlorination of difluoromethoxybenzene (α,α-difluoroanisole).

The chlorination of nonfluorinated anisoles is well studied. It occurs by the radical chain mechanism and can be successfully performed by various procedures. Chlorination of Cl–Ar–OCH_3 in the presence of PCl_5 at 150–180°C gives the corresponding trichloromethoxy derivative in approximately 76% yield [2]; chlorination of $ArOCH_3$ at 80–110°C, initiated by azobis(isobutyronitrile) (AIBN), occurs with a yield of about 80% [3], and UV-initiated chlorination of $ArOCH_3$, with a ~70% yield [4].

It is believed that the chlorination occurs by the radical chain mechanism, differing only in the way of the initial generation of atomic chlorine (substance, thermal, or photochemical initiation).

In contrast to unfluorinated anisoles, chlorination of α,α-difluoroanisole occurs difficultly. Despite the sufficient thermal stability of difluoromethoxybenzene (it is distilled without noticeable decomposition), attempts of its chlorination at 120–140°C in the presence of PCl_5 failed. Approximately 1–1.5 h after the start of chlorination, the mixture turned dark, which was followed by the formation of a dark brown tar. Among the identified liquid products, only traces of $ArOCF_2Cl$ were detected; the major components were unchanged α,α-difluoroanisole (~25%), products of chlorination in the ring (difluoromethoxypolychlorobenzenes, ~40%), and products of chlorine addition (~20%).

Chlorination with the use of radical initiators (e.g., AIBN) occurs more readily at moderate temperatures (80–110°C). Under these conditions, extensive tarring is usually avoided. However, the content of α-chlorination products does not exceed several percent, even on passing a fivefold excess of chlorine and taking up to 5% AIBN. The main reaction pathway is substitution of chlorine for hydrogen atoms of the aromatic ring.

In the case of UV initiation, chlorination of α,α-difluoroanisole occurs considerably more readily. The yield of the target product, chlorodifluoromethoxybenzene, depends on the intensity of the UV irradiation. With a 450-W UV lamp, the yield was as high as 95%, and with a 250-W lamp, it decreased to 70%, all other conditions being the same. With a common 150-W incandescent lamp, the yield was as low as 50%, with the major by-products being those of chlorination of the aromatic ring (see table).

Thus, the experimental results clearly show that the success or failure of α,α-difluoroanisole chlorination at the difluoromethoxy group depends on the initiation conditions. An acceptable result is obtained with UV initiation, with the yield of chlorodifluoromethoxybenzene increasing as the power of the UV source is raised.

In terms of the simple radical mechanism, it is difficult to explain the dramatic dependence of the reaction result on the mode of generation of atomic chlorine. An assumption that the chlorine atom generated by UV irradiation is more reactive than that generated by thermolysis of the chlorine molecule or

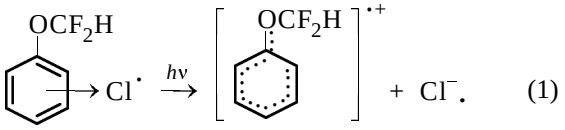
by the action of AIBN is not convincing, especially in view of the known fact that the actual reacting species in radical chlorination in aromatic solvents is a π complex of a chlorine atom with an aromatic molecule, rather than a free chlorine atom [5–7].

Such a π complex, **I**, is less reactive than a free chlorine atom and is more "remote" (along the reaction path) from the generation stage.

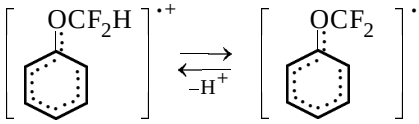
It seems more reasonable to account for the dramatic dependence of the yield of chlorodifluoromethoxyanisole on the initiation mode in terms of a reaction pattern with one-electron transfer.

Under UV irradiation, electron transfer is possible in the π complex of chlorine atom with the α,α-difluoroanisole molecule, yielding a radical cation **II** and a chloride anion:



I **II** (1)

The resulting radical cation can be stabilized by release of a proton as an easily leaving group with the formation of radical **III**:



III (2)

The subsequent transformations are typical of radical chlorination:

$$ArOCF_2^{\cdot} + Cl_2 \rightarrow ArOCF_2Cl + Cl^{\cdot}.$$

Such a reaction pattern is confirmed by the following facts. It is well known that reactions involving electron transfer are considerably accelerated under electronic photoexcitation of the reacting molecules, i.e., irradiation initates electron transfer between a substrate and a reagent [8]. There is also some indirect evidence in favor of the intermediate formation of the radical cation. Proton-donor impurities (phenol, HCl, water) in the initial difluoroanisole cause extensive tarring and strongly inhibit formation of the desired $ArOCF_2Cl$. Probably, such impurities increase the current concentration of H^+ and thus prevent deprotonation of the radical cation, shifting to the left the equilibrium of reaction (2), and hence prevent formation of the radical $[ArOCF_2]^{\cdot}$ and the target product $ArOCF_2Cl$. In this case, the main transformation pathway of $[ArOCF_2H]^{\cdot +}$ is fragmentation with the cleavage of the O–C bond and formation of tars.

Apparently, to prove the reaction mechanism involving one-electron transfer from $ArOCF_2H$ to $Cl^{\cdot}$, it is necessary to detect the radical cation $[ArOCF_2H]^{\cdot +}$ by appropriate physical methods.

EXPERIMENTAL

Photoinitiated chlorination of α,α-difluoroanisole was performed in a 350-ml quartz flask equipped with an efficient stirrer and a bubbler. As sources of UV radiation were used DRL-250 and DRL-450 lamps and also a 150-W incandescent lamp. The lamps were placed at the side of the flask, at a distance of about 5 cm from the flask wall.

Chlorination of α,α-difluoroanisole in the presence of PCl_5 or AIBN was performed in a 250-ml glass flask equipped with an efficient stirrer and a bubbler. The calculated amount of PCl_5 was charged in a single portion, and AIBN was added in 0.2–0.3-g portions every 10 min.

The amounts of reactants taken, reaction conditions, and content of major products are listed in the

table. The reaction mixtures were analyzed using a Hewlett–Packard 5890 chromatograph equipped with a 30 000 × 0.25-mm capillary column (stationary phase SE-54). The products were identified by mass spectrometry (ITD-800 device) and ^{19}F NMR spectroscopy (Bruker WP-80 spectrometer).

CONCLUSIONS

(1) The yield of chlorodifluoromethoxybenzene in chlorination of α,α-difluoroanisole depends on the initiation mode. The highest yield is attained in the case of photoinitiation.

(2) The main pathway of photoinitiated chlorination of α,α-difluoroanisole presumably involves one-electron transfer in the π complex of α,α-difluoroanisole with a chlorine atom from the aromatic substrate to the chlorine atom, to give the radical cation $ArOCF_2^{\cdot +}$.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis, Structure, and Growth-Regulating Activity of 1-(6,9-Dimethyl-1,4-dioxa-8-azaspiro[4,5]dec-8-ylmethyl)-1*H*-pyridin-2-one

A. Sh. Sharifkanov, S. K. Alimzhanova, Zh. A. Abilov, and A. A. Bektibaeva

Al'-Farabi Kazakh State National University, Almaty, Kazakhstan

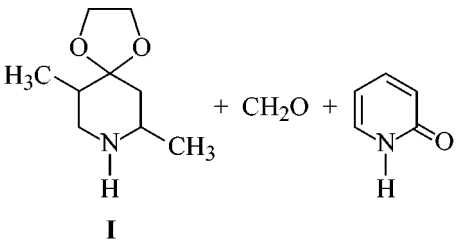
Received April 11, 2000; in final form, October 2000

Abstract—1-(6,9-Dimethyl-1,4-dioxa-8-azaspiro[4,5]dec-8-ylmethyl)-1*H*-pyridin-2-one was prepared by the Mannich reaction from 6,9-dimethyl-1,4-dioxa-8-azaspiro[4,5]decane, formaldehyde, and pyridin-2-one in alcohol. Its structure was proved by NMR spectroscopy. This compound exhibits a growth-regulating activity.

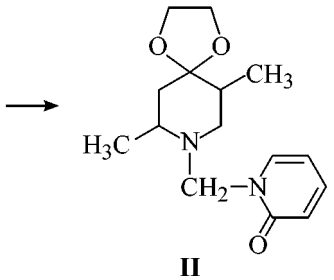
Pyridine derivatives exhibit a wide biological activity spectrum. Compounds based on them are used as drugs and plant growth regulators [1, 2].

The goal of this study was to prepare 1-(6,9-dimethyl-1,4-dioxa-8-azaspiro[4,5]dec-8-ylmethyl)-1*H*-pyridin-2-one, a new potentially bioactive compound [3], determine its structure, and study its biological activity.

1-(6,9-Dimethyl-1,4-dioxa-8-azaspiro[4,5]dec-8-ylmethyl)-1*H*-pyridin-2-one (**II**) was prepared in high yield by reaction of pyridin-2-one with 6,9-dimethyl-1,4-dioxa-8-azaspiro[4,5]decane (**I**) and formaldehyde in alcohol (pH 9) at room temperature:



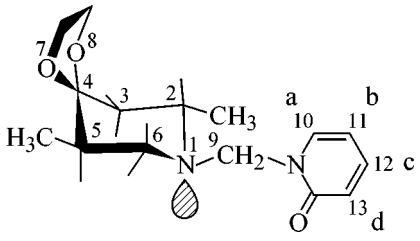
I



II

The structure of the product was proved by NMR spectroscopy.

Product **II** precipitates immediately; it is a white crystalline substance with mp 120–122°C (yield 60.5%). Product **IIa** was isolated from the mother liquor in 35% yield as pinkish crystals, mp 118–120°C. The proton chemical shifts of **II** and **IIa** (δ, ppm) are as follows (for atom numbering, see scheme below): **II** (mp 120–122°C), 1.13 d (3H, 2-CH_3) 0.79 d (3H, 5-CH_3), 2.80 m (2-H), 1.43 d.d (3-H_a), 1.72 d.d (3-H_e), 1.98 m (5-H), 2.40 t (6-H_a), 2.76 d.d (6-H_e), 3.93 m (7,8-CH_2), 4.69 d (9-H_a), 4.86 d (9-H_e), 7.61 d.d (10-H), 7.29 (11-H), 6.17 (12-H), 6.52 (13-H); **IIa** (mp 118–120°C), 1.08 d (2-CH_3), 0.84 d (5-CH_3), 2.88 m (2-H), 1.35 d.d (3-H_a), 1.68 d.d (3-H_e), 2.81 d.d (6-H_e), 7.36 d.d (10-H), 7.45 (11-H), 6.24 (12-H), 6.55 (13-H).



The proton coupling constants in **II** and **IIa** (*J*, Hz) are as follows: 2-H–2-CH_3 6.0; 5-H–5-CH_3 6.3; 2-H–3-H_a 11.7; 2-H–3-H_e 3.0; 5-H–6-H_a 11.7; 5-H–6-H_e 4.5; 3-H_a–3-H_e 12.9; 6-H_a–6-H_e 11.7; 9-H_a–9-H_e 13.2; ab 6.9; bc 6.9; cd 6.9; ac 2.1; db 1.2.

The ^{13}C NMR chemical shifts for **II** and **IIa** (δ, ppm) are as follows: 19.77 (2-CH_3), 10.40 (5-CH_3), 56.13 (C^2), 38.46 (C^3), 108.24 (C^4), 43.46 (C^5), 52.53 (C^6), 64.96 (C^7), 64.70 (C^8), 64.04 (C^9), 138.95 (C^{10}),

105.18 (C^{11}), 120.41 (C^{12}), 135.59 (C^{13}), 162.87 (C^{14}).

The ^1H and ^{13}C NMR spectra of the compound with mp 120–122°C confirm structure **II**. An analysis of the compound with mp 118–120°C showed that it is structurally similar to **II** and contains a minor (10%) admixture of the *cis* isomer.

The coupling constants of vicinal protons in rigid chair-like cyclohexane systems lie within the following limits [4]: $^3J_{aa}$ 8–13, $^3J_{ae}$ 2–6, $^3J_{ee}$ 1–4 Hz. This fact is widely used in conformational analysis of cyclohexane and piperidine derivatives.

The ^1H NMR spectrum shows that the protons at C^9 are nonequivalent. Instead of a singlet that would be observed in the case of free rotation, these protons give two doublets at 4.69 and 4.86 ppm with a geminal coupling constant of 13.2 Hz, i.e., they are diastereotopic.

To determine the orientation of substituents at C^2 and C^5, it is sufficient to know the vicinal coupling constants of 2-H and 5-H with the adjacent protons.

The axial proton at C^3 gives a doublet of doublets at 1.43 ppm with coupling constants of 11.7 and 12.9 Hz. The large vicinal constant $^3J_{2\text{-H}-3\text{-H}_a}$ = 11.7 Hz suggests the axial orientation of the proton at C^2 and, hence, the equatorial orientation of the methyl group.

The signal of 6-H_a is a triplet at 2.40 ppm, *J* 11.7 Hz. This a signal shape is possible if the vicinal and geminal constants coincide: $^2J_{6\text{-H}_a-6\text{-H}_e}$ = $^3J_{5\text{-H}-6\text{-H}_a}$ = 11.7 Hz. This vicinal constant suggests the axial orientation of 5-H and, hence, the equatorial orientation of 5-CH_3.

The signals of the methyl groups are doublets with chemical shifts of 0.79 and 1.13 pm and the coupling constants $^2J_{2\text{-H}-2\text{-CH}_3}$ = 6.0 and $^2J_{5\text{-H}-5\text{-CH}_3}$ = 6.3 Hz. The high-field signal is assigned to the 5-CH_3 protons. The equatorial protons at C^3 and C^6 appear as doublets of doublets at 1.72 and 2.76 ppm with geminal coupling constants of 12.9 and 11.7 Hz and equatorial constants of 3.0 and 4.5 Hz. The complex multiplets at 2.80 and 1.98 ppm belong to the equatorial protons at C^2 and C^5.

A group of closely located signals at 3.93 ppm corresponds to methylene protons of the five-membered ring. In the range 6.0–8.0 ppm, signals of protons of the heteroaromatic ring are observed. In this range, we can clearly distinguish four separate multiplets. The first is the triplet of doublets from 12-H, δ 6.17 ppm. The doublet of doublets at 6.51 ppm belongs to 13-H. The lower-field signals at 7.29 and 7.61 ppm belong to 11-H (triplet of doublets) and 10-H (doublet of doublets), respectively. The chemical shifts and proton coupling constants in **II** (solution in $CDCl_3$) are given above.

Thus, the ^1H NMR data confirm the suggested composition of the product and show that the piperidine ring has a regular rigid chair conformation with equatorial orientation of methyl groups at C^2 and C^5.

The ^{13}C NMR spectrum of **II** contains signals from 15 carbon atoms, which were assigned on the basis of tabulated data and substituent effects, i.e., taking into account additive screening parameters. The composition and spectra of **IIa** are similar to those of **II**, which suggests identity of these compounds. However, product **IIa** contains a 10% admixture of the *cis* isomer.

The effect of **II** (code ShA-8; treatment of tubercules before planting and leaf spraying) on the yield and quality of potatoes[1] was studied under laboratory and field conditions during three years (see table).

Treatment of potato tubercules with ShA-8 before planting increases the potato yield by 23.5%, or by 4.6 t ha^{-1}, and enhances the resistance of plants to viral diseases.

EXPERIMENTAL

The NMR spectra were taken with Mercury-300 spectrometers ($CDCl_3$, internal reference TMS).

(6,9-Dimethyl-1,4-dioxa-8-azaspiro[4,5]decane (I). A round-bottomed flask equipped with a reflux con-

denser with a calcium chloride tube was charged with 29 g (0.22 mol) of 2,5-dimethylpiperidin-4-one hydrochloride, 44 g (0.7 mol) of ethylene glycol, and 80 ml of anhydrous pyridine. The mixture was heated on an oil bath at 105–110°C for 3 h. After the reaction was complete, the pyridine was distilled off in a water-jet-pump vacuum, and excess ethylene glycol, in a roughing-pump vacuum. After being cooled, the residue was dissolved in 50 ml of water, and the solution was alkalized to pH 10 by adding a saturated NaOH solution from a dropping funnel with stirring and cooling with ice-cold water. The resulting aqueous solution was repeatedly extracted with ether. The ether extracts were dried over potassium carbonate, the solvent was distilled off, and the residue was vacuum-distilled to give 2 g (7%) of the initial 2,5-dimethyl-piperidin-4-one (bp 60–65°C/2 mm Hg, n_D^{20} 1.4670) and 13 g (60%) of 6,9-dimethyl-1,4-dioxa-8-azaspiro[4,5]decane as an almost colorless liquid, bp 77–79°C/2 mm Hg, n_D^{20} 1.4690.

1-(6,9-Dimethyl-1,4-dioxa-8-azaspiro[4,5]dec-8-ylmethyl)-1*H*-pyridin-2-one (II). A reaction flask was charged with 2.85 g (0.03 mol) of pyridin-2-ol and 2.25 g (0.075 mol) of 40% Formalin. To this mixture, a solution of 5.13 g (0.03 mol) of 6,9-dimethyl-1,4-dioxa-8-azaspiro[4,5]decane in 9 ml of alcohol (pH 9) was added dropwise with stirring. The mixture was stirred at room temperature for additional 3 h. The precipitate was separated and recrystallized from benzene to give a white crystalline substance; yield 5 g (60.5%), mp 120–122°C.

Found, %: C 64.4, H 8.2, N 9.6.

$C_{15}H_{22}N_2O_3$.

Calculated, %: C 64.7, H 7.9, N 10.1.

The solvent from the mother liquor was distilled off, and the precipitate was recrystallized from benzene to give a pinkish substance; yield 2.9 g (35%), mp 118–120°C.

Found, %: C 64.5, H 8.2, N 9.8.

$C_{15}H_{22}N_2O_3$.

Calculated, %: C 64.7, H 7.9, N 10.1.

CONCLUSIONS

(1) 1-(6,9-Dimethyl-1,4-dioxa-8-azaspiro[4,5]dec-8-ylmethyl)-1*H*-pyridin-2-one (ShA-8) was prepared; its structure was proved by NMR spectroscopy.

(2) Pyridin-2-ol reacts with formaldehyde and secondary amine under conditions of the Mannich reaction in alcohol (pH 9) in the pyridone form; condensation occurs at the nitrogen atom.

Abstract—Alkenylation of anilines with dicyclopentadiene, cyclopentadiene, and piperylene in the presence of mineral acids and Lewis acids was studied.

The discovery of the Claisen rearrangement of aromatic amines [1] provided access to 2-alkenyl-substituted arylamines, including cyclopentenyl- and pentenylanilines [2], which can be prepared from dicyclopentadiene (DCPD) or piperylene. A number of valuable compounds have been prepared from these amines, such as alkaloids [3], steel corrosion inhibitors, fungicides, plant growth stimulants, antiphytophthora agents, and local anesthetics [4–6]. The presence in allylaniline molecules of several reaction centers allows their transformations involving nitrogen atom, alkenyl fragment, or both centers simultaneously. The possibility of preparing new biologically active derivatives from 2-alkenylanilines by common reactions of amines or by certain specific reactions makes these compounds valuable synthons. To look for an alternative to the Claisen rearrangement of aromatic amines as a route to *o*-alkenylanilines, we studied alkenylation of anilines with DCPD, cyclopentadiene (CPD), and piperylene.

Reactions of DCPD with amines **I** and **II** in the presence of HCl at 130–220°C gave as main products the previously described [2] *o*-cyclopentenylanilines **III** and **IV** (yield of up to 45%) and also *N*-phenyl-(8*S*)- (**V**) and *N*-phenyl-(8*R*)-tricyclo[5.2.1.$0^{2,6}$]dec-3-en-8-amine (**VI**). Elevated temperatures (200°C) and longer reaction time favor cyclization of *o*-cyclopentenylanilines **III** and **IV** into hexahydrocyclopent[*b*]-indoles **VI** and **VIII** [7] and formation of *p*-cyclopentenylanilines **IX** and **X** [8] (Table 1). In the case of aniline (**I**), *o*,*o*-dicyclopentenylaniline (**XI**) [9] was also detected (<3%). When freshly distilled CPD is taken in reaction with aniline hydrochloride, the yield of a mixture of exo isomers **V** and **VI** decreases somewhat.

* (AA) Alkenylated aniline.

VI are formed, as well as the products of alkenylation of the aromatic ring, 2-[(3*S*)- (**XII**) and 2-[(3*R*)-tricyclo-[5.2.1.$0^{2,6}$]dec-8-en-3-yl]amines (**XIII**). With increasing amount of $AlCl_3$, the relative content of **III** and **IX** decreases. At a 1 : 1 ratio of DCPD and $AlCl_3$, only amines **XII** and **XIII** are formed. With the $FeCl_3 \cdot 6H_2O$ catalyst taken in the same amount as $AlCl_3$, the relative content of **III** and **IX** is somewhat higher than that of **V**, **VI**, **XII**, and **XIII**. In the case of *o*-toluidine (**II**) and $AlCl_3$ catalyst, the composition of products, according to GLC, is the same as with that in the case of aniline (**I**).

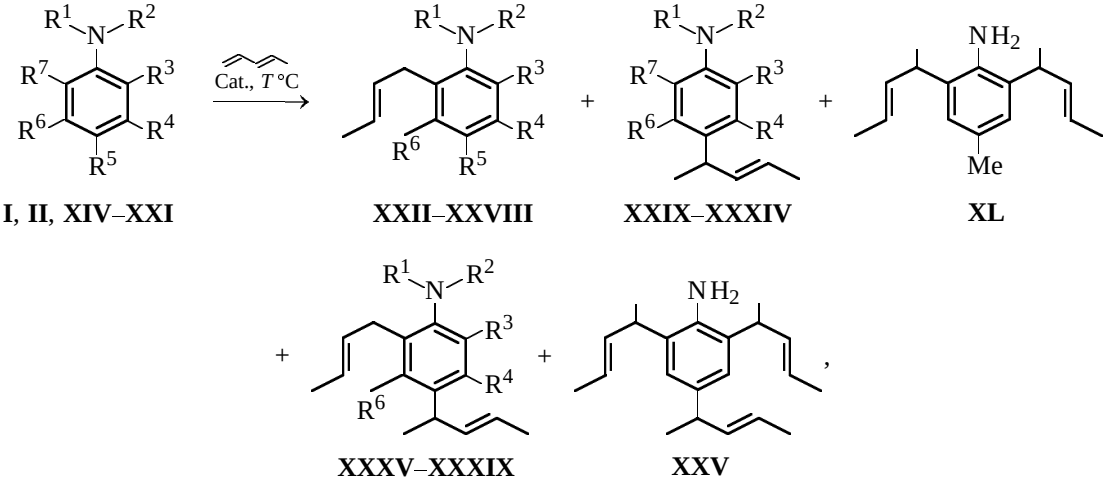
The structure of **V**–**XIII** was confirmed by spectroscopic methods [10] and elemental analysis. The IR spectra [11] of **V** and **VI** contain a characteristic band of the NH group at 3430 cm^{-1}, and the spectra of **XII** and **XIII**, the bands of the NH_2 group at 3390 and 3470 cm^{-1}. The aromatic protons in the ^1H NMR spectrum of **IX** appear as two doublets (2H each) at 6.12 and 7.00 ppm. The methine 1'-H signal is a multiplet (1H) at 3.85 ppm. The broadened singlet of the NH group is observed at 3.50 ppm. Four protons of two CH_2 groups give rise to multiplets at 1.60 (1H) and 2.40 ppm (3H).

In *N*-substituted anilines, the C^2 and C^6 atoms, as well as the C^3 and C^5 atoms, are mutually equivalent. Therefore, the corresponding region of the ^{13}C NMR spectrum contains only four aromatic carbon signals and two signals of the olefin carbon atoms of the tricyclodecene moiety.

The ^{13}C NMR spectrum of *o*-substituted anilines **XII** and **XIII** contains in the region of aromatic carbon signals two sets of signals (eight signals each). Twelve of these 16 signals were assigned to the carbon atoms of the phenyl ring using the pulse train of a *J*-modulated spin echo.

In the case of *p*-substitution, the ^{13}C NMR spectrum would be simpler owing to the symmetrical structure of the aromatic moiety. Exo addition of the *N*-phenyl substituent to DCPD in **V** and **VI** is confirmed by the upfield shift (to 39.6 and 39.4 ppm) of the triplet of the bridging C^{10} atom. The formation of isomeric products **V** and **VI** is confirmed by characteristic doublets at 52.95 (56.42) ppm in the ^{13}C NMR spectrum and by single-proton doublets of doublets of *exo* protons at 3.34 (3.33) ppm (3 : 1 ratio) in the ^1H NMR spectrum. The ^{13}C NMR spectrum of **V** and **VI** contains only one signal of the C^3 cyclopentene carbon atom (in **V**; in **VI** it is C^5), whereas the spectrum of the mixture of diastereomers **XII** and **XIII** contains in the range 26.6–33.4 ppm six signals: 29.6, 32.6, and 36.6 ppm for *anti* diastereomer **XIII** and 32.2, 33.4, and 33.5 ppm for *syn* diastereomer **XII**. The *o*-substitution of the aromatic ring is confirmed by calculations using additive parameters.

The results of alkenylation of anilines **I**, **II**, and **XIV**–**XXI** with piperylene in the presence of KU-2 are listed in Table 2. The reaction is selective and, in the case of 2,4-xylidine (**XVI**) and 2-methyl-6-ethylaniline (**XVII**), yields a single product. This is due to the availability in these amines of only one position capable of alkenylation:



I, **II**, **XIV**–**XXI** **XXII**–**XXVIII** **XXIX**–**XXXIV** **XL**

XXXV–**XXXIX** **XXV** (2)

where $R^1 = R^2 = R^3 = R^4 = R^5 = R^6 = R^7 = H$ (**I**, **XXII**, **XXIX**, **XXXV**); $R^1 = R^2 = R^4 = R^5 = R^6 = R^7 = H$, $R^3 = Me$ (**II**, **XXII**, **XXX**, **XXXV**); $R^1 = R^2 = R^3 = R^5 = R^6 = R^7 = H$, $R^4 = Me$ (**XIV**, **XXIV**, **XXXI**; $R^1 = R^2 = R^3 = R^4 = R^6 = R^7 = H$, $R^5 = Me$ (**XV**, **XXV**); $R^1 = R^2 = R^4 = R^6 = R^7 = H$, $R^3 = R^5 = Me$ (**XVI**, **XXVI**); $R^1 = R^2 = R^4 = R^5 = R^6 = H$, $R^3 = Me$, $R^7 = Et$ (**XVII**, **XXXII**); $R^1 = R^2 = R^4 = R^5 = R^7 = H$, $R^3 = R^6 = Me$ (**XVIII**, **XXXIII**); $R^1 = R^2 = R^4 = R^6 = R^7 = H$, $R^3 = R^5 = OMe$ (**XIX**, **XXVII**); $R^1 = R^2 = R^4 = R^5 = R^6 = R^7 = H$, $R^3 = Cl$ (**XX**, **XXVIII**, **XXXIV**, **XXXVII**); $R^1 = R^2 = Bu$, $R^4 = R^6 = R^7 = R^3 = R^5 = H$ (**XXI**, **XXXIX**).

In the case of 2,5-xylidine (**XVIII**), and also with *N*,*N*-dibutylaniline (**XXI**), the formation of a single product is probably due to the steric and electronic effects of substituents. Alkylation of aniline (**I**) with piperylene in the presence of supported H_3PO_4 gives a large set of products in low total yield (Table 3). With $AlCl_3$ used as catalyst for alkenylation of piperylene, the best result was achieved in synthesis of 2,4-tri(1-methylbut-2-en-1-yl)aniline. In other cases, it is impossible to selectively obtain a single product although the total yield is sometimes high, (Table 4).

The physicochemical characteristics of compounds alkenylated with piperylene were reported in [12–14].

EXPERIMENTAL

The IR spectra were taken on a UR-20 spectrometer, and the ^1H and ^{13}C NMR spectra, on a Bruker AM 300 spectrometer (working frequencies 300 and 75 MHz, respectively). Internal reference TMS, solvent $CDCl_3$. Elemental analysis was performed with an M-185B C–H–N analyzer, and the GLC analysis (including purity check), on a Chrom-5 chromatograph (carrier gas helium, flame-ionization detector, 1200 × 3-mm column, stationary phase SE-30, 5% on Chromaton N-AW DMCS, working temperature 50–300°C). Column chromatography was performed on silica gel LS 40/100 μm and Silpearl (eluent hexane). Qualitative TLC analysis was made with Silufol UV 254 and UV 254/366 plates; the chromatograms were developed under UV (λ = 254 nm) or with iodine vapor.

The alkenylation of anilines with DCPD, CPD, and piperylene was performed in a sealed heat-resistant

ampule or a 17-ml metallic autoclave, charged with the reactants and catalyst. The component ratios, reaction times and temperatures, and product yields are given in Tables 1–4. After the reaction was complete, the ampule or autoclave was cooled and opened, and the reaction mixture was transferred with chloroform into a separatory funnel. The mixture was treated with 5% KOH (2 × 100 ml), extracted with chloroform (2 × 50 ml), and dried over crystalline KOH. Then the mixture was filtered, the solvent was evaporated, and the residue was fractionated in a vacuum. With HCl catalyst, the reaction performed at 140–180°C gave after vacuum distillation monoalkenylated amine **III** or **IV**. Using the same reaction at 200°C with aniline **I** or **II**, we isolated, after vacuum distillation, amine **III** or **IV** with an admixture of indoline **VII** or **VIII** and *p*-substituted product **IX** or **X**. Indolines and *p*-substituted products were identified by GLC upon addition of authentic samples [3, 8]. The reaction with $AlCl_3$ catalyst gave, after vacuum distillation, a mixture of **III** + **IX** or **IV** + **X**, chromatographed on silica gel (eluent benzene). The products were identified by comparison of their ^1H and ^{13}C NMR spectra with those of authentic samples [2, 8, 9]. The fraction containing anilines **V** and **VI**, prepared by alkenylation of **I** in the presence of HCl, was analyzed as a mixture. The fraction containing N- (**V**, **VI**) and C-substituted products (**X**, **XI**), obtained by the reaction with $AlCl_3$ catalyst, was separated by chromatography on silica gel (eluent hexane). The **V** + **VI** and **X** + **XI** pairs were obtained as several fractions with varied component ratios. The physicochemical characteristics of 2-(cyclopent-2-enyl)anilines **II** and **IV** [2] indolines **VII** and **VIII** [7], and 4-(cyclopent-2-enyl)anilines **IX** and **X** [8, 9] were consistent with the relevant published data. Alkenylated anilines **XXII**–**XL** were isolated by column chromatography (alumina, eluent hexane), and their physicochemical characteristics were compared with those of authentic samples [12–14].

CONCLUSION

Alkenylation of anilines with dicyclopentadiene or cyclopentadiene in the presence of HCl yields *o*-cyclopentenylanilines as the main products. At higher temperatures (200°C) and longer reaction times, perhydrocyclopent[b]indolines are formed. With $AlCl_3$ catalyst, both *o*- and *p*-cyclopentenyl derivatives are obtained. Also, significant amounts of dicyclopentadiene substitution products are formed in both cases. Alkenylation of anilines with piperylene gives 2-, 4-, 2,4-di-, and 2,4,6-trialkenylated products. If the 4- or 2,4-positions of the aromatic ring are substituted, the alkenyl group is introduced at the free *o*- or *p*-position, respectively.

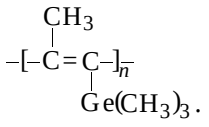
Abstract—Samples and fractions of a membrane-forming polymer poly[1-(-trimethylgermyl)propyne], with the molecular weight within $4 < M \times 10^{-4} < 170$ were studied in cyclohexane by methods of molecular hydrodynamics (centrifugal sedimentation, translational isothermal diffusion, and viscometry). The molecular-weight dependences of the hydrodynamic characteristics were determined and analyzed. These dependences were used to estimate the equilibrium rigidities of the poly[1-(trimethylgermyl)propyne] chains. The size of the macromolecules was studied as influenced by the bulk effects. The results obtained are compared with published data for poly[1-(trimethylsilyl)propyne].

Glassy polymers based on silicon- and germanium-containing vinyl monomers exhibit high selectivity in gas separation [1–3]. These polymers include poly[1-(trimethylsilyl)propyne] (PTMSP) [3–4] which exhibits extraordinary gas permeability and dissolution and diffusion coefficients [3–5]. A distinguishing feature of PTMSP is the unprecedented level of selective gas transfer, exceeding by an order of magnitude that of high-permeability rubbers. These unique membrane properties of PTMSP are attributed to a combination of at least several features of its molecular structure: (1) presence of double bonds strengthening the molecular chain; (2) composition and specific features of distribution along the chain of the double –C=C bonds in *cis* and *trans* configurations, and (3) presence of weakly interacting bulky side substituents $Si(CH_3)_3$ [5–9]. All this is likely to ensure a large free volume in the polymer matrix, essential for the unique gas permeability of the polymer membranes. The great promise of such polymers for the membrane technology [10] makes necessary a thorough investigation of the molecular characteristics of membrane-forming polymers, in particular, by various methods of molecular physics.

To gain insight into the nature of facile gas transfer in glassy organoelement polymers, it is of interest to study analogous polymers. Of importance from this viewpoint is a study of the organogermanium analog of PTMSP, poly[1-(trimethylgermyl)propyne] (PTMGP) [11] with Si atoms in the side chain replaced by Ge atoms. In this work, samples and fractions of a new membrane-forming polymer, PTMGP, are studied by molecular hydrodynamics methods such as centrifugal sedimentation, translational diffusion, and viscometry.

A PTMGP sample was synthesized using $TaCl_5$/BuLi [11] as catalyst. According to the ^{13}C NMR data, the average (per cent) ratio of the *cis*-*trans* –C=C fragments was 9 : 91. The repeating unit of the polymer has the structural formula



The sample was fractionated from a CCl_4 solution by fractional precipitation with ethanol. We obtained seven fractions (Table 1), and fraction no. 4 was subsequently refractionated (fraction nos. 8–11); as sample no. 12 served the initial unfractionated substance. The fractionation yield was 97%. The sample and its fractions were studied by the methods of molecular hydrodynamics.

* $[\eta]$ is the intrinsic viscosity, k' is the Huggins constant, D is the diffusion coefficient, $\Delta n/\Delta c$ is the refraction index increment, s_0 is the sedimentation coefficient, k_s is the Gralen coefficient, M_{sD} is the molecular weight according to Swedberg, A_0 is the hydrodynamic invariant, β_s is the sedimentation parameter, and γ is a dimensionless parameter.

** $M_{s\eta}$ and M_{ks}.

*** $M_{s\eta}$.

Centrifugal sedimentation was carried out on an MOM 3180 analytical ultracentrifuge in a one-sector cell at 40 000 rpm. As the optical recording system served a Lebedev polarization interferometer [12, 13]. The sedimentation coefficients s were calculated from the shift of the sedimentation boundary X with time. Figure 1a shows the $\Delta \ln X$-vs.-Δt dependences whose slopes provided the values of the $s = \omega^{-2}(\Delta \ln X/\Delta t)$ parameter (ω is the angular velocity of rotation of the rotor). We studied the concentration dependence of the sedimentation coefficient, satisfying the linear approximation $s^{-1} = s_0^{-1}(1 + k_s c + ...)$. Figure 1b presents the s^{-1}-vs.-c dependence from which the coefficient s_0 and the Gralen coefficient k_s were determined. The following correlation was established between the s_0 and k_s parameters: $k_s = 2.5\ s_0^{1.85 \pm 0.3}$. The average value of the dimensionless parameter $k_s/[\eta] \equiv \gamma$ for all the fractions studied was $\gamma = 1.3 \pm 0.3$.

Translational diffusion was studied by the classic method of formation of a solution–solvent boundary whose position was determined at regular time intervals using a polarization interferometer. The setup (Tsvetkov's diffusometer) and the calculational algorithm for finding the diffusion coefficient D have been described in numerous publications [12, 13]. The refractive index increments $\Delta n/\Delta c$ were calculated from the area delimited by the diffusion curve.

The intrinsic viscosities $[\eta]$ were determined from the Huggins plots $\eta_{sp}/c = [\eta] + k'[\eta]^2 c + ...$ with $[\eta]_{sp} \equiv (\eta - \eta_0)/\eta_0 = (t - t_0)/t_0$, where η and η_0 are the viscosities of the solution and solvent, respectively, and t and t_0 are the times of flow of the solution and solvent in the Ostwald viscometer, respectively. The values of the parameters $[\eta]$ and Huggins parameter k' are presented in Table 1 together with other hydrodynamic characteristics. The floatability factor $(1 - \nu\rho_0)$ (or the density increment $\Delta\rho/\Delta c$) was estimated from the pycnometrically measured data for so-

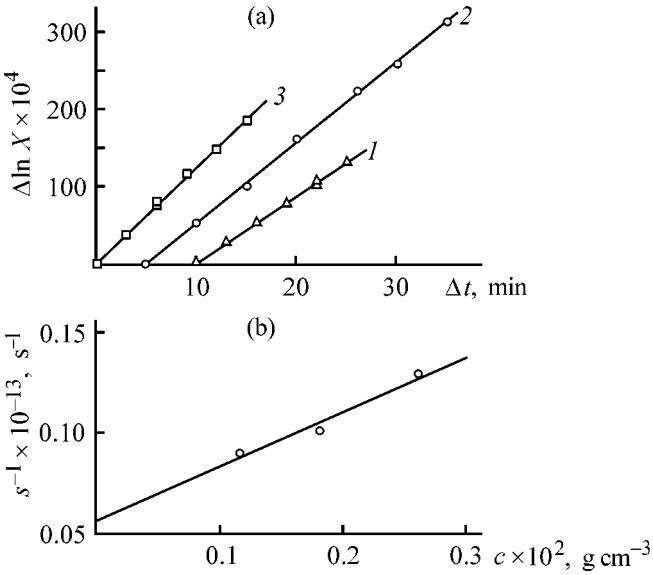

Fig. 1. (a) $\Delta \ln X$-vs.-Δt dependences for fraction no. 5 and (b) s^{-1}-vs.-c dependences for fraction no. 4 of PTMGP in cyclohexane. PTMGP concentration $c \times 10^2$, g cm^{-3}: (*1*) 0.261, (*2*) 0.181, and (*3*) 0.116.

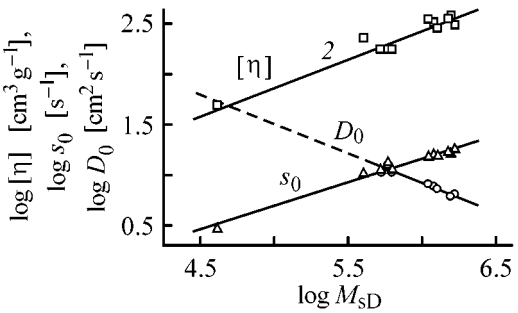

Fig. 2. K–M–H–S dependences for PTMGP in cyclohexane.

lutions in cyclohexane: $(1 - \nu\rho_0) = 0.417$. The viscosity of cyclohexane at 25°C η_0 is 0.859×10^{-2} poise.

The hydrodynamic characteristics presented in Table 1 made it possible to calculate the molecular weights M according to Swedberg [12] and to find of the hydrodynamic invariant A_0 [12] and the sedimentation parameter β_s [15], using the formulas

$$M_{sD} = R[s]/[D],$$
$$A_0 = (R[D]^2[s][\eta])^{1/3},$$
$$\beta_s = N_A(R[D]^2[s]k_s)^{1/3}.$$

Here, $[s] \equiv s_0\eta_0/(1 - \nu\rho_0)$, $[D] \equiv D_0\eta_0/T$, R is the universal gas constant, N_A is the Avogadro number, and T is the temperature, K.

The molecular weights and hydrodynamic invariants are presented for the PTMGP molecules in Table 1. The average value of the hydrodynamic invariant A_0 was estimated to be $(3.3 \pm 0.3) \times 10^{-10}$ g cm^2 s^{-2} deg^{-1} mol$^{-1/3}$, and the average value of the sedimentation parameter β_s, $(1.23 \pm 0.08) \times 10^7$ mol$^{1/3}$. These values are typical of linear polymer homologs [13, 15]; they were used in calculating the molecular weights of fraction nos. 6–8 and unfractionated sample no. 12 (Table 1) by the relations

Table 2. Parameters of scaling relations between the hydrodynamic characteristics and molecular weight for PTMGP in cyclohexane

Relation	b_i	Δb_i	K_i	r_i	n
$[\eta]$–M	0.53	0.05	0.173	0.9645	11
D_0–M	–0.59	0.06	2.79×10^{-4}	–0.9743	8
s_0–M	0.47	0.02	2.09×10^{-15}	0.9896	11

* b_i are the coefficients of the $D_0 = K_2M^{b2}$ type relations; r_i are the linear correlation coefficients for relations of the $\log k_s = \log K_4 + b_4 \log s_0$ type; n is the number of the points through which a straight line is drawn.

$$M_{s\eta} = (R/A_0)^{3/2}[s]^{3/2}[\eta]^{1/2},$$
$$M_{ks} = (N_A/\beta_s)^{3/2}[s]^{3/2}k_s^{1/2}.$$

The molecular weights obtained were used for plotting the Kuhn–Mark–Hauwink–Sakurada (K–M–H–S) dependences (Fig. 2) and calculating the corresponding scaling coefficients (Table 2). To within the root-mean-square errors, the scaling indices are described by the relations

$$|b_2| = (1 + b_1)/3, \quad (1)$$
$$|b_2| + b_3 = 1, \quad (2)$$
$$b_4 = (2 - 3b_3)/b_3, \quad (3)$$

which are typical of linear polymer homologs [12, 16, 17].

As follows from Table 1, the sample is fractionated not only with respect to the molecular weight. Certain role is probably played by uncontrolled variations in the content of the *cis* and *trans* fragments and by differences in the microblock structure (ratio of *cis* and *trans* blocks) of macromolecules for virtually identical compositions.

In view of the different numbers of the experimental points used for deriving the K–M–H–S relations and with account of expressions (1)–(3), the K–M–H–S relations were corrected within the root-mean-square errors to yield

$$[\eta] = 9.75 \times 10^{-2}M^{0.575},$$
$$D_0 = 1.19 \times 10^{-4}M^{0.525},$$
$$s_0 = 2.0 \times 10^{-15}M^{0.475}.$$

It should be noted that in this case the pre-exponential factors in the K–M–H–S equations are unambiguously related to the hydrodynamic invariant A_0

$$K_\eta^{1/3}K_D = A_0(T/\eta_0), \quad (4)$$
$$K_\eta^{1/3}K_s = A_0[(1 - \nu\rho_0)/(R\eta_0)]. \quad (5)$$

Relations (4) and (5) make it possible to estimate the average A_0 parameter for the PTMGP molecules in cyclohexane. It can be easily seen that this is identical to the average value obtained from the values presented in Table 1.

The size of the PTMGP macromolecules can be tentatively analyzed using the normalized scaling relations [18, 19], as it was done in [20]. Figure 3

presents a plot of this kind for the intrinsic viscosity. It is seen that the PTMGP molecules occupy an intermediate position between the rigid-chain and flexible-chain macromolecules. In this case we cannot rule out entirely the influence of bulk effects on the size of globules in solution. This is a common situation for macromolecules with intermediate rigidity [22, 23]; in particular, it has been observed for PTMSP molecules [23].

We will characterize the bulk effects by the parameter ε, for which holds $\langle h^2 \rangle \sim M^{1+\varepsilon}$, where $\langle h^2 \rangle$ is the root-mean-square distance between the chain ends. The parameter ε was calculated by the expressions $\varepsilon = (2b_\eta - 1)/3 = (2|b_D| - 1)$ [24]. Thus, the parameter ε may fall within $0 \le \varepsilon \le 0.05$. As is known [25, 26], the most general, and the only, theory describing the translational friction of a worm-like necklace with account of the bulk effects is the theory presented in [27], according to which for the following expression holds for [*s*]

$$[s]P_0N_A = [3/(1-\varepsilon)(3-\varepsilon)]M_L^{(1+\varepsilon)/2}A^{-(1+\varepsilon)/2}M^{(1-\varepsilon)/2} + (M_L P_0/3\pi)[\ln A/d - 1/3(A/d)^{-1} - \varphi(\varepsilon)]. \quad (6)$$

Here, *d* is the hydrodynamic diameter of the chain, and φ(ε) is a function that can be tabulated [27].

At ε = 0, formula (6) turns into relation obtained for the translational friction of a worm-like necklace without bulk interactions [28], and the corresponding φ(0) is 1.431. In terms of the theory of translational friction for a worm-like cylinder, the function φ(0) takes the value of 1.056 [29], which is known to entail slightly greater hydrodynamic cross section of the polymer chain (Table 3). Figure 4 presents the dependences corresponding to relation (6) for ε = 0 and ε = 0.05. The values estimated from these plots are presented in Table 3.

Assuming a constant size of the macromolecules in translational friction and viscosity phenomena and a constant hydrodynamic invariant A_0 in the homologous series of the polymer, we can write, similarly to [30, 31],

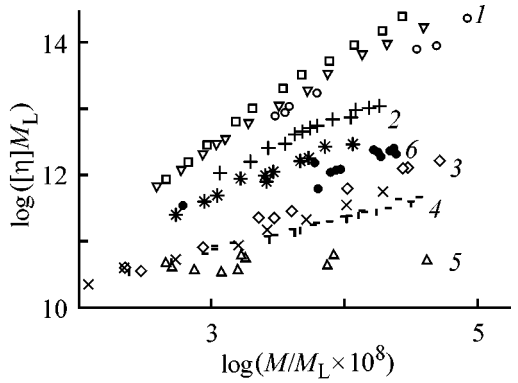

Fig. 3. Normalized scaling dependence $\log([\eta]M_L)$–$\log(M/M_L)$. Macromolecules: (*1*) extrarigid, (*2*) rigid, (*3*) flexible in thermodynamically good solvents, (*4*) flexible in θ-solvents, (*5*) globular [19, 20], and (*6*) data from Table 1.

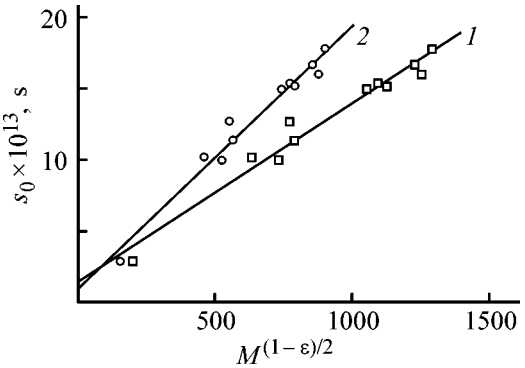

Fig. 4. Plot of s_0(c) vs. $M^{(1-\varepsilon)/2}$. ε: (*1*) 0 and (*2*) 0.05; the same for Fig. 5.

$$[s]P_0N_A = (M^2\Phi_0/[\eta])^{1/3}. \quad (7)$$

Thus, we consider the viscometric data in the coordinates $(M^2/[\eta])^{1/3} = f(M^{(1-\varepsilon)/2})$, where the function is defined by the right side of Eq. (6). This dependence was first used in [26]; for ε = 0 it turns into the known Bushin–Tsvetkov plot [13] for worm-like cylinder without bulk interactions. The plots corre-

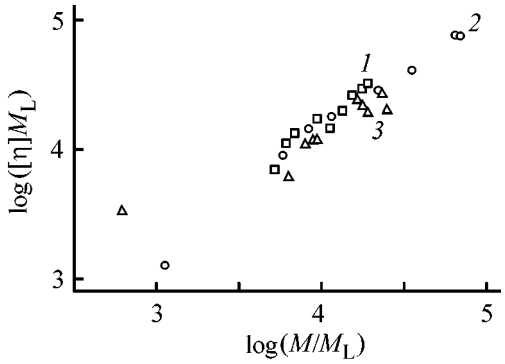

Fig. 6. $\log[\eta]M_L$–$\log(M/M_l)$ dependence for PTMGP and PTMSP. Data taken from: (*1*) [33] and (*2*) [7, 23]; (*3*) data from Tables 1 and 3.

sponding to relations (6) and (7) are presented in Fig. 5, and the data derived from these plots, in Table 3.

For objective reasons, the molecular weight range studied in this work is insufficiently wide, and the main body of the data corresponds to large M values ($M > 400 \times 10^3$). Therefore, the reliability of determining the hydrodynamic cross section of the macromolecules is not high, despite the fairly good correlation between the corresponding linear plots (linear correlation coefficients $r > 0.98$). At the same time, the Kuhn segment length is estimated with a sufficient reliability (Table 3). The translational friction measurements yielded $86 < A_f \times 10^8 < 106$ cm, and viscometric measurements gave $54 < A_\eta \times 10^8 < 68$ cm. These quantitative estimates agree well with the qualitative estimates in terms of normalized scaling relations (Fig. 3). The estimated A_f and A_η values typically disagree for linear polymers, which is explained by disagreements between the theories of translational and rotational friction of polymer chains [13].

In conclusion, we compare our results with the earlier data for PTMSP, a polymer analog of PTMGP [7, 32] differing in the presence of a Si atom in the side chain and in the ratio of *cis* to *trans* fragments. This comparison was also made for normalized scaling relations. The results are presented in Fig. 6, which suggests that the molecules of the compared polymers are close in size. This may be due to the competing influence of the composition and/or microblock structure of the polymers and the thermodynamic quality of the solvents in the polymer–solvent systems. Singling out each of these effects is not a trivial task, which calls for additional investigations over a wide range of molecular weights, including rather low M values.

CONCLUSION

Samples and fractions of a new membrane-forming polymer, poly[1-(trimethylgermyl)propyne] were studied by methods of molecular physics. The degrees of polymerization P of these fractions vary within $0.25 \le P \times 10^{-3} \le 10$. It was shown that poly[1-(trimethylgermyl)propyne] molecules belong to the intermediate group of semirigid macromolecules, for which the influence of both the hydrodynamic flow and the intrachain bulk effects on the chain size in solutions should be taken into account. Comparison of the characteristics of poly[1-(trimethylgermyl)propyne] and poly[1-(trimethylsilyl)propyne] revealed no large difference between the sizes of the chains when the Si atom in the side groups of the macromolecules was replaced with a Ge atom.

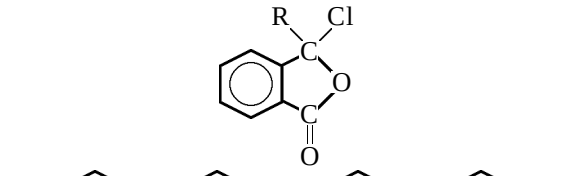
Abstract—The applicability to vinyl polymers of the procedure for quantitative determination of phthalide groups in polymeric molecules from the color of their sulfuric acid solutions was examined. The correlation between the intensity of the color of sulfuric acid solutions of polymers (polymethyl methacrylate, polystyrene) and the content of phthalide fragments incorporated into the polymer molecule was studied systematically on a quantitative level.

At present, active studies are being performed of transition of undoped polymers into a highly conducting state. Of the greatest interest in this respect are polymers containing phthalide groups [1, 2]. However, such polymers are prepared by polycondensation, and their film-forming properties are often unsatisfactory. Polyacrylates, in particular, polymethyl methacrylate (PMMA), are free of these drawbacks. Therefore, incorporation into PMMA macromolecules of phthalide fragments is of scientific and practical interest.

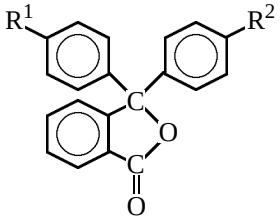
Phthalide fragments can be incorporated into a polymeric molecule in the course of radical polymerization by involving them in chain transfer or initiation reactions [3]. In this connection, determination of the content of phthalide units in a polymeric molecule becomes an urgent problem.

It is known [2, 4] that polyarylene phthalides dissolve in concentrated H_2SO_4 to form intensely colored solutions stable in time. The color probably originates from opening of the phthalide ring and formation of carbocations of the triphenylmethane series in the polymeric chain [5, 6]. The structure and properties of low-molecular-weight triphenylmethyl monocarbocations formed by dissolution of organic compounds of various classes in solvents with a high ionizing power and low nucleophilicity, such as liquid SO_2 and HCl, concentrated H_2SO_4 and $HClO_4$, etc. [7–9], have been studied in sufficient detail. It would be expected that phthalide groups incorporated into PMMA or polystyrene impart color to sulfuric acid solutions of these polymers.

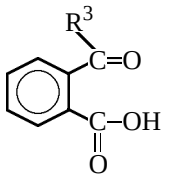
In this work we studied sulfuric acid solutions prepared both from phthalides of various structures and from polymers obtained in their presence, with the aim to determine the content of phthalide units incorporated into a macromolecule and the role of phthalides in polymerization:



R =  (**I**),  (**II**),

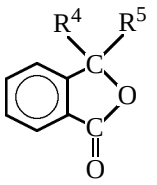


$R^1 = R^2$ = Cl (**III**), F (**IV**),

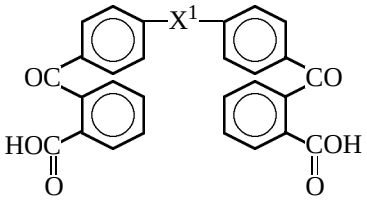


R^3 =  (**V**),  (**VI**),

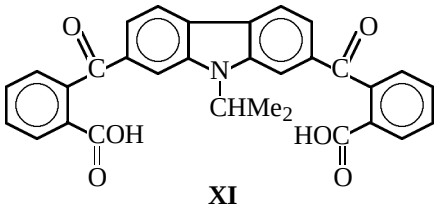
1070-4272/01/7402-0292 $25.00



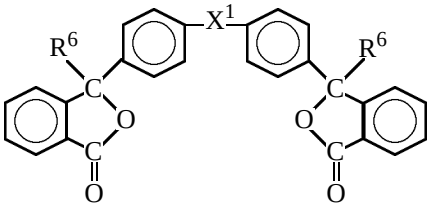
$R^4 = R^5 = H$ (**VII**),  (**VIII**),



$X^1 = O$ (**IX**), S (**X**),

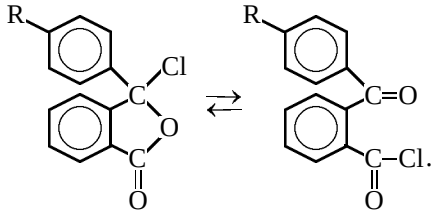


XI



$X^1 = –$, R^6 = Ph- (**XII**); X^1 =  , R^6 =  (**XIII**); X^1 =  , R^6 =  (**XIV**).

We also considered "pseudophthalides" **V**, **VI**, and **XI**–**XIV**, which contain no phthalide ring but can form it under appropriate conditions, e.g., under the action of sulfuric acid. It is known [10] that phthalides exhibit dual chemical activity owing to their possible existence as the cyclic and open tautomers:



EXPERIMENTAL

The phthalides used in this work were prepared by the Friedel–Crafts reaction [11, 12]. The procedures of their synthesis and purification and some of their properties are given in [3, 12].

Sulfuric acid was doubly distilled; bp 278°C (98.3%).

Methyl methacrylate (MMA) and styrene were purified to remove the stabilizer by shaking with a 5–10% KOH solution, washed with water to neutral reaction, dried over $CaCl_2$, and doubly-distilled in a vacuum. The fractions with bp 42°C (13.3 kPa, MMA) and 70°C (8.0 kPa, styrene) were taken for polymerization.

Initiators were repeatedly recrystallized from methanol and dried at room temperature in a vacuum to constant weight.

Polymerization was performed in the bulk [13]. After reaching 5% conversion, the polymer was extracted with methanol or hexane and dried. Its molecular weight M_η was determined viscometrically in benzene at 25 ± 0.05°C from the intrinsic viscosity $[\eta]$ [13]:

$$[\eta] = KM_\eta^\alpha,$$

where $K = 0.94 \times 10^{-4}$, $\alpha = 0.76$ (PMMA); $K = 2.70 \times 10^{-4}$, $\alpha = 0.66$ (polystyrene).

Before determining the content of phthalide groups, polymer samples were repeatedly extracted with methanol in a Soxhlet apparatus, free phthalides **I**–**XIV** being readily soluble in methanol.

The molecular-weight distribution (MWD) curves were obtained with a KhZh-1302 gel chromatograph. Columns were packed with Waters styrogel, pore size 10^2–10^6 Å. The eluent was chloroform, flow rate 1 ml min^{-1}, 25°C. The columns were calibrated by polystyrene reference samples (Aldrich, US).

The electronic absorption spectra (solutions in 98% sulfuric acid) were taken on a Shimadzu UV-3100 UV–VIS–NIR spectrophotometer using 1-cm quartz cells. Solutions of other concentrations were prepared by dilution. The molar extinction coefficients ε (l mol^{-1} cm^{-1}) were calculated by the Bouguer–Lambert–Beer equation [14]

$$D = \varepsilon Cl.$$

where D is the optical density of solution, C is the solution concentration (M), and l is the cell thickness (cm).

Table 1. Aromatic phthalides used in PMMA synthesis and spectral characteristics of their solutions in concentrated H_2SO_4

Phthalide	λ_{max}, nm	Color	ε, l mol^{-1} cm^{-1}	Phthalide	λ_{max}, nm	Color	ε, l mol^{-1} cm^{-1}
I	537	Cherry	11684	**VIII**	585	Pinkish blue	11000
II	555	Cherry-red	43555	**IX**	461	Yellow	44279
III	481	Yellow	5209	**X**	545	Crimson-violet	39301
IV	453	Lemon-yellow	15448	**XI**	527	Claret	37160

VI	553	Cherry	43408	**XIII**	645	Sky-blue	72870
VII	296	Colorless	1407	**XIV**	687	Blue	100877

One of the most important problems in studying these polymers counsists in determining the content of phthalide groups incorporated into the polymeric molecule. Previously, polymerization of MMA has been performed in the presence of phthalide-containing compounds of various classes: ketocarboxylic acids, their chlorides, and arylene phthalides [3]. Attempts to determine the composition by elemental analysis failed, because the content of phthalide units was too low to be determined reliably. Therefore, we took advantage of the property of phthalides to form intensely colored solutions in concentrated H_2SO_4.

Solutions of phthalides in sulfuric acid are intensely colored except in the case of phthalide **VII** absorbing in the UV range (Table 1). In the examined phthalide concentration range $(0.5–8.5) \times 10^{-5}$ M, the Bouguer–Lambert–Beer law is valid. The concentration dependence of the spectra, used to calculate the extinction coefficients (Table 1), is illustrated in Fig. 1 for phthalide **II** as an example.

Figure 2 (curve *1*) shows the absorption spectra of phthalide **VIII** in 98% H_2SO_4. The spectrum underwent no changes in 25 h, which confirms the published data indicating the stability of phthalide solutions in concentrated H_2SO_4 [4].

Thus, solutions of phthalides in concentrated H_2SO_4 are intensely colored and fairly stable; the validity of the Bouguer–Lambert–Beer law and high extinction coefficients allow spectrophotometric determination of the content of phthalimide units in PMMA or polystyrene macromolecules.

Figure 2 (curve *2*) shows the spectrum of a PMMA solution obtained in the presence of phthalide **VIII**. It is seen that it practically coincides with the absorption spectrum of free phthalide. This means that

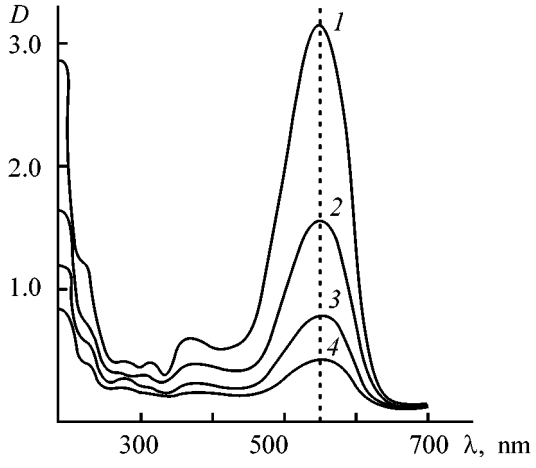

Fig. 1. Absorption spectra of sulfuric acid solutions of phthalide **II**. (*D*) Optical density and (λ) wavelength; the same for Figs. 2 and 3. Concentration of **II** in H_2SO_4, $C \times 10^5$, M: (*1*) 7.18, (*2*) 3.59, (*3*) 1.80, and (*4*) 0.90.

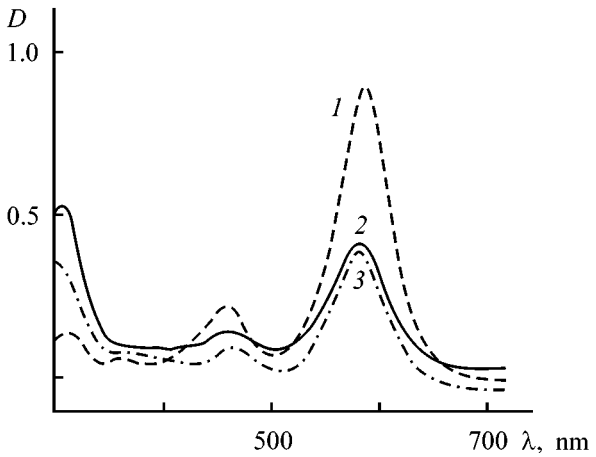

Fig. 2. Absortpion spectra of sulfuric acid solutions of (*1*) phthalide **III**, (*2*) PMMA prepared in the presence of phthalide **VIII**, and (*3*) PMMA prepared in the presence of phthalides **VIII** and **V**.

the polymeric chain of PMMA does not interfere with determination of the phthalide. Similar results are obtained in dissolution of polystyrene in H_2SO_4, but, in this case, the dissolution occurs very slowly on stirring the preliminarily pulverized polystyrene.

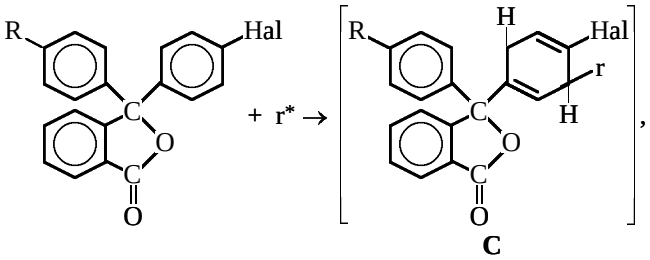
The visible-range spectra of PMMA and polystyrene solutions also remain unchanged during 24 h (Fig. 3).

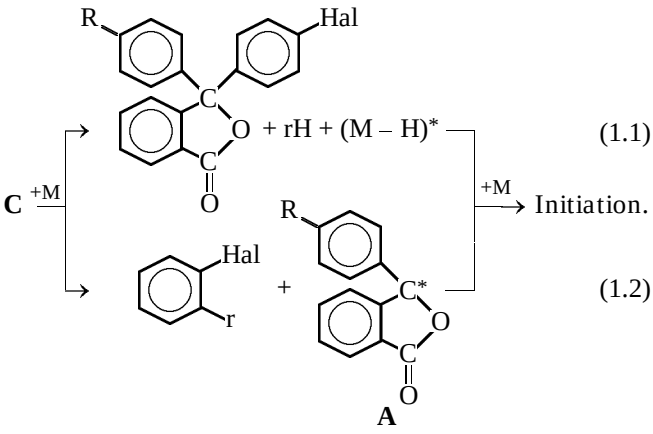
A study of sulfuric acid solutions of PMMA, prepared in the presence of phthalides, showed that not all the phthalides were incorporated into the polymeric chain. Phthalides **X** and **XI** containing no active chain-transfer centers did not enter polymerization. The qualitative reaction of the samples (after extraction) with sulfuric acid was negative. The polymer prepared in the presence of pseudophthalide **V** is not colored on dissolution in concentrated H_2SO_4, either.

A sulfuric acid solution of the polymer prepared in the presence of phthalide **III** or **IV** is colored, which indicates that the phthalide fragments have been incorporated into the polymeric chain (Table 2). This fact contradicts the known data on the mechanism of chain transfer to haloaromatic compounds [13, 15] according to which the haloarene molecule is regenerated in the course of chain transfer [scheme (1), pathway (1.1)].[1] Hence, the chain transfer involves the phthalide molecule. The most probable is the cleavage of the bond at the tertiary carbon atom [scheme (1), pathway (1.2)], since the resulting radical A is stabilized by aromatic substituents. Furthermore, migration of the second substituent at the quaternary atom of the phthalide ring has been observed in numerous studies [10, 12].

As a result of this reaction, the phthalide ring can be incorporated into the polymeric molecule as a terminal group:

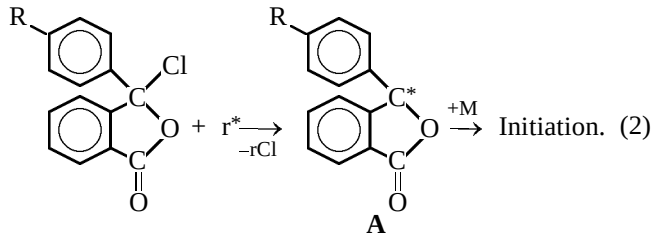
Scheme 1.





R = H, Hal (Hal = Cl, F).

Compounds **I** and **II,** containing a chlorine atom directly bound to the carbon atom of the phthalide ring, are also incorporated into the polymeric chain (Table 2); the content of phthalide units is approximately 1 unit per macromolecule. This means that phthalides **I** and **II** participate in chain transfer:



The polymer prepared by polymerization in the presence of a mixture of difluorenylphthalide (**VIII**) and chlorobenzoylbenzoic acid (**V**) forms a blue solution in sulfuric acid. The absorption spectrum of the sulfuric acid solution of this polymer is shown in Fig. 2 (curve *3*). It is seen that only difluorenylphthalide is incorporated into the polymeric chain. The absorption

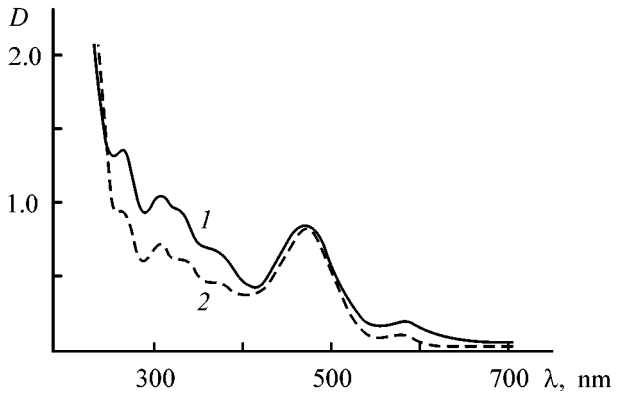


Fig. 3. Absorption spectra of sulfuric acid solutions of polystyrene prepared in the presence of phthalide **II**. The spectra were taken (*1*) 2 and (*2*) 25 h after the start of dissolution.

[1] Scheme (1) takes into account the fact that the chain transfer to phthalide **III** or **IV** involves the aromatic ring directly bound to halogen and also the fact that the radical attack at the *o*-position is more probable [15].

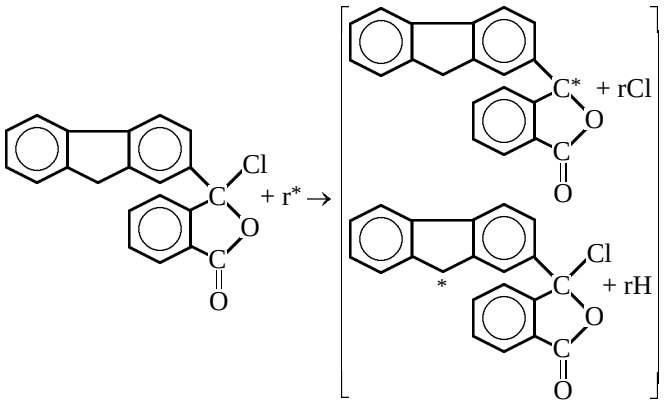
* (AIBN) azobis(isobutyronitrile); (BP) benzoyl peroxide.

bands of **V** are not detected, i.e., this compound is not incorporated into the PMMA molecule. The polymer prepared in the presence of only difluorenylphthalide shows a similar spectrum, which convincingly proves the presence of difluorenylphthalide units in the macromolecules.

Using the calibration plot for this polymer, the content of phthalide fragments was found to be 1/1900 (mole per mole of monomeric units). The molecular weight of PMMA was determined by gel permeation chromatography (number-average M_n 340 000) and viscometry (viscosity-average M_η 365 000). Hence,

there are 1.80 phthalide groups per macrmolecule (1.92 according to viscometric data). This means that phthalide groups can be located both in terminal positions and inside the chain. Apparently, two fluorenyl fragments of the phthalide participate in the initiation, with the result that the additive becomes incorporated inside the macromolecule; this means that the additive and macromolecule are relatively independent of each other. The tentative scheme below illustrates how phthalides with fluorenyl substituents participate in the process:



$\xrightarrow{+M}$ Initiation. (3)

Data on the content of the other phthalimides in the PMMA polymeric chain are listed in Table 2.

Thus, the obtained results show that phthalides of various structures take active part in radical polymerization and allow us to suggest the mechanism of their effect.

CONCLUSIONS

(1) Solutions of phthalides in concentrated H_2SO_4 are intensely colored, with the Bouguer–Lambert–Beer law obeyed, and exhibit high stability. The color of sulfuric acid solutions of polymethyl methacrylate and polystyrene prepared in the presence of phthalides is exclusively due to phthalide-containing compounds.

(2) The extinction coefficients of sulfuric acid solutions of phthalide-containing compounds of various structures were determined.

(3) The content of phthalide groups in polymeric molecules was determined. The main mechanism of their incorporation into the polymeric chain is participation in chain transfer.

Abstract—The structure of the macromolecule of an equimolar native vinyl chloride–maleic anhydride copolymer was studied. A mechanism of copolymerization of vinyl chloride with maleic anhydride is proposed.

Copolymers of maleic anhydride (MA) are used as starting substances in synthesizing ion exchangers, pharmaceuticals, cosmetics, and other substances, and also as enzyme carriers. To obtain materials with the desired properties, it is necessary to know the microstructure of the initial polymeric molecules. Macromolecules of the vinyl chloride–maleic anhydride (VCMA) copolymer undergo in solution cycloanhydride–enol tautomerism (CAET) cardinally altering the primary (native) microstructure of VCMA [1, 2]. The majority of methods for studying the composition and properties of chemical compounds are concerned with their solutions. These techniques are obviously unsuitable for studying the microstructure of VCMA copolymer, because in the course of dissolution the native microstructure formed in polyaddition is lost.

In this work we studied the VCMA microstructure by methods producing results that reflect the native microstructure, nonaltered by solvent. As such methods we chose thermogravimetry, spectroscopy, and gravimetric desorption analysis. For IR study, we cast VCMA films from THF under conditions of contact between VCMA and THF for 5–7 min. Since CAET transformations are slow, the native microstructure of VCMA is not altered within this period. A thermogravimetric study of thermal reactions in VCMA allowed us to avoid errors originating from the necessity to perform a series of experiments when the kinetics is studied in the isothermal mode; in our case all the necessary information is obtained with the same sample.

EXPERIMENTAL

The preparation conditions and characteristics of VCMA are given in [1]. Differential thermal analysis was performed on a Q 1500 derivatograph in helium at a heating rate of 10 deg min^{-1}. The DTA curves (Fig. 1) were processed taking into account the sequence of transformations: first H_2O is evolved and then HCl, CO_2, and CO. All calculations were performed proceeding from the mass balance of elimination of H_2O, HCl, CO_2, and CO, and the results

* The content of desorbed water (wt %) is given in parentheses.

were compared with those obtained in analyzing the products of thermal decomposition in a flow of oxygenfree nitrogen in a bubbling unit under isothermal conditions in the same temperature ranges. The gaseous decomposition products of VCMA-22.0 (22.0 wt % Cl as determined by the Schoeniger procedure) in regions *A*–*D* (Fig. 1) were trapped by selective absorbents: HCl, by an $Hg_2(NO_3)_2$ solution (solubility product of Hg_2Cl_2 2×10^{-18}); CO_2, by Ascarite; and CO, by a $PdCl_2$ solution. In the derivatograms of VCMA samples, we can distinguish the regions of "pure" dehydrochlorination B^1, F^1, K^1, and F^2 (see table). Above 250°C, HCl is eliminated simultaneously with CO_2 (regions B^2, F^3, and K^2). Thermal decomposition of VCMA is completed with release of CO_2 and CO (regions *D*, *G*, L^1, and L^2).

The mathematical processing of TG curves was performed by the equation

$$d\alpha/d\tau = k(1 - \alpha)^n,$$

where α is the conversion; $k = pZ\exp(-E_a/RT)$, p*Z* is the entropy parameter of the Arrhenius equation, E_a is the activation energy, *T* is temperature, and *R* is the gas constant [3].

The Arrhenius parameters and the values of *n* were computed [4, 5] (see table). All dependences were processed by the simple-iteration and Rosenbrock minimization procedures. Both methods gave consistent results.

The IR spectra were taken on a Specord M80 spectrophotometer. Films were prepared directly on NaCl plates from solutions of VCMA in THF and DMSO. The solvents were purified by conventional procedures [6]. An X-ray diffraction analysis confirmed the amorphous state of the VCMA samples (DRON-3M, Cu_{K_α} radiation).

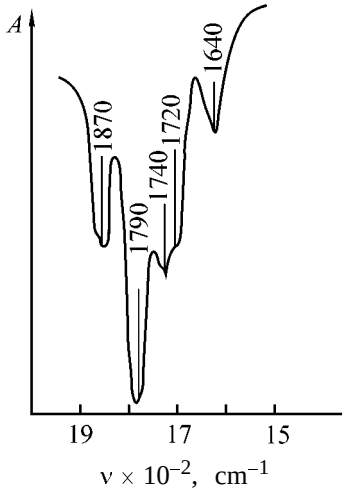

Fig. 2. IR spectrum of a VCMA-22.0 film cast from a 2% THF solution onto an NaCl plate: (*A*) absorption and (ν) wave number; the same for Fig. 3.

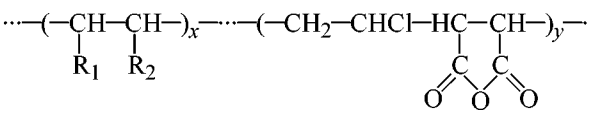
Along with the practically equimolar copolymer VCMA-22.0, we prepared two other samples: VCMA-15.45 enriched in MA and VCMA-23.5 containing, along with alternating segments, additional 6 mol % VC units decreasing the rigidity of the chain:

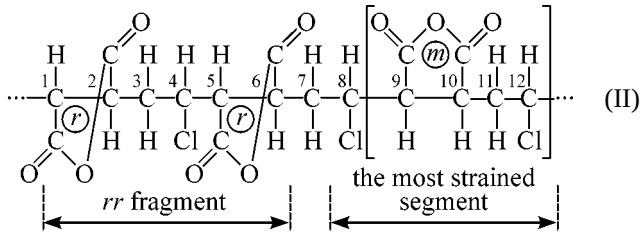


(I)

R_1 = H, R_2 = Cl, x = 0, y = 1.0 (VCMA-22.0); R_1 = H, R_2 = Cl, x = 0.06, y = 0.94 (VCMA-23.5); R_1 and R_2 = OC–O–CO, x = 0.3, y = 0.7 (VCMA-15.45).

Since dehydrochlorination of PVC (R_1 = H, R_2 = Cl, y = 0, x = 1) has been investigated in detail [7–9], we did not study it in this work.

Below we show as an example the Fischer projection of a macromolecule segment of alternating VCMA copolymer **II** incorporating succinic anhydride rings (*an*): two *r*- (*threo*) (^{1}C–^{2}C; ^{5}C–^{6}C) and one *m*- (*erythro*) (^{9}C–^{10}C):

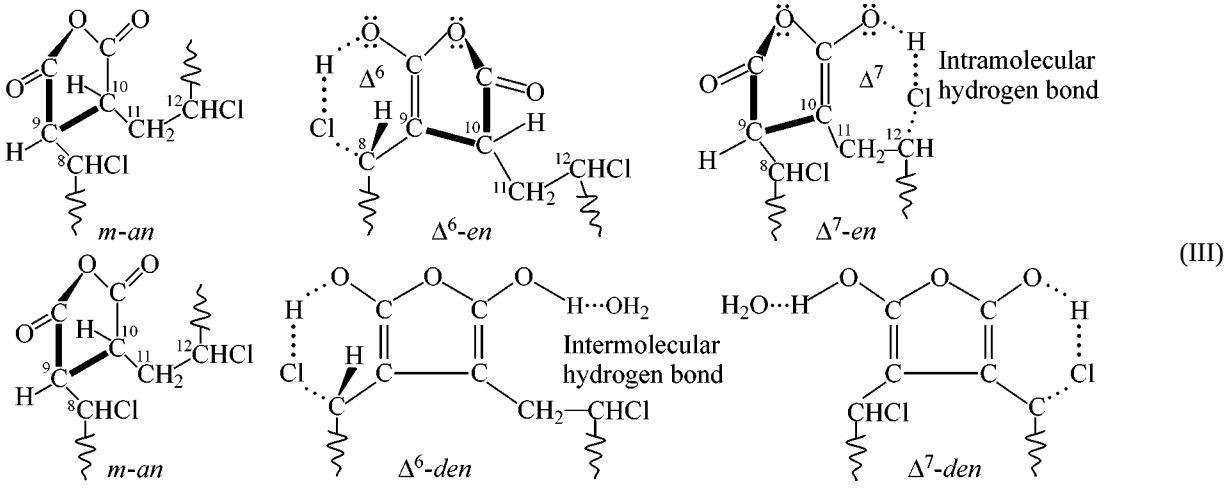


(II)

The ^{4}C, ^{8}C, and ^{12}C atoms may be both R- and S-chiral.

In view of the different chiralities of the ^{4}C, ^{8}C, and ^{12}C atoms, the C=O groups bound to ^{1}C, ^{2}C, ^{5}C, ^{6}C, ^{9}C, and ^{10}C **II** appear to be sterically and energetically nonequivalent; they are at different distances from the adjacent electronegative Cl atoms, which results in varied mutual repulsion and hence in different force constants of the C=O groups. This is manifested in the IR spectra in that the C=O groups in VCMA-22.0 films cast from THF give a set of absorption bands: one strong at 1790 cm^{-1}, two medium at 1870 and 1740 cm^{-1}, and a medium-intensity shoulder at 1720 cm^{-1}, which suggests the presence of four energetically nonequivalent states of the C=O groups (Fig. 2). Apparently, the group of bands at 1870–1720 cm^{-1} belongs to *an* structures and to the C=O groups in the enol tautomers Δ^6-*en* and Δ^7-*en*. A weak band at 1640 cm^{-1} most probably belongs to the C=C bond in *en* type macromolecule units. The fragments of microstructurally heterogeneous VCMA macromolecules are shown below.

Fragments of microstructurally heterogeneous VCMA macromolecules



(III)

The IR data for DMSO solutions suggest distortion of the VCMA microstructure under the action of DMSO and formation of tautomeric forms containing hydroxy substituents. The IR spectrum of a VCMA film cast from DMSO but not dried to remove DMSO ("wet" film) and that of the same film dried in a vacuum at 40°C (Fig. 3) confirm the presence of the suggested structures. The IR spectrum of the wet film contains strong absorption bands related to vibrations of the C=C (1680 cm^{-1}) and OH (3450 cm^{-1}, broad) groups, and also a weaker band at 1730 cm^{-1}. The IR spectrum of the dry film contains a strong band at 1730 cm^{-1} [ν(C=O)] (Fig. 3).

One of the key questions to be answered in this work is whether this microstructural heterogeneity appears in the course of copolymerization or is formed under the action of the solvent. The following experiments were performed to solve this question.

In air, amorphous VCMA samples adsorb moisture. To evaluate, using DTA and gravimetry, the amount of atmospheric moisture adsorbed by VCMA macromolecules, we studied the kinetics of its desorption from native VCMA samples after their being kept in air for 5 days ("moist" samples).

The kinetics of isothermal desorption of water at room temperature from moist VCMA samples was monitored gravimetrically, in the course of storage of the samples in a desiccator over P_2O_5. The kinetic dependences of water desorption were processed by the equation [10]

$$\theta = \theta_{eq}[1 - \exp(-k\tau)], \quad (1)$$

where θ is the current amount of desorbed water, θ_{eq} is the amount of water at $\tau \to \infty$, and k is the rate constant of the adsorption–desorption process.

It was shown that desorption from the VCMA-22.0 sample occurs with $k = 5 \times 10^{-6}$ s^{-1}, $\theta_{eq} = 5.1$ wt %, which corresponds to one adsorbed H_2O molecule per two units of VCMA-22.0 copolymer (molecular weight 160.5).

The amounts of water desorbed from the same VCMA-22.0 sample, determined by DTA (see table) and gravimetrically under isothermal conditions, are reasonably consistent (5.40 and 5.29 wt %, respectively) and practically coincide with θ_{eq} calculated by Eq. (1), 5.1 wt %.

Desorption of water from moist VCMA-22.0 sample under nonisothermal conditions occurs with the apparent activation energy $E_a = 79.4$ kJ mol^{-1}, $n = 3.03$ (see table, region *A*). Because the physicochemical sense of the parameter of the thermal degradation reaction n is not quite clear, we considered several alternatives. The values of n may correspond to the numbers of possible stages (types) of one or another thermal reaction. It is natural to assume that the desorption of water involves cleavage of three types of intermolecular hydrogen bonds *den*···H_2O, two of which are shown in scheme (III): Δ^6-*den*···H_2O and Δ^7-*den*···H_2O. The third type is probably represented by other intermolecular hydrogen bonds, e.g., by the H bonds between H_2O molecules in the outer sphere of the associate: [(*den*···H_2O)···H_2O]. This assumption is supported by the fact that ΔH_v of water in the range 20–100°C varies from 44.2 to 40.7 kJ mol^{-1} [11], which is approximately half the E_a of water desorption from the VCMA-22.0 sample in the same temperature range.

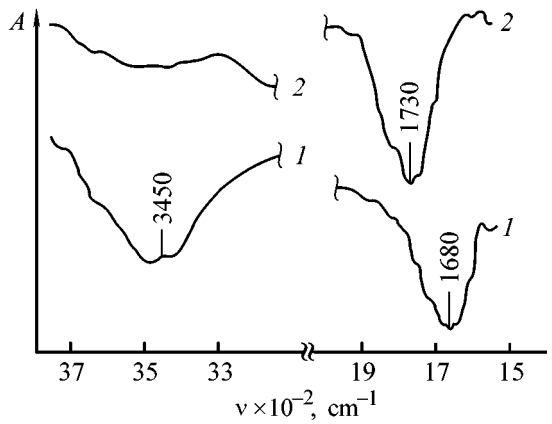


Fig. 3. IR spectra of VCMA-22.0 films cast from 2% DMSO solutions onto NaCl plates: (*1*) wet films containing DMSO and (*2*) films dried at 40°C.

In samples of the nonalternating VCMA copolymer, the content of water is a factor of 1.5 lower than that in the VCMA-22.0 sample (see table, regions *A*, *E*, *J*), and E_a of dehydration is only a factor of 1.3 higher than ΔH_v of water: 54.3 and 56.0 kJ mol^{-1}, with n equal to 1.68 and 1.63, respectively, which is due to the lower content of the *den* forms in these samples. The entropy parameter of dehydration $\log(pZ)$ = 9.1–13.5 (see table) suggests the formation of an ordered transition state of dehydration and allows water to be regarded as chemisorbed.

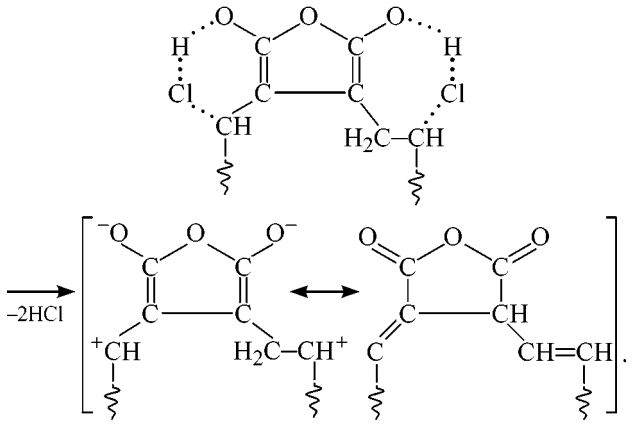
Thus, the microstructural heterogeneity of VCMA determines its capability to adsorb moisture from air and is responsible for the variability of VCMA properties. Namely, VCMA macromolecules permanently change their composition in the course of storage, depending on the storage time and air humidity; the composition may strongly differ from that of the freshly prepared samples.

The Arrhenius parameters of the dehydrochlorination of VCMA samples under nonisothermal condi-

tions also depend on their composition. For example, VCMA-22.0 eliminates 56 mol % of HCl with low E_a = 72.3 kJ mol^{-1} from two (n = 2.05) types of structures Δ^6-*en* and Δ^7-*en*; the VCMA-23.5 sample contains approximately the same amount of precursor groups that are readily dehydrochlorinated (53 mol %) and mostly belong to one type (n = 1.14). In the range 100–190°C, the VCMA-15.45 sample eliminates 91 mol % of HCl from two (n = 1.83) types of groups with higher E_{a_1} = 95.4 kJ mol^{-1} (see table, regions B^1, F^1, and K^1).

It is interesting that in the derivatogram of the VCMA-23.5 sample consisting of less rigid macromolecules there is a second range of pure dehydrochlorination (see table, region F^2) occurring very difficultly in a single (n = 1.15) stage. The high values of E_a = 322 kJ mol^{-1} and log(pZ) = 35.3 are close to the corresponding parameters of dehydrochlorination of low-molecular-weight analogs [8, 12] and exceed them because of the distortion of the favorable arrangement of units in substrates and the appearance of polyconjugated segments after the first stage of dehydrochlorination F^1. After stage F^1, there remains 43 mol % of CHCl groups incapable of forming Δ^6-*en* and Δ^7-*en* units from which elimination of HCl is facilitated. HCl is eliminated from such fragments without formation of the cyclic transition state, with E_a close to the value calculated for radical chain dehydrochlorination [8].

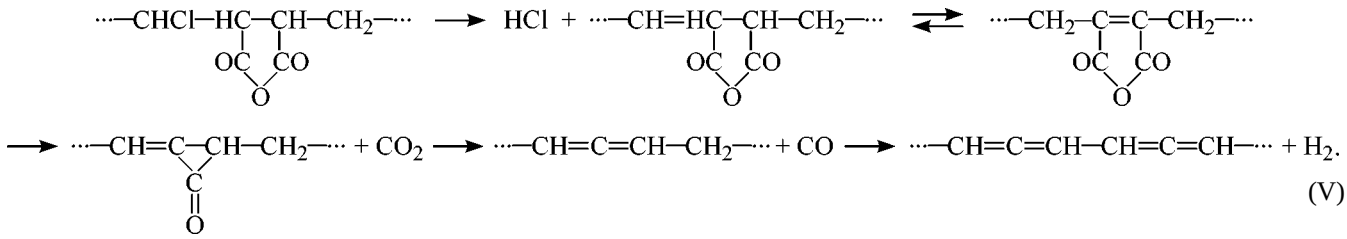
Thus, in regions B^1, F^1, and K^1 (see table) of pure VCMA dehydrochlorination, HCl is eliminated with considerably lower E_a and log(pZ) as compared with the same parameters for dehydrochlorination of PVC and model compounds [7–9, 13]. This is due to the concerted redistribution of bonds in the Δ^6-*den* and Δ^7-*den* rings and the formation of a low-energy zwitter-ion as one of the resonance structures of the final product [1]:



(IV)

For the sake of brevity, both mechanisms are shown with the same VCMA unit.

The products of thermal decomposition of VCMA under helium are black specular films, which suggests the formation of polyconjugated systems containing practically no oxygen, provided that CO_2 and CO are removed from VCMA macromolecules completely [13]. Based on the material balance of thermal reactions in VCMA in the nonisothermal mode (see table) and the results obtained in studying the isothermal decomposition at several temperatures in a bubbler unit, we suggest the following mechanism of VCMA decomposition on heating to 500°C under helium:



(V)

Whereas the presence of *m*- and *r*-anhydride rings in VCMA macromolecules is a known fact, the presence of tautomeric *en* and *den* forms in the macromolecules in the condensed state requires additional experimental support.

The IR spectra of VCMA in Figs. 2 and 3 show that the microstructure of VCMA is affected by a solvent. Let us return to considering the possibility of formation of *en* fragments during the chain growth process in the course of copolymerization. The necessary information can be obtained by computer processing of the kinetic dependences of the intensities of bands B and E (λ_{max} 246 and 268 nm, respectively) in the UV spectrum of VCMA in dioxane [2] by the equation

$$D_0 = D_{max}[1 - P\exp(-k\tau)], \quad (2)$$

where P is the factor related to the initial conditions; the concentration C of the tautomeric forms is pro-

portional to the current optical density of the corresponding absorption band D_λ, and C_{max} is proportional to D_{max} of the same band at $\tau \to \infty$.

At the instant when condensed VCMA macromolecules come in contact with the solvent ($\tau = 0$), the variation of both groups of bands *B* and *E* reflects the formation of the *en* and *den* tautomers by a pseudo-first-order reaction [2]. The group of bands with $\lambda_{max} = 246$ nm is due to $\pi \to \pi^*$ transitions in *en* forms, and that with $\lambda_{max} = 268$ nm, to $\pi \to \pi^*$ transitions in quasiaromatic structures [2]. Since D_λ is proportional to the content of the corresponding tautomeric *en* or *den* forms, Eq. (2) can be written as follows:

$$[en]_0 = [en]_{max}[1 - P\exp(-k\tau)],$$

$$[den]_0 = [den]_{max}[1 - P\exp(-kt)].$$

In this work, we processed with a computer the time dependences of the optical densities of the above UV absorption bands [2], which allowed us to calculate $[en]_0$ and $[den]_0$ at the instant of contact between native VCMA macromolecules and the solvent (mole fractions at $\tau = 0$):

λ_{max}, nm	D_{max}	P	$k \times 10^6$, s^{-1}	r^*	$[en]_0$	$[den]_0$
246	0.96	0.67	1.3	0.987	0.33	–
268	1.45	0.95	0.6	0.943	–	0.5

* Correlation coefficient.

It is significant that the results of all three independent methods: thermogravimetric, gravimetric, and UV spectroscopic [2], gave consistent values of $[en]_0$ in native VCMA-22.0 macromolecules: 33.8, 33.2, and 33.0 mol %, respectively, with $[den]_0$ in powdered VCMA not exceeding 5 mol %.

Thus, macromolecules of equimolar native copolymer VCMA-22.0 in the condensed state comprise a random sequence of alternating units VC–*r-an*, VC–*m-an* and anomalous structures Δ^6-*en* and Δ^7-*en*, which are formed in the course of copolymerization of VC with MA and are tautomerically labile units responsible for its dynamic microstructural heterogeneity:

$$\cdots\text{–[–(VC–}r\text{-}an\text{)–; –(VC–}m\text{-}an\text{)–]}_{0.67}\text{–}\cdots$$

$$\cdots\text{–[–(}\Delta^6\text{-}en\text{)-; –(}\Delta^7\text{-}en\text{)–]}_{0.33}\text{–}\cdots.$$

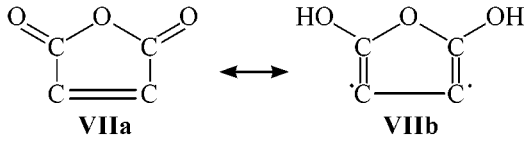
The mechanism of copolymerization of VC with MA is a matter of discussion. Equimolar copolymers were prepared at different VC to MA ratios by polymerization in the bulk and in benzene at 50°C with azobis(isobutyronitrile) as initiator [14, 15].

It is known that strictly alternating macromolecules are formed from molecular complexes of comonomers. Maleic anhydride forms complexes with many weak donors, such as vinyl ethers, olefins, styrene, acetone, DMF, DMSO, and even chloroform. The equilibrium constants *K* are, as a rule, low [14], which suggests that the concentration of the molecular complexes [VC·MA] is considerably lower than that of free molecules of VC and MA comonomers.

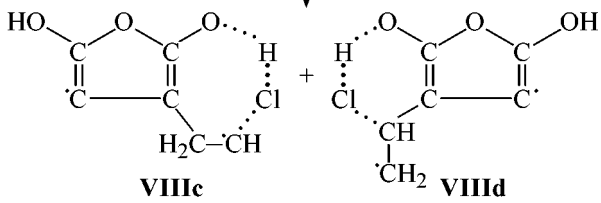
The fact of complexation between MA molecules and weak donors suggests that the equilibrium constant *K* of complexation between MA and VC at the copolymerization temperature (80°C) differs from zero. The formation of molecular complexes makes possible the chain growth by polyaddition of the complexes [VC·MA] to give alternating segments of the macromolecules of type **II**:

$$n[\text{VC}\cdot\text{MA}] \to \cdots\text{–[–(VC–}r\text{-}an\text{)–; –(VC–}m\text{-}an\text{)–]}_n\text{–}\cdots \quad \text{(VI)}$$

The incorporation of tautomeric *en* forms into growing macromolecules **VI** as segments of microstructural heterogeneity occurs as follows. An MA molecule in the biradical form **VIIb** forms a complex with a VC molecule at 80°C, yielding two biradicals **VIIIc** and **VIIId**.



$HClC{=}CH_2$ + **VIIb**



Then the chain growth continues by two pathways: polyaddition of molecular complexes [scheme (**VI**)] and their copolymerization with biradicals **VIIIc** or **VIIId** to form macromolecules containing the units –(VC-*r*- or -*m-an*)–, –(Δ^6-*en*)–, and –(Δ^7-*en*).

CONCLUSIONS

(1) Macromolecules of the equimolar native vinyl chloride–maleic anhydride copolymer prepared under

the chosen synthesis conditions comprise a random sequence of alternating comonomer units (67 mol %) and units containing the enol tautomer (33 mol %).

(2) The kinetics of desorption of atmospheric moisture and dehydrochlorination of vinyl chloride–maleic anhydride copolymer samples were studied. Elimination of HCl occurs both with low activation energy from enol tautomers and with high activation energy from segments consisting of vinyl chloride and anhydride rings.

(3) A mechanism of copolymerization of vinyl chloride with maleic anhydride was proposed, involving polyaddition of weak molecular complexes of comonomers in the ground state and in the form of biradical resonance structures.

Received September 12, 2000

Abstract—The influence of the nature of an organoaluminum compound on the molecular characteristics of 1,4-*trans*-polybutadiene prepared with vanadium-containing catalytic systems was studied.

A study of coordinated ionic polymerization of dienes on *cis*-stereospecific catalytic systems showed that the nature of an organoaluminum compound (OAC) significantly affects both the activity of the catalytic system and the properties of the resulting polydienes. It has been found [1, 2] that, with different OACs, not only the rate constants of chain transfer to OAC (k_0^{Al}) but also the rate constants of chain growth k_g are different. The OAC nature affects the microstructure of the resulting polydiene [3] and its molecular characteristics [4]. It has been suggested [2] that the OAC molecule may be a part of the active center, which can be responsible for the kinetic nonuniformity of these catalytic systems. For the case of polymerization of dienes with *trans*-stereospecific catalytic systems, such data are lacking.

In this work, we studied how the OAC nature affects the molecular characteristics of 1,4-*trans*-polybutadiene (*trans*-PB) obtained with vanadium-containing catalytic systems.

It is known that vanadium-containing catalytic systems allow preparation of polydienes with high content of *trans* units. The resulting 1,4-*trans*-polydienes are highly crystalline polymers with good cohesion properties; they can be used in adhesive formulations, for preparing films, for manufacturing orthopedic articles, etc.

The best studied are catalytic systems based on VCl_3, VCl_4, or $VOCl_3$ and aluminum trialkyls [5, 6]. These systems are highly *trans*-stereospecific (from 80 to 99% *trans* units) and active. In this work, we chose the catalytic systems $VOCl_3$–OAC with OAC = Al(*i*-$C_4H_9)_3$ (TIBA), Al(*i*-$C_4H_9)_2Cl$ (DIBAC), and Al(*i*-$C_4H_9)_2H$ (DIBAH).

Figures 1 and 2 show the weight-average (M_w) and number-average (M_n) molecular weights and the polydispersity (M_w/M_n) of *trans*-PB as functions of the monomer conversion in the course of polymerization. It is seen that these catalytic systems allow preparation of *trans*-PB with fairly high molecular weight. The molecular weights and the M_w/M_n ratio increase throughout the course of polymerization. The rate of butadiene polymerization remains constant up to high conversions of the monomer.

It is seen that the highest M_w is attained with DIBAH as organoaluminum cocatalyst (Fig. 1), and the lowest, with DIBAC. The M_n values decrease in the order TIBA > DIBAC > DIBAH (Fig. 2). This means that *trans*-PB samples prepared with DIBAH show the widest molecular-weight distribution (MWD): the polydispersity reaches 10. This is probably due to the fact that the presence in the reaction mixture of a cocatalyst containing an Al–H bond makes the catalytic system more active in chain transfer to OAC as compared to compounds containing the Al–C and Al–Cl bonds. Data on the kinetic constants of polymerization k_g, k_0^{Al}, and k_0^m (rate constant of chain transfer to the monomer) confirm this assumption (see table). Replacement of the alkyl group in the OAC molecule by a hydrogen or chlorine atom affects not only the rate constants of chain transfer to OAC but also the rate constants of chain growth. Thus, the nature of OAC affects the probability of transfer to OAC (k_0^{Al}/k_g), whereas the probability of chain transfer to the monomer (k_0^m/k_g) remains unchanged for all

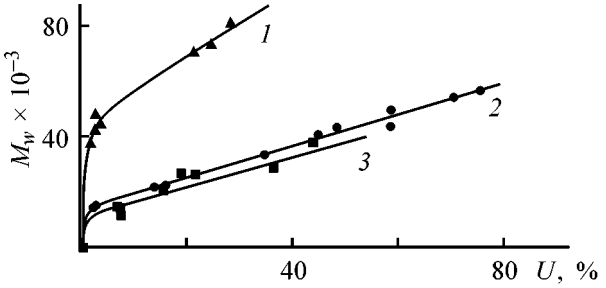

Fig. 1. M_w vs. conversion U of butadiene in polymerization with the catalytic system $VOCl_3$–OAC. Polymerization conditions: toluene; 25°C; C_m = 1.0, C_c = 5.0 × 10^{-3} M; Al/V ratio 4 (TIBA, DIBAC) or 2.5 (DIBAH); the same for Figs. 2–4. OAC: (*1*) DIBAH, (*2*) TIBA, and (*3*) DIBAC.

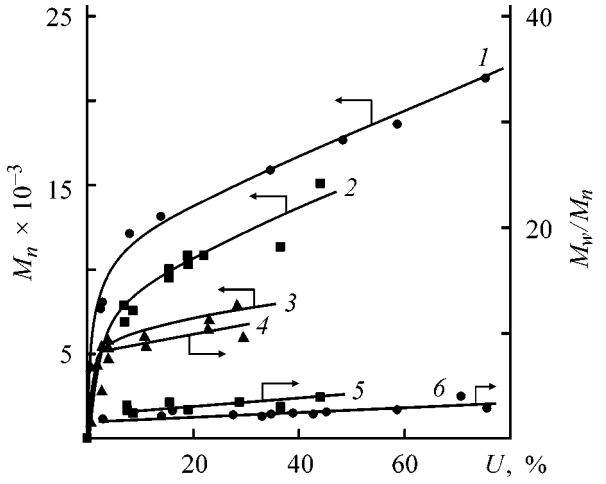

Fig. 2. (*1–3*) M_n and (*4–6*) M_w/M_n vs. butadiene conversion U in polymerization with the catalytic systems $VOCl_3$–OAC. OAC: (*1*, *6*) TIBA, (*2*, *5*) DIBAC, and (*3*, *4*) DIBAH.

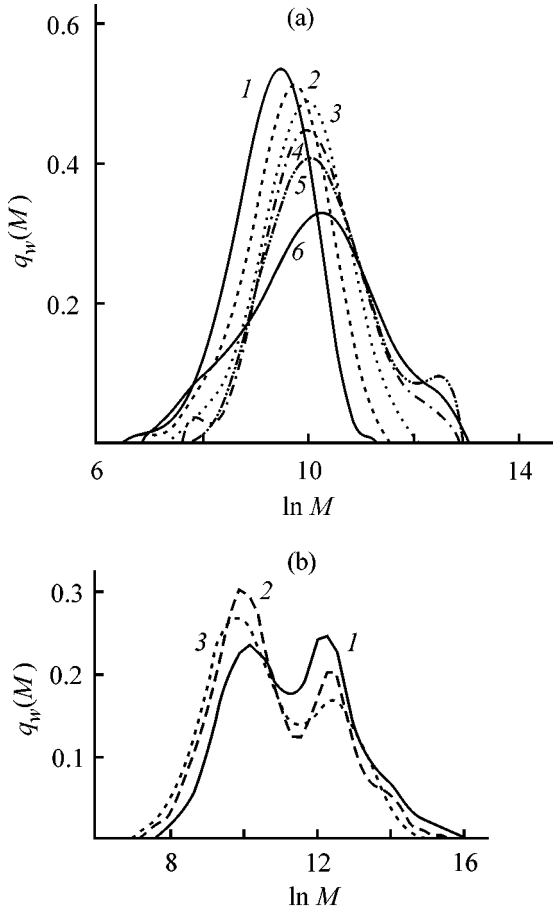

Fig. 3. MWD curves for *trans*-PB prepared with the catalytic systems (a) $VOCl_3$–TIBA and (b) $VOCl_3$–DIBAH. Monomer conversion, %: (a) (*1*) 2.5, (*2*) 14.0, (*3*) 34.7, (*4*) 45.0, (*5*) 58.7, and (*6*) 75.5; (b) (*1*) 4.7, (*2*) 16.8, and (*3*) 51.2.

the systems studied. This fact explains why polybutadienes prepared with these catalytic systems have different molecular weights.

Changing the type of OAC in the catalytic system affects not only the molecular weight but also the MWD shape.

The MWD curves of *trans*-PB at different monomer conversions are listed in Figs. 3a and 3b. At short time of butadiene polymerization on the catalytic system with TIBA (Fig. 3a), the MWD curves are unsymmetrical but unimodal, with broadening on the side of low molecular weights. With increasing conversion, the peak shifts to higher molecular weights, with simultaneous broadening on both sides. At large conversions, a shoulder appears on the side of high molecular weights, and finally MWD becomes bimodal. Similar changes in the shape of

DIBAC	50.0	0.13	2.6	1.5	3.0	11.0

* (C_a) Concentration of active centers.

MWD curves of polybutadiene were observed with DIBAC as OAC, whereas polymerization of butadiene with the catalytic system $VOCl_3$–DIBAH gives samples with polymodal MWD (Fig. 3b).

The shape of the dependences of the molecular characteristics of *trans*-PB on the concentrations of the catalytic system components and monomer is typical of Ziegler catalytic systems [7, 8]. With increasing monomer concentration, the molecular weights grow; with increasing catalyst concentration and Al/V ratio, both M_w and M_n decrease.

The dependence of the molecular characteristics of *trans*-PB on the polymerization temperature T_{pm} is unusual: In the range 20–25°C, M_w and M_w/M_n pass through a minimum, and M_n, through a maximum (Fig. 4).

Our experimental results show that one of specific features of *trans*-PB prepared with the tested catalytic systems is wide MWD, governed by the nature of OAC and synthesis conditions. This may be due to participation in the polymerization of several types of active centers differing in reactivity. Apparently, changing the nature of OAC as a component of catalytic systems affects the features of their reactivity.

EXPERIMENTAL

Butadiene was polymerized in toluene at 25°C without access of air or moisture. The catalytic complex was prepared in advance by combining solutions of $VOCl_3$ and OAC with addition of a small amount of the monomer [up to 5 mol per mole V(V)] and keeping for 0.5 h at 0°C. The polymerization was performed at monomer (C_m) and catalyst (C_c) concentrations of 1.0 and 5×10^{-3} M, respectively. The highest catalytic activity (the highest yield of the polymer) was observed at OAC/V ratio of 4.0 for TIBA and DIBAC and 2.5 for DIBAH.

The microstructure of polymers was studied by IR spectroscopy with a Specord M80 spectrophotometer [9]. The examined samples contained 83–90% 1,4-*trans* units and 17–10% 1,2-units. The gel fraction content did not exceed 1%.

Solutions of *trans*-PB were prepared by stirring the required amounts of the polymer and solvent at 80–90°C for 2–4 h just before measurements. The solutions were filtered while hot and then brought to the required temperature.

The molecular weights and MWD of polydienes were determined with a Du Pont liquid chromatograph

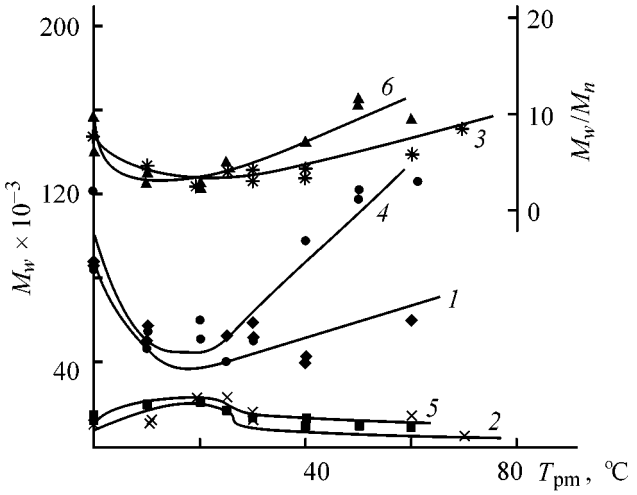

Fig. 4. (*1*, *4*) M_w, (*3*, *6*) M_n, and (*2*, *5*) M_w/M_n vs. polymerization temperature T_{pm} for samples of *trans*-PB prepared with the catalytic systems (*1–3*) $VOCl_3$–TIBA and (*4–6*) $VOCl_3$–DIBAC.

equipped with four columns packed with Shimadzu Microgel (pore size 1×10^3–10^6 Å). The separation was performed at 85°C with toluene as eluent. The column system was calibrated with polystyrene reference samples with narrow MWD ($M_w/M_n \le 1.2$), using the universal Benoit dependence [10] and the Mark–Houwink equation for *trans*-PB [11]. The MWD curves and molecular weights were corrected for instrumental broadening by the method described in [12, 13].

The kinetic constants k_g and k_0^m were calculated by the equations [14]

$$W_n = k_g C_m C_a,$$

$$1/P_n = 1/(\tau k_g C_m) + \Sigma (C_i k_0^i)/(k_g C_m),$$

$$1/P_n = 1/C_m \tau \Sigma k_0^i C_i - 1/k_g + k_0^m/k_g,$$

$$1/P_n = C_{Al} k_0^{Al}/k_g C_m + \tau \Sigma k_0^i C_i / k_g C_m,$$

where W_n is the polymerization rate, C_a is the concentration of active centers, P_n is the number-average polymerization rate, k_0^i is the rate constant of transfer with *i*th agent, C_{Al} is the OAC concentration, C_i is the concentration of the *i*th transfer agent, and τ is the polymerization time.

The constant k_g was determined using the equation

$$W_n \tau / P_n = C_a + W_0 \tau,$$

where W_0 is the overall chain-termination rate.

CONCLUSIONS

(1) The nature of the organoaluminum component of vanadium-containing catalytic systems affects both the average molecular weights of the resulting 1,4-*trans*-polybutadienes and the shape of their molecular-weight distribution.

(2) The influence of the nature of the organoaluminum compound on the molecular characteristics of 1,4-*trans*-polybutadienes is due to different probabilities of chain transfer to the organoaluminum compound, with the probability of chain transfer to the monomer remaining the same for all the systems studied.

(3) Polymerization of butadiene with vanadium-containing catalytic systems presumably occurs on centers differing in kinetic activity.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Water-Resistant Films and Coatings Based on Cross-Linking Styrene–Acrylate Latex Copolymers

Abstract—Water-resistant films and coatings were prepared from latexes of copolymers of styrene, *n*-butyl acrylate, 2-hydroxyethyl methacrylate, glycidyl methacrylate, and methacrylic acid. The degree of cross-linking of the copolymers in the course of film formation and the water resistance of the films and coatings, associated with this parameter and evaluated by the water absorption and mechanical properties of wet films, were studied in relation to the gross composition of the latex copolymer, conditions of its synthesis, distribution of functional groups responsible for cross-linking in a latex particle, and temperature of film formation.

The advantages of water-base polymer films and coatings consist in the convenience and environmental safety of their preparation. Especially promising are latex coatings prepared from highly concentrated systems, low-viscous at common temperatures, without using toxic and inflammable organic solvents. However, the specific features of film formation from latexes (by coalescence of latex particles) not always allow the potential of a polymeric system to be fully realized. Very often incomplete coalescence of particles and poor monolithization of a latex film result in poor water resistance of coatings, as judged from their equilibrium water absorption and mechanical strength of wet films.

One of the most efficient approaches to preparation of water-resistant latex coatings is the development of polymeric systems capable of cross-linking in the course of film formation. Previously, we have demonstrated the feasibility of preparing cross-linked coatings from latex copolymers containing epoxy and carboxy groups [1]. It is known that the reaction between these functional groups in homogeneous systems, e.g., in curing of epoxy resins, occurs at appreciable rate only at elevated temperatures. We found that in latex systems this reaction can be performed even at room temperature, probably owing to effects similar to micellar catalysis [2]. In [1], we introduced the required functional groups by using glycidyl methacrylate (GMA) and methacrylic acid (MAA) as comonomers in emulsion copolymerization. Usually up to 10 wt % GMA units was introduced. This, on the one hand, increased the cost of the copolymer and, on the other, resulted in partial cross-linking in the course of synthesis, which hindered coalescence of particles containing intraglobular cross-links.

Here we report the properties of films and coatings based on latex copolymers of styrene (ST), *n*-butyl acrylate (BA), 2-hydroxyethyl methacrylate (HEMA), MAA, and GMA, containing no more than 1 wt % GMA. The major comonomers ST and BA, determining the film-forming properties of latexes, were usually taken in amounts of 33–37 and 52–54 wt %, respectively; HEMA was added in an amount of 4–8% to increase the hydrophilicity of the copolymer and improve the coalescence of particles in the course of film formation. Three types of latex systems were studied.

In systems of type I, both reactive groups (epoxy and carboxy) are localized in the same reaction zone—latex particle shell.

In systems of type II, epoxy and carboxy groups are localized in different latex particles, i.e., system II is a mixture of two latexes: that of the ST–BA–HEMA–GMA copolymer and that of the ST–BA–HEMA–MAA copolymer. Both latexes were prepared using a seeding copolymer containing no functional groups. In such systems, a more efficient utilization

1070-4272/01/7402-0309 $25.00 © 2001 MAIK "Nauka/Interperiodica"

of functional groups would be expected, with their predominant participation in interglobular cross-linking in the course of coalescence.

Systems of type III are latexes with core–shell particles in which the core is ST–BA–HEMA–GMA copolymer and the shell is ST–BA–HEMA–MAA copolymer. In this system, both interglobular and intraglobular cross-linking is possible, although the latter process must be less pronounced than in systems of type I.

EXPERIMENTAL

Monomers used to synthesize latexes were purified by common procedures before copolymerization. The characteristics of the monomers agreed with reference data [3, 4]. The emulsion polymerization was initiated by potassium or ammonium persulfate. As emulsifiers were used anionic surfactant E-30 [sodium (C_{14}–C_{16})-alkylsulfonate] or nonionic surfactant OS-20 (C_{16}–C_{18} oxyethylated alcohol).

The emulsion copolymerization was performed in a 0.25–0.50 l glass vessel equipped with a stirrer, a reflux condenser, and tubes for feeding inert gas and adding reactants. In syntheses with gradual dosage of monomers, they were added from dropping funnels.

The dry residue of latexes was determined by drying a sample under an IR lamp to constant weight.

The size of latex particles was determined photometrically from the dependence of the optical density of dilute latexes on the transmitted light wavelength.

The films obtained from latex systems were cast on a glass support and studied in the free state.

The film quality was evaluated from the water absorption and gel fraction content. The water absorption was determined as the weight gain of films kept in distilled water for 24 h.

The gel fraction content and degree of swelling of the gel in the films were determined by separating the soluble fraction with acetone.

The mechanical properties of films were determined by a standard procedure [GOST (State Standard) 12589–78].

Latexes of type I were prepared in two stages. First, we prepared a seeding copolymer latex of composition (wt %) ST 54.6, BA 44.6, and HEMA 0.8 (no epoxy and carboxy groups). In the second stage, we added to the resulting seeding latex at various rates a monomeric mixture of composition (wt %) ST 35.0, BA 52.4, HEMA 5.2, MAA 6.4, and GMA 1.0. In each stage, the copolymerization was performed to practically complete conversion of the monomers, i.e., the composition of the copolymer corresponded to that of the monomer mixture. Thus, the gross composition of the copolymer (wt %) was as follows: ST 42.0, BA 49.6, HEMA 3.6, MAA 4.2, and GMA 0.6.

The two-stage process ensures increased concentration of functional groups in the surface layer, with the total content of the most expensive monomer, GMA, being less than 1%. Another advantage of the two-stage procedure is simple control of the latex particle size. The diameter of the latex particles after the second stage is actually determined by the size of the seeding particles. The conditions of latex syntheses are given in Table 1, and the characteristics of the latexes and films thereof, in Table 2.

Formation of films in this series of experiments was performed at 50°C, since films prepared at room temperature had worse strength in the wet state, which shows that the particle coalescence in unsatisfactory. It is seen that not all the latexes form cross-linked films, despite the same composition of the copolymers. Tables 1 and 2 show that the most important factors determining the possibility of preparing the cross-linked films are the rate of monomer mixture addition in the second stage of the latex synthesis and the size of the resulting particles. The highest content of the gel fraction and the lowest swelling were observed in films formed from latexes that were prepared by fast addition of the monomers, especially by their addition in a single portion (Table 2, copolymer no. 7). As seen from Table 2, the increasing particle size also favors higher gel fraction content in the film.

Our results can be accounted for by partial hydrolysis of epoxy groups, which are responsible for cross-linking, in the course of latex synthesis. The relatively fast hydrolysis of GMA in emulsion systems at elevated temperature (60°C) was observed in [5]. At fast addition of the monomer mixture, GMA units are localized in the particle volume owing to the high copolymerization rate, which prevents their hydrolysis. The increased particle diameter and hence their decreased surface area also hinder hydrolysis.

Although the water absorption of films does not strictly correlate with the gel fraction content, we see that the water absorption tends to decrease with increasing content of the gel freaction and decreasing degree of swelling of the films. As a rule, the highest water absorption is exhibited by fully soluble films (Table 2, copolymer nos. 1, 5) or by films containing a gel fraction with very high degree of swelling (copolymer no. 4).

Table 3 shows some mechanical properties of the films that exhibit the lowest water absorption (copolymer nos. 2, 8). It is seen that the film strength increases at high gel fraction content. However, films prepared from latex no. 2 are preferable. Although these films are less strong in the initial state as compared with those prepared from copolymer no. 8, their strength in the wet state decreases by no more than 15%, whereas the strength of the films prepared from latex no. 8 decreases almost by half after keeping in water for 24 h. Thus, films from copolymer no. 2 are more water-resistant. This may be due to better coalescence of the particles in the course of film formation from latex no. 2 owing to higher surface energy, since the diameter of particles of latex no. 2 is considerably smaller than that of latex no. 8 (Table 2).

Additional heat treatment of films at 125°C for 1 h increases the gel fraction content and decreases the water absorption. However, the effect is not significant. The water absorption of films prepared from latex no. 2 decreases from 4.9 to 4.0%.

Systems of type II are mixtures of epoxide- and carboxyl-containing latexes. When preparing the initial latexes, we also used the principles of seeding copolymerization and preparation of core–shell particles with incorporation of reactive functional groups in the shell copolymer only. The core copolymer was prepared by addition of an ST–BA monomer mixture (40 : 60 by weight) in a single portion to the aqueous phase containing OS-20 nonionic surfactant, followed by polymerization in the presence of $K_2S_2O_8$ at 65°C.

The shell was prepared by a semicontinuous process. To the latex of the core copolymer, we gradually added a monomer mixture containing the functional monomer. No additional amounts of the surfactant were introduced, which favored formation of the functionalized copolymer only in the shell. The conditions of latex syntheses are listed in Table 4.

Some characteristics of functionalized latexes and films thereof are listed in Table 5. It is seen that, owing to the relatively high GMA concentration, the initial epoxide-containing copolymers contain the gel fraction despite the presence in the reaction system of a small amount of the chain-terminating agent TDM. It should be noted that in most cases the gel fraction content is above 75%, which suggests that the core copolymer is partially involved in cross-linking, probably through formation of semiinterpenetrating networks. Films prepared from epoxide-containing copolymers have low water absorption, except copolymer no. 12 containing no HEMA units. Thus, HEMA introduced into the copolymer formulation improves the particle coalescence. This conclusion also refers to carboxyl-containing copolymers (nos. 13, 14).

In Fig. 1, the water absorption of films prepared from various latex mixtures is plotted vs. the content of the epoxy component. It is seen that the water absorption in these systems is not an additive quantity, which suggests interaction of the epoxide- and carboxyl-containing particles. A mixture of latex nos. 12 and 14 (curve *2*) at 50°C forms films with water absorption several times lower than that of the films formed from the individual latexes. It should be noted also that films with sufficiently low water absorption can only be formed in the case when at least one of the latex copolymers contains HEMA units (curve *2*). Otherwise, the formed films have very high water absorption (curve *1*). However, it is advisable that

HEMA units be present in both copolymers. In this case, it is possible to prepare films with low water absorption (about 4%) in a wide range of latex mixture compositions (curve *5*), including mixtures containing small amounts of the epoxide-containing copolymer at a total HEMA content of about 1 wt %.

These results suggest that the epoxy groups are the most efficient in cross-linking in systems with low content of the epoxide-containing copolymer. If the cross-linking efficiency is evaluated as the increase in the gel fraction content relative to the gel content in the initial epoxide-containing copolymer, we see that, indeed, the cross-linking efficiency increases as the content of the epoxide-containing copolymer in the latex mixture decreases (Fig. 2, curve *2*). As for the total gel fraction content in the compound film, it grows with increasing content of the epoxide-containing copolymer, although the water absorption of the films decreases to a lesser extent. This fact is consistent with the concept that the water absorption is determined to a larger extent by the cross-linking efficiency, i.e., by the number of interglobular bonds.

Despite the low water absorption of some compound films, their strength in the wet state is insufficient, which indicates insufficient interpenetration of the particles and poor monolithization of the film. However, on baking at 125°C for 2.5 h, the film strength sharply increases, and it becomes possible to form water-resistant coatings of high quality.

Systems of type III were prepared as follows. In the first stage, we formed the core of a latex particle containing epoxy groups. In the second stage, we added to the resulting seeding latex the monomer mixture ST–BA–HEMA–MAA at a rate of 0.620 % min^{-1}, with the initiator and emulsifier solutions added simultaneously. The conditions of latex synthesis are listed in Table 6.

As seen from Table 6, the formulations of latex nos. 15 and 16 are close. The main difference consists in the procedure for preparing the core copolymer. Whereas latex no. 15 was prepared with addition of the monomers in a single portion, in synthesizing latex no. 16 the monomer mixture was added gradually at a rate of 3.3 % min^{-1}. As already noted, in the first case, the epoxy groups undergo hydrolysis to a lesser extent, which results in better mechanical properties of the films prepared from latex no. 15 (Table 7).

The formed films exhibit fairly high water absorption, determined by the properties of the shell copolymers whose content in the composite particle is as high as 86.8 wt %. The shell copolymers are similar in composition and water absorption to carboxyl-containing copolymers used in mixed latex systems

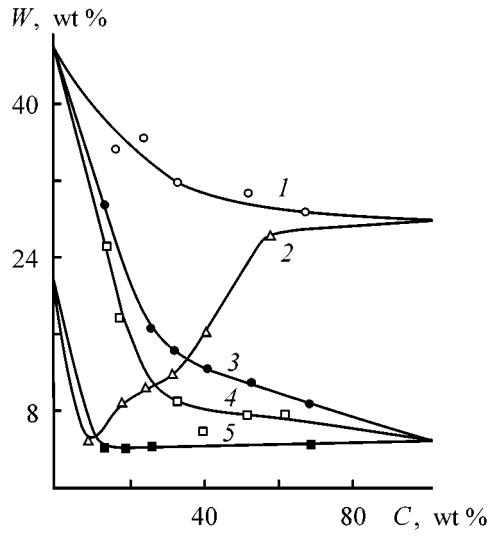

Fig. 1. Water absorption of latex films of system II *W* vs. the content of epoxide-containing copolymer in the latex mixture *C* (in terms of dry matter). Film formation temperature 50°C; the same for Fig. 2. Latex mixtures: (*1*) no. 12 + no. 13, (*2*) no. 12 + no. 14, (*3*) no. 9 + no. 14, (*4*) no. 10 + no. 13, and (*5*) no. 11 + no. 14.

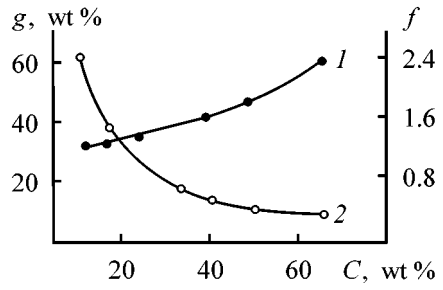

Fig. 2. (*1*) Gel fraction content *g* and (*2*) cross-linking efficiency *f* in films prepared from a mixture of latex nos. 11 and 14 vs. the content of the epoxide-containing copolymer in the latex mixture *C* (in terms of dry matter).

of type II (Tables 5, 7). The gel fraction content is low as compared with systems of type I and II, which may be due to an insufficient mobility of the functional groups fixed in different areas of the composite particle. The cross-linking efficiency can be improved by increasing the shell permeability, which, in turn, can be achieved by neutralization of carboxy groups with ammonia; simultaneously ammonia acts as cross-linking catalyst. However, formation of a very thick gel in this case apparently decreases the probability of formation of interglobular cross-links, which results in lower strength of the film and higher water absorption (Table 7). Thus, neutralization of carboxy groups in this system is not advisable.

Table 6. Preparation conditions and some characteristics of latex systems of type III [molar ratio core : shell 1 : 6.6; polymerization temperature in both stages 70°C; initiator $K_2S_2O_8$; emulsifier sodium (C_{14}–C_{16})-alkylsulfonate]

* (Numerator) film in the initial state; (denominator) film kept in water for 24 h.

Despite the relatively high water absorption of the films, they can be regarded as fairly water-resistant, insofar as the strength of the wet films remains high, and in the case of the best sample (no. 15) it is even higher than that of films formed from latexes of type I (Table 3). The major advantage of latexes of type III is the feasibility of preparing from them films and coatings at room temperature.

To conclude, the properties of the materials obtained, mainly studied with free films, show that the synthesized latexes can be used for preparing sufficiently elastic coatings with adhesion strength [measured according to GOST (State Standard) 15140–78] within 0.20–0.50 kN m^{-1} and relative hardness (M-3 testing pendulum) of about 0.7. The temperature conditions of film formation determine the application fields of the latexes. Latexes of type III, forming a film at room temperature, can be recommended for fabrication of water-resistant water-dispersible paints. As for latexes of type I, it is appropriate to use them in the final stages of leather finishing, which can be performed at 50–60°C. Latex systems of type II can be used in special coatings when temperatures of 125°C are admissible in the process.

CONCLUSIONS

(1) Procedures were developed for preparing three types of latex systems capable of forming cross-linking water-resistant films: type I, latexes with core–shell particles with the shell formed from the random copolymer styrene–*n*-butyl acrylate–2-hydroxyethyl methacrylate–methacrylic acid–glycidyl methacrylate; type II, mixtures of latexes with the particle shell of the first latex formed from the styrene–*n*-butyl acrylate–2-hydroxyethyl methacrylate–glycidyl methacrylate copolymer, and the particle shell of the second latex, from the styrene–*n*-butyl acrylate–2-hydroxyethyl methacrylate–methacrylic acid copolymer; type III, la-

texes with core–shell particles with the core formed from the styrene–*n*-butyl acrylate–2-hydroxyethyl methacrylate–glycidyl methacrylate copolymer, and the shell, from the styrene–*n*-butyl acrylate–2-hydroxyethyl methacrylate–methacrylic acid copolymer.

(2) A study of the properties of the synthesized latexes and films thereof showed that each of the developed types of latex systems can be used to prepare cross-linked water-resistant films and coatings retaining sufficiently high mechanical strength in the wet state.

(3) Conditions of formation of water-resistant films depend on the type of the latex systems. Systems of type III allow preparation of water-resistant films at room temperature; formation of films from latexes of type I is possible at temperatures ≥50°C; and latex systems of type II form water-resistant films only after additional heat treatment at 125°C.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Redox Activity of Poly-[PdSalpn-1,2] as Influenced by Thickness of Its Film and Composition of Supporting Electrolyte

L. P. Ardasheva and G. A. Shagisultanova

Herzen State Pedagogical University, St. Petersburg, Russia

Received February 29, 2000

Abstract—The electron transfer rate in the bulk of a [PdSalpn-1,2] polymeric film was studied as influenced by its thickness and the composition of the supporting electrolyte.

Procedures for preparing metal-containing polymeric films have been under development recently. Previously, brightly colored electrochromic heteronuclear and heteroligand Pd(II) complexes with bis(salicylidene)-1,2-propylenediamine ([PdSalpn-1,2]), bis(salicylidene)-1,3-propylenediamine ([PdSalpn-1,3]), and bis-(salicylidene)-*o*-phenylenediamine ([PdSalphen]) have been prepared by electrochemical oxidative polymerization [1–5] and their physicochemical properties (among which the most important are the electrical conductivity and photosensitivity) have been studied.

It should be noted that the properties of these polymers can be studied both in solutions of supporting electrolyte and in the solid state. Further study of the systems in question will give semiconductor characteristics of substances belongind to this class.

In this work the rate of electro-stimulated charge transfer in the polymers immersed in a solution of supporting electrolyte was studied as influenced by its composition and properties. In this case we deal with a system of three interrelated components: electrode, polymeric complexes immobilized on the electrode, and supporting electrolyte. A change in the properties of each component affects the properties of the whole system.

It is known that redox transformations of polymeric systems prepared by oxidative polymerization are accompanied by migration of anions of the supporting electrolyte inside and outside the polymeric matrix to maintain its electroneutrality. Such an overall process and the ions providing electroneutrality of the polymer are commonly termed [6] doping and dopants, respectively.

Levi *et al.* [7] found that the molecular structure of electron-conducting organic polymers is labile and may undergo conformational transformations caused by doping, swelling, and mechanical or electrochemical interactions of counterions and electrical charges of the polymeric chains. These transformations change the redox activity of the polymers.

The influence of various factors on the redox activity of organic polymers has been extensively studied [7–14]. However, polymeric metal complexes have not been investigated in this regard.

In this work, we studied the rate of electron diffusion in the bulk of the polymer as influenced by external factors (nature of the counterion and solvent and the concentration of the supporting electrolyte) and the thickness of the polymeric layer, one of the most important parameters of the polymer.

EXPERIMENTAL

Poly-[PdSalpn-1,2] was prepared by the procedure described in [15]. The polymer was identified by electronic absorption spectroscopy and X-ray photoelectron spectroscopy [16, 17]. The electrochemical experiments were performed in a three-electrode cell with separated compartments of the working, auxiliary, and reference electrodes.

A 0.1 M solution of tetrabutylammonium perchlorate (Bu_4NClO_4) in acetonitrile, deaerated with high-purity argon, was used as the supporting electrolyte. Acetonitrile (AN) was purified by the procedure described in [18]. To study the dependence of the redox conductivity of the polymer on the counterion

1070-4272/01/7402-0316 $25.00 © 2001 MAIK "Nauka/Interperiodica"

size, 0.1 M solutions of $Bu_4N[BF_4]$, Bu_4NF, and $Bu_4N[CF_3COO]$ in acetonitrile and dichloromethane were used. Dichloromethane (DCM), propylene carbonate (PC), and dimethylformamide (DMF) were purified as in [18].

As working electrode served platinum wire (99.99% Pt, 0.25 cm^2 surface area) sealed in glass. As auxiliary electrode was used a platinum gauze. All potentials were measured relative to a silver/silver chloride electrode filled with a saturated solution of sodium chloride.

Poly-[PdSalpn-1,2] was prepared under potentiostatic conditions by applying a 1.1 V potential to a 0.001 M solution of the monomer for a prescribed time.

Cyclochronovoltammograms (CCVA) recorded by sweeping the potential of an electrode coated with a film of poly-[PdSalpn-1,2] in a pure supporting electrolyte are shown in Fig. 1. These potentiodynamic curves indicate the occurrence of reversible redox processes in the solid phase of the polymeric film. Thus, the polymer exhibits electrical conductivity.

However, as seen from Fig. 1, the voltammograms of the polymer are bell-shaped and asymmetric relative to the abscissa axis. Levi *et al.* [7] believe that the broadening of the voltammetric peaks with respect to the theoretical peaks is due to repulsion of like-charged units of the polymeric chain, structural nonuniformity (alternation of amorphous and crystalline regions and cross-linking of the polymeric chains), and penetration of ions present in the solution and solvent molecules into the polymeric matrix.

The electrical conductivity in similar polymeric systems is provided by successive reactions of electron transfer from structural fragments, whose oxidation state is similar to that of the monomer, to the oxidized fragments of the polymeric chain through the polyconjugated system. This type of conductivity is designated redox conductivity and the systems of this kind, redoxactive systems.

There are two type of redox processes occurring in a conducting film at different potential sweep rates [7]. The first of these is the adsorption process which occurs via successive events of electron exchange between all units of the polymeric chain. This process occurs in relatively thin layers and is characterized by proportionality between the current and the potential sweep rate. The second is the diffusion process characterized by linear dependence between the peak currents of CCVA and the square root of the sweep rate. The occurrence of the diffusion process indicates that

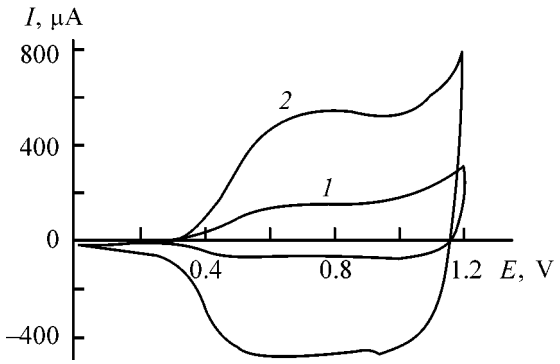

Fig. 1. Cyclochronovoltammograms of solid-phase redox processes in poly-[PdSalpn-1,2] at potential sweep rate of (*1*) 20 and (*2*) 100 mV s^{-1}. The time of polymer accumulation τ_a is 7 min; the accumulation potential E_a = 1.1 V; CH_3CN; TBAP. (*I*) current, (*E*) potential; the same for Figs. 3–5.

the rate determining step of the redox process is the ion transport (diffusion or migration) in the solution or(and) in the film. In this case, the rate of electron transfer in the bulk of the polymer between redox fragments of the polymeric chain is assumed to be considerably higher than that of ions in the electrolyte in which the polymer is immersed. If the porosity of the film is sufficiently high, i.e., there is larger polymer-free space inside the system, the deceleration of the ion transfer may be due either to interactions with cross-links in the macromolecule or to properties of the solvent and supporting electrolyte present in the pores.

Taking into account the fact that the propagation of an oxidation wave in a film is formally identical to diffusion of ions in a solution, the electron transfer rate can be characterized by the coefficient of electron diffusion along a polymeric chain D_{ct}. Thus, the electrical conductivity of a system is determined under the given conditions by the electron diffusion coefficient and depends on the properties of the medium and polymer, in particular, on the polymer thickness.

The electron diffusion coefficient D_{ct} was calculated by the Randles–Shevchik equation [19]. The peak currents were determined at the potential sweep rate $V_s \geq 100$ mV s^{-1}.

The thickness of the polymeric films was calculated from the quantity of electricity spent for complete reduction of the polymer, which, in its turn, was found by integrating cyclochronovoltammograms recorded at slow potential sweep rates (≤10 mV s^{-1}) [19]. Relatively stable polymeric films more than 2 μm thick were prepared in the course of a kinetic study of the polymer formation in acetonitrile. The time dependences of the thickness of poly-[PdSalpn-1,2] formed in di-

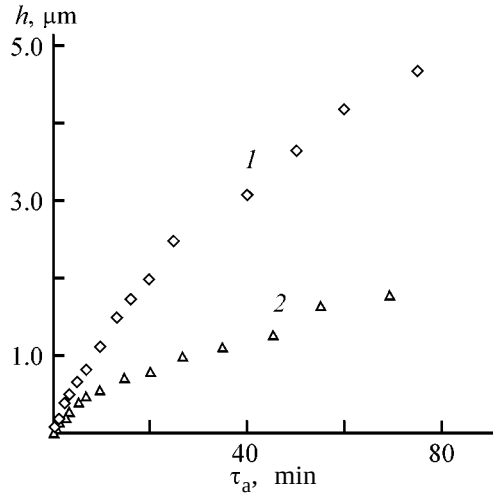

Fig. 2. Thickness of poly-[PdSalpn-1,2] film h grown in (*1*) CH_3CN and (*2*) CH_2Cl_2 vs. accumulation time τ_a. E_a = 1.1 V, TBAP.

chloromethane and acetonitrile at the optimal accumulation potential (1.1 V) are shown in Fig. 2.

It is known [19] that the diffusion coefficient D_{ct} in polymeric films may vary from 10^{-8} to 10^{-12} $cm^2\ s^{-1}$, i.e., in a wider range as compared with liquid solutions. This is due to the fact that the rate of electron transfer in a film is restricted by deformation of polymeric chains, long distances between electrochemically active fragments, diffusion of counterions from the solution, electron transfer between the oxidized and neutral fragments of the macromolecule, etc.

We studied the influence of the concentration of the supporting electrolyte on the redox activity of poly-[PdSalpn-1,2] prepared in acetonitrile at accumulation potential E_a = 1.1 V and accumulation time τ_a = 5, 10, and 20 min. A freshly prepared polymeric film was used in each experiment. As supporting electrolyte served 0.1 M tetrabutylammonium perchlorate (TBAP).

The shape of the potentiodynamic curves does not change with the Bu_4NClO_4 concentration increasing from 0.1 to 2 M. The electron diffusion coefficient along the polymeric chain also remains constant within the limits of experimental error. Thus, the redox activity of the polymer is not affected by the concentration of counterions. Apparently, the initial concentration of counterions in solution is sufficient to compensate the positive charges formed in polymer oxidation. An increase in the concentration of the supporting electrolyte has no effect on the formation and subsequent stabilization of new electrochemically active centers.

However, the diffusion coefficient D_{ct} decreases by 5–10, 10–20, 20–30, and 30–40% with the TBAP concentration in the solution decreasing to 0.08, 0.04, 0.02, and 0.01 M, respectively. The thicker the polymeric film, the stronger the decrease in D_{ct}. It should be noted that D_{ct} returned to the initial value when cyclochronovoltammograms of poly-[PdSalpn-1,2] prepared at low concentrations of the supporting electrolyte were recorded in solutions with the initial concentration of the counterions (0.1 M), used in the synthesis. Clearly, at a deficiency of counterions in solution, the probability of stabilization of all positively charged fragments formed in the polymeric chain decreases, and hence, the electron transfer in the polymer is decelerated.

The gap between the maxima of the anodic and cathodic peaks in the cyclochronovoltammograms (V_s = 100 mV s^{-1}) increases simultaneously with the decrease in D_{ct}. This difference is the most pronounced at [TBAP] = 0.01 and 0.02 M. Thus, it may be assumed that the considerable difference between in the potentials of the anodic and cathodic peaks at relatively fast potential sweep is due to kinetic restrictions. The diffusion of counterions to positively charged fragments of the polymeric chain is decelerated owing to insufficient concentration of ionic components of the solution in the polymeric matrix.

We also studied the influence exerted by BF_4^-, CF_3COO^-, and F^- ions on the redox activity of poly-[PdSalpn-1,2].

In each experiment we used a freshly prepared polymeric film. Acetonitrile solutions of Bu_4NClO_4, $Bu_4N[BF_4]$, $Bu_4N[CF_3COO]$, and Bu_4F were used as supporting electrolytes. Cyclochronovoltammograms of poly-[PdSalpn-1,2] prepared at E_a = 1.1 were recorded in (1) pure Bu_4NClO_4 solution, (2) a solution containing electrolyte ions whose influence is analyzed, and (3) pure Bu_4NClO_4 solution again. Simultaneously, the stability of poly-[PdSalpn-1,2] in supporting electrolyte containing the ions in question was studied. The results are presented in Table 1.

As seen from Table 1, the redox activities of the polymer in solutions containing ClO_4^- and BF_4^- anions are almost the same. This is clearly due to the fact that the crystallographic radii of these anions are similar [$r(ClO_4^-)$ = 0.236, $r(BF_4^-)$ = 0.232 nm] [20] and the dopant anion is known [13] to be incorporated in the polymer without solvation shell. However, it should be noted that the amount of the redox-active polymer decreases by 30% when the potential is continuously swept at a rate of 50 mV s^{-1} for 30 min in a solution containing BF_4^- anions, whereas its activity remains the same under similar conditions in the presence of ClO_4^- anions. Hence, the electrochemical inter-

9	2.6	1.3×10^{-9}	0.38	3.2×10^{-10}	0.6	4.6×10^{-12}

action of BF_4^- with an oxidized fragment of the polymer is stronger as compared with that of ClO_4^- and higher energy is required for rupture of these bonds and passage of tetrafluoroborate anion in the solution. Thus, we suggest that some BF_4^- anions remain bound to monomeric units of the polymer and are not involved in the redox process.

A decrease in the redox activity of the polymer and in the diffusion coefficient D_{ct} was observed in cyclochronovoltammograms recorded in a solution containing CF_3COO^- ions. This confirms the assumption that a large counterion causes kinetic hindrances. Clearly, when anion is larger than that used in polymer preparation, there are steric hindrances to penetration of this anion to the space between the aromatic rings. Hence, stabilization of positive charge induced by oxidation is complicated in this case. Nevertheless the D_{ct} in a polymer placed in a solution containing perchlorate anions remains equal to that calculated for a trifuoroacetate solution and does not return to the initial value. A special study of the influence of the potential sweeping on the stability of the polymeric film in a solution containing CF_3COO^- anions showed that the redox activity almost completely disappeared after 15-min potential sweep at a rate of 50 $mV\ s^{-1}$.

A study of the influence of the F^- anion showed that after a film is again placed in a Bu_4NClO_4 solution the redox activity of the polymer does not reach the initial value, but, quite the reverse, decreases. Probably, in this case the role of counterions is played by solvated F^- anions [9]. They are not desolvated, presumable because of the higher energy of solvation as compared with the energy of interaction of the ion with a unit of the polymeric chain. This is typical of small ions with large solvation shell. Thus, the large solvation shell prevents free penetration of the counterion into the cavities of the polymeric membrane and causes irreversible changes in the polymeric structure, inducing its degradation.

The above experimental data mainly refer to the influence exerted by the nature of the supporting electrolyte on D_{ct}. However, we also observed the influence of the nature of the supporting electrolyte on the shape and parameters of the voltammograms. In going from ClO_4^- to BF_4^- and back, the shape of cyclochronovoltammograms does not change at potential sweep rates of both 10 and 100 $mV\ s^{-1}$. The redox processes remain reversible. By contast, in going from ClO_4^- to CF_3COO^-, the shape of the cyclochrono-

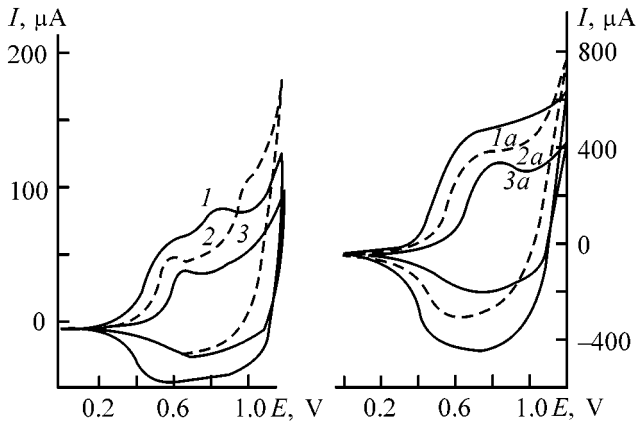

Fig. 3. Cyclochronovoltammograms of solid-phase redox processes in poly-[PdSalpn-1,2] at potential sweep rate of (*1–3*) 10 and (*1a–3a*) 100 $mV\ s^{-1}$ (the same for Fig. 4) in solutions containing (*1, 1a, 3, 3a*) ClO_4^- and (*2, 2a*) CF_3COO^- anions. τ_a = 3 min, E_a = 1.1 V, h = 0.58 μm, CH_3CN.

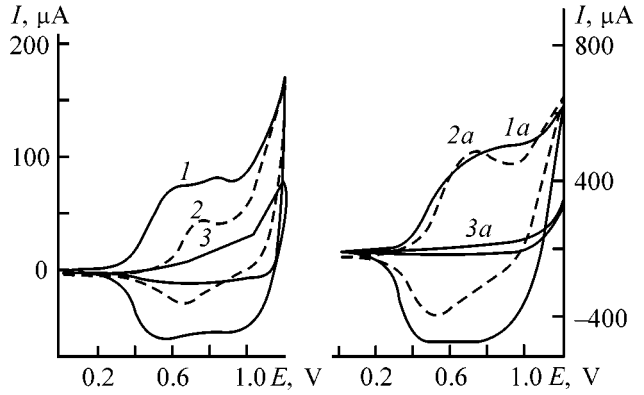

Fig. 4. Cyclochronovoltammograms of solid-phase redox processes in poly-[PdSalpn-1,2] in solutions containing (*1, 1a, 3, 3a*) ClO_4^- and (*2, 2a*) F^- anions. τ_a = 3 min, E_a = 1.1 V, h = 0.68 μm, CH_3CN.

voltammograms changes at both potential sweep rates (Fig. 3, curves *2*, *2a*). The voltammogram takes the initial shape after the polymeric system is again placed in the initial solution containing ClO_4^- anions (Fig. 3, curves *3*, *3a*). The shapes of cyclochronovoltammograms recorded in a fluoride solution at both slow and fast potential sweep rates strongly differ from that recorded in a perchlorate solution (Fig. 4, curves *2*, *2a*) and does not return to the initial state when the voltammogram is again recorded in a perchlorate solution (Fig. 4, curves *3*, *3a*).

Clearly, the total charge of the system must change in oxidation, i.e., upon appearance of positively charged sections of the polymeric chain. However, the oxidized polymer remains electroneutral owing to the compensation of the positive charge by counterions. There are two mechanisms of the compensation [7].

The cationic mechanism involves separation of the cations (C^+) of the supporting electrolyte whose molecules are partially located in the immediate vicinity of the polymer phase:

$$\{P, (C^+A^-)_m\} \rightarrow \{P^+, A^-, (C^+A^-)_{m-1}\} + C^+ + e.$$

In the case of the anionic mechanism, the charge is compensated by addition of anions of the supporting electrolyte contained in pores of the polymeric matrix:

$$\{P, (C^+A^-)_m\} + X^- \rightarrow \{P^+, X^-, (C^+A^-)_m\} + e.$$

The charge compensation by two different mechanisms results in different mechanisms of polymer functioning in solutions of different supporting electrolytes. Hence, the change in the shape of the voltammograms recorded in solutions containing CF_3COO^- and F^- anions can be accounted for using both the mechanisms. As seen from Figs. 3 and 4, the more positive current peak disappears and a pronounced peak with lower potential appears in the cathodic region of these cyclochronovoltammorgams. Migration of CH_3COO^- and solvated F^- anions in polymer pores must be sterically hindered, since their radii are greater than that of ClO_4^- in whose solution the polymer is prepared. Hence, the positive charge of the oxidized polymer must be compensated by the cationic, and not anionic mechanism. However, we suggest that the number of cations of the supporting electrolyte located in the immediate vicinity of the polymer phase is considerably smaller than that of the anions having smaller size. Hence, the number of charges of the polymeric chain compensated by the cationic mechanism is considerably smaller than that compensated by the anionic mechanism. This assumption is experimentally confirmed by the fact that current peaks corresponding to the cationic mechanism (less positive potential in the cathodic portion of the cyclochronovoltammograms) is smaller than those corresponding to the anionic mechanism of the charge compensation (more positive potential of the current peak). Thus, this explains the fast loss of the redox activity of the polymer is potential sweeping in solutions containing anions larger than those used in the synthesis. The electrical conductivity of the substance on the electrode sharply decreases because of the steric hindrances to charge compensation by the anions contained in the solution and irreversible compensation by cations fixed in the polymeric matrix.

The peak with the most positive potential is also present in the voltammograms recorded in solutions containing perchlorate and tetrafluoroborate anions. However, it is weak and overlaps with the stronger peaks located in the more positive region. There is no hindrance to migration of ClO_4^- and BF_4^- anions in pores of the polymeric matrix since their radii are almost identical and the polymeric film was prepared from a solution containing ClO_4^- anions. Hence, in this case the charge is compensated mainly by the anionic mechanism. However, the cationic mechanism is also possible. This is confirmed by the presence of current peaks at less positive potentials in the cathodic region of the cyclochronovoltammorgams.

The solvent plays an important role in the transfer of counterions in the solution and pores of the polymeric membrane. To study the influence of the solvent nature on the redox conductivity of the polymer, we calculated the electron diffusion coefficient along

the polymeric chain in different solvents. In each experiment, a film freshly prepared from an acetonitrile solution was used. Propylene carbonate (PC), dichloromethane, and DMF were used as solvents. In all experiments, Bu_4NClO_4 served as supporting electrolyte. Cyclochronovoltammograms of poly-[PdSalpn-1,2] prepared at E_a = 1.1 V were recorded (1) in pure acetonitrile supporting electrolyte, (2) in tested solvent, and (3) again in pure acetonitrile solution. Simultaneously, the stability of the polymer in the tested solvent was studied. The results are presented in Table 2.

As seen from Table 2, dichloromethane is the most inert with respect to the polymer among the tested solvents. The calculated polymer thicknesses remain virtually unchanged. However, thick polymeric layers are oxidized and reduced incompletely in a single cycle even at a sweep rate of 10 mV s^{-1}. As a result, the calculated thickness decreases from 3.1 to 2.5 μm. Thus, at this sweep rate the electron transport in a polymer film of this thickness is controlled by diffusion. On the whole, in the case of dichloromethane solution, the diffusion coefficient decreases, especially in thick films. To maintain the macroscopic electroneutrality of the system in electron transfer in a polymer, counterions of the supporting electrolyte must diffuse into the matrix in the course of oxidation and out from the matrix in the course of reduction. Therefore, an increase in the solvent viscosity (η_{DCM} = 0.441×10^{-3} Pa s, η_{AN} = 0.341×10^{-3} Pa s) [21] makes lower the counterion mobility, thus decreasing the electrical conductivity of the material.

In dichloromethane, the potentials of anodic and cathodic peaks for thin polymeric films at fast poten-

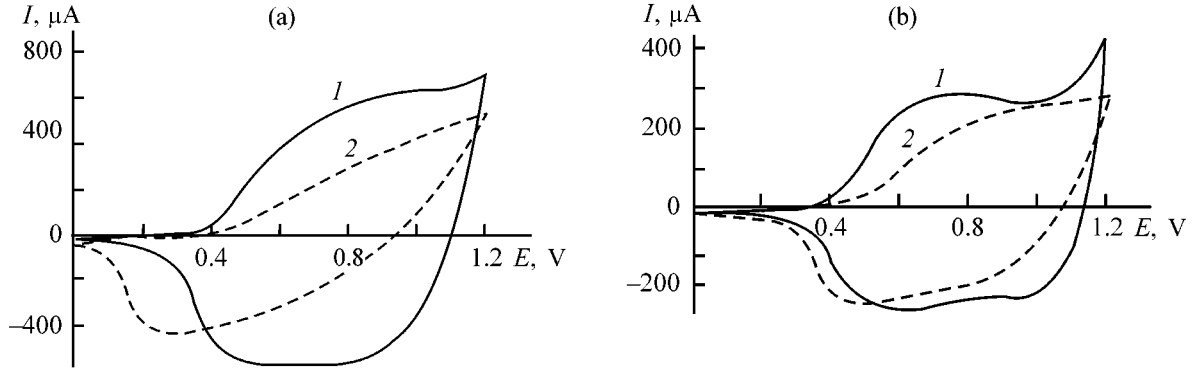

Fig. 5. Cyclochronovoltammograms of solid-phase redox processes in poly-[PdSalpn-1,2] films of thickness h (a) 0.8 and (b) 3.1 μm in TBAP in solutions of (*1*) acetonitrile and (*2*) dichloromethane at potential sweep rate V_s of (a) 100 and (b) 10 mV s^{-1}. τ_a: (a) 3 and (b) 15 min, E_a = 1.1 V.

tial sweeping and thick films at slow potential sweeping differ considerably (Figs. 5a, 5b). This may be due to kinetic hindrance to diffusion of ions of the supporting electrolyte in dichloromethane, more viscous than acetonitrile. Thus, the redox activity of the polymer is controlled by the counterion mobility.

In the case of a more viscous solvent, such as DMF ($\eta_{DMF} = 0.796 \times 10^{-3}$ Pa s) and PC ($\eta_{PC} = 2.513 \times 10^{-3}$ Pa s), the electron diffusion coefficient is lower. It should be noted that the amount of redox-active polymer on the electrode appreciably decreases after potential sweeping in PC and DMF solution and then in an acetonitrile solution ($V_s = 10$ mV s^{-1}). Thus, the polymer interacts with PC and DMF, which probably results in the swelling of the polymer and weakening of its adhesion to the electrode and bonds between the monomeric units. It should be noted that in DMF this interaction is stronger than in PC, which is possibly due to nucleophilic properties of DMF. Dimethylformamide, exhibiting more pronounced donor properties (the donor number of DMF and PC is 26.6 and 15.1, respectively) [21], interacts with positive sections of the oxidized polymeric chain and blocks their interaction with the counterions of the supporting electrolyte, thus decreasing the redox activity of the system. It should also be noted that the voltammograms of the tested polymer in DMF and PC considerably differ in shape from those recorded in acetonitrile and DCM at $V_s = 10$ and 100 mV s^{-1}.

We conclude that PC and DMF are unsuitable solvents for preparing polymers and studying their properties since they are not inert with respect to the tested polymers, decrease the redox activity of the polymers, and probably cause their physical degradation.

A study of the influence exerted by the solvent nature on D_{ct} in poly-[PdSalpn-1,2] prepared in TBAP solution in DCM at $E_a = 1.1$ V (Table 2) gave similar results.

Although the charge diffusion coefficient depends on the solvent nature, the polymer prepared in DMF exhibits a number of specific properties as compared with the polymer prepared in acetonitrile solution.

Clearly, in a solvent with low viscosity, such as acetonitrile, the electron diffusion coefficient increases negligibly and the amount of conducting polymer on the electrode does not virtually change at $V_s = 10$ mV s^{-1}. The thicker the film, the stronger the increase in D_{ct} in the polymer in acetonitrile. This is due to a strong overvoltage on the electrode coated with thick polymeric film at potential sweeping in dichloromethane, which restricts the electrical conductivity of the polymer. Strong kinetic hindrance appearing in relatively viscous solvent at fast potential sweep rates is caused by deceleration of the inward transport of counterions in the polymeric matrix. In acetonitrile this hindrance is less pronounced.

More viscous PC and DMF strongly decrease the redox activity of the polymer for the above reasons. In addition, DMF causes faster degradation of the polymer prepared from dichloromethane: the redox degradation is virtually completed in two cycles of potential sweep. Probably the films grown in dichloromethane are more friable and porous as compared with those prepared in acetonitrile. Since the difference in donor number between DCM and DMF is greater that that between acetonitrile and DMF, the displacement of charge-compensating molecules of dichloromethane by dimethylfomamide in pores of the polymeric membrane and the resulting addition of DMF molecules to the oxidized sections of the polymer prepared in DCM is faster than in the case of a polymer prepared in acetonitrile. Hence the degradation in DMF is considerably faster as compared with the case of films prepared in acetonitrile solutions.

Analysis of data presented in Table 2 confirms that the films prepared in DCM are more porous than those prepared in acetonitrile. The redox activities of the polymeric films with the same thickness in the solvent used in their preparation are virtually the same. We also found that in acetonitrile the diffusion coefficients D_{ct} for the films of similar thickness prepared in both acetonitrile and DCM are virtually the same ($D_{ct} \sim 1.6 \times 10^{-10}$ cm^2 s^{-1} at $h = 0.8$–0.9 μm). However, in DCM, the redox activity of the film prepared in acetonitrile ($D_{ct} \sim 7.2 \times 10^{-11}$ cm^2 s^{-1}) is lower than that of the films prepared in DCM [$D_{ct} \sim (1.4$–$1.6) \times 10^{-10}$ cm^2 s^{-1}] and having similar thickness ($h = 0.8$–0.9 μm). Although the redox activity of the polymer in more viscous DCM must seemingly decrease, the diffusion coefficient D_{ct} does not change. We suggest that the hindrance to diffusion of ions of the supporting electrolyte in more viscous DCM is compensated for by the larger pore space in the polymeric matrix prepared in this solvent.

Thus, the mobility of counterions depends on both the solvent viscosity and the number and size of pores in the polymeric matrix.

Acetonitrile and dichloromethane can be used as interchangeable solvents both for preparing these polymers and for studying their properties.

The dependences of the electron diffusion coefficient along the polymeric chains of poly-[PdSalpn-1,2]

films in acetonitrile and dichloromethane on their thickness h are shown in Fig. 6. The polymer was synthesized and studied in the same solvent.

As seen from Fig. 6, D_{ct} grows with increasing film thickness in the case of an acetonitrile solution. When DCM is used as the solvent, D_{ct} increases until the film thickness reaches approximately 1-μm and then decreases, tending to a constant value. The increase in the electrical conductivity of a film with its growing thickness is a somewhat surprising result. Nevertheless, this phenomenon is known for organic polymeric films.

However, no clear explanation of this phenomenon has been given. In this case, the charge diffusion front is assumed to move away from the charged centers in the bulk of the polymeric matrix rather than from the support–polymer interface [22, 23].

We offer the following explanation for this phenomenon. Thick polymeric films prepared by electrochemical polymerization are characterized by relatively high degree of cross-linking. These additional bonds facilitate electron transport in the polymeric phase. In addition, the number of structural defects (in particular, chain terminations), which can trap electrons, is negligible in the tested systems.

The fact that D_{ct} in polymeric films thicker than 1 μm does not change in DCM solutions may be due to the solvent properties. As noted above, the higher, compared with acetonitrile, viscosity of DCM prevents deeper penetration of counterions into the polymer. Clearly, the thickness of 1 μm is a threshold thickness, i.e., at definite sweep rate, counterions can penetrate only to a definite depth of the polymeric phase.

CONCLUSION

The electrochemical behavior of poly-[PdSalpn-1,2] was studied as influenced by the composition of the supporting electrolyte and thickness of the polymeric film. Contrary to fast electron transfer processes, the redox reactions in the film are subject to substantial kinetic limitations associated with the molecular movement of the polymeric chain and transport of ions and solvent molecules in the film.

Abstract—Highly selective refining of light vacuum gas oil by five-step countercurrent extraction of aromatic and heteroatomic compounds with *N*-methylpyrrolidone or dimethylacetamide in the presence of low-boiling nonpolar solvents was studied. The resulting refined oil can be used as high-quality raw material in hydrocracking and catalytic cracking.

Vacuum gas oils are used as raw material in lube oil production or for preparating lighter fractions by hydrocracking or catalytic cracking. In large petroleum refineries, it is cost efficient to combine hydrocracking with catalytic cracking, which improves the process flexibility and makes the fuel production more balanced [1].

It is known that rather strict requirements are imposed on the raw materials used in both hydrocracking and catalytic cracking, including the content of polycycloarenes, heteroatomic compounds, and heavy metals. Their increased content in vacuum gas oils promotes coke formation and catalyst poisoning and impairs the cracking level, yield of the petrol fractions, and the product quality [2]. Thus, when designing the catalytic cracking unit at the Ufa Petroleum Refinery, Joint-Stock Company, it was intended to produce diesel fuel with sulfur content below 0.2 wt % from light gas oil with sulfur content of 1.92 wt %. In fact, however, the obtained product contains 0.5 wt % sulfur [3]. The increased content of alkylaromatic hydrocarbons in the raw material and their oxidation by oxygen (presumably, adsorbed on a catalyst) resulted in that, after the unit was put in service, the level of phenols in wastewater increased by an order of magnitude from 0.27–0.62 to 3.59–5.34 mg l^{-1} [4].

Pretreatment of vacuum gas oils before hydrocracking or catalytic cracking can be performed by various methods such as hydrofining, primary hydrocracking, partial-conversion hydrocracking using two reactors in which hydrofining and hydrocracking proceed separately [5], and deep hydrogenation of the raw material at a pressure of about 30 MPa [6].

Also the raw material can be prepared for hydrocracking and catalytic cracking by extraction treatment with selective solvents [7, 8]. For example, refined oil containing 91.5 wt % saturated hydrocarbons was obtained by extraction of arenes from heavy vacuum gas oil (Romashki oil field). Catalytic cracking of the resulting refined oil provides petrol in yield higher by 7.3 wt % than that with crude vacuum gas oil [8].

The advantage of the extraction treatment of vacuum gas oils over the hydrogenation methods is that extraction can be performed under nearly atmospheric pressure, making the process more cost efficient. In its turn, the drawback of extraction treatment is that aromatic hydrocarbons and organoelement compounds are not sufficiently selectively removed with such solvents as phenol, furfural, and *N*-methylpyrrolidone. For example, the extracts after treatment oil distillates with phenol contain about 25 wt % saturated hydrocarbons [9]. Chernozhukov *et al.* [10] reported that extraction treatment of oils leads to loss of 5–15 wt % of the initial amount of saturated hydrocarbons.

The efficiency of extraction treatment can be improved by using an extraction system consisting of two partially miscible solvents, for example, furfural and isooctane [11]. It has been demonstrated [12] that addition of cetane to a polar extractant, e.g., to a mixture of *N*-methylpyrrolidone and ethylene glycol, increases the selectivity of extraction of benzene and its homologs from reforming catalyzates. It has also been reported [13] that addition of a mixture of toluene and

octane to dimethylformamide makes higher the yield of refined oil in selective refining of oil fractions.

It was shown in [14, 15] that use of low-boiling polar extractants and pentane as a nonpolar solvent is efficient in extraction of aromatic hydrocarbons from middle oil.

The goal of this work was to improve the quality of light vacuum gas oil by selective removal of aromatic hydrocarbons and organoelement compounds using extraction with a polar extractant in pentane. In experiments we used two samples of light vacuum gas oil taken before (sample no. 1) and after (sample no. 2) upgrading a vacuum block at AVT-6 unit (Kirishinefteorgsintez Production Association). The upgrading (1999) included changing direct-flow sieve trays for a Vacupack regular packing and trays with buttress valves, and also improvement of the vacuum system [16]. The characteristics of the samples used are listed in Table 1.

As a result of more distinct fractional distillation of black oil, the light gas oil obtained after upgrading is characterized by lightened fractional oil content and lower content of aromatic hydrocarbons and organoelement compounds. A polar extractant for selective refining of the raw material was chosen so that there was no formation of azeotropic mixtures by the extractant with components of the raw material. It is known that *N*-methylpyrrolidone, one of the most efficient extractants for selective refining of oil fractions, does not form azeotropic mixtures with hydrocarbons boiling above 280°C [17]. Therefore, we used this extractant for selective refining of sample no. 1. For extraction of aromatic and organoelemental compounds from sample no. 2 (lower-boiling fraction) we used dimethylacetamide, which does not form azeotropic mixtures with hydrocarbons boiling above 250–270°C under standard conditions.

Selective refining of sample no. 1 of light vacuum gas oil was carried out by five-step countercurrent extraction with *N*-methylpyrrolidone in pentane or without diluent under conditions given in Table 2. In the case of sample no. 2, we used dimethylacetamide in pentane or in a mixture of heptane with tol-

uene (1 wt %) modeling refined oil from an LG 35-8/300B benzene reforming unit. The use of higher-boiling nonpolar solvents allows an increase in the extraction temperature from 30 to 50°C at a total pressure in the extractors remaining close to atmospheric pressure.

As an example, Table 3 presents the material balance for experiment no. 1. Since pentane is more readily soluble in *N*-methylpyrrolidone than saturated hydrocarbons of the raw material, its use as a stripping solvent makes it possible to decrease their loss with the extractant phase from 10 (without pentane) to 2.65 wt % of the total amount of these components in the raw material (note that these components are valuable for further hydrocracking or catalytic cracking). The extract obtained using the extraction system *N*-methylpyrrolidone–pentane is characterized by higher content of aromatic compounds, as demonstrated by the higher sulfury content and aromaticity factor as compared with those in experiment no. 2 without pentane (Table 4). The aromaticity factors of the resulting extracts and refined oil obtained after regeneration of the extractants by fractional distillation on a 20-TP column was estimated as in [18], from ^{13}C NMR spectra (Bruker AM-500 instrument). Addition of the stripping nonpolar solvent also increases the content of sulfur- and nitrogen-containing compounds. In this case, the yield of refined oil increases by about 10%. Therefore, addition of pentane improves the selectivity of extraction refining of vacuum gas oil to remove undesired components. However, to maintain a high degree of extraction of aromatic and organoelemental compounds, one has to use an increased ratio of polar extractant to raw material.

Dimethylacetamide is a less selective solvent with respect to aromatic hydrocarbons than *N*-methylpyrrolidone [19]. However, refining of sample no. 2 with dimethylacetamide and pentane (experiment no. 3) appeared to be even more selective as compared with the refining of sample no. 1 in experiment no. 1 under the same conditions. The loss of saturated hydrocarbons with the extract is only 1.3 wt % of their total amount in the raw material, as demonstrated by the higher balance data; the content of aromatic compounds in the extract and the yield of refined oil are the highest among those obtained in all the experiments. These results can be attributed to the decreased content of undesired components in sample no. 2 and to the lower boiling end point of this fraction, i.e., to a shorter length of alkyl radicals in aromatic compounds.

In experiment no. 4, changing pentane for a mixture of heptane with toluene at simultaneously decreasing ratio of the nonpolar solvent to raw material and increasing process temperature results in lower selectivity of gas oil refining. In this case, the loss of saturated hydrocarbons with the extract increases to 5.8 wt % of their total in the raw material, and the yield of refined oil and the concentration of aromatic and sulfur-containing compounds in the extract decrease. As an advantage of the last variant we may note the highest degree of removal of aromatic and sulfur-containing compounds from refined oil.

CONCLUSIONS

(1) Extraction refining of light vacuum gas oil with *N*-methylpyrrolidone or dimethylacetamide in the presence of such nonpolar solvents as pentane and refined oil from a benzene reforming unit allows a decrease in the content of aromatic hydrocarbons in the refined gas oil by a factor of 2.5–3.5 at minimal loss of saturated hydrocarbons (1–3 wt % of their total in raw material).

(2) The degree of removal of sulfur- and nitrogen-containing compounds in extraction refining of light gas oil may be as high as 75–80%.

Abstract—Selective refining of heavy vacuum gas oil and a combined fraction of light and heavy vacuum gas oils to remove aromatic and organoelement compounds and heavy metals by five-step countercurrent extraction with *N*-methylpyrrolidone or dimethylacetamide in the presence of heptane containing 1 wt % toluene was studied.

Heavy vacuum gas oil, similarly to the light one, is used as a raw material in lube oil and motor oil production. It is known that rather strict requirements are imposed on the raw material used in both hydrocracking and catalytic cracking, including the content of polycycloarenes, sulfur- and nitrogen-containing compounds, and heavy metals. The increased content of these undesirable components promotes coke formation and poisoning of catalysts and deteriorates the cracking level, yield of the petrol fractions, and the product quality [1, 2]. It is known that they can be removed from the raw material by the hydrogenation and extraction methods (for fuel-oil residue, by deasphalting).

The goal of this work was to improve the quality of heavy vacuum gas oil by selective extraction refining with polar and nonpolar solvents.

In experiments we used a sample of heavy vacuum gas oil taken after upgrading of AVT6 unit (Kirishinefteorgsintez Production Association). The upgrading (1999) included changing direct-flow sieve trays for a Vacupack regular packing with low hydrodynamic resistance, and also modification of the vacuum system. As a result, the content of the fraction boiling below 350°C in heavy vacuum gas oil decreased to 2.5 wt %, and the boiling end point (96% distillation) increased to 532°C [3]. The characteristics of the sample used are listed in Table 1.

As polar solvents were selected *N*-methylpyrrolidone and dimethylacetamide, forming no azeotropic mixtures with components of the raw material but showing high efficiency in selective refining of oil fractions [4, 5]. To raise the concentration of undesirable components in the extract and simultaneously to decrease the loss of saturated hydrocarbons, we also used a nonpolar solvent, heptane, containing 1 wt % toluene, modeling refined oil from an LG 35-8/300B benzene reforming unit.

Selective refining was carried out by five-step countercurrent extraction at 50°C and polar extractant (moisture content 3 wt %) to raw material ratio of 5 : 1. The mass ratio of the nonpolar solvent to the raw material was 1 : 1 and 0.5 : 1 in extraction with *N*-methylpyrrolidone and dimethylacetamide, respectively. Heavy metals were determined by X-ray spectral analysis on a BARS-2 instrument.

The results show that selective extraction refining of heavy vacuum gas oil with both *N*-methylpyrrolidone (Table 1) and dimethylacetamide (Table 2) ensures a sufficiently high degree of removal of undesirable components (62–75%) and high concentration of these components in the extract. The content of saturated hydrocarbons in the extract is 10–15 wt %, which corresponds to their loss with the extract at a level of only 6.2–11.4% of their initial content in the raw material. The extraction system with *N*-methylpyrrolidone provides more exhaustive refining, whereas the system with dimethylacetamide ensures more selective refining of the raw material to remove undesirable components. The difference between the obtained results can be attributed in part to different nonpolar solvent to raw material ratios.

We also studied the extraction refining of a wide vacuum gas oil fraction prepared by mixing samples of light and heavy vacuum gas oils at a mass

ratio of 12.8 : 87.2. It is this ratio that is characteristic of the actual vacuum gas oil produced by AVT-6 unit [3].

Table 3 demonstrates that the parameters of extraction refining of this wide fraction are somewhat worse than those estimated theoretically using the additivity rule from data on extraction of undesirable components from light and heavy vacuum gas oils. The results obtained are consistent with the existing concept of the effect exerted by the fractional composition of the raw material on the efficiency of selective refining of oil fractions. According to this concept, extraction of arenes and organoelement compounds from wide fractions is relatively low-efficient [6]. The decreasing selectivity of extraction of undesirable components from the combined vacuum gas oil fraction can be attributed to the fact that the wider the gap between the initial and end boiling points of a raw material, the closer the solubilities in the extractant of high-boiling aromatic (or heterocyclic) compounds to be removed and low-boiling saturated hydrocarbons. This must be most clearly pronounced for strongly associated extractants whose selectivity is strongly dependent on the molecular weight of components to be removed [7]. However, neither *N*-methylpyrrolidone nor dimethylacetamide are classified with such extractants. Therefore, even in the case of a combined vacuum gas oil fraction, the degree of removal of undesirable components remains sufficiently high (55–72%).

CONCLUSIONS

(1) Extraction refining of heavy vacuum gas oil with *N*-methylpyrrolidone or dimethylacetamide in the presence of heptane containing 1 wt % toluene allows a 67–75% removal of aromatic hydrocarbons, sulfur- and nitrogen-containing compounds, and heavy metals. Addition of a nonpolar solvent to the polar extractant improves the extraction selectivity and reduces the loss of saturated hydrocarbons to 6% of their total in the raw material.

(2) The efficiency of extraction refining of the combined fraction of light and heavy vacuum gas oils is lower than the theoretical value estimated by the additivity rule. Nevertheless, in this case, too, the extraction systems proposed allow 55–72% removal of undesirable components.

BRIEF COMMUNICATIONS

Synthesis of Mordenite-like Zeolite from Secondary Silicon-containing Raw Materials

M. L. Pavlov, R. A. Makhamatkhanov, B. I. Kutepov, and U. M. Dzhemilev

Institute of Petrochemistry and Catalysis, Academy of Sciences of the Republic of Bashkortostan, Ufa Scientific Center of the Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Received November 2, 2000

Abstract—A low-waste method is proposed for synthesizing a mordenite-like zeolite from secondary silicon-containing raw materials.

Specific features of the chemical composition and structure of the crystal lattice of a mordenite-like zeolite impart to it distinctive adsorption and catalytic properties and make it promising for practical use as support and component of catalysts for hydromerization of *n*-paraffins and hydrocracking of oil fractions and sorbents for drying of acid gases [1–3]. Therefore, development of techniques for synthesizing mordenite-like zeolites is a promising direction in the chemistry of zeolites.

The present communication describes, an industrially promising method for synthesis of mordenite from silicon-containing raw materials—wastes produced in manufacture of crystalline silicon (WMSC), with recycling of the mother liquor formed in the preceding synthesis of zeolite.

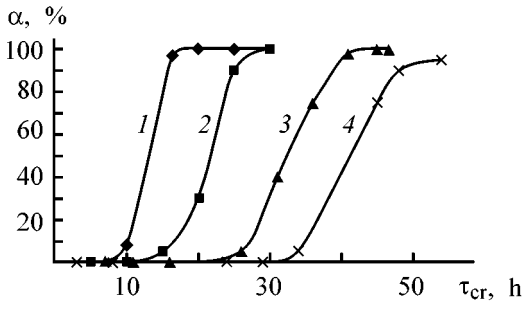
EXPERIMENTAL

Mordenite was synthesized from aqueous solutions of sodium aluminate and sodium hydroxide, and also from a new silicon-containing raw material—WMSC containing no less than 98 wt % SiO_2. The synthesis was done in an autoclave with a stirrer and a device that allowed sampling in the course of synthesis without disturbing the crystallization mode, in the interval 125–165°C with reaction mixtures of composition $(2.2–3.6)Na_2O \cdot Al_2O_3 \cdot (12–20)SiO_2 \cdot 300H_2O$.

The synthesized samples were washed to remove impurities, dried at 150°C for 3 h, and then calcined in air at 540°C for 4 h. The chemical composition of the liquid and solid phases was determined by the methods described in [4]. An X-ray diffraction analysis was done with a DRON-3 diffractometer with monochromatized Cu_{K_α} radiation (graphite monochromator in reflected beam). The adsorption properties of the obtained samples were characterized by static capacity with respect to H_2O, C_6H_6, and *n*-C_7H_{16} vapors.

Preliminary experiments demonstrated that WMSC can be used for mordenite synthesis. Further, the kinetic aspects of mordenite crystallization with the use of these raw materials were studied to reveal the influence exerted by the composition of the reaction mixture and by the temperature and duration of crystallization on the properties of the obtained product.

The figure shows kinetic curves describing the crystallization of a $2.2Na_2O \cdot Al_2O_3 \cdot 12SiO_2 \cdot 300H_2O$ reaction mixture at 125, 135, 145, and 155°C. The curves have S-like shape characteristic of similar curves taken in synthesizing other types of zeolites. The first portion of a curve reflects the induction period; the second, the period of exponential formation and growth of crystals; and the third, the period of a slowing-down crystallization.



Crystallinity α of a sample vs. time τ_{cr} of crystallization of a reaction mixture of composition $2.2Na_2O \cdot Al_2O_3 \cdot 12SiO_2 \cdot 300H_2O$. Temperature (°C): (*1*) 155, (*2*) 145, (*3*) 135, and (*4*) 125.

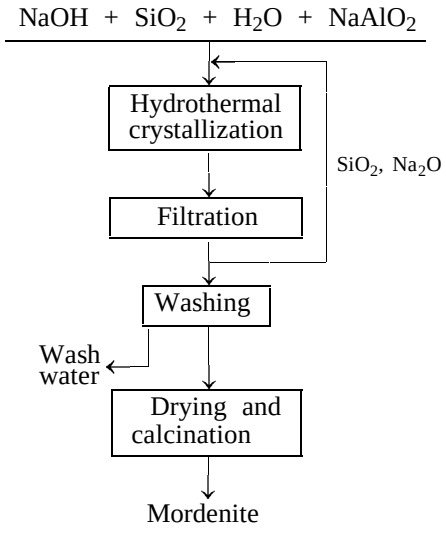
	30	100	0.12	0.12	0.12	77.3	14.1	9.3
160**	25	100	0.11	0.12	0.11	76.0	14.3	8.9

* T_{cr} is the crystallization temperature, and τ_{cr} is the time of crystallization.

** Sample synthesized by the conventional method.

It can be seen that formation of mordenite with high crystallinity at 145°C requires 28–30 h. With the synthesis temperature raised to 155°C, a sample of the same quality can be synthesized in 23–25 h, i.e., the duration of crystallization at which nearly 100% zeolite crystallinity can be achieved decreases with increasing crystallization temperature.

On the basis of the results obtained in the kinetic studies, conditions were chosen making it possible to synthesize from WMCS a mordenite with characteristics comparing well with the parameters of mordenite obtained from Na_2SiO_3, $NaAlO_2$, and NaOH (see the table). It should be noted that the crystallization times of mordenite with high phase purity by both variants are also close.



Scheme of synthesis of a mordenite-like zeolite.

In synthesis of mordenite, mother liquor containing silicon and sodium cations is formed in the stage of its hydrothermal crystallization. This solution is not always utilized, thereby making larger the amount of wastewater. The possibility was also studied of synthesizing mordenite with recycling of the mother liquor. The experiments performed demonstrated that such a technique is possible (see the scheme).

CONCLUSION

A method was developed for synthesizing mordenite from waste produced in manufacture of crystalline silicon used as silicon-containing raw material. The method assumes utilization of the mother liquor by its repeated use in zeolite synthesis.

BRIEF COMMUNICATIONS

High-Temperature Fuel Cell Operating on Products of Incomplete Charcoal Combustion

N. M. Gamanovich, V. A. Gorbunova, A. I. Lamotkin, and G. I. Novikov

Belarussian State Technological University, Minsk, Belarus

Received April 12, 2000; in final form October 2000

Abstract—A high-temperature fuel cell operating on gaseous products of incomplete combustion of technical-grade charcoal and equipped with electrodes made of platinum and electrocatalytic oxide materials containing no noble metals was studied experimentally.

Previously [1], experimental data have been published obtained in testing a high-temperature fuel cell (HTFC) operating on gaseous products of incomplete combustion of coal (anthracite). As is known [2], this high-quality coal contains no sulfur that could poison HTFC electrodes. Lower-quality coals contain up to 12% sulfur and cannot serve as fuel for HTFC. In addition, in some CIS regions, the coal deposits are poor or coal is not mined at all, whereas there are ample opportunities for using charcoal. Charcoal is characterized [3] by calorific value of 31.4–34.2 mJ kg^{-1}, primary and storage humidity in the range from 2–4 to 7–15 wt %, ash content of no more than 3 wt %, content of volatiles (CO, CO_2, CH_4, etc.) of no more than 20 wt %, and porosity of 72 (birch charcoal) and 80 vol % (fir-tree charcoal). An important compositional feature of charcoal is the complete lack of sulfur. A sufficiently detailed thermodynamic analysis of the process in question was made in [1].

EXPERIMENTAL

Electrochemical oxidation of gases (CO and H_2) liberated in incomplete combustion charcoal (obtained by the method described [4]) was performed with an HTFC based on a solid oxide electrolyte of composition $0.9ZrO_2$–$0.1Y_2O_3$ (YSZ) [1] in the temperature range 770–1170 K.

The fuel cell comprising a cylindrical electrochemical cell with total working area of about 3.0 cm^2 was placed in the active zone of charcoal combustion. Charcoal was ignited and temperature was maintained with SNOL laboratory electric furnace [1].

The fuel electrode (anode) of the HTFC was prepared from Ni–YSZ nickel–zirconium-oxide cermet obtained using various techniques. Its specific consumption was about 0.100 kg per 1 m^2 of electrolyte surface. The air electrode (cathode) was deposited using two materials (synthesized by thermal decomposition of aqueous solutions of a mixture of nitrate salts prepared from pure and analytically pure reagents) based on rare-earth manganites of composition $La_{0.6}Sr_{0.4}MnO_3$ and $Ln_{0.8}Ca_{0.2}Mn_{0.94}Cr_{0.04}Ni_{0.02}O_3$ (close to that of the material used in [5]) where Ln is a mixture of La, Nd, Pr, and Ce. The specific expenditure of the cathode material was 0.120 kg m^{-2}, with its layer on the electrolyte being composite and including 10.0 wt % YSZ powder.

The fuel electrodes (anodes) of the HTFC were fabricated as follows. To obtain anode no. 1, finely dispersed Raney nickel (70%) and YSZ mass (30 wt %) were mechanically mixed and used to prepare an electrode paste (with 10% solution of rosin in C_2H_5OH). The paste was fired-in in a flow of technical grade helium at 1150 K in the course of 2.5 h. After depositing the anode, the cathode layer was fired-in in air at 1150 K for 2.5 h, with the anode layer of nickel simultaneously oxidized to NiO_x oxide.

In fabricating anode no. 2, an aqueous suspension of a finely dispersed YSZ powder in a solution of nickel nitrate $Ni(NO_3)_2 \cdot 6H_2O$ (70 wt % in terms of NiO) was prepared, dehydrated by evaporation, and finally calcined in air at 870 K. The obtained powder was used to prepare the electrode paste which was fired-in in air with the simultaneous firing-in of the cathode material into the electrolyte at 1470 K for 2.5 h.

The working cermet Ni–YSZ electrode was formed by reducing the nickel oxide phase in the NiO_x–YSZ

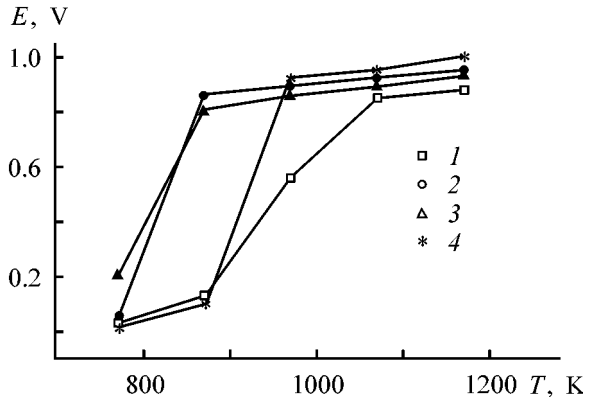
layer with fuel gases (CO, H_2) liberated in incomplete combustion of charcoal in operation of an electrochemical HTFC. The reduction of NiO_x to Ni favors the creation of porosity in the anode, necessary for the cell operation, and the sufficiently uniform distribution of disperse YSZ particles in the anode cermet hinders recrystallization of nickel particles via sintering [6], thereby ensuring prolonged electrochemical activity of the fuel electrode under the HTFC conditions.

As current lead was used 0.5-mm-thick platinum wire. As oxidizing agent served atmospheric oxygen supplied into the cathode space at a rate of 1.80 $cm^3\ min^{-1}$. To obtain comparative characteristics of HTFC, gases formed in incomplete combustion of charcoal were electrochemically oxidized in a cell with platinum layers as anode and cathode.



Potential difference *E* across an HTFC operating on products of incomplete charcoal combustion vs. temperature *T*. (*1*–*4*) Numbers of HTFC electrodes in the table.

The results obtained in measuring the potential difference, voltage, and current in the HTFC under study are presented in the table. It can be seen that the lowest potential difference is obtained with platinum electrodes, which can be attributed to the rather high polarizability of the platinum electrodes and their unipolar conductivity [7]. The best electrochemical parameters of an HTFC operating on gaseous products of incomplete combustion of charcoal (E = 1.0 V, U = 0.76 V, I = 0.80 mA) were obtained with cermet anode no. 2 and cathode of composition $Ln_{0.8}Ca_{0.2}Mn_{0.94}Cr_{0.04}Ni_{0.02}O_3$, which is apparently due to the high electrochemical activity of these electrodes (caused, among other factors, by the high permeability to oxygen of the electrode material with perovskite structure and by the catalytic activity of nickel in CO oxidation to CO_2) to be considered in further studies. On the whole, the given type of HTFC, operating on products of charcoal combustion, compares well in basic parameters with a similar cell operating on anthracite combustion gases [1].

The figure shows the potential difference across an HTFC in relation to its temperature. It can be seen

that the HTFC with platinum electrodes gradually passes into the optimal temperature mode of operation and yields the highest potential difference of 0.88 V at 1170 K. The HTFC with a Ni–YSZ cermet anode and manganite cathode is characterized by faster rise in potential, voltage, and current in the range 870–970 K, with nearly the best performance parameters reached. This steep change in the parameters is presumably due, in the first place, to chemical reduction of NiO_x at 870–970 K to give electrochemically active nickel metal in the anode cermet.

CONCLUSIONS

(1) It is established that the high-temperature fuel cell operating on gaseous products of incomplete combustion of technical-grade charcoal compares well in its electrochemical parameters with a similar cell operating on gases produced in anthracite combustion and can be recommended for practical use.

(2) The best parameters of HTFC (E = 1.0 V, U = 0.76 V, I = 0.80 mA) operating on the given fuel at a flow rate of the oxidizing agent—atmospheric oxygen, of 1.80 $cm^3\ min^{-1}$ were obtained with a cermet Ni–YSZ anode no. 2 and a $Ln_{0.8}Ca_{0.2}Mn_{0.94}Cr_{0.04}Ni_{0.02}O_3$ cathode at 1070–1170 K.

Calculation of Current Strength in Reactor with Combined Anodes

T. N. Ostanina, V. M. Rudoi, N. I. Ostanin, and E. I. Kosheleva

Ural State Technical Univrersity, Yekaterinburg, Russia

Received February 16, 2000; in final form, May 2000

Abstract—A method is proposed for calculating the potentials of anodes made of various metals, total voltage across reactor, and current distribution among dissimilar anodes. Calculated data are compared with the performance parameters of a real reactor.

One of the most efficient methods for wastewater purification is electrocoagulation [1]. Anodes (made of iron and aluminum) dissolve in the reactor situated in a purification unit. In the process, metal cations pass into solution, which leads, in neutral medium, to formation of insoluble hydroxides. Molecules of hydroxides coagulate to form flakes onto which impurities (oil product wastes, fine suspended particles, etc.) are adsorbed. The purification process, as a rule, starts already in the reactor and is completed in the next chamber. The main process occurring at the anode is hydrogen evolution, which makes higher the degree of purification because of the carry-over of coagulating particles by gas bubbles. The basic problem in the operation of the reactor is the anode passivation. The passive film drastically retards the process of metal cation formation, the anode potential is shifted to the positive region, and oxygen evolution starts. In choosing technological conditions of reactor operation, it is necessary that the anode potential should be more negative than the potential of the onset of passivation of the corresponding metal. The calculation of the potential becomes complicated when anodes of different metals (iron and aluminum) are used, since it is not known how the current is distributed among the anodes.

In this communication, a method is proposed for calculating the potentials of anodes made of different metals and the distribution of the current in a reactor with combined anodes.

The voltage U across the electrolyzer is determined [2] by the difference of the potentials E_a and E_c of the anode and cathode, ohmic voltage drop across the electrolyte (ΔU_{el}), voltage drop across the electrode bulk ($\Delta U_{s.e}$), and that across the contacts (ΔU_{cont}).

$$U = E_a - E_c + \Delta U_{el} + \Delta U_{s.e} + \Delta U_{cont}. \quad (1)$$

If combined anodes are installed in the reactor [e.g., iron (1) and aluminum (2)], then, by virtue of the different kinetic parameters of ionization of the metals, their dissolution will proceed at different rates and, therefore, the current densities at different anodes and their potentials will differ. In this case, the electric balance will be preserved ($U_1 = U_2$). If the voltage drops across the electrode bulk and contacts are neglected, then it can be written

$$E_{a,1} + \Delta U_{el,1} = E_{a,2} + \Delta U_{el,2}. \quad (2)$$

The ohmic voltage drop across the electrolyte is determined, in accordance with Ohm's law, by the current load I of the electrolyzer, anode surface area S, distance L between the anode and cathode, and electrical conductivity of the electrolyte æ

$$\Delta U_{el} = I\frac{L}{æS} = \frac{iL}{æ}, \quad (3)$$

where i is the current density.

In the calculation it was assumed that the anodic process occurs by the retarded ionization mechanism [3] and the cathodic component can be neglected under the conditions considered

$$i_a = i_{ex}\exp\left[\frac{\beta zF}{RT}(E_a - E_{eq})\right], \quad (4)$$

where i_{ex} is the exchange current density, and E_{eq} is the equilibrium potential.

1070-4272/01/7402-0338 $25.00 © 2001 MAIK "Nauka/Interperiodica"

Taken as a whole, the processes of dissolution of the iron and aluminum anodes can be represented by the equations

$$Fe^0 - 2e \rightarrow Fe^{2+},$$
$$Al^0 - 3e \rightarrow Al^{3+}.$$

If account is taken of the dependence of the exchange current i_{ex} on the concentration C_{ox} of the oxidized form of a substance in solution (with metal being the reduced form), then it is necessary to introduce into the expression for the exchange current the accepted concentration standard St, equal, in SI units, to 1000 mol m^{-3} [4]:

$$i_{ex} = zFk^s C_{ox}^{\beta} St^{(1-\beta)}. \quad (5)$$

The equilibrium potential E_{eq} is found from the Nernst equation

$$E_{eq} = E^0 + \frac{RT}{zF} \ln \frac{C_{ox}}{St}. \quad (6)$$

On being transformed, Eq. (4) is written as

$$i_a = A\exp\left(\frac{\beta zF}{RT} E_a\right), \quad (7)$$

$$A = zFk^s St \exp\left(-\frac{\beta zF}{RT} E^0\right).$$

The anode current density is determined by the heterogeneous rate constant of the electrode process, k^s, transfer coefficient of the anodic process β, and standard potential E^0, i.e., depends on the nature of a metal being dissolved.

With account of (3) and (7), Eq. (2) takes the form

$$E_{a,1} + \frac{L}{æ}\left[A_1\exp\left(\frac{\beta_1 z_1 F}{RT} E_{a,1}\right)\right] = E_{a,2} + \frac{L}{æ}\left[A_2\exp\left(\frac{\beta_2 z_2 F}{RT} E_{a,2}\right)\right]. \quad (8)$$

The total current through the electrolyzer is the sum of the currents flowing through all the anodes

$$I = i_{a,1}S_1 + i_{a,2}S_2. \quad (9)$$

Solving the system of equations (8), (9) allows calculation of the potentials of anodes made of different metals (iron and aluminum). Then Eq. (7) can be applied to calculate the current densities for different anodes. If known, the anode potentials enable evaluation of the probability of passivation of electrodes made of various metals; a knowledge of the dissolution rates makes it possible to calculate the amount of iron and aluminum hydroxides in solutions, which is important for achieving the required level of water purification.

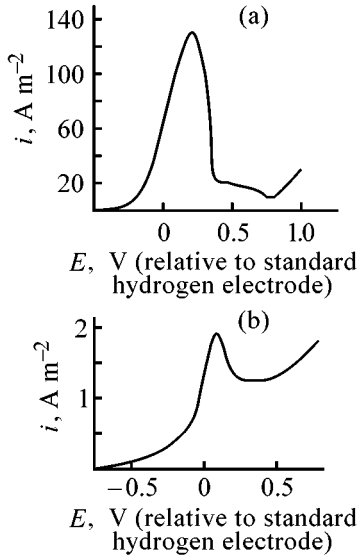

Fig. 1. Anodic polarization curves for dissolution of (a) iron and (b) aluminum in water subjected to purification, with addition of 1000 mol m^{-3} of sodium sulfate. (*i*) Current density and (*E*) potential (relative to standard hydrogen electrode).

The approach described above was used to analyze the technological mode of operation of the reactor in the UKOS-AVTO-5 unit employed to purify wastewater from car washes. The water subjected to purification contained 0.1 kg m^{-3} of oil products and 0.95 kg m^{-3} of suspended particles. The reactor of volume 1 × 0.38 × 0.73 m has 12 anodes (6 iron and 6 aluminum) and 12 iron cathodes of area 0.81 × 0.44 m each. The distance between the electrodes was 0.006 m. The overall load was 10 A.

An R-577 ac bridge was used to measure the electrical conductivity of the water being purified (æ = 0.38 S m^{-1}). Anodic polarization curves of iron and aluminum dissolution were taken with a P-5848 potentiostat (Fig. 1). The measurements were done in a three-electrode cell. The surface area of the working electrode was 0.36×10^{-3} and 0.09×10^{-3} m^2 for, respectively, iron and aluminum. An iron plate served as auxiliary electrode, and a saturated silver chloride electrode, as reference. In polarization studies, 1000 mol m^{-3} of sodium sulfate was added to the starting water to diminish the measurement error associated with the large voltage drop across the electrolyte. This compound has no effect on the anode passivation, but makes higher the electrical conductivity of the solution. The potentials of the onset of passivation, measured relative to the standard hydrogen elec-

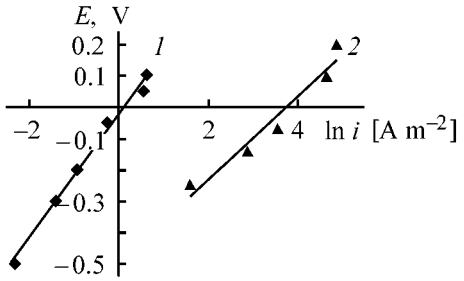

Fig. 2. E–ln i dependences taken with (*1*) aluminum and (*2*) iron electrodes. Solution: water subjected to purification, with addition of 1000 mol m^{-3} of sodium sulfate.

trode, were 0.21 and 0.09 V for iron and aluminum, respectively (Fig. 1). The dependence of the anode potential on the current density was obtained via transformation of Eq. (7)

$$E_a = -\frac{RT}{\beta zF}\ln A + \frac{RT}{\beta zF}\ln i_a. \qquad (10)$$

Analysis of the region of active dissolution of metals in the polarization curves plotted in the semilogarithmic coordinates does not contradict the assumption that the dissolution of both iron and aluminum electrodes occurs by the retarded ionization mechanism (Fig. 2). Regression analysis technique was applied to determine the coefficients in the straight-line equation (10) and then to calculate the kinetic parameters of iron and aluminum ionization (k^s and β). All the calculations were done on a PC with Mathcad 6 PLUS software. Solving the system of equations (8), (9) demonstrated that the potential of iron and aluminum anodes in the reactor E_{Fe} = –0.303 V and E_{Al} = –0.275 V. It can be seen from the polarization curves in Fig. 1 that no passivation must be observed at these potentials, which is the case. The dissolution current densities i_{Fe} = 2.055 A m^{-2} for the iron anode and i_{Al} = 0.283 A m^{-2} for the aluminum anode, which corresponds to the values found experimentally from the polarization curves (Fig. 1). The total voltage across the reactor, calculated by Eq. (1), was 0.4 V, which is also close to the measured value.

The agreement between the calculation results and the operation parameters of a real reactor suggests that the proposed method can be used to prognosticate the working conditions of an electrolyzer with combined anodes in choosing an optimal technological mode and intensifying the purification process.

CONCLUSIONS

(1) A method is proposed for calculating the potentials of anodes made of dissimilar materials and connected in parallel. A calculation using the basic equations of electrochemical kinetics was done taking in account the total number of electrons involved in the reaction.

(2) Anodic polarization curves were obtained for dissolution of iron and aluminum in water subjected to purification. The potentials of the onset of metal passivation under the experimental conditions were determined.

(3) The operation of the reactor in a unit for water purification was analyzed. The potentials of the iron and aluminum anodes and the current distribution among the anodes were calculated. It is shown that no anode passivation occurs under the conditions under consideration.

Combined Air Electrode Based on Polyaniline with Addition of Manganese Dioxide

M. O. Danilov and N. V. V'yunova

Institute of General and Inorganic Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received July 3, 2000

Abstract—Air electrodes based on polyaniline with an additive were studied in a prototype zinc–air power cell with salt electrolyte. Electrolytic manganese dioxide was chosen as additive. Discharge current–voltage (*I*–*V*) characteristics of the prototype chemical power cell based on a combined air electrode composed of polyaniline and manganese dioxide taken in 1 : 1 ratio are presented.

An electrically conducting polymer, polyaniline (PA), obtained by various methods from aniline, is widely used in electrochemical devices. One of its applications is that as a cathode material for chemical power cells with salt electrolyte [1–3]. The problem of obtaining this polymer and accounting for its electrical conductivity was discussed in [1, 4]. Polyaniline shows pronounced capacity for cycling in power cells, but has low working voltage [3]. To eliminate this disadvantage, it has been proposed to introduce into PA an additive possessing electrical conductivity and involved in the current-forming reaction at the air electrode.

The aim of this study was to verify the possibility of improving the electrical characteristics of PA-based electrodes by introducing into PA an additive having electrical conductivity higher than that of polyaniline and contributing to current generation at the air electrode. A possible additive of this kind is electrolytic manganese dioxide (EMD) possessing these properties.

A schematic of the conventional air electrode is presented in Fig. 1. The electrode comprises an active and a hydrophobic layers. It can be represented as a two-layer membrane separating the electrolyte and air. The layer adjacent to the electrolyte is hydrophilic, and that facing air, hydrophobic. In the operation of the air electrode, atmospheric oxygen diffuses through the hydrophobic layer and comes in contact with electrolyte penetrating through the active, hydrophilic layer. Therefore, the reaction of oxygen reduction is localized at the electrode–electrolyte–air interface.

In making a combined matrix, a mechanical mixture of PA and EMD was pressed in the hydrophobic layer to obtain a more diffuse electrode–electrolyte–air interface. Polyaniline was obtained by dc electrolysis of a 0.1 M solution of aniline in 1 M hydrochloric acid [5]. The starting aniline solution was colorless, i.e., unoxidized. All the reagents were of analytically pure grade. Polyaniline was deposited on a carbon fabric anode at current density of 5 mA cm^{-2}. A VT 1.0 titanium plate served as cathode. The PA layer was detached from the carbon fabric and dried at 90°C in a drying box. An EMD of chemically pure grade (Rustavi, Georgia) was used to prepare the mechanical mixture.

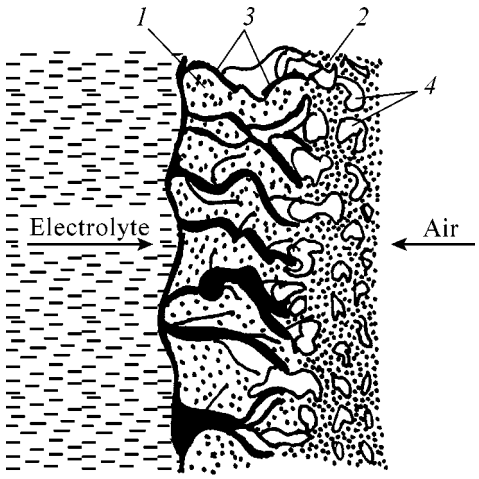

Fig. 1. Schematic of the air electrode: (*1*) active layer, (*2*) hydrophobic layer, (*3*) pores filled with electrolyte, and (*4*) pores filled with air.

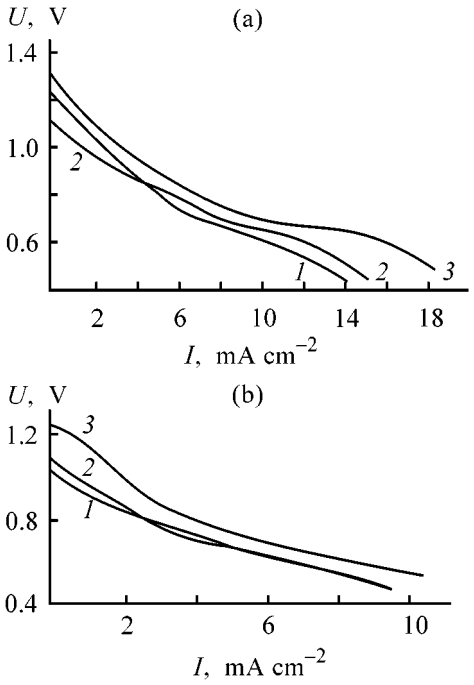

Fig. 2. *I–V* curves for prototype zinc–air power cell. Mass of the active layer in the air electrode (g): (a) 0.2 and (b) 0.1. (*U*) Voltage and (*I*) current density. Electrode material: (*1*) EMD, (*2*) PA, and (*3*) Combined PA–EMD matrix.

Electrodes used in the study were compacted in the form of pellets 3 cm in diameter from PA, EMD, and a 1 : 1 mechanical mixture of these compounds. Sets of electrodes with active layer mass of 0.2 and 0.1 g were fabricated. A hydrophobic layer of mass 0.3 g contained 70% acetylene black and 30% F-4D fluoroplastic emulsion in terms of dry substance.

Investigations were performed in galvanostatic mode with a prototype zinc–air power cell with electrolyte of composition 5 M NH_4Cl + 2 M $ZnCl_2$. The potentials of the air electrode were measured with high-resistance voltmeter relative to a silver chloride reference electrode. The prototype power cell voltage and the potential of the air electrode at each current density were recorded after a delay of 5 min.

Prior to cycling, the prototype power cell with a zinc–air electrode was discharged at a current density of 6 mA cm^{-2} until the voltage became 0.5 V. The current densities of power cell charging and discharge were the same and chosen in such a way that the charge capacity was twice the discharge capacity. The prototype power cell was cycled until the discharge capacity became less than half the charging capacity at a current density chosen for each air electrode.

Figure 2a presents *I–V* discharge curves for electrodes with active mass of 0.2 g. It can be seen from the discharge curves that a combined matrix of PA and EMD (Fig. 2a, curve *3*) with component ratio of 1 : 1 gives a better discharge curve than its separate components—PA (curve *2*) and EMD (curve *1*). Comparison of the discharge curves for PA and EMD shows that, at discharge current densities of up to 4 mA cm^{-2}, the working voltage of EMD electrodes exceeds that of electrodes made of polyaniline. At current densities in the range from 4 to 13 mA cm^{-2} the working voltage of polyaniline electrodes is the same as, or somewhat higher than the discharge voltage of the EMD electrodes.

Figure 2b shows *I–V* discharge curves for electrodes with active layer mass of 0.1 g. It can be seen that the combined matrix (curve *3*) has better discharge characteristics in this case, too. At current densities of up to 2 mA cm^{-2}, the electrode of pure PA (Fig. 2b, curve *2*) works better than the EMD electrode at smaller active layer mass. With the current density increasing from 2 to 8 mA cm^{-2}, the *I–V* discharge curves for PA and EMD are virtually the same.

Thus, the combined matrix of PA and EMD with component ratio of 1 : 1 shows better discharge characteristics, compared with air electrodes made of pure components. Cycling of PA + EMD electrodes in a prototype zinc–air power cell demonstrated the possibility of performing up to 30 charging–discharge cycles without capacity loss after the primary complete discharge of the power cell. These characteristics are inferior to those for pure PA (300 cycles), but better than the characteristics of EMD (10–15 cycles).

Possibly, the increase in the catalytic activity of the combined PA + EMD matrix is associated with the appearance of oxygen-containing groups on PA. These groups accumulate in the course of electrosynthesis on the surface of PA particles. When PA is combined with EMD, these oxygen-containing groups provides the electrode with oxygen, ensuring chemical oxidation of MnOOH to MnO_2. Therefore, the amount of EMD decreases in the course of discharge not so strongly owing to the conversion of MnO_2 into MnOOH. Intercalation by chlorine occurs in PA [3]. Schematically, all the processes occurring in the combined matrix of the air electrode can be represented by the reactions

$$2PACl_n + 2ne \rightarrow 2PA + 2nCl^-, \quad (1)$$

$$O_2 + 4H^+ + 4e \rightarrow 2H_2O, \quad (2)$$

$$MnO_2 + H_2O + e \rightarrow MnOOH + OH^-, \quad (3)$$

$$4MnOOH + O_2 \rightarrow 4MnO_2 + 2H_2O. \quad (4)$$

A conclusion can be made from reactions (1)–(4) that current generation at the combined matrix occurs by reactions (1)–(3). Reaction (4) gives, additionally, MnO_2 via chemical oxidation of MnOOH to MnO_2 by oxygen from the oxygen-containing groups on PA.

Thus, to improve the discharge characteristics of PA-based power cells, it is necessary to introduce into PA electrically conducting additives involved in the current-forming reactions. In particular, air electrodes with better electrolytic characteristics can be obtained on the basis of a combination of PA with EMD.

Mechanism of Coagulation Purification of Wastewater with Aluminum Oxochloride

Yu. A. Feofanov and N. L. Litmanova

St. Petersburg University of Architecture and Construction, St. Petersburg, Russia

Received August 1, 2000

Abstract—Results of a coagulation purification of solutions modeling weakly contaminated wastewater from dairy shops are presented. The influents of detergents (HNO_3 and NaOH) and aluminum oxochloride on the process of contaminant removal from a milk solution in the pH range 2–12 is considered. Distinctions are noted in the behavior of model milk solutions with contaminant concentration. The results of studies performed at varied doses of aluminum oxochloride by the optical and electrophoretic methods are used to explain the mechanism of coagulation purification of model wastewater.

The great bulk of waste produced by plants is constituted by wastewater formed in washing of the dairy equipment. The washing process consists in several successive operations, each using one of the following reagents: acids, alkalis, or sterilizing agents, with the entire process completed by rinsing in pure water. As a result, the wastewater delivered to the purification facilities has qualitative and quantitative composition abruptly varying with time.

The results obtained in a study of the coagulation purification of solutions modeling strongly contaminated wastewater of dairy shops with the use of aluminum oxochloride (AOC) were reported in [1].

The aim of the present study was to analyze the behavior of wastewater with low content of impurities upon addition of various reagents: detergents and AOC. To reveal the influence exerted by each kind of contaminant on the process of coagulation, wastewater was replaced by model solutions.

The solution under study, obtained by diluting milk with distilled water, contained (mg l^{-1}): fat 350 and protein 280, and were characterized by chemical oxygen demand of 900 mg O_2 l^{-1}, which corresponds to the composition of dairy plant wastewater with moderate contamination. The pH was varied by adding industrial detergents: 1% solution of nitric acid and 0.1 N solution of sodium hydroxide. As coagulant was used freshly prepared 1% solution of AOC with basicity factor [$OH^-/(OH^- + Cl^-)$ ratio] of 5/6.

After mixing a milk solution with a coagulant by the procedure described in [2] and allowing the samples to stand for 1 h, the efficiency of purification was evaluated by the residual content of organic substances, determined from the loss in calcination of the dry residue [3].

The kinetics of impurity sedimentation was studied by measuring the optical density of solutions treated with a coagulant for 1 h on a KFK-2MP photocolorimeter in 1-cm-long cuvettes at light wavelength λ = 440 nm.

The electrokinetic potential of milk particles without AOC and with varied concentration of this compound was determined by microelectrophoresis [4] in a modified Abramson cell and PZO microscope (Poland). The ξ-potential was calculated using the Smoluchowski formula from the arithmetic-mean value of the electrophoretic velocity of 15–20 particles.

The efficiency of removal of organic impurities, E_{org}, is presented in Figs. 1 and 2 in relation to the pH value. The presence of only detergents without AOC in weakly contaminated solutions (Fig. 1, curve *1*) destabilizes the system (acid coagulation) at pH 4.75–5.10, with the maximum degree of purification (40%) observed at pH 5.0, which can be attributed to the electrical properties of the emulsion stabilizer—casein, whose isoelectric point lies in the above pH interval [5]. This is confirmed by the results of electrophoretic measurements (Fig. 1, curve *3*) indicating that the particle charge is the smallest in this pH range. In a more concentrated solution [1], the system coagulated at pH 4–5, with 50% removal of impurities

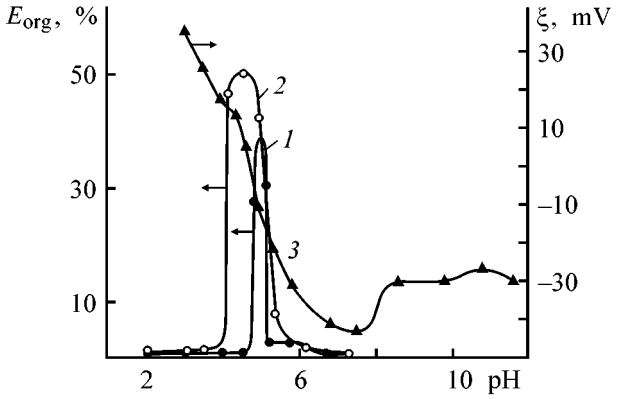

Fig. 1. (*1, 2*) Efficiency of organic substance removal, E_{org}, and (*3*) ξ-potential of particles vs. the pH of the model milk solution. Concentrations of fat and protein (mg l^{-1}): (*1, 3*) 350 and 280, (*2*) 1750 and 1450 {(*2*) data of [1]}.

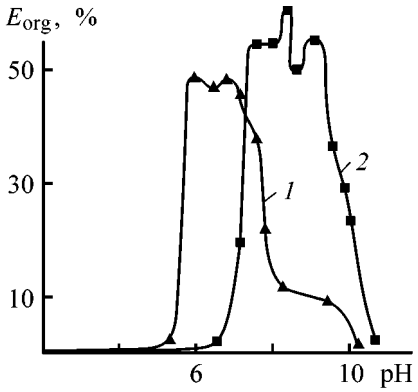

Fig. 2. Efficiency of organic substance removal, E_{org}, in the presence of AOC vs. the pH of the model milk solution. Concentrations of fat and protein 350 and 280 mg l^{-1}, respectively; the same for Fig. 3. Coagulant dose (mg l^{-1} in terms of Al_2O_3): (*1*) 60 and (*2*) 180.

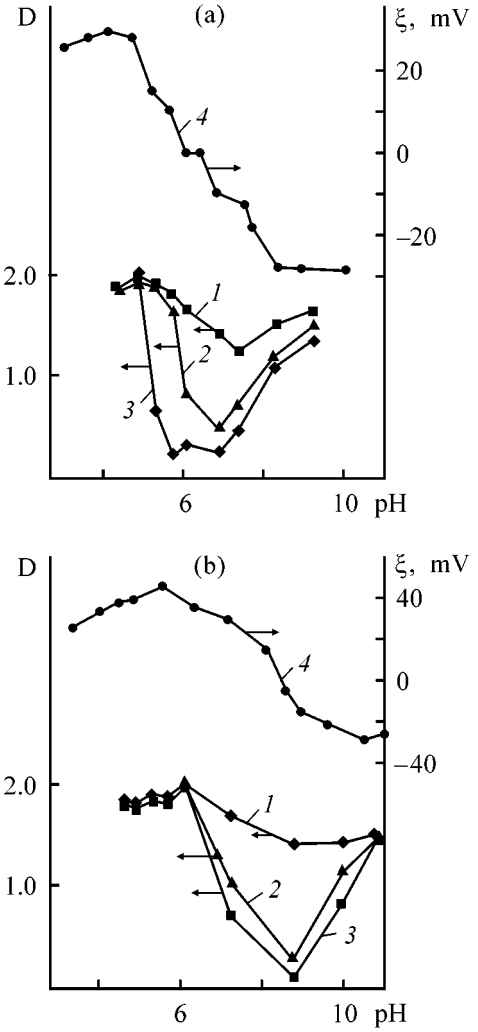

Fig. 3. (*1–3*) Optical density and (*4*) ξ-potential of particles vs. the pH of the model milk solution. AOC dose (mg l^{-1} in terms of Al_2O_3): (a) 60, (b) 180. Time of coagulation upon AOC introduction (min): (*1*) 1, (*2*) 10, and (*3*) 60.

achieved at pH 4.5 (Fig. 1, curve *2*). The observed slight differences in purification efficiency and pH ranges of efficient impurity removal between two model solutions can be accounted for by the fact that the number of collisions between protein particles grows with their increasing concentration. Under conditions close to the isoelectric state, when the stability of the system is the lowest, this leads to appearance of coarser aggregates of the disperse phase and its more complete sedimentation.

The peak in the curve describing the purification of a weakly contaminated solution is shifted to the less acid region (pH 4.9; Fig. 1, curve *1*), compared with that in a solution containing a greater amount of impurities (curve *2*), and, therefore, a smaller amount of acid is to be introduced to bring negatively charged protein molecules into the isoelectric (or nearly so) state. This can be attributed to the smaller density of surface charge of the colloid phase in the first case.

The run of the curves describing the efficiency of removal of organic impurities as a function of the pH of the medium is strongly affected by addition of AOC (Fig. 2). Adding 60 mg l^{-1} of coagulant (in terms of Al_2O_3) at pH < 5.1 does not destabilize the milk solution (curve *1*). This pH range is characterized by high, and invariable with time, values of the optical density of the system (Fig. 3a, curves *1–3*). With the AOC concentration increasing to 180 mg l^{-1} in terms of Al_2O_3 (3.6×10^{-3} M in terms of aluminum), a similar behavior is observed at pH < 6.1 (Fig. 3b, curves *1–3*).

It can be seen from the electrokinetic data that rather high positive ξ-potentials of the particles in the system under study are observed in these pH regions (Figs. 3a and 3b, curves *4*). The reason is that the strongly (positively) charged hydroxo complexes of aluminum, appearing at the above pH values and having high adsorbability, interact with the initially uncharged or weakly charged particles of the milk solution, recharging these latter and stabilizing the entire system. As it can be seen from Figs. 3a and 3b (curves *4*), the charge of particles formed as a result of such an interaction grows with increasing coagulant dose. This can be attributed to the favorable influence of the increasing concentration of aluminum on the hydrolytic polymerization, with polycations having greater charge formed in this pH range [6].

The coagulation of the given model solution and removal of impurities at AOC content of 180 mg l^{-1} in terms of Al_2O_3 is observed in the pH range 6.5–10.25 (Fig. 2, curve *2*). The process reaches the maximum efficiency (up to 60% removal of organic substances) in the pH range 7.3–9.5. Lowering the coagulant dose to 60 mg l^{-1} in terms of Al_2O_3 shifts this region to the left along the pH scale and restricts it to pH of 5.75–7.5 with the maximum purification of 48% (Fig. 2, curve *1*). It is in these pH ranges, where the peak efficiencies of purification to remove organic impurities are observed, that the electrokinetic potentials of particles belonging to the system under study are the lowest at both AOC concentrations (Figs. 3a and 3b). These data indicate a neutralization mechanism of coagulation.

However, a small coagulation zone observed in Fig. 2 (curve *2*) in alkaline medium (pH 9.5–10.25) at an AOC concentration of 180 mg l^{-1} coincides with the region of rather high negative values of the ξ-potential of particles (Fig. 3b, curve *4*). The partial sedimentation of the milk dispersion under these conditions is, in all probability, due to the occurrence of a heterocoagulation process with efficiency much lower than that of the neutralization coagulation.

CONCLUSIONS

(1) Use of aluminum oxochloride to purify weakly contaminated milk wastes allows efficient removal of organic impurities in a rather wide pH range.

(2) The maximum efficiency of purification of a model solution in the case of coagulant addition is ensured by the action of neutralization mechanisms.

(3) The pH range in which the neutralization coagulation proceeds depends on the concentration of aluminum oxochloride in solution.

(4) In the absence of aluminum oxochloride, the position of the peak in the curve describing the dependence of the purification efficiency on the pH value is determined by the initial concentration of contaminants.

Sorption Capacity of Nitrogen-containing Derivatives of Wood for Ions of Various Metals

M. V. Efanov and A. G. Klepikov

Altai State University, Barnaul, Russia

Received July 13, 2000

Abstract—Sorption capacity of nitrogen-containing derivatives of aspen wood for Fe(III), Cu(II), Cd(II), and Ca(II) ions was studied. The possibility of using the products formed in oxyammonolysis of wood as sorbents of these metals from dilute aqueous solutions was examined.

Nitrogen-containing derivatives of lignin have ion-exchange properties and can be used as sorbents of heavy metal ions and organic dyes [1, 2]. The main drawbacks of these products are relatively low exchange capacity and low mechanical strength.

Previously, a procedure has been proposed for production of nitrogen-containing sorbents based on lignin by treatment of the industrial lignin with tetraalkylammonium salts [3]. The resulting sorbents exhibited improved mechanical strength and high sorption capacity for dyes (50–80 mg g^{-1}).

However, in the proposed procedure the yield of the target product is relatively low (up to 30–40% of the lignin weight in 1–3 days). To produce nitrogen-containing sorbents in quantitative yield, hydrolyzed lignin was treated with aqueous ammonia solutions of ammonium peroxodisulfate under mild conditions at 20°C for 1–5 days [4]. Along with hydrolyzed lignin, poor wood can be used as a raw material for production of nitrogen-containing sorbents.

In this work we studied the sorption capacity of nitrogen-containing derivatives of aspen wood, produced under conditions described in [4] and also by mechanochemical procedure, for ions of some metals.

EXPERIMENTAL

As raw materials we used air-dry sawdust of aspen wood approximately 50 years of age crushed to 0.4–0.75-mm fraction. The wood was analyzed by the well-known procedures [5]. The chemical composition of aspen wood was as follows:

Component	Content, % relative to absolutely dry raw material
Cellulose	49.6
Lignin	21.2
Pentosan	21.6
Extractives	3.96
Ash	0.26

Nitrogen-containing derivatives of wood were obtained by two procedures. According to the first procedure, the sawdust was treated with large excess of ammonia solution of ammonium peroxodisulfate at 20–25°C for 1–3 days [4]. According to the second, the sawdust combined with ammonium peroxodisulfate (0.1 g of available oxygen per 1 g of wood) was mechanically crushed in a ball mill in 25% aqueous ammonia (0.5 g of NH_3 per 1 g of wood) for 0.5–2 h.

Then, the products were washed with water to negative reaction for sulfate ion and dried in air to constant weight. The nitrogen content in the resulting samples was determined by the Kjeldahl semimicromethod [6], and the number of carboxyl groups, by conductometric titration [7]. The characteristics of the resulting products are listed in Table 1.

The sorption capacity of the resulting products was studied by establising equilibrium by means of the procedure described in [8]. For this purpose, weighed portions of samples (0.1–0.2 g) were placed in flasks, and 25 cm^3 of a solution of metal nitrates with concentration varying from 0.01 to 0.1 g-equiv dm^{-3} was added to each flask. When the equilibrium was

* Sample no. 6 obtained by procedure 2.

attained (after 24 h), the concentration of the corresponding ion in the solution was determined conductometrically.

The absorption was evaluated by the formula

$$A = (C_{in} - C_{eq})V/1000g, \quad (1)$$

where A is the absorption (g-equiv g^{-1}), C_{in} is the concentration of metal ion in the initial solution (g-equiv dm^{-3}), C_{eq} is the concentration of metal ion in the equilibrium solution (g-equiv dm^{-3}), V is the volume of the equilibrium solution (cm^3), and g is the weighed portion of the sorbent.

To estimate quantitatively the distribution of cations between the sorbent and solution, we evaluated the distribution coefficient K_d at low concentrations:

$$K_d = (C_{in} - C_{eq})V/1000gC_p. \quad (2)$$

The selectivity coefficient D characterizing the efficiency of separation of cations A and B was determined by the formula

$$D_{B/A} = K_{d(A)}/K_{d(B)}. \quad (3)$$

As the experimental results show, the sorption capacity of the products of oxidative ammonolysis of wood for the cations studied depends on the content of nitrogen and COOH groups (Table 2).

The sorption capacity of nitrogen-containing derivatives of wood is sufficiently high for all the cations studied, which is caused by the high content of carboxy groups and nitrogen (Table 2).

The high sorption power with respect to multicharged cations of the products of oxidative ammonolysis of wood with high content of COOH groups and nitrogen content of 1.86–8.95% is due to their chelating characteristics. Therefore, ions of *d* elements (Cu^{2+}, Cd^{2+}, and Fe^{3+}) are sorbed to the greatest extent, and Ca^{2+} ions, to the lowest. The sorption power with respect to the ions under the study decreases in the order: $Cu^{2+} > Cd^{2+} > Fe^{3+} > Ca^{2+}$ (Tables 2, 3). Making lower the concentration of ions in solution does not result in any significant decrease in their absorption with wood sorbents, i.e., the sorbents show high sorption power even in the case of dilute solutions (Table 3).

It was found that the sorbents produced from nitrogen-containing derivatives of wood are the most selective with respect to Cu(II) ions (Table 4).

The products obtained by the mechanochemical procedure (sample nos. 4–6) have, even at low nitrogen content and practically the same amount of COOH groups as in sample nos. 1–3, comparable sorption powers (Table 2). This can be explained by an increase in their specific surface area on milling.

Thus, the products of oxidative ammonolysis of aspen wood can be used as efficient sorbents with re-

Table 4. Selectivity coefficients of nitrogen-containing derivatives of wood with respect to the studied ions

6	6.29	5.17	3.04	1.78	0.95

spect to cations of transition metals in their recovery from dilute solutions.

CONCLUSIONS

(1) The sorption capacity of modified wood with respect to Fe(III), Cu(II), Cd(II), and Ca(II) ions depends only slightly on their concentration and decreases in the order: Cu(II) > Cd(II) > Fe(III) > Ca(II).

(2) The exchange capacity of nitrogen-containing derivatives of wood is sufficiently high (1.0–7.0 g-equiv g^{-1}) and depends on the content of nitrogen and carboxy groups.

(3) Nitrogen-containing sorbents based on wood are the most selective with respect to Cu(II) ions.

Alkylation of *p*-Cresol with Isohexyl Alcohol

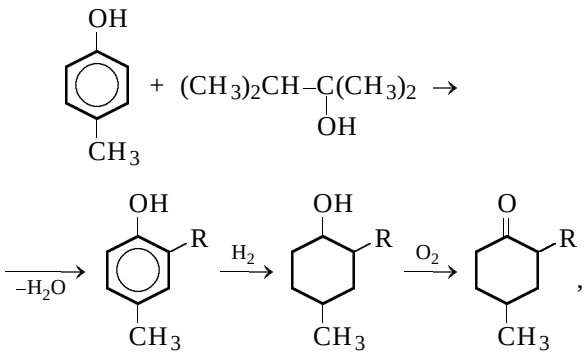
I. M. Osadchenko and A. P. Tomilov

State Research Institute of Organic Chemistry and Technology, Moscow, Russia

Received June 23, 2000

Abstract—The feasibility of *p*-cresol alkylation with isohexyl alcohol, using phosphotungstic heteropoly acid as catalyst, was examined.

Alkyl derivatives of *p*-cresol find application as antioxidants, surfactants, and perfumes. In particular, products of *p*-cresol alkylation with isohexyl alcohol are used in synthesis of vetinone perfume (see scheme).



where R = $(CH_3)_2C(OH)–CH(CH_3)_2$.

Kheifits *et al.* [1, 2] studied the alkylation of *p*-cresol in the presence of various catalysts including $Fe_2(SO_4)_3$, $ZnCl_2$, BF_3, and H_2SO_4. Sulfuric acid appeared to be the most suitable. At a 2 : 1 molar ratio of *p*-cresol to alcohol and a temperature of 110–120°C, the target product was obtained in about 50% yield. A major drawback of the process is the appreciable tarring of the reaction mixture containing about 15 wt % tar.

The tarring, and also the high corrosive activity of sulfuric acid stimulated us to look for new catalysts for this process. We decided to test heteropoly acids which have recently found use as catalysts in many processes [3]. Among the tested heteropoly acids, the best results were obtained with reagent-grade phosphotungstic acid $H_7PW_{12}O_{42}$ [TU (Technical Specifications) 6-09-4376–78]. With this catalyst, the formation of tars under the conditions recommended for the process with sulfuric acid decreased by more than a factor of 2.

The experiment with phosphomolybdic acid $H_7PMo_{12}O_{42}$ failed, because the catalyst appeared to be reactive toward the starting compounds.

Below is given a typical procedure for condensation of *p*-cresol with isohexyl alcohol.

A reactor equipped with a reflux condenser with a Dean–Stark trap, a stirrer, a thermometer, and a dropping funnel was charged with 102 g (0.982 mol) of *p*-cresol and 2.0 g of $H_7PW_{12}O_{42}$. The mixture was heated on an oil bath to 85–95°C, and 51 g (0.50 mol) of isohexyl alcohol was added dropwise at this temperature over a period of 40 min. The temperature was gradually raised to 105–120°C, and the mixture was refluxed for 4 h 40 min. In the process, water was separated in the Dean–Stark trap. After the reaction was complete, the content of the target product was determined by GLC to be 50.5%. To isolate the product, the mixture was neutralized with 3 g of sodium carbonate. The neutralized mixture was vacuum-distilled. The target fraction (bp 125–140°C/8–10 mm Hg) contained, according to GLC, 97% 4-methyl-2-isohexylphenol. The product yield was 53 g (55.2% in terms of loaded isohexyl alcohol), and the amount of bottoms, 7.2 wt % relative to the target fraction (with sulfuric acid as catalyst, the amount of bottoms was 15 wt %).

The alkylation of *p*-cresol with 2-methyl-2-pentanol was performed similarly. The yield of the condensation product, 4-methyl-2-(2-methyl-2-pentyl)phenol, was 50%.

Received July 10, 2000

Abstract—The feasibility of high-paraffin raw material treatment by the action of ferromagnetic needles and electromagnetic field was examined with the aim to produce bitumens of improved quality.

Intensification of oil refining is possible on the basis of the theory of controlled phase transitions, according to which intermolecular interactions can be controlled by external actions converting the petroleum raw material to an active state. At the same time, traditional processes are only based on data on the chemical structure of molecules present in the petroleum raw material, without taking into account the origination and growth of supramolecular structures.

One of ways to exert effective influence on petroleum systems with the aim to convert them to an active state is physical activation (mechanical, electric, magnetic, ultrasonic, etc.) shifting the dynamic equilibrium dispersed phase–dispersion medium in the desired direction. For example, under the action of a strong nonuniform electromagnetic field in an apparatus with a vortical bed, paramagnetic particles become involved in directional motion, which results in their mutual approach and aggregation. The resulting aggregates of paramagnetic components are crystallization centers for solid hydrocarbons and favor their concentration in definite close-cut fractions.

There are different procedures, chemical and physical, for activating a raw material in bitumen production. By chemical activation is meant alteration of the group chemical composition of the dispersion medium by introducing special chemical additives (extract from selective purification of oils, sulfur with black solar oil, etc.) or removal of certain components, which alters the solvency of the dispersion medium and the particle size of the dispersed phase.

In physical activation of a bitumen raw material, the external effect is directed mainly at the dispersed phase, which causes changes in the composition and volume of the dispersion medium. For example, ultrasonic treatment of asphalt in the course of its oxidation raises the content of asphaltenes and the softening point of the resulting bitumen [1]. Owing to the high chemical activity of asphalt components as a consequence of the dispersing effect of ultrasonic treatment, and also to the high quality of bitumens, the process of asphalt oxidation under ultrasonic treatment has been implemented in industry.

Whereas mechanical and thermal actions, raising the extent and rate of breakdown of the petroleum structure, have only a minor effect on the subsequent formation of this structure after the end of treatment, such a treatment combined with application of an electromagnetic field will favor ordering of molecules having a dipole moment.

Experiments showed that, in an apparatus with a vortical bed, the sample properties are affected by electromagnetic field, and this effect depends on the treatment temperature. For example, on heating black oil to 140°C, its density somewhat decreases, but at higher temperatures (≥220°C) it noticeably increases. The black oil treated at high temperatures is characterized by increased content of asphaltenes. Since the temperature of 140°C is too low for thermal decomposition to occur, variation of the fractional and component compositions is probably due to rearrangement of the polar and nonpolar components of black oil with the formation of associates of varied structure.

On high-temperature treatment of black oil in a vortical-bed apparatus (280 and 320°C), the total con-

1070-4272/01/7402-0351 $25.00 © 2001 MAIK "Nauka/Interperiodica"

tent of light fractions (bp <350°C) increases by 1.1–1.5 wt %. The onset of sample boiling after high-temperature treatment is observed at a temperature 20°C higher than with the initial samples.

A combined effect of the electromagnetic field and the mechanical action of ferromagnetic needles placed in a capsule with samples results in phase redistribution in the disperse system and isolation of high-molecular-weight *n*-alkanes and ceresines in fractions with narrow boiling range. The fraction of modified black oil, boiling above 470°C, is characterized by low content of solid paraffins as compared with the same fraction of the initial black oil and can be of interest as raw material for production of petroleum bitumens.

Thus, application of various external actions affecting the chemical and structural transformations of petroleum disperse systems allows intensification of various oil refining processes, namely, pretreatment of high-paraffin raw materials with the aim to produce bitumen of improved quality.

Received June 6, 2000

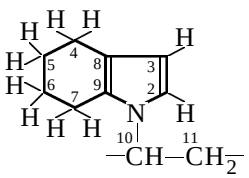
Abstract—Radical copolymerization of *N*-vinyl-4,5,6,7-tetrahydroindole with acrylamide in dimethylformamide was studied, and the relative activity constants of the monomers were determined.

N-Vinylpyrroles are reactive monomers in both cationic and radical polymerization processes and allow preparation of polymeric materials with a wide spectrum of valuable properties: special semiconductors, photosensitive materials, flotation agents, biologically active compounds, synthetic dyes, etc. [1].

In this work we studied the activity of *N*-vinyl-4,5,6,7-tetrahydroindole (VTHI) in radical copolymerization with acrylamide (AA).

Copolymerization of VTHI with AA in dimethylformamide (DMF) yields cream-colored powders soluble in DMF, DMSO, and *N*-methylpyrrolidone. The IR spectra of these products show that they contain units of both monomers (absorption bands of the pyrrole ring at 1300, 1380, 1490, and 1540 cm^{-1} and those of acrylamide at 510 and 965 cm^{-1}) and no double bonds (no bands at 859, 946, and 1585 cm^{-1}). The copolymers are free from homopolymer impurities, which is confirmed by the smooth shape of the turbidimetric titration curves.

The ^{13}C NMR spectra contain strongly broadened signals from the carbon atoms of the VTHI and AA fragments (ppm): 130.9–125.3 ($C^{8,9}$), 117.5–112.5 (C^{3}), 108.0–105.8 (C^{2}), 52.3–47.8 (C^{10}), 44.2–40.0 (C^{11}), 23.1–19.0 ($C^{4,5,6,7}$) and 180.0–174.0 (C=O), 38.8–33.6 (CH_2), respectively.



From the ^{13}C NMR spectra, we calculated the mole fractions of VTHI and AA and also the elemental composition of the copolymers (see table). The mole fraction of the VTHI units in the copolymer grows with increasing fraction of VTHI in the initial mixture, but does not exceed 0.4 even at the VTHI : AA ratio in the initial mixture of 4 : 1. This fact is consistent with the relatively low rates of radical polymerization of VTHI [2]. For the system VTHI–AA, the copolymerization constants are as follows: r_{VTHI} = 0.02, r_{AA} = 3.2.

With the fraction of VTHI units in the copolymer increasing by a factor of ~4, the viscosity of the product grows twofold.

EXPERIMENTAL

The copolymerization of the monomers was performed in sealed ampules at 60°C in the presence of azobis(isobutyronitrile) under argon. The reaction mixture was dissolved in DMF, and the copolymer was precipitated with acetone. Then the copolymer was reprecipitated from DMF solution into acetone and dried in a vacuum to constant weight. The intrinsic viscosity was determined in DMF at 20°C by the dilution procedure.

The relative activity constants were calculated by the Fineman–Ross and Kelen–Tudos procedures using G.I. Deryabina's program, with the Mortimer–Tidwell experimental design. The calculations were based on the results of experiments with conversion of ≤10%. The IR spectra were taken on a Specord 75-IR spectrometer from KBr pellets or mulls in mineral oil.

0.825	0.175	0.391	0.609	4.6	0.27	68.3	8.1	13.9	9.7

* Calculated from the ^{13}C NMR spectra.

The ^{13}C NMR spectra of the copolymer samples (solutions in DMSO-d_6) were recorded on a Varian VXR-500S spectrometer (125.5 MHz) with the relaxation delay of 2.5 s and 90° pulse. As relaxant served chromium *tris*-acetylacetonate (0.02 M). The molar ratios of the copolymer components were determined from the ^{13}C NMR spectra by a common procedure: The relative intensity of the C=O signal q_{AA} was referred to one carbon atom and 1 mol of AA. The number of VTHI moles was calculated by the formula

$$M_{VTHI} = q_{VTHI}/q_{AA},$$

where q_{VTHI} is the relative intensity of the C^2 signal (or one of the signals from C^4, C^5, C^6, or C^7) of VTHI, $q_{VTHI} = I_{VTHI}/I_{tot}$ (I_{VTHI} and I_{tot} are the integral intensity of the C^2 signal and the total integral intensity, respectively).

The relative integration error was 3%. The relative error of the quantitative determination of the mole fractions of the comonomers and the elemental composition of the copolymers did not exceed 6.7%.

CONCLUSION

Radical copolymerization of *N*-vinyl-4,5,6,7-tetrahydroindole with acrylamide was studied. The second comonomer is more reactive. With increasing content of *N*-vinyl-4,5,6,7-tetrahydroindole in the initial mixture, its content in the copolymer and the viscosity of the reaction products become higher.

Tenth Kola Workshop on Electrochemistry of Rare Metals

On December 4–7, 2000, a regular workshop on electrochemistry of rare metals was held in Apatity (Murmansk oblast) at the Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences. Forty-five specialists, including representatives of research and higher school institutions of Moscow, St. Petersburg, Yekaterinburg, Novokuznetsk, Lipetsk, and Novomoskovsk took part. The Ukraine was represented by scientists from the Vernadskii Institute of General and Inorganic Chemistry, National Academy of Sciences of Ukraine. Among the co-authors of many reports were scientists from France (University of Provence, Marseilles; Sabatier University, Toulouse), Switzerland (University of Lausanne), Poland (Wroclaw University), and Finland (Technical University, Helsinki).

A wide variety of problems of general science and technology were discussed in 52 reports and brief communications. L.A. Petrii (Moscow) in his report "Electrochemistry at the End of the XX Century" considered topical problems of modern theoretical and applied electrochemistry and emphasized the important role of electrochemical science in solving energetic, ecological, and medical problems the mankind is confronted with. To the most important applied directions the author referred the development and optimization of chemical power cells and fuel cells, supercapacitors, electrochromic devices, membrane technologies, and electrochemical sensors. Particular attention was given to problems of electrocatalysis, possibility of using various rare metals in multicomponent metal and metal oxide catalysts. In the conclusion of his report, Petrii made an attempt to formulate some yet unsolved problems of fundamental electrochemistry. By contrast, the report by A.G. Morachevskii (St. Petersburg) was retrospective and concerned with the role played by Russian scientists in the development of high-temperature electrochemistry in the XX century. Prominent scientific schools, headed by Professors N.A. Pushin and P.P. Fedot'ev, formed at the beginning of the last century in St. Petersburg at the Electrotechnical and Polytechnic Institutes. This enabled the setting-up of the manufacture of light metals in Russia in the 1930s. An important stage in the development of physicochemical and electrochemical investigations of ionic melts is associated with the foundation in Sverdlovsk (Yekaterinburg) in 1957 of the Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences, and the activities of Professor M.V. Smirnov and his colleagues and pupils. An important contribution was made by the Kiev school of electrochemists, headed for a long time by Yu.K. Delimarskii, academician of the National Academy of Sciences of the Ukraine. The author noted that in the 1960s–1980s the USSR held the leading position in the world as regards the amount of information obtained in the field of physical chemistry and electrochemistry of molten salts and its scientific importance. Intensive investigations were being conducted in scientific centers of Moscow, Leningrad, Kiev, Tbilisi, Yekaterinburg, Krasnoyarsk, Irkutsk, Rostov-on-Don, Apatity, Nal'chik, and Novomoskovsk.

V.S. Kublanovskii (Kiev) considered and evaluated, on the basis of experimental data, components of the activation energy of the electrochemical process. A report by N.Kh. Tumanova and coauthors (Kiev) was concerned with passivation effects in dissolution of high-melting metals (Nb, Ta, Ti) in carbamide–halide melts.

A number of reports presented the results of new investigations in the field of high-temperature electrochemistry of niobium and tantalum. E.G. Polyakov, L.P. Polyakova, and P.T. Stangrit (Apatity) demonstrated by the example of oxofluoride complexes of tantalum that concentration changes in the near-electrode layer, affecting the course of an electrochemical reaction, are observed in melts with two ligands. By controlling the ligand composition of the electrolyte and current density, one can obtain materials with prescribed composition and structure. The reports by S.V. Kuznetsova and S.A. Kuznetsov (Apatity) were devoted to electrochemical synthesis of tantalum silicides and niobium–hafnium coatings from chloride–fluoride electrolytes. In particular, the authors demonstrated the possibility of obtaining continuous Nb–Hf coatings up to 20–30 μm thick. O.V. Makarova, Polyakova, and T.V. Stogova (Apatity) studied the thermal stability (700–730°C) of an oxofluoride electrolyte used to synthesize tantalum borides. Makarova

and co-authors (Apatuty, Moscow) confirmed experimentally the possibility of existence of heterocomplexes with tantalum and boron in oxofluoride melts.

V.V. Grinevich, A.V. Arakcheev, and Kuznetsov (Moscow, Apatity) reported the results obtained in studying the electrodeposition of niobium and its compounds from oxofluoride complexes dissolved in molten rubidium and cesium chlorides and fluorides. This study completed systematic investigations of the influence exerted by outer-sphere cations of alkali metals on the nature of cathodic processes occurring in electrolysis of niobium-containing halide-oxohalide melts. It was noted that stabilization of oxofluoro complexes of niobium with increasing size of solvent cation is only observed to rubidium inclusive, and not to cesium, as it might be assumed. Arakcheeva and co-authors (Moscow; Lausanne, Switzerland) presented the results obtained in preparing a new type of tantalum bronzes and studying their structure. The bronzes were grown at the cathode in electrolysis of oxofluoride melts, with Ta or TaO anodes. The electrolyte used contained K_2TaOF_5 or $K_3TaO_2F_4$. As solvent served ternary eutectic LiF–NaF–KF. Arakcheeva, Grinevich, and F.I. Shamrai (Moscow) studied the localization of oxygen atoms in cubic crystals of niobium suboxides in high-temperature electrolysis.

The report by Kolosov *et al.* (Apatity), concerned with the diffusion saturation of nickel with tantalum in a molten NaCl–K_2TaF_7 mixture in the presence of powdered tantalum metal, presented characteristics of the coatings obtained in the process. E.S. Matychenko and co-authors (Apatity) studied the formation of intermetallic compounds Ni_3Ta and Ni_2Ta through electroless transport of tantalum in chloride-fluorotantalate melts. V.Yu. Novikov and S.L. Sukhorzhevskaya reported the formation of tantalum carbide TaC on the surface of low-carbon St. 3 steel in a NaCl–K_2TaF_7 melt at 750°C in the electroless mode. V.P. Yurkinskii, E.V. Afonicheva, and E.G. Firsova (St. Petersburg) reported the results obtained in studying the growth kinetics of anodic oxide films on tantalum in low-melting nitrate mixtures (410–510 K).

G.A. Bukatova, E.G. Polyakov, and J. Aromaa (Apatity; Helsinki, Finland) demonstrated that electrolytically obtained pore-free tantalum coatings on such materials as St. 3 and Kh18N9T stainless steel impart to them high corrosion resistance in chloride-ion–containing media. The report by Yu.N. Zhirkova and co-authors (Novomoskovsk) was devoted to electrochemical synthesis of bimetallic powdered formulations containing rhenium, niobium, tantalum, and aluminum.

V.P. Baklanov, V.N. Bezumov, *et al.* (Moscow, Glazov) considered processes of optimization of the industrial manufacture of zirconium by electrolysis of fluoride-chloride melts. L.P. Polyakova and P. Taksil (Apatity; Toulouse, France) reported on investigations of the cathodic reduction of titanium in a NaCl–KCl–NaF melt containing K_2TiF_6 by a set of modern electrochemical methods.

Reports by Z.I. Valeeva, N.O. Esina, *et al.* (Yekaterinburg) were concerned with synthesis of cathode deposits of molybdenum and rhenium by electrolysis of chloride melts, investigation of the structure of the deposits, and vapor-phase deposition of molybdenum onto a nickel substrate. I.A. Novoselova and co-authors (Kiev) considered specific features of co-electroreduction of MoO_4^{2-} and SO_4^{2-} ions in melts of varied cationic composition.

Some reports were devoted to physicochemical investigations of molten systems containing compounds of rare earths and electrolysis processes involving them. Kuznetsov and co-authors (Apatity; Marseilles, France; Wroclaw, Poland) studied thermodynamic properties of molten mixtures of scandium(III) chloride with chlorides of alkali metals by means of electrochemical and calorimetric methods. A.V. Novoselova, V.Yu. Shishkin, and V.A. Khokhlov (Yekaterinburg) measured by the direct potentiometric method the redox potentials of Sm(III)/Sm(II) and Eu(III)/Eu(II) in molten cesium chloride. V.F. Goryushkin *et al.* (Novokuznetsk) determined, by measuring the emf of solid-phase cells, the standard thermodynamic characteristics of a number of lanthanide dichlorides. L.F. Yamshchikov and A.A. Zyapaev (Yekaterinburg) discussed from the thermodynamic standpoint the possibility of lanthanide separation on various liquid-metal electrodes (Al, Ga, In, Zn, Sn, and Bi) in molten salts. I.R. Elizarova, Polyakova, and Stangrit (Apatity) reported on a study of the Gd_2O_3 solubility in KCl–KF melt and electroreduction of gadolinium(III) complexes in chloride-fluoride melts. The report by A.I. Kononov (Lipetsk) was concerned with the cathodic process in a chloride neodymium-containing melt. Stangrit and A.I. Krasnoramenskii (Apatity; Zheltye Vody, Ukraine) demonstrated the possibility of obtaining aluminum–scandium alloys by electrolysis of Na_3AlF_6–Al_2O_3–Sc_2O_3 melts.

A.M. Potapov and M. Gaune-Escar (Yekaterinburg; Marseilles, France) studied the electrical conductivity of melts formed by $EuCl_2$ or $TbCl_2$ with chlorides of alkali metals in a wide range of compositions and temperatures. The same authors investigated, together with A.B. Salyulev (Yekaterinburg), absorption spectra

of diluted $TbCl_3$ solutions in chlorides of alkali metals. D.V. Makarov and co-authors (Apatity) compared various methods for synthesis of fluorides of rare-earth elements (yttrium, neodymium, and gadolinium).

Khokhlov (Yekaterinburg) discussed in detail in his report the investigations conducted at the laboratory of molten salts at the Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences. Its main direction of research is an integrated physicochemical study of molten salt electrolytes, including ionic-electronic melts. The laboratory proceeds with large-scale investigations commenced by Professor M.V. Smirnov and aimed at establishing fundamental relationships between the nature and energy of chemical bond and the structure, actual ionic composition, and properties of salt melts. The laboratory also studies complexation processes and conducts a search for ways of practical application of ionic melts.

I.A. Novoselova *et al*. (Kiev) reported the results obtained in studying the deposition of refractory coatings on nitride insulators (boron or aluminum nitrides) in their cathodic polarization in tungsten-containing melts at 850–900°C. O.I. Rebrin and co-authors (Yekaterinburg) studied the kinetics of anodic oxidation of beryllium and cathodic reduction of its ions in chloride melts. In a series of communications by A.V. Volkovich and co-workers (Novomoskovsk) considered the reaction of calcium, strontium, and barium oxides with individual chlorides of alkali metals and their binary mixtures in molten state (973–1173 K). The report by V.N. Zaichenko (Kiev) was concerned with the role of magnetic fields in the electrochemistry of ionic melts.

The workshop demonstrated that the most intensive and best-directed investigations in Russia in the field of high-temperature electrochemistry are conducted in Yekaterinburg and Apatity. The works in this field of other scientific centers are mainly occasional. In Yekaterinburg, investigations in a variety of directions, covering a wide range of problems, are being carried out at the Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences, and the Ural State University. The Institute of Chemistry, Kola Research Center, Russian Academy of Sciences, achieved the most pronounced success in the field of electrochemistry of niobium, tantalum, and rare-earth elements. Rather valuable, in the first place in methodological regard, are joint works carried out at scientific centers abroad.

One cannot but admit the high level of organization of the workshop and the friendly climate. The abstracts of all the presented reports are well published. The workshop was held with the support of the Russian Foundation for Basic Research, ZAO Rossiiskie redkie metally, the administration of Apatity town, and the Tananaev Institute Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Crystallochemical Aspect of Phase Formation in the γ-FeOOH–H_2O–NaOH System

A. V. Tolchev, R. R. Bagautdinova, and D. G. Kleshchev

Chelyabinsk State Pedagogical University, Chelyabinsk, Russia

Received June 3, 2000

Abstract—Phase transition of metastable γ-FeOOH into α-FeOOH and its chemical transformation into α-Fe_2O_3 upon hydrothermal treatment in 0–5 M NaOH solutions at 100–230°C were studied. The regions of formation of the above phases were specified. The probable composition of the crystallizing complexes formed in the solutions and the reactions occurring at their incorporation into various atomically smooth faces of α-FeOOH and α-Fe_2O_3 were considered.

Metastable iron(III) oxyhydroxides of γ and δ modifications are formed by oxidation of aqueous solutions of iron(II) salts or iron(II) hydroxide suspensions under the conditions of high supersaturation. Upon thermal treatment in alkaline solutions they undergo phase transition (PT) or chemical transformation (CT) into the equilibrium phases α-FeOOH and α-Fe_2O_3, respectively, which are widely used as inorganic pigments and as starting materials for preparing magnetic powders, ceramics, etc. The kinetics and type of the transformation of metastable FeOOH as well as the crystal size and habit of the formed phases depend on many parameters, the main of which are thermal treatment temperature, alkali and FeOOH concentrations in suspension, and the structure and average size of crystals of the initial iron(III) oxyhydroxides.

In this work we studied possible factors affecting the phase composition and crystal habit of the iron(III) oxide compounds formed by hydrothermal treatment of γ-FeOOH in NaOH solutions.

The single-phase γ-FeOOH sample, as evidenced by X-ray phase analysis and electron microscopy, in the form of platelike crystals with the average size $60 \times 20 \times 5$ nm, was obtained by oxidation in air at 25 ± 2°C of aqueous solution of chemically pure grade iron(II) sulfate at pH 7.3 ± 0.5 adjusted by continuous addition of aqueous solution of chemically pure grade sodium hydroxide, similarly to [3]. The precipitate was separated from the mother solution on a Buchner funnel, washed with water to the absence of sulfate ions in the filtrate, and resuspended in distilled water and 0.1 to 5.0 M aqueous NaOH. The hydrothermal treatment of γ-FeOOH suspensions was performed in 0.07 dm^3 autoclaves filled to 0.8 volume at 110, 135, 170, 200, and 230°C for 2.5 h. The time of preheating the autoclave to prescribed temperature did not exceed 1 h. The temperature was controlled to within ±5°C.

The phase composition and dispersity were controlled by X-ray phase analysis (DRON-3 diffractometer, filtered FeK_α radiation) and electron microscopy (UEMV-100K microscope), and the solution composition was determined by chemical analysis. The mass fraction of α-FeOOH and α-Fe_2O_3 in the thermally treated samples was determined by the known procedure of quantitative X-ray phase analysis [7].

The experimental data show that, depending on C_{NaOH} and t, the hydrothermal treatment of the γ-FeOOH phase leads to phase transition or chemical transformation, which can occur in parallel (Fig. 1).

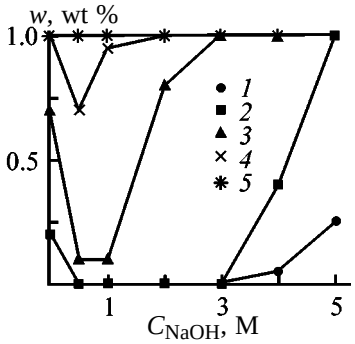

Fig. 1. Concentration w of the α-Fe_2O_3 phase in samples obtained at different temperatures of hydrothermal treatment vs. the NaOH concentration C_{NaOH} in the solution. Temperature (°C): (*1*) 110, (*2*) 135, (*3*) 170, (*4*) 200, and (*5*) 230. The same for Fig. 2.

1070-4272/01/7403-0359$25.00

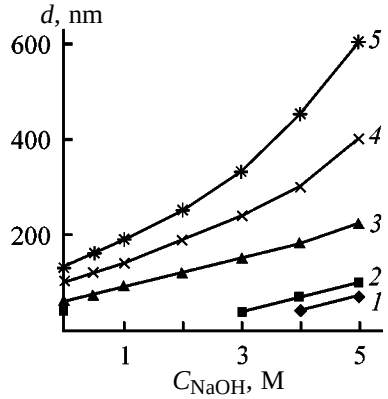

Fig. 2. Average size d of the α-Fe_2O_3 crystals vs. the NaOH concentration C_{NaOH} in the solution.

Note that at the fixed NaOH concentration in the solution the γ-FeOOH $\rightarrow$ α-FeOOH PT occurs at lower temperatures than CT γ-FeOOH $\rightarrow$ α-Fe_2O_3. The sequence of phase formation as a function of C_{NaOH} at T = const within 135–200°C is irregular: at C_{NaOH} < 0.5 and > 3 M the γ-FeOOH phase transforms into α-Fe_2O_3, whereas in the intermediate concentration region it transforms into α-FeOOH.

The average size and the habit of crystals of the forming phases are also functions of heat treatment parameters. For example, the α-FeOOH and α-Fe_2O_3 crystals, products of hydrothermal treatment of γ-FeOOH in distilled water, are acicular and isometric, respectively. With increasing NaOH concentration in the solution at T = const, the crystal habit of these phases changes regularly. In the process, the form factor f of the acicular α-FeOOH crystals increases from f = 2–4 at C_{NaOH} = 0 M to f = 6–8 at C_{NaOH} = 3 M, and at C_{NaOH} > 3 M a transition occurs from isometric habit of α-Fe_2O_3 crystals to the platelike habit. As the temperature or NaOH concentration in the solution grows at the fixed value of the other parameter, the average size of the α-FeOOH and α-Fe_2O_3 crystals in the directions of primary crystallization increases regularly (Fig. 2).

The fact that the habit and average size of crystals of the starting phase (γ-FeOOH) and those of the α-FeOOH and α-Fe_2O_3 phases formed by hydrothermal treatment change considerably indicates that in alkaline solutions, as in weakly acidic solutions, PT and CT of metastable FeOOH occur by the dissolution–precipitation mechanism (DPM) [4, 5, 8]. The latter involves the elementary stages of dissolution of metastable-phase crystals, formation of crystallizing complexes (CCs) in the solution, their transfer through the solution, and incorporation into the forming crystals of the equilibrium phase. It is generally accepted [9] that the formation of two-dimensional nuclei on an atomically smooth face is the limiting stage of layer-by-layer crystal growth. Since for sparingly soluble compounds, including α-FeOOH and α-Fe_2O_3, a two-dimensional nucleus is comparable in size with CCs present in the solution [7], the nucleation mechanism is reduced to the CC incorporation into the surface layer of these crystals. Let us consider the structure of the α-FeOOH and α-Fe_2O_3 faces and the CC composition and configuration in the solutions varying in compositions.

If the interaction of the crystal surface with the dispersion medium is negligible, as in neutral solutions including distilled water, then atomically smooth face (001) of α-FeOOH consists of the rows of water molecules (layer *I*) alternating with the rows of hydroxy groups (layer *II*), and faces (100) and (010) are formed by three and two adjacent rows of hydroxide ions, respectively, separated by one vacant row (Fig. 3a). The (100) face of α-Fe_2O_3 involves alternating layers of water molecules (layer *I*) and oxygen anions (layer *II*), and the (001) face, only the hexagonal network of hydroxy groups (Fig. 3b). The crystallizing complex in the given solutions consists of two octahedra sharing the base edge of the bipyramid (Fig. 3c) and has the composition $Fe_2(OH)_6 \cdot 4H_2O$ [10]. Incorporation of CCs into α-FeOOH crystals on the atomically smooth (001) face in points *1–4* is accompanied by olation. For the face (100) the oxolation reaction takes place in points *5* and *7* and the olation reaction, in point *6*. As for the face (010), oxolation occurs in points *8* and *10* and olation, in point *9*. For the (100) phase of α-Fe_2O_3, olation takes place in points *1–3* and dehydration, in points *4* and *5*. The face (001) is characterized by oxolation in points *6–8* and by olation in points *9* and *10*.

In alkaline solutions, especially at high temperatures, sodium hydroxide can react with the ligand molecules adsorbed on the crystal surface and incorporated into the crystallizing complexes. Therefore, in dilute NaOH solutions the reactions of complete or partial substitution of water molecules by hydroxide ions can occur on the (001) face of α-FeOOH and on the (100) face of α-Fe_2O_3. In concentrated solutions, along with these reactions, the oxolation reaction between the hydroxide ions of NaOH and those of the surface layer of (001), (010), and (100) faces of α-FeOOH or (001) face of α-Fe_2O_3 is probable. These reactions impart to the faces a negative charge, which is compensated by the positive charge of Na^+ ions in the near-crystal adsorption layer. Apparently, this fact can explain the increased solubility of iron(III) oxide compounds in alkaline solutions compared to neutral

and weakly acidic solutions, which is manifested as the increase in the equilibrium concentration of hydroxo aqua complexes (HACs) of iron(III) [11]. Second, the reaction of alkali with the electroneutral HACs $[Fe(OH)_3]_{aq}$ in alkaline solutions yields negatively charged HACs $[Fe(OH)_4]^-_{aq}$, the concentration of which changes regularly with growing C_{NaOH}. Thus, it can be presumed that, along with CCs of the composition $Fe_2(OH)_6 \cdot 4H_2O$, the negatively charged complexes $[Fe_2(OH)_7 \cdot 3H_2O]^-$ (Fig. 3d, CC') and $[Fe_2(OH)_8 \cdot 2H_2O]^{2-}$ (Fig. 3d, CC") can be present in NaOH solutions, with the maximum concentration of the first and the second complexes being attained in dilute and concentrated solutions, respectively.

As a result, the type of the reactions accompanying incorporation of CCs into the surface layer of crystals in alkaline solutions changes compared to neutral solutions. For example, incoprporation of CC' into α-FeOOH in dilute NaOH solutions is accompanied by olation on the (001) face in points *1–3* and by oxolation in point *4*, whereas on the (100) face in points *5* and *7* and on the (010) face in points *8* and *10* it is accompanied by oxolation. In points *6* and *9*, the dehydroxylation reaction occurs, resulting in release of OH^- ions from CC' into the solution: $O^{2-}_{cr} + OH^-_{CC} \rightarrow O^{2-}_{cr} + OH^-_{sol}$.

On the (100) face of α-Fe_2O_3 the oxolation takes place in points *1–3* and dehydration, in points *4* and *5*, whereas on the (001) face the oxolation occurs in points *6–8* and the olation, in points *9* and *10*. In concentrated NaOH solutions the incorporation of CC" into the (001) face of α-FeOOH is accompanied by olation in point *1*, dehydroxylation in points *2* and *3*, and oxolation in point *4*. On the (100) and (010) faces dehydroxylation proceeds in all the points *5–10*. In α-Fe_2O_3 the reaction type does not change on the (100) phase, but on the (001) face in points *6–8* there takes place dehydroxylation and in points *9* and *10*, dehydration.

Thus, depending on NaOH concentration in the solution, the incorporation of crystallizing complexes into α-FeOOH and α-Fe_2O_3 can be accompanied by the following concurrent reactions: dehydration, olation, oxolation, and dehydroxylation. The first two reactions, in which instead of weakly bound van der Waals complex [Fe(III)–H_2O] the strong hydroxide or oxide bridging bonds decreasing the Gibbs energy *G* of the crystal–CC system are formed between iron(III) ions adsorbed on the crystal surface and the crystallizing complex, are the most favorable from the thermodynamic standpoint. Compared to olation and dehydration reactions, the oxolation reaction $OH^-_{cr} + OH^-_{CC} \rightarrow O^{2-}_{cr} + H_2O_{sol}$ accompanied by deprotonation of the hydroxide ion with the strong covalent bond has the higher activation energy and, consequently, occurs at higher temperatures [13]. The activation energy of the dehydroxylation reaction is equal to the dissociation energy of the Fe(III)–OH^- bond of the crystallizing complex and is comparable with the dissociation energy of the hydroxide and oxide bridging bonds in the crystals, i.e., $\Delta G \sim 0$. Compared with the reactions considered, the latter reaction is noncompetitive.

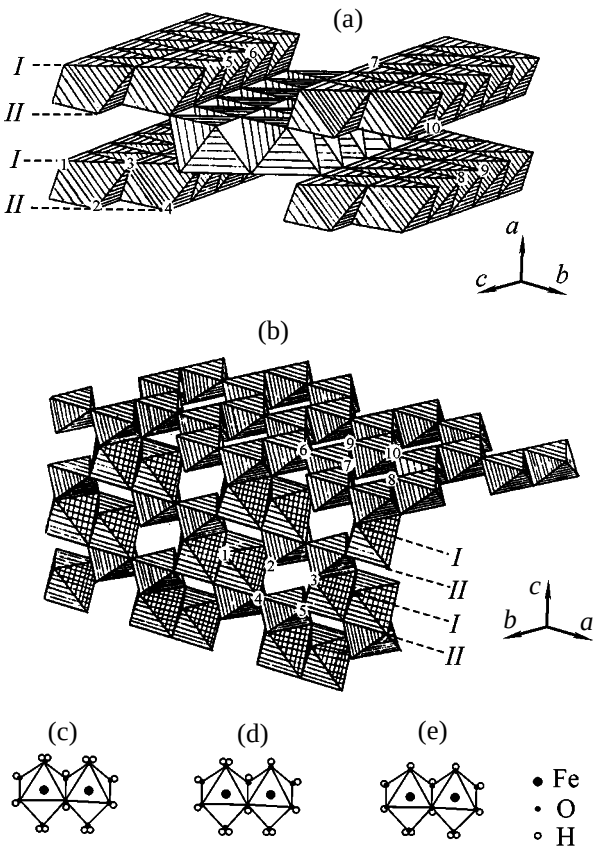

Fig. 3. Structure of (a) α-FeOOH and (b) α-Fe_2O_3 phases in polyhedral interpretation and structure of crystallizing complexes (c) $[Fe_2(OH)_6 \cdot 4H_2O]$, (d) $[Fe_2(OH)_7 \cdot 3H_2O]^-$, and (e) $[Fe_2(OH)_8 \cdot 2H_2O]^{2-}$.

The experimental data are analyzed based on the qualitative estimate of the probability of nucleation on the different crystal faces as determined from the number and type of the reactions occurring at incorporation of crystallizing complexes. For example, preferential growth of α-FeOOH crystals in the crystallographic direction *c*, and, consequently, their acicular habit were previously explained [10] by the smaller number of bonds (three bonds) formed on incorporation of CCs into the (100) and (010) faces

compared to that (four bonds) formed on incorporation into the (001) face. At higher temperatures of hydrothermal treatment at C_{NaOH} = const, all reactions, including oxolation, are activated on the (100) and (010) faces, which increases the average length and decreases the form factor of the α-FeOOH crystals. On the contrary, as the NaOH concentration in the solution increases owing to dehydroxylation, the probability of formation of nuclei on the (100) and (010) faces decreases, which predetermines the increase in the form factor of the α-FeOOH crystals. The incorporation of the complexes into the (100) and (001) faces of α-Fe_2O_3 involves formation of the similar number of bonds (five bonds). As a result, the α-Fe_2O_3 crystals formed upon CT of γ-FeOOH in neutral and weakly alkaline solutions are isometric. In concentrated alkalis, the nucleation on the (001) face is impeded by dehydroxylation and the platelike α-Fe_2O_3 crystals are formed, oriented normally to the crystallographic axis *c*, as evidenced by X-ray diffraction analysis [3, 4]. The influence of the hydrothermal treatment conditions on the γ-FeOOH transformations in alkaline solutions can also be understood in terms of the concept ot formation of crystallizing complexes. For example, as the number of oxide bridges formed upon α-Fe_2O_3 crystallization is two times higher, on the average, compared to those formed upon α-FeOOH crystallization, the chemical transformation γ-FeOOH → α-Fe_2O_3 at C_{NaOH} = const occurs at higher temperatures than the phase transition γ-FeOOH → α-FeOOH. For neutral solutions and dilute (C_{NaOH} < 1 M) and concentrated (C_{NaOH} > 3 M) NaOH solutions the type and the number of the reactions accompanying the incorporation of CC, CC', and CC" into the (001) face of α-FeOOH and the (100) face of α-Fe_2O_3 vary in the sequence: 4 olation reactions → 3 olation reactions + 1 oxolation reaction → 1 olation reaction + 1 dehydration reaction + 2 dehydroxylation reactions and 3 olation reactions + 2 dehydration reactions → 3 oxolation reactions + 2 dehydration reactions (for low and highly concentrated solutions, respectively). Therefore, compared to α-FeOOH, the probability of formation of the α-Fe_2O_3 nuclei at *T* = const is higher in neutral and concentrated alkali solutions and lower in the solutions of the intermediate concentrations, which is in line with the experimental data on phase formation in the γ-FeOOH–H_2O–NaOH system.

CONCLUSION

(1) The phase transition of metastable γ-FeOOH into α-FeOOH and its chemical transformation into α-Fe_2O_3 were studied upon hydrothermal treatment in 0–5 M NaOH solutions at 110–230°C. The regions of formation of the above phases were specified.

(2) The transformations of γ-FeOOH in alkaline solutions occur by the dissolution–precipitation mechanism. The probable composition of the crystallizing complexes formed in the solutions and the reactions occurring at their incorporation into various atomically smooth faces of α-FeOOH and α-Fe_2O_3 were considered. The established dependences of the phase composition and dispersity of the resulting products on the conditions of hydrothermal treatment were explained.

Received September 25, 2000

Abstract—Comparative study of extraction of tantalum(V) and niobium(V) with octanol and tributyl phosphate was made. The data on distribution of tantalum(V) and niobium(V) between octanol and hydrofluoric and hydrofluoric–sulfuric acid aqueous solutions were obtained. The flowsheet for preparation of pure tantalum and niobium oxides was developed.

Extraction technique is widely used for preparation of rare metal compounds. Octanol is the promising extractant for recovery of tantalum(V) and niobium(V) from aqueous solutions [1–4]. According to the data reported in [1], the extractive efficiency of octanol is not inferior to that of methyl isobutyl ketone (MIBK) commonly used in industrial preparation of tantalum(V) and niobium(V) compounds [5]. However, compared to octanol, MIBK exhibits such substantial drawbacks as the explosion hazard and high solubility in aqueous solutions.

In this work we made a comparative study of the extraction power of octanol and tributyl phosphate (TBP) with respect to tantalum(V) and niobium(V). TBP was chosen by us since this extractant is widely used for extraction of rare metals, among them tantalum(V) and niobium(V) [5]. We also studied the separation of tantalum(V) from niobium(V) in their simultaneous extraction from concentrated aqueous solutions and extractive purification of these metals to remove impurities.

In the experiments we used *n*-octyl alcohol $CH_3(CH_2)_6CH_2OH$ [1-octanol] (OCL). The main characteristics of octyl alcohol are as follows: solubility in water 0.05 wt %, density 0.824 g cm^{-3}, mp 15–16°C, bp 195°C, flash point 81°C, main substance content about 98%, and the maximum permissible concentration in air 10 mg m^{-3}. The equilibrium distribution of tantalum(V) and niobium(V) between aqueous phase and octanol is attained at a contact time less than 5 min. It was found in preliminary experiments that the extraction characteristics of OCL are close to those of other octanol isomers (2-octanol, 2-ethylhexanol). These organic solvents are commercially available and have acceptable cost. The extraction experimental technique was reported in detail in [6].

Figures 1 and 2 show the curves of extraction of tantalum(V) and niobium(V) from their dilute solutions in sulfuric–hydrofluoric acid mixtures used in several flowsheets of processing of Russian loparite [5]. The extraction was performed at the constant HF_{free} concentration equal to 3 M, where HF_{free} is the HF concentration calculated as the difference bet-

ween the total HF concentration and the HF amount combined in the main complexes $HTaF_6$, $HNbF_6$, and H_2SiF_6 formed in the systems studied.

1-Octanol is less basic than TBP [7] and, therefore, the extraction of tantalum(V) and niobium(V) with octanol should be performed at higher ratio of the organic and aqueous phases $V_o : V_{aq}$. It is known [7] that niobium(V) and tantalum(V) are extracted from hydrofluoric acid solutions with neutral organic solvents by the mechanism of formation of $HMeF_6$ acids. The extraction of these complexes increases with increasing H^+ concentration. The difference between extraction recovery of these metals with OCL and TBP becomes the most pronounce at the deficiency of H^+ at the H_2SO_4 and H_2SiF_6 concentrations lower than 1 M. As compared to TBP, OCL virtually does not recover not only fluoroniobic acid $HNbF_6$ but even more extractable fluorotantalic acid $HTaF_6$. Therefore, to provide efficient extraction of tantalum(V) and niobium(V) with OCL, the higher concentration of acid in the aqueous phase is required.

It was found by us previously [6] that extraction of tantalum(V) and niobium(V) from hexafluosilicic acid solution with TBP exceeds that from sulfuric acid solutions. In extraction with OCL this effect is even more pronounced. Concentrated solutions of hexafluorosilicic acid are used, for example, in processing of several types of tantalite and columbite. We can expect that at the H_2SiF_6 concentration higher than 4 M the extraction powers of OCL and TBP are similar even at the equal ratio of volumes of the organic and aqueous phases. This fact shows that efficiency of extraction of tantalum(V) and niobium(V) is controlled not only by the acid type (tetrafluorooxotitanic, hexafluorosilicic, hexafluorostannic, sulfuric, hydrochloric [6, 8]), but also by the nature of the extractant. These facts call for systematic studies of extraction of the rare metals from fluorometallic acid aqueous solutions as influenced by the nature of the extractant. Such studies are of the current interest taking into account the increase in processing of the tantalum(V) and niobium(V)–lean raw materials including large amounts of foreign metals [titanium(IV), zirconium(IV), silicon(IV), etc.].

Along with the above-noted drawbacks of OCL as compared to TBP, OCL exhibits several advantages. The main advantage is its stability in long-term contact with process solutions. We found that with increasing contact time of OCL with solution containing 4 M HF and 5 M H_2SO_4 at the ratio of organic and aqueous phases $V_o : V_{aq} = 1 : 1$ to 280 h the degree of recovery of HF and H_2SO_4 decreases gradually from 36 to 26% and from 15 to 10%, respectively. After completion of these experiments OCL can be reused for further extraction. On contact of TBP with the aqueous phase under the identical conditions for 70 days the initial two-phase system was converted to a homogeneous solution. It is evident that homogenization of the system is due to decomposition of the extractant. The products of hydrolytic degradation of TBP contaminate niobium and tantalum materials with phosphorus(V) and other impurities [5], which prevents preparation of high-purity compounds of tantalum and niobium. Among other drawbacks of TBP are its toxicity and high density which deteriorates phase separation and, as a result, complicates and raises the price of the extraction installation [5].

Figure 3 shows extraction of tantalum(V) and niobium(V) from their concentrated solutions with OCL and TBP. These data show that the trends in extraction of tantalum and niobium with both TBP and OCL

Extraction of tantalum(V) and niobium(V) from hydrofluoric acid aqueous solutions

Run no.	Composition of initial solution, M				$V_o : V_{aq}$	Recovery, %	
	Ta(V)	Nb(V)	HF_{tot}	HF_{free}		Ta(V)	Nb(V)
1	0.45	0.75	5.7	–1.5	0.8 : 1	38	2.7
2	0.45	0.75	22.2	15	0.8 : 1	22	40
3	0.59	1.14	9.08	–1.3	0.8 : 1	33	2.1
4	0.59	1.14	9.08	–1.3	2.5 : 1	70	4.3

are similar. In extraction of tantalum from 2 M H_2SO_4 the degree of recovery of this metal with both OCL and TBP becomes identical. The degrees of niobium recovery with OCL and TBP become similar in extraction from approximately 3.5 M H_2SO_4. Figure 3 shows also that extraction of niobium and tantalum with octanol is more sensitive to variation in the H_2SO_4 content than extraction of these metals with TBP.

The results on extraction of tantalum(V) and niobium(V) from their concentrated solutions with OCL are analyzed below. In separate experiments we found that, in spite of the relatively low extractive power of OCL, the extracts containing the sum of Ta(V) + Nb(V) in amount of 0.8 M and larger can be obtained.

The data on recovery with octanol of tantalum(V) and niobium(V) from hydrofluoric acid aqueous solutions containing no sulfuric acid are listed in the table. These results show that with increasing HF concentration the separation of Ta(V) and Nb(V) is deteriorated (run nos. 1 and 2). It is known [5, 7], that tantalum(V) is extracted in the form of complex $HTaF_6$. Extraction by this mechanism is suppressed with excess HF due to a competitive extraction of hydrofluoric acid. In contrast to tantalum, extraction of niobium is mainly controlled by formation of the complex $HNbF_6$, and, therefore, excess HF increases the niobium transfer in the organic phase. To improve separation of Ta(V) from Nb(V), the extraction should be carried out at deficiency of HF and a large ratio of organic and aqueous phases (run nos. 3 and 4). In run no. 4 in continuos countercurrent extraction, tantalum(V) is virtually completely recovered with low coextraction of niobium(V).

Extraction of Nb and Ta with OCL sharply increases on introduction of sulfuric acid into the aqueous phase. For example, in extraction of tantalum(V) from aqueous solution containing 0.7 M Ta(V), 1.5 M HF_{free}, and 3 M H_2SO_4 at $V_o : V_{aq} = 1.2 : 1$ the degree of recovery of the metal is 86% in one cycle, increasing to 91% with decreasing HF_{free} concentration to 0.25 M. In extraction of niobium(V) and tantalum(V) from aqueous solution containing 0.45 M Ta(V), 0.75 M Nb(V), 6.5 M HF_{free}, and 4 M H_2SO_4 at $V_o : V_{aq} = 1.5 : 1$ the degree of extraction of tantalum(V) and niobium(V) is 85 and 88%, respectively, in one cycle. These data show that with continuous countercurrent extraction technique the exhaustive simultaneous recovery of tantalum and niobium can be reached in four extraction stages. The content of Ta(V) and Nb(V) in the resulting extract is 0.3 and 0.5 M, respectively.

Figure 4 shows the extractive separation of tantalum(V) from niobium(V) with *n*-octanol as influenced by sulfuric acid concentration. The mutual arrangement of curves *1* and *2* in Fig. 4 shows that at H_2SO_4 concentration higher than 2 M the increase in recovery of niobium(V) is more pronounced as compared to tantalum(V) and, as a result, the separation of these elements deteriorates. Therefore, taking into account the above-analyzed results, the separation of tantalum from niobium should be performed by extraction from solutions containing approximately 2 M H_2SO_4 at the minimal HF content.

We studied also separation of tantalum(V) from niobium(V) and their purification to remove foreign

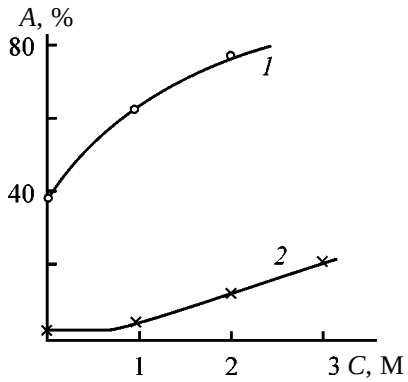

Fig. 4. Extraction of (*1*) Ta(V) and (*2*) Nb(V) from aqueous solution containing 0.45 M Ta(V) and 0.75 M Nb(V) with 1-octanol at $V_o : V_{aq} = 1 : 1$.

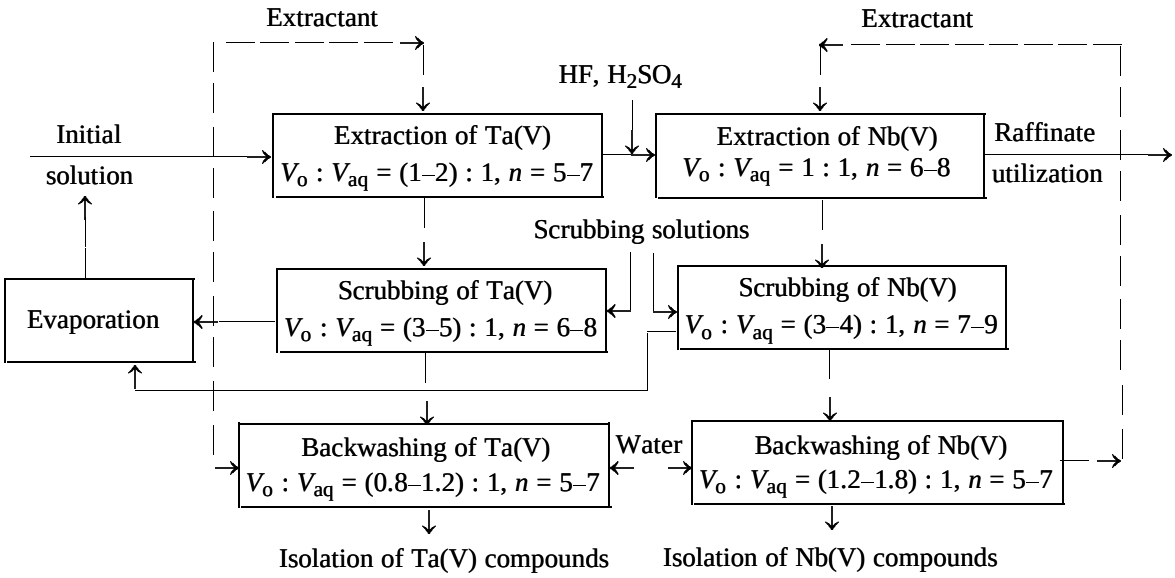
Flowsheet of extraction recovery of Ta(V) and Nd(V) from concentrated solutions with 1-octanol. Composition of initial solution (M): Ta(V) 0.45–0.65, Nb(V) 0.75–1.10, and H_2SO_4 ~2



metals in the backwashing stage. In the case of the extraction system containing hydrofluoric acid only, the separation of tantalum(V) from niobium(V) is the most efficient at backwashing with water at $V_o : V_{aq}$ approximately equal to 10 : 1.5. We found that 72% of niobium(V) and only 10% of tantalum(V) pass into the aqueous phase in one backwashing stage. Sufficiently efficient purification of niobium(V) to remove titanium(IV), which is one of the most difficultly separable foreign metals [5], can be performed by backwashing with 15–20 M HF at $V_o : V_{aq}$ of about 10 : 1. In this case 86–68% of titanium(IV) and only 22–12% of niobium(V) pass into the aqueous phase in one backwashing stage. In the extraction systems containing an HF–H_2SO_4 mixture the purification of tantalum(V) in the organic extract is the most efficient at backwashing with 1.5–2 M H_2SO_4 at $V_o : V_{aq}$ = (3.5–4.5) : 1. The purification of niobium(V) in the organic extract is the most efficient at backwashing with 5–10 M HF and 5–6 M H_2SO_4 at $V_o : V_{aq}$ = (3–4) : 1.

The flowsheet for extraction recovery of tantalum(V) and niobium(V) is shown below. This technique allows recovery of the target metals from their concentrated solutions in hydrofluoric–sulfuric acid mixtures. Such solutions are used, for example, in processing of tantalite and (or) columbite. According to this flowsheet, tantalum(V) and niobium(V) are extracted successively. In contrast to the flowsheet based on extraction of the sum of niobium(V) and tantalum(V) followed by their separation in the backwashing stage, in the flowsheet developed in this work niobium(V) and tantalum(V) are extracted separately. Such modification results in the lower price of the process, improves its separation efficiency, and simplifies the process control [5]. The operative parameters were chosen from both the results of our studies and the reference data [1–5, 7].

With this flowsheet the samples of pure tantalum and niobium oxides were prepared using a batch extraction technique. The content of the metal impurities (recalculated on metal) in Ta(V) and Nb(V) oxides was as follows (wt %). Tantalum(V) oxide: Mn < 0.001; (Mg, Al, Sn, V, Cr, Fe) < 0.003; (Ca, Ti, Si, Pb, Nb, Mo) < 0.01; Zr ≪ 0.03. Niobium(V) oxide: Mn < 0.001; Sn < 0.003; (Mg, Al, Ti, Si, Pb, V, Ta, Cr, Mo, W, Fe) < 0.01, and Ca, Zr < 0.03. Our further studies showed that the content of the metal impurities in tantalum and niobium oxides can be decreased to the levels lower than 1×10^{-5}–1×10^{-3} wt %.

Thus, extraction of tantalum and niobium from their concentrated solutions with octanol is the promising technique for their purification to remove metal impurities and preparation of pure oxides.

CONCLUSION

(1) Comparative study of extraction of tantalum(V) and niobium(V) with octanol and tributyl phosphate shows that octanol can be used in industrial process for efficient separation of these metals.

(2) Separation of tantalum(V) from niobium(V)

and their purification to remove metal impurities by extraction with octanol were studied in relation to the process parameters. A flowsheet of the extraction process for preparation of pure tantalum(V) and niobium(V) oxides was developed.

Abstract—The reactions of manganese hydroxocarbonate $MnCO_3 \cdot mMn(OH)_2 \cdot nH_2O$ with calcium aluminates $CaAl_2O_4$ and $CaAl_4O_7$ in aqueous medium were studied by X-ray phase and differential thermal analyses and by IR spectroscopy.

Catalysts prepared by mixing metal hydroxocarbonates (MHCs) with calcium aluminates in various media show promise for industry and are widely discussed in the literature [1].

It was shown earlier [1–4] that the reactions of MHCs (M = Cu, Zn, Mg, Ni, Co) with calcium aluminates in aqueous medium occur as a heterogeneous ion exchange between an aqueous solution of calcium aluminates and solid metal hydroxocarbonates. As a result of such exchange the MHC crystal structure is either retained or rearranged to give the structure of the metal hydroxoaluminate or hydroxocarbonoaluminate.

In this work we studied specific features of reactions of manganese hydroxocarbonates (MnHCs) with calcium aluminates in aqueous medium, which directly concerns the problem of synthesizing manganese–aluminum–calcium catalysts for redox processes.

EXPERIMENTAL

Manganese hydroxocarbonate $MnCO_3 \cdot mMn(OH)_2 \cdot nH_2O$ [GOST (State Standard) 7205–77] and high-alumina cement of the Talyum[1] type [$CA : CA_2$ = 0.26, TU (Technical Specifications) 5737-006-00 284 345–99] were used as starting components for sample preparation. Manganese hydroxocarbonate was stirred with Talyum in aqueous medium at 75°C for 5 h. The resulting samples were dried for 2 h at 100°C. The manganese content (in terms of Mn_3O_4) was varied from 0 to 100%. Mechanical mixtures of the starting reagents were studied in parallel.

The X-ray phase analysis (XPA) was carried out on a DRON-2 X-ray diffractometer using CuK_α radiation and a graphite monochromator. The IR spectra of samples pressed with KBr were recorded on a Specord

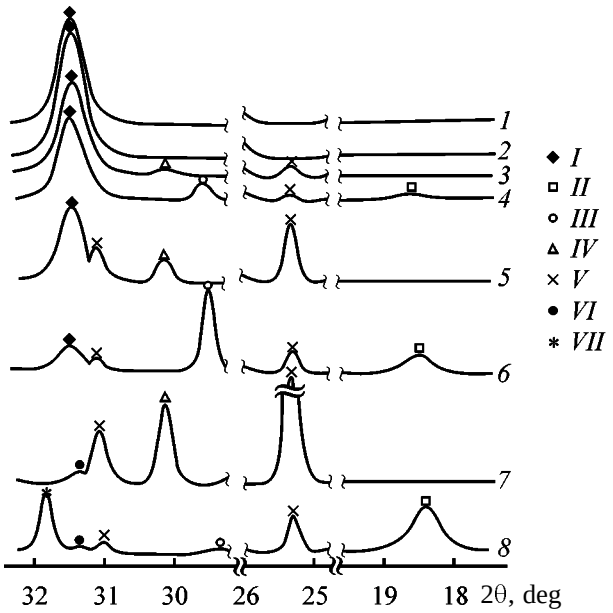

Fig. 1. Fragments of diffraction patterns of samples with various manganese content. (2θ) Bragg angle. Sample: before treatment with water: (*1*) MnHC, (*3*) 70% Mn_3O_4, (*5*) 30% Mn_3O_4, and (*7*) Talyum (0% Mn_3O_4); after treatment with water: (*2*) MnHC, (*4*) 70% Mn_3O_4, (*6*) 30% Mn_3O_4, and (*8*) 0% Mn_3O_4 (scanning rate v = 0.25 deg min^{-1}). [1] Talyum is a mixture of calcium monoaluminate $CaO \cdot Al_2O_3$ and dialuminate $CaO \cdot 2Al_2O_3$. Here and hereinafter we use notations accepted in the chemistry of cements: (A) Al_2O_3, (C) CaO, and (H) H_2O.

1070-4272/01/7403-0368$25.00

75-IR spectrophotometer. The differential thermal analysis (DTA) was carried out on an OD-103 derivatograph in air. The heating rate (final temperature 1000°C) was 5 deg min^{-1}.

Fragments of diffraction patterns of the starting manganese hydroxocarbonate (MnHC), Talyum, and samples before and after treatment with water are shown in Fig. 1.

According to the XPA data, the components do not react during mechanical mixing; the mixture contains the phases of the starting MnHC and calcium aluminates (curves *3*, *5*). On mixing Talyum with water (without MnHC) it is hydrated to give calcium hydroxoaluminate C_3AH_6, gibbsite, and small amounts of calcium hydroxocarbonoaluminate owing to the reaction of calcium hydroxoaluminate with atmospheric CO_2 (curve *8*). The diffraction patterns of MnHC before and after treatment with water are identical (curves *1*, *2*). Mixing MnHC with calcium aluminates in aqueous medium results in the appearance of strong reflections of calcium carbonate (in the form of calcite) in the diffraction patterns of the samples. According to the earlier data [1–4], this is due to the reaction of Ca^{2+} ions with carbonate ions from metal hydroxocarbonates (in this case from manganese hydroxocarbonate). The dependence of the intensity of the $CaCO_3$ line (d = 3.03 Å) on the sample composition passes through a maximum at a 30–40% content of Mn_3O_4 (Fig. 2a) (this composition corresponds to the equimolar ratio $Ca^{2+} : CO_3^{2-}$ in the system). Along with this phase, the phases MnHC, $Al(OH)_3$ (gibbsite), calcium hydroxocarbonoaluminate, and unchanged CA_2 are present in the samples (curves *4*, *6*). Reflections characteristic of calcium hydroxoaluminate are observed only in the X-ray patterns with low content of manganese (less than 10–15% Mn_3O_4).

The integral intensity of MnHC reflections considerably decreases in the course of mixing with water; e.g., for samples with 30–40% Mn_3O_4 it is as low as 36–48% of the intensity measured for mechanical mixtures of the starting components. However, no other manganese compounds were detected.

These phenomena may be due to release of carbonate ions from the MnHC lattice and their possible replacement by aluminate and hydroxide ions generated on dissolution and hydrolysis of calcium aluminates [1–4]. Owing to a low solubility of MnHC in water (SP ~10^{-11}) the reaction is localized on the interface of the solid phase of MnHC and a solution of calcium aluminates. On the replacement of CO_3^{2-} by hydroxide ions, MnHC can be partially destroyed to give X-ray

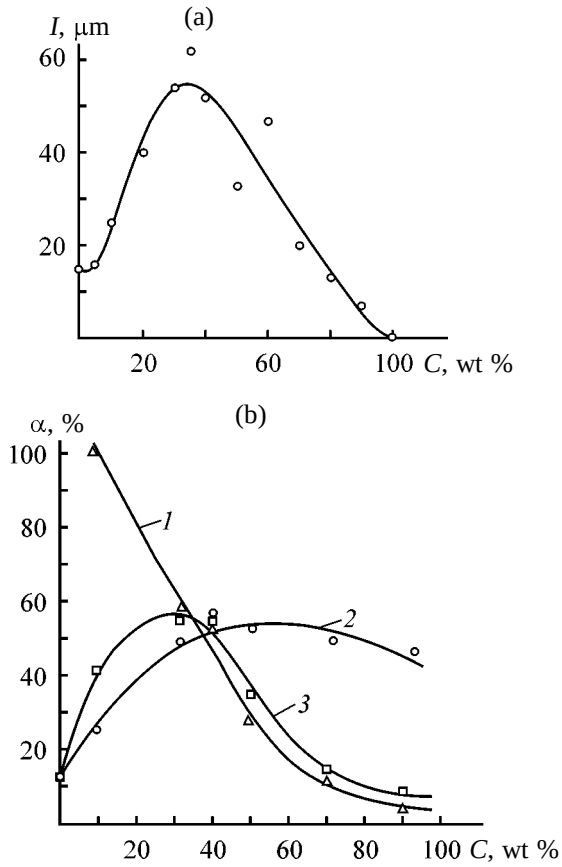

Fig. 2. (a) Intensity I of the $CaCO_3$ line (d = 3.03 Å) and (b) degree of the transformation of the starting compounds α as functions of the Mn_3O_4 content C in the system. (*1*) Degree of extraction of carbonate ions from the MnHC lattice, (*2*) degree of Ca^{2+} conversion to $CaCO_3$, and (*3*) total degree of conversion of the starting compounds to the reaction products.

amorphous manganese compounds such as $MnO_x \cdot yH_2O$, for example, by the scheme

$$MnCO_3 \cdot mMn(OH)_2 \cdot nH_2O \xrightarrow[-CaCO_3]{+Ca^{2+}} Mn\square mMn(OH)_2 \cdot nH_2O$$

$$\xrightarrow{+2OH^-} (m+1)Mn(OH)_2 \cdot nH_2O \xrightarrow{O_2, OH^-} (m+1)MnO_x \cdot yH_2O,$$

where a square means a vacancy.

The participation of aluminate ions in the exchange suggests formation of hydroxoaluminates or hydroxocarbonoaluminates in the system. However, such compounds (MnHA, MnHCA) were not detected. Nevertheless, the exchange of CO_3^{2-} with $[Al(OH)_4]^-$ can also occur without rearrangement of metal hydroxocarbonate, as was shown in [1–4]. The formation on heat treatment of disordered solid solutions

$MO \cdot Al_2O_3$ based on MO lattices suggests existence of aluminum-containing precursors; MnHC with aluminate ions dissolved in the lattice can be one of such precursors.

According to the XPA data, calcination of samples in air results in the formation of manganese oxides Mn_3O_4 and MnO_2. However, because of superposition of reflections of the forming oxides MnO_x and other phases (CA_2 and $CaCO_3$), it was impossible to estimate correctly the changes in the lattice parameters of these manganese oxides to make sure that $MnO_x \cdot Al_2O_3$ solid solutions are formed in the system.

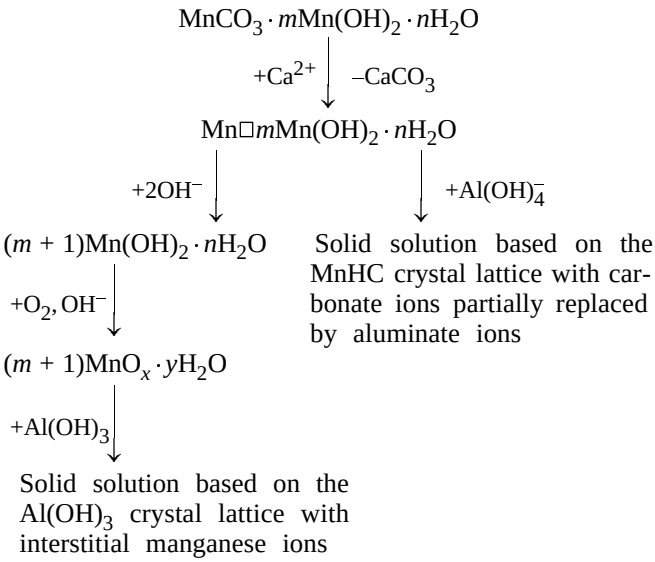
In this connection we attempted to obtain manganese(II) oxide whose diffraction peaks would not overlap with those of the other phases. It was attained by heating samples to 500°C in an H_2 flow (at lower temperatures MnHC decomposed incompletely). It was found that the resulting MnO has a lower lattice constant compared to the tabulated value of 4.445 Å. For example, the decomposition of samples with 20 and 40% Mn_3O_4 gave MnO with a = 4.429 and a = 4.438 Å, respectively, whereas for MnO obtained by thermal decomposition of mechanical mixtures of MnHC with Talyum under similar conditions the lattice constant (4.444–4.446 Å) was close to the tabulated value. Therefore, we can conclude that solid solutions $MnO \cdot Al_2O_3$ based on the MnO lattice are formed in calcined samples, and, as the manganese(II) content in the system increases, the concentration of Al^{3+} dissolved in MnO seems to decrease.

Thus, taking into account our previous experience of studying similar systems [1–4], we can suggest that the above-mentioned phenomena occurring in the course of water treatment are due to formation of a solid solution based on the MnHC crystal lattice, in which carbonate ions are partially replaced by aluminate ions formed by hydration of Talyum. In this case the initial structure of MnHC is retained, and MnHC is decomposed on heating to form $MnO_x \cdot Al_2O_3$ solid solutions based on MnO_x lattices.

The examination of the diffraction patterns of the obtained samples shows that the diffraction maxima of the forming gibbsite are shifted relative to the tabulated values, and the shifts linearly correlate with the composition of the samples. For example, the maximum with d = 4.82 Å (hydrated Talyum) is shifted to d = 4.80 (sample with 30% Mn_3O_4) and d = 4.78 Å (sample with 70% Mn_3O_4). These data suggest distortion of the gibbsite crystal lattice, which is most likely due to insertion in its structure of manganese ions released from the initial MnHC in the course of its partial degradation. Their concentration in the gibbsite lattice seems to increase with increasing content of manganese in the system. The possibility of such insertion is provided by the layered structure of gibbsite and by significant content of octahedral vacancies in it [5].

When MnHC and calcium aluminates are mixed in an aqueous medium, they react with each other according to the following probable scheme: (a) dissolution of calcium aluminates in water with the formation of Ca^{2+} and $[Al(OH)_4]^-$ ions, (b) dissociation of tetrahydroxoaluminate ions with the formation of OH^- ions, and (c) chemical reaction of MnHC with the resulting dissociation products (scheme).

Scheme of the reaction of MnHC and products of $[Al(OH)_4]^-$ dissociation



The IR spectra of the obtained samples are shown in Fig. 3. A number of absorption bands are present in the spectrum of hydrated Talyum (curve *1*). The absorption bands 750–800 and 500–700 cm^{-1} belong to the Al–O vibrations in the cases of tetrahedral and octahedral coordinations of oxygen atoms around aluminum, respectively. The absorption at 1400–1500 cm^{-1} is due to vibrations of the carbonate structures, which are formed by the reaction of Ca^{2+} ion with atmospheric CO_2; the absorption bands at 975 and 1030 cm^{-1} belong to the bending vibrations of OH^- groups of the forming gibbsite; the bands at 3465, 3530, 3620, and 3660 cm^{-1} are assigned to the stretching vibrations of the same groups.

The following changes in the IR spectra are observed on introduction of MnHC. As the manganese content in the system increases, the intensity of the

absorption bands of carbonate ions regularly increases; however, because of strong absorption in the 1400–1500 cm^{-1} range, it is impossible to resolve the bands of CO_3^{2-} ions in MnHC, $CaCO_3$, and calcium hydroxocarbonoaluminate. In the region of bending vibrations of OH^- groups of gibbsite the relative intensity of the observed absorption bands changes: the intensity of the band at 1030 cm^{-1} relative to the band at 975 cm^{-1} decreases. In the region of stretching vibrations of gibbsite OH^- groups the intensity of the band at 3660 cm^{-1} regularly decreases, and all the bands are broadened. Such changes in the IR spectra result from the formation of a system of new hydrogen bonds. The changes are the most pronounced in the spectra of the samples containing 30–40% Mn_3O_4 (curves *3*, *4*). In the region of OH^- stretching vibrations new absorption bands at 3550 and 3420 cm^{-1} appear, and all absorption bands in this region merge together to form a single broad band at 3420–3550 cm^{-1}. In the region of bending vibrations of OH^- groups of $Al(OH)_3$ the relative intensity of the absorption bands at 1030 and 975 cm^{-1} changes, their maxima shift to 1020 and 980 cm^{-1}, and a shoulder appears at 1020–1080 cm^{-1}.

On the whole, the spectrum of gibbsite becomes close to the spectrum of bayerite.

The observed changes in the IR spectrum of $Al(OH)_3$ are attributable to the insertion of manganese ions in the lattice with the formation of a system of new hydrogen bonds, to the changes in the characteristics of existing OH^- groups, and to the formation of new OH^- groups. The obtained data well agree with the XPA data on the shift of interplanar spacings in gibbsite.

Thus, the data of IR spectroscopy and XPA suggest that one more solid solution based on the gibbsite lattice is formed in the system, which is accompanied by the insertion of manganese ions in this lattice and by its partial reconstruction to the bayerite structure.

The fact that these changes in the IR spectrum are due to a reaction between the components of the system, but not to a change in their ratio, is obviously illustrated by the comparison of these spectra with the spectra of additionally prepared mechanical mixtures of MnHC with hydrated Talyum (Fig. 4). Furthermore, it follows from this comparison (namely, from the intensity of the absorption band at 870 cm^{-1} which is the most convenient to estimate the MnHC content) that MnHC has degraded to a considerable extent as a result of the reaction, which is confirmed by the XPA data.

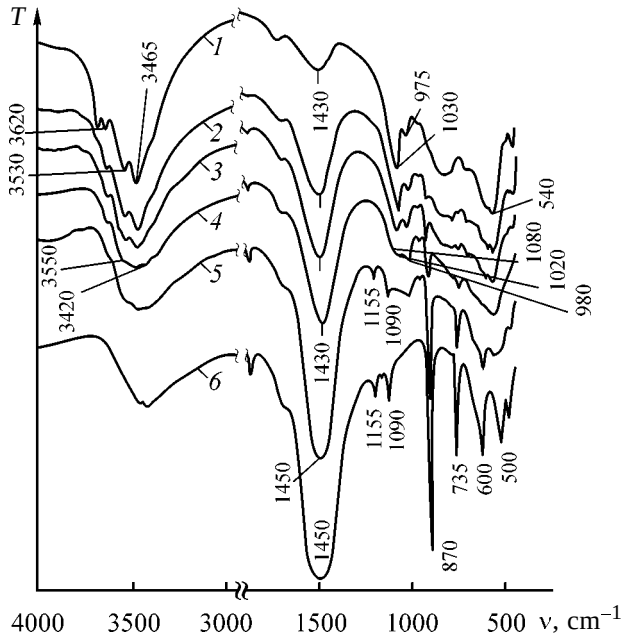


Fig. 3. IR spectra of samples with various content of manganese. (*T*) Transmittance and (ν) wave number; the same for Figs. 4 and 5. Mn_3O_4 content (wt %): (*1*) 0 (hydrated Talyum), (*2*) 20, (*3*) 30, (*4*) 40, and (*5*) 70; (*6*) MnHC.

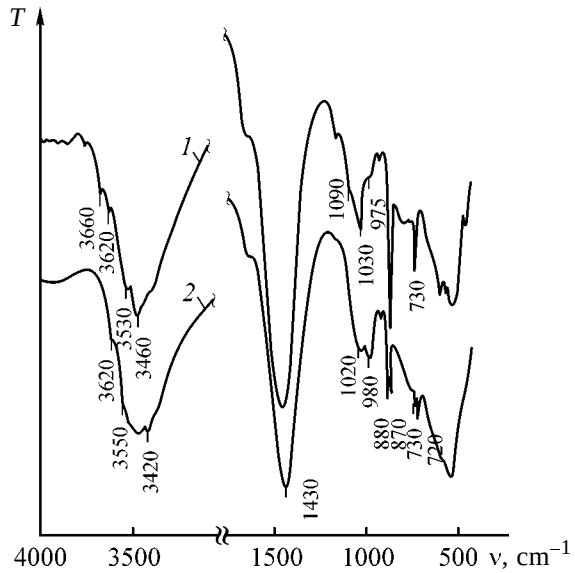

Fig. 4. IR spectra of (*1*) mechanical mixture of hydrated Talyum with MnHC (30% Mn_3O_4) and (*2*) sample of the same composition.

The formation in the system of solid solutions involving manganese compounds is proved by the fact that the intensity of the absorption bands of manganese oxides (in the range 490–650 cm^{-1}) in the IR spectra of the sample calcined in air is less than that of mechanical mixtures of calcined MnHC with cal-

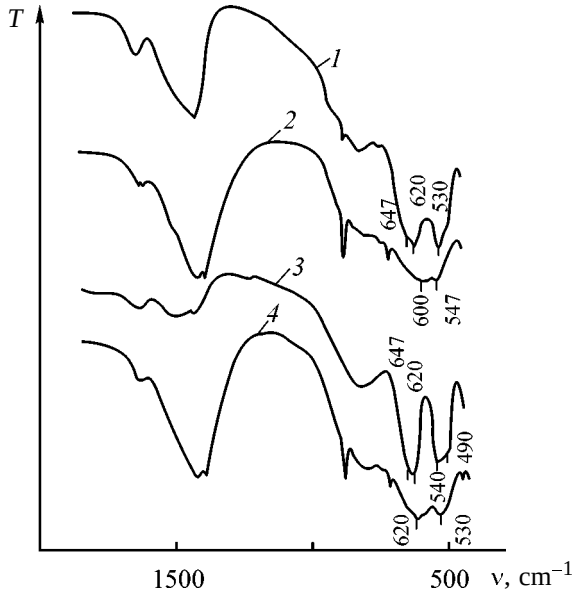

Fig. 5. IR spectra of (*1, 3*) mechanical mixture of calcined hydrated Talyum with calcined MnHC (40% Mn_3O_4) and (*2, 4*) calcined sample of the same composition. Calcination temperature (°C): (*1, 2*) 500 and (*3, 4*) 700.

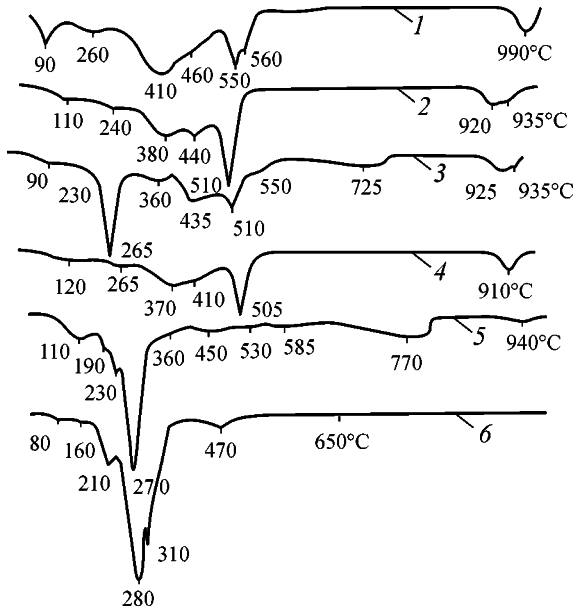

Fig. 6. DTG curves for (*1, 2, 4*) mechanical mixtures MnHC–calcium aluminates with various manganese content and (*3, 5, 6*) samples. Mn_3O_4 contents (wt %): (*1*) 100, (*2, 3*) 70, (*4, 5*) 30, and (*6*) 0 (hydrated Talyum).

cined hydrated Talyum of the same composition (Fig. 5).

The DTA data for the samples and mechanical mixtures of MnHC and calcium aluminates are given in Fig. 6. To interpret these data, we used the published data [6, 7] and the XPA data.

For example, the thermogram of the starting Talyum contains one endothermic peak at 90–100°C related to the removal of physically bound water. The curve of the decomposition of hydrated Talyum (curve *6*) involves seven endothermic peaks. The peak at 80°C corresponds to the loss of adsorbed water. At 160 and 210°C, calcium hydroxocarbonoaluminate is partially dehydrated. The strongest endothermic effect at 280°C is due to the dehydration of gibbsite with the formation of γ-Al_2O_3. At 310°C C_3AH_6 decomposes to lose 4.5 water molecules. The peak at 470°C corresponds to further dehydration of calcium hydroxoaluminate with the formation of $C_{12}A_7$. A very weak effect at 650°C corresponds to the decomposition of $CaCO_3$ formed in the samples as a result of the reaction of Ca^{2+} with atmospheric CO_2.

A number of endothermic peaks were detected in the thermogram of the starting MnHC (curve *1*). At 110°C adsorbed water is lost. At 240°C the decomposition of a γ-MnOOH impuirity and removal of structural water are possible. At 380 and 430°C MnHC decomposes stepwise with simultaneous oxidation of the forming MnO to β-Mn_2O_3, Mn_3O_4, and β-MnO_2. At 505 and 520°C β-MnO_2 is reduced to β-Mn_2O_3, and at 930°C β-Mn_2O_3 decomposes to Mn_3O_4. A very weak effect at 600°C is due to the conversion of small amounts of α-Mn_2O_3, formed by dissociation of MnHC and γ-MnOOH, to Mn_3O_4.

The same peaks as in the case of MnHC are detected in the thermograms of mechanical mixtures of MnHC with Talyum (curves *2, 4*).

The following pattern was observed in the case of samples obtained by mixing components in water. As the content of manganese in the samples increases, the amount of forming gibbsite decreases, the temperature of its dehydration is lowered, and the effect corresponding to the decomposition of C_3AH_6 at 300°C disappears. In the range 670–770°C an intense endothermic effect of $CaCO_3$ decomposition appears, the dependence of the amount of $CaCO_3$ on the composition passing through a maximum at a 30–40% content of Mn_3O_4. It is well consistent with the X-ray diffraction data (Fig. 1). Changes in the region of transformations of manganese compounds also take place: unlike mechanical mixtures, in the samples the intensity of the effect at 380°C decreases, as compared to 430°C, and new effects appear in the range 510–580°C.

The strongest changes are observed for the sample containing 30–40% Mn_3O_4: the effects of MnHC transformation are absent; instead of them endothermic effects are detected in the range 340–660°C.

Comparison with the XPA data allows these effects to be assigned to the removal of CO_3^{2-} and OH^- from the solid solution based on MnHC and to the transformation of manganese oxides.

Thus, the thermograms of samples obtained by mixing in water considerably differ from the thermograms of mechanical mixtures of the starting components and hydrated Talyum, which suggests a chemical reaction between the starting reagents.

We calculated the content of separate phases in samples of various compositions from the degrees of Talyum conversion, as determined by X-ray diffraction, and from the thermogravimetric and analytical data. We found that the amount of $Al(OH)_3$ formed in the sample with 30% Mn_3O_4 (DTG data) is less by 5–6% (in terms of Al_2O_3) than that calculated from the degree of Talyum transformation and analytical data. At the same time the contents of CAO in the system were in a good agreement. These facts suggest that approximately 10% of the total amount of Al_2O_3 in a sample takes part in the formation of a solid solution based on the MnHC crystal lattice. Furthermore, it follows from such calculations that in the case of a sample with 30% Mn_3O_4 about 60% of CO_3^{2-} ions from the MnHC structure seem to participate in the heterogeneous ion exchange.

It follows from the calculations for other samples that, as the content of manganese in the system increases, the degree of extraction of carbonate ions from the MnHC lattice decreases, the degree of the conversion of Ca^{2+} to $CaCO_3$ increases, the total degree of conversion of the starting substances to the reaction products being maximal at intermediate compositions (30–40% Mn_3O_4) corresponding to the equimolar ratio $Ca^{2+} : CO_3^{2-}$ in the system (Fig. 2b). Furthermore, as the manganese content in the system increases, the amount of $Al(OH)_3$ formed in the samples (by the DTG data) approaches the calculated value.

Our experimental and calculated data suggest that, as the manganese content in the system increases, the concentration of aluminate ions dissolved in the MnHC structure decreases, and the concentration of manganese ions in the gibbsite lattice, on the contrary, increases; the maximal amount of reaction products is formed at intermediate compositions.

CONCLUSIONS

(1) The reaction between manganese hydroxocarbonate and calcium aluminates in aqueous medium is similar in nature to the reactions in the systems cobalt hydroxocarbonate–calcium aluminate and nickel hydroxocarbonate–calcium aluminate. In these cases the structure of the metal hydroxocarbonate is retained and is not rearranged into the structure of the metal hydroxoaluminate (hydroxocarbonoaluminate).

(2) The concentration of aluminum ions dissolved in the lattice of manganese hydroxocarbonate tends to decrease with increasing manganese content in the system.

(3) A solid solution based on the gibbsite crystal lattice with interstitial manganese ions is formed in the system under study. The concentration of manganese ions in the gibbsite lattice tends to increase as the manganese content in the system increases.

(4) The maximal conversion of starting substances to the reaction products is reached in the samples containing 30–40% Mn_3O_4.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Kinetic of Leaching of Cadmium and Zinc from Their Oxides and Hydroxides

V. V. Tarasov, A. D. Fedoseev, and Chzhan Dun Syan

Mendeleev Russian University of Chemical Technology, Moscow, Russia

Received August 28, 2000

Abstract—The rotating disc method was applied to study the kinetics of leaching of zinc and cadmium from their oxides and hydroxides by sulfuric acid at pH 2–5, temperature of 288–313 K, and disc rotation velocities of 300–3600 rpm. The kinetic regions of the topochemical processes of zinc and cadmium leaching were revealed.

A considerable amount of zinc- and cadmium-containing waste has been accumulated in Russia. One of the sources of such waste is the viscose production. Even though the manufacture of viscose fiber declines, vast amounts of zinc and cadmium hydroxide sludges have been accumulated as a result of many years' work of viscose plants. The content of zinc in the sludges may be as high as 20%, and that of cadmium, tenths of percent. The total amount of zinc in such "technological deposits" is as large as tens of thousands of tons, and that of cadmium, tens of tons. In view of the loss by Russia of the former sources of zinc, these deposits are of interest as potential sources of these metals. At the same time, sludge dumps have seized large areas of lands suitable for agricultural purposes and created a danger of groundwater contamination with heavy metals. Of particular interest from the environmental standpoint are the problems of migration of zinc and cadmium ions in underground water horizons, occurring as a result of acid rains. In contrast to the processes of the recovery of zinc and cadmium ions with concentrated acids, studied and described in ample detail [1–5], leaching by highly dilute acids, modeling acid rains, has been little studied.

The aim of this study was to establish kinetic laws of leaching of zinc and cadmium ions from their oxides and hydroxides by weak sulfuric acid solutions at pH ~2–5.

EXPERIMENTAL

The rate of reactions in the solid–liquid systems is commonly analyzed in terms of the topochemical kinetics [6, 7]. The specificity of such processes is determined by the development with time of the reaction zone in the solid and the related change of reaction regimes of the process. If we consider dissolution (leaching) of some components of a microscopically inhomogeneous solid, it seems reasonable to assume that the surface, "ideally smooth" in the beginning of the process, is gradually pierced by pores and covered with reaction products. This leads to the appearance of a surface porous layer largely determining the macrokinetics of the process. In this case, the surface reaction can be considered quasi-homogeneous and a description method can be used, similar to that used in describing the kinetics of gas absorption with a chemical reaction. The reaction kinetics and diffusion are closely related, and the rate of such a process may be independent of the stirring intensity [8].

One of the most widely used methods of investigation of topochemical reactions [6] is the so-called method of equally accessible surface [7], assuming that such hydrodynamic conditions are created under which all points on the solid surface react at equal rates with the reagent diffusing from the core. This is only possible when the thicknesses of the hydrodynamic and diffusion boundary layers do not vary between the points. It has been established using methods of physicochemical hydrodynamics that the necessary conditions are created when a solid disc is rotated far from the vessel walls [9, 10]. Indeed, in this case the thickness of the diffusion boundary layer, δ, can be expressed, as shown by Levich [9], as follows:

$$\delta = 1.62D^{1/3}\nu^{1/6}\omega^{-1/2}, \quad (1)$$

where D is the molecular diffusion coefficient, ν is the

1070-4272/01/7403-0374$25.00

kinematic viscosity coefficient, and ω is the angular velocity of disc rotation.

According to the first Fick's law, the mass flux j can be expressed in terms of the diffusion coefficient D and concentration gradient at the disc surface

$$j = -D\,\mathrm{grad}C = -D(C^* - C_i)/\delta. \quad (2)$$

Substituting (1) into Eq. (2), we have

$$j = 0.620\,D^{2/3}\nu^{-1/6}\omega^{1/2}(C^* - C_i). \quad (3)$$

The limiting disc dissolution rate is achieved in the external diffusion region, when the reagent concentration at the disc surface, C_i, becomes zero. In this case, the mass flux is proportional to the volume concentration of acid, C^*, and grows in proportion to $\omega^{1/2}$:

$$j = 0.620\,D^{2/3}\nu^{-1/6}\omega^{1/2}C^*. \quad (4)$$

In passing to the external kinetic, internal diffusion, or internal kinetic regions [7], the mass flux must become independent of ω, i.e., we have a self-similar mode with respect to the Reynolds number Re, which means that the Re number appears in Eqs. (3) and (4) to zero power. The theoretical values of the rate constants k_t were calculated by the formula

$$k_t = 0.620\,D^{2/3}\nu^{-1/6}\omega^{1/2}. \quad (5)$$

The rotating disc method is widely used for studying the kinetics of electrochemical processes and dissolution of various compounds [10].

The experiment was carried out with a rotating Teflon cylinder having a hollow 0.5 cm in diameter for a disc to be dissolved. A pellet of a substance under study was inserted into this hollow by means of an oil press developing a pressure of up to 40 kg cm^{-2}. The rotation velocity of the disc was varied between 330 and 3600 rpm. The leaching was done in a 200 cm^3 thermostated vessel. The pH value was monitored with an Anion 410 pH meter. Control measurements of the cadmium and zinc ion concentrations were performed by atomic absorption spectroscopy.

A schematic of the setup used to study the kinetics of leaching by the rotating disc method is presented in Fig. 1. The concentration change in the bulk of a solution flowing around the disc, dC/dt, can be expressed as

$$\mathrm{d}C/\mathrm{d}t = -aD(C^* - C_i)/\delta = -ak_e(C^* - C_i). \quad (6)$$

Thus, we can calculate from experimental data the effective rate constant of dissolution, k_e:

$$k_e = -(\mathrm{d}C/\mathrm{d}t)/a(C^* - C_i), \quad (7)$$

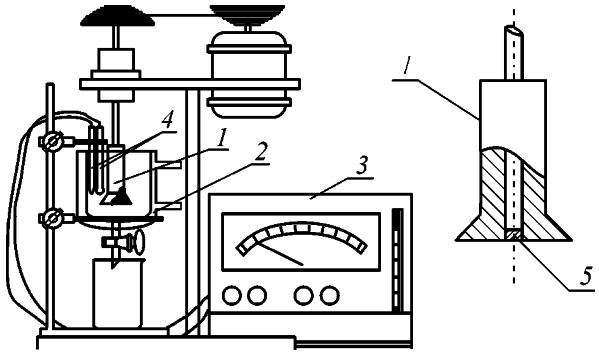

Fig. 1. Setup for studying the kinetics of leaching by the rotating disc method: (*1*) rotating disc with inserted pellet of a substance under study, (*2*) thermostated vessel, (*3*) Anion 410 A pH meter, (*4*) electrodes, and (*5*) pellet of a substance under study.

where $a = S/V$ is the specific surface area of the disc, i.e., the ratio of the apparent disc surface area S to the volume V of the solution flowing around the disc.

The k_e value coincides with the mass-transfer coefficient in the external diffusion region or with the rate constant k_c of a pseudo-first-order reaction in the external kinetic case. In the transition mode $k_e = f(k, k_c)$.

The k_e can also be found using the integral method. Separating variables in Eq. (6) and setting for simplicity $C_i = 0$ (i.e., taking that the process occurs in the external diffusion region), we get

$$-\int_{C^*}^{C} \mathrm{d}C/C = \int_0^t ak_e\,\mathrm{d}t. \quad (8)$$

Integration gives the equation for the kinetic curve

$$-\ln C = -\ln C^* + ak_e t, \quad (9)$$

or, with hydrogen ions consumed,

$$\mathrm{pH} = \mathrm{pH}^* + ak_e t. \quad (10)$$

Thus, having plotted the functions pH = $f(t)$, we can calculate the ak_e values from their slopes and, knowing a, determine k_e:

$$a = 0.785d^2/V, \quad (11)$$

where V is the volume of the leaching solution.

Figure 2 presents the pH of the aqueous medium in relation to the time of zinc oxide dissolution in the interval pH 2–5 at 298 K and disc rotation velocity of 1400 rpm.

Figure 2 shows that the dependence of pH on the

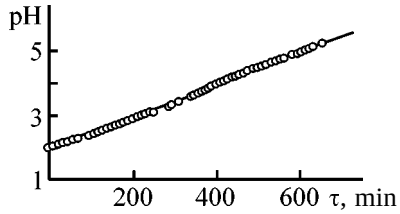

Fig. 2. pH of the reaction medium vs. the time τ of zinc oxide dissolution at 298 K and disc rotation velocity of 1400 rpm.

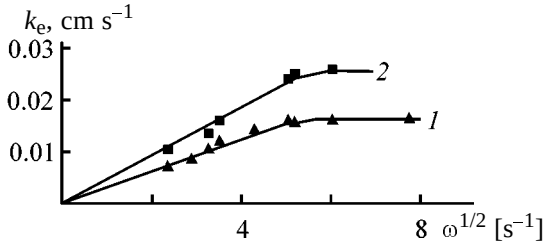

Fig. 3. Experimental rate constants k_e of zinc oxide leaching vs. the angular rotation velocity ω of the disc at (*1*) 293 and (*2*) 308 K.

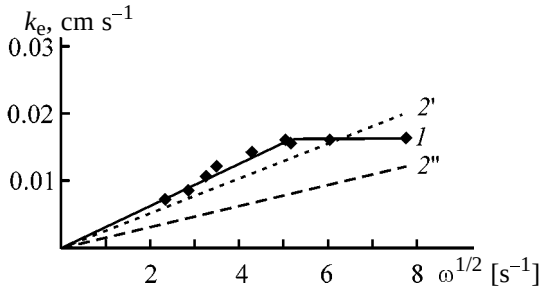

Fig. 4. Experimental rate constants k_e of zinc oxide leaching vs. the angular rotation velocity ω of the disc at 293 K. (*1*) Experiment; calculation: (*2*') for sulfuric acid and (*2*") for zinc sulfate.

process duration is linear, in accordance with Eq. (10). This indicates that the process rate is first-order with respect to the acid concentration. Indeed, as follows from extensive published evidence, the first order with respect to the leaching agent occurs the most frequently. For dissolution of zinc and cadmium hydroxides the time dependence of the pH is also linear. Changes in the concentrations of zinc(II) and sulfuric acid are exponential.

Figure 3 presents the experimental rate constants of zinc oxide leaching versus the square root of the angular velocity of disc rotation at 298 and 308 K. It can be seen that at disc rotation velocities in the range 330–1600 rpm (in the plot this interval corresponds to $\omega^{1/2}$ values up to 5.2 s$^{-1/2}$) the leaching rate constants k_e linearly depend on $\omega^{1/2}$. In this region the rate-determining stage of the process is either diffusion of acid toward the rotating disk of diffusion of zinc sulfate away from it.

At disc rotation velocities in the range 2200–3600 rpm the rate constants k_e of zinc oxide leaching are independent of the disk rotation velocity, which indicates a transition to the self-similar region. The nature of this self-similar region remains not quite clear. However, three reasons for such a kinetic behavior have been discussed, namely, transition of the process to (1) internal diffusion, (2) internal kinetic, or (3) external kinetic region. The last reason should be rejected since no significant dependence of k_e on T was observed in this region. In all probability, the true reason is the first one since the disc compacted from zinc oxide powder cannot be considered an absolutely smooth body and we have to reckon the possibility of development of a porous reaction zone. The second reason cannot be ignored, either, but it also assumes the development of a porous reaction zone.

Calculation by formulas (3)–(5) shows that, if the diffusion coefficient of sulfuric acid in the concentration range studied is taken to be 1.5×10^{-5} cm^2 s^{-1}, the calculated k_e are approximately 20% lower than the experimental values (Fig. 4). If we assume that the rate-determining stage of the process is the transport of zinc sulfate away from the disc ($D_{ZnSO_4} = 0.86 \times 10^{-5}$ cm^2 s^{-1}), then the agreement with experiment is much worse (the calculated k_e are half the experimental values). Presumably, it should be assumed that, up to a disc rotation velocity of 2000 rpm, the rate-determining stage is still the supply of sulfuric acid to the reaction zone, and a certain disagreement between the calculation and experiment can be attributed to the effect of the disc surface roughness, i.e., to a difference between the true and apparent surface areas. From the hydrodynamic standpoint, the roughness itself must only reduce the k_e value in a turbulent, but not laminar, mode of flow around the disc [9].

The obtained results indicate that (1) the reaction of sulfuric acid with zinc oxide is irreversible even at so low acid concentrations and (2) in the entire investigated range of sulfuric acid concentrations the rate-determining stage is the diffusion of sulfuric acid from the volume of the leaching aqueous solution.

As also in the case of zinc oxide, a linear dependence of experimental rates of the process on $\omega^{1/2}$ is observed in zinc hydroxide leaching at disc rotation velocities in the range 330–2600 rpm. However, in contrast to the oxides, this dependence is preserved up to 3600 rpm. This fact confirms once again the above assumption about the nature of the self-similar mode. Indeed, in the case of an essentially smooth and per-

Rate constants of the topochemical process of (a) zinc oxide, (b) zinc hydroxide, and (c) cadmium hydroxide leaching

ω, s^{-1}	Rate constant of leaching, k_e, cm s^{-1}, at indicated T, K

meable boundary of gel-like zinc hydroxide, there is no plateau in the $k_e = f(\omega^{1/2})$ plot. Thus, the plateau in this plot in dissolution of oxides is due to the porosity of the surface layer of the pellet.

The dependence of the experimental rate constants of cadmium hydroxide leaching on $\omega^{1/2}$ is also linear in the range ω = 330–2600 rpm.

The table lists the experimental rate constants of the topochemical process of leaching of zinc and cadmium oxides and hydroxides at various temperatures and disc rotation velocities. Comparison of the experimental rate constants of zinc oxide and hydroxide suggests that the rate of hydroxide dissolution somewhat exceeds the rate of oxide dissolution. We do not venture to account for this by higher kinetic hindrance in dissolution of the oxide, compared with that of the hydroxide, since such details already belong to the microkinetics of the process, which can only be discussed in the kinetic mode.

The dependence of $\ln k$ on $1/T$ in leaching of zinc oxide and zinc and cadmium hydroxides is linear. The following activation energies were obtained for the respective processes: 16 ± 2 (ZnO), 14 ± 2 [$Zn(OH)_2$], and 17 ± 3 kJ mol^{-1} [$Cd(OH)_2$]. These activation energies, coinciding within experimental error, are characteristic of diffusion-controlled processes.

CONCLUSIONS

(1) Rate constants of leaching of zinc oxide and hydroxide, and also cadmium hydroxide, with sulfuric acid solutions are obtained at pH 2–5 and 288–313 K at disc rotation velocities in the range 300–3600 rpm.

(2) Kinetic regions of the topochemical processes of zinc and cadmium leaching were revealed and it was demonstrated that under the conditions studied the dominant process is external diffusion of sulfuric acid from the bulk of the leaching solution. The activation energies of zinc oxide and hydroxide, and also cadmium hydroxide, were found.

(3) A transition of the kinetics of leaching to the self-similar mode region, possibly due to the roughness of the zinc oxide surface, was established.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Kinetics of Formation of Cobalt Carbonyls from Aqueous Solution of Cobalt Acetate in the Presence of Cyclohexanone in the Liquid–Liquid–Gas Heterogeneous System

Yu. T. Vigranenko, V. M. Gavrilova, and G. N. Gvozdovskii

VNIINeftekhim Joint-Stock Company, St. Petersburg, Russia

Received September 7, 2000; in final form, December 2000

Abstract—Cobalt carbonyls was prepared from an aqueous solution of cobalt acetate containing or not containing pyridine in the presence of the organic solvent immiscible with water. The product in the form of an organic solution can be used as hydroformylation catalyst. The kinetic equation taking into account the distribution of the reagents between the three phases was derived. The apparent rate constants and activation energies were calculated.

Industrial preparation of aldehydes form olefins and a CO + H_2 gas mixture is performed by hydroformylation [1]:

$$RCH{=}CH_2 + CO + H_2 \xrightarrow{\text{Cat.}} RCH_2CH_2CHO. \quad (1)$$

One of the steps of this process is preparation of the catalyst. The most suitable procedure for preparing cobalt carbonyls from solutions of cobalt salts is based on the reaction

$$4Co(RCOO)_2 + 16CO + 5H_2 \rightarrow Co_2(CO)_8 + 2HCo(CO)_4 + 8RCOOH. \quad (2)$$

We used cobalt acetate as the precursor since it is available and the resulting catalyst can be readily separated from the reaction products. Cyclohexanone was the solvent. Data on the kinetics of formation of cobalt carbonyls from an aqueous solution of $Co(OAc)_2$ in the presence of organic solvent in the liquid–liquid–gas system are lacking. It is only reported [2] that cobalt carbonyl is formed in a $Co(OAc)_2$ + toluene mixture. This reaction is heterogeneous and is controlled by diffusion. In this work we studied the kinetics of cobalt carbonyl formation in the above system.

Synthesis of cobalt carbonyls was studied in a 0.5-l ideal mixing batch reactor of the Vishnevskii screw type [3]. The unit consists also of high-pressure surge tanks for hydrogen, carbon oxide, and their mixture and a 0.25-l high-pressure charger for introducing the components of the reaction mixture into the reactor. The reactor purged with carbon monoxide was charged with cyclohexanone. A CO + H_2 mixture was fed at a pressure of 9.0 MPa, and stirring and heating were switched on. An aqueous solution of $Co(OAc)_2$ was poured into the charger. When pyridine was used it was introduced in the reactor with the organic solvent. The mixture was heated to the required temperature with stirring, and the $Co(OAc)_2$ solution was fed by the synthesis gas into the reactor. In the course of the synthesis the samples of the liquid were taken, and the aqueous and organic phases were separated. The cobalt(II) content was determined spectrophotometrically [4]; and the content of cobalt carbonyls, by iodometric titration [5].

Since cobalt acetate is practically nonvolatile, reaction (2), apparently, does not occur in the gas phase. The general kinetic equation of the reaction in the system of two immiscible liquid is as follows:

$$W = -\alpha\frac{d[Co(OAc)_2]^{(1)}}{dt} - (1-\alpha)\frac{d[Co(OAc)_2]^{(2)}}{dt}, \quad (3)$$

where α and $(1 - \alpha)$ are the volume fraction of the first (aqueous) and second (organic) phases, respectively.

Since $Co(OAc)_2$ is insoluble in cyclohexanone, $[Co(OOAc)_2]^{(2)} = 0$. Hence Eq. (3) can be written as

$$W = -\alpha\frac{d[Co(OAc)_2]^{(1)}}{dt}.$$

In accordance with the law of mass action

$$W = \alpha k[Co(OAc)_2]^{n_1} p_{H_2}^{n_2} p_{CO}^{n_3},$$

where n_1, n_2, and n_3 are the reaction orders with respect to $Co(OAc)_2$, H_2, and CO, respectively.

1070-4272/01/7403-0378$25.00

Finally, the kinetic equation of reaction (2) of formation of cobalt carbonyls is as follows:

$$W = k_{app}[Co(OAc)_2]^{n_1} p_{H_2}^{n_2} p_{CO}^{n_3}, \quad (4)$$

where $k_{app} = \alpha k$ is the apparent rate constant of reaction (2).

The kinetics of reaction (2) was studied as influenced by the salt concentration, partial pressures of hydrogen and carbon monoxide, and temperature. The rate of formation of cobalt carbonyls was calculated by numerical differentiation of the kinetic curves of $Co(OAc)_2$ consumption in the liquid phase. For this purpose we used the Lagrangian interpolation polynomial constructed using the experimental data [7]. The reaction order n_1 with respect to $Co(OAc)_2$, calculated by the van't Hoff procedure (Fig. 1a) from Eq. (5)

$$\log W_0 = \log [Co(OAc)_2]_0 + \text{const}, \quad (5)$$

was 1. This is also indicated by the fact that a given $Co(OAc)_2$ conversion at different salt concentrations (see table) is attained in the same time. The orders of reaction (2) with respect to hydrogen and carbon monoxide n_2 and n_3, calculated similarly, are 0.8 and 0.4, respectively (Figs. 1b, 1c).

The apparent rate constants of reaction (2) were calculated by the first-order equation [8]:

$$k_{app} = \tau^{-1} \ln \frac{[Co(OAc)_2]_0}{[Co(OAc)_2]_\tau}: \quad (6)$$

T, °C	135	150	165	180
$k_{app} \times 10^2$, min^{-1}	1.78	2.4	3.6	5.5

The activation energy E_A and the pre-exponential factor k_0 calculated form the temperature dependence of k_{app} are 41.7 kJ mol^{-1} and 2.9×10^3 min^{-1}, respectively.

Along with cobalt hydrocarbonyl $HCo(CO)_4$, cobalt carbonyl pyridine complex (CCP) is used as hydroformylation catalyst. This complex allows single-step preparation of alcohols form olefins [9]. The pyridine complex is a mixture of $[CoPy_6]^{2+}[Co(CO)_4]_2^-$ and $PyH^+Co(CO)_4^-$ salts and is formed by the reaction

$$8Co(OAc)_2 + 24CO + 9H_2 + 14Py \rightarrow 2[CoPy_6]^{2+}[Co(CO)_4]_2^- + 2PyH^+Co(CO)_4^- + 16HOAc. \quad (7)$$

Irreversibility of reaction (7) is also conformed by stability of CCP on relatively long storage. The kinetic equation (4) for reaction (7) takes the following form:

$$W = k'_{app}[Co(OAc)_2]^{n_1} p_{H_2}^{n_2} p_{CO}^{n_3} [Py]^{n_4}, \quad (8)$$

where k'_{app} is the apparent rate constant of reaction (7)

Influence of the initial concentration of cobalt acetate on the time of its 90% conversion in reaction (2) at T = 165°C, p = 29.4 MPa, CO : H_2 volume ratio = 1 : 1, and α = 0.5

$[Co(OAc)_2]$, M, in the aqueous phase	Time, min
1.94	65
3.77	63
6.0	64

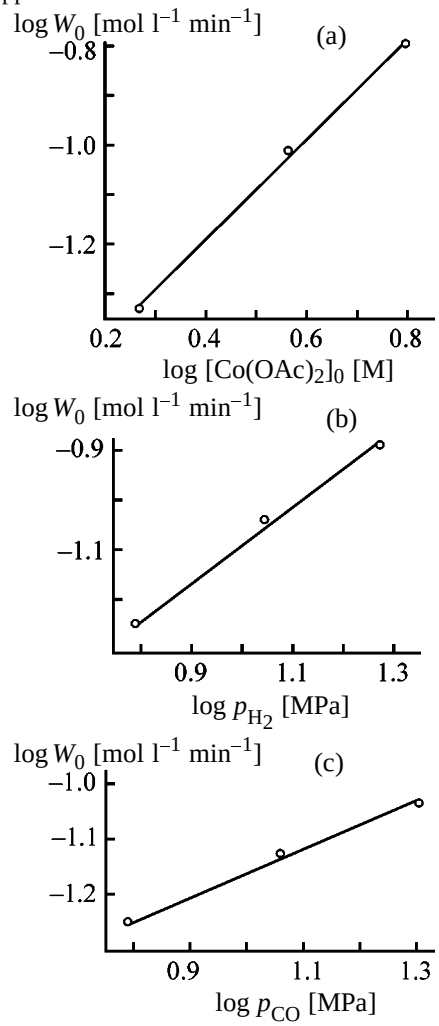

Fig. 1. Rate of $HCo(CO)_4$ formation W_0 at 150°C as a function of (a) the initial concentration $[Co(OAc)_2]_0$, (b) the partial pressure of hydrogen p_{H_2}, and (c) the partial pressure of carbon monoxide p_{CO}. (a) p_{CO+H_2} = 29.4 MPa, CO : H_2 volume ratio = 1 : 1; (b) p_{CO} = 6.0 MPa, $[Co(OAc)_2]_0$ = 6.0 M; (c) p_{H_2} = 6.0 MPa, $[Co(OAc)_2]_0$ = 6.0 M; the same for Fig. 2.

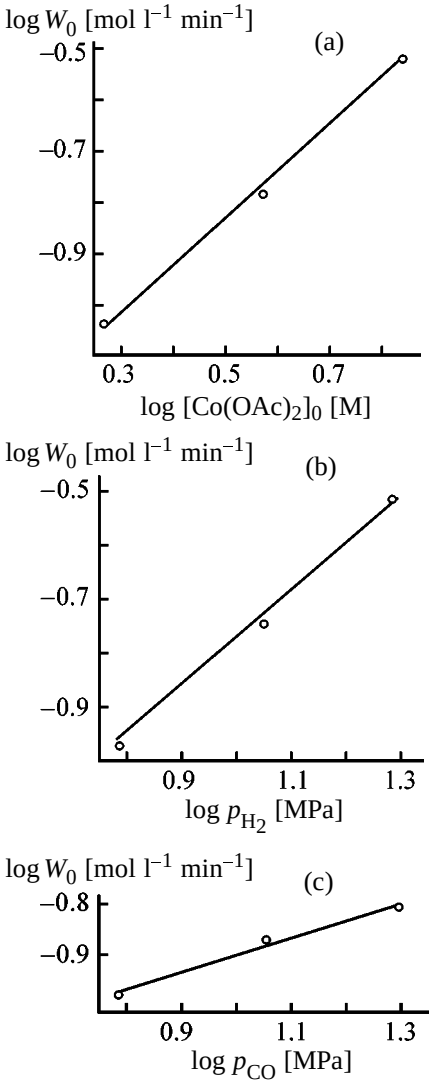

Fig. 2. Rate of CCP formation W_0 at 155°C as a function of (a) the initial concentration $[Co(OAc)_2]_0$, (b) the partial pressure of hydrogen p_{H_2}, and (c) the partial pressure of carbon monoxide p_{CO}.

and n_4 is the order of reaction (7) with respect to pyridine.

The kinetic features of CCP formation from $Co(OAc)_2$ and pyridine in cyclohexanone (Py/Co molar ratio 2, $\alpha = 0.5$) are similar to those of formation of $Co(CO)_8$ and $HCo(CO)_4$ (Figs. 2a–2c): the orders of reaction (7) with respect to $Co(OAc)_2$ ($[Co(OAc)_2] = 0–6.0$ M), H_2 (0–19 MPa), and CO (6–20 MPa) are 1, 0.9, and 0.3, respectively; E_A = 44.8 kJ mol^{-1} at 140–185°C; and $k_0 = 9.7 \times 10^4$ min.

The apparent rate constants of CCP formation by reaction (7) form $Co(OAc)_2$ and pyridine in cyclohexanone at $\alpha = 0.5$ and Py/Co molar ratio of 2 are as follows:

T, °C	140	155	175	185
$k'_{app} \times 10^2$, min^{-1}	2.76	4.37	6.0	10.5

CONCLUSIONS

(1) Formation of cobalt carbonyls from an aqueous solution of cobalt acetate, pyridine (or without pyridine), and the synthesis gas CO + H_2 in the presence of cyclohexanone in the liquid–liquid–gas heterogeneous system has the first order with respect to $Co(OAc)_2$ and the positive fractional orders with respect to H_2 and CO.

(2) The kinetic equation for calculation of the apparent rate constants and activation energies of formation of cobalt carbonyls in the liquid–liquid–gas heterogeneous systems were derived from the law of mass action.

Received April 27, 2000; in final form, January 2001

Abstract—A deposit formed on the surface of steel chips in the course of prolonged interaction of their water-sprayed bed with air containing small amounts of hydrogen chloride was studied by thermogravimetry. The quantitative and qualitative composition of the deposit was established.

The absorption of HCl (0.01–0.05 g m^{-3}) by water-sprayed steel chips (4–6-mm fragments) from air at ambient humidity results in the formation of a dark suspension in solution and in formation of a black deposit on the surface of the chip bed. This deposit is not removed as the spraying intensity increases. At the same time it can be easily removed by mechanical stirring of the chips in the working solution or in water in a beaker. Particles of the deposit filtered off and dried at 105°C present a finely dispersed soot-like powder. In storage this powder randomly agglomerates into lumps of various size, easily crushed on weak pressing. The main part of the particles and agglomerates is magnetic. As the above-described procedure allows the residual content of HCl in air to be decreased to a level less than 0.02 mg m^{-3}, it is important to establish the composition of the deposit under discussion.

EXPERIMENTAL

According to the published data [1–5], reactions in the system air–HCl–water–steel chips yield, in particular, iron oxides and hydroxides whose properties directly depend on their genesis [2].

The presence of oxygen and HCl in gas and liquid phases, water, and iron in the steel chips, pH of the solution (ca. 5), and also the color and magnetic properties of the powder obtained suggest the following sequence of reactions in the system:

$$Fe + 2HCl \rightarrow FeCl_2 + H_2,$$

$$FeCl_2 + 2H_2O \rightarrow Fe(OH)_2 + 2HCl,$$

$$4Fe(OH)_2 + O_2 \rightarrow 4FeOOH + 2H_2O,$$

$$2FeOOH + Fe(OH)_2 \rightarrow Fe_3O_4 + 2H_2O.$$

Black magnetite Fe_3O_4 is deposited in similar systems at pH 5.2–12.4 [5]. Lepidocrocite γ-FeO(OH) colored from dark red to reddish black can be synthesized from iron(II) compounds [2]. Slow hydrolysis of Fe(II) and Fe(III) salts and the oxidation of iron powder in water [2] are possible ways of the formation of goethite α-FeOOH (dark brown or black powder). The magnetic properties of the main part of the powder under study and its color suggest that magnetite prevails in the powder.

The thermogravigram obtained on heating the powder in air in a derivatograph furnace at a heating rate of 9 deg min^{-1} (Fig. 1a) suggests a complicated pattern of the sample transformations.

The TG curve reflects minor weight changes (within 1%) up to 900°C. The weight loss in the range from the start of heating to approximately 550°C is surpassed within the 100–230°C range by a relatively significant weight gain. In the range 550–640°C the weight of the sample remains almost constant, and from 640°C to 900°C it gradually increases.

On the whole, the shape of the DTG curve is in a good agreement with that of the TG curve. In a flat concave part of the DTG curve corresponding to the total weight loss at 20–550°C there are a noticeable positive peak (at ~100–290°C with a maximum at 200°C) corresponding to the weight gain recorded in the TG curve and a much smaller negative peak (at ~480–540°C with a minimum at ~520°C) correspond-

1070-4272/01/7403-0381$25.00

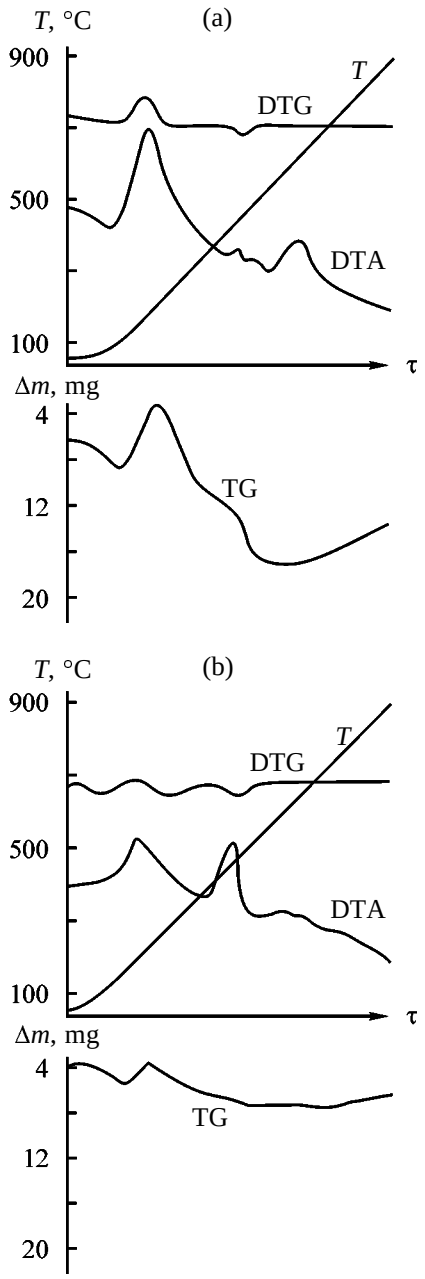

Fig. 1. Thermogravigram of the powder formed on water-sprayed steel chips through which an HCl–air mixture was filtered. The powder was dried at 105°C and kept in air. Heating rate 9 deg min^{-1}; (*T*) temperature, (Δm) weight change, and (τ) time. Sample (g): (a) 1.4243 and (b) 0.4271. Heating (a) in air and (b) in a helium atmosphere.

ing to the most intense weight loss. The weight gain within the 640–900°C range is not reflected in the DTG curve, which seems to result from its small value and insufficient sensitivity of the DTG galvanometer (1/15).

The initial portion (~20–80°C) of the DTA curve and its general downward trend at increasing temperature are indicative of a weak extended endothermic effect at 20–550°C with the weight loss. This effect overlaps with three exothermic transformations within this range. The first of them is the most pronounced (~100–460°C, maximum at ~220°C), it well agrees with the weight gain detected in the TG and DTG curves. The second (~480–525°C, maximum at ~505°C) and the third (~525–585°C, maximum at ~550°C) relatively weak peaks correspond to the weight loss at 480–585°C detected in the TG and DTG curves. The fourth clearly expressed exothermic deviation of the DTA curve corresponds to the part of the TG curve that reflects a very weak weight change at 585–730°C. The final almost linear part of the DTA curve is free of any peaks (temperatures above 730°C).

The final product of oxidative roasting of the deposit is a partially sintered powder containing rather easily crushed aggregates of characteristic red color typical for hematite α-Fe_2O_3. According to [2, 4, 5] this latter is a product of high-temperature treatment of magnetite in the presence of oxygen. Its magnetic properties are very weak.

Published data [2, 4, 5], as applied to Fig. 1, allow us to draw the following reasonable and reliable conclusions. The initial portion of the TG curve is obviously related to the loss of physically bound water. The weight growth at 100–230°C accompanied by the broad exothermic peak in the DTA curve, which is completed near 380°C, is attributable to the oxidation of magnetite (in practice, the oxidation of magnetite to maggemite γ-Fe_2O_3 is carried out at 200–250°C [5]) by the reaction

$$4Fe_3O_4 + O_2 \longrightarrow 6Fe_2O_3.$$

The weight growth in this reaction is

$$(1424.3 \times 32)/928 = 49.1 \text{ mg}.$$

This estimate is based on its stoichiometry and on the assumption that the whole mass of the sample under test (1.4243 g) is related to magnetite, which is a stable phase at room temperature [5].

However, the weight growth detected by the TG curve in this temperature range is significantly less. Moreover, the shape of the TG curve points to the simultaneous and finally prevailing competitive process of weight loss. It seems to be due to the presence of substances other than magnetite, which lose weight at this temperature. These substances, proba-

bly, mask (reduce) the real growth of the sample weight. Taking into consideration the color of the sample, we assume that γ-FeO(OH) and α-FeOOH can be such substances.

For example, goethite α-FeOOH transforms to hematite α-Fe_2O_3 upon dehydration at 50–500°C [2]. This transformation occurs without intermediate stages and is accompanied by a significant increase in surface area due to crystal destruction. Lepidocrocite γ-FeO(OH) is dehydrated at 180–300°C to give maggemite γ-Fe_2O_3, which is ferromagnetic like Fe_3O_4. On further heating maggemite also transforms to hematite with an exothermic effect.

Therefore, the total weight loss at 20–540°C can be assigned to the evaporation of both physically bound water and structural water. It should be noted that bonding of excess water in hydrated iron oxides and hydroxides is intermediate between adsorption and chemical bonds [2].

The TG curve allows us to estimate the composition of the powder under study. We assume that the resulting weight loss in the range 20–350°C (10.5 mg) is a consequence of two parallel processes, namely, the oxidation of magnetite and the dehydration of iron hydroxides by the reaction

$$2FeOOH \rightarrow Fe_2O_3 + H_2O.$$

If we denote weights (mg) of magnetite and iron hydroxide in a sample (1.4243 mg in total) as x and y, respectively, the weight gain due to the oxidation of Fe_3O_4 Δm_{ox} and the weight loss due to the dehydration of FeO(OH) and FeOOH Δm_{deh} in the chosen temperature range can be expressed, according to the stoichiometry of these reactions, as $\Delta m_{ox} = 32x/928$ and $\Delta m_{deh} = 18y/178$. This allows us to construct the following system of equations:

$$\begin{cases} 18y/178 - 32x/928 = 10.5, \\ x + y = 1424.3. \end{cases}$$

A solution of this system with respect to x and y shows that 69.14% of the sample weight is Fe_3O_4 and 30.86% is a sum of iron hydroxides FeOOH and FeO(OH).

The exothermic doublet in the DTA curve at 480–590°C corresponds to the parts of the TG curve with increasing intensity of weight loss. This doublet can be assigned to the transformation of maggemite into hematite. However, we cannot rule out a relation between this doublet and other modifications of Fe_2O_3 present in the starting sample (or formed by its thermal oxidation), which are capable of phase transformations (for example, δ-Fe_2O_3 and ε-Fe_2O_3). It is known [2] that ε-Fe_2O_3 is an unstable compound irreversibly transforming into α-Fe_2O_3 at 550°C. This temperature clearly corresponds to the maximum of the second peak in the doublet under discussion. Finally, there is an apparent, but not clearly explained in available literature, relation between this doublet and final (and definitely dissimilar) stages of dehydration of the sample in the temperature range under consideration.

A significant exothermic effect in the DTA curve at 580–710°C with a maximum at 660°C corresponds to the almost linear part of the TG curve. This effect is presumably related to the Curie point of γ-Fe_2O_3 (675°C) [4], which can exist in this region, and (or) to a change in magnetic properties of α-Fe_2O_3 (677°C).

When the temperature in similar systems rises to 700°C, traces of wustite FeO can appear [4]. Its oxidation seems to give rise to a weak growth of the sample weight detected in the final portion of the TG curve.

To refine our data, we recorded a thermogravigram of the powder heated in a helium atmosphere under the same conditions (Fig. 1b). The TG, DTG, and DTA curves of this thermogravigram differ essentially from the curves in Fig. 1a.

Despite general similarity of the TG curves, the curve in Fig. 1b even at room temperature exhibits a weak weight gain, which at approximately 30°C gives way to weight loss. In the range 180–255°C the sample weight grows again. At higher temperatures (up to 550°C) the weight loss again becomes prevailing, and then the sample weight remains almost constant up to 770°C. The weight of the sample grows only at higher temperatures up to the end of the heating.

The TG curve in Fig. 1b differs from the TG curve in Fig. 1a in the shape of the initial section, in much higher temperatures of the onset of weight gain (180 against 105°C), its maximum (~255 against 225°C), and completion (~415 against 380°C), of practical termination of weight loss (~550 against 540°C), and also of the beginning of the final weak and gradual weight gain (770 against 650°C).

In Fig. 1b the DTG curve is consistent in shape with the TG curve. A weak weight gain recorded in the TG curve at a near-room temperature is confirmed by the initial portion of the DTG curve. This increase is followed by a flat lowering of the DTG curve in the

range 30–500°C, which also confirms the total weight loss observed in the TG curve. There is a maximum in the DTG curve in Fig. 1b at 210°C in the range 100–325°C, which partially coincides with the range of the weight gain in the TG curve (~180–410°C). The subsequent negative peak in the DTG curve covers the range 460–600°C and has a minimum at 530°C. This minimum is in a good agreement with a well pronounced weight loss at 460–550°C in the TG curve. The region of the DTG curve above 600°C is almost linear, and a tendency to its extremely weak and gradual rise can be a very insignificant evidence for a certain weight growth detected in the TG curve above 770°C.

A comparison of the DTG curves in Figs. 1a and 1b shows that, in spite of their general similarity, the curve in Fig. 1b has a positive deviation near room temperatures, its peak with a maximum close to 200°C is more stretched and somewhat shifted to higher temperatures (~210 against ~200°C), its negative peak with a minimum at 530°C is also more stretched and shifted by approximately 5°C to higher temperatures, and its final portion has a certain slope.

It should be also noted that the products of calcination of the powder in a helium atmosphere and under oxidative conditions have the same color and properties.

The DTG curve in Fig. 1b is characterized by a broad exothermic peak in the 20–600°C range and by two well pronounced peaks covering the 20–450°C and 450–600°C ranges and having maxima at 235 and 520°C, respectively. Above 600°C there is a weak exothermic doublet in the DTA curve in the range 600–740°C with two maxima at 660 and 720°C. Above 740°C the DTA curve monotonically descends, exhibiting two very weak exothermic deviations with maxima at approximately 805 and 890°C.

The DTA curves in Figs. 1a and 1b differ to the greatest extent. The initial portion of the curve in Fig. 1b shows a definitely exothermic effect in contrast to that in Fig. 1a. The first exothermic peak in the curve in Fig. 1b spans the range 20–450°C, whereas the similar peak in Fig. 1a corresponds to the range 100–460°C. The maxima of these peaks are also situated at different temperatures: 235 and 220°C, respectively. In the range 450–600°C the curve in Fig. 1b has a well-pronounced second exothermic peak with a maximum at 520°C, and the curve in Fig. 1a has a significantly less distinct exothermic doublet with maxima at 500 and 560°C. On the contrary, in the range 600–740°C a well pronounced exothermic transformation with a maximum at 660°C in Fig. 1a corresponds to a weak exothermic doublet in Fig. 1b with maxima at 660 and 720°C. Finally, the region of the DTA curve in Fig. 1b above 740°C corresponds to the exothermic process in contrast to that in Fig. 1a.

The above-mentioned differences in thermogravigrams of Figs. 1a and 1b can be caused by the following reasons. At the beginning of the sample heating under helium, this gas is adsorbed by finely dispersed particles of the sample, which results not only in the weight gain detected in the TG and DTG curves, but also in heat liberation detected in the DTA curve below 100°C as an exothermic peak in Fig. 1b, unlike the same region in Fig. 1a where an endothermic deviation was found. The shapes of the both TG curves at temperatures higher than 100°C are almost the same. The dehydration of iron hydroxides and the oxidation of Fe_3O_4 on heating under helium begin and end at considerably higher temperatures, as follows from the comparison made above.

Calculations of the composition of the powder sample characterized by Fig. 1b gave 68.49% Fe_3O_4 and 31.51% iron hydroxides (the absolute difference from our earlier estimation is 0.65%).

Thus, as in the previous case, the weight gain in the range 180–250°C detected in the TG and DTG curves in Fig. 1b and the corresponding exothermic peak in the DTA curve are due to the oxidation of magnetite with oxygen, which is possibly present around crucibles in a small amount sufficient for oxidation. The limited oxygen content in this space causes the shift in the parameters of Fe_3O_4 oxidation (onset, end, and maximum) toward higher temperatures, as seen from the TG, DTG, and DTA curves.

The exothermic doublet in the DTA curve in Fig. 1a at 480–590°C corresponds to a single exothermic peak in the DTA curve in Fig. 1b at almost the same temperatures (460–600°C) with a maximum at 515°C. As in Fig. 1a, it probably results from the exothermic transformation of maggemite into hematite. The greater value of this peak suggests in this sample the increased content of lepidocrocite among iron hydroxides.

Probably, oxygen deficiency around crucibles suppresses the formation of one or more modifications of Fe_2O_3 and, in contrast, facilitates formation of other modification(s), which leads to degeneration of the doublet into a single peak. As a consequence, a single exothermic effect at 580–730°C in the DTA curve in Fig. 1a is transformed into a smooth exothermic effect, extended along the temperature axis (~600–

770°C) and having a clear tendency to splitting in two peaks. This effect also corresponds to the more extended portion of the TG curve, where no essential weight changes are observed. As assumed earlier, this effect is attributable to the magnetic properties of Fe_2O_3 modifications. Low oxygen content in the furnace atmosphere is probably responsible also for a significant shift of the onset of certain weight gain, completing sample heating, toward higher temperatures (from ~650 to ~770°C).

CONCLUSIONS

(1) Thermogravigrams were obtained under helium and in air for a deposit formed on steel chips at their treatment with humid air containing 0.01–0.05 g m^{-3} HCl. A comparative examination of the thermogravigrams was carried out.

(2) It was found that the deposit contains about 68.5–69.1% magnetite and 30.9–1.5% iron hydroxides. Lepidocrocite is the prevailing fraction among the hydroxides.

Abstract—The fractionation of sulfur isotopes, namely, enrichment of the cinder with the heavy isotope ^{34}S in the course of roasting of various sulfide ores and concentrates in neutral and oxidative atmospheres at 773–973 K was studied.

High-temperature oxidative roasting is widely used today as one of main overhead stages in processing copper–nickel and copper sulfide concentrates. Therefore, roasting processes attract steady researches' interest. A significant attention is paid to the mechanisms of oxidation and dissociation of sulfur,[1] which is the major component removed upon the roasting.

It is well known that isotopes can be fractionated in the course of chemical reactions, i.e., fractions of isotopes in products can differ from those in the starting reagents. Therefore, it is not improbable that studying the fractionation of sulfur isotopes can give a new qualitative information on reaction mechanisms, as compared to traditional techniques (chemical analysis, XRD, X-ray spectral microanalysis, etc.).

The fractionation of sulfur isotopes in the course of high-temperature oxidative roasting of copper–nickel sulfide ore of Pechenga ore field was established previously [1]. However, the data obtained could not be considered as fully reliable because of insufficient number of the experiments.

In this work the possibility of fractionation of sulfur isotopes was confirmed not only for sulfide ores but also for Pechenga ore concentrates and natural pyrite at various temperatures in oxidative and neutral atmospheres.

[1] Oxidation of sulfur and dissociation of higher sulfides can occur simultaneously in spite of the fact that roasting is carried out in an oxidative atmosphere.

The composition of starting materials is given in Table 1. Pyrite was roasted at 773 and 873 K under argon in an installation shown in Fig. 1.

A 5-g pyrite sample in an alundum boat was first placed in a quartz tube and then in a furnace with a Silit heater. The tube was blown through with argon before switching on the furnace. On reaching a temperature of the experiment the quartz tube was moved to place the sample in the furnace hot area. In the course of the experiment the temperature was kept constant by an automatic apparatus. After roasting the sample was removed from the hot area by shifting the tube. The furnace was switched off, but the gas was passed through up to complete sample cooling.

After thorough grinding and mixing, the cooled sample was divided into two equal parts. One of them was chemically analyzed for the total sulfur and sulfate sulfur. The other part was used in the isotope mass-spectral analysis.

Copper–nickel sulfide ore and concentrate were roasted in air at 823 and 973 K. Preliminarily the ore and concentrate with the grain size less than 0.1 mm were pelletized with water added. A 4-g pellet sample was placed in a quartz reactor roughly modeling a fluidized-bed furnace (Fig. 2). The reactor was placed in a Silit furnace and heated. On reaching the required temperature, air was passed through the reactor bottom at a rate of 1.35 l min^{-1}. The oxidation time was varied from 1 to 15 min. On completion of the experiment, the air flow was ceased and the reactor

Table 1. Chemical composition of starting materials

Material	Content, wt %									
	Ni	Cu	Co	Fe_{total}	S_{total}	$S_{sulfate}$	SiO_2	Al_2O_3	CaO	MgO
Pyrite	0.09	0.10	0.01	39.8	44.60	1.01	8.4	0.42	0.24	0.22
Copper–nickel ore	2.44	0.65	0.06	27.4	13.78	0.41	22.0	0.66	1.90	19.20
Copper–nickel ore concentrate	7.68	4.00	0.23	30.4	20.18	0.13	16.8	3.70	0.66	11.20

was removed from the furnace. The cooled cinder was ground, weighed, and after thorough mixing divided into two parts. One of the parts was chemically analyzed for total sulfur and sulfate sulfur. The other part was used in the isotope analysis.

Determination of the sulfur isotope composition involves sample preparation, namely, complete conversion of sulfur in the sample to sulfur dioxide, and subsequent analysis of SO_2 by mass spectrometry [2].

A ground weighed sample was thoroughly mixed with a threefold excess of an oxidant. Copper(II) oxide of analytical pure grade was used as the oxidant. A mixture of the ore and copper(II) oxide was loaded in a porcelain boat placed in a quartz reactor. The system was evacuated to a pressure of 2×10^{-2} mm Hg. After evacuation the reactor was placed in a tubular furnace, the temperature was gradually raised to 573 K, and the sample was degassed within 30 min. Then the reactor was removed from the furnace, the temperature was raised to 1053–1083 K, and the reactor with the combustion boat was placed back in the furnace. The system was disconnected from the vacuum pump, and the trap was placed in a Dewar flask with liquid nitrogen. The evolved sulfur dioxide was frozen out in the trap. Sulfur from the sample was oxidized for 80 min. Sulfur dioxide from the trap was evaporated and refrozen in a quartz ampule, which was sealed and then analyzed by a standard technique on a double-beam mass spectrometer with a two-channel lap system. Sulfur from a reference sample was oxidized similarly.

Cinders after oxidative roasting of copper–nickel sulfide ore were analyzed on an MI-1330 mass spectrometer,[2] and cinders obtained by pyrite roasting and oxidative roasting of the ore concentrate, on an MI-1201V mass spectrometer.[3]

The sulfur isotope composition in the samples under study is usually characterized by the ratio $^{32}S/^{34}S$ of only two isotopes [3], because the concentration of the other natural isotopes, ^{33}S and ^{36}S, is negligible. Variations in the sulfur isotope composition are expressed by the value of $\delta^{34}S$ (‰), which is calculated by the equation

$$\delta^{34}S = \frac{^{34}S/^{32}S_s - {}^{34}S/^{32}S_{ref}}{^{34}S/^{32}S_{ref}} \times 1000, \quad (1)$$

Table 2. Experimental conditions and data on pyrite roasting under argon

T, K	τ, min	S_{total}	$S_{sulfate}$	$\delta^{34}S$, ‰
		wt %		
initial sample		44.6	1.01	–2.0
773	1	44.4	1.03	5.6
773	2	44.2	0.17	5.2
773	10	43.9	1.03	0.1
873	5	44.1	0.84	1.4
873	10	44.7	0.74	0.5

where $^{34}S/^{32}S_s$ is the isotope ratio in a sample and $^{34}S/^{32}S_{ref}$ is that in a reference.

Troilite sulfur of the Canyon Devil meteorite is used as a universally recognized world [4]. In everyday practice an intermediate (working) reference is used instead of the absolute reference. The following formula is used for the conversion:

$$\delta^{34}S = (1 + \delta^{34}S_{ref/met}/1000)\delta^{34}S_{s/ref} + \delta^{34}S_{ref/met}, \quad (2)$$

where $\delta^{34}S_{ref/met}$ characterizes variations in the isotope composition of the working reference relative to the meteorite, and $\delta^{34}S_{s/ref}$ characterizes variations in the isotope composition of a sample relative to the working reference.

The positive sign of $\delta^{34}S$ indicates that sulfur is enriched with ^{34}S, and the negative sign, that sulfur is enriched with ^{32}S with respect to the meteorite sulfur. Further all analytical data are given relative to the above-mentioned international reference.

The accuracy of the $\delta^{34}S$ determination on MI-1330 and MI-1201V mass spectrometers was ±0.3 and ±0.1‰, respectively.

Experimental data on pyrite roasting are given in Table 2 and Fig. 3. They reveal appreciable fractionation of sulfur isotopes in the course of the pyrite dissociation. The maximal fractionation takes place in the initial stages of the roasting.

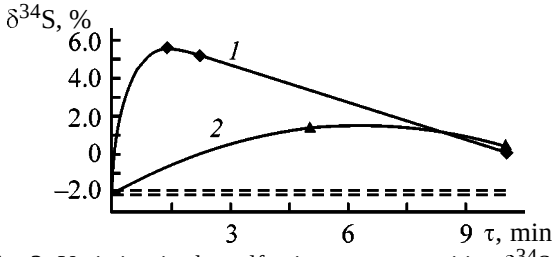

Fig. 3. Variation in the sulfur isotope composition $\delta^{34}S$ in a cinder obtained by pyrite roasting under argon. (τ) Time; the same for Fig. 4. Temperature (K): (*1*) 773 and (*2*) 873. Dashed lines denote limits of the accuracy of $\delta^{34}S$ determination in the initial sample; the same for Fig. 4.

Before discussing these data, we consider some aspects of the isotope separation theory. It was noted before that chemical transformations of molecules containing various sulfur isotopes are usually accompanied by their fractionation due to distinctions in their physicochemical properties, i.e., isotope distributions in the reagents and products change in a chemical reaction. This results from different mobility of molecules with light and heavy isotopes, which affects the reaction rate. Naturally, the rate is lower in the case of a heavier isotope.

The difference in rates may be partially caused by the difference in vibration frequencies of molecules with different isotopes [5]. However, this difference is unlikely to be significant at high temperatures.

The kinetic isotope effect is defined as the ratio of reaction rate constants of isotope species [6]:

$$k/k^* = (\mu^*/\mu)^{1/2} e^{-(E-E^*)/RT}, \quad (3)$$

where μ is the reduced mass of a molecule (asterisk designates a heavy isotope), E and E^* are activation energies of the reactions involving light and heavy isotopes, T is the absolute temperature, and R is the universal gas constant.

It is clear that the activation energy of the reaction involving a heavy-isotope species is higher that with a light-isotope form.

According to Eq. (3), the kinetic isotope effect depends on temperature and differences in the isotope masses and activation energies of various isotope forms. As the temperature increases, the isotope effect decreases. In the limiting case of $T \to \infty$ the exponential term approaches unity, and the isotope effect is determined by only the mass ratio. It should be noted that the mass difference between ^{32}S and ^{34}S is 7%.

Since bonds formed by a light isotope are weaker than those of a heavy isotope, the inequality $k/k^* > 1$ is valid, i.e., reaction products are usually enriched with a light isotope, and a heavy isotope is accumulated in the residue. Data in Fig. 3 are in a good agreement with these theoretical statements.

A significant enrichment of the cinder with ^{34}S is observed at the beginning of the dissociation (773 K), i.e., the $Fe^{32}S_2$ molecules dissociate preferentially. The enrichment decreases in time. The effect of cinder enrichment with ^{34}S at 873 K is less pronounced, which well agrees with Eq. (3).

Table 3. Experimental conditions and data on oxidative roasting of ore concentrate in fluidized bed

T, K	τ, min	S_{total}, wt %	$S_{sulfate}$, wt %	δS^{34}, ‰
Ore				
Starting	sample	13.78	0.41	5.3
973	1	11.48	0.14	5.6
973	5	4.73	0.37	5.0
973	10	0.90	0.58	6.8
Ore concentrate				
Starting	sample	18.9	1.48	8.2
823	3	14.5	1.00	9.5
823	10	10.6	1.78	9.2
823	15	10.2	2.02	7.5
973	1	16.9	0.57	7.9
973	3	13.3	0.71	9.4

To prove conclusively the fact of the enrichment with ^{34}S, it is necessary to correlate the content of sulfate sulfur with $\delta^{34}S$. Such a correlation is needed because ^{34}S is always accumulated preferentially in oxidized sulfur compounds in the following order: S^{2-}, S^0, SO_2, SO_3, SO_4^{2-}. This trend was the most completely demonstrated by Sakai and Bachinskii [4].

Consequently, if the sulfate content in pyrite samples strongly changes, a question arises whether the enrichment of a cinder with a heavy isotope results only from the lower content of sulfate sulfur in the sample under study. Table 2 demonstrates no explicit correlation between $\delta^{34}S$ and $S_{sulfate}$; however, during the first minutes of dissociation the cinder is appreciably enriched with ^{34}S irrespective of the content of sulfate sulfur in the sample.

The data on the oxidative roasting of the ore and concentrate are given in Table 3. Time dependences of the isotope compositions are presented in Fig. 4, which shows that the cinder is enriched with ^{34}S.

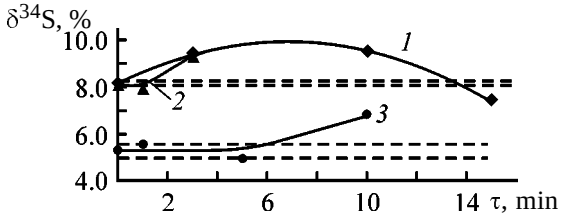

Fig. 4. Variation in sulfur isotope composition $\delta^{34}S$ in a cinder formed in the course of oxidative roasting of copper–nickel sulfide ore and ore concentrate. Sample: (*1*, *2*) concentrate and (*3*) ore. Temperature (K): (*1*) 823 and (*2*, *3*) 973.

At 823 K the enrichment is observed in the initial process stage, as is the case with pyrite dissociation.

In the case of roasting at 973 K the curves are differently shaped. However, in this case the cinder is also enriched with ^{34}S. We note that the enrichment at 973 K was found in the cases of various materials using different mass-spectrometric installations.

Thus, the experiments have shown that high-temperature (773–973 K) roasting of various sulfide ores and concentrates in neutral and oxidative atmospheres is accompanied by fractionation of sulfur isotopes, namely, enrichment of the cinder with ^{34}S.

The data on variation in time of the sulfur isotope composition in roasting gases would be no less valuable; however, such experiments require special equipment and development of appropriate technique.

CONCLUSIONS

(1) The greatest enrichment in roasting of natural pyrite under argon was observed within the first minutes at low temperatures. The maximal enrichment at 773 K was 6‰. In the case of roasting of copper–nickel sulfide ores and concentrates at 823 and 973 K, the maximal enrichment was 1.3–1.5‰.

(2) The regular trends revealed can be used in development of oxidative roasting theory for various sulfide materials.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

On the Accuracy of Calculation by the Clapeyron–Clausius Equation

I. B. Sladkov and M. S. Nedoshivina

St. Petersburg State Technical University, St. Petersburg, Russia

Received October 8, 2000

Abstract—The accuracy of calculations by the Clapeyron–Clausius equation in the entire region of existence of a liquid phase is discussed in relation to temperature or pressure.

By now, equations have been developed allowing reliable prediction of the saturated vapor pressure over the entire region of existence of the liquid phase [1]. However, these methods rely upon a vast body of difficultly accessible input data and cannot be applied to poorly studied substances.

The Clapeyron–Clausius equation gives in the simplest form the temperature dependence of the vapor pressure and is widely used in thermodynamic calculations. For some substances it yields an acceptable error in comparatively narrow temperature intervals, which is accounted for by the assumptions made in deriving and integrating the equation. At the same time, the Clapeyron–Clausius equation is valid for many substances in rather wide temperature intervals, which has been substantiated by the compensation effect recently [1, 2].

The temperature at which the pressure is determined may vary within the existence range of the liquid phase, beginning at the triple point and ending at the critical point. The problem of how the choice of temperature affects the error of the Clapeyron–Clausius equation has not been studied. In the present study, data were obtained making it possible to relate the conditions of application of the Clapeyron–Clausius equation (range of temperatures or pressures in which a calculation is performed) to the expected error in calculating the saturated vapor pressure.

As objects of study were chosen 10 substances for which precise data on the saturated vapor pressure are available in the literature for the entire range of existence of the liquid phase. These substances, their fundamental constants [2], and also sources of tabulated data on the saturated vapor pressure are listed in Table 1.

For the above substances, calculations by means of the Clapeyron–Clausius equation were performed in the entire range of existence of the liquid phase, i.e., in the temperature interval between the triple and critical points.

As is known, in integrating the approximate Clapeyron–Clausius equation

$$\mathrm{d}\ln P/\mathrm{d}T = \Delta H_\mathrm{v}/(RT^2)$$

the enthalpy of vaporization is taken to be equal to its value at the boiling point, ΔH_b, and the constant of integration is found from the saturated vapor pressure at the boiling point. This yields the equation

$$\ln P = -A/T + B, \qquad (1)$$

$$A = \Delta H_\mathrm{b}/R, \qquad B = \Delta S_\mathrm{b}/(RT_\mathrm{b}).$$

The pressures calculated using Eq. (1) were compared with experimental values, and the relative error of pressure calculation by the Clapeyron–Clausius equation was determined. An example of calculations for two substances is given in Table 2.

Further, the absolute values of the above errors were averaged for some temperatures or pressures over all the 10 substances considered. This average error is given in Tables 3 and 4 and is considered a measure of the accuracy of the Clapeyron–Clausius equation.

It was found that the following behavior is observed in the temperature interval between the triple and critical points: for all of the substances the calculation error grows with decreasing temperature (which corresponds to decreasing pressure). In the temperature interval between the boiling and critical points,

two types of behavior with temperature are observed for the calculation error Δ: for some substances Δ grows with increasing temperature, while for the others it remains approximately constant up to the critical point. Both types of dependences, plotted on the basis of the data in Table 1 for NH_3 and $CHClF_2$, are shown in Fig. 1. The difference $T - T_b$ is plotted along the abscissa, in order to bring into coincidence the zeros of the function and the argument (since the constant of integration of the Clapeyron–Clausius equation is found from the boiling point parameters, the equation gives zero error just for the boiling point).

The obtained data indicate that it is advisable to further analyze the accuracy of the Clapeyron–

Clausius equation for two temperature intervals: low-temperature ($T < T_b$) and high-temperature ($T > T_b$).

In the low-temperature region, the saturated vapor pressures of all the substances vary within the range from 0 to 0.1 MPa (the last figure is the rounding of a value of 0.10325 which gives in megapascals the saturated vapor pressure at the boiling point). Therefore, the accuracy of the Clapeyron–Clausius equation can be related both to pressure (Table 3) and to temperature (Table 4). Tables 3 and 4 show that the error in calculating the saturated vapor pressure becomes significant at pressures lower than 0.01 MPa or at temperatures deviating from the boiling point by more than 40 K.

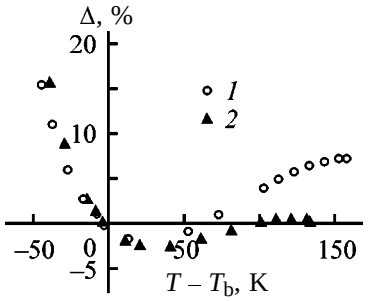

Fig. 1. Variation of the error of calculation by the Clapeyron–Clausius equation, Δ, with the distance from the boiling point. (*T*) Temperature. (*1*) NH_3 and (*2*) $CHClF_2$.

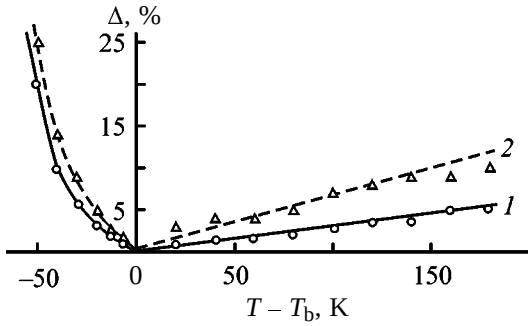

Fig. 2. (*1*) Average and (*2*) maximum error in calculating the saturated vapor pressure by the Clapeyron–Clausius equation vs. the calculation temperature *T*.

In the high-temperature region, it is impossible to set unambiguously the upper pressure limit because of the different critical pressures of all substances. Therefore, the accuracy of the Clapeyron–Clausius equation is given in relation to temperature (Table 4). It can be seen that in calculations above the boiling point the Clapeyron–Clausius equation ensures reliable prognosis of the saturated vapor pressure in sufficiently wide temperature intervals.

The results presented in Table 4 are summarized by the plot in Fig. 2, readily providing information about the expected average error in determining the pressure and the maximum error of calculation by the Clapeyron–Clausius equation in different temperature ranges. As seen from Fig. 2, the average error in calculating the saturated vapor pressure by the Clapeyron–Clausius equation in the temperature range from $T - T_b = -20$ to $T - T_b = 110$ K is relatively low and constitutes ±3%.

CONCLUSIONS

(1) It is shown that the accuracy of the Clapeyron–Clausius equation depends on calculation conditions (interval of temperatures or pressures for which a calculation is performed).

(2) In the low-temperature region ($T < T_b$) the calculation error increases dramatically when the pressure becomes lower than 0.01 MPa (or the calculation temperature deviates from the boiling point by more than 40 K).

(3) In the high-temperature region ($T > T_b$), the calculation error gradually grows when the critical point is approached, ensuring high reliability of the prediction of the saturated vapor pressure in a wide range of temperatures.

Received October 31, 2000

Abstract— The boiling point, molar volume of liquid at the boiling point, and enthalpy of vaporization at the boiling point were found by calculation for little-studied tin compounds SnH_2Cl_2 and $SnHCl_3$.

In the homologous series formed upon substitution of hydrogen atoms in the tin hydride molecule by chlorine (SnH_4, SnH_3Cl, SnH_2Cl_2, $SnHCl_3$, $SnCl_4$), only the end members of the series (SnH_4 and $SnCl_4$) have been studied in sufficient detail. Only scarce information is available about the properties of SnH_3Cl [1]. Published data on properties of dichlorostannane SnH_2Cl_2 and trichlorostannane $SnHCl_3$ are completely lacking. In particular, there is no information about such fundamental constants of the substances as boiling point parameters. In the present study, these properties of two poorly studied tin compounds are determined using calculation methods.

A reliable evaluation of the boiling point T_b of a compound under study can be made by comparative calculation methods, if boiling points are known for substances of the same type. Such methods are based on an analysis of variation in the boiling point in a series of compounds thermodynamically similar to the compound under study. The boiling points were determined using methods that were recommended in [1] and tested on a wide variety of molecular inorganic compounds. As compounds thermodynamically similar to those under study were chosen chlorosilanes. The properties of the compounds used to determine the physicochemical constants of little studied tin compounds are listed in Table 1.

The following relations were studied: (a) that between the boiling points of silicon and tin compounds in the homologous series EH_4, EH_3Cl, and ECl_4, where E is an element (Si or Sn); (b) that between the molar mass and the quantity $(T_bM)^{0.5}$ in the series of compounds SnH_4, SnH_3Cl, and $SnCl_4$; and that between the molar mass and the product of T_b by the parachor $\prod$ in the series of compounds SnH_4, SnH_3Cl, and SnH_4 (the parachor was calculated by the method described in [1]).

As an example, one of these dependences is shown in Fig. 1. It was established that all the three dependences are obviously linear. Their processing by the least-squares method gives the following equations:

$$T_b(SnH_mCl_n) = 0.98T_b(SiH_mCl_n) + 65.0, \quad (1)$$

$$(T_bM)^{0.5} = 1.07M + 40.81, \quad (2)$$

$$T_b\prod = 9.67M - 669.39. \quad (3)$$

The correlation coefficients and rms errors for dependences (1)–(3) are presented in Table 2.

Table 1. Input data for the calculation [1]*

Substance	M, g mol^{-1}	$\prod$, J$^{1/4}$ cm$^{5/2}$ mol^{-1}	T_b, K	V_b, cm^3 mol^{-1}
SnH_4	122.7	2.24	221.0	63.3
SnH_3Cl	157.2	2.87	306.7	83.0
$SnCl_4$	260.5	4.76	387.0	131.7
SiH_4	32.1	1.78	161.2	50.5
SiH_3Cl	66.2	2.48	242.6	65.1
SiH_2Cl_2	101.0	3.07	281.3	84.3
$SiHCl_3$	135.4	3.67	305.2	102.8
$SiCl_4$	170.0	4.30	330.5	121.2

* M is the molar mass, $\prod$ is the parachor, and V_b is the molar volume of liquid at boiling point.

Table 2. Correlation coefficient r and rms error S of Eqs. (1)–(6)

Equation	r	S, %
(1)	0.9992	1.2
(2)	0.9926	4.7
(3)	0.9993	4.0
(4)	0.9913	1.1
(5)	0.9992	1.9
(6)	0.9967	3.8

1070-4272/01/7403-0394$25.00

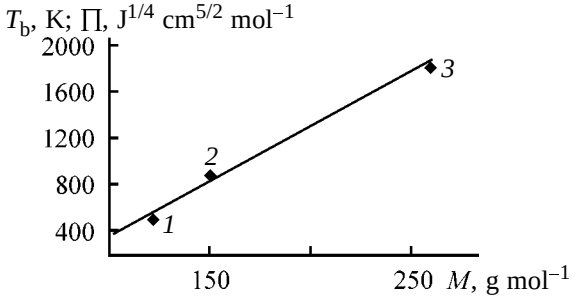

Fig. 1. Product of the boiling point T_b by the parachor ∏ vs. molar mass of a substance studied. (*1*) SnH_4, (*2*) SnH_3Cl, and (*3*) $SnCl_4$; the same for Fig. 2.

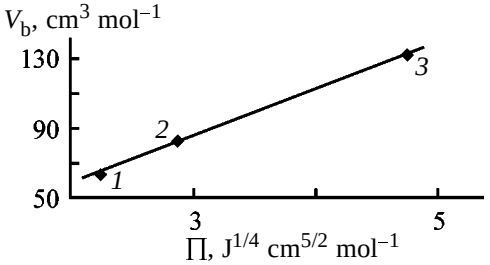

Fig. 2. Molar volume of the liquid at boiling point, V_b, vs. the parachor ∏.

To determine the molar volume of the liquid at the boiling point, V_b, the following relationships were studied: (a) that between the logarithm of V_b and the molar mass M in the series of compounds SnH_4, SnH_3Cl, and $SnCl_4$; (b) that between V_b and the parachor ∏ in the series of compounds SnH_4, SnH_3Cl, and $SnCl_4$; and (c) that between V_b of silicon and tin compounds in the homologous series EH_4, EH_3Cl, and ECl_4.

Table 3. Boiling point parameters of chlorostannane

Substance	T_b, K			V_b, cm^3 mol^{-1}		
	by equation					
	(1)	(2)	(3)	(4)	(5)	(6)
SnH_2Cl_2	340.7	315.8	339.4	94.0	98.3	97.4
$SnHCl_3$	364.2	354.0	368.4	112.1	115.2	114.2

Table 4. Recommended values of boiling point parameters of little studied chlorostannanes

Parameter	SnH_2Cl_2	$SnHCl_3$
T_b, K	332	362
V_b, cm^3 mol^{-1}	97	114
ΔH_b, kJ mol^{-1}	28.7	31.3

As an example, one of these dependences is presented in Fig. 2. It was established that all the three dependences are obviously linear. Their processing by the least-squares method gives the following equations:

$$\ln V_b = 0.00512M + 3.56, \quad (4)$$

$$V_b = 26.83\prod + 4.5, \quad (5)$$

$$V_b(SnH_mCl_n) = 0.94V_b(SiH_mCl_n) + 18.2. \quad (6)$$

The correlation coefficients and rms errors for dependences (4)–(6) are listed in Table 2.

The molar masses of SnH_2Cl_2 and $SnHCl_3$, equal to 192.0 and 226.5, and also the parachors of these substances (3.50 and 4.13, respectively) were used to calculate using Eqs. (1)–(6) the boiling points and molar volumes of liquids at the boiling points of these substances.

As seen from the data in Table 3, the T_b and V_b values obtained by various methods are reasonably consistent. The recommended values of the boiling point parameters of SnH_2Cl_2 and $SnHCl_3$ can be obtained by averaging data obtained by three independent methods (Table 4). The values in Table 4 are given with account of the expected error of ±2%.

The enthalpies of SnH_2Cl_2 and $SnHCl_3$ vaporization, lacking in the literature, were calculated for the boiling point by the equation

$$\Delta H_b = T_b[73 + 2.09\ln(T_bM/V_b)],$$

whose accuracy was estimated to be ±4% in [1] (Table 4).

CONCLUSIONS

(1) The applicability of calculation methods to predicting the boiling point parameters for two little studied tin compounds SnH_2Cl_2 and $SnHCl_3$ was demonstrated.

(2) The boiling point parameters of these compounds, lacking in the literature, were determined.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Resistance to Hydrogen of Al–Sc Alloys

M. M. Antonova and V. B. Chernogorenko

Institute of Materials Science Problems, Ukrainian National Academy of Sciences, Kiev, Ukraine

Received August 24, 2000

Abstract—The behavior of aluminum–scandium alloys in hydrogen at an equilibrium pressure of 0.1 MPa was studied on a Sieverts apparatus.

The most efficient modifier of aluminum is scandium [1]. Addition of 1% Sc to AV000 aluminum yields the maximal number of grains (1090 per 1 cm^2) compared to other modifiers. Aluminum and aluminum alloys modified with scandium have the improved strength, plasticity, corrosion resistance, and other operation characteristics [2]. Scandium-doped aluminum has found application as structural material for aircrafts. Electrodes made of aluminum wire doped with 1% Sc facilitate welding of aluminum parts [3, 4], which allows fabrication of compact light articles. However, the strength of these materials, when operating for a long time under conditions of sharp temperature gradients, depends on their resistance to the environment in which they are exploited, in particular, air and hydrogen plasma.

In this work we studied the hydrogen absorption capacity of Al–Sc alloys. As known, compact aluminum does not interact with hydrogen. Aluminum hydride (AlH_3) as a white amorphous mass can be prepared solely by the chemical method from the ether solution [5]. Scandium absorbs hydrogen in the elemental state, forming the hydride ScH_2 [6], and also as a component of intermetallic compounds with metals that are not hydrogenated. For example, the intermetallic compound $ScMn_2$ yields hydrides $ScMn_2H_{3.8}$ [7]; $ScFe_2$, $ScFe_2H_4$; and $ScCo_2$, $ScCo_2H_4$ [8].

In the Al–Sc system, four intermetallic compounds are formed: Al_3Sc, Al_2Sc, AlSc, and $AlSc_2$ [9, 10]. The solubility of Al in Sc reaches about 6.25%. The limiting solubility of Al in Sc is 0.30%. At high crystallization rates the solubility of Sc can reach 5.1%. The data on the crystal structure of the phases in the Al–Sc system are given in Table 1. The crystal structures and the unit cell parameters of aluminum and the nearest intermetallic Al_3Sc are close. Therefore, as was shown by practical experience, cracks resulting from internal stresses do not appear in aluminum alloys containing up to 30% Sc at their various mechanical and thermal treatments. The behavior of these alloys in hydrogen-containing media was not studied previously.

EXPERIMENTAL

The alloys under study were obtained from aluminum (A999 ultrapure grade) and SkM-2 grade scandium containing (wt %) 99.88 Sc, 9×10^{-3} Fe, less than 0.001 Cu, 0.0051 Al, 0.05 Ca, 0.02 Mg, less than 0.001 Y, less than 0.0005 Yb, less than 0.005 Zr, less than 0.005 Ti, and 0.016 Si. The starting materials were smelted in an electric arc furnace with a permanent tungsten electrode under purified argon. Each sample was melted sixfold. The content of the elements in the alloys was determined by X-ray fluorescence analysis on a VRA-30 device. In some tests, chemical analysis was also used.

The alloys were hydrogenated at a 0.1 MPa hydrogen pressure on the improved quartz apparatus of the Sieverts type [6]. The volume of the reaction chamber was 60 cm^3. The pressure was measured with a mercury manometer. The hydrogen uptake was monitored by the pressure change in the system. The pressure was adjusted to the initial value every 5 min. Hydrogen was obtained by decomposing titanium hydride or $LaNi_5$ hydride in a reactor connected to the reaction chamber. Owing to plasticity, aluminum alloys containing up to 2% Sc were used as powder, which was prepared from finely disperse cuttings washed with ethyl alcohol and sieved. The other alloys were used as crushed ingots. Metallic scandium was hydrogenated without crushing.

We measured the sorption isobars at 0.1 MPa hydrogen pressure. Before hydrogenation, the alloys were activated by heating to 600–800°C at 13 Pa.

Sample	H_2 content, $cm^3\ g^{-1}$, at indicated temperature, °C							H_2 content in alloy, %
	600	500	400	300	200	100	20	
Al + 0.3% Sc:								
compact	0	1.4	2.0	4.3	5.3	7.1	8.9	0.08
powder	1.1	1.3	18.1	18.5	24.2	27.5	39.3	0.35
Al + 2% Sc:								
compact	0.4	2.0	3.5	4.0	7.1	13.1	13.9	0.14
powder	6.0	6.0	7.5	10.9	15.0	25.1	58.8	0.52

After activation, hydrogen was fed into the reactor, where the sample preheated to the maximal temperature was located, and the hydrogen sorption was observed and recorded at constant temperature till the saturation was complete. After that, the temperature was decreased by 100°C. The sorption process was resumed till the saturation was observed at the given temperature. The test was performed at stepwise decrease in the temperature to room temperature. The incubation period was observed in none of the cases. The total time of the experiment reached 3–5 days.

We found that all the compositions studied are hydrogenated reversibly and after decomposition in a vacuum and subsequent hydrogenation the final content of hydrogen in them is similar to the results of the first hydrogenation. The exception was metallic scandium. In the course of the first hydrogenation it took up only 86.6 cm^3 of H_2 per 1 g and disintegrated by cracking. No hydrogen was released in a vacuum at 900°C, and only at 1000°C it started decomposing. The results of the second hydrogenation are given in Table 2. Heating it in a vacuum was accompanied by intense cracking, indicative of transformation of the hydride structure. It can be presumed that, as in the Ti–H system [12, 13], hydrogen shifts the temperature of the β-Sc → α-Sc transition toward lower temperatures (the temperature of the α-Sc → β-Sc transition in air is 1337°C). In this case, as in the majority of studies, no scandium hydride of the composition ScH_2 was obtained. The hydrogen content in the hydride obtained corresponds to the composition $ScH_{1.39}$.

The hydrogen content in solid solution and scandium–aluminum alloys depends on dispersity (Table 2). Hydrogen absorption is stronger for powders owing to developed surface. On heating Al + 0.3% Sc and Al + 2% Sc samples to 600°C in a vacuum, about 7–10 cm^3 of adsorbed hydrogen per gram of the alloy is released, with most of hydrogen remaining in the alloy lattice. Concerning the effect of hydrogen on aluminum alloys, Dobatkin *et al*. [14] report that "...hydrogen content exceeding 0.2 cm^3 per 100 g drastically deteriorates impermeability of ingots. Also, it can affect impermeability of deformed semifinished products. Unfortunately, study of this effect, which is so important for estimating the potential of metals in spacecrafts, is given little attention yet."

The data on hydrogenation of the intermetallic compounds are given in Table 3. Before interaction with hydrogen, the alloys were activated in a vacuum

Table 3. Data on hydrogenation of intermetallic compounds of the Al–Sc system and scandium after the first cycle of hydrogenation–dehydrogenation

Sample	Activation		P_{H_2}, MPa	H_2 content, $cm^3\ g^{-1}$, at indicated temperature, °C									H_2, %**

* After the third cycle.
** Maximal H_2 content at 20°C.

at 800–900°C. The exception was Al_3Sc, which was activated at 600°C to prevent possible partial peritectic decomposition at 660°C. The maximum amount of hydrogen absorbed by $AlSc_2$ was smaller compared to similar AB_2 alloys (e.g., $NiMg_2$ and $NiTi_2$: 404 and 298 $cm^3\ g^{-1}$, respectively). As known [15], the solubility of hydrogen in aluminum and scandium and the diffusion rate of hydrogen in these metals grow with increasing pressure. It is presumed that the hydrogen pressure of 0.1 MPa is insufficient for complete saturation of $AlSc_2$. Therefore, the intermetallic compounds were hydrogenated at 2.5 MPa in a stainless steel installation. Additional activation of the alloy grains was performed by repeated hydrogenation–dehydrogenation cycles without removing the sample from the reaction chamber (Table 3).

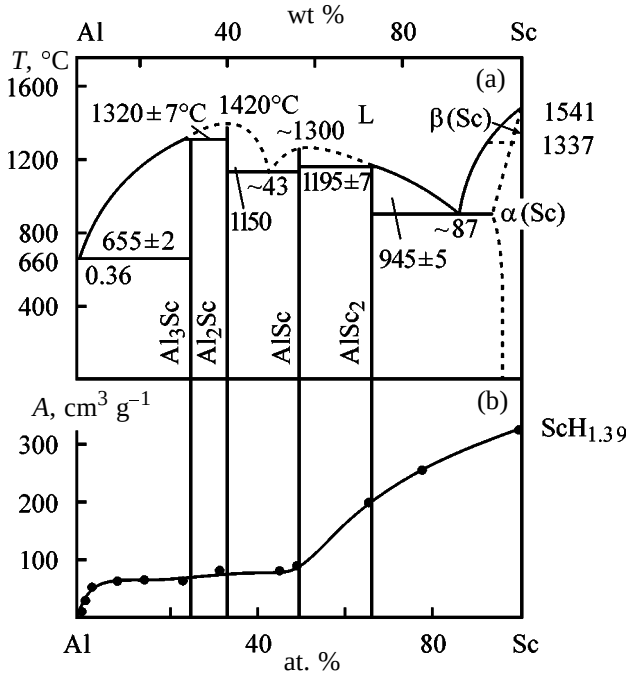

Fig. 1. (a) Phase diagram of the Al–Sc system and (b) maximal sorption capacity for hydrogen of the system alloys vs. alloy composition. (*T*) temperature and (*A*) sorption capacity at P = 0.1 MPa and 20°C.

We studied the influence of activation temperature and number of activation cycles on hydrogenation. After the third cycle the amount of sorbed hydrogen reached 241.9 cm^3 H_2 per gram of the alloy. Only minor amount of hydrogen (9.9 cm^3 H_2 per gram) was revealed by chemical analysis of the material hydrogenated at 200°C and 2.5 MPa. Thus, the hydride of $AlSc_2$ is extremely unstable, instantaneously decomposing at room temperature as the hydrogen pressure is quickly relieved from 2.5 to 0.1 MPa. For its storage the special stabilization procedures are necessary. Many hydrides, including $LaNi_5$ hydride, behave similarly. To stabilize them, the surface is saturated with oxygen or carbon dioxide at the temperature of liquid nitrogen.

The sorption capacity for hydrogen as a function of composition of the Al–Sc system is plotted in Fig. 1. All alloys of the system, especially intermetallic compounds, absorb hydrogen. If during fabrication of scandium-doped aluminum, namely, in the stage when aluminum–scandium charge is introduced into aluminum melt, the homogenization of the melt was not attained and scandium segregated in the course of subsequent crystallization, then, for example, in spacecraft articles and liquid-hydrogen cylinders, especially on warming them from the sun side, Al_3ScH_x or Al_2ScH_x can be formed with high probability. Scandium can segregate into intermetallic compounds in the course of rolling ingot and during welding with a scandium-containing wire owing to crystallization of a weld material. The resulting hydrides decompose with hydrogen evolution, resulting in the formation

of pores during diffusion. The hydrogen accumulation in a spacecraft in the presence of oxygen can cause explosion and fire.

In this work, the influence of the other components of traditional aluminum alloys, for example, magnesium and lithium alloys, on their resistance to molecular hydrogen was not studied. Presumably, the presence of these elements easily forming hydrides MgH_2 and LiH would deteriorate the hydrogen resistance of aluminum–scandium alloys.

CONCLUSION

(1) All alloys of the Al–Sc system interact with hydrogen. The intermetallic compounds Al_3Sc, Al_2Sc, AlSc, and $AlSc_2$ form hydrides.

(2) The amount of sorbed hydrogen grows with increasing hydrogen pressure.

(3) The $AlSc_2$-based alloy can be used for preparing hydrogen-accumulating materials.

(4) The aluminum alloys containing scandium can be recommended for aerospace technology only after testing them for hydrogen resistance.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Lead(II) from Aqueous Solutions by Synthetic Zeolites

I. V. Karetina, M. A. Shubaeva, L. F. Dikaya, and S. S. Khvoshchev

Grebenshchikov Institute of Silicate Chemisty, Russian Academy of Sciences, St. Petersburg, Russia
Corning Research Center, St. Petersburg, Russia

Received November 2, 1999; in final form, January 2000

Abstract—A comparative study of the sorption of lead(II) from dilute aqueous solutions by synthetic faujasites, chabazites, mordenites, erionites, phillipsites, and type A zeolites was performed. The most promising sorbents are low-silica chabazites and potassium erionites with relatively high SiO_2/Al_2O_3 ratio.

Recently, interest in the possibility of recovering heavy-metal ions from natural water and wastewater has been again aroused by the increasingly stringent environmental regulations. The high selectivity of zeolites with respect to lead ions has long been known [1–3]. For obvious reasons the preference has been given to natural zeolites [4–9]. At the same time, there are no published comparative data for main types of synthetic zeolites. This communication presents some results obtained in studying the ion-exchange capacity for lead(II) of synthetic faujasites, type A zeolites, chabazites, erionites, mordenites, and phillipsites treated with solutions with low concentration of Pb^{2+} ions in the presence of predominant amounts of Ca^{2+} ions.

All the zeolites studied were synthesized by the technique described in [10].[1] The composition of the crystals was determined by methods of chemical analysis (Table 1).

The estimates of the ion-exchange capacity of some zeolites for lead are presented in Table 2.

In the first case, weighed portions of zeolites (1.5–2.0 g) were treated with solutions containing lead(II) in amounts equivalent to the content of cations in crystals. In the second case, the solutions used for treatment contained the same amount of lead(II) and a 10-fold excess of calcium and magnesium ions. Each zeolite was thrice treated with the solution for 6 days at room temperature with intermediate washings. In the process, up to 2 l of the solution was used, depending on the required component ratios.

As seen from Table 2, Na^+ ions in zeolites are only in part replaced by Pb^{2+} ions even upon treatment with purely lead solutions. Under the conditions of competition with Mg^{2+} and Ca^{2+} ions, the degree of exchange for Pb^{2+} markedly decreases, but the selectivity order CHA > FAU > LTA remains unchanged. As seen from Table 2, the contents of PbO and CaO are comparable, even though the Ca^{2+} concentration in solutions is 10 times that of Pb^{2+}. At the same time, only an insignificant part of Na^+ ions is replaced under these conditions by Mg^{2+} ions.

The presence of Ca^{2+} ions has practically no effect, either, on the possibility of lead(II) recovery from solutions containing only 0.00006% Pb^{2+} (Table 3), with zeolites of different structural types exhibiting similar behaviors. A similar conclusion was made in [5] in reference to a number of natural zeolites. As seen from Table 3, the NaFAU-2 faujasite with SiO_2/Al_2O_3 ratio of 2.87 and low-silica chabazite NaCHA-1 show the highest capacity for lead(II).

The main results obtained in studying the absorption of Pb^{2+} ions by zeolites are presented in Table 4. Here, too, the solutions used contained 0.00006% lead(II). The treatment was performed at room temperature in the course of 15 days.

At so low degrees of exchange (the PbO/Al_2O_3 ratio in the zeolite crystals subjected to treatment was 0.001–0.004) it is difficult to speak of any clear relationship between the composition of zeolites and their ability to absorb lead(II). However, some conclusions can be made. Large cations are less firmly bound to the zeolite lattice, and, with increasing size of alkali metal cation in a zeolite, the ion-exchange sorption of lead(II), as a rule, becomes stronger. This is observed in going from Li^+ to Na^+ in the case of faujasites, and

from Na^+ to K^+ for chabazites and erionites. The opposite tendency is only observed for a chabazite with the smallest SiO_2/Al_2O_3 ratio.

Ca^{2+} ions are bound to the lattice more firmly than Na^+ ions, and it could be expected that the ability of calcium zeolites to absorb lead(II) would be lower than that of sodium zeolites. For faujasites with $SiO_2/Al_2O_3 \cong 2.9$ this is indeed so, and further decrease in this ability is observed on replacing Ca^{2+} by Mg^{2+} ions. However, with the SiO_2/Al_2O_3 ratio decreasing to approximately 2.3, replacement of Na^+ by Ca^{2+} and Mg^{2+} has absolutely no effect on the sorption of lead(II) ions.

With decreasing total charge of the lattice and increasing SiO_2/Al_2O_3 ratio, the binding of cations to the lattice becomes weaker and they must be replaced more easily. Correspondingly, the ability of nearly all zeolites with like cations to absorb lead(II) grows within each structural type with increasing SiO_2/Al_2O_3 ratio. Only low-silica sodium chabazites and high-

silica faujasites remain outside this pattern. Presumably, the prevailing effect is exerted here already by the increasing number of bonds between cations and the aluminosilicate skeleton, rather than by their becoming stronger or weaker.

The noted relationships are, on the whole, also preserved in passing to solutions containing a four times smaller amount of lead(II). In this case, faujasite with particularly low SiO_2/Al_2O_3 ratio, synthesized by the method described in [11], and also phillipsite having rather high selectivity [6] exhibit under these conditions relatively low capacity for lead(II). It seems that the most promising are low-silica chabazites known as selective absorbers of strontium(II) from concentrated salt solutions [12] and potassium erionites with relatively high SiO_2/Al_2O_3 ratio. As seen from Table 4, both of these are low-sensitive to a fourfold decrease in the concentration of lead(II) in the solutions used.

It is possible to get a certain insight into the kinetics of lead(II) absorption from the data in Table 5. In all cases, the total volume of solution was 5 l at weighed portions of 0.5 g. The equilibrium state is not achieved even after several days; however, even under dynamic conditions the zeolite exhibits a quite appreciable capacity for lead(II) absorption.

CONCLUSION

Synthetic zeolites, especially low-silica chabazites and potassium erionite with relatively high SiO_2/Al_2O_3 ratio, show appreciable ion-exchange capacity for lead(II) in the presence of predominant amounts of calcium and magnesium ions in solutions.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Carbon Disulfide from Air–Gas Mixtures on Carbon Materials with Various Nature of the Surface

Abstract—The sorption of carbon disulfide on carbon materials was studied as influenced by the chemical nature of their surface and presence of surface oxygen-containing functional groups and metal ions differently bound on the sorbent surface. Cation-substituted carbons with considerably higher capacity as compared with the initial sorbents were prepared.

Activated carbons (ACs) are widely used for sorption recovery of carbon disulfide from industrial exhaust gases to decrease environmental contamination and to return this product in production [1–3]. However, in most cases the residual content of CS_2 in the exhaust gases significantly exceeds the maximal permissible concentration (MPC, 0.03 mg m^{-3}). More exhaustive removal of CS_2 and other toxic sulfur compounds is of particular importance for environmental safety; it is also required in systems for deep purification of air for operation of analytical and medical equipment, individual protection of breath organs, etc. Though the interaction of carbon disulfide with ACs was studied rather extensively [1–5], data on recovery of CS_2 to the levels about MPC and lower from low-concentrated air–gas mixtures (AGMs) are scarce. Thus, studies in this direction and search for more efficient sorbents are still urgent.

The sorption capacity of various carbon materials (CMs) with respect to certain gas mixtures can be increased by addition of various modifying agents (e.g., metal compounds) chemically interacting with the sorbed materials. Impregnation with various solutions is the most common way to modify CMs. For example, such chemical sorbents based on activated carbons are widely used in gas-protection apparatus [1–5]. As seen from published data [6–8], the ion-exchange substitution of the protons in the surface acidic functional groups of oxidized carbons (OCs) [9] with metal ions can be more efficient as compared with impregnation. In this case the surface complex OC–M^{n+} acts as a sorption center and the molecules of sorbed compounds (L) occupy the free sites of the metal coordination environment, forming the structures like –C–O–M···L_n. This process is termed "ligand" sorption [7–10]. It was found that, due to such processes, the cationic forms of OCs are more efficient in sorption of water vapor [8], ammonia [10, 11], sulfur dioxide [7, 11], carbon disulfide [7], etc., as compared with unmodified and even initial nonoxidized activated carbons.

In this work we studied the possibility of ligand sorption and the dependence of carbon disulfide sorption on carbon materials as influenced by the chemical nature of their surface and presence of the surface oxygen-containing functional groups (OCFGs) and metal ions differently bound with the carbon surface. It should be noted that the data on the feasibility and efficiency of CM modification with metal cations for carbon disulfide sorption are virtually lacking.

In our study we used various industrial carbons (AR-3, KAU, SKN, Sorbon). The samples were oxidized with air or nitric acid by the known procedures [9]. The cation-substituted forms of oxidized carbons containing copper, iron, and cobalt ions on the sorbent surface were prepared by the ion-exchange procedure [6, 9]. Moreover, some AC samples were modified by impregnation with solutions of the corresponding metal nitrates [6]. In this case we obtained the samples containing the modifying agents differently bound with the surface in amounts of 0.10–0.12 mg-ion g^{-1}. In the oxidized carbons (samples are denoted as AC-O-M-1) the metal cations substitute the protons in the OCFGs forming surface complexes. At certain preparation regimes during impregnation of nonoxi-

AR-3-O-Cu-1	0.70	0.42	0.28	720	–	–
AR-3-Cu-2	0.69	–	–	–	–	–

* W_s is the total pore volume; V_{mic}, V_{mes} are the volumes of micro- and mesopores; S_{sp} is the specific surface area; SEC is the static exchange capacity characterizing the content of the basic (for HCl) and acidic (for NaOH) surface groups; AC-O is the oxidized carbon; AC-O-M-1 are cation-substituted samples; and AC-M-2 are the metal-substituted samples prepared by impregnation.

dized carbons (AC-M-2 samples) metal compounds penetrate into the sorbent pores either in the initial (water-soluble) form, or as specifically sorbed whole molecules, or as hydroxides or basic salts formed in the side reactions [6, 9]. The physicochemical and sorption properties of CMs studied by common procedures [1, 9] are listed in Table 1.

The recovery of CS_2 from the air–gas mixtures was studied at various temperatures under the dynamic conditions in the columns containing 3–4 cm^3 of sorbent at constant flow rate of the gas mixture (200–250 ml min^{-1}). The concentration of carbon disulfide was determined by known chemical procedures [12]. In some cases the composition of the exhaust gas mixture at the column outlet was analyzed by gas chromatography. The desorption of carbon disulfide was also studied under the dynamic conditions in an argon flow. Our experimental data showed that the temperature of 100°C and argon flow rate of 100 ml min^{-1} are the optimal for efficient desorption.

Our tests showed that in the case of common ACs at 20–120°C the sorption of H_2S is reversible, decreasing with increasing temperature (Fig. 1); under the similar conditions it is mainly determined by the structural characteristics of the sorbent such as porosity, specific surface area, etc. The reversibility of CS_2 sorption is illustrated by almost complete removal of carbon disulfide with argon and by the possibility of performing several sorption–desorption cycles using a single sample (Table 2). At temperatures higher than 120°C the fraction of desorbed CS_2 significantly decreases, and the products of catalytic oxidation of carbon disulfide such as sulfur and carbon oxides appear in the exit gases. In the case of air–gas mixture containing 0.01–0.02 wt % ozone the protective life (up to appearance of CS_2 at the column outlet) remains constant up to 120°C, whereas at 130°C it strongly increases, which is probably due to intense oxidative decomposition of carbon disulfide.

The interaction of carbon disulfide with OCs differs from that described above. Under the similar conditions the sorption capacity of oxidized samples with respect to CS_2 was significantly lower as compared with the corresponding activated carbons (Fig. 2, Table 2), but the amount of reversibly sorbed carbon

** Presence (+) and absence (–) of the oxidation products.

disulfide was smaller than in the case of ACs. Modification of the carbon surface with metal cations increased the recovery of CS_2 from air–gas mixtures (Table 2), and the amount of strongly bound or converted carbon disulfide increased to a still greater extent. The sorption of CS_2 (protective life) in the presence of water vapor decreases (Table 2, Fig. 1). In the cation-substituted sorbents the oxidation products appear at lower temperatures as compared with ACs (Table 2), which indicates that the sorbents containing metal cation are more efficient catalysts of carbon disulfide oxidation. Addition of ozone to the air–gas mixture at elevated temperatures promotes the recovery of CS_2, and this process is more efficient as compared with unmodified activated carbons (Fig. 3). It should be noted that the breakthrough concentration after the sorption (conversion) on the cation-substituted carbons is significantly lower than after sorption on unmodified sorbents (Table 2, Fig. 3), i.e., they provide more exhaustive purification of the exit gases.

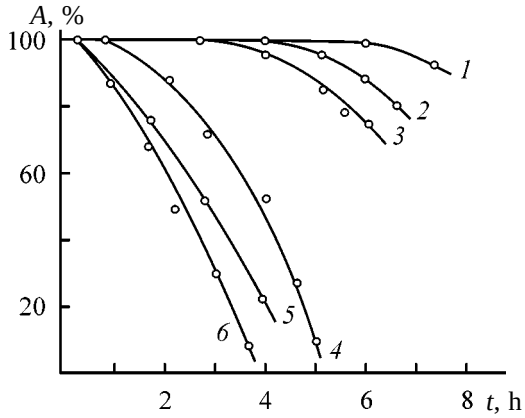

Fig. 2. Sorption of carbon disulfide *A* on (*1*) KAU, (*2*) SKN, (*3*) AR-3, (*4*) KAU-O, (*5*) SKN-O, and (*6*) Ar-3-O sorbents at 20°C.

As seen from Table 1, oxidation slightly decreases the volume of sorption pores and the specific surface area as compared with the initial AC, but the decrease in the carbon disulfide sorption on OC is probably due

not only to the above factors and blocking of the sorption pores, but also to certain chemical processes, because significant amount of CS_2 is sorbed irreversibly. However, the detailed analysis of this process requires further studies.

During interaction of CS_2 with the cation-substituted OCs the ligand sorption probably occurs yielding the surface complex –C–O–M···$(CS_2)_n$. The promoting effect of this surface complex –C–O–M··· on sorption and catalytic oxidation of carbon disulfide is also confirmed by the fact that in the case of modified sorbents prepared by impregnation and containing similar amounts of modifying metals the sorption and the amount of irreversibly sorbed CS_2 are significantly smaller (Table 2). Similar effects were observed for different carbon materials.

The decrease in the protective life in the case of wet air–gas mixtures is probably due to the competitive sorption of water molecules with formation of the complex –O–C–O–M···$(CS_2)_n(H_2O)_m$. The increase in sorption (conversion) in the presence of ozone can be due to reaction of the oxidant (ozone) with the substrate (CS_2) in the surface complex –O–C–O–M···$(CS_2)_n(O_3)_m$, i.e., to the catalytic activity of the cation-substituted carbons (as found in [13]).

We found that the prolonged (multicycle) operation of the cation-substituted carbons especially in the regimes of catalytic decomposition is rather difficult. At low temperatures this is due to the fact that significant amount of CS_2 is strongly sorbed on the sorbent surface and is not removed in the inert atmosphere. At elevated temperatures the catalytic conversion is observed, and the reaction products decrease the catalyst activity. Our experimental data suggest that one of the reaction products (elemental sulfur) can block the pores [1, 2], whereas sulfur oxides can react with metal cations.

Thus, we found that sorption of carbon disulfide on the carbon materials depends not only on the pore structure [1–3], but also on the chemical nature of their surface and on the presence of modifying agents. In this case the ion-exchange modification of the oxidized carbons with cations of such metals as iron, cobalt, and copper allows us to prepare efficient sorbents with high capacity and the protective life with respect to carbon disulfide significantly exceeding that of the initial ACs, including those containing metal cations, but prepared by impregnation.

Such modified carbon materials can be used in air treatment to remove CS_2 to the levels of MPC and lower. These sorbents are the most efficient in disposable filters for analytical and medical devices, individual breath-protection respirators, in the catalyst poisoning protection, etc.

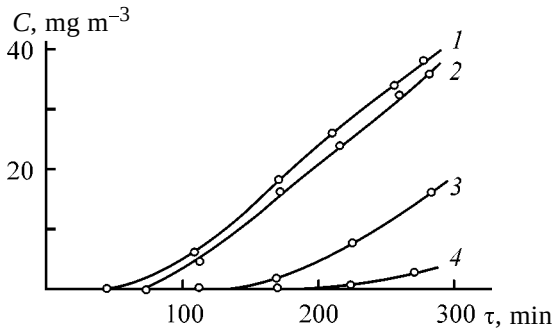

Fig. 3. Sorption of carbon disulfide on (*1, 2*) initial AR-3 and (*3, 4*) its oxidized forms modified by ion-exchange with iron (*1, 3*) in the absence and (*2, 4*) in the presence of ozone at 50°C. (*C*) Concentration of CS_2 and (τ) time.

These dependences are of practical importance in common use of activated carbons for gas purification or recuperation of carbon disulfide, because the operation of sorption columns requires taking into account gradual decrease in the sorption capacity of coals due to their oxidation (formation of OCFG). Such oxidized sorbents cannot be regenerated by treatment with steam or with solvents. In this case sorbents can be regenerated by high-temperature treatment.

CONCLUSIONS

(1) Sorption of carbon disulfide from air–gas mixtures on various carbon materials under various conditions was studied. This process is determined by the chemical nature of the sorbent surface and the presence of the surface oxygen-containing functional groups and modifying agents differently bound with the sorbent surface (ion-exchange treatment, impregnation with metal salts).

(2) Cation-substituted sorbents were prepared with the higher capacity and longer protective life with respect to carbon sulfide as compared with the initial sorbents.

(3) The fields of possible application of the modified carbon sorbents with the highest capacity for CS_2 are suggested.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of CO_2 from Humid Gases on Potassium Carbonate Supported by Porous Matrix

Abstract—Kinetics of sorption of carbon dioxide on potassium carbonate supported by different porous matrices was studied in a flow reactor at 40°C. The structural and chemical changes of potassium carbonate–aluminum oxide composite sorbents were studied by powder X-ray diffraction, thermogravimetry, and low-temperature nitrogen sorption.

The capacity and selectivity of porous sorbents can be increased by introduction in their pores of a compound which reversibly reacts with the gaseous adsorbate. For example, the most promising composites of this type are silica gel containing calcium chloride or lithium bromide in its pores and used as a water sorbent [1, 2] and potassium carbonate–activated carbon and potassium carbonated–aluminum oxide systems used for sorption of carbon dioxide [3, 4]. In particular, the sorption capacity of these systems with respect to CO_2 is several times higher than that of conventional sorbents such as activated carbons, aluminum oxide, and zeolites [4]. Important advantages of these composites are the absence of corrosion, low regeneration temperature, and effective sorption of CO_2 form humid gaseous mixtures. These sorbents can be used for removal of CO_2 form waste gases of thermal power plants, in creation of protecting and reducing atmospheres, in survival systems of submarines, in hydrogen production by steam conversion of methane, etc. [3, 5].

Carbon dioxide sorption from humid gas mixtures in a flow adsorber was studied and the time dependence of the outlet CO_2 concentration was measured by Hayashi *et al*. [3, 4]. They suggest that potassium carbonate–porous matrix composites sorb carbon dioxide owing to occurrence of reversible chemical reaction

$$K_2CO_3 + H_2O + CO_2 \rightleftarrows 2KHCO_3. \quad (1)$$

At $T < 100$°C the forward reaction prevails and the reverse reaction used for sorbent regeneration occurs at $T > 150$°C. The important parameters of composite sorbents are the residual concentration of carbon dioxide at the outlet of an adsorber C_{out} and the dynamic sorption capacity A_{dyn}. Hayashi *et al.* [4] showed that the dynamic capacity of the tested sorbents strongly depends on the nature of the support matrix and on the distribution of the active component in its pores. For example, low activity of potassium carbonate supported by silica gel can be due to reaction of these components to form inert surface potassium silicates, which is confirmed by electron microscopy [5]:

$$K_2CO_3 + SiO_2 = K_2SiO_3 + CO_2. \quad (2)$$

When activated carbon is used as the matrix, large salt crystals blocking penetration of the reagents in the sorbent pores can be formed on the hydrophobic surface of the carbons depending of their pore structure. As a result, the reactive surface of potassium carbonate decreases, thus decelerating the sorption of carbon dioxide [4]. Hayashi *et al.* [4] also studied sorption of carbon dioxide from smoke on the potassium carbonate–porous carbon composite. It was found that the dynamic capacity of the sorbent can be as high as 1 mol CO_2/1 g sorbent. Unfortunately, Hayashi *et al.* [4, 5] gave little attention to sorption properties of potassium carbonate on other supports and did not substantiate the choice of porous carbons for practical application.

In this work we studied not only potassium carbonate supported by silica gel and activated carbon but also the potassium carbonate–vermiculite composite and systematically studied the potassium carbonate–aluminum oxide system. The detailed study of the

latter composite was caused by the fact that it can be used for removal of CO_2 form gas mixtures, for example, in short-cycle adsorption of carbon dioxide [7]. To study the influence of the nature of the porous matrix-host on the sorption of carbon dioxide by supported potassium carbonate, we used both hydrophilic (silica gel, aluminum oxides, inflated vermiculite) and hydrophobic (porous carbon) matrices. Inflated vermiculite is a mainly macroporous sorbent; the other matrices are mainly mesoporous. Along with the sorption kinetics of carbon dioxide in a flow adsorber, we also studied, using X-ray diffraction (XRD), thermogravimetry (TGA), and low-temperature nitrogen sorption, the changes in the texture and phase composition of the sorbents during the sorption and regeneration.

EXPERIMENTAL

The sorbents were prepared by impregnation of porous supports (the parameters are presented in Table 1) with 40% aqueous K_2CO_3, followed by drying on a water bath (T = 100°C) at continuous removal of water vapor with a water-jet pump. The content of potassium carbonate in the samples ranged from 22 to 47% depending on the moisture capacity of the sample. We studied sorption of carbon dioxide at 40°C in an 5-ml adsorber (a 180-mm glass tube 6 mm i.d.). Air fed in the adsorber was saturated with a water vapor to the dew point of 30°C. Then CO_2 was introduced to its content in the inlet gas flow of 2 vol %. The flow rate of the gas fed in the adsorber was 150 $cm^3\ min^{-1}$. The CO_2 content at the outlet was measured chromatographically with an accuracy of 2% in the range of 10^{-2}–2.0 vol %.

As seen from Fig. 1a, the general shape of the time dependences of the CO_2 concentration at the outlet of the adsorber depends on the nature of the sorbent matrix. Freshly prepared alumina composites A1 and A2 almost completely sorb carbon dioxide

within the first 40–50 min. The residual CO_2 concentration does not exceed $(20–25)\times10^{-4}$ vol %. Then the CO_2 concentration at the outlet C_{out} increases up to the inlet value. The dynamic capacity of these sorbents A_{dyn} defined as the ratio of the CO_2 amount adsorbed by the moment when the outlet CO_2 concentration starts to increase (i.e., by the start of breakthrough) to the initial weight of the sorbent reaches 0.06–0.094 g g^{-1}. This is 65–75% of their limiting capacity calculated in accordance with the stoichiometry of reaction (1). The measured dynamic capacity of the samples is about 20 times higher than that of the initial Al_2O_3 matrix (Fig. 1a), i.e., the main part of carbon dioxide is adsorbed by reaction (1).

The time of CO_2 sorption on C1 and C2 sorbents based on porous carbon is considerably shorter (5–12 min) (Fig. 1a). Then the outlet carbon dioxide concentration increases monotonically, with the increase slightly decelerating at C_{out} = 1.0–1.2 vol %. The curves of CO_2 sorption on potassium carbonate supported by silica gel (S1) and vermiculite (V1) indicate breakthrough of CO_2 already at the first steps of the experiment. In the case of vermiculite sorbent the curve flattens out at 50% adsorption of CO_2 fed at the inlet. The dynamic capacity of these sorbents is low and does not exceed 0.006 g g^{-1} (Table 2).

Thus, among the tested sorbents only potassium carbonate–aluminum oxide composites having high dynamic capacity and providing low CO_2 concentration at the adsorber outlet are of practical interest. We studied these composites in more detail. Since at T > 150°C equilibrium (1) is shifted to decomposition of potassium carbonate, regeneration of the samples was performed at 200–350°C in an air flow. However, under these conditions the dynamic capacity of alumina composites does not return to the initial value. As seen from Fig. 1b, in the first step carbon dioxide is completely sorbed on the initial A1 sorbent and the sorbents regenerated at 200 and 350°C. Then CO_2 breakthrough is observed, and the curve flattens out at the level of 25–40% sorption. The time to the breakthrough increases with increasing the regeneration temperature from 200 to 350°C but does not exceed 15–30% of the time for the initial freshly prepared sorbent A1. It should be noted that calcination of the initial A1 and A2 sorbents at 200–350°C decreases their dynamic capacity several times (Fig. 1b).

For comparison we studied regeneration of C1 and C2 sorbents, since Hayashi *et al.* [4] found that the sorption properties of composites based on porous carbons can be completely regenerated by calcination.

Table 2. Dynamic capacity for carbon dioxide

Sorbent	A_{dyn}, g g^{-1} (% of the maximal value*), to indicated C_{out}, vol %	
	0.005	1.0
A1	0.063 (73)	0.067 (78)
A2	0.094 (64)	0.121 (82)
C1	0.008 (10)	0.044 (55)
C2	0.025 (35)	0.034 (48)
S1	0 (0)	<0.001 (<1)
V1	0 (0)	0.006 (4)

* The maximal capacity of the sorbents was calculated in accordance with the stoichiometry of reaction (1).

Table 3. Specific surface area S_{sp} and mesopore volume V_{me} of A1 sorbent calcined at different temperatures T_c

Sample	T_c, °C	S_{sp} (BET), m^2 g^{-1} support	V_{me}, m^3 g^{-1} support
Initial A1 support	200	248	0.41
Initial sorbent	200	142	0.34
	350	149	0.40
After CO_2 sorption	200	173	0.35
	350	174	0.38

Indeed, C1 and C2 sorbents were completely regenerated by heating at 150–200°C for 1–2 h (Fig. 1c).

To understand the different behavior of the sorbents, the changes in their texture and phase composition during the sorption and regeneration were studied by XRD, low-temperature nitrogen sorption, and TGA. The TG curves of A1 sorbent, measured on a Rigaku Thermoflex thermobalance, have two regions

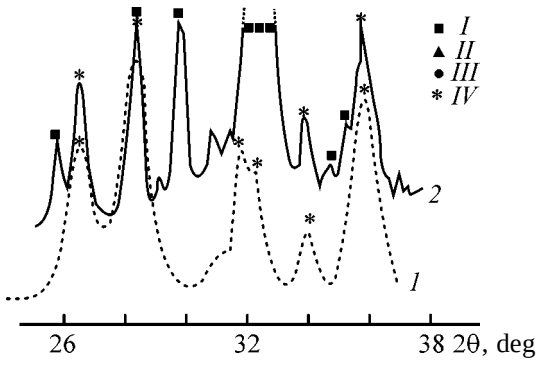

Fig. 2. Powder X-ray diffraction patterns of pure potassium aluminocarbonate (*1*) $KAl(CO_3)_2\cdot1.5H_2O$ and (*2*) freshly prepared A2 sorbent. (2θ) Braggs' angle; the same for Figs. 3 and 4. (*I*) $K_2CO_3\cdot1.5H_2O$, (*II*) K_2CO_3, (*III*) $KHCO_3$, and (*IV*) $KAl(CO_3)_2\cdot1.5H_2O$.

of weight loss at 80–100 and 320–350°C. The first peak is assigned to elimination of the crystallization water from $K_2CO_3 \cdot 1.5H_2O$. The second peak is probably due to CO_2 liberation in reaction of potassium carbonate with the matrix. Similar reaction [reaction (2)] was observed [5] between potassium carbonate and silica gel. The TG curve of pure alumina contains a single peak at 50–130°C due to removal of physically and chemically bonded water.

The specific surface area and pore size distribution of the samples were determined by low-temperature nitrogen adsorption performed on an ASAP-2400 Micromeritics unit. The results show that the surface area accessible for nitrogen slightly decreases after introduction of the salt (Table 3). Knowing the density of potassium carbonate $\rho_{K_2CO_3} = 2.428$ g cm^{-3}, we can estimate its content in pores accessible for nitrogen. The specific weight of potassium carbonate (g g^{-1}) in alumina pores, normalized to the weight of alumina Al_2O_3-1, is

$$m_{K_2CO_3} = V_w \rho_s \times 0.4 = 0.396,$$

where $\rho_s = 1.414$ g cm^{-3} is the density of a 40% solution of potassium carbonate at the impregnation temperature (25°C).

The volume occupied by potassium carbonate, $m_{K_2CO_3}/\rho_{K_2CO_3} = 0.163$ cm^3 g^{-1} Al_2O_3, is larger than the decrease in the pore volume measured by nitrogen porosimetry (Table 3). This is likely due to partial fixation of potassium carbonate particles in the macropores of the support. Interestingly, an increase in the pore volume of the sorbents with increasing regeneration temperature indirectly confirms reaction of potassium carbonate with alumina matrix to form carbon dioxide.

The phase transformations in the sorbents were studied by powder X-ray diffraction performed *ex situ* (HXG-4 diffractometer, graphite monochromator, CuK_α radiation). Freshly prepared A1 and A2 sorbents contain, along with anhydrous potassium carbonate and its sesquihydrate, also potassium aluminocarbonate $KAl(CO_3)_2 \cdot 1.5H_2O$ (Fig. 2) formed during preparation of the sorbent. After sorption the reflections of anhydrous potassium carbonate disappear and reflections of potassium hydrogen carbonate formed by reaction (1) appear (Fig. 3), whereas the amount of the aluminocarbonate phase decreases negligibly. The reflections of the X-ray patterns of the composites calcined at 350°C are strongly blurred, which makes it impossible to determine the phase composition of the samples (Fig. 4). The X-ray patterns of the spent and initial A1 sorbents calcined at 200°C are similar to that of the initial sample. However, some redistribution of the intensities of the reflections and their broadening are observed.

As determined by XRD, the initial C1 sorbent contains only the sesquihydrate and anhydrous potassium carbonate. Potassium carbonate completely reacts with carbon dioxide to form potassium hydrogen carbonate which reversibly decomposes to the initial K_2CO_3 at 200°C. These transformations are similar to those described by Hirano *et al.* [3]. Potassium aluminosilicate prepared by the procedure in [6] and isolated in the pure state weakly sorbs CO_2. This can cause the difference between the experimental dynamic capacity of A1 and A2 sorbents and the maximal dynamic capacity of these samples calculated from the stoichiometry of reaction (1).

CONCLUSIONS

(1) Sorption of carbon dioxide on supported potassium carbonate strongly depends on the chemical nature and pore structure of the host matrix. Freshly prepared composites based on γ-alumina have the

highest dynamic capacity (0.06 – 0.094 g g^{-1}, which is 65–75% of the limiting value) at 2-s contact of the gas flow with the sorbent, with the CO_2 concentration at the adsorber outlet being less that 25×10^{-4} vol %.

(2) The dynamic sorption capacity of the alumina composites decreases 3–4 times after the first sorption–regeneration cycle, whereas the sorbents based on porous carbons are regenerated reversibly.

(3) As determined by XRD, in the course of preparation of A1 and A2 samples a solution of potassium carbonate reacts with alumina to form $KAl(CO_3)_2 \cdot 1.5H_2O$ which does not sorb CO_2.

(4) Although the alumina composite has low dynamic capacity, it can be used in gas purification when application of zeolites is impossible because of high humidity of the gas phase and adsoption purification requires large investments (primarily in laboratories and small plants).

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Purification of Scandium(III) To Remove Zirconium(IV) Impurity in Hydrochloric Acid Solutions

Yu. V. Sokolova

Moscow State Institute of Steel and Alloys (Technological University), Moscow, Russia

Received December 20, 1999; in final form, September 2000

Abstract—A study was made on separation of the Zr(IV) impurity from scandium(III) in hydrochloric acid solutions by sorption with KRF-20t-60 cation exchanger, including sorption kinetics and sorption under dynamic conditions. The sorbent regeneration with 5% ammonium fluoride or 10% potassium carbonate at 22°C was considered.

Separation of Zr(IV) impurity from scandium(III) is a complicated problem because of close chemical properties of these elements. OS-99.9 grade scandium oxide with 0.005% and lower ZrO_2 content [1] was prepared using precipitation methods (e.g., zirconium iodate precipitation), or extraction with mixed extractants. However, these methods do not always provide the required purity of the product. In this work, we removed Zr(IV) from scandium(III) by sorption from hydrochloric acid solution with the H form of KRF-20t-60 cation exchanger containing phosphonic $PO(OH)_2$ functional group.

It was shown earlier that the recovery of cations with KRF-20t-60 cation exchanger is characterized with a mixed kinetics. The equilibrium in multicomponent salt solutions is attained in several weeks. A series of cation sorption selectivity (including the above elements) in acid solution (i.e., under conditions suppressing dissociation of phosphonic group) is as follows: REE(III) $\ll$ Sc(III) < Zr(IV) [2, 3].

Filatova *et al.* [4] believe that functional groups of swollen phosphonic cation exchangers in the H form are bound with each other by water molecules. Probably, this feature of such resins explains the high selectivity of KRF-20t-60 resin with respect to multicharged cations and the long time required to attain the sorption equilibrium, because during sorption from the multicomponent solution under conditions suppressing dissociation of the ionogenic groups of the resin the complex formation proceeds repeatedly.

The ability of KRF-20t-60 cation exchanger to separate REE(III) and the other cations from Sc(III) in acid solution was used for primary scandium concentration [5]. To separate Zr from scandium, we used in this work the greater affinity of the resin for Zr(IV) as compared to Sc(III) and the capability of Zr(IV) to displace Sc(III) from the resin phase because of complex formation.

EXPERIMENTAL

The main physicochemical characteristics of KRF-20t-60 cation exchanger are as follows: total static exchange capacity 6.6 mg-equiv g^{-1}, bulk density 0.38 g ml^{-1}, equivalent moisture capacity coefficient 2.90 H_2O g^{-1}, total pore volume 0.31 cm^3 g^{-1}, pK_{dis} for the first stage 3.0–3.2, divinylbenzene content 20%, and grain size 0.5–1.0 mm.

Cation exchanger samples were preliminarily conditioned by the standard method [6]. The scandium chloride solution was prepared by dissolution of OS-99.0 grade scandium oxide with the ZrO_2 content less than 0.1 wt % in chemically pure grade hydrochloric acid under boiling; the insoluble residue was separated by filtration. The scandium and zirconium concentrations were about 3 g l^{-1} and 3 mg l^{-1}, respectively.

The scandium concentration in the solution was determined by titration with EDTA in the presence of xylenol orange as an indicator. The impurity contents were determined using inductively-coupled plasma on a Labtam V-310 Plasma spectrometer and a Model 300 Perkin–Elmer AA spectrometer. The Zr detection limit was 10^{-5}%; the determination error was no more than 20%.

The degree of Zr sorption is independent of hydrochloric acid concentration within the 1–8.5 M range, and at the taken water-to-sorbent volume ratio V_w/V_s is close to 100% (Fig. 1). Experiments on scandium

1070-4272/01/7403-0414$25.00

purification procedure were performed with 1 M HCl. This acidity is enough to suppress dissociation of the cation exchanger phosphonic groups and to realize complexing properties of the cation exchanger.

The kinetics of Zr(IV) sorption on KRF-20t-60 cation exchanger from the scandium chloride solution was studied by the method of the limited solution volume. The degree of conversion equal to the ratio of Zr(IV) sorption at the instant τ to the equilibrium sorption value, after 6 h of sorption was equal to 84 and 74% for cation exchanger in the H and Sc forms, respectively, i.e., Zr sorption is slow (Fig. 2). Therefore, for sorption under dynamic conditions, we used a sorption column with the sorbent bed height to column diameter ratio d/h no less than 10: the solution flow velocity through the sorbent V did not exceed 0.4 ml min^{-1} cm^{-2}.

During the experiment, the H form of the sorbent was transformed into the Sc form by passing the scandium chloride solution through the sorbent. The comparison of the Sc(III) and Zr(IV) elution curves, when metals are sorbed by the H form of KRF-20t-60 from solutions of various compositions (Fig. 3), shows that Zr is efficiently sorbed by the cation exchanger also after the Sc concentration in the eluate becomes equal to the initial Sc concentration. This is explained by the preferential sorption of Zr(IV) during complex formation.

It follows from the data obtained that at Sc concentration of 3 g l^{-1}, Zr concentration of 3 mg l^{-1}, h/d ratio of 10, and the solution flow velocity of 0.4 ml min^{-1} cm^{-2} sorption with KRF-20t-60 allows removal of Zr impurity from a scandium chloride solution with a purification coefficient of 50 in the solution volume greater than 42 resin volumes. When the Sc and Zr concentrations were 2.94 g l^{-1} and 28.1 mg l^{-1}, respectively (Zr was introduced additionally), the purification efficiency under the same conditions decreased. In this case, the required purification degree for obtaining OS-99.9 grade scandium oxide (~1.5 mg l^{-1} of Zr) is attained for solution volume equal to 1.5–2 resin volumes (V_{rel} = 1.5–2).

Calculation showed that in run no. 1 the sorbent capacity was about 100 mg of Zr per liter of the resin; in run no. 2 (V_{rel} = 2) 55 mg of Zr was sorbed. The characteristics of the sorbent show that Zr occupies 0.02 and 0.03% of the ion exchanger capacity in run nos. 2 and 1, respectively. Hence, poor separation of Zr(IV) impurity in run no. 2 is probably due to the insufficient time of cation exchanger contact with the solution (~0.5 h), rather than to Zr excess over the ion exchanger capacity. This problem can be solved by repeated sorption under static conditions.

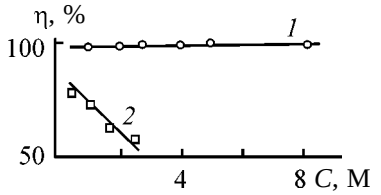

Fig. 1. Degree of Zr sorption η from scandium chloride solution on KRF-20t-60 cation exchanger in the Sc form as a function of acid concentration C. $C_{Sc(III)}$ = 9.80 and $C_{Zr(IV)}$ = 10^{-4} g l^{-1}; V_w/V_r = 2.0. Acid: (*1*) HCl and (*2*) H_2SO_4.

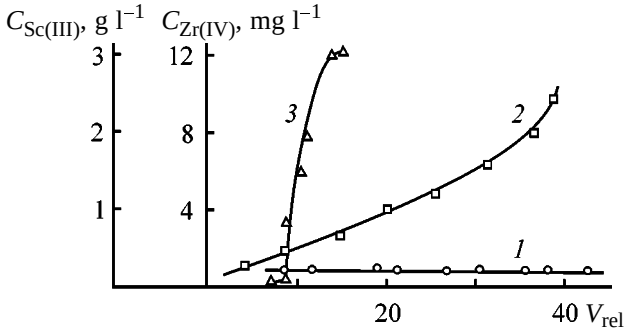

Fig. 3. (*1, 2*) Output curves of Zr and (*3*) Sc at their sorption on KRF-20t-60 in H form under dynamic conditions. h/d = 10, v = 0.4 ml min^{-1} cm^{-2}. ($C_{Sc(III)}$) Sc(III) concentration, ($C_{Zr(IV)}$) Zr(IV) concentration; (V_{rel}) volume of the solution passed, expressed in the resin volumes. Solution composition (g l^{-1}): (*1*) Sc(III) 3.00, Zr(IV) 0.0023, HCl 73 (run no. 1); (*2*) Sc(III) 3.00, Zr(IV) 0.0281, HCl 73 (run no. 2); (*3*) Sc(III) 3.00, Zr(IV) 0.003, HCl 80.

To regenerate the ion exchanger, it was washed with distilled water to remove the initial solution and

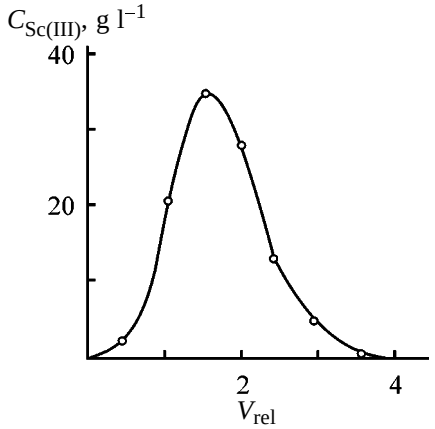

Fig. 4. Sc(III) desorption from KRF-20t-60 cation exchanger with 5% NH_4F. ($C_{Sc(III)}$) Sc(III) concentration in NH_4F solution; (V_{rel}) volume of NH_4F solution expressed in the resin volumes.

with 2% ammonia to neutralize the acid in the ion exchanger pores, and then Sc(III) was desorbed with 5% NH_4F at 20–25°C (Fig. 4). The degree of Sc(III) desorption was 90 and 99% when elution was performed by the volume of the NH_4F solution V_{rel} equal to 4 and 8. Then, Sc(III) was recovered as scandium fluoride by adding hydrochloric (or another) acid to the resulting solution up to free acid concentration of about 100 g l^{-1} and calcination of the precipitate at 450°C. The residual Sc concentration in the mother liquor did not exceed 10–20 mg l^{-1}.

If required, scandium can be recovered as oxide by calcination of scandium(III) hydroxide. In this case, scandium desorption is performed with 10% potassium carbonate at room temperature. The desorption degree is close to 100% when the regenerating solution for scandium elution is taken in amount of V_{rel} = 10. Scandium hydroxide is precipitated from the carbonate medium by neutralization with hydrochloric acid to pH ~ 7. The residual Sc concentration in the solution is 20–30 mg l^{-1}.

After conversion of the cation exchanger into the H form by treatment with 3% HCl, it can be used again for scandium purification to remove Zr impurity.

Scandium oxide recovered from the solution in run no. 1 by precipitation of scandium hydroxide with 25% NH_4OH (chemically pure grade) followed by drying and calcination contained less than 0.005% ZrO_2.

We should expect that the high affinity of phosphonic acid cation exchanger KRF-20t-60 for multicharged cations allows also efficient separation of Th(IV) and U(VI) impurity from scandium under conditions suppressing the dissociation of the phosphonic acid group, when the complexing properties of resin ionogenic groups can be realized.

CONCLUSION

A study of the kinetics and dynamics of the Zr(IV) sorption from acidic scandium chloride solution with KRF-20t-60 cation exchanger showed that the Zr concentration can be decreased by a factor of 50 and more by sorption purification. Procedures of the sorbent regeneration with 5% NH_4F or 10% potassium carbonate at room temperature were proposed.

Received November 20, 2000

Abstract—K-Selective solid-contact electrodes with potential-stabilizing transient layers based on two different electron-conducting polymers, poly(3-octyl)thiophene, polyaniline, and also on their mixture are developed. These electrodes are characterized by the operation limits, selectivity, and stability of the potentiometric response as well as by their electrochemical impedance.

Improvement of the design of ion-selective electrodes (ISEs) and search for novel materials for their construction are regarded as the most important lines in chemical sensor research. From the practical standpoint solid-contact electrodes (SCEs), i.e., electrodes having no inner filling solution, show considerable advantages such as eliminated need in regular change of the inner filling solution, possibility of any spatial orientation of a sensor, easier transportation, etc.

The first SCEs were coated wire electrodes with a film membrane in direct contact with an electronic conductor [1, 2]. The potential of such electrodes strongly and randomly varies in time. To stabilize the potential at the membrane/lead interface, Stefanova and others [3–5] proposed to introduce a polymer-based redox system in the inner membrane layer contacting with the electronic conductor. As such potential-stabilizing systems they successfully used powdered EO-7 and EI-21 ion-exchange redox resins (redoxites). The potential of thus modified electrodes appeared to be much more stable as compared to the first wire electrodes with film membranes. However, the modified electrodes were characterized by sudden change in their potential by 0.5–1 mV, which causes a need in regular (at interval of several hours) recalibration of the sensors. In industrial process control such a frequent calibration is not always permitted, so that further search for new potential-stabilizing materials for SCEs still remains urgent.

One of the reasons for insufficient stability of the potential of SCEs with redoxites can be heterogeneity of the transient layer. Indeed, even if every particle of a finely dispersed resin is in ion-exchange equilibrium with the membrane organic phase and the bulk of each particle of the resin is in the state of the redox equilibrium, these are insufficient conditions to maintain the equilibrium potential in the transition zone from ionic to electronic conductance. Keeping of the equilibrium potential requires realization of a direct contact of a lead with a great number of the resin particles. Only in this case one may expect that the electron current from the lead to the resin particles (and back) will be sufficiently high to provide certain value of the electrode potential stable in time and within a series of electrodes. In this context redox couples seems to be more favorable as compared to polymer resins. In its turn, it was demonstrated in [3–5] that the intrinsic drawback of these SCEs is that they are sensitive to the redox potential of test solutions as a result of diffusion of soluble redox couples from the intermediate layers to the outer side of the membrane.

The combination of solubility and low mobility of redox couples can be realized with the use of soluble electron-conducting polymers (EPs) introduced in the intermediate layer between the membrane and the lead. More or less successfully such polymers were used in various SCEs [6–10]. The electronic conductance of EPs is caused by the presence of delocalized π electrons in the polymer structure. Electron-conducting polymers become electron-ionic transducers by the *p* and *n* doping mechanisms according to Eqs. (1) and (2):

$$p \text{ doping: } P^0 + X^- = p^+X^- + e, \quad (1)$$

$$n \text{ doping: } P^0 + C^+ + e = P^-C^+. \quad (2)$$

The existing EPs are characterized by low conductivity [6–9]. The goal of this work is to develop a

1070-4272/01/7403-0417$25.00

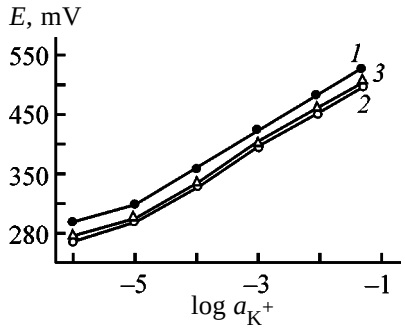

Fig. 1. emf of voltaic cell II E as a function of $\log a_{K^+}$ for K^+-SCEs based on various EPs: (*1*) PA, (*2*) POT, and (*3*) POT + PA; the same for Fig. 2.

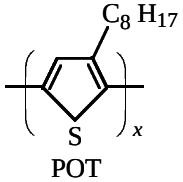
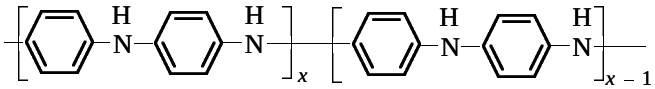
K-selective SCE stabilized with soluble EPs. The distinctive feature of this work is that we used not only the individual EPs, poly(3-octyl)thiophene (POT) and polyaniline (PA), as was the case in [6–9], but also their mixtures. Furthermore, we used a partly soluble electron-conducting composite as a lead material, instead of carbon glass used in [6–9], providing more continuous transition from one type of conductance to another in the transition layer.

In this work we used the electron-conducting polymers POT and PA (Application Technologies, France) as ion-electronic transducers for K-selective SCEs.



POT



PA

POT is soluble in most organic solvents. In the undoped form it is a *p* semiconductor, showing nonselective cationic response toward some alkali and alkaline-earth metals [6]. Undoped PA in the form of emeraldin base (EB) is poorly soluble in organic solvents. However, PA can be doped (protonated) by introducing organic acid molecules in its structure [9]. The resulting electron-conducting emeraldin salt (ES) is readily soluble in certain organic solvents. In this work PA was doped with di-(2-ethylhexyl) hydrogen phosphate (HDEHP) (Aldrich).

Solutions of POT in THF were obtained by dissolution of 0.015 g of POT in 2 ml of freshly distilled THF. To obtain a solution of PA in THF, 0.02 g of PA in the form of EB was added to 0.05 M HDEHP in THF (2 ml) [9]. In doped PA the molar ratio of HDEHP to PA monomeric unit was 0.5. The resulting mixture was allowed to stand for 3 days, and the insoluble fraction was then filtered off. The filtrate (soluble fraction of PA-HDEHP in THF, where PA is in the ES form) was used in manufacture of SCEs.

The K-selective membranes were prepared as follows. Polyvinyl chloride (PVC) (matrix material), dioctyl phthalate (DOP) (plasticizer), valinomycin (membrane active compound), and potassium tetra-*p*-chlorophenylborate (ion exchanger) were dissolved in THF. The PVC and DOP were taken in 1 : 3 ratio. The valinomycin and potassium tetra-*p*-chlorophenylborate concentrations were 2×10^{-3} and 1×10^{-1} mol kg^{-1}, respectively. The electron-conducting polymers (POT, PA, or POT + PA equimolar mixture) were added in amount of 1 wt % against the membrane composition of the transition layer.

The membrane of SCEs consisted of two layers successively applied to a support of an electron-conducting composite (PVC : carbon black : DOP = 1 : 1 : 0.5). The inner transition layer contacting the support was prepared by applying 200 μl of the appropriate composition using an HTL V-3 micropipet. The outer layer directly contacting an aqueous solution was represented by the membrane composition without EP, applied similarly over the transition layer after it became dry. The thickness of the inner and outer layers was the same (about 200 μm).

The electrode characteristics of K-selective electrodes were studied with liquid–junction voltaic cells I and II (see below).

Solid-contact electrode

First of all we studied the K^+ function of SCEs in pure KCl solutions.

For comparison we performed measurements with the ordinary K-selective electrodes with inner filling solution. The results obtained for K^+-SCEs 3 days after they were brought in contact with 0.01 M KCl solution are given in Fig. 1. The time of establishment of stationary potential was 1–3 min, which practically does not differ from that for the corresponding elec-

trodes with inner filling solution. Figure 1 demonstrates that for all K^+-SCEs studied, regardless of the nature of a polymer entering the composition of the inner membrane layer, the operation limit was 1×10^{-1}–1×10^{-5} M at a slope of the K^+ function of 57 ± 2 mV/pK^+. Similar results were obtained for the corresponding electrodes with inner filling solution. It should be pointed out that the SCEs with two different polymers, POT and PA, showed K^+ function throughout the observation time (4 months).

However, in contrast to the electrodes with inner filling solution, the potential of SCEs measured in 0.01 M KCl drifts with time (Fig. 2). It is seen that the potential of SCEs with POT and PA decreased quite rapidly (by 5–7 mV day^{-1}) in the first three weeks and then the drift was at a level of 1–2 mV day^{-1} in the entire observation period (4 months).

For SCEs with POT + PA the potential increased in the first several days and then decreased at a rate of 4–5 mV day^{-1} in the entire observation period (about 40 days for these electrodes).

To elucidate the source of the observed instability of the potential of the SCEs, they were studied by the electrochemical impedance method in 0.01 and 0.1 M KCl. The impedance spectra were registered and processed with an Autolab PGstat FRA 2 impedance analyzer (Eco Chemie) over the frequency range of the polarizing sine-shaped signal from 100 kHz to 0.01 Hz. The polarization amplitude was ± 5 mV. The typical impedance spectra are presented in Fig. 3. The spectra distinctly demonstrate semicircles corresponding to the bulk of the membrane phase, whose resistance is practically independent of the solution concentration. We found no indication of a process decelerating the establishment of the electrochemical equilibrium at the membrane/lead interface.

In fact, electrochemical impedance data provide information on the polarizability of an object (SCE in our case) with electric current of a given amplitude and frequency. The results obtained suggest that at the membrane/lead interface the electrochemical equilibrium is established between the oxidized (doped) and reduced (undoped) forms of EP. At each moment of time this equilibrium is controlled by the ratio of the thermodynamic activities of these forms. The corresponding electric potential should be stable for certain time until this activity ratio is changed. However, this ratio can change as a result of, for example, oxidation of the membrane components by atmospheric oxygen, resulting in long-term drift of the electrode potential.

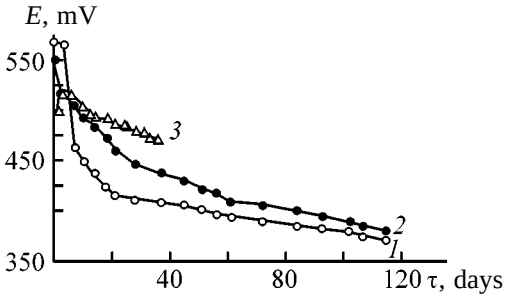

Fig. 2. emf of voltaic cell II E as a function of the contact time with 0.01 M KCl τ for K^+-SCEs based on various EPs.

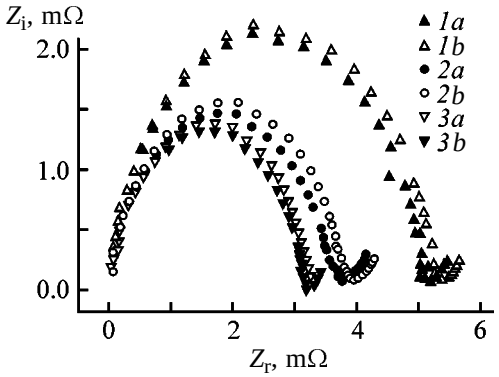

Fig. 3. Impedance spectra in KCl solutions of K^+-SCEs based on various EPs. Z_r and Z_i are the real and imaginary parts of the total resistance Z. KCl concentration (M): (*1a*–*3a*) 0.1 and (*1b*–*3b*) 0.01. EP: (*1a, 1b*) PA, (*2a, 2b*) POT, and (*3a, 3b*) POT + PA.

Figure 2 shows that the potentials of all the SCEs studied drift toward less positive values. But oxidation of EP should initiate potential drift in the opposite direction. Therefore, it is unlikely that oxidation with atmospheric oxygen may be regarded as the major reason for the insufficient stability of SCE operation. Another possible reason can be spontaneous reduction of the doped form of EP. It is this process that can provide the observed potential drift.

At last we studied the K^+ selectivity of SCEs in the presence of various interfering cations. The selectivity coefficients were estimated by the Nikol'skii equation from the biionic potentials measured in 0.1 M solutions of the corresponding chlorides (see table). The results show that initially (in the first 10 days) the SCEs studied practically do not differ from the electrodes with inner filling solution in their selectivity with respect to K^+ in the presence of Na^+, NH_4^+, Ca^{2+}, and Mg^{2+}. However, the K^+ selectivity of the SCEs decreases with time, which can be attributed to diffusion of the membrane-active components, primarily valinomycin, from the outer layer to the

Selectivity coefficients of K^+-ISEs determined by BIP method

Contact time	$\log K^{sel}_{K^+/M^{z+}}$ for indicated M^+

3 h	–4.14	–1.73	–3.66	–4.04	–4.88
7 days	–3.61	–1.67	–3.39	–3.86	–4.55
14 days	–3.72	–1.64	–2.65	–2.93	–4.19
21 days	–3.31	–1.51	–2.99	–2.85	–3.52
102 days	–3.28	–1.49	–1.61	–2.65	–3.33
K^+-SCE with PA					
3 h	–3.79	–1.68	–3.24	–3.93	–4.61
7 days	–3.54	–1.64	–3.16	–3.62	–4.42
14 days	–3.37	–1.52	–2.34	–2.89	–4.01
21 days	–2.92	–1.33	–2.29	–2.41	–3.01
102 days	–3.27	–1.51	–1.54	–2.40	–2.72

plasticized supporting layer. As a result, the ionophore concentration in the membrane gradually decreases, causing deterioration in the selectivity.

It is typical that the SCE selectivity with respect to K^+ in the presence of hydrogen ions is lower than that of the corresponding electrodes with inner filling solution, and this parameter tends to substantially decrease with time (see table). This is probably due to the fact that the electron-conducting polymers (especially PA) entering the composition of the membrane inner layer are pH-sensitive [10]. It follows from data given in the table that SCEs with POT in the membrane inner layer generally demonstrate higher selectivity as compared to the PA-containing SCEs.

CONCLUSIONS

(1) The K-selective solid-contact electrodes studied demonstrate the K function over the concentration range 1×10^{-1}–1×10^{-5} M at a slope of 57 ± 2 mV/pK^+, which is well consistent with the characteristics of the corresponding electrodes with inner filling solution. The K^+ function is preserved over the entire observation period (4 months).

(2) The K selectivity of the SCEs in the presence of various interfering cations in the first 10 days practically does not differ from that of the electrodes with the classical design, but gradually decreases in the subsequent period.

(3) The potential of the SCEs drifts at a rate of 5–7 mV day^{-1} in the first 10 days and of 1–2 mV day^{-1} thereafter. The electrodes can operate for 10 h without recalibration.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrolytic Deposition of the Zinc–Cobalt Alloy

O. S. Vinogradov and Yu. P. Perelygin

Penza State University, Penza, Russia

Received February 3, 2000; in final form, June 2000

Abstract—The influence of the electrolyte composition and process conditions on electrolytic deposition of the zinc–cobalt alloy was studied.

Corrosion-resistant electroplated coatings for items used in marine atmosphere are mainly prepared from cadmium. However, cadmium and its salts are toxic, which severely restricts their application. When looking for a substitute for cadmium, it is necessary to ensure not only high corrosion resistance of a coating in marine atmosphere but also the low friction coefficient, so that screw joints be readily dismantlable and articles be soft-solderable with acid-free fluxes. The most promising in this respect can be zinc–cobalt coating. The zinc–cobalt alloy can be electroplated from acidic and weakly acidic [1–6], ammonium chloride and sulfate [7–11], and diphosphate [12] electrolytes.

The goal of this work was to study the influence of the composition of the ammonium chloride electrolyte and electroplating conditions on the composition of the zinc–cobalt alloy, current efficiency (CE), and physicomechanical properties and corrosion resistance of the coating.

Semilustrous and lustrous coatings of the alloy are deposited from ammonium chloride electrolyte. The alloy composition and properties are influenced by the concentration of discharging metal ion and electroplating conditions. The cobalt content in the alloy increases with increasing Co(II) concentration in the electrolyte at a Zn(II) concentration of 35 g l^{-1}, current density of 1.5 A dm^{-2}, temperature of 20°C, and pH 4.75 (Fig. 1, curve *1*).

In the range of Co(II) concentrations 2.5–15 g l^{-1}, under optimal electroplating conditions, the dependence of the cobalt content in the alloy (%) on the cobalt concentration in the electrolyte (g l^{-1}) is described by the equation

$$[Co]_{all} = 2.04 + 6.86\log[Co(II)] \quad (R = 0.976). \quad (1)$$

The alloy composition correlates with the concentration ratio of Zn(II) and Co(II) in the electrolyte as follows:

$$\log\frac{[Zn]_{all}}{[Co]_{all}} = 0.79 + 0.43\log\frac{[Zn(II)]}{[Co(II)]} \quad (R = 0.955). \quad (2)$$

As the Co(II) concentration in the electrolyte is increased, the current efficiency (Fig. 1, curve *2*) decreases, which is due to the fact that the overvoltage of hydrogen evolution decreases with increasing content of cobalt in the alloy [13]. The current efficiency of alloy deposition (%) linearly correlates with the Co(II) concentration in the electrolyte:

$$CE = 94.67 - 0.37[Co(II)] \quad (R = 0.996). \quad (3)$$

When examining the influence of electroplating conditions on the alloy composition and current efficiency, each parameter was varied at fixed values of the other parameters. With increasing current efficiency from 1 to 2 A dm^{-2}, temperature from 20 to 40°C, and electrolyte pH from 4 to 5.5, the cobalt content in the alloy increases (Fig. 2, curves *1–3*); the current efficiency decreases with inceasing current density (Fig. 2, curve *4*) and grows with temperature (curve *5*) and with increasing pH (curve *6*). The decrease in the current efficiency at increased current densities may

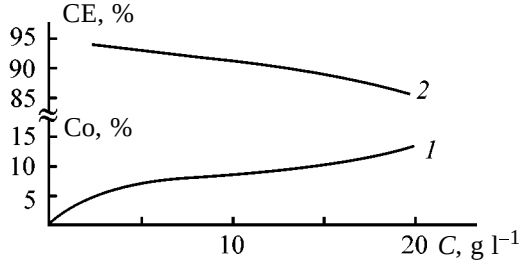

Fig. 1. (*1*) Alloy composition (Co content) and (*2*) current efficienct CE as functions of the Co(II) concentration in the electrolyte *C*.

1070-4272/01/7403-0421$25.00

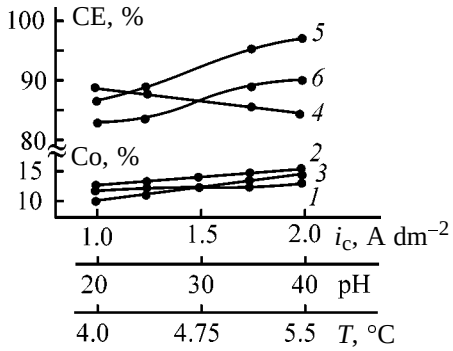

Fig. 2. (*1–3*) Co content in alloy and (*4–6*) current efficiency CE as functions of the (*1, 4*) current density i_c, (*2, 5*) temperature, and (*3, 6*) pH.

be due to a shift of the cathode potential toward negative values and hence to increased contribution of hydrogen evolution. The increase in the current efficiency with temperature is due to the shift of the cathode potential toward positive values and to increasing ion mobility in the electrolyte.

To obtain lustrous coatings containing 3–5% Co in the alloy, the following electrolyte composition can be suggested (g l^{-1}): $ZnCl_2$ (in terms of metal) 30–40, $CoCl_2$ (in terms of metal) 2–4, NH_4Cl 220–260, boric acid 20–30, and bone glue 2–3. Electroplating is performed at room temperature, current density of 1–2 A dm^{-2}, and pH 4.5–5.0.

To optimize the compositions of the alloy and electrolyte and the electroplating conditions for preparing the alloy containing 3–5% Co, we performed a four-factorial experiment. The optimization parameter was the Co content in the alloy *Y*, which should be 3–5%. The factors affecting the alloy composition are Co(II) concentration in the electrolyte x_1, current density x_2, temperature x_3, and electrolyte pH x_4.

After determining the coefficients of the regression equation, we evaluated their significance by the Student's test. For this purpose, we performed three parallel experiments in the plan center (at the base level of all the factors). The chemical analysis of the alloy samples obtained gave Y_1 = 3.6, Y_2 = 4.0, and Y_3 = 4.4. Then, the insignificant coefficients of the regression equation were canceled, and the resulting model was checked for adequacy using the Fisher's test. The regression equation adequately describing the effect of the process parameters on the Co content in the alloy is as follows:

$$Y = 4.2 + 0.9x_1 + 1.15x_2 + 1.0x_3 + 0.8x_4 + 0.15x_1x_2 + 0.15x_2x_3 + 0.15x_2x_4. \quad (4)$$

As seen from Eq. (4), the alloy composition is influenced both by separate factors (Co concentration in the electrolyte, current density, temperature, and pH of the electrolyte) and by a combination of factors (to an insignificant extent) current density–Co(II) concentration in the electrolyte, current density–temperature, and current density–pH of the electrolyte.

The phase composition of the coating at a cobalt content in the alloy of 1–6% was studied with a DRON-2 X-ray diffractometer. The alloy is a solid solution of cobalt in zinc and consists of the homogeneous phase γ^2 + zinc. Such a structure ensures enhanced corrosion resistance of the coating.

The electroplated coatings of the alloy without passivation are white, lustrous, and smooth under magnification of 300, 1000, and 3000.

The solderability of the alloy coating was evaluated by the time τ and area *S* of spilling of POS-61 solder with an alcohol–rosin flux. The results obtained with a 0.13-g portion of POS-61 are given in the table.

It is seen that, as the cobalt content in the alloy is increased, the solderability is improved, and the alloy containing 12% Co surpasses in this paremeter the cadmium coating.

The antifriction properties of the Zn and Zn–6%Co coatings were studied without passivation of the coating on a special unit allowing determination of the friction force at various loads on the couple. The friction coefficient at a load of 50–200 g for Zn and Zn–6% Co is 0.27 and 0.25, i.e., coating with the alloy makes screw joints more readily dismantlable than coating with zinc.

Climatic tests performed in a chamber with a humid (93±3%) atmosphere at 40±2°C for 56 days and in a chamber containing salt aerosol for 7 days [GOST (State Standard) 9.308–85] showed that the corrosion resistance of the coating depended on the cobalt content. Tests in a chamber with humid atmosphere

Solderability of coatings of zinc, cadmium, and zinc–cobalt alloy

Coating	*S*, mm	τ, s
Zn	18.3	6
Cd	170	8
Alloy with Co content, %:		
1	18.5	6
3.5	18.5	2
12	172	2

showed that the coatings containing 3–5% Co with or without passivation well compare with the cadmium coating in the corrosion resistance. The only change observed was the change in the color of the passive film. Tests with salt aerosol showed no corrosion for the passivated alloy coating, whereas without passivation corrosion products were observed as a white deposit. Thus, the passivated coatings of alloy containing 3–5% Co well compare in the corrosion resistance with the cadmium coating.

Based on the results obtained, we suggested the electrolyte composition and process conditions for deposition of alloys containing 1, 3–5, and 9–11% Co. Coatings with different cobalt content can be used under different service conditions. The coating containing up to 1% Co is more corrosion-resistant than the purely zinc coating and can be used as protective and decorative coating instead of zinc coatings. The coating containing 3–5% Co approaches the cadmium coating in corrosion resistance and can be used as protective and decorative coating for items subjected to impact of marine atmosphere. The coating containing 9–11% Co well compares with the cadmium coating in corrosion resistance and can be used as a protective and decorative coating with a low friction coefficient for parts subjected to impact of marine atmosphere.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Deposition of Copper from Dilute Solutions onto Disperse Graphite Cathode

G. M. Zagorovskii, G. P. Prikhod'ko, V. M. Ogenko, and I. G. Sidorenko

Institute of Surface Chemistry, Ukrainian National Academy of Sciences, Kiev, Ukraine

Received March 22, 2000; in final form, June 2000

Abstract—Results obtained in studying copper(II) recovery from sulfate solutions with concentrations less than 1 g l^{-1} in an electrolyzer with disperse graphite cathode are presented.

Closed systems with circulating water supply are environmentally the safest. Technologies of this kind can be used in electroplating, hydrometallurgy, and other industries provided that washing water having the form of low-concentration (< 1 g l^{-1}) solutions of salts of non-ferrous metals is purified by nonchemical methods.

One of promising methods for solving this problem is electrolysis making it possible to obtain metals in the most concentrated state requiring minimum energy expenditure for further processing. However, electrolytic recovery of non-ferrous metals from low-concentration aqueous solutions is hindered by diffusion limitations on the current. This problem can be solved by using bulk-porous flow-through electrodes and, in particular, cathodes made of fibrous carbon materials [1–3].

The effect of carbon fiber splicing by crystals of deposited metal and the resulting deterioration of the electrode characteristics [4] necessitates a search for disperse carbon materials with developed surface, which would enable fabrication of a "pseudofluidized" cathode devoid of this shortcoming.

The present study used thermally expanded graphite as a material of this kind [5].

EXPERIMENTAL

Thermally expanded graphite with a bulk density of 8–10 g l^{-1} was obtained by fast heating of GAK-2 natural graphite intercalated with sulfuric acid in an electric furnace preliminarily heated to 900°C, with $(NH_4)_2S_2O_8$ as oxidizing agent [5].

Voltammograms were taken with a PI-50-1.1 potentiostat in a three-electrode glass cell, with the working electrode polarized at potential sweep rate of 5 mV s^{-1}. As auxiliary electrode served a $40 \times 10 \times$ 3-mm graphite plate. As reference electrode was used saturated silver chloride electrode. The working electrode was fabricated from compacted thermally expanded graphite by pressing the disperse material in a glass tube with inner diameter of 3 mm, placed in a cell filled with electrolyte. The role of the working surface was played by the lower edge of the obtained graphite rod, and that of a current lead, by a copper wire pressed into graphite.

The disperse working electrode was fabricated by pouring 10 mg of thermally expanded graphite in a glass tube 3 mm in diameter, placed in a cell filled with electrolyte. A copper current lead 2.5 mm in diameter was dipped into the tube to such a depth that the lower edge of the column of thermally expanded graphite was level with the edge of the glass tube.

As supporting electrolyte was used 0.01 N sodium sulfate solution.

Copper(II) was deposited from solution in a flow-through electrolyzer made of a glass tube 30 mm in diameter and 150 mm long, with a disperse cathode in its upper part. As current lead served a nickel foil circle 29.5 mm in diameter and a Nichrome wire. The electrolyte flow was effected through a clearance between the edge of the nickel circle and the electrolyzer wall. As anode was used graphite rod 6 mm in diameter, placed in a glass tube to prevent its coming in contact with cathode particles.

The electrolyte was pumped through using an RR1-05 peristaltic pump providing solution flow rate in the range from 0.1 to 200 ml min^{-1}. The pumping rate was chosen so that the quantity of electricity passed through a given solution volume (at a current

1070-4272/01/7403-0424$25.00

established at voltage of 35 V across the electrolyzer terminals) was sufficient for recovery of the entire amount of copper contained in the solution. The electrolyzer was connected to a B5-49 dc stabilized power supply. The current strength was monitored with an Shch-4300 multimeter.

The content of copper(II) in solution was determined by the method described in [6] with a KFK-2MP photoelectric concentration colorimeter.

The solutions were prepared from analytically pure grade chemicals.

Because of the specific character of the preparation technology, thermally expanded graphite contains a residual amount of the intercalating agent (sulfuric acid) in its crystal lattice and various oxygen-containing groups (lactone, quinone, etc.) on its surface [5]. Therefore, cathodic polarization of electrodes made of thermally expanded graphite is accompanied by deintercalation and reduction of oxygen-containing groups.

The fact that the concentration of reducible oxygen-containing groups on the working surface of the electrode will decrease with increasing time of cathodic polarization can account for the decrease in current in electrode cycling. This made necessary a study of the time dependence of the polarization current. For this purpose, the electrode was polarized for 5 min in the supporting electrolyte in the potentiostatic mode at a potential of 1 V, and after that a voltammogram was taken. Then the procedure was repeated. The obtained voltammograms are shown in Fig. 1.

Upon cathodic polarization of a compacted electrode for 30 min the current ceases to change. Therefore, all further studies were performed on electrodes subjected to preliminary polarization in a supporting electrolyte for 30 min.

Introduction of Cu(II) ions into the solution changes the shape of the polarization curves, and, at a copper(II) content in solution of 20 mg l^{-1}, the process of copper deposition on thermally expanded graphite becomes predominant. The polarization curves show portions of limiting currents depending on the concentration of the depolarizing agent (Fig. 2).

The results of polarization studies on an electrode made of compacted thermally expanded graphite indicate that hydrogen starts to evolve on reaching a potential of –1.3 V, which enables this material to be used in recovery of non-ferrous metals from aqueous solutions.

The same phenomena are observed on a disperse electrode made of thermally expanded graphite

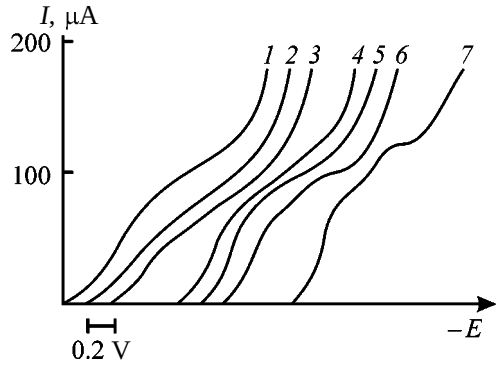

Fig. 3. Polarization characteristics of a disperse electrode in solutions with varied copper(II) content. (*I*) Current and (*E*) voltage. Copper(II) content (mg l^{-1}): (*1*) 0, (*2*) 0.1, (*3*) 0.2, (*4*) 0.5, (*5*) 1.0, (*6*) 2.0, and (*7*) 5.0.

(Fig. 3), but the currents are an order of magnitude higher than those in the case of compacted electrodes and limiting currents of copper deposition start to be observed at a copper content in solution of 2 mg l^{-1}. The cathode current density is as high as 0.15 A dm^{-2},

Current efficiency CE by copper at varied copper content in solution

Run no.	I, mA	C_{in}	C_{out}	Degree of copper recovery, %	CE %
		mg l^{-1}			
1	4.0	1	0.08	92.0	2.5
2	2.0	1	0.4	60.1	5.3
3	2.2	5	0.6	88.4	9.5
4	2.5	10	0.1	99.0	15.6
5	2.8	20	0.3	98.5	17.2
6	3.5	50	0.2	99.5	29.8
7	3.7	100	0.5	99.5	37.2
8	4.0	200	0.7	99.6	44.5
9	6.0	500	0.6	99.8	50.0

calculated per visible working surface area of the electrode, which is quite acceptable for performing electrolysis with sufficient intensity.

Owing to the occurrence of side processes at the cathode made of thermally expanded graphite, the current efficiency by the metal will not reach 100%, which is confirmed by the results of electrolysis, presented in the table.

As would be expected, the current efficiency by the metal steadily grows with increasing copper(II) concentration in solution.

Comparison of the results of run nos. 1 and 2 shows that aqueous solutions can be purified to remove copper ions to residual concentrations corresponding to the maximum permissible concentration in an electrolyzer with disperse cathode made of thermally expanded graphite at higher power consumption.

CONCLUSION

The possibility is demonstrated of copper recovery from dilute aqueous solutions in electrolyzers with disperse cathode made of thermally expanded graphite. Electrolyzers of this kind can be employed in straight-flow water consumption schemes, although their use in circulation schemes is preferable.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of Lead(II) Complexation on Solubility of β-PbO in Alkaline Solutions in the Presence of Certain Alcohols

V. P. Yurkinskii, N. V. Sokolova, and V. A. Popov

St. Petersburg State Technical University, St. Petersburg, Russia

Received September 9, 1999; in final form, November 2000

Abstract—Complex formation of lead(II) was studied, and the solubility of β-PbO was determined by potentiometric titration in solutions containing sodium hydroxide (0.3–4 M) and a series of mono- and polyhydric alcohols. A correlation between the lead monoxide solubility and Pb(II) complex formation function was considered.

The major fraction of the secondary lead raw material is lead(II) oxide. Its processing involves treatment with alkaline solutions in which fairly high solubility of PbO is caused by formation of strong Pb(II) hydroxo complexes [1–3]. To increase the PbO solubility, it is suggested to add alcohols (e.g., glycerol [1]) into the alkaline solution.

In this work, the solubility of β-PbO in alkaline solutions containing additives of mono- and polyhydric alcohols (1-propanol, ethanol, ethylene glycol, glycerol, and sorbitol) was determined. Simultaneously, complex formation of Pb^{2+} ions in these solutions was studied to determine the correlation between the PbO solubility and the lead(II) complex formation function.

To determine the complex formation function, we used potentiometric titration [2, 3].

It is known that in alkaline solutions Pb^{2+} ions form strong complexes, mainly $Pb(OH)_3^-$ [2].

To determine the composition of lead(II) hydroxo-alcoholic complexes, we used a method developed by us previously for studying complex formation of Pb(II) in alkaline solutions with glycerol [3]. The average ligand number n in the complex was determined as a slope of the linear dependence of the indicating lead amalgam electrode on the logarithm of the ligand (hydroxide ion, alcohol) concentration [3]. The calculated $\bar{n}_{OH^-}$ and $\bar{n}_{alc}$ are listed in the table.

As seen, $\bar{n}_{OH^-}$ is close to 3 for all alcohols, similarly to glycerol [3]. Hence, complexes $Pb(OH)_3^-$ prevail in the solution [2]. The n_{alc} value shows that the Pb(II)-to-alcohol ratio is 1 : 1 for sorbitol and 2 : 1 for the other alcohols.

Thus, the composition of the prevailing complexes in the solution can be presented by the formula $[Pb(OH)_3 \cdot C_6H_8(OH)_6]^-$ for sorbitol and $[2Pb(OH)_3 \cdot$ alcohol molecule$]^{2-}$ for the other alcohols.

Using the known equation [4]

$$\Delta E = \frac{RT}{zF} \ln \frac{C^0_{Pb^{2+}}}{[Pb^{2+}]} = \frac{RT}{zF} \ln \Phi,$$

where ΔE is the experimental difference between potentials of the indicating electrode in the initial solution and in the solution containing sodium hydroxide, we calculated the complex formation function Φ as influenced by the hydroxide ion concentration for all the solutions studied.

Then, the functions Φ were obtained for solutions with fixed $[OH^-]$ and variable concentrations of alcohols. In Fig. 1, these dependences are shown for $[OH^-] = 0.3$ M. For the other sodium hydroxide concentrations such dependences are similar.

The presence of 1-propanol or ethanol in alkaline solutions changes the lead(II) complex formation function weakly (by no more than 10%). As for ethyl-

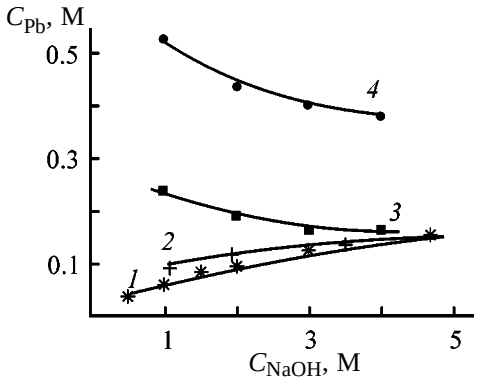

Fig. 2. β-PbO solubility C_{Pb} as a function of sodium hydroxide concentration C_{NaOH} at C_{alc} = 0.5 M. Alcohol: (*1*, *2*) none {(*2*) data of [8]}, (*3*) glycerol, and (*4*) sorbitol.

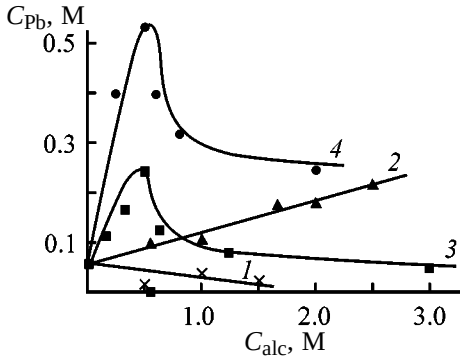

Fig. 3. β-PbO solubility C_{Pb} as a function of the alcohol concentration C_{alc} in 1 M NaOH. Alcohol: (*1*) 1-propanol, (*2*) ethylene glycol, (*3*) glycerol, and (*4*) sorbitol.

ene glycol or sorbitol, Φ increases practically linearly with the alcohol concentration (Fig. 1). The Φ values exceeded those for alcohol-free solutions maximally by about 70% for ethylene glycol and by a factor of 70 for sorbitol. It was shown in [3] that glycerol addition increases F maximally by a factor of 4.5.

Spectroscopic study of Pb(II) complex formation with ethylene glycol, glycerol, and xylitol [5] showed that these alcohols are active ligands and form 1 : 1 complexes with lead(II). Participation of hydroxide ions in complex formation and the Pb-to-OH^- ratio in the complexes were not considered in that work.

The solubility of β-PbO in the solutions studied was determined as follows. Solutions were stored for a long time in a thermostat at 298 ± 0.1 K contacting with the solid phase at intermittent agitation. The lead content in the solution was determined complexometrically [6]. The equilibrium was thought to be reached when in two successive measurements at a 7-day interval the lead concentration changed by no more than 1%. On the average, the equilibrium was reached in 30 days. After determination of the equilibrium lead(II) concentration, the potential of the indicating lead electrode was measured to calculate the lead(II) complexation function Φ.

The solubility of β-PbO in alcohol-free solutions was studied within the 0.5–4.7 M NaOH concentration range and in solutions containing one of the above alcohols with its concentration varied from 0.06 to 3.0 M and NaOH concentration varied from 1.0 to 4.0 M (Figs. 2, 3).

Earlier, the PbO solubility in the PbO–NaOH–H_2O system was studied in [7, 8] (in [8], at 298 K). For comparison, the data of [8] are presented in Fig. 2.

In solutions free of organic additives, the PbO solubility increases with the NaOH concentration. The results reasonably agree with data of [8]. In solutions containing glycerol and sorbitol, the PbO solubility weakly decreases with increasing alkali concentration; the optimal alkali concentration is about 1.0 M.

Curves in Fig. 3 show that the PbO solubility in 1.0 M NaOH initially increases with increasing concentration of glycerol or sorbitol, passes through a maximum at C_{alc} 0.5 M, and then noticeably decreases. For ethylene glycol, the solubility increases monotonically with increasing alcohol concentration.

Visual observation showed that the decrease of the PbO solubility in the solutions containing glycerol and sorbitol at C_{alc} > 0.5 M is caused by the change of the solid phase composition: Dense yellow β-PbO precipitate converts into voluminous white precipitate (its composition was not determined). In solution containing 2.5 M ethylene glycol, the PbO solubility is 3.7 times greater as compared to the solution containing no alcohol. In such solutions, the β-PbO phase is

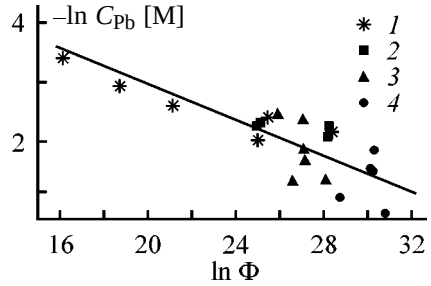

Fig. 4. β-PbO solubility C_{Pb} as influenced by complexation function Φ. Alcohol: (*1*) none, (*2*) glycerol, (*3*) ethylene glycol, and (*4*) sorbitol.

stable for all ethylene glycol concentrations studied. Propanol does not noticeably affect the PbO solubility.

In Fig. 4, the correlation between the PbO solubility and Pb(II) complex formation function is shown for all solutions studied. As seen, within the experimental error this correlation is linear in $\ln C_{Pb}$–$\ln \Phi$ coordinates. Hence, in the systems under consideration the PbO solubility is determined by Pb(II) complex formation, with both hydroxide ions and alcohols acting as ligands.

CONCLUSIONS

(1) In the β-PbO–NaOH–H_2O–alcohol systems studied, the hydroxo–alcoholic complexes of Pb(II) are formed.

(2) The β-PbO solubility in the above systems depends on the Pb(II) complexation.

(3) The optimal concentrations of sodium hydroxide (1.0 M) and alcohols were determined in solutions intended for β-PbO dissolution.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Role of Heterophase Interactions between Cadmium and Nickel in Cadmium Electrode Activation

I. A. Kazarinov, M. M. Burashnikova, and A. N. Stepanov

Chernyshevskii State University, Saratov, Russia

Received February 23, 1999; in final form, July 1999

Abstract—The structural and electrochemical characteristics of cadmium electrodes with nickel introduced in metallic state into the active material of the electrode by electroless plating were studied. The specific role played by heterophase interactions between nickel and cadmium in the mechanism of cadmium electrode activation was substantiated experimentally.

The key role in the mechanism of the activating action exerted by nickel on the operation of a cadmium electrode is played by the interaction of cadmium and nickel metallic phases in charged state [1, 2], resulting in the formation of nonequilibrium solid solutions of nickel in cadmium in the course of cycling. This system being unstable, it decomposes under certain electrode operation conditions into more stable phases, in particular, into an intermetallic compound (IMC) of cadmium and nickel, $Cd_{21}Ni_5$ [3–5].

Analysis of the whole body of experimental data and theoretical concepts concerning the activating effect of nickel suggests that the "concept of nonequilibrium solid solution" as the sole reason for the formation of a highly dispersed state of the charged cadmium electrode is of limited value. For example, it follows from the experimental data [4] that the dispersity of the active material of a charged cadmium electrode grows by an order of magnitude in the presence of nickel(II), which points to a rather strong interatomic interaction between cadmium and nickel to give covalent or mixed covalent-ionic type of bonding [6]. At the same time, data on the saturated vapor pressure of cadmium over cadmium–nickel melts indicate the absence of noticeable departures from the Raoult law for the cadmium vapor [7], suggesting a weak interatomic interaction between the components. The same is indicated by the Gibbs energy of $Cd_{21}Ni_4$ IMC formation ($\Delta G_f^0 \approx -1$ kJ mol^{-1} [8]), by the type of crystal lattice (γ-brass) [9, 10] characterized by metallic bonding between the atoms [6], and by close electronegativities of the metals (1.7 for cadmium and 1.8 for nickel) [11]. Consequently, the mechanism of the high dispersing action of nickel on the charged state of the cadmium electrode cannot be accounted for only in terms of the interatomic interaction of cadmium and nickel in the formation of solid solutions.

With account of the fact that, according to chemical phase analysis, the amount of reduced nickel in the cadmium electrode may be as high as 1–6 wt % [12], the following conclusion is justified: Under equilibrium conditions, metallic nickel exists in charged cadmium electrodes in two forms: as a highly diluted solid solution in cadmium and as an intrinsic finely crystalline phase, which is X-ray amorphous [13]. The lack of a consistent concept of the dispersing action of metallic nickel on the charged state of a cadmium electrode is, in the authors' opinion, due to the misjudgment of the role played by the heterophase interaction between metallic nickel and cadmium, despite the apparent probability of the predominant existence of nickel as an independent phase in ultramicrodispersed state.

The present study is devoted to an experimental substantiation of the important role played by heterophase interactions between nickel and cadmium in the activation of the cadmium electrode. A direct proof of the possibility of a heterophase interaction between nickel and cadmium could be furnished by high structural and electrochemical characteristics of cadmium electrodes with metallic nickel introduced in the active material. However, a complicated problem of achieving high dispersity and uniformity of nickel distribution in the active material is to be solved in this case. Such a dispersity of mixture components can be achieved either through occurrence of chemical processes in the solution bulk [e.g., by coprecipitation of cadmium and nickel(II) hydroxides] or by depositing nickel onto the surface of the disperse phase.

1070-4272/01/7403-0430$25.00

Introduction of highly dispersed nickel by electroless plating onto cadmium oxide in hypophosphite nickel-plating solutions was found to be a promising method [14, 15]. In [15], the possibility was demonstrated of obtaining a highly dispersed metallic phase with grain size on the order of 0.01 μm, depending on the solution composition and thermolysis regime.

EXPERIMENTAL

To solve the problem at hand, we studied the structural and electrochemical characteristics of cadmium electrodes made of cadmium oxide treated under special conditions with hypophosphite-based electroless nickel plating solution. The cadmium electrodes were fabricated by the technology of porous metallic cadmium electrodes with 1 wt % polyvinyl alcohol introduced as a binder in the form of an aqueous suspension [16]. The cadmium electrodes under study differed in the method of introduction of the nickel additive and in its amount and had the following composition: electrode 1 (control), cadmium oxide and 3 wt % Ni/Cd in the form of coprecipitated nickel and cadmium hydroxides; electrode 2, cadmium oxide treated with blank electroless nickel plating solution containing no nickel(II) ions; electrodes 3–7, cadmium oxide treated with electroless nickel plating solution containing 0.8, 1.4, 2.4, 4.1, and 7.0 wt % Ni/Cd, respectively.

Figure 1 shows the coefficient of cadmium utilization, K_u, in the electrodes under study in cycling in an 8.1 M KOH solution (i_{disch} = 0.01 A cm^{-2}, i_{ch} = 0.005 A cm^{-2}). The electrodes with addition of metallic nickel (Fig. 1, curve *2*) introduced by electroless nickel plating onto cadmium oxide show higher K_u values [75–80% against 68% for the control (curve *1*)].

Eliminating nickel from electroless plating solutions (curve *3*) leads to a dramatic decrease in K_u from 64% in the first cycle to 35% in the seventh. This result, which is in good agreement with the behavior of cadmium electrodes without activating additives [12], indicates that the other components of the electroless nickel plating solution exert neither positive nor negative influence on how the high-activity state of the cadmium electrode is formed.

The introduction of metallic nickel into the active material of the cadmium electrode by the method of electroless nickel plating also leads to a pronounced increase in the specific surface area of the cadmium electrodes, determined by the pulsed potentiostatic method [17] (Fig. 2): with the nickel content increasing from 0.8 to 7.0 wt % Ni/Cd, the specific surface area changes from 8.8 to 27 m^2 g^{-1}. The most pronounced increase in the specific surface area of the electrodes is observed on raising the concentration of nickel to 2–3 wt % Ni/Cd.

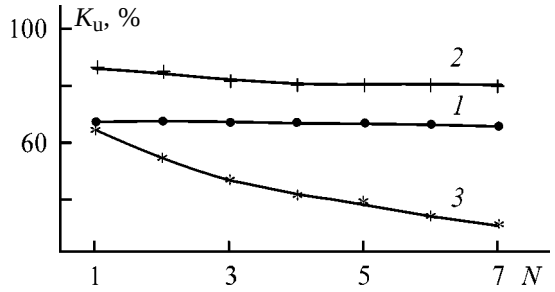

Fig. 1. Variation of K_u of cadmium in porous cadmium electrodes in the course of cycling. (*N*) Cycle number. Method of nickel compound introduction: (*1*) coprecipitation of $Ni(OH)_2$ + $Cd(OH)_2$ (3 wt % Ni/Cd) and (*2*) electroless nickel plating; and (*3*) no nickel additive.

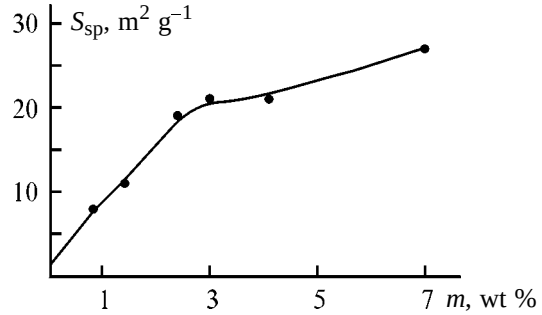

Fig. 2. S_{sp} of charged cadmium electrode vs. the nickel content m in its active material produced by electroless nickel plating of cadmium oxide.

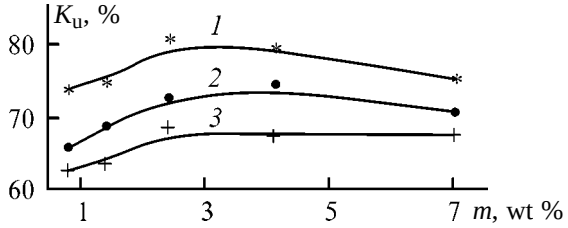

Fig. 3. K_u of cadmium in the active material of cadmium electrodes vs. its nickel content m at different discharge current densities. i_{disch} (A cm^{-2}): (*1*) 0.005, (*2*) 0.0135, and (*3*) 0.027.

The dependence of K_u on the nickel content in the active material shows a maximum at 2–4 wt % Ni/Cd (Fig. 3).

The presented structural and electrochemical characteristics of cadmium electrodes fabricated from cadmium oxide subjected to electroless nickel plating point to the high activating effect of metallic nickel

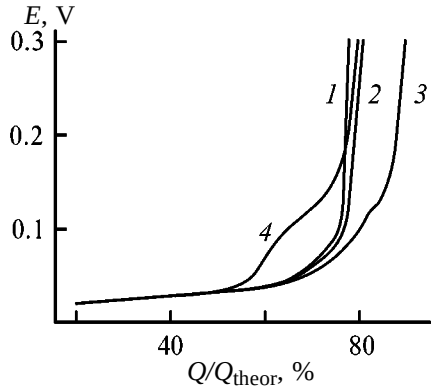

Fig. 4. Discharge curves for porous cadmium electrodes (fabricated from cadmium oxide subjected to electroless nickel plating and containing varied amount of nickel) in an 8.1 M KOH solution in the second cycle (i_{disch} = 0.01 A cm^{-2}). (*E*) Potential and (Q/Q_{theor}) discharge capacity normalized to the theoretical electrode capacity. Nickel content (wt %): (*1*) 0.82, (*2*) 1.4, (*3*) 4.1, and (*4*) 7.0.

introduced into the cadmium electrode as an independent phase in a highly dispersed state.

Figure 4 presents discharge curves for cadmium electrodes 3, 4, 6, and 7 in the second forming cycle (with the electrode potentials measured relative to a reversible cadmium electrode in the same alkali solution). With the nickel content of cadmium oxide increasing to 4 wt % Ni/Cd, a second potential delay appears in the discharge curves of the cadmium electrodes at polarizations of 120–140 mV. This delay is associated with the formation in the course of electrode charging of the $Cd_{21}Ni_5$ intermetallic phase [3–5].

The formation of the $Cd_{21}Ni_5$ IMC already in charging of the cadmium electrode can only be accounted for by the occurrence of interphase interaction of nickel with cadmium formed in the course of charging.

In [18, 19], the possibility of occurrence of solid-state diffusion processes with a sufficiently high rate at temperatures lower than the melting points of the systems in ultradispersed state (0.01–0.10 μm) was substantiated theoretically and confirmed experimentally. Phenomena of this kind are characteristic of some diffusion pairs with strongly different interdiffusion coefficients of the components [20–22]. A certain contribution to the mechanism of development of mechanical strain in the diffusion zone may come from the difference in density between the starting components and the phase formed in the diffusion zone. The initial introduction of nickel in the form of an individual highly dispersed metallic phase enabled a heterophase interaction between cadmium and nickel already in the first forming cycles.

CONCLUSION

The heterophase interaction of cadmium and nickel in the active material of charged electrodes, resulting in the formation of $Cd_{21}Ni_5$ IMC, accounts for the particularly strong activating effect of the nickel additive on the charged state of the cadmium electrode. The mechanism of this activating effect can be understood as follows: heterodiffusion in the cadmium–nickel binary system gives rise to mechanical stresses in the boundary region of the interphase contact with the subsequent relaxation through formation of micropores and cracks on the surface of active material grains.

Abstract—Results of investigations aimed at creating a material possessing selective sensitivity to gaseous hydrogen sulfide are presented. Polycrystalline films of doped tin dioxide were obtained by pyrolysis of an aerosol of appropriate organometallic compounds. The effect of copper and nickel oxides on the electrical properties, actual structure, and composition of polycrystalline tin dioxide films was studied. The influence of trace amounts of gaseous H_2S on the electrical conductivity of the films was analyzed in detail.

The problem of determining trace amounts of hydrogen sulfide in the atmosphere is of particular interest for environment protection in large cities, at chemical centers, and at oil and gas fields. The high toxicity of hydrogen sulfide and the presence, together with H_2S, of appreciable amounts of hydrogen, hydrocarbons, and other noxious gases in natural gas additionally complicate detection of hydrogen sulfide. In this connection, a search for materials that could be used in gas sensors for hydrogen sulfide is aimed at achieving their high sensitivity and selectivity [1–4].

Tin dioxide films are widely used in resistive chemical sensors, which are of particular interest because of their high sensitivity, simple design, and low cost [5, 6]. The principle of operation of such sensors is based on the dependence of the electrical conductivity of the material on the content of trace amounts of reducing or oxidizing gases in the ambient atmosphere. The change in the electrical conductivity of polycrystalline films can, as a rule, be accounted for by the interaction at the surface of SnO_2 grains between chemisorbed O_2^- ions and molecules adsorbed from the gas phase. Such interactions result in that the electron concentration in the conduction band of tin dioxide increases or decreases. The sensor characteristics of the material: sensitivity, response time, selectivity, and stability, are determined by a number of factors, of which the most important are the microstructure of the films, their thickness, departures from stoichiometry, and the type and concentration of dopants. In the present study, it is proposed to improve the sensitivity to hydrogen sulfide by using a heterogeneous nanocrystalline system composed of two oxides, one of which is chemically stable and provides for the semiconducting properties of the material, and the other enters into selective reaction with a gas being analyzed (Fig. 1).

The oxides were chosen on the basis of criteria among which of fundamental importance is the possibility of reversible chemical reaction with the system upon a change in the composition of the ambient atmosphere. Thermodynamic estimates of reactions in heterogeneous systems including solid oxides, metal sulfides, and gaseous hydrogen sulfide and air demonstrated that in the range 100–500°C nickel and copper oxides form sulfides in the presence of trace amounts of hydrogen sulfide in air, whereas tin dioxide remains a stable phase. Such compositional changes are reversible and may strongly affect the

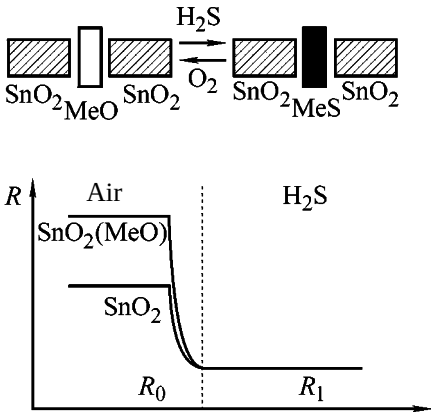

Fig. 1. Model of a heterogeneous nanocrystalline system.

1070-4272/01/7403-0434$25.00

electrical properties of the system, since copper and nickel oxides are *p*-type wide-band-gap semiconductors and sulfides of these metals are characterized by metallic conduction. The possibility of using SnO_2(CuO) for detecting trace amounts of hydrogen sulfide was first demonstrated in [7]. The increase in the sensitivity of tin dioxide samples to H_2S in the concentration range 50–1200 ppm upon doping with copper oxide was confirmed in later studies [8, 9]. However, the main effort has gone into achieving high sensor parameters, whereas the mechanism by which the system reacts with hydrogen sulfide has not been studied in detail and the role played by copper ions in sensor signal formation has not been revealed.

EXPERIMENTAL

Synthesis of polycrystalline SnO_2(CuO) and SnO_2(NiO) films by aerosol pyrolysis was described in detail in [9–11]. The film thickness was determined on cross sections with a Jeol JSM-35 scanning electron microscope. The phase composition and microstructure of the films were studied by means of X-ray diffraction analysis on a Siemens Cristalloflex instrument with CuK_α radiation.

The content of copper and nickel in the films was determined using local X-ray fluorescence analysis (Cameca-SX50). The analysis was made at four electron energies of 8, 12, 16, and 20 kV, with average intensity ratio of sample and reference lines calculated for each energy for the lines SiK_α, SnL_α, CuK_α, NiK_α, and OK_α. The obtained results were processed using SAMx-Strata special-purpose software for thin films and multilayer objects. The film composition was calculated in terms of the Pouchou–Pichoir model [12] for an SnO_2(MO)/SiO_2/Si(substrate) two-layer structure.

The surface composition of the films was determined and layer-by-layer composition analysis across the film thickness was made by Auger electron spectroscopy (AES) on a Jeol Jump IO-CCS instrument. Local analysis was done at 6–8 points, with spectra recorded in differential form in the energy range 50–1000 eV and intensities of the following Auger transitions used in the analysis: Sn (432 eV), O (510 eV), C (272 eV), Ni (848 eV), and Cu (924 eV).

The electrical resistance of the films was measured in the temperature range 77–523 K in the stabilized voltage mode at U = 1 V. The change in the circuit current, proportional to the conductivity of the films under study, was recorded. The distance between the current leads was 5 mm, and the film width was 4 mm.

The interaction of the obtained films with various gas mixtures was studied in an automated cell allowing control over the gas phase composition and temperature. The measurement scheme was described in detail in [13]. The electrical conductivity of the films was measured in the temperature range 100–450°C in an atmosphere of dry synthetic air and in gas mixtures of varied composition (ppm): 300 CO, 80 C_2H_5OH or 1000 CH_4 in dry air and 100 H_2S in nitrogen. The kinetics of variation of the electrical conductivity of the films, measured in air (G_0) and in the atmosphere of the above gas mixtures (G_t) at different temperatures, allowed estimation of the film sensitivity $S_t = (G_t - G_0)/G_0$.

The mechanism of interaction between SnO_2(CuO) and hydrogen sulfide was studied *in situ* by Raman spectroscopy with electrical properties recorded simultaneously. The Raman spectra were obtained on a Dilor XY multichannel spectrometer with Ar laser as radiation source (λ = 514.5 nm, 50 mW). The area of the analyzed section was 1 μm^2.

Sets of SnO_2 and SnO_2(MO) films were prepared, with copper concentration varying within 0.09–2.5 at. %, and nickel concentration, within 0.16–2.83 at. %. According to X-ray phase analysis data, the SnO_2 phase (tinstone) is present in all the synthesized films, with no copper- or nickel-containing phases found in the samples. This may be due both to the insufficient concentration of these phases and to the small size of their crystallites. The average dimensions of SnO_2 crystal grains were evaluated using the Debye–Scherrer formula on the basis of the reflection broadening in X-ray diffraction spectra and was found to be in the range from 3 to 10 nm, depending on synthesis conditions. The obtained data were confirmed by studying the film microstructure by transmission electron microscopy. No significant influence of copper or nickel in the concentration range 0–2.0 at. % on the SnO_2 grain size was revealed. An analysis of the real structure of the films by scanning electron microscopy indicated that they possess porous structure and are formed from agglomerates 50–100 nm in size.

A study of the composition of SnO_2(CuO) and SnO_2(NiO) films across their thickness by AES with the use of ion etching by means of an Ar^+ beam demonstrated that films doped with copper and nickel oxides exhibit different kinds of impurity distribution across the thickness. Films doped with nickel oxide are characterized by uniform distribution of nickel

Energy difference $\Delta = E(\mathrm{O1}s) - E(\mathrm{Sn3}d_{5/2})$ in XPS spectra of films

Sample	[M], at. %	Δ, eV	Δ – Δ1, eV (Δ_1 = 43.95 eV)
SnO_2	–	44.00	0.05
SnO_2(CuO)	1.26	43.90	–0.05
SnO_2(NiO)	1.25	44.80	0.85

across the entire thickness of a film. An analysis of the composition of an SnO_2(NiO) film (0.89 at. % Ni) gave values coinciding within measurement error for the surface composition ($I_{Ni}/I_{Sn} = 0.13 \pm 0.1$) and the bulk average ($I_{Ni}/I_{Sn} = 0.13 \pm 0.1$). In the case of SnO_2(CuO), a significant decrease in copper concentration was observed in going from the surface of a film into its bulk: $I_{Cu}/I_{Sn} = 0.24 \pm 0.1$ and 0.06 ± 0.1, respectively, for a film containing 1.84 at. % Cu. This effect may be due to segregation of copper on the surface of SnO_2 grains. In this case the total concentration of copper can be represented as the sum

$$[\mathrm{Cu}] = [\mathrm{Cu}]_s + [\mathrm{Cu}]_v,$$

where $[\mathrm{Cu}]_s$ and $[\mathrm{Cu}]_v$ are, respectively, the concentrations at the surface of a grain and in its bulk.

If we assume that $[\mathrm{Cu}]_s > [\mathrm{Cu}]_v$, then the obtained experimental data can be explained by taking into account the fact that $[\mathrm{Cu}]_s$ makes a major contribution to the composition of the surface layer of the film.

The state of copper and nickel in the synthesized films was analyzed by X-ray photoelectron spectroscopy (XPS). It was shown that the dopants are in oxidized state. The electronic state of nickel corresponds to NiO, whereas the data obtained for copper indicate an intermediate oxidation level (CuO, Cu_2O). The intermediate oxidation level of copper, also observed in studying the films by AES, may be due to the effect of high vacuum and ion sputtering on the composition of the surface being analyzed.

It is of interest to study the effect of copper and nickel ions on the Sn–O bond energy. The table lists the energy differences $\Delta = E(\mathrm{O1}s) - E(\mathrm{Sn3}d_{5/2})$ for films of pure and doped SnO_2, compared with a similar value calculated from reference data for pure SnO_2 (Δ_1 = 43.95 eV). The obtained data indicate that copper ions have no effect on the Sn–O bond energy ($\Delta - \Delta_1 = 0.05$ eV). Introduction of nickel in the same concentration leads to a pronounced change in the Sn–O bond energy ($\Delta - \Delta_1 = 0.85$ eV). The different effects of the same concentration of copper and nickel ions on the Sn–O bond energy may be due to differences between the distributions of copper and nickel ions between the crystal lattice and the surface of SnO_2 grains. It may be assumed that, at equal total concentrations, most part of copper is distributed in the form of segregates over the surface of tin dioxide grains, whereas nickel is mostly incorporated in the SnO_2 crystal lattice, occupying Sn sites. This assumption is in agreement with the results of layer-by-layer analysis of the composition of SnO_2(CuO) and SnO_2(NiO) films by AES. Calculations in terms of the percolation theory [14] demonstrated that the concentration of copper ions in the samples studied is insufficient for a thin (1 nm) copper oxide layer to be formed on the surface of every SnO_2 grain: a percolation cluster can be formed in the case of copper oxide distribution over boundaries of SnO_2 agglomerates.

A study of the electrical properties of the obtained films revealed a high sensitivity of the electrical conductivity of the material to the content of copper and nickel ions. Raising steadily the concentration of dopants results in the increasingly pronounced rise in resistance on lowering the temperature [15]. A portion of thermally activated behavior appears in the $\log R$–$(100/T)$ curves, with the activation energy E_a, determined from the relation $R \approx \exp(E_a/kT)$, gradually growing with increasing dopant concentration to become 0.5–0.6 eV in films containing 1.45 at. % Cu and 0.45 at. % Ni. Raising the dopant concentration further does not lead to any changes in the behavior of the conductivity of the films. The data obtained indicate that doping with copper or nickel oxides changes the mechanism of conduction in tin dioxide films. Presumably, with growing Cu and Ni concentration, the barrier mechanism plays an increasingly important role, with the barrier height (E_a) depending on the concentration of doping impurities. The temperature dependence of the electrical conductivity is in this case expressed as $G = G_0 \exp(-E_a/kT)$. The appearance of an energy barrier upon doping may be due to lowering of the Fermi level because of the compensation of donor oxygen vacancies $V_O^{\cdot\cdot}$ by acceptor-type substitution defects $Cu_{Sn''}$ ($Ni_{Sn''}$) or to formation of a *p*-CuO(NiO)/*n*-SnO_2 junction near the surface of tin dioxide grains.

The dynamic sensitivity of the films, $S_t = (G_t - G_0)/G_0$, was studied in relation to temperature, dopant concentration, and gas phase composition. Figure 2 shows typical dynamic curves in the S_t–t coordinates for SnO_2, SnO_2(CuO), and SnO_2(NiO) films under the conditions of a cyclic change in the gas phase composition at a temperature of 200°C. In the interac-

tion of the samples with a 100 ppm $H_2S + N_2$ gas mixture, the electrical conductivity of the films grows and then decreases reversibly on replacing the atmosphere with dry air. Multiple cycling of the gas phase composition (>100 cycles) has no effect on the nature and magnitude of changes in the electrical conductivity of the doped films. The long time necessary for the maximum change in electrical conductivity to be achieved is due to the relation between the measuring cell volume (2 l) and the gas mixture flow rate (4 $l\,h^{-1}$). The maximum sensitivities are observed at 150°C for SnO_2(CuO) films and at 250°C for SnO_2(NiO).

Figure 3a shows in the form of a three-dimensional diagram the dependence of the sensitivity of SnO_2(CuO) films to 100 ppm $H_2S + N_2$ on the content of copper in the films and size of SnO_2 crystalline grains. The maximum sensitivities to hydrogen sulfide correspond to average grain size of 5–6 nm and copper content in the films of 1.2–1.4 at. %. A similar analysis for SnO_2(NiO) films demonstrated (Fig. 3) that the maximum gas sensitivity is observed for films with the same average grain size of 5–6 nm, but containing 0.6–0.7 at. % Ni. The obtained optimal SnO_2 grain size corresponds to doubled thickness of the depleted layer in polycrystalline SnO_2, evaluated in [16].

An analysis of the whole set of the obtained experimental data revealed the main distinctions between the effects of copper and nickel oxides on the properties of SnO_2:

(1) According to AES and XPS data, copper oxide is mainly concentrated on the surface of SnO_2 grains, whereas nickel oxide is evenly distributed between the surface and the bulk of the crystalline grains.

(2) The interaction of SnO_2(NiO) films with the gas phase is much slower, compared with the case of SnO_2(CuO) films, in the entire temperature range studied.

(3) In determining hydrogen sulfide, the optimal working temperature of SnO_2(NiO) films is 100°C higher than that of SnO_2(CuO) films.

(4) In contrast to the case of copper, introduction of nickel into SnO_2 increases the sensitivity of this material to CO, C_2H_5OH, and CH_4.

Thus, it would be expected that the reaction of the SnO_2(CuO) and SnO_2(NiO) systems with hydrogen sulfide gas occurs by different mechanisms.

The mechanism of the reaction between polycrystalline SnO_2(CuO) and SnO_2(NiO) films and hydrogen sulfide was studied. Changes in the state of surface atoms upon interaction of SnO_2 and SnO_2(CuO) nanocrystalline films with an atmosphere containing 300 ppm of hydrogen sulfide in nitrogen was studied by *in situ* Raman spectroscopy at T = 150°C (Fig. 4). It was found that the intensity of vibrations of surface SnO_2 molecules (broad band at 570 cm^{-1}) decreases; copper sulfide Cu_2S (472 cm^{-1}) is formed in the

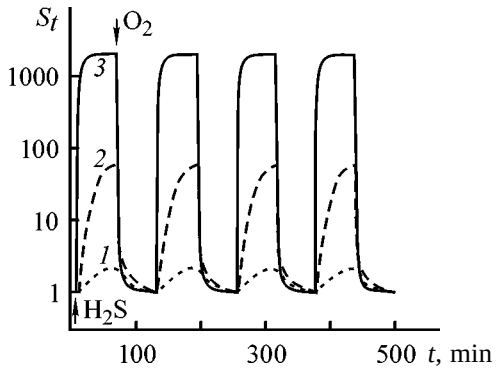

Fig. 2. Relative electrical conductivity S_t of (*1*) SnO_2, (*2*) SnO_2(CuO), and (*3*) SnO_2(NiO) films in cyclic replacement of dry air by a 100 ppm $H_2S + N_2$ gas mixture at 200°C. (*t*) Time.

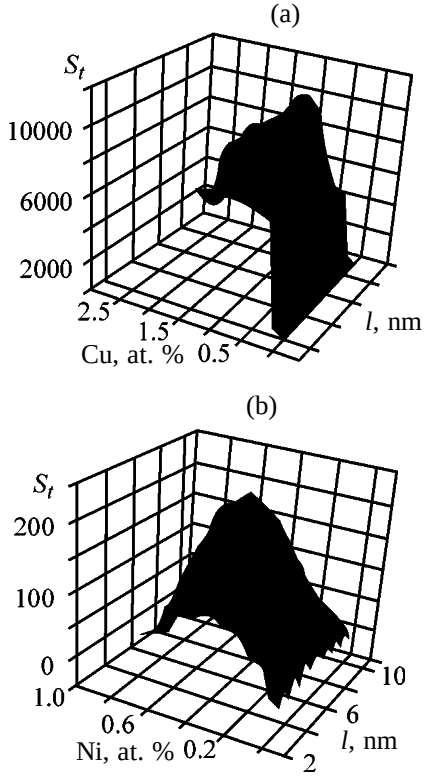

Fig. 3. Sensitivity S_t of (a) SnO_2(CuO) and (b) SnO_2(NiO) films to 100 ppm $H_2S + N_2$ vs. content of doping impurities of Cu and Ni ions in the films and size l of SnO_2 crystalline grains.

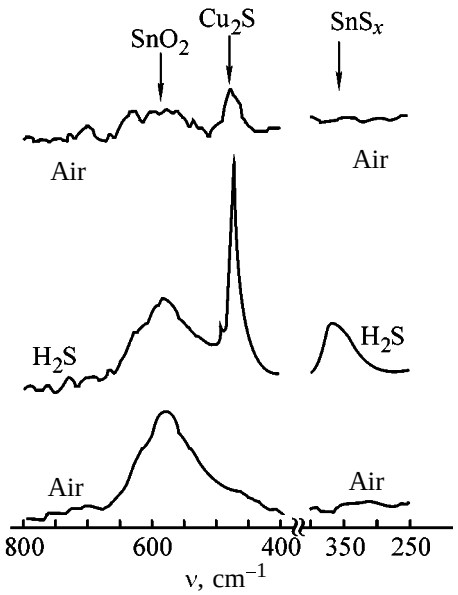

Fig. 4. Changes in Raman spectra of SnO_2(CuO) in cycling replacement of dry air with 300 ppm $H_2S + N_2$ gas mixture at 150°C. (ν) Wave number.

atmosphere of hydrogen sulfide in samples doped with copper oxide; tin sulfide SnS_x (broad band at 350 cm^{-1}) is formed in pure and doped tin dioxide.

Thus, the mechanism of interaction of SnO_2(CuO) with the gas phase involves the following basic processes.

(1) Adsorption of oxygen molecules onto the tin dioxide surface, with a depleted layer formed and the electrical conductivity decreasing because of the binding of a part of conduction band electrons by the adsorbed oxygen

$$O_{2g} \rightleftarrows 2O_s,$$

$$O_s + 2e \rightleftarrows O_s^{2-}.$$

(2) Adsorption of hydrogen sulfide molecules and their interaction with adsorbed oxygen

$$H_2S_g + 3O_s^{2-} = SO_{2g} + H_2O + 6e.$$

This reaction leads to an increase in the electron concentration n in the SnO_2 conduction band and makes higher the electrical conductivity

$$G = en\mu,$$

where e is the electron charge, $\mu = \mu_0 \exp(-E_a/kT)$ is the electron mobility, and E_a is the height of the barrier appearing at the p-CuO/n-SnO_2 interface, proportional to the concentration of introduced copper in the range 0–1.5 at. %.

(3) Chemical reaction of copper oxide with hydrogen sulfide gas to give copper(I) sulfide

$$6CuO_s + 4H_2S_g = 3Cu_2S_s + SO_{2g} + 4H_2O.$$

This reaction eliminates the energy barrier and thereby leads to a dramatic increase in the electron mobility μ and, consequently, in the electrical conductivity.

In the absence of hydrogen sulfide molecules, copper sulfide is reversibly converted into copper(II) oxide upon reaction with atmospheric oxygen

$$Cu_2S_s + 2O_{2g} = 2CuO_s + SO_{2g}.$$

(4) Chemical reaction of tin dioxide with hydrogen sulfide to give tin sulfide exerting no significant influence on the electrical properties of the system but changing the state of the material surface.

(5) Oxygen diffusion from the bulk of SnO_2 grains toward their surface to give neutral and doubly ionized vacancies

$$O_O^x = V_O^x + O_s$$

$$V_O^x = V_O^{\cdot\cdot} + 2e.$$

The role of nickel in the interaction of SnO_2(NiO) with the gas phase may be due to the effect of Ni redistribution between the bulk and the surface of an SnO_2 grain, depending on the redox properties of the atmosphere. In an oxidizing medium (in air), Ni^{2+} cation [$r(Ni^{2+})$ = 0.70 Å] may occupy sites on the cationic sublattice of SnO_2 [$r(Sn^{4+})$ = 0.69 Å], whereas in a reducing atmosphere containing hydrogen sulfide, CO, C_2H_5OH, or CH_4, reduction of nickel(II) is possible, with its transport toward the SnO_2 grain surface. This eliminates the effect of compensation of donor oxygen vacancies $V_O^{\cdot\cdot}$ by acceptor-type substitution defects $Ni_{Sn''}$, making higher the electrical conductivity of the material.

CONCLUSION

Nanocrystalline systems based on metal oxides are of interest as sensitive materials for resistive gas sensors. Introduction of copper and nickel oxides into the tin dioxide matrix gives high-resistivity samples. The increase in the resistance of SnO_2(MO) films is due to the compensation of intrinsic atomic defects by impurity centers and the formation of energy barriers at contacts between grains of semiconductors with different conduction types. Copper and nickel oxides were found to exert strong influence on the sensor

properties of tin dioxide films, leading to a 10^2–10^3-fold increase in the sensitivity of films to hydrogen sulfide. The obtained results can be used in developing high-sensitivity sensors for hydrogen sulfide gas. The mechanism of gas sensitivity is associated with changes in the electronic state of copper and nickel in the surface layer in relation to the gas phase composition.

Abstract—Problems associated with developing gas-sensitive inorganic materials are discussed. The principle of operation of a semiconductor gas sensor of resistive type is considered, and main band structure parameters sensitive to the gas phase composition are determined. Ways to solve the problem of selectivity of semiconducting oxides are discussed. The influence of microstructure, dopants, and analysis temperature is looked into on the basis of experimental results obtained in studying nanocrystalline tin dioxide and zinc oxide. Prospects for use of systems based on two or more nanocrystalline oxides (nanocomposites) are considered.

Nanocrystalline materials are being extensively studied with the aim of a search for novel properties [1, 2]. Much progress has been made in the field of directed synthesis of nanocrystalline systems based on metal oxides possessing high gas sensitivity, which can be used as catalysts and materials for gas sensors [3, 4]. With decreasing crystallite size, the contribution from the surface energy to the total free energy of the system increases dramatically, which leads to high activity of materials of this kind in heterogeneous interactions. The fact that the geometric dimensions of nanocrystallites and molecular sizes are comparable predetermines the difference between the kinetics of chemical transformations in nanocrystalline systems and similar processes in coarsely crystalline materials. These specific features make nanocrystalline semiconducting oxides very promising for development of high-sensitivity fast-response gas sensors, in which just surface processes play the key role in the formation of a sensor signal.

Despite the achieved high gas sensitivities, putting semiconducting oxides into practice is hindered by the poor selectivity of these materials and the lack of data on the mechanism of their interaction with the gas phase. The high rates of adsorption and redox processes make difficult studying the mechanism of surface reactions experimentally by the conventional methods. Under these conditions, the most complete information could be furnished by *in situ* investigation techniques.

The present communication discusses the nature of the gas sensitivity of semiconducting nanocrystalline metal oxides, the principle of operation of gas sensors on their base, and ways to improve the selectivity of the sensors.

The main elements in analyzing the composition of the ambient atmosphere are (see scheme) object being analyzed, sampling system, filter, sensitive unit, signal converter, and a system for analysis control with the possibility of processing of the electric signal and information storage and transfer. According to the classification presented in [5], semiconducting gas sensors belong to the group of electric chemical sensors furnishing information about the ambient composition directly in the form of an electric signal. The possibility of combining in the same material the functions of a sensitive element and signal converter markedly simplifies the design of a sensor and constitutes the main advantage of resistive-type sensors over biochemical, optical, acoustic, and other devices.

The principle of operation of semiconducting gas sensors is based on the dependence of the electrical properties of a material on the concentration of chemisorbed molecules. The formation of surface acceptor levels in real semiconductors may be due to oxygen adsorption from the gas phase. This process involves physical adsorption of O_2 molecules and capture by these molecules of electrons from the surface layer of the semiconductor.

$$1/2O_{2(gas)} + V_O^x \rightleftarrows O_s, \quad (1)$$

$$O_s + 2e \rightleftarrows O_s^{2-}, \quad (2)$$

where V_O^x are oxygen vacancies, and O_s is oxygen adsorbed onto the surface.

As a result, a depletion layer is formed near the crystal surface, with the electron concentration lower than that in the bulk. Figure 1 presents a band diagram illustrating the effect of adsorption on the parameters of the semiconductor band structure. The main of these: band gap E_g, Fermi level position E_F, electronic work function φ, and depletion layer width L, determine the electrical properties of a semiconducting material [7]. It should be noted that, in selecting a material for gas sensors, the absolute values of these parameters are not so important as their change upon chemisorption. The depletion layer width L is determined by the Debye screening length in the given material L_D [7] and the height of the surface Schottky barrier V_s [8].

$$L = L_D(eV_s/kT), \quad (3)$$

where e is the electron charge, k is the Boltzmann constant, and T is absolute temperature.

The Debye screening length in a given material is determined by the equation

$$L_D = \varepsilon kT/e^2n, \quad (4)$$

where ε is the dielectric constant of the material, and n is the carrier concentration.

The surface barrier height is, in its turn, determined by the surface charge Q_s^2:

$$V_s = Q_s^2/2\varepsilon\varepsilon_0 en. \quad (5)$$

The presence in the atmosphere of molecules of gases differing in their redox properties from atmospheric oxygen may lead, even under normal conditions (T = 25°C), to a pronounced change in electrical properties. Reducing gases, such as H_2, CO, and

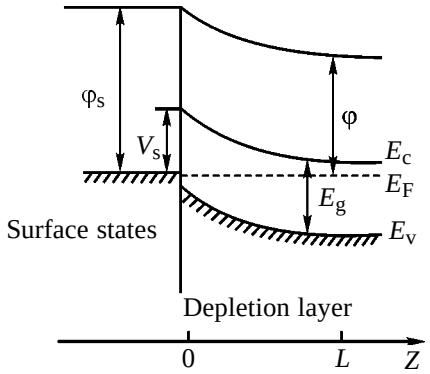

Fig. 1. Band structure of the surface layer of the semiconductor: (E_v) valence band top, (E_c) conduction band bottom, (E_g) band gap, (E_F) Fermi level position, (φ) electronic work function, (φ_s) work function for emission of an electron from a surface level, (V_s) surface barrier, and (L) depletion layer width.

NH_3, make the electronic work function lower and the electrical conductivity higher, whereas the presence of oxidizing gases (O_3, NO_2) leads to the opposite effect. The interaction of the surface of a semiconducting oxide with a reducing gas, e.g., CO, can be described by the equations

$$CO_{gas} \rightleftarrows CO_s, \quad (6)$$

$$CO_s + O_s^{2-} \rightleftarrows CO_{2(s)} + 2e, \quad (7)$$

$$CO_{2(s)} \rightleftarrows CO_{2(gas)}. \quad (8)$$

Reactions (6)–(8) decrease the concentration of oxygen adsorbed on the surface of crystal grains and lead to delocalization of electrons, making the electrical conductivity of *n*-type material higher (Fig. 2, curve *1*) and that of the *p*-type material lower. The presence of oxidizing gases in the atmosphere leads to decrease in the concentration of electrons in the surface layer, increase in the height of intergrain barriers, and decrease in the electrical conductivity of *n*-type materials (Fig. 2, curve *2*). The atmosphere-induced changes in the electrical properties of semiconducting materials are reversible in the temperature range 100–500°C.

The height of the surface barrier is also fundamentally important in selecting a material for gas sensors. By analogy with the Schottky barrier at the metal–semiconductor interface, the height of the barrier at the semiconductor surface can be represented as [6, 8]

$$V_s = X(\varphi_s - \varphi), \quad (9)$$

where φ_s is the work function for emission of an electron from a surface level, φ is the thermionic work

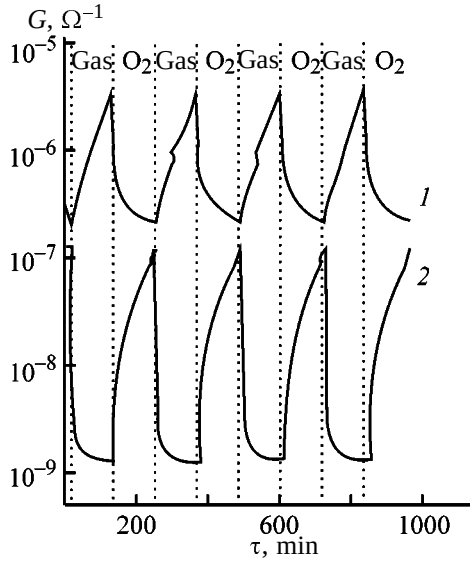

Fig. 2. Variation of the electrical conductivity G of polycrystalline ZnO with time τ in the presence of (*1*) reducing gas and (*2*) oxidizing agents.

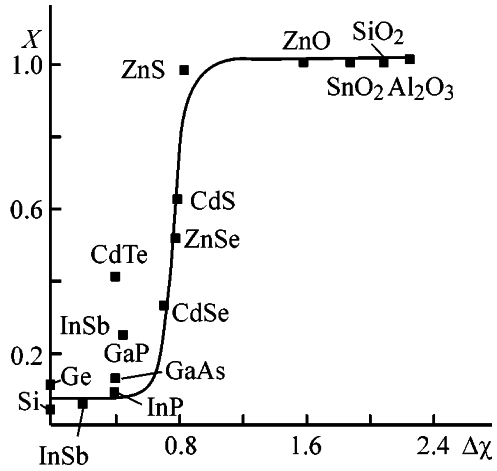

Fig. 3. Parameter X vs. difference of electronegativities $\Delta\chi$ of the anion and cation forming the semiconductor.

function, and X is a chemical parameter depending on the nature of a semiconductor.

The parameter X is defined as a coefficient of a linear dependence relating V_s and φ_s and can be interpreted as a manifestation of the sensitivity of the electrical properties of a semiconductor to the state of its surface. Figure 3 presents the parameter X in relation to the difference of electronegativities $\Delta\chi$ (by Pauling) of the anion and cation forming the semiconductor. The abrupt change in the X value at $\Delta\chi = 0.8$ corresponds to a transition from materials with covalent bonding (Si, Ge, GaAs) to those in which ionic bonds predominate (ZnO, SnO_2). Thus, the highest sensitivity to changes in the concentration of molecules adsorbed onto the surface and, consequently, to changes in the gas phase composition is exhibited by materials with predominantly ionic bonding. Oxides characterized by exceedingly high resistivity, SiO_2 and Al_2O_3, are not used in resistive gas sensors in pure state because of the difficulties encountered in electrical conductivity measurements.

Despite the considerable success in improving the sensitivity and speed of response of semiconducting gas sensors, there remain a number of problems among which the most important are the poor selectivity and the sensitivity to atmospheric moisture, which is due to the nonselective nature of adsorption. Let us consider successively the effect of microstructure and dopants on the gas-sensitive properties of the material.

The contribution of the surface to the electrical properties of a semiconductor can be achieved by passing from a single crystal to a polycrystalline system. In this case, each crystalline grain is to be considered a closed volume with a depletion layer near its surface (Fig. 4). The decrease in the carrier concentration at grain boundaries leads to formation of intergrain energy barriers whose height determines the electrical conductivity of a polycrystalline material as a whole. The strongest influence of the state of the surface on the electrical properties of the material is observed when the following condition [3] is met:

$$l/2 \le L, \tag{10}$$

where l is the crystallite size and L is the depletion layer width, varying between 3 and 10 nm for various oxides.

All other conditions being the same, the depletion layer width depends on the redox properties of chemisorbed molecules. The reducing gases H_2, CO, H_2S, and NH_3 make the depletion layer narrower, whereas the oxidizing gases O_3 and NO_2, conversely, lead to an increase in the depletion layer width, being involved in competitive adsorption together with atmospheric oxygen. Thus, when forming the real structure of an oxide, account should be taken of the chemical nature of a gas being analyzed: the optimal grain size for detecting molecules possessing reducing properties is to be smaller, compared with the case of oxidizing gases.

In order to raise the adsorption activity, semiconducting oxides are doped with noble metals: Pt, Pd, Au, and Ru. It has been established that these metals form on the oxide surface clusters whose presence facilitates adsorption and dissociation of reducing

gases. The presence of Pd, Pt, or Au clusters, in particular, lowers the electronic work function and decreases the activation energy of the reaction occurring on the surface of the semiconducting oxide. However, in addition to the catalytic effect, the above metals exert influence on the electrical properties and real structure of the polycrystalline matrix and can also change the intrinsic chemical state on the oxide surface. It has been shown that the state of Pt (Pt or PtO_2) in SnO_2 depends on the cluster size and changes depending on the gas phase composition. The authors believe that the transition of platinum from the oxidized state (in air) to the metallic state (in a gas mixture of 900 ppm CO in N_2) leads to high gas sensitivity of SnO_2(Pt) films. Reaction with a gas mixture containing 1% H_2 in nitrogen results in the reduction of palladium to metallic state, accompanied by a 1000-fold increase in the electrical conductivity of the films. The photoelectron spectrum of the surface of an SnO_2(Pd) film annealed in an inert atmosphere of N_2 contains peaks corresponding to both states of palladium: Pd and PdO. The manifestation of reducing properties by an inert medium is due in this case to the lack of oxygen in the gas phase, which makes lower the concentration of adsorbed oxygen on the oxide surface.

Recently, complex nanocrystalline systems (nanocomposites) containing two or more oxides have been widely used for solving the problem of selectivity of materials. The nanocomposite composition can be represented as M_1O/M_2O, where M_1O is the nanocrystalline matrix and M_2O is the doping oxide distributed between the surface and the bulk of the M_1O nanocrystalline grain. The advantage of nanocomposites over simple nanocrystalline oxides, when used in gas sensors, is associated with the redistribution of M_2 between the bulk and the surface of M_1O grain, depending on the redox properties of the gas phase. Low oxidation levels of M_2 cation, corresponding to larger ionic radius and predominant distribution of M_2 over the surface of M_1O grains, occur in the reducing atmosphere. By contrast, cations in higher oxidation states are formed in an oxidizing atmosphere, with increasing probability that M_2 cations occupy regular cationic positions in M_1O. The lability of the chemical state of the M_2 cation in the nanocrystalline system may result in a dramatic change in the state of grain boundaries and in modification of the electronic properties of the material in the presence of even trace amounts (0.1–10 ppm) of reducing or oxidizing gas molecules in the gas phase. The table lists as examples nanocomposites that are of interest for creating gas-sensitive materials. The oxides to be used in creating nanocomposites are chosen with account of the ionic radii of the elements [12].

Scheme of formation of intercrystallite electrical barriers in the polycrystalline system: (*1*) electrode, (*2*) potential barrier, (*3*) crystallite bulk, (*4*) depletion layer, (*5*) height of potential barrier in air, and (*6*) height of potential barrier in the presence of a reducing gas.

CONCLUSION

The effect of gas sensitivity of nanocrystalline metal oxides is based on the chemisorption process and chemical reactions on the surface, involving chemisorbed oxygen. High gas sensitivity can be achieved with systems based on simple and complex semiconducting oxides. An important parameter is the high dispersity of a material with microstructure stable under conditions of prolonged annealing at 60–100°C.

Abstract—A study was made of the low-temperature hydrolysis of high-moleculer-weight polyacrylamide Praestol under the action of NaOH in dilute aqueous solution. The performance of the hydrolyzed and nonhydrolyzed polymer when combined with aluminum sulfate in treatment of natural water was estimated.

The most important reaction in polymer-analogous transformations of polyacrylamide (PAA) is alkaline hydrolysis. It is often used for partial replacement of the amide groups in PAA macromolecules by carboxylate groups. The degree of hydrolysis can affect the flocculating power, viscosity, and adhesion properties of the polymer [1, 2]. There are numerous publications on hydrolysis of PAA and its behavior in various media, but published data on low-temperature hydrolysis of PAA in dilute aqueous solutions are scarce [3, 4]. These investigations are motivated by the possibility of modifying PAA during application. For this reason, hydrolyzed PAA in a number of cases is preferable over acrylamide–sodium acrylate copolymers. In this connection, we studied in this work hydrolysis of high-molecular-weight PAA Praestol 2500[1] which currently receives much attention.

EXPERIMENTAL

We used Praestol 2500 produced by Stockhausen (Krefeld, Germany) with $[\eta] = 1550$ cm^3 g^{-1} and $M_\eta = 8.7 \times 10^6$; pure grade aluminum sulfate $Al_2(SO_4)_3 \cdot 18H_2O$ [GOST (State Standard) 3758–65]; pure grade SO brand kaolin [TU (Technical Specifications) 21-5494310–92]; and distilled water. Other chemicals were of chemically pure grade.

In the laboratory experiments, Praestol 2500 was dissolved at room temperature under continuous stirring (stirrer rotation rate 600 rpm during feeding of the polymer and 300 rpm during the subsequent 1-h period). Hydrolysis was carried out in a three-necked flask equipped with a power-driven stirrer, a thermometer, and a tube for taking samples. In the course of the reaction we took samples from the reaction solution at regular intervals so as to determine the degree of hydrolysis of the polymer A [mol % of the units of sodium acrylate (SA)] by potentiometric titration [5]. The relative standard deviation and relative error of determination were within 1.4 and 3.3%, respectively [5].

In industrial tests, hydrolysis of Praestol 2500 was combined with its dissolution in the acting unit for preparing the polymer solution,[2] and the degree of hydrolysis was monitored [5].

Potentiometric measurements were carried out with a pH-121 pH-millivoltmeter with an ESL-43-07 glass inidicating electrode and an EVL-1M3 silver chloride reference electrode.

The intrinsic viscosity $[\eta]$ was determined in 0.5 M NaCl solution at 25°C, and the data obtained were used for calculating the viscosity-average molecular weight of the hydrolyzed Praestol 2500 by the Mark–Houwink equation $[\eta] = kM_\eta^\alpha$, with the constants k and α varied depending on the degree of hydrolysis of the polymer; their values were taken from [6]. In accordance with [7–9], we judged the effective size of the macromolecular coils $\langle r^2 \rangle^{1/2}$ of the hydrolyzed

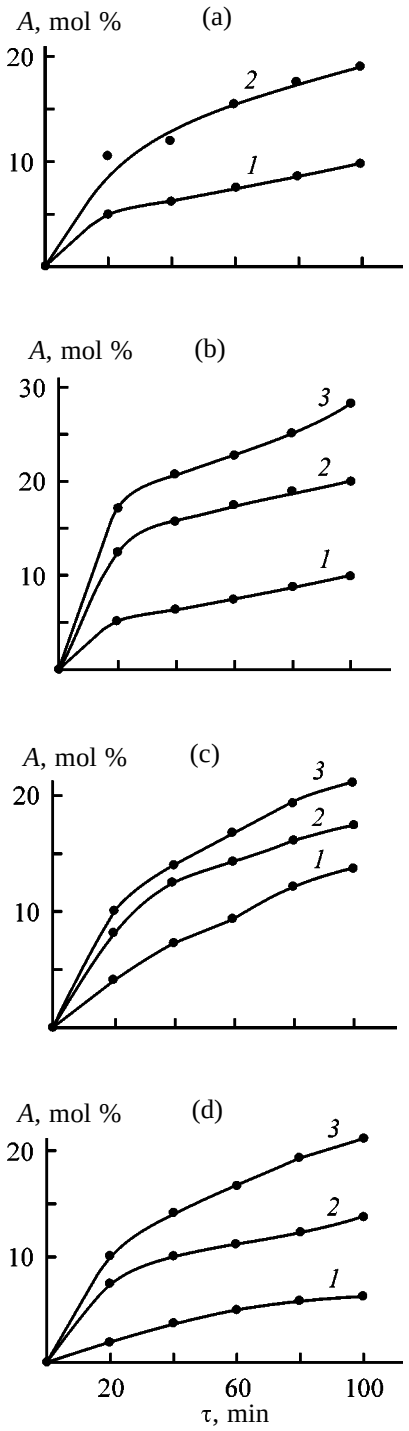

Fig. 1. Content of the SA units in the copolymer *A* as a function of the time τ in hydrolysis of PAA. (a) Initial mass ratio [PAA]/[NaOH] = 5; 20°C; [PAA], %: (*1*) 0.005 and (*2*) 0.1. (b) [PAA] = 0.05%, 22°C, initial mass ratio [PAA]/[NaOH]: (*1*) 3.3, (*2*) 1.6, and (*3*) 0.5. (c) [PAA] = 0.05%, initial mass ratio [PAA]/[NaOH] = 1.6. Temperature, °C: (*1*) 5, (*2*) 15 and (*3*) 25. (d) [PAA] = 0.5%, initial mass ratio [PAA]/[NaOH] = 1.6; 25°C. Water: (*1*) riverine, (*2*) tap, and (*3*) distilled.

Praestol 2500 indirectly, from the reduced viscosity η_{sp}/C_p (as measured in water at C_p = const).

Sedimentation analysis was carried out in 0.14% kaolin suspensions in a sedimentometer with VT-500 torsion balance scales after tenfold stirring of the suspension with a disk stirrer with perforations.

In industrial tests, the quality of the water after treatment was monitored basing on the standards set in the Sanitary Rules and Regulations (SanPiN) [10].

To prepare modified PAA suitable for natural water treatment [11], we chose the hydrolysis conditions at which the degree of hydrolysis of the polymer did not exceed 30 mol %. Namely, hydrolysis was carried out for 1.5 h in dilute aqueous solutions ([PAA] = 0.05–0.1%) intended for preparing polymer solutions at water treatment plants, in the presence of NaOH at 5, 15, and 25°C.

Under the actual conditions, PAA is hydrolyzed by the scheme

$$-(-CH_2-\underset{\displaystyle CONH_2}{\underset{|}{CH}}-)_{n-} + m\mathrm{NaOH} + H_2O$$

$$\rightarrow -(-CH_2-\underset{\displaystyle CONH_2}{\underset{|}{CH}}-)_{n-m}-(-CH_2-\underset{\displaystyle COO^-Na^+}{\underset{|}{CH}}-)_{m-} + m\mathrm{NH_4OH}.$$

Figure 1a presents the kinetic curves for PAA hydrolysis obtained by the potentiometric method. The polymer concentration in the experiments was varied at [PAA]/[NaOH] = const. Figure 1a shows that with increasing concentration of the polymer the initial rate of hydrolysis and the content of the SA units in the hydrolysis products tend to increase (going from curve *1* to curve *2*). Individual kinetic curves in Fig. 1a evidence high rates of hydrolysis in the initial stages of the reaction, which can, probably, be attributed to anchimeric promotion of hydrolysis of the amide groups by the neighboring hydrolyzed (carboxylate) groups [12]. Figure 1a also evidences deceleration of hydrolysis in the course of the reaction. This is probably due to the electrostatic repulsion between the OH^- ions and the carboxylate anions COO^- accumulating in the macromolecules during hydrolysis.

The influence of the NaOH concentration on the hydrolysis kinetics was elucidated at [PAA] = const, other conditions remaining unchanged. As seen from Fig. 1b, with increasing NaOH concentration the initial rate of hydrolysis tends to increase, and the macromolecules of the forming copolymer get enriched with

the SA units (going from curve *1* to curve *3*). This is due to increase in the concentration of OH^- ions in the reaction system.

Figure 1c presents the kinetic curves characterizing hydrolysis of Praestol 2500 over the 5–25°C range at constant concentrations of the polymer and NaOH. It is seen that the initial rate of hydrolysis and the content of the SA units in the macromolecules of the forming copolymer tend to increase with rising temperature (going from curve *1* to curve *3*). This dependence is consistent with the general relationships in alkaline hydrolysis of polyvinylamides.

Figure 1d demonstrates the influence of the medium on hydrolysis of Praestol 2500. The reaction was run in distilled, tap (turbidity 1.1 mg l^{-1}, color index 15 deg), and riverine (turbidity 4.9 mg l^{-1}, color index 46 deg, total alkalinity 1.6 mg l^{-1}) water. In this series of runs, the concentrations of the polymer and NaOH, as well as the temperature (25°C), were kept constant. Figure 1d shows that the initial rate of hydrolysis and the SA content in the forming copolymer tend to decrease in the series distilled water > tap water > riverine water.

This is explained by the fact that this series characterizes the decrease in the efficiency of alkaline hydrolysis of the polymer with increasing content of the impurity.

The impurity hydrocarbonates contained in tap, and in a greater amount, in riverine water could react with NaOH, thus decreasing its concentration and, thereby, the hydrolysis efficiency.

To determine the degree of hydrolysis of Praestol 2500 ensuring the greatest flocculation effect, we studied sedimentation of the model kaolin suspension under the action of aluminum sulfate and Praestol 2500 samples differing in the degree of hydrolysis and having close M_η values (Table 1). The sedimentation conditions were chosen basing on the results of our previous investigations [13]. As known [14], when added to an aqueous kaolin suspension, aluminum sulfate is hydrolyzed to form positively charged particles of aluminum hydroxide adsorbed on the negatively charged kaolin particles (ζ potential of the kaolin surface was –4.2 mV) forming complex aggregates. Upon subsequent introduction of Praestol 2500, larger floccules formed, which caused joint flocculation of all the partciles. Figure 2 demonstrates the flocculation effect as a function of the content of the SA units in the hydrolyzed Praestol 2500. The flocculation effect was estimated by the formula

$$D = (t_0 - t)/tz,$$

Table 1. Characterization of Praestol 2500 based flocculants

Sample no.	[η], $cm^3\ g^{-1}$	$M_\eta \times 10^{-6}$	Content of indicated units, mol %	
			AA	SA
1	1500	4.4	89	11
2	1500	4.0	83	17
3	1500	3.8	80	20
4	1500	3.2	76	24
5	1600	4.4	72	28

where t_0 and t are the times required for accumulation of 50% of the sediment mass on the pan of the torsion balance with and without polymer, respectively (for 0.14% kaolin suspension t_0 = 30 min).

The $D = f(A)$ dependence presented in Fig. 2 (curve *1*) has an extremum due to the parallel run of the $\eta_{sp}/C_p = f(A)$ plot (curve 2). This fact suggests that the flocculation effect D is strongly dependent on the parameter $\langle r^2\rangle^{1/2}$ for hydrolyzed Praestol 2500. It takes a maximal value at $A \approx 20$ mol % (curve *1*), which corresponds to the greatest η_{sp}/C_p values (curve *2*). It can be assumed that this composition of the macromolecule corresponds to the optimal relation between the charge density and the flexibility of the chains and, therefore, the largest $\langle r^2\rangle^{1/2}$ values. As a result, polymer bridges link a greater number of kaolin particles, which favors formation of large floccules and accelerates their sedimentation. The greatest flocculation power of the hydrolyzed Praestol was observed at $A \approx 20$ mol %, which is consistent with the previous data [15]. For this reason, in industrial tests Praestol was hydrolyzed up to the degree of hydrolysis of 19 mol %, and the resulting hydrolyzed polymer (HP) was used for water tretament. Its performance was compared with that of nonhydrolyzed

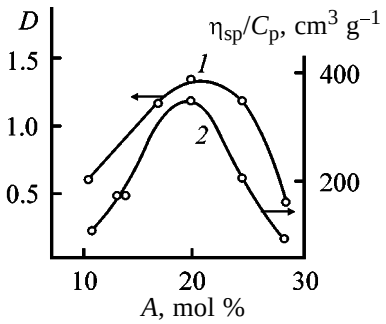

Fig. 2. (*1*) Flocculation effect D and (*2*) reduced viscosity η_{sp}/C_p as functions of the content of the SA units in the copolymer A in hydrolyzed Praestol 2500. $C_c = 6.4 \times 10^{-4}$%, η_{sp}/C_p was measured in water at 25°C at C_p = 0.0002%.

polymer (P) combined with coagulant, aluminum sulfate, in treatment of the water samples taken from the Volga river and intended for potable water and industrial water supply purposes. Praestol 2500 was hydrolyzed in the operating unit for preparing polymer solution.

The water treatment flowsheet comprised two lines with identical sets of the water treatment facilities (flocculation chambers, horizontal settlers, and quartz filters) with the capacity of 1700 $m^3 h^{-1}$. The P polymer was fed to one line, and HP, to the other, and in both lines the quality of the treated water was assessed basing on the standards of SanPiN [10]. The results are summarized in Table 2. It is seen that the indices of water treated with P and HP satisfy the standards (SanPiN [10] sets the MPC for turbidity at 1.5 mg l^{-1} and for aluminum(III), at 0.5). Other indices of the water after treatment also satisfied the SanPiN standards. It should be noted that owing to large M_η values, very low doses of Praestol 2500 were sufficient for improving the standardized indices. The tabulated data also evidence that on changing from P to HP the turbidity of the treated water decreased by 18%, and the content of Al(III), by 26%. The latter fact is due to the presence in the HP macromolecules of carboxylate groups able of forming complexes with Al(III) ions. Thus, low doses of HP afforded more efficient treatment of natural water compared to P.

CONCLUSIONS

(1) Alkaline hydrolysis of Praestol 2500 in dilute aqueous solutions at 5–25°C yields polymers with controllable degree of hydrolysis (up to 30 mol %).

(2) The water treatment efficiency was improved on going from P to HP with the degree of hydrolysis of 19 mol% when the polymers were used in combination with aluminum sulfate.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Intensification of the Flotation Treatment of Water with Natural Polyelectrolytes

Murmansk State Technical University, Murmansk, Russia

Received August 24, 2000

Abstract—The influence of natural polyelectrolytes, sodium alginate and chitosan, on the efficiency of water treatment by flotation to remove fish oil was elucidated by studying the kinetics of formation of adsorption layers at the aqueous polyelectrolyte solution–air and aqueous polyelectrolyte solution–fish oil interfaces. The stability of fish oil emulsions stabilized by sodium alginate and chitosan was studied.

Removal of fatty substances from water and aqueous solutions has become an especially urgent problem [1]. Fat-containing wastewater is not appropriate for biological and other water treatment works because fat impurities depositing on pipeline walls prevent transportation of wastewater and disturb operation of the water treatment works. Fat removed from wastewater can find use as a valuable supplement to mixed feed for domestic animals and poultry.

The biopolymers studied in this work, sodium alginate ANa and chitosan, are not toxic and exhibit a set of properties making them suitable for removal of fat and protein substances from wastewater generated by food industry enterprises with their subsequent utilization as food supplement [2–7].

Wastewaters generated at fish enterprises are complex disperse systems whose main components are fat and protein. Fat occurs in wastewater as emulsions and films.

Coarsely dispersed systems are treated, in particular, by flotation and settling; finer emulsions are broken down by coagulation, flocculation, and chemical and biological methods. Additives of natural polyelectrolytes such as ANa and chitosan can be used for intensifying the flotation treatment of water, as they can affect the stability of fat droplets and air bubbles and their hydrophobic and hydrophilic properties. The suitability of ANa and chitosan as flocculants in wastewater treatment was pointed out in a number of publications [2, 5, 7–11]. However, in Russia these polymers have not as yet found wide application because of their relative expensiveness [5]. Recently, a fairly inexpensive electrochemical method of preparing polyelectrolytes of diverse nature from hydrobiontics has been developed [12].[1] Sodium alginate and chitosan prepared by this method have low prime cost and are suitable for development of waste-free technologies and closed water circuits, e.g., in production of hydrolyzates, isolates, and concentrates from hydrobiontics.

The aim of this work was to elucidate how natural polyelectrolytes ANa and chitosan affect the efficiency of the flotation treatment of water to remove fish oil.

EXPERIMENTAL

We used ANa and chitosan with molecular weights of 13000 and 14000, respectively.[1] As fat additives served food-grade fish oil [GOST (State Standard) 3714–72]. We prepared aqueous solutions of ANa with concentrations ranging from 0.000025 to 0.25 g l^{-1}. Chitosan solutions of the same concentrations were prepared in 1% acetic acid. The acidity of the medium was adjusted using 0.1 M HCl and 0.1 M NaOH. The pH value was measured with an I-135 pH-meter. The kinetics of formation of the adsorption layers at the water–air and water–fish oil interfaces were monitored by variation of the surface tension of the solution σ at the interface with time τ. The surface tension of the solutions was determined by the Wilhelmi's method [13]. The half-relaxation time was calculated by the procedure described in [14]. The fish oil–water emulsions were prepared using a PT-2 tissue microcrusher (rotation rate 20 rps, stirring time 15 s), and the content of ANa and chitosan additives in the aqueous phase was varied within 0.2–1 g l^{-1}. stability of the emulsions was estimated from the time of breakdown of the half of the initial amount of the emulsion $t_{1/2}$ [15] and from the lifetime of droplets at the interface [16]. The conformations taken by the molecules of the biopolymers were determined by the procedure proposed in [17]. To this end, we measured the viscosity of aqueous solutions of ANa and chitosan with a capillary viscometer at various pH values.

The flotation treatment of water to remove oil impurities was carried out on a pilot setup for pressure flotation.[2] The flotation time was 15 min at the pressure of 0.25 Pa cm^{-1}. The oil content before and after flotation was determined photometrically using phosphovanillin reagent [18]. The experimental results are presented in Figs. 1–4 and in Tables 1 and 2.

The efficiency of removal of emulsified hydrophobic substances by flotation is governed by a number of factors [19]. The deciding factor is the state of the adsorption layers on the surface of the particles and air bubbles being floated [20]. The maximal degree of removal will, evidently, be achieved in the case when the adsorption layers form at both interfaces with equal intensity. This will involve flocculation of the oil molecules by the "bridge" mechanism and coalescence of oil droplets with air bubbles via the polymer "bridge." If the polyelectrolyte is adsorbed predominantly at the solution–air interface, only polyelectrolyte is removed from the solution. In the case of the predominant adsorption at the solution–oil interface, the oil–surfactant macromolecule complex will remain in the solution. The removal will be less intensive. Thus, it can be assumed that the degree of oil removal by flotation will be at a maximum for a polymer for which the rates of formation of the adsorption layers at the solution–air and oil–air interfaces will be approximately the same. It is believed that efficient flotation implies surface tension at the interface of 60–65 mN m^{-1}. At greater surface tensions intense frothing is observed, and at smaller, the size of the bubbles increases and their number decreases. As a result, the flotation efficiency decreases [21].

[2] Murmansk State Technical University.

Figure 1 presents the kinetic curves showing a decrease in the surface tension of the polyelectrolyte solutions of interest (concentration 0.000025 g l^{-1}) at the solution–air and solution–fish oil interfaces at the solution temperature of 20°C and pH 5.5–6. For polyelectrolytes with the concentrations of 0.00025 and 0.0025 g l^{-1} we obtained analogous curves.

Since the procedure of interest implies taking the first measurement within 4–5 s after formation of the layer, the σ_0 values shown in the figure are essentially the surface tensions at the initial moment of the layer formation which differ from the surface tension of the solvent. For double-distilled water σ_0 = 72.44 mN m^{-1} at 25°C.

As seen from Fig. 1, the surface tension decreases to the greatest extent within the first 10–15 min of formation of the adsorption layer for both polyelectrolytes studied and for both interfaces. The equilibrium surface tension is achieved for chitosan at the solution–air and solution–oil interfaces 100 min after the onset of formation of the adsorption layer (curves *2*, *4*) and for ANa, after 100 min at the solution–oil interface (curve *3*) and after 250 min at the solution–air interface (curve *4*). In the case of ANa under the actual conditions the surface tension decreases to the greatest extent at the solution–air interface: 15–20 min after the onset of formation of the adsorption layer the surface tension is equal to 62–65 mN m^{-1} (curve *1*). Our experimental data suggest that both ANa and chitosan exhibit surface activity at the solution–oil interface. The surface activity $(d\sigma/dC)_{C \to 0}$ calculated from the σ–*C* plots for ANa and chitosan at the solution–air interface is equal to 0.4×10^{-4} and 2.4×10^{-3} N m^2 mol^{-1}, respectively, and at the solution–oil interface, to 2.61×10^{-6} and 2.65×10^{-6} N m^2 mol^{-1}, respectively. Low surface activity of certain derivatives of chitin was mentioned in [22]. It should be noted that in the case of chitosan at the aqueous solution–oil interface (curve *4*), 30 min after the onset of formation of the adsorption layer the curve σ–τ exhibits a minimum. This is, evidently, due to formation of a microemulsion at the chitosan–fish oil interface. The influence of the impurities contained in chitosan on its surface activity also cannot be ruled out [23].

Formation of the adsorption layers was quantitatively estimated by the procedure described in [14], using the equation proposed originally by Rebinder:

$$\log(\sigma_\tau - \sigma_\infty) = \log(\sigma_0 - \sigma_\infty) - (\tau/2.3\theta),$$

where, σ and σ_τ are the surface tensions of the solution at the initial moment and the moment τ, mN m^{-1}, respectively; σ_∞ is the equilibrium surface tension, mN m^{-1}; θ is the relaxation time, min; and τ is the time, min.

Table 1. Relaxation time θ of solutions (0.000025 g dl^{-1}) of ANa and chitosan at the solution–air and solution–fish oil interface. Temperature 20°C; pH 5.5–6

By graphically solving this equation, we determined the relaxation times for the systems under study.

Trapeznikov *et al*. [24] studied solutions of an amphoteric polyelectrolyte (protein) and found that initially the surface tension sharply decreased and then $\log(\sigma_0 - \sigma_\infty) = f(\tau)$ exhibited a linear section with a smaller slope. From the $\log(\sigma_0 - \sigma_\infty)$ plot, we can estimate the so-called relaxation time θ corresponding

to adsorption and rearrangement of the adsorption layers and desorption [24].

Figure 2 presents the $\log(\sigma_\tau - \sigma_\infty) = f(\tau)$ plots for the adsorption layers of ANa and chitosan. Basing on the procedure proposed in [24], we estimated from the initial straight-line sections of these plots the relaxation times for ANa and chitosan at the solution–air and solution–oil interfaces (Table 1).

Table 1 shows that the maximal relaxation time of 45 min is characteristic of ANa at the solution–air interface. For chitosan the relaxation time is smaller compared to ANa for both interfaces. As seen from Fig. 2, for both polymers and the solution–oil interface (curves *3*, *4*) the slope of the second section in the plot is very small. This suggests that virtually no rearrangement of the adsorption layers and desorption occur [24]. This can probably be explained by formation at the interface of a thin oil microemulsion stabilized by polyelectrolytes. In the case of chitosan, irreversible adsorption is probably due to electrostatic interaction of the positively charged functional groups of the chitosan macromolecules with negatively charged groups of oil molecules.

The rate of formation of the adsorption layers of a surfactant affects the stability of the emulsions: The higher the rate, the greater the stability of the emulsion by the moment of its formation [25].

Figure 3 (curves *1*–*4*) shows the stability of the fish oil emulsions stabilized by the biopolymers studied and the degree of removal of oil by flotation α as functions of polyelectrolyte concentration in solution (pH of the polyelectrolyte solutions 5.5–6). Figure 3 shows that at concentrations lower than 0.2 g l^{-1} (Fig. 3, curve *2*) chitosan exerts a sensitizing effect: $\tau_{1/2}$ tends to markedly decrease, and at concentrations up to 1 g l^{-1} it does not exceed $t_{1/2}$ for emulsions without these additives. In accordance with Fig. 2, chitosan has a somewhat greater surface activity at the solution–oil interface compared to ANa. At low concentrations chitosan is rapidly adsorbed at the surface of oil droplets, favoring coalescence of droplets and affecting flocculation by the "bridge" mechanism [26]. At chitosan concentrations corresponding to formation of saturated adsorption layer (over 0.2 g l^{-1}) the macromolecules are adsorbed on the entire surface of the oil droplets, thus increasing the stability of the emulsions within this range of the polyelectrolyte concentration. Figure 3 suggests that the most stable emulsions are formed in the presence of ANa (curve *1*): $t_{1/2}$ for them is by a factor of 5–6 greater than for emulsions forming in the presence of chitosan. It should be emphasized that although ANa is somewhat less surface-active than chitosan, it is superior to chitosan in the emulsifying power. This can be explained in our case by a greater viscosity of chitosan solutions, which is responsible for the fact that under identical intensity of stirring the emulsions stabilized by chitosan will be less dispersed and will break down at a higher rate than those stabilized by ANa.

Figure 3 shows the degree of removal by flotation of oil from water (curves *3*, *4*) depending on the polyelectrolyte concentration. The oil–polyelectrolyte solution contact time was 15 min, which correponds to the maximal rate of decrease in the surface tension at the interface (Fig. 1). The maximal degree of removal of oil by flotation in the case of chitosan is achieved at the concentration of 0.2 g l^{-1}. This can be explained by the flocculation effect of chitosan: The minimum in the $\tau_{1/2}$–C curve corresponds to the maximum in the α–C curve (Fig. 3, curves *2*, *4*, respectively). In the case of ANa the decrease in the degree of removal of oil from water in the concentration range 0.2–0.6 g l^{-1} is probably due to its relatively high surface activity at the solution–air interface (Fig. 1, curve *3*). This is responsible for formation of stable air bubbles during frothing and, thereby, for increased degree of removal of oil from water. In the case of ANa the removal of oil is less efficient (Fig. 3, curve *3*), as ANa, compared to chitosan, forms more stable emulsions with oil. With increasing time of contact between oil particles and polyelectrolyte solution before flotation to 100–150 min the residual amount of oil in water significantly increases.

It is known that the stability of the adsorption layers widely varies with time and attains maximal values after establishment of the adsorption equilibrium [25]. This effect is, evidently, manifested not only under static conditions of formation of the adsorption layer but also under treatment of emulsions by flotation. Thus, under actual conditions the optimal time of contact of oil with polyelectrolyte solution during flotation is 10–15 min. To explain the influence of the polyelectrolyte on the stability of the emulsions and the removal of oil by flotation it is also necessary to take into account the conformation of the polyelectrolyte macromolecules in solution, which is markedly affected by the pH of the solution.

The influence of pH on the stability of the emulsions was estimated from the average lifetime of oil droplets at the oil–aqueous polyelectrolyte solution interface τ_{av}. The time of formation of the adsorption layer was 150 min, which corresponds to the time required for establishment of the adsorption equilibrium at this interface (Fig. 1). The concentration of

the polyelectrolyte corresponded to formation of saturated adsorption layer and was equal to 0.25 g l^{-1}. The results obtained are presented in Table 2.

As follows from Table 2, the longest τ_{av} for chitosan is observed at pH 5.1–7 and 9–12, and for ANa, at pH 6.6 and 12. The influence of pH on the lifetime of the droplets is probably due to the conformational changes in the polyelectrolyte macromolecules.

Our findings concerning the conformation taken by the chitosan macromolecules as influenced by pH of the medium suggest that in acidic medium (pH < 3) the chitosan macromolecules take the most unfolded conformation. At pH 4–7 they roll up into loose globules. In alkaline medium compact dense structures, globules, form. This is consistent with the nature of the macromolecules of chitosan, which are cationic surfactants, and with the solubility of chitosan whose isoelectric point is at pH 5.2 [3].

The ANa macromolecules in alkaline medium take the most unfolded conformation. On going to acidic medium, the viscosity of the solution of this polyelectrolyte decreases, which suggests formation of compact structures. Acidification of the medium (pH < 4) does not change the viscosity, as this pH value, evidently, corresponds to the most compact polymeric ANa chains. This dependence is explained by the fact that ANa is anionic surfactant which is virtually insoluble in acidic media [3, 27].

Thus, under actual conditions (at pH 5.5–6) the chitosan and ANa macromolecules take loose coil conformation corresponding to formation of the most stable oil–water emulsion (Table 2). It should be noted that in strongly alkaline medium (pH 11–12) the lifetime of droplets also increases. A possible reason is the presence of a large amount of alkali in the polyelectrolyte solution. Probably, owing to oil hydrolysis certain amount of the molecules (more precisely, alkaline salts) of free fatty acids forms at the polyelectrolyte solution–oil interface. These molecules present an additional structural and mechanical barrier in the form of ultramicroemulsion and hinder coalescence of oil droplets with the allied surface.

Figure 4 presents the degree of removal of oil by flotation depending on the pH of the polyelectrolyte solutions. It is seen that the maximal degree of removal of oil from water corresponds to pH 5.5–6. At this pH the macromolecules of the polyelectrolytes occur in a loose coil conformation.

Our results suggest complex interaction between the natural polyectrolytes and fat components contained in water. Evidently, it is also necessary to take into account the fact that polyelectrolytes are solubilized by lipid substances as pointed out in [28].

CONCLUSION

The polyelectolytes sodium alginate and chitosan acting as surfactants at the solution–air and solution–oil interfaces affect the stability of the oil–water emulsions and intensify removal of fat and protein components from water by flotation. The stability of the emulsions and the efficiency of water treatment by flotation depends on the conformation taken by the polyelectrolyte macromolecules in solution.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Hydrodynamic Model of a Free Jet of Atomized Fluid

S. V. Aniskin and O. I. Protod'yakonova

St. Petersburg State Technological University of Plant Polymers, St. Petersburg, Russia

Received December 20, 2000

Abstract—The formation and development of a gas–fluid jet outflowing from a single-flare atomizer of a spray absorber are analyzed theoretically, and a hydrodynamic model taking into account the nonuniformity of spraying density and gas flow velocity across the jet is developed on the basis of this analysis.

Developing methods for calculating mass-exchange processes in spraying apparatus requires a detailed theoretical study of jet flows. Such flows occur, in particular, in direct-flow spray absorbers.

One of important kinds of jet flows is a flow of drops formed in spraying a fluid with a single-flare atomizer. It is known that a gas jet is always formed inside such a drop flow. Thus, the jet of atomized fluid, considered as a whole, is a gas–fluid jet.

The main distinction of single-jet atomizers is that fluid drops are present within the entire flare cone.

Let us represent the structure of the jet flow under consideration as the following scheme (Fig. 1). The gas–fluid jet is conventionally divided into three zones. In the first zone, the fluid jet outflowing from the atomizer *1* is deformed and then disintegrates into drops and some coarse formations of indeterminate shape, which, in turn, also disintegrate into large and fine drops. There are no formations of this kind in the second and third zones, and inclusions of the disperse phase are only composed of large and fine drops. The mechanisms of interaction between phases are different in these zones.

As the gas–fluid jet moves, its flare expands, with the volume density of the fluid phase, correspondingly, decreasing:

$$\beta = \frac{V_l}{V_g + V_l}, \quad (1)$$

where V_l and V_g are, respectively, the fluid and gas volumes in the gas–fluid jet.

In the initial part of the first zone, the forming drops are so close to one another that their hydrodynamic boundary layers come in contact. This gives rise to a certain structure of interconnected fluid phase inclusions, with the motion of gas through this structure comparable with the filtration process.

In the final part of the first zone, beginning with the instant when the β value becomes approximately equal to 0.02 [1], there is no mutual influence of drops any more and they move further entirely independently of one another. In this case, the momentum exchange between the fluid and the gas will depend on the size, shape, and relative velocities of drops and of fluid formations whose disintegration into drops continues in the flow zone in question.

In accordance with the results obtained in experimental studies of the hydrodynamics of the gas–fluid jet by the photographic method [2], the mentioned disintegration is complete at the instant when β becomes 0.003. It should be noted that the estimated β values at which moving drops cease to affect one another may be somewhat different for atomizers of special types. For example, for atomizers in which

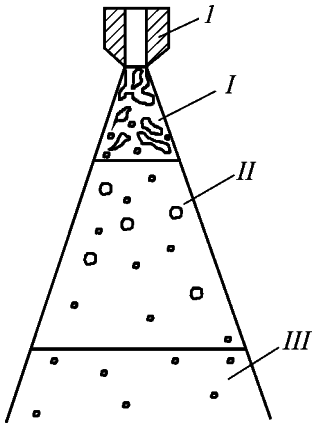

Fig. 1. Structure of gas–fluid jet in fluid spraying with a single-flare atomizer: (*1*) atomizer and (*I–III*) jet zones.

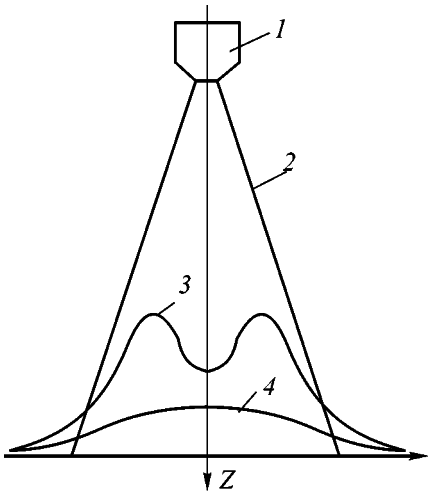

Fig. 2. Distribution of gas flow velocity and fluid spraying density across the flare: (*1*) atomizer, (*2*) conventional flare boundary, (*3*) distribution of spraying density J (m s^{-1}), and (*4*) distribution of gas flow velocity v_i (m s^{-1}).

the fluid flow is divided into separate small jets forming chains of drops this β value may be much lower than 0.02.

In the second zone, the momentum of the gas jet formed inside the drop flow steadily grows because of the drop deceleration [2] which can be described by the known hydrodynamic equations [3]. Here, it is important to take into account the fact that drops in this zone do not change their shape and size.

A distinctive feature of the third zone is that the drops in it have already lost a major part of the initial momentum. Therefore, the momentum that can be transferred by drops to gas in this stage of development of the gas–fluid jet can be considered negligibly small as compared with the momentum of the gas jet formed in the second zone.

Consequently, the momentum of the gas jet in the third zone remains constant. The motion of a jet satisfying the conditions of the third zone corresponds to the known model of a submerged gas jet with disperse inclusions [4].

Thus, the relative phase motion velocities are comparatively low in the third zone of the gas–fluid jet. It is this fact that gives no way of effectively performing in this zone such mass-exchange processes in which the main resistance to mass transfer is associated with the gas phase. In this connection, it is advisable to ensure by using one or another factor (pressure of the fluid outflowing from the atomizer nozzle, drop size, shape and size of apparatus, directed jet flow, fluid jet flare angle, etc.) sufficiently high relative velocities of phases throughout the reaction volume of the apparatus. Under such conditions, no third zone appears in the gas–fluid jet.

Therefore, it is advisable, when studying the flow of gas–fluid jets in spray mass-exchange apparatus intended to perform processes with the main resistance to mass transfer associated with the gas phase, to limit the zone of problem setting to the first two flow zones.

Models have peen proposed [5–7] describing the flow of a gas–fluid jet in the first and second of the considered zones. In describing the relative motion of gas and fluid in these zones [6], the flow of a gas was identified with the process of its filtration through a disperse fluid medium. In doing so, the Ergun equation, originally proposed for describing the process in an apparatus with solid filter, was employed as an equation relating the hydraulic resistance of the disperse medium to the relative velocity of phases and the volume concentration of the disperse phase.

However, the use of this approach in modeling the flow in question is only justified for the first zone of the jet. In the second zone, the volume concentration of the disperse phase goes beyond the validity limits of the Ergun equation.

A shortcoming of [5] consists in the assumption of a uniform distribution of the gas flow velocity over the gas–fluid jet. In doing so, the authors determine the jet boundary from the initial flare angle and trajectory of drop motion at the thus determined jet boundary.

Actually, as indicated by the results obtained in experimental studies of flows of this kind [2, 8], the distribution of the gas flow velocity in the jet is not uniform, but resembles a Schlichting profile.

Figure 2 shows a typical gas flow velocity distribution and spraying density (amount of fluid passing through unit cross-section of the gas–fluid flow) across the flare at a certain distance from the atomizer [9].

In using [5] the assumption of a uniform gas flow velocity distribution in the gas–fluid jet, it is rather essential how a method for reliably determining the gas jet boundary is chosen (Fig. 2). Galustov [5] determines the boundary of the gas flow with gas velocity uniformly distributed across the gas–fluid jet from the boundary of the drop flow. The latter is preliminarily found from the prescribed spraying density J defined as a fluid flow Q_l passing through a jet flare cross-section S

$$J = Q_l/S. \quad (2)$$

Meanwhile, it is known that the gas flow boundary should be found from the type of gas flow velocity distribution across the jet. However, with this method used, the boundaries of the drop and gas flows are found to be in different places of the flare. Thus, the condition used to introduce the gas flow boundary determines the cross-section area of the gas–fluid jet and the intensity of momentum exchange between the fluid and gas in the jet. Consequently, the adequacy of the hydrodynamic model [5] describing the flow of a gas–fluid jet with uniform cross-sectional distribution of the gas to the actual process strongly depends on a method used to determine the jet boundary, not specified in [5]. It should be noted that developing such a method is a complicated independent task.

The main problem to be solved in a theoretical analysis of a gas–fluid jet flow in the first and second zones, made in this study, is to construct a flow model free of the above shortcomings. The model was developed under the following assumptions. The jet flow is considered to be established. There is no drop fragmentation or coagulation in the second zone of the jet. There is no heat exchange within the jet. The distribution of the spraying density in the gas–fluid jet is axially symmetric. The stresses in the turbulent gas jet developed inside the flare in the first and second zones of the gas–fluid flow are negligibly small as compared with the stresses created in this jet by the moving fluid.

The size distribution of drops formed in fluid jet fragmentation is the same across the flare. The process of drop fragmentation in the gas–fluid jet is complete at a volume concentration of the disperse phase $\beta = 0.003$. Since the intensity of new drop formation markedly decreases along the first zone, it is natural to use in constructing the model the assumption that changes in the average drop size with β varying between 0.02 and 0.003 can be considered negligible.

In order to take into account the nonuniformity of spraying density distribution across the jet flare, let us divide the flare with conical surfaces into n separate jets within which the flow rate remains the same (Fig. 2a), i.e. the following condition is met for an arbitrary ith jet:

$$G_i = \text{const}, \tag{3}$$

where G_i is the mass flow rate of the fluid (kg s^{-1}).

Let us determine the variation of the gas flow momentum along the Z-axis within ith jet. To do so, let is distinguish a thin layer of the cone with height dz, as shown in Fig. 3a. Let us consider the cross-section of this layer in a plane passing through the Z-axis (Fig. 3b). We assume that the velocity v_i and pressure P_i of the gas are constant within each ith layer. Changes in the momentum of the gas flow between the cross-sections ab and cd occur for the following three reasons: stresses appearing in fluid deceleration, partial momentum transfer resulting from the shift of the gas flow through lateral surfaces bd and ac toward the Z-axis, and pressure drop ΔP across the distance Δz.

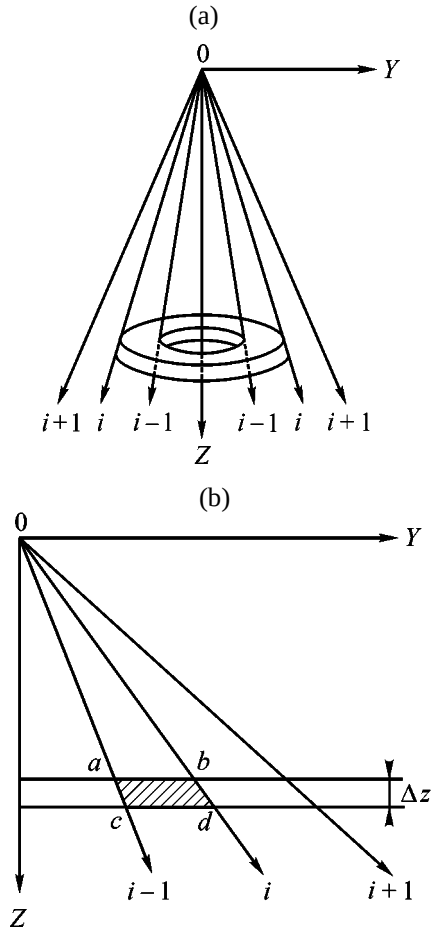

Fig. 3. Schematic of how the gas–fluid flow flare is subdivided by flow lines: (a) volume scheme and (b) section in a plane passing through the Z-axis.

With account of the aforesaid, the following equation can be written for the variation of momentum in the distinguished ith layer of the cone:

$$\Delta(\rho_g Q_{gi} v_{zi}) + \rho_g v_{z(i+1)} \Delta Q^y_{g(i+1)} - \rho_g v_{zi} \Delta Q^y_{gi} + S_i \Delta P_i + G_i \Delta u_{zi} = 0, \tag{4}$$

where ρ_g is the gas density (kg m^{-3}); S_i, the area of cross-section ab (m^2); v_i, the gas velocity within ith layer (m s^{-1}); Q_{gi}, the volumetric flow rate of gas

through area S_i ($m^3 s^{-1}$); $\Delta Q^y_{g(i+1)}$ and ΔQ^y_{gi} are, respectively, the part of the volumetric gas flow rate coming to layer i from layer $i + 1$ and that coming to layer i from layer $i - 1$; P_i, the gas pressure in layer i ($N m^{-2}$); and u_{zi}, the fluid velocity along the Z-axis ($m s^{-1}$).

With account of the introduced designations, the quantity ΔQ_{gi}, equal to the change in the gas flow rate in ith layer from section ab to section cd, is defined by the equation

$$Q_{gi} = \Delta Q^y_{g(i+1)} - \Delta Q^y_{gi}. \quad (5)$$

The quantity $\Delta Q^y_{g(i+1)}$ appearing in Eq. (4) can be determined from the condition for conservation of the gas flow rate in a jet of radius y_i:

$$\Delta Q^y_{g(i+1)} = \sum_{i+1}^{i} \Delta Q_{gi}. \quad (6)$$

Let us denote the radial gas flow velocity in ith element of space (i.e., in the $abcd$ element) by v_{yi}, and that in $(i + 1)$th element, by $v_{y(i+1)}$. With account of these designations the volumetric flow rate of gas coming into ith element through its lateral surface from $(i + 1)$th element of a distinguished layer of a gas–fluid jet of height dz can be expressed as

$$\Delta Q^y_{g(i+1)} = -2\pi y_{i+1} v_{y(i+1)}. \quad (7)$$

From relations (6) and (7) we obtain, passing from finite differences to differentials, the following conservation equation for the gas flow rate in the form

$$\sum_{i=1}^{i} (dQ_{gi}/dz) = -2\pi y_{i+1} v_{y(i+1)}. \quad (8)$$

In order to obtain equations describing changes in the momentum in a layer of the cone, bounded by a lateral surface of radius y_i and horizontal sections z and $z + \Delta z$, we sum Eq. (4) from $i = 1$ to i. In doing so, account should be taken of the fact that, by virtue of the axial symmetry, there is no gas flow along the Y-axis at the Z-axis of the jet, and, therefore, $\Delta Q^y_{g1} = 0$. As a result of the summation, we obtain, passing from Δz to dz, the sought-for equation in the following form:

$$\frac{d}{dz}\sum_{i=1}^{i} (\rho_g Q_{gi} v_{zi}) + \rho_g v_{z(i+1)} \sum_{i=1}^{i} (dQ_{gi}/dz) + \sum_{i=1}^{i} G_i (du_{zi}/dz) + \sum_{i=1}^{i} S_i (dP_i/dz) = 0. \quad (9)$$

To determine the P_i value, we use the following considerations. Within an elementary volume $abcd$ of the jet (Fig. 3b) there exists some gas pressure P_i. The gas flow velocity along the Y-axis is constant within the volume $abcd$. Under these conditions, the variation of the pressure P_i in the direction of the Y-axis will be entirely determined by the stress created by the flow of drops along the Y-axis in the elementary volume in question. This dependence is expressed by the relation

$$(P_{i+1} - P_i) \times 2\pi y_i dz + G_i du_{yi} = 0. \quad (10)$$

Further, we derive an expression describing the variation of the fluid flow velocity in ith elementary volume of the $abcd$ space. Let us assume that the direction of the Z-axis coincides with that of the gravity force. In obtaining this expression, account should be taken of the fact that, by virtue of the different kinds of mutual influence of moving drops within these regions, this expression will have different forms for regions of the first zone of the jet, satisfying the conditions $\beta > 0.02$ (initial region of the first zone) and $\beta < 0.02$ (final region of the first zone and the second zone).

Let us first find the expression describing the variation of the fluid flow velocity along the Z-axis in the initial part of the first zone of the gas–fluid jet, satisfying the condition $\beta > 0.02$. For this purpose, let us write an equation characterizing the deceleration of the fluid flow G under the action of the gas-medium resistance force F_{ri} and the gravity force F_{gri}:

$$G_i du_{zi} = -(F_{ri}\cos\alpha - F_{gri}), \quad (11)$$

where α is the angle between the Z-axis and the direction of action of the resistance force F_{ri}.

The F_{gri} value is given by

$$F_{gri} = g G_i \Delta z_i / u_{zi}, \quad (12)$$

where g is the acceleration of gravity.

In deriving the expression for the mentioned resistance force for the initial part of the first zone of the jet, we can rely upon an analogy between the mechanism of gas–fluid interaction in the gas–fluid jet and that of gas filtration through a packing bed moving as a whole [6]. The reason for applying the above analogy is the sufficiently high volume density of the fluid phase in the considered initial part of the first zone of the jet, where, as mentioned above, $\beta \geq 0.02$. With account of the analogy, the force arising in the

fluid deceleration in *i*th elementary volume of the *abcd* space will be given by the filtration pressure drop dP_{fi} across the mentioned volume

$$F_{ri} = S_{fi}dP_{fi}. \quad (13)$$

If a straight line is drawn through the planes *ab* and *cd* in the direction coinciding with that of the F_{ri} force, then these planes will intercept a portion d*l* on the straight line. To obviate unnecessary graphical complications, this line portion is not shown in Fig. 3. Apparently, the ratio of S_i to S_{fi} will be proportional to the ratio of d*l* and d*z*, which allows use of the following relation in further analysis:

$$S_i/S_{fi} = dl/dz. \quad (14)$$

Then, for the considered initial part of the first zone of the jet, the variation of the fluid velocity u_{zi} in a layer of thickness d*z* will be given, with account taken of expressions (11)–(14), by

$$du_{zi}/dz = (S_i dP_{fi}\cos\alpha)/G_i dl + g/u_{zi}. \quad (15)$$

To determine dP_{fi}/dl, we use the known calculation procedure [10] based on the Darcy equation

$$dP_f/dl = \xi\rho_g u_{rel}^2/2d_{eq}, \quad (16)$$

where u_{rel} is the relative motion velocity of fluid and gas, d_{eq} is the equivalent packing channel diameter, and ξ_f is the filtration resistance coefficient.

For packings of arbitrary shape the ξ_f value can be determined using the Ergun relations [11]

$$\xi_f = 133/Re_g + 2.34. \quad (17)$$

The equivalent dimater of packing channels is determined using the known relation [10]

$$d_{eq} = 4\varepsilon/a, \quad (18)$$

where *a* is the specific surface area of the packing (m^{-1}) and ε is the packing bed porosity.

To apply this method for dP_f/dz calculation to the gas–fluid jet in the region in question, it is necessary to find the relationship between d_{eq} and the size of the forming drops. We assume that d_{eq} is constant in fluid jet disintegration into drops. Then, with account of $\varepsilon = 1 - \beta$, it follows from (18) that

$$d_{eq} = 4(1 - \beta)/a. \quad (19)$$

At the end of the zone in which the jet disintegrates into drops the β value is small and the specific surface area of the fluid becomes equal to the specific surface area a_d of drops in the disintegrated jets. The a_d value can be determined from the average volume-surface diameter, or the Sauter diameter d_{32}, using the relation

$$a_d = 6/d_{32}. \quad (20)$$

From (19) and (20) follows that

$$d_{eq} = 2d_{32}/3. \quad (21)$$

Relation (21) gives an expression describing the variation of the velocity u_{zi} within *i*th elementary volume *abcd*. This expression can be written, with account of Eqs. (15)–(17), in the form

$$du_{zi}/dz = 3S_i\xi_f 3\rho_g u_{rel}^2\cos\alpha/4G_i d_{32} + g/u_{zi}. \quad (22)$$

The same equation written for the projections onto the *Y*-axis has the form

$$du_{yi}/dz = 3S_i\xi_f\rho_g u_{rel}^2\sin\alpha/4G_i d_{32}. \quad (23)$$

In deriving Eq. (23), which is simpler than Eq. (22), account was taken of the fact that the *Y*-component of the gravity force is zero.

In the part of the gas–fluid jet satisfying the condition $\beta < 0.02$, drops move independently of one another. Therefore, the variation of the fluid motion velocity can be evaluated from that of the velocities of separate drops. The expression describing this variation has the form

$$du_{zi}/dz = -3\xi_d\rho_g u_{rel}^2\cos\alpha/4d_{32}u_{zi} + g/u_{zi}, \quad (24)$$

$$du_{yi}/dz = 3\xi_d\rho_g u_{rel}^2\sin\alpha/4d_{32}u_{zi}, \quad (25)$$

where ξ_d is the resistance coefficient of a drop moving in a gas medium.

A formula for determining the ξ_d value is chosen depending on the Reynolds number Re. For the conditions under consideration, we can use the formula valid for the range $0.1 < Re < 1000$ [3]:

$$\xi_d = 24(1 + 0.125Re^{0.72})/Re. \quad (26)$$

Using the apparent relations $u_y = dy/dt$, we can obtain an expression necessary for determining the dependence $y_i(z)$

$$dy_i/dz = u_{yi}/u_{zi}. \quad (27)$$

Thus, the developed hydrodynamic model of a free

flare of atomized fluid includes 6*n* first-order differential equations for 10*n* unknowns: Q_{gi}, v_{zi}, v_{yi}, u_{zi}, u_{yi}, u_{rel}, P_i, S_i, y_i, and α_i, which are to be supplemented with an appropriate number of closing relations with apparent meaning. These are algebraic equations of the form

$$Q_{ri} = S_i v_{zi}, \quad (28)$$

$$S_i = \pi(y_i^2 - y_{i-1}^2), \quad (29)$$

$$u_{rel} = [(u_{yi} - v_{yi})^2 + (u_{zi} - v_{zi})^2]^{1/2}, \quad (30)$$

$$\alpha_i = \arctan[(u_{yi} - v_{yi})/(u_{zi} - v_{zi})]. \quad (31)$$

In accordance with the assumption of a practically instantaneous establishment of a stationary gas–fluid jet flow immediately after the fluid outflow from the atomizer nozzle, the constructed system of equations of the hydrodynamic model should only be supplemented with boundary conditions. At $z = 0$, $G_i = G_i^{(0)}$, $u_{zi} = u_{zi}^{(0)}$, $u_{yi} = u_{yi}^{(0)}$, $v_{zi} = u_{zi}^{(0)}$, $v_{yi} = u_{yi}^{(0)}$, $y_i = y_i^{(0)}$, $\alpha_i = \alpha_i^{(0)}$; at $y = 0$, $v_{y1} = 0$.

On the outer boundary of the jet, i.e., at $y > y_n$, $v_{y(n+1)} = 0$, $v_{z(n+1)} = 0$, $G_{n+1} = 0$, $P_{i+1} = P_a$, where P_a is the atmospheric pressure (Pa). This system can be solved numerically by the Runge–Kutta method.

CONCLUSIONS

(1) A detailed theoretical analysis of the gas–fluid jet formed by an atomizer in a spraying apparatus served as a basis for constructing a hydrodynamic model taking into account the nonuniformity of gas velocity distribution and the variation of gas pressure in the jet.

(2) The main advantage of the developed model consists in that there is no need to preliminarily determine the gas jet boundaries in applying the model to calculations of spraying mass-exchange apparatus.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Effect of Stirring Devices on the Intensification of Gas–Fluid Processes

V. N. Ivanets, S. N. Al'brekht, and G. E. Ivanets

Kemerovo Technological Institute of Food Industry, Kemerovo, Russia

Received April 3, 2000; in final form, November 2000

Abstract—A comparative analysis is made of the operation of apparatus of rotary-pulsation and ejector types with self-suction turbine agitator. The dependence of the efficiency of operation on the output capacity and energy-related characteristics determining power consumption for agitation of gas–fluid mixtures were determined experimentally.

One of the main parameters characterizing the efficiency of a gas–fluid apparatus is the phase surface contact area. Present attempts to raise its value are commonly associated with reducing the geometric dimensions of gas bubbles by using, as a rule, various bubbling and mechanical stirring devices [1–3]. However, gas–fluid apparatus presently used in chemical and other industries have a number of serious disadvantages and frequently fail to satisfy modern requirements to the output capacity, quality, and energy expenditure per unit product. Therefore, development of new absorber designs and improvement of the existing types of apparatus are, beyond any doubt, urgent tasks. One of possible ways to solve this problem is to provide intensive stirring ensuring a significant rise in the phase boundary area and concentration of a considerable amount of energy in small volumes. It is known that the use of low-frequency (20–20 000 Hz) acoustic elastic vibrations allows in most cases a substantial intensification of the homogenization process. In this case, such phenomena as cavitation, acoustic pressure, and pulsing microflows occur in the medium being treated, making higher the rate of physicochemical processes in heterogeneous systems [3].

Acoustic vibrations are generated by means of hydrodynamic transmitters. In transmitters of this kind, acoustic vibrations are generated by rotary-pulsation devices. In view of their great potentiality, it may be assumed that that use of gas–fluid rotary-pulsation apparatus (RPA) for performing absorption will allow a substantial intensification of this process.

The goal of this study was to analyze the efficiency of conventional gas–fluid apparatus (of ejector type and with turbine agitator) and RPA for performing nitrosation of diphenylamine (DPA) in an organic solvent (trichloroethylene, TCE, fluid phase) with a mixture of nitrose gases, NO and NO_2 (gas phase), with the aim to develop a multifunction apparatus for intensifying processes of absorption, homogenization, and dispersion.

In the first stage, the influence exerted by the main parameters (temperature, concentration, solubility of the gas phase, its amount and means of delivery) on the time of process completion was studied. For this purpose, a laboratory rig was designed and fabricated. The experiments were performed as follows. A pretreated 1.01 : 1 gas mixture of nitrogen oxides, NO + NO_2, was fed through a rotameter into the reactor, together with a 15% solution of DPA in TCE. The temperature of the reaction mixture was monitored with a thermocouple; its prescribed value was maintained with thermostat and supply lines for a cooling agent. The reactor of volume 0.65×10^{-3} m^3 was equipped with a mechanical agitator and a bubbling device. Samples were taken at 30-s intervals and analyzed for the content of DPA in solution by thin-layer chromatography and spectrometry on an SF-46 instrument.

Originally, the effect of the nitrosing agent flow rate on the time of complete DPA conversion was studied. Analysis of the results furnished by mathematical processing of experimental data shows that at a gas phase flow rate exceeding 0.3 $m^3 h^{-1}$ the time in which the process is complete remains practically unchanged. Therefore, in further experiments, the gas phase flow rate was taken to be, in a certain excess, 0.35 $m^3 h^{-1}$. Then the dependence of the time of complete DPA conversion on the process temperature was

studied in the range 10–30°C with a step of 5°C. It was found that the shortest time (1.5 min) is achieved at a temperature of 20 ± 2°C [4]. The dependences of the process duration on the intensity of stirring and method of gas phase feeding into the reactor (into the over-solution space or through a bubbler situated at the bottom) were studied. It was found that the time of complete DPA conversion decreases with increasing agitator speed. The minimum time corresponds to an agitator rotation rate of 157 s^{-1}. In this case, the method by which the gas phase is fed has virtually no effect on the time of process completion. Analysis of experimental data shows that under the found optimal conditions [temperature 20 ± 2°C, atmospheric pressure, nitrogen oxide mixture composition $NO : NO_2$ = (1.01–1.04) : 1, initial DPA concentration 15 wt %, stirring intensity $Re = 5 \times 10^3$] the DPA nitrosation is kinetically controlled. Vigorous stirring eliminates the effect of the mass exchange at the phase boundary on the rate of the chemical reaction.

After the basic process parameters were found, the most efficient of the three kinds of gas–fluid apparatus (with ejector, with self-suction turbine agitator, and of rotary-pulsation type) was determined. The DPA nitrosation was studied on a semicommercial installation comprising rotameters and control equipment serving to vary the flow rates of components within prescribed limits, reaction unit including one of the compared apparatus, and redox potentiometer for determining the completion time of the chemical reaction. The reaction mixture volume was constant (0.018 m^3) in all the experiments.

As a criterion for comparing the operation of the three apparatus served the efficiency

$$E = V/(N\tau), \quad (1)$$

where V is the reaction mixture volume (m^3), N is the power consumed for performing the process (W), and τ is the process duration (min).

The power consumed for performing the process consists of the following components:

$$N = N_1 + N_2 + N_3 + N_4 + N_5,$$

where N_1, N_2, N_3, N_4, and N_5 are, respectively, the powers consumed for stirring of the gas–fluid system, preparing the starting solution, cooling the oxidizing agent, pumping the cooling agent to lower the temperature of the reaction unit, and feeding the gas. The N_2–N_5 values are approximately the same in performing the same process in apparatus of different types. Therefore, they can be disregarded in comparing the efficiencies of the apparatus under study. The N_1 values were determined for each apparatus experimentally.

In each experiment the duration of DPA nitrosation is a function of the flow rates of fluid and gas phases without taking into account conditions common to all of the three apparatus studied. The ejector-type apparatus comprises an ejector and a bottom reactor. A chemical reaction occurs in the mixing chamber of the ejector during motion of the fluid and gas phases, with the fluid simultaneously saturated with dissolved gas. The reaction continues in the lower part of the reactor, but the amount of gas phase dissolved in the fluid phase is smaller, compared with that in the ejector. The residual kinetic energy of the jet goes to agitation of the reaction mixture, which leads to leveling of substance concentrations over the entire volume. For the studied flow rate ranges for the fluid (0.2–0.35 $m^3\ h^{-1}$) and gas phases (0.66–2 $m^3\ h^{-1}$), the minimum (10 $m\ s^{-1}$) and maximum (20 $m\ s^{-1}$) velocities of the fluid outflowing from the ejector nozzle of diameter 2.6×10^{-3} m were taken according to the known recommendations [5]. The obtained experimental data are presented in Table 1. Mathematical processing of these data for the batch mode yielded the dependence

$$\tau = 115.43 - 68.26Q_g - 32.22Q_gQ_l + 16.15Q_g^2. \quad (2)$$

In the continuous mode, the maximum output capacity V_l of the ejector-type apparatus was studied experimentally at different velocities W of working medium outflow from the nozzle and different gas flow rates (Table 2). Analysis of the experimental results shows that shorter time τ is achieved in the batch mode at ejector flow velocity of 20 m s^{-1} and gas phase flow rate of 2 m^3 h^{-1}. In the continuous mode, the maximum output capacity of the installation is achieved at the same flow rates.

The total hydraulic loss of pressure, ΔP, in the circulation circuit consists of losses in suction and pumping lines and in the ejector itself. The working-medium pressure at the nozzle outlet P_w = 0.1 MPa, whereas the total loss of pressure in the circulation circuit will be given, with account of the working-medium pressure, by

$$\Delta P = \Delta P_{suc} + \Delta P_{pump} + \Delta P_{ej} + P_w. \quad (3)$$

Figure 1 shows the dependence of ΔP on the fluid phase flow rate Q_l, described by the equation

$$\Delta P = 8.02Q_l^2 - 1.256Q_l + 1.97. \quad (4)$$

With account of (4), the power consumed for pumping the working medium through the circulation circuit is given by

$$N = \frac{724.35Q_l^2 - 267.22Q_l + 35.81}{\eta}, \quad (5)$$

where η = 0.55 is the pump efficiency.

With account of expressions (1), (2), and (5) and V = 0.018 m^3, the formula for determining the efficiency of ejector-type apparatus will have the form

$$E = [(73.17Q_l^2 - 26.99Q_l + 3.6)(115.43 - 68.26Q_g - 32.22Q_gQ_l + 16.15Q_g^2)]^{-1}. \quad (6)$$

Analysis of (6) shows that the highest efficiency is achieved for apparatus of this type at a fluid phase nozzle velocity of 10.43 m s^{-1} and gas phase flow rate of 2 m^3 h^{-1} (Table 2).

In studying the operation of a self-suction turbine agitator (STA), the gas phase was delivered, under the action of the pumping effect created by the mixer, into the central, hollow part of the rotating shaft and dispersed directly into the fluid phase. The flow rate of the nitrose gases was varied between 1 and 2 m^3 h^{-1}. The rotation speed of the mixer was 110 s^{-1}, volume

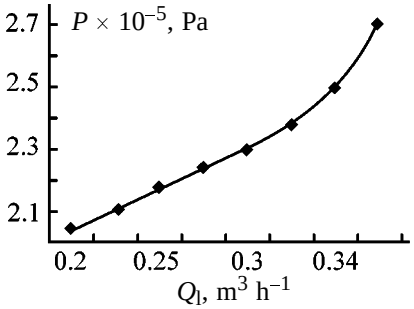

Fig. 1. Total loss of the pressure P of the working medium in the circuit vs. the fluid phase flow rate Q_l.

of the reaction mixture 0.018 m^3, and volume of apparatus with STA 0.01 m^3. In the batch mode, the time of process completion in the entire volume of the reaction mixture was determined. The obtained experimental data are presented in Table 3.

The equation describing the time τ (min) of complete conversion in relation to the flow rate of the gas phase in an apparatus with STA has the form

$$\tau = 9.9Q_g^2 - 43.02Q_g + 66.3. \quad (7)$$

The self-suction turbine-type agitator used in the experiments had the following characteristics: diameter 0.1 m, number of blades 6, blade width 0.01 m. In calculating the power consumed by the STA for agitation of the gas–fluid system, two circumstances were taken into account: (1) the dynamic viscosity coefficient of the main component was chosen as

Table 4. Experimental values of power N_e

Flow rate, $m^3\ h^{-1}$		N_e, W
gas phase in RPA	fresh solution	
1	0.03318	37.70
1.25	0.04147	36.62
1.5	0.04976	35.77
1.75	0.05916	35.16
2	0.06510	34.80

the key factor for a reaction mixture with gas saturation $\varphi < 0.3$, and (2) the reaction mixture density ρ_m ($kg\ m^{-1}$) in the apparatus was calculated at gas flow rates in the range from 1 to 2 $m^3\ h^{-1}$ by the equation

$$\rho_m = 38.86Q_g^2 - 181.37Q_g + 1327.8. \quad (8)$$

Under these conditions, the values of the centrifugal criterion Re_c are within $(2.18–24) \times 10^5$. For the turbine agitator of the given type [1], the power criterion K_N remains constant (0.76) in the above range of Re_c values. Then, use of the known formula [1] and expression (8) gives a theoretical relation for determining the power consumption N_t (W) for agitation with STA:

$$N_t = 0.041\rho_m = 1.59Q_g^2 - 7.43Q_g + 54.4. \quad (9)$$

However, analysis of the experimental dependence

$$N_e = 1.68Q_g^2 - 8.9Q_g + 56.1 \quad (10)$$

shows that, with increasing flow rate of the gas component, the experimental power values are somewhat lower than the theoretical values, which is presumably due to lower density of the reaction mixture near the agitator.

With account of (7) and (10), the dependence of the efficiency of a gas–fluid apparatus with STA on the flow rate of the gas component can be represented as

$$E = 1\times10^{-3}(0.92Q_g^4 - 8.9Q_g^3 + 58.3Q_g^2 - 166.78Q_g + 206.56)^{-1}. \quad (11)$$

Analysis of (11) shows that the efficiency of an apparatus with STA grows with increasing flow rate of the gas phase because of the decreasing power consumed for agitation and shorter process duration. An RPA of original design has been developed to intensify gas–fluid processes [5].

The rotary-pulsation apparatus operates as follows. The fluid phase is fed into the working cavity via the inlet pipe. Under the action of inertia forces created by a rotating rotor it passes through rectangular slits in the rotor and stator rings. With the shaft rotating, the slits are periodically closed. In this zone of strong turbulence, there exist pulsation forces and high velocity gradients. The gas phase delivered via two pipes goes through channels inside the stator teeth and arrives in the space formed by slits in the rotor ring. During rotor rotation, the outlet channels are periodically closed at the same frequency, which favors fine dispersion of the gas phase.

Thus, to achieve complete interaction of the gas and fluid phases, a unit volume of fluid is subjected to multiple treatment in the active zone of the RPA. The clearance between the rotor and stator teeth was 1×10^{-4} m, and the speed of rotation, 314 s^{-1}. The main goal of the performed sets of experiments was to determine the time τ of completion of diphenylamine nitrosation in RPA at gas phase flow rates in the range from 1 to 2 $m^3\ h^{-1}$ and reaction mixture volume of 0.001 m^3. The obtained experimental data are presented in Table 3.

The equation obtained by processing the data in Table 3 has the form

$$\tau = 12.37Q_g^2 - 53.02Q_g + 73.16. \quad (12)$$

The power N_e consumed for agitation of the gas–fluid mixture in RPA was measured experimentally at varied flow rates of the gas and fluid phases; the averaged results are given in Table 4.

The obtained experimental data are described by the regression equation

$$N_e = 1.95Q_g^2 - 8.76Q_g + 44.5. \quad (13)$$

Analysis of Eq. (13) clearly shows that the consumed power decreases somewhat with increasing flow rate of the gas phase, which is presumably due to a decrease in the density of the gas–fluid mixture in the active zone of the apparatus.

The operation efficiency of an installation with STA can be calculated using Eqs. (12) and (13). Then the dependence of the RPA efficiency on the gas phase flow rate has the form

$$E = 1\times10^{-3}(1.34Q_g^4 - 11.75Q_g^3 + 64.34Q_g^2 - 166.75Q_g + 181.1)^{-1}. \quad (14)$$

To compare the efficiencies of the apparatus under

study, the following parameter values are taken: for apparatus with ejector, Q_g = 2 $m^3 h^{-1}$, flow velocity of the fluid phase 10.46–18.3 m s^{-1}; for apparatus with STA and for RPA, Q_g = 1–2 $m^3 h^{-1}$, output capacity 0.032–0.065 $m^3 h^{-1}$.

Graphical interpretation of the obtained relations describing the dependence of the efficiency of the apparatus on their output capacity is done in Fig. 2.

Analysis of the experimental data in Fig. 2 shows that the apparatus with STA has much lower efficiency than its competitors, becoming comparable with an ejector-type apparatus only at an output capacity of 0.05 $m^3 h^{-1}$. In contrast to the apparatus under consideration, the ejector-type apparatus shows high efficiency only at low output capacities, and its efficiency steeply decreases when this parameter grows. Already at an output capacity of 0.0425 $m^3 h^{-1}$ it becomes comparable in efficiency with RPA. An undisputed leader in efficiency, beginning with output capacity of 0.045 $m^3 h^{-1}$, is RPA, and it is this apparatus that should be used to perform the process under consideration.

The results obtained in studying the operation of a semicommercial RPA in performing gas–fluid processes were used to produce an intermediate, *N*-nitrosodiphenylamine, in manufacture of an antioxidant for rubber articles Diafen FP[1] and commercial *p*-nitrosophenol.[2]

CONCLUSIONS

(1) The dependences of the time in which diphenylamine nitrosation is complete on the flow rates of the gas and fluid phases were obtained for apparatus with a self-suction turbine agitator and those of rotary-pulsation and ejector types. Mathematical models of the occurring processes were developed for these cases. The power expenditure for agitation of the gas–fluid system under study was found for these apparatus.

(2) The efficiencies as functions of the output capacity were compared for apparatus with ejector or self-suction turbine and apparatus of rotary-pulsation type in performing a gas–fluid process. It was found that the ejector-type apparatus is the most efficient at low output capacities (up to 0.042 $m^3 h^{-1}$), and the rotary-pulsation apparatus, at higher values of this parameter (more than 0.045 $m^3 h^{-1}$).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Base Hydrolysis and Use of Cationic Ammonium Dyes in Which the Chromophore System Is not Conjugated with the Nitrogen Atom

A. P. Mikhailovskaya, T. Yu. Dyankova, and N. P. Novoselov

St. Petersburg State University of Technology and Design, St. Petersburg, Russia

Received July 26, 2000; in final form, October 2000

Abstract—The capability of cationic dyes in which the onium group is not conjugated with the chromophore system to form aqueous dispersions in a weakly alkaline medium was examined. Such dyes can be fixed on a fiber in increased amounts owing to their binding not only in the cationic form but also in the hydrolyzed monomolecular form.

Dispersible dyes are widely used for dyeing of manmade fibers, including heat-resistant fibers based on polyheteroarylenes (PHAs). These dyes are practically insoluble in water but can be used in the form of aqueous dispersions. The degree of dispersity of the dye in the aqueous phase strongly affects the coloristic properties and color fastness.

One of the ways to prepare the molecularly dispersed form of a dye is to use cationic dyes in which the onium group is not conjugated with the chromophore system. Owing to the presence of such a cationic center, these dyes are water-soluble. In a weakly alkaline solution, the onium groups are eliminated to give particles of size close to that of separate molecules [1, 2]. Of interest in this connection are ammonium compounds derived from tertiary amines (including heterocyclic amines) with hydrogen, alkyl, or arylalkyl substituents. Quaternization of tertiary amines with alkyl halides occurs in organic solvents. The resistance of quaternary ammonium salts to hydrolysis depends on the nature of substituents at nitrogen. Published data on cationic dyes of such structure are consistent with the well-known stabilizing effect of alkyl substituent on onium compounds. Alkyl substituents exert a *+I* effect and weaken the polar character of NH and NC bonds [1]. Cationic dyes in which the ammonium group is not conjugated with the chromophore are hydrolyzed in alkaline solutions with release of the tertiary amines. The presence of electron-withdrawing substituents at nitrogen (as, e.g., in aniline and diphenylamine derivatives) facilitates cleavage of the onium compounds. The hydrolysis pathways of quaternary ammonium bases are as follows [1]:

$$OH^- + R{-}CH_2{-}CH_2{-}N^+(CH_3)_3 \xrightarrow{+H_2O} \begin{cases} R{-}CH_2{-}CH_2{-}OH + :N(CH_3)_3 \\ R{-}CH{=}CH_2 + H_2O + :N(CH_3)_3 \\ R{-}OH + CH_3{-}CH_2{-}OH + :N(CH_3)_3. \end{cases}$$

EXPERIMENTAL

Below are the structural formulas of the selected cationic (**I**) and dispersible (**II**–**IV**) dyes:

Spectrophotometric studies showed that the state of cationic dyes depends on pH of the aqueous solution. This is illustrated in Fig. 1. As pH is increased from 3 to 11, the absorption intensity decreases, and at pH > 12 a dispersion of the base released from the cationic dye is formed (Fig. 2). Figure 3 shows the spectra of the cationic dye and its hydrolyzed form. Hydrolysis of the dye was performed in 1 N NaOH at 98°C for 30 min. Comparison of the spectra of dispersible dyes **II**–**IV** and of the hydrolyzed form of cationic dye **I** shows that the changes in the spectra are due to base hydrolysis of the cationic dye and release of a new dye in the form of a dispersion.

The kinetics of cleavage of the initial cationic dye was monitored by measuring the amount of the molecularly dispersed form from the hypsochromic shift of the short-wave absorption band with $\lambda_{D\max} = 610$ nm, which corresponds to a 100% content of the cationic dye. The short-wave absorption band at $\lambda_{D\max} = 565$ nm was considered to correspond to a 100% content of the hydrolyzed form. This is confirmed by analysis of fiber samples dyed with the cationic dye under conditions of hydrolysis and with a dispersible dye as a component of a composite dye bath in the presence of appropriate tertiary amine. Hydrolysis of the cationic dye was performed in aqueous solution at pH 10.5 for 100 min at 90 and 98°C. The content of the hydrolyzed dye was evaluated from the shift of the absorption bands in the range 500–600 nm, monitored with a 2-nm step. The results are shown in Fig. 4. The kinetic curves of hydrolysis of the cationic dye exhibit two sections. In the section corresponding to the content of the hydrolyzed form of up to 7–9%, the hydrolysis proceeds actively with increasing rate. The amount of the dye hydrolyzed in the first 20 min is 6.88% at 90°C and about 10% at 98°C. As the molecularly dispersed form of the dye accumulates, the degree of aggregation increases; it is determined by the solubility of the chromophore at these values of pH and temperature.

Comparison of the electronic absorption spectra of alcoholic solutions of dispersible dyes **II**–**IV** and hydrolyzed form of cationic dye **I** shows that the product of base hydrolysis of the onium dye containing the chromophore structure is structurally similar to dye **II**.

Thus, cationic dyes containing onium fragments can be cleaved with release of the insoluble chromophore structure in the monomolecular state, which facilitates its diffusion into the substrate. This property of cationic dyes in which the onium group is not conjugated with the chromophore allows dyeing to be

combined with treatment of aramide fibers with alkaline agents to remove or neutralize structurally bound acidic impurities. Furthermore, the hydrolysis conditions can be adjusted so as to make the rate of sorption of the hydrolyzed form equal to the rate of cleavage of the initial dye (Fig. 5). As follows from the Langmuir and Henry's data, dyeing under such conditions allows simultaneous fixation of the soluble and insoluble forms of the cationic dye, which increases the extent of dyeing of PGA fibers with a dense chemically inert microstructure and difficultly accessible nanostructure.

The process suggested in [2] successfully passed industrial trials at the Gor'kii Silk-Twisting Factory (Moscow) and Sport Private Company.

Dyeing of PGA fibers with cationic dyes in which the ammonium group is not conjugated with the chromophore moiety gives intense uniform colorings highly resistant to wet treatments [3].

CONCLUSIONS

(1) The cationic onium dye is hydrolyzed in an alkaline solution with release of the chromophore structurally similar to the dispersible dye.

(2) Quaternary ammonium bases in which the positively charged nitrogen atom is not conjugated with the chromophore moiety can be efficiently used for dyeing of highly oriented polyheteroarylene fibers.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

New Route to Vicasol, a Water-Soluble Form of Vitamin K_3

K. I. Matveev, V. F. Odyakov, and E. G. Zhizhina

Boreskov Institute of Catalysis, Siberian Division, Russian Academy of Sciences, Novosibirsk, Russia

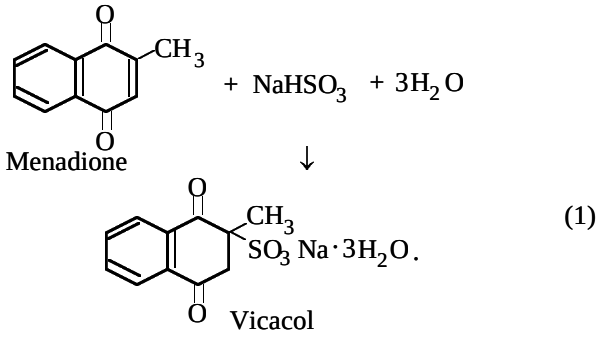
Received June 23, 2000

Abstract—A procedure was suggested for preparing vicasol in an approximately 85% yield in a two-phase system consisting of concentrated (~5–6 M) aqueous solution of $NaHSO_3$ and a solution of 2-methyl-1,4-naphthoquinone in an incombustible organic solvent (e.g., chloroform or trichloroethylene).

Vicasol (sodium 2-methyl-1,2,3,4-tetrahydronaphthalene-1,4-dione-2-sulfonate) is a water-soluble form of vitamin K_3 [1, 2]. More than 90% of the produced vicasol is used in cattle-breeding [3], and only up to 10%, in medicine. The use of vicasol in cattle-breeding increases the productivity by 17–23% depending on the species and age of animals [4]. Vicasol is added to forage in amount of 2–4 g per ton of forage [5] in the form of vitamin additives (premixes) together with vitamins A, E, and D and with microelements. The demand of Russia for vicasol today is about 45–50 tons annually and tends to grow.

Vitamins of group K are noy produced in Russia and CIS countries. In some other countries, vicasol is produced from 2-methylnaphthalene by outdated processes [1] which cannot be used in Russia because of environmental problems and the lack of the required raw materials.

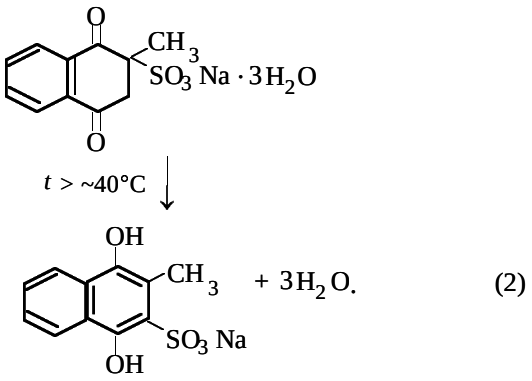
We have developed the principles of the new Vikasib process for production of vicasol and other vitamins of group K [6] starting from α-naphthol which is, in turn, a petrochemical product.[1] In this process, the final stage is reaction of 2-methyl-1,4-naphthoquinone (menadione) dissolved in an organic solvent with an aqueous solution of sodium hydrosulfite [7, 8]:



(1)

[1] Institute of Catalysis, Siberian Division, Russian Academy of Sciences.

The equilibrium constant of reaction (1) is high (~1×10^6 l mol^{-1} [9]); therefore, the 100% yield of vicasol is readily attainable. However, isolation of vicasol from the reaction mixture involves problems. Vicasol is readily soluble in water [2], and therefore it cannot be quantitatively recovered from aqueous solution. Furthermore, vicasol is thermally unstable and in the course of boiling readily isomerizes into sodium 3-methyl-1,4-dihydroxynaphthalene-2-sulfonate [10, 11] showing no vitamin properties:



(2)

Such isomerization slowly proceeds even in the course of prolonged storage of vicasol at elevated temperatures [12]. Therefore, aqueous solutions of vicasol should not be concentrated by evaporation, and crystallization of vicasol should occur without heating.

Previously [13], crystallization of vicasol was performed in the presence of a large excess of $NaHSO_3$ which acted as a salting-out agent. However, the resulting vicasol contained up to 33% $NaHSO_3$ [14]. At the same time, the presence of only up to 2% $NaHSO_3$ in vicasol is prescribed by the State Pharmacopeia [15], and this amount is necessary and sufficient for enhancing the resistance of vicasol to light at subsequent storage [16].

1070-4272/01/7403-0469$25.00

Up to the 1970s, vicasol was prepared by mixing solid menadione with an aqueous solution of $NaHSO_3$ containing Na_2SO_3 impurities [17]. The resulting vicasol was contaminated with unchanged menadione and its decomposition products. In [14] it was suggested to dissolve menadione in CCl_4 with subsequent addition of water and excess $Na_2S_2O_5$ and vigorous stirring of the resulting two-phase system. We suggested [8] to perform reaction (1) in the two-phase system $CHCl_3$–H_2O, with the aqueous phase containing 4–6 M $NaHSO_3$ prepared from pure Na_2SO_3 and SO_2. In this case the amount of water taken for synthesis is reduced, and pure vicasol can be obtained even from crude menadione prepared in the preceding stage of the Vikasib process [6].

EXPERIMENTAL

Menadione was prepared by catalytic methylation of 1-naphthol [18] followed by oxidation of the resulting 2-methyl-1-naphthol with solutions of phosphomolybdovanadic heteropoly acids [19, 20]. Along with the main substance (88–90%), the product contained an impurity of dimeric quinones C_{22} and polymers $C_{x.11}$. Recrystallization from methanol gave 98–99% pure menadione.

Aqueous 4.0–6.5 M solutions of $NaHSO_3$ were prepared from analytically pure grade anhydrous Na_2SO_3 and pure gaseous SO_2 from a cylinder. These solutions were stored in the dark for no more than a week, because of occurrence of slow oxidation $HSO_3^- \rightarrow SO_4^{2-}$ [21].

Vicasol was prepared in a 1.1-l three-necked flat-bottomed shaked cylindrical vessel with one wide neck. The vessel was placed in a shaker operating at a rate of 400 shakings per minute. As solvents for menadione we used pure grade chloroform and trichloroethylene. For washing of vicasol and its additional precipitation from aqueous solution we used chemically pure grade isopropanol.

The sum of HSO_3^- + SO_2 in $NaHSO_3$ solution was determined by iodometric titration [22], and the content of Na^+ was calculated from the weight of the initial Na_2SO_3.

The menadione content in solutions was determined by GLC using a 40-m capillary column coated with SE-30; the internal reference was duroquinone. Analysis was performed with a Tsvet-500 chromatograph; the results were processed with a Multichrom automated system [23].

The main substance content in crystalline vicasol was determined by iodometric titration after hydrolysis of vicasol to menadione in the presence of $LiIO_4$ and lithium borate buffer solution [24]. The content of excess $NaHSO_3$ in vicasol was determined by iodometric titration, and the content of Na_2SO_4 impurity, colorimetrically with poorly soluble barium chloranilate $Ba(C_6Cl_2O_4)_2 \cdot xH_2O$ whose colored $C_6Cl_2O_4H^-$ anion passed into solution in the presence of SO_4^{2-} anions [25].

Concentrated solutions of $NaHSO_3$ were prepared from the calculated amount of anhydrous Na_2SO_3 by bubbling of SO_2 through an aqueous suspension of $Na_2SO_3 \cdot 7H_2O$. A 1-l volumetric cylinder containing 700 ml of water and a 361.5-g portion of anhydrous (98%) Na_2SO_3 (2.81 mol) were weighed. The first (~120–150 g) portion of Na_2SO_3 was suspended and partially dissolved with vigorous stirring, so as to avoid formation of $Na_2SO_3 \cdot 7H_2O$ clots. Through the resulting solution of Na_2SO_3 containing suspended $Na_2SO_3 \cdot 7H_2O$, SO_2 was bubbled at a rate of 50–200 ml min^{-1} through a glass tube with a capillary tip. The bubbling rate was adjusted so as to ensure complete dissolution of the rising SO_2 bubbles. In the process, the solution warmed up, and its volume increased by approximately 15%.

After the first portion of Na_2SO_3 mostly dissolved, the remaining Na_2SO_3 (~210–240 g) was gradually added, with the bubbling of SO_2 being continued. The cylinder with the Na_2SO_3 + SO_2 solution was intermittently cooled and weighed. After the solution took up 180–182 g of SO_2 (2.81–2.84 mol), the feeding of SO_2 was stopped, and the solution volume was brought to 1 l.

The resulting 5.62 M solution of $NaHSO_3$ had pH ~4–5. Its composition was as follows (M): $[Na^+]$ = 5.62, $[S^{IV}] = [HSO_3^-] + 2[S_2O_5^{2-}] + [SO_2\ (\text{impurity})]$ = 5.62–5.65.

Vicasol was prepared at a molar ratio $[NaHSO_3]$: [menadione] from 1.5 to 1.7, starting from both purified and crude menadione. For example, 75.4 g of crude (88%) menadione was dissolved in chloroform to obtain 200 ml of a brown solution containing 66.4 g (0.347 mol) of menadione. The solution was filtered and transferred into the reactor, and 105 ml of a 5.62 M aqueous solution of $NaHSO_3$ (0.58 mol) was added. The solution was purged with nitrogen or CO_2, and the vessel was sealed and vigorously shaken. In the course of shaking, a thick suspension of fine vicasol crystals formed, and the mixture warmed up from 20 to 40°C. Intermittently the shaking was stopped, a sample was taken for analysis, and the reactor was

turned to change the shaking direction and eliminate dead zones. The total time of reaction (1) was ~2 h.

The resulting suspension having a brown color due to tar impurities was transferred onto a Nutsch filter, and the liquid phases were thoroughly separated. The filtrate consisting of aqueous and organic phases was separated for subsequent recovery of the second portion of vicasol from the aqueous phase. The crystals on the filter were washed first with 40 ml of $CHCl_3$ and then with 4–6 20-ml portions of anhydrous isopropanol until the filtrate became colorless.[2] The resulting yellowish white finely crystalline mass was placed on an enameled tray and air-dried to constant weight (101 g). The product composition was as follows (%): main substance (vicasol) 96.3, $NaHSO_3$ + $Na_2S_2O_5$ 0.8, Na_2SO_4 2.7, which meets the requirements of the State Pharmacopeia [15]. The yield of vicasol recalculated on dry substance was 97.3 g (0.295 mol, 85%).[3]

From the filtered aqueous phase, after combining with the filtrates containing isopropanol, we isolated an additional 15 g of vicasol. The main substance content in this fraction was 65–85%, the remainder being $NaHSO_3$ ($Na_2S_2O_5$) (15–25%) and Na_2SO_4.

With pure (recrystallized) menadione, the synthesis is performed similarly. In this case, however, there is no need to wash the obtained vicasol crystals with chloroform.

To prepare $NaHSO_3$ solution, it is preferable to use analytically pure grade Na_2SO_3[4] rather than technical-grade $Na_2S_2O_5$ containing much more impurities.

In synthesis of vicasol by reaction (1), solvents other than $CHCl_3$ (preferably incombustible, e.g., trichloroethylene [8]) can be also used. In any case the reaction takes about 2 h.

The long time of reaction (1) is due to two factors. First, concentrated aqueous solutions of $NaHSO_3$ are a complex system containing three anions. The dimeric anion $S_2O_5^{2-}$ (hydrosulfite) prevailing in solution occurs in equilibrium with the monomeric anions $HOSO_2^-$ (protonated sulfite with the O–H bond) and HSO_3^- (sulfonate with the S–H bond) [26, 27]:

$$2HOSO_2^- \xrightleftharpoons{K_{iSO}} 2HSO_3^- \xrightleftharpoons[-H_2O]{K_{dim}} S_2O_5^{2-}. \qquad (3)$$

The active nucleophile attacking the molecule of menadione (or another quinone) is apparently sulfonate HSO_3^-.[5] The equilibrium between it and the $HOSO_2^-$ anion is shifted toward HSO_3^- (K_{iSO} ~4.9 [28]). However, at a high total concentration of $NaHSO_3$ the equilibrium between the monomers and the dimer $S_2O_5^{2-}$ is shifted toward the dimer.[6] Therefore, the low rate of vicasol formation may be due to the low concentration of HSO_3^- in concentrated aqueous solutions which are actually solutions of $Na_2S_2O_5$ and contain $HOSO_2^-$ and HSO_3^- only in low equilibrium concentrations.

The second and apparently the major cause of the low rate of reaction (1) is the high viscosity of the three-phase system consisting of the aqueous $Na_2S_2O_5$ solution, solution of menadione in $CHCl_3$, and suspension of the forming vicasol. Reaction (1) occurs on the boundary of the aqueous and organic phases and is controlled by diffusion of menadione from the bulk of the organic phase to the phase boundary. When the third phase (suspended vicasol) appears, the concentration of menadione in the organic phase decreases, the viscosity grows, and hence the diffusion of menadione and the reaction as a whole decelerate.

Although the rate of reaction (1) is low, the use of ~5–6 M solutions of $NaHSO_3$ (~2.5–3 M solutions of $Na_2S_2O_5$) containing the minimal amount of water ensures the most complete crystallization of vicasol and its isolation in up to 85% yield. In less concentrated (~2–3 M) solutions of $NaHSO_3$ [7] reaction (1) is faster but it is possible to isolate no more than 60% of the forming vicasol.

CONCLUSIONS

(1) The use of a two-phase system consisting of a concentrated (~5–6 M) aqueous solution of $NaHSO_3$ and a solution of menadione in chloroform or trichlo-

[2] After washing the filtrate containing $CHCl_3$ was combined with the organic phase, and the filtrates containing *i*-C_3H_7OH, with the aqueous phase.

[3] If required, vicasol was sieved through a 0.2-mm sieve. It was stored at room temperature in a dark glass vessel.

[4] Analytically pure grade Na_2SO_3 can contain an Na_2SO_4 impurity. Therefore, to prepare very pure solutions of $NaHSO_3$, it is appropriate to start from $NaHCO_3$ or Na_2CO_3.

[5] Sulfonate ions HSO_3^- attack by hidride atom the 3-position of menadione having the lowest electron density; this results in formation of vicasol and not of the isomeric 3-methyl-1,4-dihydroxynaphthalene-2-sulfonate.

[6] Published data on the dimerization equilibrium constant K_{dim} are contradictory; in any case, it increases with increasing ionic strength of the $NaHSO_3$ solution. In ~4.9 M $NaHSO_3$ solution it is about 0.34 l mol^{-1} [29]; therefore, in the 5.62 M solution the fraction of the reactive species HSO_3^-, apparently, does not exceed 5–10%.

roethylene allows preparation of the purest vicasol in a yield of about 85% owing to its more complete crystallization from aqueous solutions containing smaller amount of water.

(2) By addition of anhydrous isopropanol to the aqueous phase of the mother liquor, it is possible to isolate an additional amount of 65–85% vicasol.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Properties of Crystalline Polyvinylenes Prepared by Phase-Transfer Dehydrochlorination of Vinyl Chloride Copolymers

Received January 10, 2000; in final form, June 2000

Abstract—Crystalline polyvinylenes were prepared by phase-transfer dehydrochlorination of binary copolymer of vinyl chloride with vinyl acetate (9 : 1 molar ratio) and ternary copolymer with vinyl acetate and vinyl alcohol (27 : 1 : 2 molar ratio), and the chemical and electrical properties of these substances and of products of their thermolysis were studied.

Polymers with a system of conjugated bonds in the main chain, including polyvinylenes, are of particular interest due to their semiconductor, paramagnetic, and other properties, which are not typical of common macromolecular compounds. The variety of specific properties is due to the features of their electronic structure and conformation of conjugated molecules. These properties depend on the polymer structure; and the presence of the crystalline phase in the polymer increases the electrical conductivity and decreases the concentration of paramagnetic centers as compared with the amorphous sample [1]. The crystalline structure provides high anisotropy of the polymer properties, necessary for application in microelectronics.

The properties of crystalline polyvinylenes formed by acetylene polymerization using Ziegler–Natta catalysts are described in detail (e.g., [2, 3]). A method for preparing highly crystalline polyvinylene by dehydrochlorination of polyvinyl chloride under the conditions of phase-transfer catalysis was developed in [4]. The resulting polyvinylene exhibits unique chemical and physical properties. It is highly stable with respect to oxidants and is easily dehydrogenated at high temperatures [4]. The products of its thermolysis exhibit high strain sensitivity [5] and paramagnetic properties [6].

Crystalline polyvinylenes were also prepared by phase-transfer dehydrochlorination of a binary copolymer of vinyl chloride with vinyl acetate and a ternary copolymer with vinyl acetate and vinyl alcohol [7]. Some properties of these polyvinylenes were studied in this work.

EXPERIMENTAL

In our work we studied crystalline polyvinylenes prepared by phase-transfer dehydrochlorination of commercial samples of a binary copolymer of vinyl chloride with vinyl acetate (9 : 1 molar ratio) and a ternary copolymer of vinyl chloride with vinyl acetate and vinyl alcohol (27 : 1 : 2 molar ratio) in aqueous solutions of potassium hydroxide in the presence of phase-transfer catalysts [7].

The properties of crystalline polyvinylenes were compared with those of amorphous samples prepared from the same vinyl chloride copolymers [7] and of crystalline polyvinylenes prepared from polyvinyl chloride (PVC) [4]. The products of conversion of vinyl chloride homo- and copolymers are coarse black or dark brown powders (0.8–1.0 mm particle size).

The polymer structure was studied using polarization-optical microscopy. The polyvinylene crystals prepared from copolymers are significantly smaller than those prepared from polyvinyl chloride and larger than the crystals obtained by acetylene polymerization: the crystal size is 1–2 [7], 1×10^3 [4], and $(2–5) \times 10^{-3}$ μm [8], respectively.

The thermal treatment of the samples at 100–1200°C was carried out in a quartz tube in a vacuum ($\approx 10^{-3}$ mm Hg); at higher temperatures a ceramic tube was used. The sample was heated with a heating rate of 1.5 deg min^{-1} and kept at chosen temperature for 2 h. All manipulations were performed under argon.

The specific electrical resistivity was measured by the four-probe procedure in cells equipped with stain-

less-steel electrodes using an E 7–8 ac potentiometer (1 kHz). The design of the measuring cells allowed preparation of 50–300-μm thick polymer pellets. The samples were oxidized with air dried over P_2O_5. The stability with respect to thermal oxidative degradation was studied using an MOM derivatograph (0.08 deg s^{-1} heating rate, 0.1×10^{-3} kg sample weight).

The nucleophilic properties of polyconjugated systems determine their interaction with electrophilic reagents, e.g., molecular oxygen. Polyvinylenes are the polymers with a system of conjugated double bonds prepared by phase-transfer dehydrochlorination of vinyl chloride copolymers; they are easily oxidized with oxygen, with the color changing from black to red and light yellow. The reactivity of polyvinylenes is also determined by packing of the polymer molecules. On passing from crystalline to amorphous samples the X-ray diffraction (XRD) patterns of these polymers demonstrate shifting of the diffraction peaks toward larger scattering angles. Due to higher ordering of crystalline polyvinylenes as compared with amorphous polymers, the rate and the extent of their oxidation are lower. As seen from Fig. 1 (curves *1, 2* and *3, 4*), the kinetic curves of oxygen uptake, illustrating the polymer oxidation, by the crystalline samples lie below those corresponding to the amorphous samples.

Polyvinylenes prepared from copolymers of vinyl chloride with vinyl acetate and vinyl alcohol are the products with the polyene structure of the *trans* polyacetylene type. The IR spectra of these compounds, similar to those prepared from PVC, contain no stretching (3044–3057 cm^{-1}) and in-plane (1249, 1329 cm^{-1}) and out-of-plane (740 cm^{-1}) bending vibrations of the =C–H group of the *cis* configuration. The IR spectra exhibit the bands at 1292, 3010–3015 cm^{-1} belonging to the in-plane bending and stretching vibrations of the =C–H group of the *trans* configuration. The IR spectrum of the product of PVC conversion exhibits a strong peak at 1000–1015 cm^{-1} belonging to the out-of-plane bending vibrations of =C–H in the *trans* configuration of the $–(CH=CH)_n$ units ($n \gg 2$). In the spectra of the conversion products of the vinyl chloride copolymer this band is split in two bands at 1008 and 996 cm^{-1}. Moreover, new peaks appear at 980 and 940 cm^{-1}, which are due to the vibrations of shorter polyvinylene series ($n = 2$ and $n = 1$) [9]. The presence of smaller conjugation blocks in the macromolecules of polyvinylenes prepared from vinyl chloride copolymers, in contrast to those prepared from PVC, decreases their reactivity toward oxygen, because the nucleophilicity of polyconjugation systems decreases with decreasing conjugation length [10]. However, as seen from Fig. 1, these polyvinylenes react with oxygen more actively than the product of PVC dehydrochlorination: their kinetic curves of oxygen uptake (curves *1, 2*) lie higher as compared with curve *5*.

As for molecules forming a crystal, their reactivity, determined by the electronic structure, is less decisive for the reaction than the mode of crystal packing [11]. The diffraction peak in the XRD pattern of crystalline polyvinylene prepared from vinyl chloride copolymer is shifted toward larger angles ($2\theta = 21°$) as compared with the sample prepared from vinyl chloride homopolymer ($2\theta = 20°$), which suggests lower ordering of the polymer structure. The oxidation of crystalline samples is probably controlled by diffusion of the oxidant gas into the polymer bulk, which is more hindered in the perfect crystal lattices of polyvinylenes prepared from PVC as compared with those prepared from vinyl chloride copolymer with less ordered structure. Moreover, the polyvinylene crystals prepared from vinyl chloride copolymers are smaller than those prepared from PVC (1–2 and 1×10^3 μm, respectively).

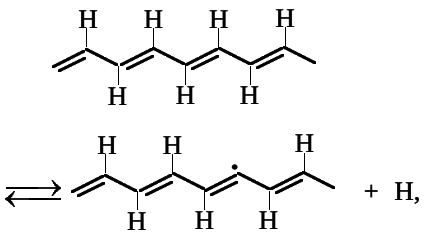
Oxidation of polyvinylenes with similar supramolecular structure prepared from binary and ternary vinyl chloride copolymers proceeds with similar rate (Fig. 1, curves *1, 2* and *3, 4*). Since the history of these polyvinylenes does not affect their heat resistance and electrophysical properties, in our further work we studied only the products of conversion of the binary copolymer of vinyl chloride with vinyl acetate.

The thermal oxidative degradation of polyvinylene

prepared from vinyl chloride copolymer with significant weight loss starts at 200–220°C and yields volatile (predominantly benzene) and viscous products of aromatic nature. At higher temperature almost no benzene is observed in the pyrolysis products. The supramolecular polymer structure affects the degradation processes. In the crystalline polyvinylene the degradation of the polymer macromolecules proceeds with a lower rate than in the amorphous samples (Fig. 2, curves *1*, *2*). As compared with the product of PVC dehydrochlorination, the less ordered polyvinylene prepared from vinyl chloride copolymer promotes degradation processes: curve *1* lies above curve *3* (Fig. 2).

The rigid crystalline structure hinders cleavage of the polyvinylene fragments of the macromolecule, but promotes carbonization during its thermal treatment. Dehydrogenation of the crystalline polymer prepared from vinyl chloride copolymer starts at 350–400°C, proceeds with a greater rate as compared with amorphous polymer (Fig. 3, curves *1*, *2*), and yields completely carbonized samples at 1400–1500°C, whereas the carbonization of the amorphous polyvinylenes starts at 450–500°C and is completed at temperatures higher than 2000°C. The less ordered structure of crystalline polyvinylene prepared from vinyl chloride copolymer shifts the processes of hydrogen elimination toward higher temperatures as compared with the polymer prepared from PVC (Fig. 3, curves *1*, *3*). In the latter case elimination of hydrogen starts at 250–300°C and terminates at 1100–1200°C.

Dehydrogenation of polyvinylenes follows the common dependences of hydrocarbon dehydrogenation. At a given temperature the following dehydrogenation–hydrogenation equilibrium is attained:



which is confirmed by the fact that the kinetic curve of hydrogen loss is a curve with saturation. The above equilibrium shifts toward dehydrogenation with increasing temperature. At thermal treatment at 300°C of polyvinylenes prepared from vinyl chloride homo- and copolymers, virtually constant C/H ratio in the polymer is attained within 2 h (Fig. 3, curves *1'*, *3'*). With increasing temperature to 400°C the C/H ratio increases and reaches a constant value within for 2 h

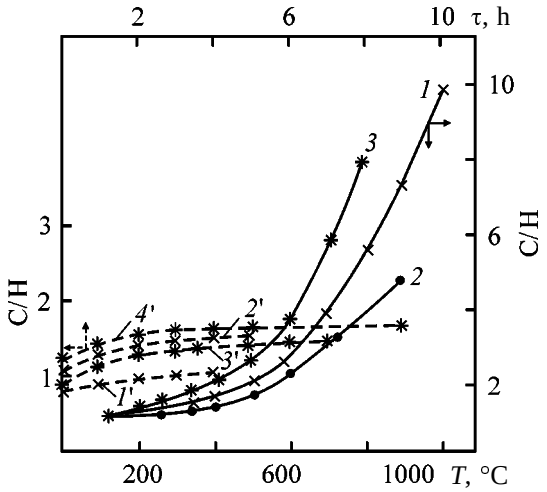

Fig. 3. C/H ratio as a function of (*1'–4'*) time and (*1–3*) temperature *T* of thermal treatment of polyvinylenes of (*1'–4'*, *1, 3*) crystalline and (*2*) amorphous structure. Polyvinylenes prepared from vinyl chloride (*3, 3'*, *4'*) homo- and (*1, 2, 1'*, *2'*) copolymers. Thermal treatment: (*1'*, *3'*) at 300°C after preliminary heating of polyvinylenes to 200°C and (*2'*, *4'*) at 400°C after preliminary heating of polyvinylenes to 300°C.

(Fig. 3, curves *2'*, *4'*). Hydrogen elimination proceeds without catalysts and hydrogen acceptors at temperatures significantly lower than the temperature of olefin dehydrogenation (>500°C).

The chemical and electrophysical properties of the polymers in question are determined by the specific electronic structure of polyvinylenes and especially by conjugation chains and delocalization of π electrons in them. The synthetic polymers with a linear conjugation system exhibit low electrical conductivity at room temperature [1]. The specific electrical conductivity σ_{20} of crystalline and amorphous polyvinylenes pre-

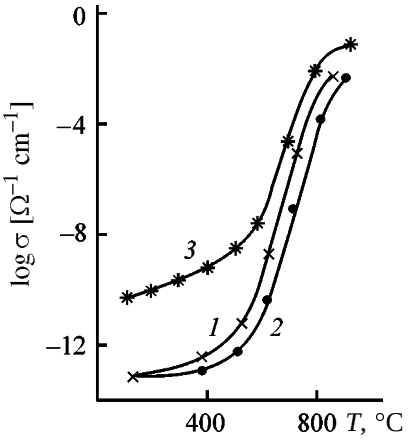

Fig. 4. Specific electrical conductivity σ of polyvinylenes of (*1, 3*) crystalline and (*2*) amorphous structure as a function of the temperature of thermal treatment *T*. Polyvinylenes prepared from vinyl chloride (*3*) homo- and (*1, 2*) copolymers.

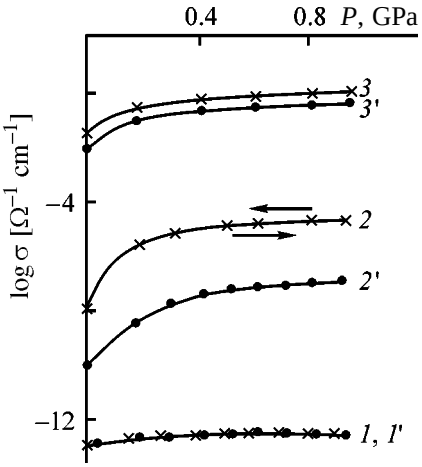

Fig. 5. Specific electrical conductivity σ of (*1*–*3*) crystalline and (*1*'–*3*') amorphous polyvinylenes prepared from copolymer of vinyl chloride and vinyl acetate and heat-treated at (*1, 1*') 100, (*2, 2*') 600, and (*3, 3*') 900°C as a function of pressure *P*.

pared from vinyl chloride copolymers does not exceed 10^{-13} Ω^{-1} cm^{-1}, i.e., they are actually insulators. It is known that the charge transfer involves the intrachain transfer along the conjugated chains and the interchain transfer. The transfer of the charge carriers along the conjugated bond system in macromolecules and between the molecules is probably more hindered in these polymers than in the product of PVC conversion (σ_{20} = 10^{-9} Ω^{-1} cm^{-1}). This is due to more random packing of macromolecules and the presence of shorter blocks of conjugated bonds as compared with the above copolymer. The decrease in the length of conjugated blocks decreases the polymer conductivity due to the increase in the band gap and in the number of intermolecular barriers.

The probability of the electron exchange, i.e., the mobility of the charge carriers should increase with decreasing distance between the separate sections during thermal treatment [12]. In this case, the supramolecular structure of polyvinylenes affects the resulting electrical conductivity. The carbonized samples of crystalline polyvinylene have greater electrical conductivity as compared with the pyrolysis products of amorphous polymer, because the dependences of the specific electrical conductivity of the polymer samples on the temperature of their thermal treatment for crystalline polyvinylenes lie above those of the amorphous samples (Fig. 4, curves *1*, *2*). This phenomenon is probably due to easier transfer of the charge carriers between macromolecules as compared with the amorphous polymer. During pyrolysis of these polyvinylenes at low temperatures (up to 400–500°C) σ_{20} monotonically increases. In this temperature range these polymers undergo transformations accompanied by formation of three-dimensional structures and accumulation of double bonds. The σ_{20} values of these products are lower as compared with the pyrolysis products of polyvinylenes prepared from PVC and fired at the same temperatures (Fig. 4, curves *1*, *3*). The specific conductivity of the products of polyvinylene pyrolysis at 600–700°C becomes approximately equal. As seen from Fig. 3, the composition of the products obtained at 600–700°C can be described by the formula $-(C_xH)_n-$, where $x \geq 2.0$.

High-temperature pyrolysis (above 400–500°C) increases σ_{20} by 9–10 orders of magnitude to values typical of semiconductors. Such a sharp change in the electrical properties is probably due to the steep increase in the number and size of conjugated blocks, which facilitates the electron transfer.

The increase in the electrical conductivity with increasing mobility of the charge carriers can be also attained by compression of the polymer sample, which decreases the intermolecular distances and increases the overlap of the electron orbitals of the neighboring atoms, and thus decreases the energy barrier between the conjugation blocks [1]. With increasing pressure, the electrical conductivity reaches saturation at 0.2 GPa. At the same time, the electrical conductivity of the crystalline polyvinylenes prepared from vinyl chloride copolymers only slightly changes with increasing pressure (Fig. 5, curves *1, 1*'). The effect of pressure is stronger on passing to the heat-treated samples and increases at pyrolysis temperatures of 600–700°C. Sharp increase in the electrical conduc-

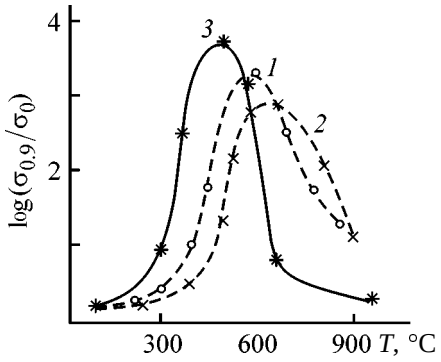

Fig. 6. Relative change in the electrical conductivity $\sigma_{0.9}/\sigma_0$ in the samples of heat-treated polyvinylenes of (*1*, *3*) crystalline and (*2*) amorphous structure as influenced by the pyrolysis temperature *T*. Polyvinylenes are the products of conversion of (*1*, *2*) vinyl chloride and vinyl acetate copolymer and (*3*) polyvinyl chloride. $\sigma_{0.9}$ and σ_0 are the specific electrical conductivities at uniaxial pressure of 0.9 GPa and without pressure.

tivity is observed for the samples treated at 600–700°C with the $(C_2H)_n$– composition: The increase in the specific electrical conductivity with increasing pressure to 0.9 GPa reaches nearly three orders of magnitude (Fig. 5, curve *2*). With increasing pyrolysis temperature above 700°C the effect of pressure on the electrical conductivity of the polymers in question decreases.

The extrema are the most pronounced in the temperature dependence of the function $\log(\sigma_{0.9}/\sigma_0)$, where $\sigma_{0.9}$ and σ_0 are the specific electrical conductivities at uniaxial pressure of 0.9 GPa and without pressure, respectively (Fig. 6).

The strain sensitivity of the heat-treated crystalline polyvinylene prepared from vinyl chloride copolymer is higher than that of the amorphous polymer, but lower as compared with the heat-treated polymer prepared from PVC.

There is no hysteresis in the pressure dependence of the specific electrical conductivity of the heat-treated crystalline polyvinylenes (Fig. 5, curve *2*). This feature is also typical for the pyrolysis products of polyvinylenes prepared from PVC and vinyl chloride copolymer, but distinguishes them from known semiconductors.

CONCLUSIONS

(1) As compared with amorphous samples, the ordered structure of crystalline polyvinylenes prepared by phase-transfer dehydrochlorination provides smaller rate and extent of their oxidation with atmospheric oxygen, lower rate of the weight loss, and higher rate of hydrogen elimination at high temperatures.

(2) The electrical conductivity and strain sensitivity of heat-treated crystalline polyvinylenes (conversion products of vinyl chloride copolymer) are higher than those of the amorphous samples, but smaller than those of the heat-treated products of polyvinyl chloride conversion.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Some Properties of Crystalline Polyacetylenes of Various Density

V. N. Salimgareeva, N. S. Sannikova, S. V. Kolesov, and Z. Kh. Kuvatov

Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Abstract—The resistance of crystalline polyacetylenes of various density to oxidants and high temperatures was studied. The electrophysical and magnetic properties of these polymers and of the products of their thermolysis were determined.

Polyacetylene (PAc) is a polymer with a linear system of conjugated double bonds, which possesses semiconductor and magnetic properties due to the presence of delocalized π electrons in the macromolecule [1]. This compound is promising for electronics, which utilizes predominantly crystalline semiconductor materials in the form of single crystals or thin mono- and polycrystalline layers [2].

Crystalline PAc is prepared by polymerization of acetylene using Ziegler–Natta catalysts [3]. The PAc films and powders are agglomerates of randomly bound fibrils with the thickness of 10–80 nm and length of tens micrometers. The resulting films are rather porous; the pore volume reaches 2/3 of the total polymer volume, and the apparent volume density is 0.4 g cm^{-3}. The PAc samples with the density reaching 0.7–1.1 g cm^{-3} were also prepared [4]. The properties of these samples are significantly different. For example, the specific electrical conductivity of the foam-type material (0.02–0.04 g cm^{-3}) is nearly two orders of magnitude smaller than that of the pressed films (0.1–0.4 g cm^{-3} density) [5].

Crystalline PAc can be prepared by conversion of polyvinyl chloride (PVC) under the conditions of phase-transfer catalysis [6]. The crystals of the polymer prepared by this method are the largest; their size reaches 1.0×10^3 μm. This procedure allows control of the packing density of the polymer crystals and yields samples with a density of 1.15–1.20 and 1.30–1.35 g cm^{-3}.

Here we report on some properties of crystalline PAc of various densities prepared by phase-transfer dehydrochlorination of PVC.

EXPERIMENTAL

We studied crystalline PAc prepared by phase-transfer dehydrochlorination of PVC with 50% aqueous solutions of potassium hydroxide in the presence of phase-transfer catalysts [6]. The polymer of 1.2 g cm^{-3} density was obtained using potassium hydroxide solution in the amount of 0.42 g (recalculated on the dry weight) per 1 ml of the organic phase (PVC solution in nitrobenzene), and that of 1.35 g cm^{-3} density, with a smaller amount of KOH (0.25 g ml^{-1}). The product of PVC conversion is a coarse black or dark brown powder (0.8–1.0 mm particle size).

The polymer structure was studied using optical (Amplival Poi U unit) and electron (EMMA-4 unit) microscopy. The X-ray diffraction (XRD) patterns were registered on a DRON-2 diffractometer (CuK_α radiation).

The thermal treatment of the samples was carried out in a quartz tube in a vacuum ($\approx 10^{-3}$ mm Hg); at higher temperatures a ceramic tube was used. The sample was heated with a heating rate of 1.5 deg min^{-1} and kept at a chosen temperature for 4 h. All manipulations were performed under argon. The thermal stability was studied using a du Pont 900 derivatograph at a 3 deg min^{-1} heating rate in a helium flow (40 ml min^{-1}).

The specific electrical resistivity was measured by the four-probe procedure in cells equipped with stainless-steel electrodes using an E 7–8 ac potentiometer (1 kHz). The design of the measuring cells allowed preparation of 50–300-μm thick pellets. The magnetic susceptibility of the powdered PAc samples was measured by the Faraday procedure [7] in the 20–100°C

1070-4272/01/7403-0478$25.00

temperature range and at the 2–15 kOe magnetic field intensity.

The samples were oxidized with atmospheric oxygen and ozone; oxygen was dried over P_2O_5. The ozone–oxygen mixture (1–2 vol % ozone concentration) was passed through a 7×0.5-cm tube packed with the polymer at room temperature, at a rate of 2–5 l h^{-1}.

According to the data of electron microscopy, the PAc sample (1.20 g cm^{-3} density) prepared by phase-transfer dehydrochlorination of PVC contains the crystals of three modifications with the following lattice parameters (Å): hexagonal $a = b = 5.2$, $c = 2.52$; orthorhombic $a = 4.0$, $b = 7.9$; and monoclinic $a = c = 3.9$, $b = 2.52$. It was found that the crystal modifications with analogous parameters are also present in the PAc sample (1.35 g cm^{-3} density), which is confirmed by similar electron microscopic patterns. Their diffraction patters are also similar: The scattering angles ($2\theta = 20°$) and reflection intensities are equal. Thus, the XRD densities of both PAc samples are equal, whereas their pycnometric densities are different. These difference in the XRD and pycnometric densities can be due to different content of closed pores [8]. At similar XRD density the porosity is lower in the samples with higher pycnometric density.

As seen from the reactions of PAc with electrophilic reagents, in particular atmospheric oxygen and ozone, the volume of micropores affects the chemical and physical properties of crystalline PAc. The PAc sample with the pycnometric density of 1.20 g cm^{-3} absorbs up to 1.2 wt % of atmospheric oxygen in 60 h, whereas the polymer with the 1.35 g cm^{-3} density does not noticeably absorb oxygen. The polymer with a small density flames up immediately on contact with ozone, whereas the reaction of ozone with the high-density polymer is relatively slow: the polymer weight increases by only 5% after ozone bubbling for 5 h. Thus, the polymer oxidation is probably controlled by diffusion of oxygen and ozone into the sample bulk, and in the high-density polymer the diffusion is significantly hindered.

The behavior of PAc samples with different crystal packing at high temperature is also different. In general, thermal degradation of the macromolecules of the crystalline polymer with significant weight loss starts at 300–320°C and is complete at 600–650°C with formation of a coke residue (yield 35–45%). In the PAc sample of 1.20 g cm^{-3} density the polymer degradation proceeds at a higher rate and with a lower yield of the coke residue as compared with the less-

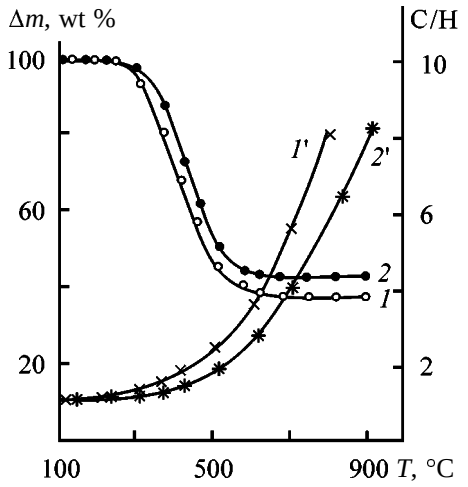

Fig. 1. (*1*, *2*) Weight loss Δm and (*1'*, *2'*) C/H ratio of crystalline PAc as functions of pyrolysis temperature *T*. Polymer density (g cm^{-3}): (*1*, *1'*) 1.20 and (*2*, *2'*) 1.35.

porous high-density polymer: curve *1* of the weight loss lies below curve *2* (Fig. 1).

The decrease in the content of closed pores in crystalline PAc hinders release of the volatile products of the polymer degradation and carbonization. The dehydrogenation of crystalline PAc of 1.20 g cm^{-3} density starts at 250°C and yields, via formation of several intermediate structures, completely carbonized samples at 1100–1200°C. In the high-density polymer elimination of hydrogen is hindered: The dependence of the C/H ratio characterizing hydrogen loss with temperature for the PAc sample of 1.35 g cm^{-3} density lies below that for the sample of 1.2 g cm^{-3} density (Fig. 1). The elevated thermal stability of high-density PAc is probably due to the hindered diffusion of hydrogen in the compact sections and possible hydrogen bonding between the π electrons and H atoms of the neighboring molecules.

The samples of crystalline PAc with different densities exhibit different electrophysical properties. The polymer with a high density (i.e., with a low porosity) exhibits higher specific electrical conductivity σ than the low-density sample: 10^{-9} and 10^{-10} Ω^{-1} cm^{-1}, respectively. High density and regular packing of the polymer probably facilitate the transfer of the charge carriers (e.g., electrons in the case of electronic conductivity) between macromolecules owing to high stability of high-density crystalline PAc to oxidation with atmospheric oxygen; its increased electrical conductivity is preserved for about 500 h on storage under argon or in air.

The electrical conductivity of the PAc sample slowly increases on heating to 400–500°C, and this

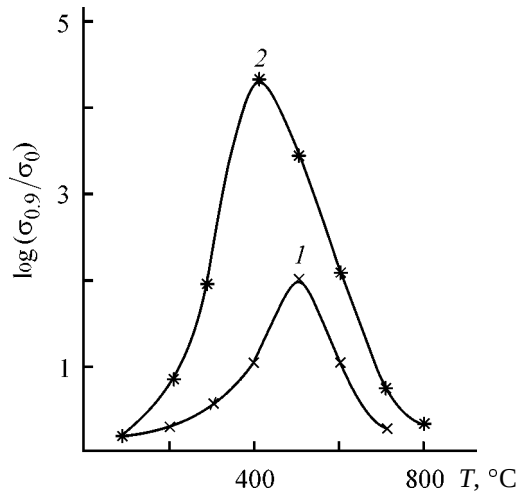

Fig. 4. Relative change in the electrical conductivity $\sigma_{0.9}/\sigma_0$ of crystalline PAc provided by uniaxial pressure of 0.9 GPa as influenced by the pyrolysis temperature *T*. Polymer density (g cm^{-3}): (*1*) 1.20 and (*2*) 1.35.

process intensifies at higher temperatures (Fig. 2). This is probably due to the fact that the probability of electron exchange, i.e., the mobility of charge carriers should increase with decreasing distance between the separate conjugated blocks during the thermal treatment [9]. The difference in the electrical conductivity is also observed in the products of PAc pyrolysis with the initial density of 1.20 and 1.35 g cm^{-3} (Fig. 2).

The increase in the mobility of the charge carriers can be also attained by compression of the polymer sample, which probably decreases the intermolecular distances and thus decreases the energy barrier between the neighboring conjugation blocks [7]. The uniaxial pressure only slightly increases the PAc conductivity (Fig. 3), which reaches a constant value at 0.20–0.24 GPa.

The thermal treatment of crystalline polymer yields the products whose electrical conductivity significantly increases with compression. At the same temperatures of heat treatment, in the pressure range 0–0.9 GPa, crystalline PAc with high density of crystal packing exhibits higher electrical conductivity than the low-density polymer samples (Fig. 3, curves *3, 4* and *5, 6*). As seen from the dependences of σ of the polymers at pressure of 0.9 GPa on the temperature of their thermal treatment, the heat-treated samples of PAc polymer with a high density are more strain-sensitive than the low-density samples (Fig. 4). The curve for the high-density PAc sample lies higher than that for the low-density polymer in the entire temperature range studied. These curves pass through a maximum; the greatest change in σ (by nearly 4.5 orders of magnitude) is observed for the high-density polymer (1.35 g cm^{-3}) heat-treated at 400°C.

The intrinsic paramagnetism of the polymers with a system of conjugated double bonds distinguishes PAc from the other polymers. We observe a single strong signal in the ESR spectrum with g = 2.003 typical for a free electron. The π electron is a paramagnetic center or a defect, which determines the magnetic properties of the polymer including its magnetization in an applied magnetic field.

The crystalline PAC prepared by phase-transfer dehydrochlorination of PVC is a weakly magnetic material; its static magnetic susceptibility does not exceed 10^{-6} g^{-1}. The static magnetic susceptibility χ is a response of the material on the applied magnetic field and characterizes the electronic effects related to structural features of the solid polymer and determined by only the physical nature of the given material [10]. The PAc susceptibility depends on the field intensity (Fig. 5a) with the saturation attained at relatively low

field intensities, which suggests that the polymer contains certain ordered areas where the cooperative spin interaction is possible. This polymer belongs to magnetically hard materials, because magnetization takes place at the magnetic field intensities $H \geq 10^{-3}$ Oe. In the area of field intensities studied (2–15 Oe) the magnetic susceptibility χ of the samples with densities of 1.20 and 1.35 g cm^{-3} is negative, which suggests their diamagnetism.

The crystalline polymer with the lower density is more diamagnetic than the high-density polymer. This is due to the fact that the magnetic susceptibility depends on the mutual location of the molecules in the solid. The stronger electron interaction in the sample with higher density probably increases χ.

The susceptibility of the molecules without intrinsic magnetic moment is equal to the sum of diamagnetic χ_d component characterizing the Langevin diamagnetism and paramagnetic component χ_p characterizing the van Vleck paramagnetism [7]:

$$\chi = \chi_d + \chi_p.$$

Diamagnetism originates from the interaction of the magnetic field with the partially or completely occupied electron orbitals, whereas paramagnetism is due to the interaction with unpaired electrons and uncompensated electron orbital moments. Therefore, the van Vleck paramagnetism should be proportional to the number of electrons.

Obviously, the contribution of the van Vleck paramagnetism to the susceptibility of the PAc molecule is predominant, because with increasing magnetic field intensity the polymer magnetization increases, which is typical for classical paramagnets (Fig. 5a). With increasing temperature (H = 14 kOe) χ of crystalline polymer with low density (1.2 g cm^{-3}) decreases, whereas in the high-density polymer (1.35 g cm^{-3}) it linearly increases (Fig. 5b).

The magnetic susceptibility is sensitive to the changes in the electronic structure occurring in the course of thermal treatment. Upon thermolysis, PAc passes from the diamagnetic to paramagnetic state; χ becomes positive and decreases with increasing field intensity (Fig. 5a). The increase in the packing density of the PAc crystals decreases their paramagnetism: The curve of χ vs. field intensity for the pyrolysis products of high-density polymer lies below the curve determined for low-density crystalline PAc (1.20 g cm^{-3}) heat-treated at the same temperature (Fig. 5a). The temperature dependence of the magnetic susceptibility of the pyrolysis products differs

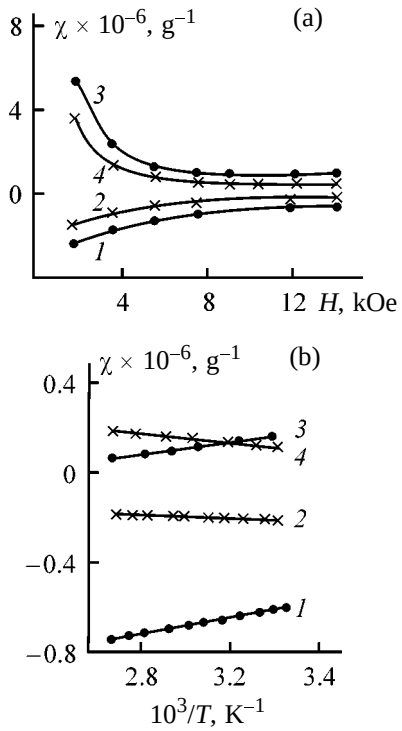

Fig. 5. Static magnetic susceptibility χ of the (*1*, *2*) initial and (*3*, *4*) heat-treated at 450°C samples of crystalline PAc as a function of (a) field intensity H and (b) temperature T. (a) Temperature 20°C; (b) field intensity 14 kOe. Polymer density (g cm^{-3}): (*1*, *3*) 1.20 and (*2*, *4*) 1.35.

from that found for the crystalline samples with low density. It increases with temperature, which corresponds to the increase in the number of paramagnetic centers due to the activation process. The apparent activation energy of the appearance of paramagnetic carriers is 1.1 eV.

Thus, the density of crystal packing in the initial polymer sample determines the properties of crystalline PAc and of the products of its thermal treatment.

CONCLUSIONS

(1) The chemical, electrophysical, and magnetic properties of crystalline polyacetylene prepared by phase-transfer dehydrochlorination of polyvinyl chloride depend on its density. As compared with low-density polyacetylene (d = 1.20 g cm^{-3}), the high-density polymer (d = 1.35 g cm^{-3}) is more resistant to atmospheric oxygen, ozone, and high temperatures.

(2) This polymer and the products of its pyrolysis exhibit higher electrical conductivity and strain sensitivity as compared with the low-density samples.

(3) The initial crystalline high-density polyace-

tylene exhibits lower diamagnetism, whereas the products of its thermolysis exhibit lower paramagnetism as compared with the corresponding low-density polymer samples.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation of Chemically Cross-Linked Swollen Gels from Spent Rubbers and Their Use as Components of Rubber Stocks

S. V. Usachev, O. Yu. Solov'eva, M. E. Solov'ev, D. N. Babyuk, and V. M. Voronov

Yaroslavl State Technical University, Yaroslavl, Russia

Received December 23, 1999; in final form, March 2000

Abstract—A study was made of cross-linking of gelatinous compositions to obtain products classed with gels of the first type in which a part of the plasticizer is firmly retained by the gel structure of the elastomer. The elastic-hysteresis properties of the rubbers were studied.

According to the existing physicochemical concepts of structure formation and properties of elastomer blends, enhancement of fatigue-strength properties of rubbers based on them is due to a specific structure of the boundary zone between the polymer phases, incorporating along with the segmental interdiffusion layer also the boundary layers [1]. A thin contacting layer of one of the phases is characterized by a less close packing of macromolecules and in some cases by the lower degree of cross-linking [2]. The thinned layers provide efficient relaxation of stresses, which is one of the causes of the mutual reinforcement effect. Apparently, addition and distribution in a rubber stock of microparticles of a polymeric substance with *a fortiori* thinned stated of macromolecules due to filling of the interchain space with a plasticizer could enhance the conformational mobility of chains and accelerate relaxation of local overstresses arising under applied mechanical field.

In this work we examined the efficiency of using as such disperse phase swollen chemically cross-linked polymer gels. Usually swollen polymer gels (polymer jellies) are obtained from primary polymers [3]. However, in our case it is interesting to prepare gels from secondary polymeric materials, e.g., from spent rubbers, since products of spent rubber reprocessing are widely used as components of rubber stocks, decreasing their cost and modifying their properties.

EXPERIMENTAL

Polymer jellies were prepared by plasticization of crushed resins (CRs) of model composition and of crushed spent heating tubes (HTs) which are an inevitable waste of tire production. Plasticization was performed in hydrocarbon media at 160–200°C; the CR : plasticizer ratio was 1 : 3. Model rubbers were prepared from SKI-3 rubber; the polymer base of HT rubbers was a combination of SKI-3 and SKD rubbers. As a plasticizer we used Vaseline oil which is well compatible thermodynamically with SKI-3 and SKD rubbers, and also PN-6sh aromatic oil whose thermodynamic affinity for these rubbers is lower.

Plasticization at 160–200°C was performed until visually uniform compositions were obtained; owing to a low content of the polymer gel fraction and a high content of the plasticizer, these gels can be classed with jellies of the second type (swollen gels with a physical network) [4]. Degradation of the vulcanization structure of CRs was monitored by variation of the content of the sol (S) and gel (G) fractions and from the variation of the equilibrium swelling Q of the insoluble fraction in toluene.

We calculated the index of degradation of the vulcanization structure of the resins I_d by the formula [5]

$$I_d = Q(100 - S),$$

where Q and S are expressed in percents.

For example, at the process temperature of 180°C I_d of the rubber in the final product obtained from vulcanized unfilled SKI-3 rubber was 40.5, and the viscosity-average molecular weight of the sol fraction of the rubber was 42 000.

Figure 1 shows variation with time of the gel fraction content in HT reprocessing products heated in air and in the Vaseline oil medium. It is seen that the

1070-4272/01/7403-0483$25.00

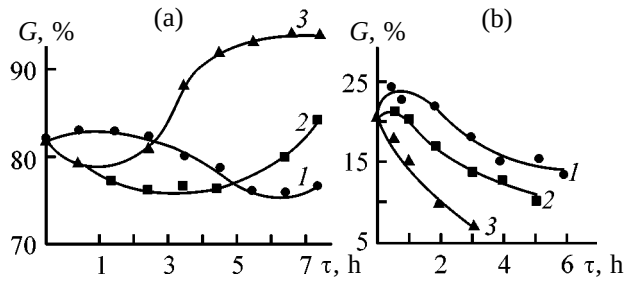

Fig. 1. Variation of the gel fraction content *G* in HTs in the course of heating (a) in air and (b) in Vaseline oil (1 : 3) at (*1*) 160, (*2*) 180, and (*3*) 200°C. (τ) Heating time.

initial stage of plasticization in the oil at 160–180°C is characterized by increase in the content of the insoluble fraction until a maximum is reached. This is probably due to cross-linking of the elastomer under the action of vulcanizing agents that had not reacted in the course of primary vulcanization and subsequent crushing. Cross-linking can also be effected by active sulfur fragments released in rearrangements of polysulfide bonds. On further heating, the gel fraction content decreases. At 200°C, no maximum is detected, which shows that degradation essentially prevails. With increasing temperature the apparent rate constant of gel degradation increases (Table 1).

Heating of HTs in air at 180 and 200°C in the absence of the plasticizer initially also causes the gel fraction content to decrease. After reaching a certain minimum, the amount of the gel starts to grow, suggesting the prevalence of cross-linking.

The degradation processes are more pronounced at 160°C. Comparison of the curves in Figs. 1a and 1b shows that addition of oil prevents cross-linking and accelerates thermal degradation of the gel. Analysis of the obtained curves shows that it is appropriate to perform thermal degradation of HTs at 180°C. At 160°C the process takes long time: After heating for 6 h, gel particles of ~1 mm size are still detected visually in the composition. When the process is performed at 200°C, the polymer strongly degrades before the composition becomes visually uniform, which is indicated by a decrease in viscosity.

Table 1. Kinetics of gel degradation during thermal plasticization of HTs in Vaseline oil

T, °C	Apparent rate constant of gel degradation, h^{-1}
160	0.426
180	0.616
200	0.912

When developing a procedure for preparing swollen chemically cross-linked gels, we took into account the following facts. The high content of the plasticizer certainly determines the specific features of cross-linking of rubber macromolecules. As noted in [3], an important condition for cross-linking of the polymer in such systems is the contact of separate molecules. Otherwise, either three-dimensional aggregates can form from a limited number of macromolecules, or separate macromolecules can undergo intramolecular cross-linking. The concentration of the polymer in the jellies under consideration exceeds the level theoretically required to ensure mutual contact of the revolution spheres of separate macromolecules in the unrolled state (several tenth fractions of percent [3]). Nevertheless, in the presence of a plasticizer the relative contribution of intramolecular cross-linking inevitably increases, and that of intermolecular cross-linking decreases [3, 6]. Another specific feature of the swollen gels in hand is the decreased (owing to strong degradation in the stage of secondary reprocessing) molecular weight of the rubber component. Therefore, it seems apparently necessary to take cross-linking agents in larger amounts as compared to cross-linking of a high-molecular-weight rubber. When choosing the type and content of cross-linking agents, we took into account in this case the recommendations given in [7].

The curing of the compound prepared by thermal degradation of HTs in Vaseline oil at 180°C [vulcanizing group, wt parts per 100 wt parts of rubber component): mercaptobenzothiazolyl disulfide 6.0, diphenylguanidine 3.0, zinc oxide 15.0, stearic acid 9.0, sulfur 45.0] is characterized by data in Fig. 2. It is seen that addition of sulfur is accompanied by an increase in the content of the insoluble fraction and a decrease in the degree of its swelling. At a certain instant marked with a triangle in the curves, the viscosity of the compound sharply increases, and its stirring with a power-driven propeller stirrer becomes impossible. This instant was identified as gelation point.

However, when a jelly prepared from HTs and Vaseline oil at 200°C was heated under similar conditions with the same amounts of the cross-linking agents, no gelation was observed at the vulcanization temperature. Apparently, in this case vulcanizing agents add mostly intramolecularly without formation of a common three-dimensional structure, which is probably due to the significantly decreased molecular weight of the rubber and fairly uniform distribution of macromolecules in the plasticizer. After cooling to

room temperature, this compound acquires a jelly-like consistence.

Figure 3 shows the kinetics of curing of compounds prepared by dispersion of HTs in PN-6sh oil at 200°C with various amounts of sulfur (20 and 40 wt parts per 100 wt parts of rubber) in the presence of accelerators and activators whose content and type are given above. As seen, compounds with PN-6sh oil as plasticizer differ from those with Vaseline oil in the higher concentration of free sulfur at the same curing time. Gelation occurs also in compounds prepared at 200°C. This is presumably due to worse thermodynamic compatibility of SKI-3 and SKD with aromatic PN-6sh oil, owing to which the fragments of the rubber chains can be more densely packed in microvolumes and hence can be cross-linked more readily. The gel content in all the examined compounds does not exceed a definite level of 15–18 wt %. The initial gel content in the compounds before degradation of HTs in the plasticizers is 20%. This means that the degree of cross-linking of the rubber macromolecules is fairly high. After cooling, the compound vulcanized at 143°C for 60 min with the vulcanizing group containing 40 wt parts of sulfur is a soft elastic pasty mass. After heating for 5 h and subsequent cooling, the product becomes solid. The jelly-like consistence of the compound with 20 wt parts of sulfur is preserved after curing.

We have examined the possibility of accelerating curing of swollen gels with ultraaccelerators, in particular, zinc dimethyldithiocarbamate (Zimate). In parallel, we performed for comparison vulcanization of jellies with sulfur in the presence of other, less active accelerators. In both cases we also used activators. The content of vulcanizing substances in the jellies and the vulcanization temperatures are listed in Table 2.

The vulcanization time of the jellies was 60 min. The products were added to tread rubber stocks in amounts of 10 and 15 wt parts per 100 wt parts of rubber. The stocks containing chemically cross-linked jellies prepared by cross-linking of the components with sulfur at 143°C and with sulfur in the presence of various amounts of zinc dimethyldithiocarbamate at 70 and 90°C are similar to the common rubber stock in the vulcanization rate. The physicomechanical characteristics of tread rubbers with additions of swollen gels, prepared using various vulcanizing systems, are listed in Table 3.

Data in Table 3 show that the properties of rubbers depend on the content and composition of jellies and on the temperature of their vulcanization. The best

diphenylguanidine. The rubbers containing these jellies, exhibiting the modulus of strength similar to that of serial samples, show higher endurance, lower heat build-up, and lower abradability. The rubbers containing jellies prepared using zinc dimethyldithiocarbamate exhibit somewhat worse characteristics.

When evaluating the structural features of rubbers prepared with addition of swollen gels with a chemical network of cross-links between rubber macromolecules, it should be taken into account that a part of the plasticizer is firmly retained in the gel structure. This is suggested by the fact that, when such samples are

treated with toluene, the amount of the extracted plasticizer is appreciably lower (60.7, 66.2, and 55.3 wt % for compound nos. 2, 4, and 6, respectively) than its total amount in the swollen gel (73–75 wt %). It should be noted also that in the case of vulcanization with sulfur in the presence of Altax and diphenylguanidine at 143°C the vulcanization network incorporates a larger amount of the plasticizer then in vulcanization in the presence of Zimate at 70 and 90°C. This may be due the higher density of the vulcanization network formed at 143°C. Apparently, the effect of the ultraaccelerator at a large amount of the plasticizer is manifested in more efficient intramolecular addition of sulfur.

The properties of rubbers containing swollen gels are largely affected by the character of dispersion of the gels in the matrix rubber stock. The particle-size distribution of swollen chemically cross-linked gels dispersed in the matrix of butadiene–styrene rubber by stirring [8, 9] is given in Table 4.

Table 4 shows that the swollen gels whose polymeric fraction is cross-linked in the presence of common accelerators of sulfur vulcanization at 143°C are readily dispersed in the rubber matrix. The content of fine (50–200 μm) particles is 70%. At the same time, in the jellies cross-linked using Zimate the majority of particles have a size of 250–350 μm. These data suggest that the prevalence in the swollen gel of intramolecular sulfur bridges (compound no. 4) makes the resulting compound more rigid, since vulcanization is accompanied by formation of a new type of the polymer with the molecular structure containing chemically bound sulfur. As a result, the cohesion energy density increases, the difference in solubility between the butadiene–styrene rubber and the newly prepared polymer becomes more pronounced, and coarser jelly particles are formed on mixing.

Thus, the structure of the rubber stock containing swollen chemically cross-linked polymer gels can be represented as a combination of elastomers of different chemical nature. The specific feature of such structure is the increased conformational mobility of macromolecules in dispersed phase particles and the decreased particle modulus, which enhances the endurance of the compounds [10]. The mass transfer of excess plasticizer to the matrix mixture forms a boundary layer around particles with a higher plasticizer content and hence with a decreased modulus. This layer also enhances the endurance, since it provides relaxation of local stresses. A valuable property of such compositions is decrease in the hysteresis loss, manifested in decreased heat build-up under conditions of repeated deformations at constant elastic-strength characteristics.

CONCLUSIONS

(1) Thermal plasticization of crushed model rubbers based on SKI-3 rubber and spent heating tubes based on SKI-3 + SKD rubbers in plasticizers and in air at 160–200°C was studied. The kinetic features of degradation of the three-dimensional structure of the vulcanized rubbers were found, and the apparent rate constants of gel degradation were determined. Swelling in hydrocarbon media makes formation of jellies of the second type less probable. At decreased molecular weight, rubber macromolecules preserve the long-chain structure in thermal plasticization products.

(2) The process for preparing chemically cross-linked gels by sulfur cross-linking of thermal plasticization products of the above-mentioned rubbers in the presence of accelerators and activators was studied. When added to rubber stocks, swollen chemically cross-linked gels are broken down to microparticles in the course of mixing under the influence of shear stress and give the disperse phase. The resulting elastomer compounds acquire enhanced elastic-hysteresis properties after vulcanization.

Abstract—Emulsion polymerization of methyl methacrylate initiated by a carboxyl-containing azo initiator in the presence of a polymeric stabilizer (dextran or its functionalized derivatives) was studied with the aim to prepare monodisperse microspheres of polymethyl methacrylate with surface carboxy, amido, and aldehyde groups. The optimal conditions for formation of monodisperse microspheres were found, allowing control of their diameter in the submicrometer range and of the nature and content of surface functional groups.

Synthesis of monodisperse microspheres in the presence of polymeric stabilizers shows promise since stabilizers not only enhance the aggregative stability of particles in the course of polymerization but also, in subsequent transformations, play the role of spacers containing functional groups for covalent binding of ligands. With biologically active substances (BASs) as ligands, such microspheres are used in immunoassay as immunoreagents visualizing the progress of immunochemical reactions. Most often BASs are bound to microspheres via surface carboxy groups capable, after activation, to form amide bonds with BAS amino groups, or via aldehyde groups reacting with a amino groups under very mild conditions to form Schiff bases [1–3]. Suitable polymeric stabilizers in preparation of microspheres can be dextran and its functionalized derivatives which are widely used for modification of water-soluble pharmaceuticals with the aim to prolong their effect and reduce the toxicity [4, 5]. Preparation of polystyrene [6] and polyalkyl cyanoacrylate [7] microspheres in the presence of dextran and β-cyclodextrin was reported previously. Of interest for immunoassay are also microspheres based on polymethyl methacrylate (PMMA), a polymer with a higher density and a lower refractive index, which is advantageous for processes involving fast sedimentation or optical monitoring of immunochemical reactions [8]. Samples of PMMA microspheres obtained both in the absence and in the presence of dextran were tested in immunization processes [9, 10]. The microspheres in this case acted not only as carriers of immunoreagents but also as an adjuvant enhancing the immune response. It was found that the microspheres undergo slow biodegradation, which facilitates elimination of PMMA from the body. At present, additional surface modification of dextran-coated microspheres is performed with the aim to obtain active functional groups. For example, hydroxy groups of dextran are oxidized to aldehyde groups with periodate. To obtain directly in the course of synthesis monodisperse PMMA particles with the carboxylated surface coated with a polymeric stabilizer, it seems promising to perform emulsion polymerization of MMA initiated with a carboxyl-containing azo initiator in the presence of dextran. It is also interesting to study the features of a similar process performed in the presence of functionalized dextran derivatives, with the aim to introduce into the microsphere surface layer not only carboxy but also other functional groups, to increase the surface concentration of functional groups, and to control their content depending on the nature of the derivative in hand.

EXPERIMENTAL

Methyl methacrylate, isoamyl alcohol, and dimethylformamide (DMF) were purified by standard procedures. The procedures for purification and characteristics of 4,4'-azobis(4-cyanovaleric acid) (CVA) are described elsewhere [2]. Synthesis was performed in double-distilled water as dispersion medium. Dextran (M 60 000 ± 10 000) produced by the St. Petersburg Academy of Pharmaceutical Chemistry was used without additional purification.

Dextran derivatives differing in the nature of functional groups and degree of substitution (DS) were prepared and characterized according to [4, 5]. We

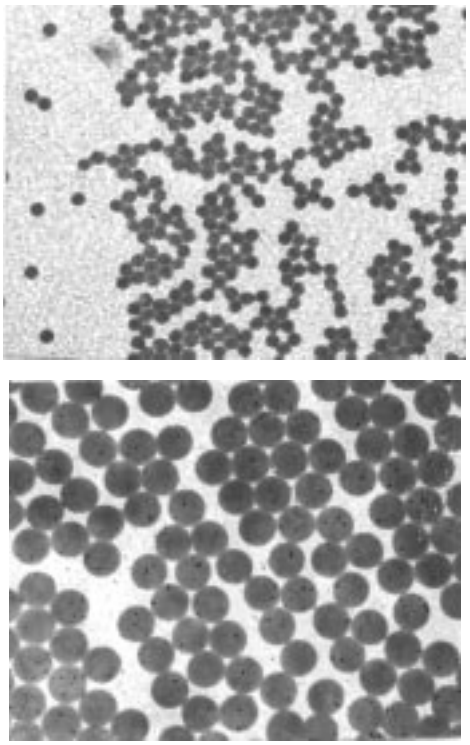

Fig. 1. Influence of the nature of the initiator on the size of PMMA microspheres. Initiator: (a) potassium persulfate and (b) CVA.

prepared carboxymethyl dextran (CMD) (DS 0.6), carboxyethyl dextran (CED) (DS 0.91), dextran polyaldehyde (DPA) (DS 1.15), and carboxyethyl dextran amides (CEDAs) containing both carboxy and amide groups ($CEDA_1$: DS_{carb} 0.31, DS_{amide} 0.32; $CEDA_2$: DS_{carb} 0.27, DS_{amide} 0.58).

The CVA-initiated emulsion polymerization was performed at 348 ± 1 K by the procedure described in [2, 3] in the presence of dextran or its derivatives. The ratio of MMA to the aqueous phase was 1 : 10, the initiator concentration was 0.2 wt % relative to water, and the dextran content was varied from 0.1 to 0.4 wt % relative to water. To reveal the effect of the nature of the initiator on the characteristics of the forming PMMA microspheres, polymerization in the presence of dextran (0.2 wt %) was also initiated with potassium persulfate, which is commonly used for preparing monodisperse latexes. The polymerization temperature in this synthesis was decreased to 343 K, since even at this temperature the rate constant of persulfate decomposition ($\log K = -1.3$ [11]) is higher than that of CVA at 353 K ($\log K = -3.94$ [12]). In some runs the conversion of the monomer in the course of polymerization was monitored by gas chromatography, with isoamyl alcohol as internal reference (determination error 5%).

0.40	0.36

* Concentrations: MMA 10 wt %, CVA 0.2 wt %, Na_2HPO_4 0.02 M, and NaOH 0.0168 M.

The particle diameters in the forming latexes were determined with a JEM 100 S electron microscope (JEOL, Japan). After triple washing of the latexes to remove water-soluble impurities by successive centrifuging and redispersion, the surface concentration of carboxy groups was determined by conductometric titration [2]. The surface concentration of aldehyde groups was determined by the same method, after reaction of the aldehyde groups with hydroxylamine hydrochloride [13].

We found that monodisperse PMMA particles (Fig. 1) are formed when the polymerization is initiated with both carboxyl-containing azo initiator CVA and persulfate. However, in synthesis with CVA the particle diameter was larger (0.42 μm) than with persulfate (0.18 μm). Also considerably higher was the concentration of carboxy groups on the particle surface (1.47 vs. 0.42 μg-equiv m^{-2}), which is advantageous for subsequent chemical binding of BASs. Thus, the carboxyl-containing azo initiator is apparently more efficient for preparing PMMA microspheres in the presence of dextran.

As shown in [3], in emulsifier-free emulsion polymerization of styrene initiated by CVA the diameter of the forming microspheres is largely affected by the ionic strength and pH of the dispersion medium [3]; therefore, to control the particle size, it is advisable to choose appropriate buffer systems. Therefore, we performed a series of experiments on preparation of PMMA microspheres in the presence of Na_2HPO_4 (to provide weakly alkaline medium) and 0.2 wt % dextran (Table 1). We found that PMMA particles obtained in the presence of dextran and without it at low concentration of the buffer additive Na_2HPO_4 have a comparable size (Fig. 2). As the concentration of Na_2HPO_4 was increased to 0.08 M, the diameter of PMMA microspheres formed in the presence of

dextran linearly increased, with the monodispersity and stabillity of the latex being preserved. On the contrary, in the absence of dextran the particle size drastically increased with increasing ionic strength, a large amount of coagulum formed, and the latex lost monodispersity. Thus, at high Na_2HPO_4 concentration the electrostatic barrier produced by repulsion of ionized carboxy groups appears to be insufficient to provide the aggregative stability of the forming latex, whereas steric stabilization of microspheres with dextran imparts to them additional stability in the course of polymerization. This fact makes it possible to finely control, by varying the salt concentration, the diameter of microspheres in the submicrometer range, with the monodispersity being preserved.

As shown in [6], dextrans with the molecular weight ranging from 70 000 to 2 000 000 enhance the resistance of polystyrene dispersions formed in their presence to the action of electrolytes. This trend was explained in [6] by formation of highly viscous strong surface adsorption layers consisting of dextran and the forming polymer, preventing the particle coalescence. The highest stability is attained at $M \geq 500\,000$. However, experiments in [6] were performed at constant molar concentration of dextrans of different molecular weights, so that with increasing M the weight content of dextran in the reaction mixture increased, and the surface concentration of the polymeric stabilizer could increase also. By contrast, in this work, to determine the synthesis conditions ensuring aggregative stability and monodispersity of the resulting PMMA latexes, we took the same dextran sample (M = 60 000) and varied its concentration in the range 0.1–0.4 wt %, at an Na_2HPO_4 concentration of 0.02 M (Table 1). We found that the aggregative stability of the latex in the course of the synthesis, evaluated by the amount of the forming coagulum, largely depends on the dextran concentration in the reaction mixture (Fig. 3). At a dextran concentration of 0.20–0.25 wt %, no coagulum was formed. At lower concentrations of the steric stabilizer, as expected, the aggregative stability of the latex decreased. However, the latex stability also decreased at dextran concentrations above the optimal level; it is interesting that the concentration of the carboxy groups on the particle surface increased in parallel with the amount of the coagulum. If the aggregative stability were controlled by the electrostatic factor, an opposite trend would be expected. Apparently, the experimentally observed decrease in the aggregative stability of microspheres with increasing concentration of carboxy groups in the surface layer consisting of dextran and the forming polymer is due

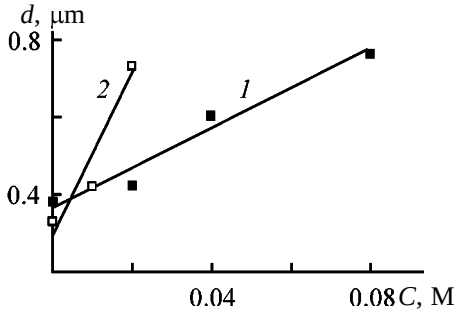

Fig. 2. Diameter d of the forming PMMA microspheres as a function of the concentration C of Na_2HPO_4 (*1*) in the presence (0.2 wt %) and (*2*) in the absence of dextran.

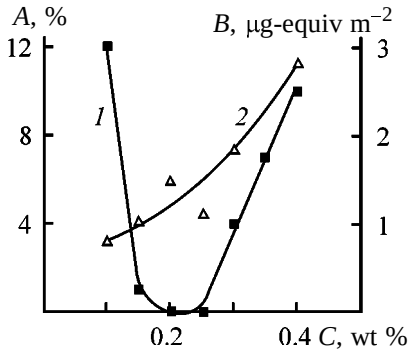

Fig. 3. Influence of dextran concentration C in the reaction mixture (*1*) on formation of coagulum A and (*2*) on concentration of surface carboxy groups B.

to destabilization of the surface layer as a result of mutual repulsion of the ionic groups.

To obtain microspheres with different surface functional groups, we performed a series of experiments in the presence of various dextran derivatives, taken in a concentration of 0.25 wt % (Table 2). We found that the concentration of carboxy groups on the surface of particles obtained in the presence of CMD, $CEDA_1$, and $CEDA_2$ is higher as compared to the microspheres prepared in the presence of dextran (Fig. 3). This may be due to incorporation of carboxyl-containing polymeric stabilizers into the surface layer of the microspheres. The diameter of these microspheres is somewhat larger than that of the particles formed in the presence of unmodified dextran. This fact suggests differences in the character of the particle stabilization and hence in the structure and strength of the forming surface layer, which may be caused by mutual repulsion of the ionic carboxy groups of the dextran derivatives as it was observed in preparation of microspheres in the presence of large amount of unmodified dextran.

The degree of ionization of carboxy groups in the surface layer of the particles was decreased by replac-

ing Na_2HPO_4 by KH_2PO_4 providing a more acidic medium. We found that, in the presence of dextran and KH_2PO_4, coarser monodisperse microspheres are formed (Table 2), which suggests that the electrostatic factor also contributes to their stabilization. This assumption is also supported by the polydispersity of latexes prepared in the presence of carboxylated dextran derivatives in a weakly acidic medium. By contrast, synthesis under the same conditions of a PMMA latex in the presence of a dextran derivative with nonionic aldehyde groups (DPA) gave a monodisperse latex in a good yield.

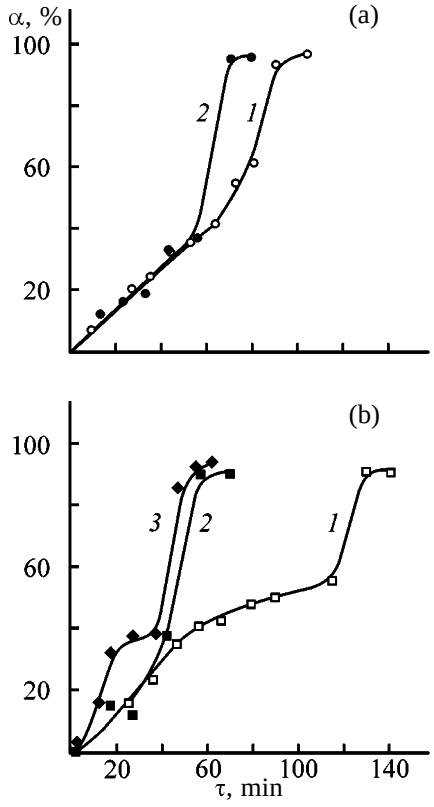

Fig. 4. Variation with time τ of MMA conversion α. Polymer added: (*1*) none, (*2*) dextran, and (*3*) DPA (0.25 wt %). Salt added: (a) Na_2HPO_4 and (b) KH_2PO_4.

To examine the influence of the composition of the reaction mixture on polymerization, we studied the conversion of MMA in the course of the synthesis in the presence of dextran or DPA, or without addition of a polymeric stabilizer. The reaction medium also contained Na_2HPO_4 or KH_2PO_4 (Fig. 4). In the weakly alkaline medium (Fig. 4a), the initial linear sections of the kinetic curves coincide for experiments performed in the presence and in the absence of dextran. However, in the presence of dextran this section is followed by sharp acceleration of the process, and the resulting particles are appreciably smaller than the microspheres obtained without adding dextran (Table 3). In the weakly alkaline medium, the kinetic curves of synthesis of PMMA microspheres in the presence of dextran or DPA show practically no linear section (Fig. 4b). The shape of the conversion curves depends on the nature of the steric stabilizer, which may be due to different structures of the forming surface layers. In the presence of dextran, highly viscous surface adsorption layers can form, restricting penetration of the growing radicals from the aqueous phase inside polymer–monomer particles (PMPs); as a result, the lifetime of the macroradical in PMP becomes

Table 3. Diameter d and number N of particles formed in experiments on determination of MMA conversion (Fig. 4)*

longer and the gel effect is enhanced. Presumably, with DPA formation of adsorption layers can be accompanied by grafting of PMMA by reaction of the growing radicals with DPA aldehyde groups. This process accelerates formation of PMPs at the beginning of the synthesis and enhances the aggregative stability of the PMPs owing to formation of stronger surface layers with chemical links between PMMA and DPA. Therefore, the number of particles formed in the presence of DPA appreciably increases (Table 3).

CONCLUSION

Emulsion polymerization of methyl methacrylate, initiated with a carboxyl-containing azo initiator and performed in the presence of dextran or its derivatives, allows preparation of monodisperse polymethyl methacrylate microspheres. The optimal preparation conditions were found, allowing control of the particle diameter (in the submicrometer range) and functionality (introduction into the surface layer of carboxy and aldehyde groups required for binding immunoreagents and of amide groups improving the biocompatibility of these microspheres).

Abstract—Radical polymerization of methyl methacrylate initiated by dicyclohexyl peroxydicarbonate in the presence of a chain-terminating agent, *C*-phenyl-*N*-*tert*-butylnitrone, as a potential source of stable nitroxyl radicals, was studied.

"Pseudoliving" radical polymerization is a relatively new field of synthetic polymer chemistry; in the past decade, it received much researchers' attention [1–6]. The main feature of such processes is termination of material chains by recombination of macroradicals with stable radicals added to control the chain propagation. In this case, a labile bond is formed at the end of the polymer chain, capable of cleavage with regeneration of the active macroradical:

$$\sim P_n^{\cdot} + A^{\cdot} \rightleftarrows [\sim P_n\text{–}A], \quad (1)$$

$$[\sim P_n\text{–}A] + M \rightarrow [\sim P_{n+m}\text{–}A], \quad (2)$$

where $A^{\cdot}$ is a stable radical.

As a result, the periods of "sleep" and "life" of polymer chains alternate, and the molecular weight of the polymer successively increases; as a result, polymers with narrow MWD are formed. The most widely used stable radicals acting as chain-terminating agents are sterically hindered nitroxyls [1–3]. In this case the "pseudoliving" mechanism is realized at relatively high temperatures exceeding 100°C. Under these conditions the chain termination on nitroxyls becomes reversible. It was shown previously that polymerization of methyl methacrylate (MMA) initiated by azobis(isobutyronitrile) (AIBN) in the presence of spin traps as potential sources of stable nitroxyl radicals, e.g., *C*-phenyl-*N*-*tert*-butylnitrone (PBN) [7] or 2-methyl-2-nitrosopropane (MNP) [8], occurs by the mechanism of pseudoliving chains at lower temperatures (323–343 K).

In this connection, it is interesting to study polymerization of MMA in the presence of PBN, initiated by the widely used commercial initiator, dicyclohexyl peroxydicarbonate (CPC).

EXPERIMENTAL

The monomer was purified by a common procedure [9]. PBN was prepared following the protocol in [10]. The physicochemical constants of the compounds agreed with published data. The polymerization kinetics was monitored gravimetrically, dilatometrically [11], and calorimetrically [12]. The samples were pretreated by the following procedure: The monomer was placed in a glass ampule, degassed by three freeze–pump–thaw cycles, and polymerized at a residual pressure of 1.3 Pa. The molecular weight was determined viscometrically [13]. The molecular-weight distribution (MWD) of polymethyl methacrylate (PMMA) was determined by gel-permeation chromatography (GPC) using a set of five styrogel columns with a pore diameter of 1×10^5, 3×10^4, 1×10^4, 1×10^3, and 250 Å (Waters, the United States). The detector was an R-403 differential refractometer (Waters), and the eluent was tetrahydrofuran. Narrow-MWD polystyrene references were used for calibration [14]. The recalculation of the average molecular weight from polystyrene to PMMA was done by the formula $\log M_{PMMA} = 1.019 \log (0.664 M_{PS})$.

We found that PBN as a potential source of stable nitroxyl radicals can efficiently control the kinetic parameters of CPC-initiated polymerization of MMA and the molecular-weight characteristics of the resulting polymer. Figure 1 shows the kinetic curves of polymerization, obtained gravimetrically. It is seen that addition of PBN in amount comparable with that

of the initiator suppresses the autoacceleration effect.

It is interesting and important from the practical viewpoint that PBN exerts no appreciable inhibiting effect on the propagation rate of the polymer chain (Table 1): The initial polymerization rate V_p, determined dilatometrically, in the presence of PBN decreases insignificantly. This fact is of major practical importance, because a significant drawback of presently known chain-terminating agents is their substantial decelerating effect on polymerization [1–3], which somewhat limits the efficiency of their industrial use.

0.4	–	82.2	2.5

The effect of nitrone on the kinetics of CPC-initiated polymerization of MMA is revealed still more clearly from the differential kinetic curves obtained calorimetrically at 323 K (Fig. 2). At successively increased concentration of nitrone, the autoacceleration effect considerably decreases and the lifetime of the polymer chain increases, which allows the gel effect, undesirable in commercial polymerization processes, to be practically totally suppressed.

The decrease in the gel effect is indirectly confirmed by the ratio of V_p of CPC-initiated MMA polymerization in the presence of various concentrations of PBN to the maximal rate, i.e., the rate in the stage of the gel effect V_g. As seen from Table 2, this ratio gradually decreases as the PBN concentration is increased and becomes close to 3.5 at a PBN concentration of 0.4 and 0.8 mol %.

Our results show that in the presence of CPC and PBN polymerization of MMA occurs by the mechanism of pseudoliving chains. The chain-terminating agents are stable nitroxyl radicals containing a macromolecular fragment and formed by the scheme

$$\sim P_n^{\cdot} + \underset{\displaystyle H\ \ O}{\overset{\displaystyle |\ \ \downarrow}{Ph–C=N–C_4H_9}} \rightarrow \underset{\displaystyle Ph\ \ O^{\cdot}}{\overset{\displaystyle |\ \ |}{\sim P_n Ph–CH–N–C_4H_9}} \quad (3)$$

$$A^{\cdot}$$

Then, the chain grows in the "living" chain mode [Eqs. (1), (2)].

The most exhaustive information on the possibility of realization of this mechanism under specific experimental conditions is furnished by measuring the molecular weight of the polymeric product as a function of conversion and by studying in detail the MWD of the synthesized samples.

The dependence on conversion of the MWD of PMMA prepared using the PBN–CPC system at a fixed concentration of nitrone is shown in Fig. 3. With increasing conversion, the curve shifts toward higher-molecular-weight products. The polydispersity coefficients somewhat increase with conversion but remain considerably lower than those of PMMA prepared with CPC initiator in the absence of PBN (Table 1). The increased polydispersity of PMMA synthesized with CPC initiator may be due to occurrence, along with the living mechanism, of bimolecular chain termination resulting in formation of a certain amount of the "dead" polymer.

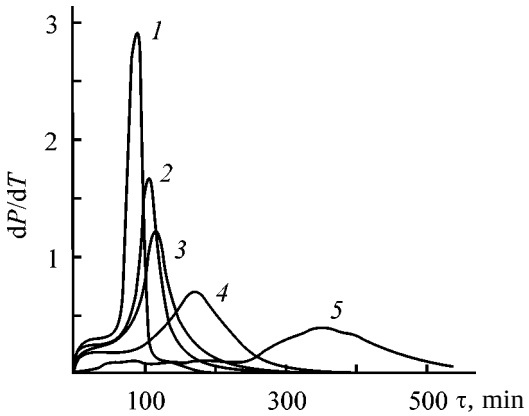

Fig. 2. Differential kinetic curves (d*P*/d*T*) of MMA polymerization in the presence of PBN at 323 K. (τ) Time. [PBN], mol %: (*1*) 0, (*2*) 0.1, (*3*) 0.2, (*4*) 0.4, and (*5*) 0.8.

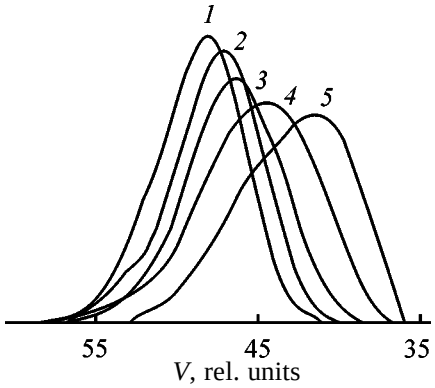

Fig. 3. GPC curves for PMMA samples of various conversions prepared at 323 K in the presence of 0.1 mol % CPC and 0.4 mol % PBN. (*V*) Volume. Conversion, %: (*1*) 3.1, (*2*) 11.0, (*3*) 35.8, (*4*) 62.1, and (*5*) 82.2.

Considerable differences between the polydispersity coefficients of polymers synthesized in the presence of PBN with AIBN and CPC initiators are probably due to the following factors.

First, the rate constants of the reactions of nitrone with the radicals produced by decomposition of these initiators differ. The rate constant of scavenging by the spin trap of the alkoxy radical $RO^{\cdot}$ generated by thermal decomposition of CPC is 10^7–10^8 l mol^{-1} s^{-1}, whereas for tertiary carbon-centered radicals, e.g., $[(CH_3)_2C(C{\equiv}N)^{\cdot}]$ or polymethyl methacrylate propagating radical, it is less than 0.8×10^4 l mol^{-1} s^{-1} [15]. In polymerization of MMA, the propagation rate constant is 0.7×10^3 l mol^{-1} s^{-1} [16], and the rate constant of addition of the alkoxy radical across the >C=C< bond is about 10^3–10^4 l mol^{-1} s^{-1} [17]. Probably, in the initial period of CPC-initiated MMA polymerization nitrone will be largely consumed for reaction with radicals generated by decomposition of CPC, in contrast to the AIBN-initiated MMA polymerization, because the constants of scavenging of alkoxy radicals with PBN are 2–4 orders of magnitude higher than those of the radicals generated by decomposition of AIBN and of similar radicals. Thus, in CPC-initiated MMA polymerization the chain propagation is controlled by nitroxyl radicals with the lower-molecular-weight fragment as compared to the AIBN-initiated polymerization when the nitroxyl spin adducts contain macromolecular polymeric chains. The structural differences between the nitroxyl spin adducts are responsible for some specific features of CPC-initiated MMA polymerization in the presence of PBN and for the increased polydispersity coefficients. Thus, nitroxyl radicals incorporating macromolecular fragments react with the propagating macroradical to form a less strong and hence more labile bond, which allows living polymerization to be performed under milder conditions.

Table 2. Ratio of the rate in the gel effect stage to the initial rate of MMA polymerization. T = 323 K, [CPC] = 0.1 mol %

[PBN], mol %	$V_g \times 10^4$	$V_p \times 10^4$	V_g/V_p
	mol l^{-1} s^{-1}		
–	45.9	5.8	7.9
0.1	25.9	4.6	5.6
0.2	18.9	4.1	4.6
0.4	10.9	3.0	3.6
0.8	5.8	1.7	3.4

Second, as noted above, the propagation constant in MMA polymerization and the rate constant of addition of the alkoxy radical to the double bond are 3–4 orders of magnitude lower than the rate constant of scavenging of the alkoxy radical by PBN. However, as the concentration of PBN is as low as 0.2–0.8 mol % relative to the monomer, the probability of reaction of the alkoxy radical with the monomer is many times higher than that of the reaction with PBN, which can result in formation of the dead polymer.

Third, at a relatively high initial concentration of nitroxyl radicals at the beginning of the process the decay of the propagating radicals mainly occurs by reversible recombination with nitroxyl radicals. In a certain period, polymerization continues owing to both reinitiation and initiation due do decomposition of the initiator. It should be noted that the half-life of CPC is much longer than that of AIBN at 323 K (40 and 4.5 h, respectively). Apparently, PBN initially reacts mostly with alkoxy radicals generated by decomposition of CPC to form a labile adduct capable

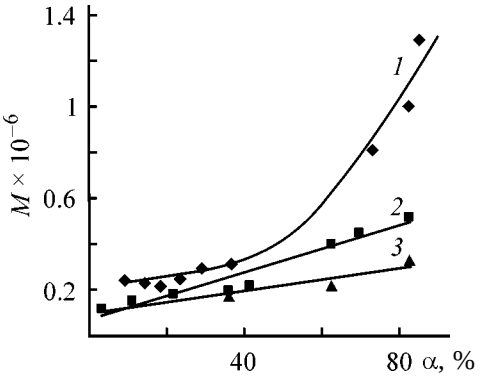

Fig. 4. Molecular weight M of PMMA as a function of conversion α. Initiator: 0.1 mol % CPC. Molecular weight: (*1*, *2*) viscosity-average and (*3*) number-average. [PBN], mol %: (*1*) 0 and (*2*, *3*) 0.4.

of subsequent decomposition and chain propagation. Owing to further radical generation by CPC, common radical polymerization occurs along with the living process, which results in formation of the dead polymer and hence in the increased polydispersity coefficient.

The data obtained indirectly show that polymerization is accompanied by steady growth of the average molecular weight of the resulting PMMA. To experimentally confirm this assumption, we studied the molecular weight of PMMA as a function of conversion (Fig. 4). The results show that in the presence of PBN the molecular weight linearly increases with conversion. This fact proves that the number of propagating chains remains constant in the course of polymerization, which is typical for polymerization in the pseudoliving chain mode.

CONCLUSIONS

(1) The kinetic features of polymerization of methyl methacrylate in the presence of *C*-phenyl-*N*-*tert*-butylnitrone and the molecular-weight characteristics of the resulting polymer show that in this system radical polymerization occurs in the living chain mode. In the presence of excess *C*-phenyl-*N*-*tert*-butylnitrone relative to dicyclohexyl peroxydicarbonate, the main decay pathway of the propagating radicals is their reaction with nitroxyl radicals. This fact determines the living character of polymerization, namely, steady increase in the molecular weight throughout the process, with practical absence of the gel effect.

(2) Our results allow *C*-phenyl-*N*-*tert*-butylnitrone to be considered as agent terminating the polymeric chain and controlling its lifetime; it shows promise for preparing macromolecules of preset structure under conditions of industrial synthesis of polymethyl methacrylate.

Abstract—Effect of molecular weight of poly-(1,2-dimethyl-5-vinylpyridinium methyl sulfate) on flocculation of aqueous kaolin suspension is studied.

Up-to-date water treatment processes suggest the use of reagents providing destabilization and enhanced separation of a dispersed phase contained in water [1, 2]. Among these reagents cationic polymer electrolytes usually show high performance. Their dissociation in a solution with formation of high-molecular-weight polycations ensures a complex flocculating effect by virtue of neutralization of a negative surface charge of suspended particles and simultaneous formation of bridging bonds between them [2, 3]. In our opinion, poly-(1,2-dimethyl-5-vinylpyridinium methyl sulfate) (poly-1,2-DM-5-VPMS) shows promise as such a cationic polyelectrolyte.

Previously we demonstrated that poly-1,2-DM-5-VPMS with desired molecular and rheological characteristics can be synthesized in the presence of a series of peroxide initiators, *tert*-butylperoxypropanol being the most efficient among them [4, 5]. Based on this result a process for synthesis of poly-1,2-DM-5-VPMS was developed and production of KF-91 cationic flocculant based on it was organized. This flocculant was tested in various processes [6], and its high performance as a reagent for water treatment is beyond question. However, we believe that the efficiency of using KF-91 may be increased by virtue of optimization of the process conditions.

In this work we studied the effect of the molecular weight of poly-1,2-DM-5-VPMS on flocculation of aqueous kaolin suspension.

EXPERIMENTAL

Poly-1,2-DM-5-VPMS was synthesized and isolated as in [5]. As a dispersion phase we used kaolin (KSD brand) with a mean particle size of 7 μm.

In flocculation experiments the kaolin concentration was 4%, and the poly-1,2-DM-5-VPMS concentration C_p was 0.0125–2.0 mg/g kaolin. The system was stirred, and the travel time of the flocculi/supernatant boundary from the first to the second mark on a cylinder was measured to estimate the sedimentation rate V_s. Also the turbidity of the supernatant τ was measured 30 min after.

From the experimental data thus obtained we determined the optimal concentrations of the polyelectrolytes. The criterion was the minimal turbidity of the supernatant, i.e., the maximal degree of clarification, and the maximal rate of floccule sedimentation. The clarification and flocculation factors D_τ and D_V were estimated by the following equations:

$$D_\tau = (\tau_0/\tau_{min}) - 1, \quad D_V = (V_{max}/V_0) - 1,$$

where τ_0 and τ_{min} are the supernatant turbidity, respectively, without and with the polyelectrolyte added in the optimal concentration; and V_0 and V_{max} are the floccule sedimentation rates under the same conditions.

Introduction of poly-1,2-DM-5-VPMS of various molecular weights considerably increases both the suspension sedimentation rate and the rate of sedimentation of flocculi of the kaolin suspension (Fig. 1). The supernatant turbidity plotted against the flocculant concentration shows extrema (Fig. 1a), which is typical of the systems solid–water–polyelectrolyte [1]. The polyelectrolyte concentration providing flocculation of the dispersed system ranges from 0.025 to

1070-4272/01/7403-0498$25.00

0.750 mg g^{-1}. Beyond this range the turbidity of treated water increases. In the case of lower concentrations this can be attributed to the presence of unflocculated and partially flocculated particles. At C_p > 0.750 mg g^{-1} this is due to stabilization of the suspension by the polyelectrolyte, which is particularly pronounced in the case of the lower-molecular-weight poly-1,2-DM-5-VPMS with $M_\eta = 1.7 \times 10^6$. For this sample efficient flocculation is observed only at a concentration of 0.125–0.200 mg g^{-1}. With increasing molecular weight of the flocculant the instability range of the system kaolin–water–flocculant expands.

Data on the floccule sedimentation rate are given in Fig. 1b. The concentration dependences of the sedimentation rate have extrema also. For the poly-1,2-DM-5-VPMS sample with M_η 1.7×10^6 the sedimentation rate only slightly changes with the concentration, ranging within 0.003–0.004 m s^{-1}. For the other samples the maximal sedimentation rate is observed at the flocculant concentration of 0.750–0.875 mg g^{-1}.

Figure 2 demonstrates the effect of the molecular weight of the polyelectrolyte on the clarification and flocculation factors. The clarification factor characterizing the degree of suspension sedimentation remains practically unchanged for the samples having lower molecular weights, and considerably increases with increasing molecular weight to $(3–5) \times 10^6$. The flocculating effect increases rapidly to M_η 3.5×10^6 and remains practically unchanged with further increasing molecular weight of the flocculant.

The results show a considerable effect of the molecular weight of poly-1,2-DM-5-VPMS on flocculation (Fig. 2). Most likely this effect is due to different flocculation mechanisms (surface charge neutralization and bridging bond formation mechanisms) prevailing at a given M_η. In the case of the flocculant with lower M_η having a high charge density on the polycation, flocculation proceeds predominantly by the charge neutralization mechanism. As a result, the clarification effect remains constant at $M_\eta = (1.7–3) \times 10^6$ (Fig. 2). In this case bridge formation contributes insignificantly because of small size of the macromolecules, as clearly demonstrated by data on the sedimentation rate, which does not increase with increasing concentration of the lowest-molecular-weight flocculant with $M_\eta = 1.7 \times 10^6$ (Fig. 1b). Increasing sedimentation rate and flocculation effect with increasing M_η is associated with increasing size of the flocculi primarily by the bridging bond formation mechanism. Therefore, a combination of a high molecular weight [$M_\eta = (3–5) \times 10^6$] and charge density (~ 4 mequiv g^{-1}) provides a condition for effective

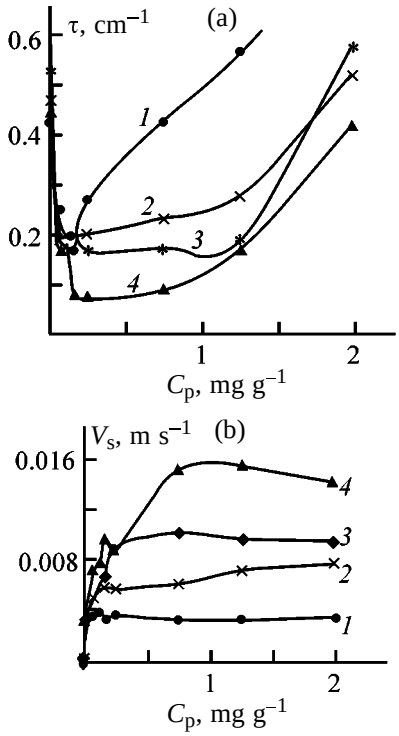

Fig. 1. (a) Residual turbidity of the supernatant τ and (b) floccule sedimentation rate V_s as functions of the concentration C_p of the polyelectrolyte of various molecular weights. $M_\eta \times 10^{-6}$: (*1*) 1.7, (*2*) 2.62, (*3*) 2.75, and (*4*) 5.31.

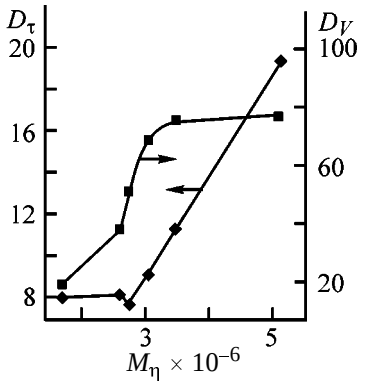

Fig. 2. Flocculation factor D_τ and clarification factor D_V as functions of the molecular weight of poly-1,2-DM-5-VPMS M_η.

adsorption of the polymer on the dispersed particles, decreasing surface charge, and formation of bridging bonds. However, to confirm the proposed flocculation mechanism, it is necessary to study adsorption of poly-1,2-DM-5-VPMS on the dispersed particles as well as the polyelectrolyte effect on the electrokinetic properties and disperse composition of the dispersions in more detail.

At present time widely spread flocculants are various cationic and anionic derivatives of polyacrylamide

(PAA). It was demonstrated [7, 8] that sequential introduction of PAA cationic and anionic derivatives provides the best flocculation effect for kaolin. However, in this case D_V changes from 3 after introduction of a cationic derivative to 10 after additional treatment with an anionic PAA [9], whereas introduction of poly-1,2-DM-5-VPMS increases D_V to 9–70.

The results obtained showed that the flocculation efficiency of poly-1,2-DM-5-VPMS as a function of M_η is the highest at $M_\eta = (3–5) \times 10^6$. This fact should be taken into account in practical use of commercial flocculants based on poly-1,2-DM-5-VPMS from various sources. Thus, the molecular weight of poly-1,2-DM-5-VPMS of PPS brand is $(1.5–1.8) \times 10^6$ [10] or 2.5×10^6 [9]. Therefore, according to our results, its flocculating effect is relatively low. KF-91 flocculant has a higher M_η [$(3–4) \times 10^6$] [5, 6], so that it can be recommended for separation of dispersions.

Indeed, it was demonstrated in [6] that KF-91 flocculant shows higher performance in treating wastewater of various origins as compared to other flocculants. Water treated with KF-91 is characterized by the lowest residual content of suspended and oxidizable (organic) compounds. The performance of this flocculant is well comparable with that of Sedipur (BASF) [6]. Furthermore, KF-91 has the maximal biodissimilation coefficient (BDC = COD/BOD) characterizing biodegradation of the residual flocculant in water. The high BDC of KF-91 (0.84) (for comparison, BDC of Sedipur is 0.58) characterizes it as the most environmentally friendly reagent among the related ones.

CONCLUSION

Poly-(1,2-dimethyl-5-vinylpyridinium methyl sulfate) demonstrates high flocculation effect on aqueous kaolin suspension, which allows recommendation of this polyelectrolyte for treatment of water to remove suspended material. The results obtained suggest that higher-molecular-weight samples of poly-1,2-DM-5-VPMS with $M_\eta = (3–5) \times 10^6$ should provide stronger flocculation effect in separation of concentrated suspensions and dewatering of precipitates. The optimal flocculant concentration was found to be 0.03–0.90 mg g^{-1}, depending on the dispersion nature and concentration.

Abstract—An experimental study is made of the effect of the solution ionic strength and the nature of a cation (Li, Na, K, Mg, Ca, Sr, and Ba) on fixation of counterions on polysulfonate anions in aqueous solutions of poly-2-acrylamido-2-methylpropanesulfonic acid and copolymers of acrylamide and *N*-vinylpirrolidone with 2-acrylamido-2-methylpropanesulfonic acid.

It is well known that the nature of interaction of polyions with counterions considerably influences the thermodynamic and hydrodynamic properties of polyelectrolyte solutions [1] and also controls the conformation state and reactivity of macroradicals growing in radical polymerization of ionic monomers in ionizing media [2]. It was demonstrated previously that the nature of a cation has an effect on radical polymerization of Li, Na, and K [3] and Mg, Ca, and Ba salts of 2-acrylamido-2-methylpropanesulfonic acid (HAMS) [4] and copolymerization of acrylamide (AA) with Li, Na, and K salts of HAMS in aqueous solutions [5] and also on flocculating properties of poly-2-acrylamido-2-methylpropanesulfonic acid (HPAMS) salts [6]. To gain a better insight into the effect of the nature of cations on polymerization and copolymerization of HAMS salts in aqueous solutions and also on the properties of the resulting polymers, in this work we studied the features of fixation of single-charged (Li, Na, K) and double-charged cations (Mg, Ca, Ba) on polysulfonate anions in aqueous solutions of HPAMS and copolymers of acrylamide and *N*-vinylpirrolidone (*N*-VP) with HAMS salts.

EXPERIMENTAL

In the work we used samples of NaPAMS and copolymers of AA and *N*-VP with NaAMS obtained by radical polymerization and copolymerization of the monomers in aqueous solutions. For polymerization we used HAMS [Lubrizol 2404, mp 185°C (Lubrizol Corp., the Great Britain)]; acrylamide [mp 84.5°C (Mitsubishi Chem. Ind., Ltd., Japan)]; and *N*-vinylpirrolidone (Merck, FRG) purified by vacuum distillation in the presence of 0.1% KOH. All other chemicals used were of chemically or analytically pure grade. NaAMS was prepared by neutralization of HAMS to pH 9 in an aqueous solution by titration with NaOH. The copolymerization procedure was as in [7]. After copolymerization the resulting polymers were precipitated by adding aqueous solutions into acetone, filtered, washed with acetone, and vacuum-dried to constant weight at room temperature. The characteristics of the polymers used in this work are summarized in the table.

Before carrying out viscometric measurements the samples of NaPAMS and AA/NaAMS and *N*-VP/NaAMS copolymers were converted into the H form on KU-2×8 cation-exchange resin.

The intrinsic viscosity $[\eta]$ of the polymers was determined in 0.5 NaCl at 25 ± 0.5°C using an Ubbelohde viscometer (capillary diameter 0.56 mm). The viscosity-average molecular weight of the polymers M_η was estimated as follows [8]:

$$[\eta] = 1.95 \times 10^{-5} M_\eta^{0.83},$$

where $[\eta]$ is expressed in dl g^{-1}.

The composition of AA/NaAMS and *N*-VP/NaAMS copolymers (SO_3H group content) was determined by titration with NaOH after conversion of the copolymers into the H form on KU-2×8 cation-exchange resin.

The reduced viscosity η_{sp}/C_p, where η_{sp} is the specific viscosity and C_p is the copolymer concentration, was determined at various solution ionic strengths μ

where R = –NH–C(CH$_3$)$_2$–CH$_2$–SO$_3$Na.

provided by adding inorganic salts. The measurements were performed with a VPZh-3 viscometer (capillary diameter 0.43 mm) at 30°C and C_p = const. In determination of η_{sp}/C_p the viscosities of the polymer solutions and a solvent was measured at the same μ.

In studying the state of the macromolecules of HPAMS salts and copolymers of AA and *N*-VP with HAMS salts in water and aqueous salt solutions one should take into account the effect of the medium on the ionization equilibrium of ionic groups:

$$\underset{\mathbf{I}}{A^-X^+} \rightleftarrows \underset{\mathbf{II}}{A^- \| X^+} \rightleftarrows \underset{\mathbf{III}}{A^- + X^+},$$

where A^- is a macroanion, X^+ is a cation, and **I, II**, and **III** are, respectively, contact ion pairs, ion pairs separated by a solvent, and free ions.

Increasing μ and the degree of association of cations with polysulfonate anions results in a shift of the ionization equilibrium to the left and hence in weakening of the Coulombic repulsion between similarly charged units along the macromolecular chain. This leads also to decreasing effective size of the macromolecular globules $\langle r^2 \rangle^{1/2}$ and manifests itself in decreasing η_{sp}/C_p measured at C_p = const. Therefore, the shape and size of the polyelectrolyte macromolecules can be characterized on the basis of η_{sp}/C_p [9, 10]. The reduced viscosity can be used also in solving the reverse task, i.e., in determination of the degree of association of cations with the polyanions, as we made in this work. The effect of the nature of cations on the degree of their association with the polyanions was studied with HPAMS samples of various molecular weights (samples **A** and **B**), and in the case of copolymers of AA and *N*-VP with HAMS, with samples of various molecular weights (estimated from $[\eta]$) and various chemical compositions of the macromolecules (samples **C, D, E, F**).

Let us analyze the dependence of η_{sp}/C_p of HPAMS (sample **A**) solutions on μ preset by additions of inorganic salts of single-charged (Li_2CO_3, NaCl, KCl) and double-charged cations ($MgCl_2$, $CaCl_2$, $SrCl_2$, $BaCl_2$) (Fig. 1a). The results show that the reduced viscosity decreases with increasing μ, which can be attributed, as noted above, to decreasing effective size of the macromolecular globules as a result of weakening Coulombic repulsion between similarly charged units along the macromolecular chain. At a given μ the reduced viscosity decreases in the order $Li^+ > Na^+ > K^+ > Mg^{2+} > Ca^{2+} > Sr^{2+} > Ba^{2+}$ (Fig. 1a, curves *1*–*7*). Similar pattern was observed for another HPAMS sample (B) at C_p = 0.5%. These effects are due to increasing degree of association of the counterions with polysulfonate anions with increasing μ and cationic radius in the order $Li^+ < Na^+ < K^+ < Mg^{2+} < Ca^{2+} < Sr^{2+} < Ba^{2+}$.

These results are consistent with the fact that the degree of association of Na^+ in NaPMS solutions increases with the ionic strength [11] and also with data on the degree of association of alkali and alkaline-earth metal ions in solutions of other strong polyelectrolytes such as poly-*p*-styrenesulfonic and polyethenesulfonic acids, obtained by various physicochemical methods [12].

The degree of association of single- and double-charged cations with the polyions of AA/HAMS copolymers was determined for samples **C** and **D** having different chemical composition and $[\eta]$. Data on η_{sp}/C_p for sample **C** (AA/HAMS copolymer) as a function of μ preset by addition of salts of single- (LiCl, NaCl, KCl) and double-charged cations ($MgCl_2$, $CaCl_2$, $SrCl_2$, $BaCl_2$) are given in Fig. 1b. The results show that as μ increases, the reduced viscosity decreases as a result of reduction of the size of macromolecular globules $\langle r^2 \rangle^{1/2}$. At μ = const η_{sp}/C_p decreases in the order $K^+ < Na^+ < Li^+ < Ba^{2+} < Sr^{2+} <$

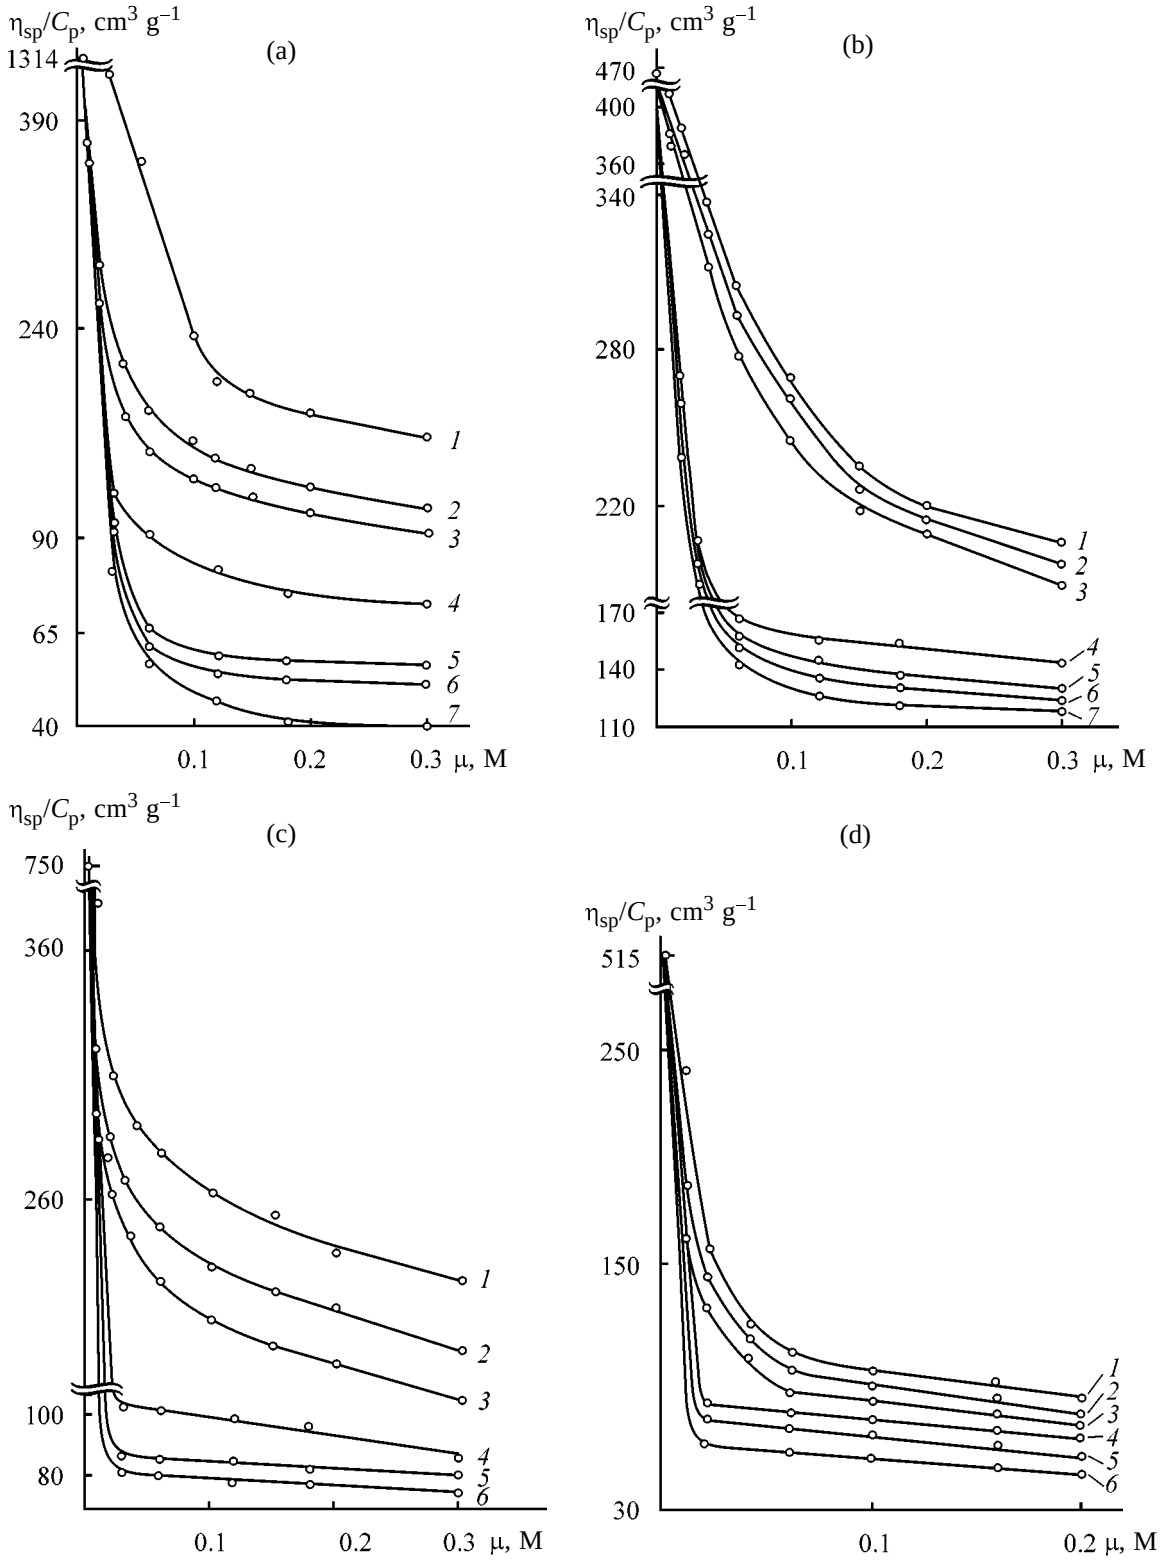

Fig. 1. Reduced viscosity η_{sp}/C_p of aqueous solutions of samples (a) **A**, (b) **C**, (c) **E**, and (d) **F** as a function of the ionic strength μ at C_p = 0.1%. Supporting electrolyte: (a) (*1*) Li_2CO_3, (*2*) NaCl, (*3*) KCl, (*4*) $MgCl_2$, (5) $CaCl_2$, (6) $SrCl_2$, and (*7*) $BaCl_2$; (b) (*1*) KCl, (*2*) NaCl, (*3*) LiCl, (*4*) $BaCl_2$, (*5*) $SrCl_2$, (*6*) $CaCl_2$, and (*7*) $MgCl_2$; and (c, d) (*1*) KCl, (*2*) NaCl, (*3*) Li_2CO_3, (*4*) $BaCl_2$, (*5*) $CaCl_2$, and (*6*) $MgCl_2$.

$Ca^{2+} < Mg^{2+}$ (Fig. 1b, curves *1–7*). The similar pattern was obtained for sample **D** also. Figure 1b demonstrates strong decrease in η_{sp}/C_p on passing from single- to double-chagred cations (at C_p = const), which can be attributed to more effective shielding by them of the polyanion charges and also to contraction caused by the chelation effect. Results obtained with copolymers with various molecular characteristics over a wide range of the supporting electrolyte concentrations suggest that the degree of association of the cations with polysulfonate anions of the AA/HAMS copolymers increases with increasing μ. Depending on the nature of the cation the degree of association increases in the order $K^+ < Na^+ < Li^+ < Ba^{2+} < Sr^{2+} < Ca^{2+} < Mg^{2+}$.

As in the case of AA/NaAMS copolymers (Fig. 1b), for *N*-VP/HAMS copolymers with various molecular characteristics (samples **E** and **F**) the degree of association of cations with the polyanions increases with increasing μ. Similarly, depending of the nature of the cation the degree of association increases in the order $K^+ < Na^+ < Li^+ < Ba^{2+} < Ca^{2+} < Mg^{2+}$ (Figs. 1c and 1d).

Thus, in the case of AA/HAMS and *N*-VP/HAMS copolymers the effect of the nature of cations on the degree of association differs from that observed for HPAMS homopolymers. It should be pointed out that under the experimental conditions changing chemical composition and molecular weight of the polymers (see table) did not change the order of variation of the degree of association of cations with the polyanions. It may be suggested that the observed trends are caused by interaction between the sulfonate and amide groups in the case of AA/HAMS [13] and *N*-VP/HAMS copolymers [14].

To conclude, the general nature of observed trends of counterionic association in solutions of the polyelectrolytes studied was demonstrated in experiments with polymers and copolymers with various molecular characteristics over wide concentration ranges of copolymers and supporting electrolytes. The results obtained allows general interpretation of the effect of the nature of a cation on the kinetics of homopolymerization of HAMS salts [3, 4] and of their copolymerization with AA [5] and *N*-VP in aqueous solutions.

CONCLUSIONS

(1) In poly-2-acrylamido-2-methylpropanesulfonic acid solutions the degree of association of cations with the polyanions increases with increasing ionic strength and cationic radius in the order $Li^+ < Na^+ < K^+ < Mg^{2+} < Ca^{2+} < Sr^{2+} < Ba^{2+}$.

(2) In the case of AA/HAMS and *N*-VP/HAMS copolymers the degree of association of cations with the polyanions increases with increasing ionic strength also, but the effect of cations on the degree of association differs from that for HPAMS, changing, respectively, in the order $K^+ < Na^+ < Li^+ < Ba^{2+} < Sr^{2+} < Ca^{2+} < Mg^{2+}$ and $K^+ < Na^+ < Li^+ < Ba^{2+} < Ca^{2+} < Mg^{2+}$.

Abstract—Kinetic features of homogeneous radical copolymerization of acrylamide with magnesium 2-acrylamido-2-methylpropanesulfonate in concentrated aqueous solutions in the presence of the initiating system potassium peroxosulfate–sodium hydrosulfite at pH 9 and 50°C were studied by dilatometric technique.

Copolymers of acrylamide (AA) with salts of 2-acrylamido-2-methylpropanesulfonic acid (H-AMS) are the efficient flocculants, stabilizers, lubricants, and thickening agents. They are used in water purification, hole drilling, and oil production [1, 2]. Valuable commercial characteristics of copolymers, insufficient data on their synthesis, and specific kinetic effects in copolymerization of ionogenic monomers [3, 4] motivate the urgency of studying copolymerization of AA with salts of H-AMS. It is well known [3, 4] that one of the factors of the efficient control of (co)polymerization of ionogenic monomers is ionic strength of a solution μ. The effect of the ionic strength μ on polymerization [5, 6] and copolymerization of AA with salts of single-charged cations and H-AMS [7] was studied previously. In this report, we considered the effect of μ on the features of radical copolymerization of AA with magnesium salt of H-AMS (Mg-AMS) in aqueous and aqueous-salt solutions.

EXPERIMENTAL

We used acrylamide produced by the Mitsubishi Chem. Ind. Ltd. (mp 84.5°C), H-AMS (mp 185°C) produced by the Labrizol Corp., cation exchanger KU-2 × 8 [GOST (State Standard) 10896–78], distilled water, and other chemicals of chemically pure grade. The copolymer of Mg-AMS was produced by neutralization of H-AMS to pH 9 in aqueous solution under the action of 20% suspension of $Mg(OH)_2$ and was used in the form of aqueous solution.

Copolymerization was carried out in dilatometers to low conversion (x < 4%) and in glass weighing bottles to high conversion. The procedures of copolymerization and dilatometric study of copolymerization kinetics were similar to those described in [7]. After completing the copolymerization, the copolymers were precipitated from aqueous solutions to acetone, washed with acetone, and dried at room temperature in a vacuum drier to constant weight. The yield of copolymers was determined gravimetrically, and the chemical composition was determined by elemental analysis for sulfur [8].

Potentiometric measurements were carried out on a pH-121 unit with the use of glass (ESL 63-07) and silver chloride (EVL 1M3) electrodes at 25°C.

The molecular weight of copolymers was evaluated from the intrinsic viscosity [η] of the solutions, determined by isoionic dilution in 0.5 M NaCl in an Ubbelohde viscometer (d_c = 0.5 mm) at 25°C.

Copolymerization of AA (M_1) with Mg-AMS (M_2) was carried out in concentrated aqueous solutions of the monomeric mixture ([M_1 + M_2] = 10–20%) at pH 9 and 50°C. The reaction was initiated by the system potassium peroxosulfate (PP)–sodium hydrosulfite (SHS), which is widely used and is highly efficient in polymerization of water-soluble monomers. The reaction was carried out at PP concentration of 5.2×10^{-4} and SHS concentration of 3.5×10^{-4} M. The pH was kept at the level of 9, which excluded hydrolysis of Mg-AMS [9] and imidization of amide groups [10] and also provided highly efficient initiation of copolymerization by the system PP–SHS [11] and constancy of the initiation rate at variation of Mg-AMS concentration and addition of low-molecular-weight salts, since the rate of PP decay in alkaline media is independent of μ [12]. Preliminary experi-

ments confirmed that under experimental conditions copolymerization of AA with Mg-AMS does not proceed in the absence of initiators and, in the presence of initiators, proceeds under homogeneous conditions at any conversion owing to sufficiently high solubility of the monomers and copolymers in water.

The effect of the ionic strength on copolymerization of AA with Mg-AMS was evaluated in experiments with variation of the initial concentration of Mg-AMS and addition of the low-molecular-weight salt $MgCl_2$. In so doing, we took into account that the apparent reactivity in copolymerization of AA is independent of μ [13, 14]. The kinetic data on the process were obtained from the linear portions of the kinetic curves of copolymerization, plotted from the dilatometric data at low conversions ($x < 4\%$). The kinetic parameters of copolymerization are listed in Table 1. It is seen that with increasing initial concentration of Mg-AMS the initial rate of copolymerization v_0, yield, and molecular weight of copolymers increase in parallel. The rate v_0 also increased with an increase in the concentration of the low-molecular-weight electrolyte $MgCl_2$ in the range 0.1–0.5 M in the experiments performed at a constant concentration of the mixture M_1 + M_2 (Fig. 1). To determine the reaction order of copolymerization with respect to Mg-AMS concentration, we analyzed data in Fig. 2. In the studied range of Mg-AMS concentrations the dependence $\log v_0$–log[Mg-AMS] is not linear (Fig. 2a, curve *1*). In passing to solutions with higher concentrations of the monomer (0.35–0.59 M) the reaction order with respect to Mg-AMS increases from 1.5 to 1.7. The similar variation of the reaction order with respect to the monomer was observed in polymerization of *N*,*N*-diethylaminoethyl methacrylate hydrochloride [15], potassium and sodium salts of H-AMS [5, 6], and also in copolymerization of AA with Na salt of H-AMS [7], which is caused by an increase in viscosity of the reaction mixture [5].

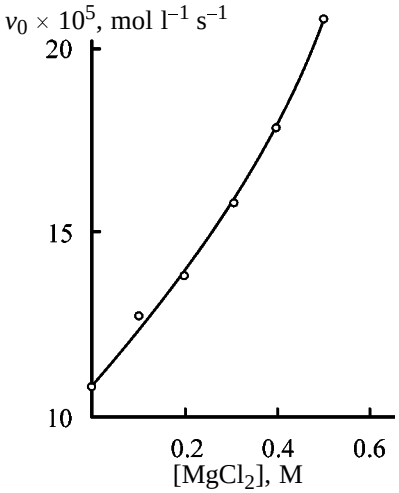

Fig. 1. Initial rate of copolymerization of AA with Mg-AMS v_0 in aqueous solutions as a function of concentration [$MgCl_2$]. [AA + Mg-AMS] = 10%, molar ratio [AA] : [Mg-AMS] = 5 : 5.

To establish the equation for the total rate of copolymerization of AA with Mg-AMS, we performed the experiments for variable concentrations of AA and the components of the initiating system with the concentrations of the other components and the reaction conditions kept constant. The effect of the AA concentration on copolymerization was evaluated in the range 0.14–0.48 M. It is evident from Fig. 2a (curve *2*) that with an increase in AA concentration v_0 decreases, and the reaction order of copolymerization with respect to AA is equal to 1. The effect of PP and SHS concentrations on copolymerization is illustrated in Fig. 2b and Table 2. From Fig. 2b and Table 2 it follows that with increasing concentrations of PP and SHS v_0 and the yield of the copolymers increase and the molecular weight decreases. The decrease in the molecular weight with increasing concentration of PP (Table 2) is caused by the increase in the concentration of free radicals in the system, which is typical of radical copolymerization. The decrease in the molecular weight with increasing concentration of SHS (Table 2) may be due to growing contribution of chain transfer to the macroradical ~M$^{\cdot}$, which can be represented by the scheme

$$\sim M^{\cdot} + HSO_3^- \longrightarrow \sim MH + SO_3^{-\cdot}. \qquad (1)$$

In aqueous solutions, HSO_3^- ions are formed at 20°C when [SHS] < 10^{-3} M, which can be presented

by the scheme

$$S_2O_5^{2-} + H_2O \longrightarrow 2HSO_3^-. \quad (2)$$

From data in Fig. 2b, we determined the orders of the copolymerization with respect to the concentrations of PP and SHS, which are 0.5 and 0.1, respectively. Based on the results of the experiment, we found the empirical equation for the total rate of copolymerization of AA with Mg-AMS, which is as follows:

$$v_c = k_c[AA]^{1.0}[\text{Mg-AMS}]^{1.5}[PP]^{0.5}[SHS]^{0.1}, \quad (3)$$

where k_c is the rate constant of copolymerization.

In Eq. (3) $k_c = (k_g/k_t^{1/2})(2fk_{dec})^{1/2}$, where k_g, k_t, and k_{dec} are the rate constants of chain growth and termination and of initiator decomposition, respectively; f is the initiation efficiency.

Taking into account the reaction orders found by Eq. (3), we evaluated the k_c values presented in Table 1. It is seen that with increasing the initial concentration of Mg-AMS the k_c values initially increase and then become constant at [Mg-AMS] > 0.35 M. This variation of k_c can be caused by variation of μ. The effect of μ on the rate constant of the reaction between A and B ions can be determined from the Debye–Hückel theory by the simplified equation

$$\log k = \log k_0 + 2Z_AZ_B\gamma\mu^{1/2}, \quad (4)$$

where k_0 is the rate constant of the reaction at $\mu = 0$, Z_A and Z_B are the degrees of oxidation of A and B ions, and γ is a constant for the given solvent and temperature. Equation (4) can be used for estimation of the effect of μ on copolymerization with participation of ionogenic monomers. The experimental data presented in the coordinates of Eq. (4) are shown in Fig. 3. The increase in $k_c = (k_g/k_t^{1/2})(2fk_{dec})^{1/2}$ with increasing μ, observed in Fig. 3 at low μ, is caused by an increase in the k_g/k_t ratio, since under the experimental conditions $k_{dec} \neq f(\mu)$ [12]. An increase of μ weakened the electrostatic repulsion of sulfonate

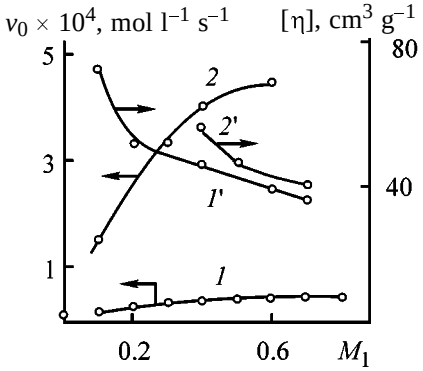

Fig. 5. Dependences of (*1*, *2*) copolymerization initial rate v_0 and (*1*', *2*') [η] of copolymers of AA with Mg-AMS on the mole fraction of AA in the initial monomeric mixture M_1. [AA + Mg-AMS] (%): (*1*, *1*') 10 and (*2*, *2*') 20.

anions in Mg-AMS and in terminal units of Mg-AMS macroradicals (in the events of chain growth) and also between sulfonate anions at the ends of two macroradicals (in the events of chain termination). This should favor increase in k_g and k_t. It is evident that with increasing μ the predominant increase in k_g is the reason of an increase in $k_g/k_t^{1/2}$ and k_c values, since in this case the molecular weights of the resulting copolymers increased (Table 1). In the range of low μ the conformation state of the macromolecules also varied, which was confirmed by data presented in Fig. 4. As seen, with increasing μ η_{sp}/C_p decreased (at C_p = const) owing to weakening of electrostatic repulsions of like charges of macromolecules and contraction of macromolecular globules in the solution. At high μ, η_{sp}/C_p varied slightly at changing μ (Fig. 4). This is caused by stabilization of the size of the copolymer macromolecules, which evidently leveled the accessibility of the growing macroradical for the ionogenic monomer and the reactivity of Mg-AMS in copolymerization. As a result, k_g and k_t did not vary and the ratio $k_g/k_t^{1/2}$ and k_c were constant in the range of high μ (Fig. 3).

Let us consider the effect of the composition of the initial monomeric mixture on copolymerization of AA with Mg-AMS. As seen from Fig. 5, throughout the studied range of the initial ratios of monomers at $[M_1 + M_2]$ = const an increase in the AA content in the monomeric mixture results in an increase in v_0 (curves *1*, *2*) and a decrease in [η] (curves *1*', *2*') of the copolymers. These data suggest higher reactivity of AA in copolymerization in comparison with Mg-AMS and formation of copolymers with higher molecular weight in monomeric mixtures enriched with Mg-AMS units. It is also seen from Fig. 5 that with increasing initial concentration of the monomeric mixture $M_1 + M_2$ the v_0 values (passing from curve *1* to curve *2*) and the molecular weights (passing from curve *1*' to curve *2*') increase.

In Fig. 6 is presented the instant composition of the copolymer as a function of composition of the initial monomeric mixture in copolymerization of AA with Mg-AMS. This curve corresponds to the relative activities of monomers $r_{AA} < 1$ and $r_{Mg\text{-}AMS} < 1$. The values of r_{AA} and $r_{Mg\text{-}AMS}$ were not determined, since in the system under consideration the variation of the ionic strength of the solution under conditions of synthesis (owing to variation of μ with variation of the Mg-AMS concentration and in the course of the reaction) results in variable copolymerization constants; therefore, copolymerization cannot be de-

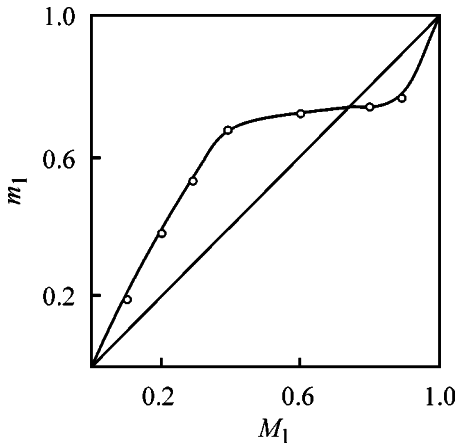

Fig. 6. Composition of copolymer of AA with Mg-AMS as a function of AA mole fraction in the initial monomeric mixture M_1 at the conversion $x < 4\%$. [AA + Mg-AMS] = 10%. (m_1) Mole fraction of AA units in the copolymer.

scribed by fixed constants with the use of classic equations [4].

The above data suggested the possibility of production of macromolecular copolymers of AA with Mg-AMS with a high yield and controllable values of v_0, molecular weight, and copolymer composition by copolymerization of monomers in concentrated solutions in water and aqueous-salt solutions.

CONCLUSIONS

(1) The copolymerization rate v_0 increases with increasing concentration of the monomeric mixture acrylamide + Mg 2-acrylamido-2-methylpropanesulfonate, acrylamide, Mg 2-acrylamido-2-methylpropanesulfonate, potassium peroxosulfate, and sodium hydrosulfite, and also on addition of $MgCl_2$. The k_g/k_t ratio increases with increasing μ in the range of low μ and does not vary in the range of high μ.

(2) The intrinsic viscosities [η] of copolymers increase with increasing concentration of the mixture acrylamide + Mg 2-acrylamido-2-methylpropanesulfonate and Mg 2-acrylamido-2-methylpropanesulfonate and also with decreasing concentration of potassium peroxosulfate and sodium hydrosulfite.

(3) The reactivity of acrylamide in copolymerization is relatively high in comparison with Mg 2-acrylamido-2-methylpropanesulfonate.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Ionic Polyacrylamide Flocculants as Promoters of Sedimentation of Ocher Suspension and Thickening of Its Precipitates in Aqueous and Aqueous-Salt Solutions

V. E. Proskurina and V. A. Myagchenkov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received June 8, 2000

Abstract—The kinetic features of flocculation of an ocher suspension and thickening of its precipitate in aqueous and aqueous-salt solutions containing ionic and nonionic acrylamide copolymers with different composition and molecular properties were studied.

Water-soluble arylamide (co)polymers produced in large scale are widely used in industry as highly efficient, cheap, readily available, and technologically safe flocculants and stabilizers of various dispersion systems (DSS) [1–3].

The performance of polyacrylamide flocculants (PAAFs) depends not only on their chemical nature and molecular parameters, the nature and physicochemical properties of the dispersed phase (DP) (first of all the specific surface area, concentration of the adsorption centers, lyophilic nature of the surface, etc.), and the nature of dispersion medium, but also on the conditions of sedimentation of the DP (free or hindered) and parameters of the flocculation process [4]. The study of the correlation between flocculation processes under conditions of hindered sedimentation and thickening of the precipitates [5, 6] is of scientific and practical interest since kinetics of these processes is poorly understood [7, 8].

It should be noted that the liquid phase of a number of DSs used in practice contains various active additives (in particular, salt additives) which can strongly affect the flocculation.

In this work we studied the kinetic features of flocculation of model DS, an ocher suspension, and thickening of the precipitate in aqueous and aqueous-salt (0.5 N NaCl) media in the presence of nonionic and ionic (anionic and cationic) PAAFs with different compositions and molecular properties.

EXPERIMENTAL

We studied five samples of PAAFs differing in the chemical nature of the copolymer and molecular parameters: nonionic polyacrylamide (N) and ionic (A_1, A_2, C_1, and C_2) copolymers of acrylamide with different concentrations of ionic units. The viscosity-average molecular weight of sample N with the structural formula

$$(-CH_2-\underset{\displaystyle CONH_2}{\underset{|}{CH}}-)_n$$

is $\overline{M}_\eta = 7.4 \times 10^6$. Anionic PAAFs ($A_1$ and A_2) are random copolymers of acrylamide with sodium acrylate with viscosity-average molecular weight $\overline{M}_\eta = 5.4 \times 10^6$ and $\overline{M}_\eta = 7.66 \times 10^5$ and content of ionic units $\beta = 17.4$ and $\beta = 80\%$, respectively. Samples C_1 and C_2 are random copolymers of acrylamide and dimethylaminoethyl methacrylate hydrochloride with $\overline{M}_\eta = 2.3 \times 10^6$ and 1.06×10^6, $\beta = 16.3$ and 62%, respectively.

The viscosity-average molecular weight $\overline{M}_\eta$ of the flocculants was calculated from the intrinsic viscosity $[\eta]$ by the Mark–Houwink equation

$$[\eta] = K\overline{M}_\eta^a, \quad (1)$$

where K and a are tabulated constants [9, 10].

To eliminate the polyelectrolytic effect in determination of $[\eta]$, 0.5 N aqueous solution of NaCl was used as the solvent.

To provide more reliable and comprehensive estimation of the flocculating properties of acrylamide (co)polymers, we also studied polyoxyethylene (POE) widely used in industry. The viscosity-average molecular weight of POE having the structural formula $(CH_2–CH_2–O)_n$ is $\overline{M}_\eta = 2.2 \times 10^6$.

1070-4272/01/7403-0510$25.00

The kinetics of sedimentation of an ocher suspension ["golden" trade name, TU (Technical Specifications) 301-019–90] under hindered conditions [4] in the presence of the tested polymeric additives (in all experiments the initial concentration of DP was C_d = 8%) was studied in 2000-ml volumetric cylinders by the shift of the boundary between the clarified and nonclarified suspension. This method allows reliable monitoring of the sedimentation in the steps of both accelerated sedimentation (flocculation) and thickening of the precipitate [11, 12].

Ocher was kept in the dispersion medium for 1 day. The suspension was mixed by 10-fold overturn of the cylinders just before the experiment.

The flocculation effect was quantitatively characterized by the specific dimensionless parameter D:

$$D = (\bar{V}/\bar{V}_0) - 1, \quad (2)$$

where $\bar{V}$ and $\bar{V}$ are average sedimentation rates of DF in the presence and in the absence of the flocculants, respectively.

It should be noted that in all experiments $\bar{V}$ and $\bar{V}_0$ were measured at constant degree of clarification of the working suspension Q = 0.5.

The efficiency of the polymeric additives was quantitatively estimated by the flocculating power λ [1]:

$$\lambda = \frac{(\bar{V}/\bar{V}_0 - 1)}{C} = \frac{D}{C}, \quad (3)$$

where C is the flocculant concentration.

When D and λ are positive, a polymeric additive is a flocculant; at $D < 0$ and $\lambda < 0$ it is a stabilizer.

Viscometric analysis of PAAF and POE solutions was performed on an Ostwald viscometer with a capillary 0.54×10^{-3} m in diameter. The correction for the kinetic energy of the flowing liquid was less than 1.5% and was neglected in calculation of the viscosity numbers:

$$\frac{\eta_{sp}}{C} = \frac{\tau - \tau_0}{\tau_0 C}, \quad (4)$$

where τ and τ_0 are the time of effluence of solution with the polymer concentration C and the solvent, respectively.

Let us consider the kinetics of flocculation of an ocher suspension in water in the presence of PAAF and POE. The kinetic curves are shown in Fig. 1. To simplify comparison of curves *2–7*, the amount of flocculants introduced in the suspension was the same (2×10^{-3}%). Considerable differences in the location of curves *5*, *7* and *2*, *4* (Fig. 1) and hence in the flocculation effects D and flocculation power λ (see table) can be due to differences in the molecular weights $\bar{M}_\eta$ of the tested polymers and in the charge densities on their macromolecules β.

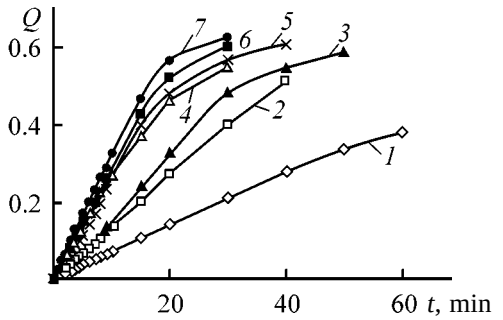

Fig. 1. Kinetic curves of sedimentation of an aqueous ocher suspension. Flocculant: (*1*) none, (*2*) C_2, (*3*) POE, (*4*) A_2, (*5*) C_1, (*6*) PAA, and (*7*) A_1. [PAAF] = [POE] = 2×10^{-3}%. (*Q*) The degree of clarification and (*t*) time; the same for Figs. 2 and 3.

The molecular weights $\bar{M}_\eta$ of copolymers A_1 and C_1 are considerably higher than those of copolymers A_2 and C_2. The root-mean-square size of these macromolecules $\langle \bar{R}^2 \rangle^{0.5}$ varies in parallel with $\bar{M}_\eta$ [9]. The fact that $\langle \bar{R}^2 \rangle^{0.5}$ of A_1 and C_1 is larger than that of A_2 and C_2 is also due to lower parameters β for A_2 and C_1 since the shielding of the charges localized along the macromolecules of A_2 and C_2 with higher content of ionic groups is more pronounced. The stronger shielding decreases the electrostatic potential of repulsion between similarly charged units of the macromolecules and hence decreases $\langle \bar{R}^2 \rangle^{0.5}$ [13, 14]. The higher $\langle \bar{R}^2 \rangle^{0.5}$, the higher is probability of formation of bonds of a macromolecule with two and more ocher particles (bridge formation). As a consequence, experimental D and λ of copolymers A_1 and C_1 are considerably higher than those of copolymers A_2 and C_2. These correlations between the flocculation parameters and M of ionic PAAF (A_1, A_2, C_1, and C_2) confirm additionally the bridge mechanism of flocculation in the tested systems.

As seen from kinetic curves *5* and *7* (Fig. 1) and values of parameters D and λ (see table), anionic copolymer A_1 is stronger flocculant with respect to ocher than cationic copolymer C_1.

Taking into account the negative charge of DP particles, the ratio between the flocculation parameters of copolymers A_1 and C_1 additionally supports the bridge mechanism of flocculation in the tested systems.

Summary of data on flocculation of an ocher suspension and thickening of the precipitate in aqueous and aqueous-salt (0.5 N NaCl) solutions in the presence of PAAF and POE

Parameter	Sequence of introduction of components	Flocculant					
		N-2000	POE	A_1	C_1	A_2	C_2
$D_{0.5}$	F	83.0	0.300	154	2.56	3.25	1.13
	NaCl + F	54.5	–	142	1.94	3.25	3.25
	F + NaCl	19.0	0.660	37.5	1.08	3.25	1.13
	(NaCl + F)	36.6	0.850	9.00	1.50	4.72	1.13
$\lambda \times 10^{-3}$, $m^3\ kg^{-1}$	F	4.15	0.015	7.73	0.128	0.163	0.057
	NaCl + F	2.73	–	7.09	0.097	0.163	0.163
	F + NaCl	0.950	0.033	1.88	0.054	0.163	0.057
	(NaCl + F)	1.83	0.043	0.45	0.075	0.236	0.057
$\gamma \times 10^5$, s^{-1}	F	132	18.3	95.0	35.4	10.1	14.7
	NaCl + F	21.2	2.03	109	24.3	10.8	12.2
	F + NaCl	52.7	18.1	64.8	19.3	14.9	10.3
	(NaCl + F)	113	22.7	101.7	20.1	29.8	10.6
$\rho_{pr} \times 10^{-3}$, $kg\ m^{-3}$	F	1.25	1.28	1.24	1.24	1.26	1.19
	NaCl + F	1.24	1.26	1.24	1.24	1.18	1.21
	F + NaCl	1.24	1.26	1.24	1.24	1.21	1.22
	(NaCl + F)	1.24	1.26	1.24	1.25	1.21	1.21

Note: F is flocculant; γ is the constant of precipitate thickening; ρ_{pr} is the precipitate density; $\gamma \times 10^5$, s^{-1} and $\rho_{pr} \times 10^{-3}$, $kg\ m^{-3}$ for ocher and ocher + 0.5 N NaCl are 4.22 and 16.3; 1.30 and 1.29, respectively.

The experimental relations $D(A_1) \gg D(C_1)$ and $\lambda(A_1) \gg \lambda(C_1)$ indicate different nature of ocher sorption on polymer A_1 and C_1 since these results cannot be explained by the differences in $\overline{M}_\eta$ and $\langle \overline{R}^2 \rangle^{0.5}$ because D and λ of polymers with $\overline{M} > 1 \times 10^6$ are almost independent of $\overline{M}_\eta$ [1, 4]. If the numbers of PAAF macromolecules forming "bridge" and "anchor" bonds (since adsorption occurs on a single DF particle, these macromolecules are not involved in the flocculation) with particles of the DP are denoted as N_1 and N_2 [4], respectively, then, apparently, $y_1(A_1) \gg y_2(C_1)$ and $y_2(A_1) < y_2(C_1)$ where

$$y_1 = \frac{N_1}{N_1 + N_2}, \qquad y_2 = \frac{N_2}{N_1 + N_2},$$

The strong differences in parameters y_1 and y_2 for copolymers A_1 and C_1 can be due to the presence of both positively (owing to Fe^{3+}) and negatively (owing to silanol groups) charged areas on the surface of DP particles [15]. To complete the analysis, it should be noted that the tested PAAFs are irreversibly and almost completely adsorbed on ocher particles (the degree of adsorption is $\alpha > 0.98$) [16].

The parameters y_1 and y_2 depend not only on the macroion charge but also on the nature and concentration of active centers on DP particles and the [PAAF]/C_d ratio [1, 4].

As seen from curves *3* and *6* (Fig. 1) and the table, PAA is more efficient flocculant than POE. The fact that D and λ of POE are lower than those of PAA is due to more compact conformation of POE macromolecules. This, in particular, is indicated by considerably smaller values of $\langle \overline{R}^2 \rangle^{0.5}$ for POE, which can be indirectly estimated by comparing the viscosity numbers at C = const. For example, $(\eta_{sp}/C) \times 10^{-3}$ for PAA and POE at $C = 0.1\%$ are 3.58 and 0.635 $cm^3\ g^{-1}$, respectively.

Let us consider ocher sedimentation when PAAF (or POE) and inorganic electrolyte (NaCl) are present simultaneously. The influence of the ionic strength on flocculation of ocher suspension in the presence of PAAF under conditions of hindered sedimentation (C_d = 6%) was studied in [17].

It was of interest to estimate the influence of the ionic strength on the kinetics of ocher sedimentation in the presence of not only anionic but also other samples of PAAF and POE. The influence of process parameters on ocher sedimentation should be also

taken into account, since, as noted in [18–20], the sedimentation stability strongly depends on the sequence of introduction of the active additives in the system.

Three modes of flocculant (F) introduction were tested: (1) first NaCl and then F; (2) first F and then NaCl; (3) simultaneous introduction of NaCl and the flocculant in an ocher suspension. It should be noted that the amount of PAAP and NaCl additives was the same in all experiments. As seen from Fig. 2, the flocculation effect strongly depends on the sequence of introduction of the cationic flocculants C_1 and C_2 and NaCl electrolyte.

When F is introduced after NaCl, the flocculation effect D is maximal (Fig. 2, curves *5*, *7*).

These results suggest that introduction of NaCl into an ocher suspension yields dense coagulation aggregates of DP particles, which are suitable "nuclei" for formation of relatively large floccules in subsequent introduction of the flocculant. The floccules contain, along with DP particles and NaCl, macromolecules of cationic acrylamide copolymers with a medium and high content of ionic groups β.

The kinetic curves of ocher sedimentation in the presence of copolymers A_1 and A_2 and NaCl electrolyte are shown in Figs. 3a and 3b. Even visual comparison of the kinetic curves shows that the flocculation parameters of copolymer A_1 are considerably higher than those of A_2 at all sequences of introduction of PAAF and NaCl. The quantitative difference in these parameters is seen from the table: $D(A_1) > D(A_2)$ and $\lambda(A_1) > \lambda(A_2)$.

The flocculation parameters D an λ of ionic PAAF, C_1, C_2 (Fig. 2) and A_1 (Fig. 3b) in 0.5 N NaCl, as influenced by the introduction mode, decrease in the order F after NaCl > NaCl after F > NaCl + F simultaneously. Our experimental results show that macromolecular globules strongly "contract" at direct contact of polymeric additives C_1, C_2, A_1, with NaCl coagulant. This is clearly confirmed by the results of viscometric analysis (Fig. 4). Sharp decrease in the viscosity numbers $\langle \bar{R}^2 \rangle^{0.5}$ changes similarly) with increasing electrolyte concentration is due to weakening of electrostatic repulsion of similarly charged groups of the macromolecules owing to shielding of negative charges of A_1 and positive charges of C_1 and C_2. As a result, the macromolecules roll up in globules. The parameters $\langle \bar{R}^2 \rangle^{0.5}$, D, and λ change similarly (see table).

It should be noted that the flocculation parameters of PAA and POE nonionic polymers with respect to

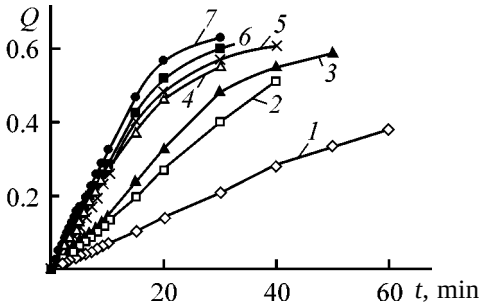

Fig. 2. Kinetic curves of sedimentation of an aqueous ocher suspension (*1*) in the absence and (*2–7*) in the presence of PAAF cationic flocculant [(*2, 3, 5*) C_2 and (*4, 6, 7*) C_1] and NaCl electrolyte. Introduction mode: (*5, 7*) F after NaCl, (*2, 4*) NaCl after F, and (*3, 6*) NaCl + F simultaneously. $[C_1] = [C_2] = 2 \times 10^{-3}$%, [NaCl] = 0.5 M.

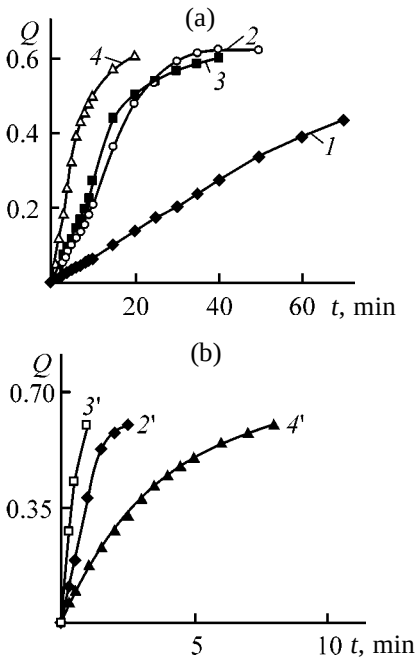

Fig. 3. Kinetic curves of sedimentation of an aqueous ocher suspension (*1*) in the absence and (*2–4*, *2'–4'*) in the presence of anionic acrylamide copolymers (a, *2–4*) A_2 and (b, *2'–4'*) A_1 and NaCl electrolyte. Introduction mode: (*3*, *3'*) F after NaCl, (*2*, *2'*) NaCl after F, and (*4*, *4'*) NaCl + F simultaneously. $[A_1] = [A_2] = 2 \times 10^{-3}$%, [NaCl] = 0.5 M.

ocher in aqueous media fundamentally differ from those in aqueous salt media (see table). Unlike PAA, introduction of inorganic electrolyte has virtually no effect of the flocculation parameters of POE. This is mainly due to globular conformation of POE macromoleculs. Low flocculation parameters of POE were noted in [22].

This is also confirmed by the weak dependence of the viscosity numbers of POE (Fig. 4, curves *4*) on

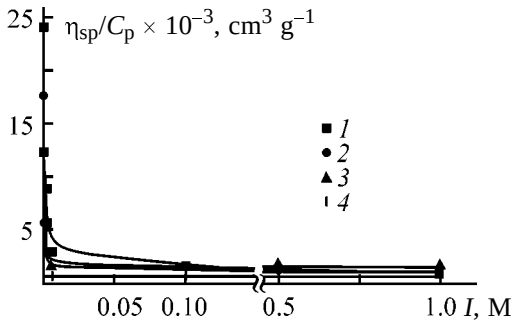

Fig. 4. Viscosity number η_{sp}/C of (*1*) A_1, (*2*) C_2, (*3*) N, and (*4*) POE flocculants as a function of the ionic strength of the solution I = [NaCl]. [PAAF] = [POE] = 0.1%.

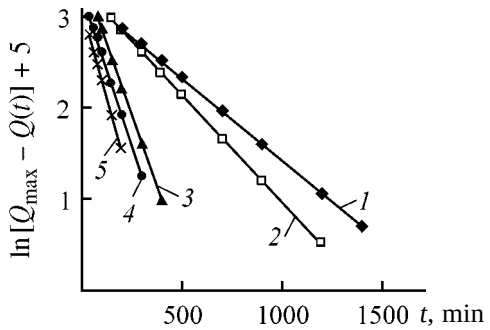

Fig. 5. Kinetic curves of thickening of precipitates of an ocher suspension (*1*) in the absence of additives, (*2*) in the presence of NaCl ([NaCl] = 0.5 M) and (*3*–*5*) in the presence of C_2 PAAF ([C_2] = 2×10^{-3}%) and NaCl. Introduction mode: (*4*) F after NaCl, (*5*) NaCl after F, and (*3*) NaCl + F simultaneously. (Q) Degree of clarification and (t) time.

the ionic strength of the solution I. These results indirectly indicate that $\langle \bar{R}^2 \rangle^{0.5}$ of POE remains virtually the same since the dependences $\eta_{sp}/C = f(I)$ and $\langle \bar{R}^2 \rangle^{0.5} = f(I)$ are similar.

As seen from Fig. 4 (curve *3*), η_{sp}/C of PAA appreciably decreases with increasing [NaCl]. This is probably due to the fact that PAA contains small amount (1–2 mol %) of carboxy groups formed by hydrolysis of the amide groups during preparation of the polymer. The decrease in the flocculation parameters D and λ of sample N with increasing I is manly due to the decrease in the size of its macromolecules.

The aim of second step of our work was to study the kinetics of thickening of ocher precipitates in the presence of the same PAAFs. The kinetic curves of thickening of an ocher precipitate in the presence of copolymer C_2 or NaCl or of their mixture are shown in Fig. 5. Using the procedure described in our previous work [7], we calculated the constant of the precipitate thickening γ from the slope of the $\ln[Q_{max} - Q(t)] = f(t)$ curves constructed from the experimental data (Fig. 5).

As seen from the table, in all the tested systems the constants of thickening of ocher precipitates γ in the presence of PAAF and POE exceed those for pure ocher and the ocher–NaCl system. This is obviously due to flocculation in the first step of ocher sedimentation in the presence of the polymers and NaCl coagulant depending of the sequence of their introduction.

It should be noted that the most important parameter of the precipitate is its density ρ_{pr}. The structure of the precipitate and the degree of its thickening and dehydration can be estimated from ρ_{pr}. The precipitate density ρ_{pr} depends on the weight content and density of its solid phase [6] and is calculated by the equation

$$\rho_{pr} = \frac{m + (V_{pr} - m/\rho)\rho_0}{V_{pr}}, \quad (5)$$

where ρ and ρ_0 are the density of ocher ($\rho = 2.7 \times 10^3$ kg m^{-3}) and water ($\rho_0 = 2.7 \times 10^3$ kg m^{-3}), respectively, and m is the ocher weight.

The precipitate volume is calculated by the equation

$$V_{pr} = (1 - Q_{max})V_0, \quad (6)$$

where V_0 is the working volume of an ocher suspension in a volumetric cylinder.

The experimental results presented in the table show that ρ_{pr} of the precipitates formed in the presence of the flocculants and NaCl coagulant is slightly lower than that of the ocher precipitate formed in the absence of these additives. This is due to formation of macromolecular bridges between particles of DP. The floccules thus formed are more friable including the region of Q values close to Q_{max}.

CONCLUSIONS

(1) The kinetics of flocculation of an ocher suspension and thickening of the precipitates in aqueous and aqueous-salt (0.5 N NaCl) media in the presence of nonionic and ionic (anionic and cationic) acrylamide copolymers having different composition and molecular parameters was studied.

(2) The flocculation power was correlated with the molecular parameters of the flocculants. The sedimentation stability strongly depends on the sequence of introduction of the flocculants and the electrolyte.

(3) The thickening constants and densities of ocher precipitates formed in the presence of the flocculants

in aqueous and aqueous-salt (0.5 N NaCl) media were calculated.

Effect of Aqueous Solutions of Biuret, Dimethyl Sulfoxide, and Acetamide on the Paper-Forming Properties of Cellulose

I. I. Osovskaya and G. M. Poltoratskii

St. Petersburg State Technological University of Plant Polymers, St. Petersburg, Russia

Received June 20, 2000

Abstract—Chemical activation of cellulose material was studied as a means to improve the mechanical characteristics of experimental paper.

This report is a continuation of our previous article [1] in which we suggested a principally new approach to choosing a cellulose activator, based on thermodynamic studies and a few available publications [2–8]. We showed in [1] that the degree of cellulose activation with an aqueous solution of a chemical reagent depends on the structure of the solvent (liquid water), which is, in turn, determined by the nature and concentration of the solute. Based on thermodynamic studies (calorimetry, densimetry), we proved that water in the presence of structure-breaking and structure-making electrolytes transforms the hydrophilic and sorption properties of cellulose by affecting its structure [1–3]. It was shown that the most promising activating agent is biuret which, when added in small concentrations (3–5 wt %), facilitates maximal development of the capillary-porous structure of cellulose and makes it more accessible for the liquid medium.

The goal of this study was improvement of the paper-forming properties of the cellulose material by optimization of cellulose activation with aqueous solutions of organic substances. We studied the physicomechanical properties of experimental paper that was obtained from cellulose activated with aqueous solutions of biuret, dimethyl sulfoxide (DMSO), and acetamide. Experiments were performed with bleached sulfate cellulose (Arkhangelsk Pulp-and-Paper Plant, Joint-Stock Company) which had the following characteristics: α-cellulose content 91.8%, degree of polymerization 1700, degree of crystallinity 65%, and ash residue 6%. Activated cellulose was prepared by stirring a 6% cellulose suspension for 2 min in the presence of an activator, washed with distilled water, and squeezed to a cellulose concentration of 50 wt %. Experimental castings of 100 ± 1 g m^{-2} weight were prepared on a sheet-casting machine and subjected to standard physicomechanical tests. The concentration of the organic component was varied within 0–5 wt %. The results of physicomechanical tests are given in Figs. 1 and 2 and in the table.

Figures 1a and 1b show that the effect of cellulose activation with aqueous solution of an organic substance depends on its nature and concentration. The breaking length BL and relative elongation ε_0 of paper substantially increase as the concentrations of biuret and DMSO are increased to 1.5 and 5 wt %, respec-

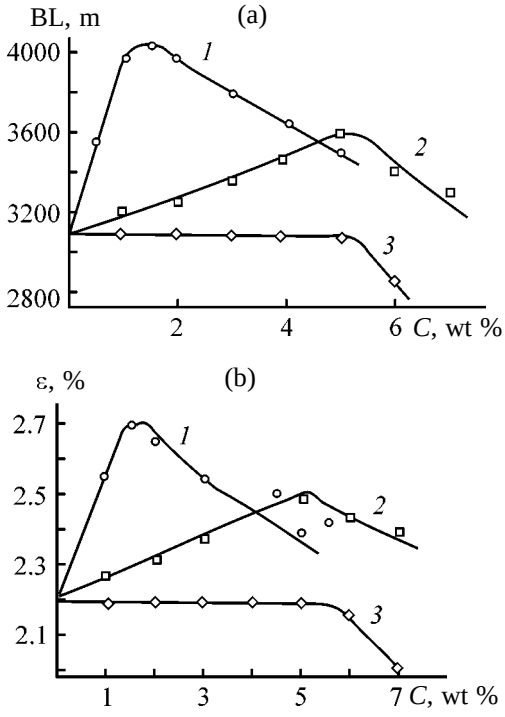

Fig. 1. Effect of concentration *C* of (*1*) biuret, (*2*) DMSO, and (*3*) acetamide in aqueous solution on the (a) breaking length BL and (b) relative elongation ε_0 of paper formed by the traditional procedure.

1070-4272/01/7403-0516$25.00

tively (Figs. 1a, 1b). As the concentration of the organic substance is increased further, these parameters decrease. As seen from the table, the tear resistance E varies in parallel with BL and ε_0.

Figure 2 shows the influence of cellulose activation with biuret on the degree of polymerization of cellulose and strength of a single fiber BL_0. The degree of polymerization was determined viscometrically at 25°C in a solution of the sodium iron tartrate complex (SITC).

As seen from Fig. 2, treatment of cellulose with biuret is accompanied by insignificant degradation of cellulose and the loss of the strength of a single fiber.

The physicomechanical characteristics of the experimental paper sample (see table; Figs. 1, 2) are consistent with the previously measured [1] physicochemical properties of cellulose (heat of wetting, water-retaining power, and density) activated with biuret, DMSO, and acetamide.

The parallel variation of the mechanical characteristics of paper and physicochemical properties of activated cellulose allows us to explain the dependence of these properties on the nature and concentration of the organic agent. Addition of biuret and DMSO, which are structure-breaking agents with respect to water, increases the content of weakly associated water molecules whose penetration into previously inaccessible very fine pores and capillaries of the cellulose fiber becomes possible. For development in cellulose of microareas comparable in size with water molecules, biuret is preferable, since it contains a larger number of groups actively interacting with water and breaking its clusters. From this standpoint, it is possible to explain the dependence of the physicomechanical characteristics of paper on the nature and concentration of the organic additives.

Figures 1a and 1b show that BL, ε_0, and E increase only at small concentration of the activator. This is due to formation and growth of the total volume of microareas of the cellulose fiber. In such a fiber, in the course of dehydration of the fibrous mass for paper production, the pores are closed to a greater extent, ensuring formation of a uniform and less strained macrostructure [1]. An increase in the pore size at a higher content of the activator causes formation of fibers with a more strained and less regular, and hence more defective, structure [1]. Furthermore, swelling of cellulose in a biuret aqueous solution is accompanied not only by weakening of hydrogen bonds and alteration of the capillary-porous structure

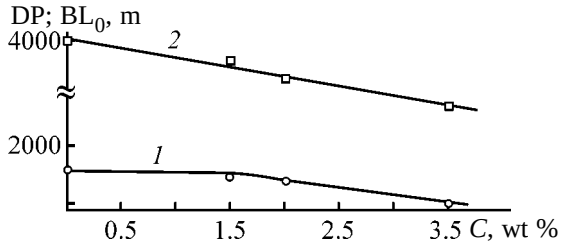

Fig. 2. Effect of concentration C of biuret aqueous solution on the (*1*) degree of polymerization DP and (*2*) strength of the single fiber BL_0.

of the polymer, but also by chemical processes decreasing the degree of polymerization (Fig. 2). Degradation of cellulose macromolecules is responsible for a decrease in the strength of single fibers and hence in the strength of paper as a whole (Fig. 2). At a biuret concentration less than 1.5 wt %, BL_0 and the degree of polymerization also slightly decrease (Fig. 2), but the paper-forming properties of cellulose are not noticeably affected.

Figures 1a and 1b show that acetamide (structure-making agent with respect to liquid water) does not enhance the strength of the experimental paper, and at its content higher than 5 wt % the mechanical characteristics of the paper drastically decrease. Measurements [1] of the density, water-retaining power, and sorption showed that addition of acetamide to the cellulose–water system favors formation of a coarse-porous structure of cellulose. The lack of developed submicroscopic system of pores and capillaries impairs the paper-forming properties of the cellulose fiber and decreases the paper strength.

Synthesis and Some Characteristics of Magnetic Matrices for Fixation of Biologically Active Substances

S. S. Airapetyan, G. G. Balayan, and A. G. Khachatryan

Yerevan State University, Yerevan, Armenia

Received August 1, 2000

Abstract—A possibility of production of nonporous magnetic matrices with two-layer coating based on cobalt ferrite with the aim to use these matrices for fixation of biologically active substances was considered. The function of the first layer (silica coating) is to shield the cobalt ferrite surface and provide conditions for applying the second (polymer) layer containing various functional groups.

With advances in modern procedures of recovery and purification of various chemical compounds, particularly biologically active substances, the necessity arises to produce matrices with a set of useful specific characteristics. In this connection, production of matrices that, among other things, are capable of magnetization is an urgent problem. These matrices can be used for fixation in bioengineering and also for recovery and purification of enzymes and other biologically active substances, when the use of standard matrices is impossible (e.g., in the case of highly viscous homogenate of biologically active substances). In addition, carriers based on magnetic matrices can be recovered from a suspension by applying magnetic fields instead of centrifuging [1].

At present, magnetic matrices for affine sorbents and supports are produced by KLB Co. (Sweden), IBF (France), etc. They consist of agarose and acrylamide gels, swelling in solvents, with admixed magnetite (up to 7 wt %).

However, these matrices do not fully meet the requirements placed upon them; the main requirements are mechanical strength of the matrix material, chemical resistance to biologically active substances and chemical reagents, insolubility in a wide range of solution pH, the features of wettability and swelling in the eluent, and the reactivity providing the possibility of chemical modification [2].

Instead of the above gels of the organic origin, a silica gel shell having low nonspecific sorption, ideal rigidity, and soft hydroxyl cover can be used [3]. However, it should be borne in mind that in modification of these matrices with hydrophobic radicals (ethyl C_2, octyl C_8, and others) only about 40% of silanol groups at the matrix surface are involved in the modification. The residual silanol groups can cause undesirable silanol reactions deteriorating the quality of the operations. To avoid this, after modification the surface of these matrices is additionally treated with a low-molecular-weight hydrophobic modifier, e.g., trimethylchlorosilane. However, in this case, too, shielding of the residual silanol groups is incomplete.

Another drawback of silica gel matrices is their operating range of pH restricted to neutral and acidic solutions (pH 3–8).

To eliminate the above drawbacks and produce magnetic matrices most fully meeting the imposed requirements, it seems appropriate to apply two-layer coatings on the surface of powdered magnetic materials. As the first layer, silica having active silanol groups at its surface can be used, owing to which a great variety of chemical compounds with various functional groups can be fixed at the silica surface. The second layer can be formed by macromolecular compounds chemisorbed at the SiO_2 surface and shielding all the surface silanol gropus.

The possibility of applying silica coating on various supports is described in sufficient detail in [4–6], where the application conditions and characteristics of protecting silica coatings on the surface of nickel, iron, aluminum, and other oxides, and also various metals and alloys are presented.

Thus, the aim of this work is to study a possibillity of production of nonporous two-layer magnetic matrices based on cobalt ferrite for fixation of biologically active substances.

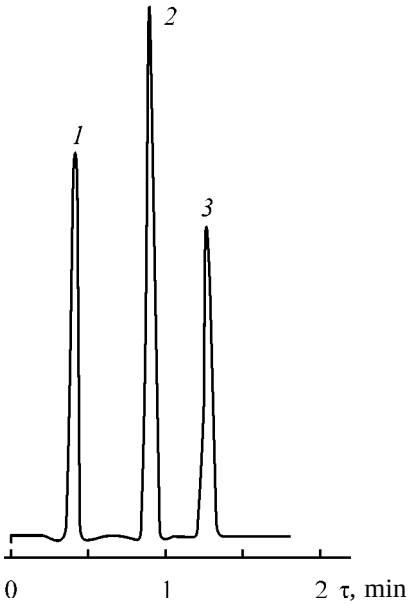

Fig. 1. Chromatogram of the test mixture uracil (*1*)–benzene (*2*)–toluene (*3*). Support: cobalt ferrite with silica coating and grafted C_8 phase, pressure 154 bar. (τ) Time; the same for Fig. 2.

EXPERIMENTAL

As the initial magnetic material we used finely dispersed powdered cobalt ferrite synthesized by the procedure described in [7]. All chemicals (cobalt and iron chlorides, and also sodium hydroxide) were of chemically pure grade.

The procedure of applying silica coating on the surface of cobalt ferrite particles was as follows. Powdered cobalt ferrite was suspended at continuous stirring in distilled water heated to boil. Then, dilute sodium silicate solution with a concentration of 2 wt % recalculated to SiO_2 and a silicate modulus (SiO_2/Na_2O molar ratio) no less then 3 was slowly added to the resulting suspension. The amount of sodium silicate solution ensured the weight ratio of cobalt ferrite to silicon dioxide of approximately 7–8. In addition of sodium silicate solution, the volume of the initial suspension was kept constant.

After addition of the required amount of sodium silicate solution, heating was stopped, and the suspension was cooled to room temperature, decanted, washed with distilled water on a filter, and filtered. The resulting powder was dried in a drying chamber at 150°C and subjected to heat treatment at 900°C in a muffle for 5 h.

To rehydroxylate the silica surface and to provide a possibility of its modification, the resulting powder was kept in boiling 20% nitric acid for 20 h. In so doing, dissolution of the magnetic support was not observed. This suggests that the surface of cobalt ferrite particles is completely coated with silica.

The second, polymeric, layer was applied on the silica surface according to the procedure described in [8, 9]. As a macromolecular compound, we used copolymer of methyl methacrylate with octadecyl methacrylate at a molar ratio of 1 : 1.

To assess the quality of coatings, the resulting magnetic matrices with single- and two-layer coatings were tested by the reversed-phase high-performance liquid chromatography (HPLC).

This procedure was selected owing to its higher efficiency and accuracy in comparison with the other well-known procedures. The surface of magnetic matrices with single-layer silica coating was modified with octylsilane (C_8).

In all chromatographic experiments, we used columns 4.6 mm in diameter and 50 mm long. A Beckman HPLC chromatograph equipped with double-beam UV detector operating at 254 nm was used. As an eluent, we used an acetonitrile–acetone mixture with the component ratio of 30 : 70; the flow rate of the eluent was 1 ml min^{-1}.

Figure 1 illustrate separation of a test mixture (uracil, benzene, and toluene) in a column packed with the magnetic matrix (particle size 1.5 μm) with a single-layer coating containing a grafted C_8 phase. The chromatogram shows that on the magnetic support it is possible to obtain a high-grade silica coating with active silanol groups, to which the C_8 phase can be covalently grafted. However, the use of these matrices as packing materials for reversed-phase chromatography is beyond the scope of this report. This chromatogram should be considered only as illustration of possibility of applying a high-quality thin-layer silica coating to magnetic support and blocking its surface.

Figure 2 illustrates separation of a test mixture (uracil, pyridine, phenol, and toluene) in a column filled with the magnetic matrix (particle size 1.5 μm) with a two-layer coating. The chromatogram shows that the retention time of pyridine (Fig. 2c, 0.475 min) is less than that of phenol (Fig. 2d, 0.512 min). This fact proves that "silanol" interaction of the surface of the resulting matrices with pyridine is not manifested, i.e., the surface of magnetic matrices with the two-layer coating contains no silanol groups [10].

Thus, this study showed that film magnetic matrices can be produced by applying a two-layer coating

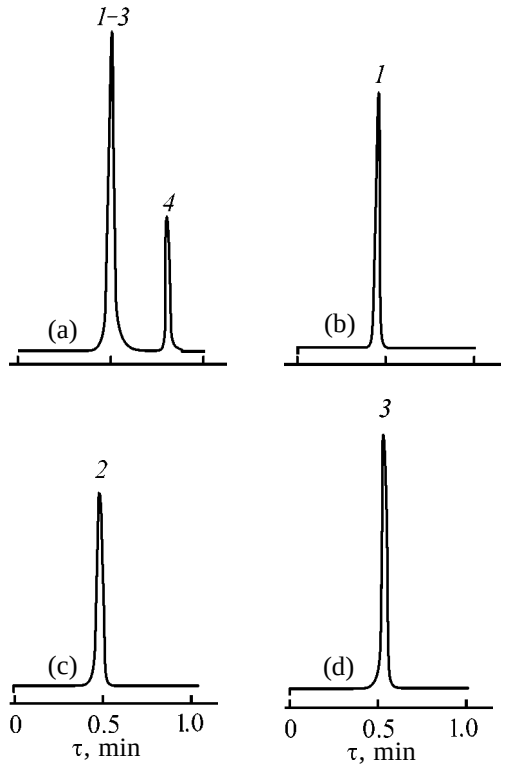

Fig. 2. Chromatogram of (a) the test mixture uracil (*1*)–pyridine (*2*)–phenol (*3*)–toluene(*4*) and (b–d) its components. Support: cobalt ferrite with silica and polymer coatings, pressure 130 bar.

to the surface of highly dispersed particles of magnetic materials. These film magnetic matrices completely conform to the requirements imposed on matrices used for fixation of biologically active substances [2]. The specific surface area of the resulting magnetic matrices is relatively low (1–3 $m^2 g^{-1}$) owing to their minimum porosity. Therefore, they are more suitable for bulky biomolecules, for which the problem of intraporous penetrability becomes of decisive importance.

CONCLUSIONS

(1) On a magnetic support (cobalt ferrite), it is possible to prepare a nonporous silica coating with active silanol groups to which aliphatic chains of various length can be covalently grafted.

(2) Application of the second layer, polymeric coating, provides inactivation of silanol groups at the matrix surface and also the presence of functional groups required for fixation of biologically active substances.

BRIEF COMMUNICATIONS

Synthesis of Dioxolanylmethyl Methacrylates from Aldehydes, Glycerol, and Methyl Methacrylate

A. S. Shevchuk, V. A. Podgornova, and O. P. Yablonskii

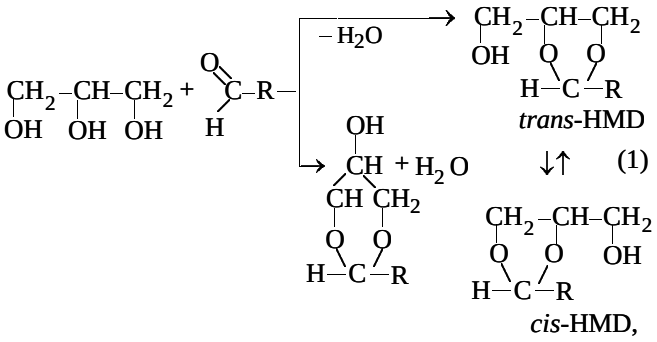
State Technical University, Yaroslavl, Russia

Received February 12, 2000; in final form, July 2000

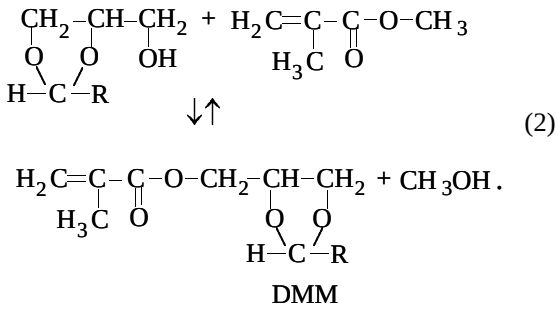
Abstract—The feasibility of preparing dioxolanylmethyl methacrylates from aldehydes in two stages (without purification of intermediate 4-hydroxymethyl-1,3-dioxane) was examined.

Proceeding with studies on synthesis of dioxolanylmethyl methacrylates (DMMs), we examined the feasibility of their synthesis from aldehydes. Previously [1, 2] we found conditions for preparing DMMs from ketones and revealed specific features of preparation of 4-hydroxymethyl-2-alkyl-1,3-dioxolanes (HMDs), intermediates in DMM synthesis. We suggested that these compounds are formed as mixtures of isomers. The goal of this study is synthesis of DMMs both from separate HMD isomers and their mixture.

The two-stage procedure for preparing dioxolanylmethyl methacrylates from aldehydes can be represented by the scheme



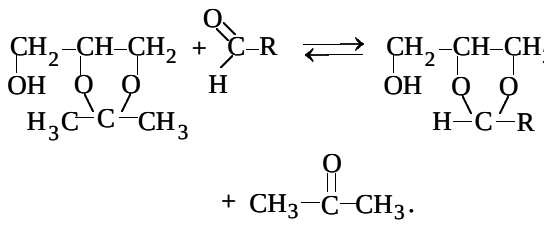
(1)



(2)

DMM

Studies were performed with acetaldehyde (in the form of paraldehyde) and propionaldehyde, following the previously described synthetic and analytical procedures [2]. First, we examined the possibility of formation of isomeric 1,3-dioxan-5-ol. For this purpose we performed an independent synthesis of HMD from 4-hydroxymethyl-2,2-dimethyl-1,3-dioxolane:



(3)

Formation of the six-membered ring in reaction (3) is impossible, and the occurrence of reaction (3) can be judged from the release of acetone. The reaction product in the chromatogram gave the same peaks with the same retention time as the HMD prepared from glycerol. This fact confirms the assumption about the isomeric composition of HMD. Furthermore, these results showed that reaction (3) can be used for preparing 1,3-dioxolane alcohols difficultly accessible by the direct route, since reaction (3) occurred under fairly mild conditions. We also prepared HMD from glycidol, i.e., by reaction also excluding formation of 1,3-dioxan-5-ol. The retention times of HMD isomers prepared by this reaction and from glycerol coincided. These facts convincingly prove that reaction of glycerol with aldehyde does not yield 1,3-dioxan-5-ol, and HMD is formed as a mixture of isomers.

To elucidate the full pattern of the two-stage synthesis, it was important to determine whether all the isomers undergo ester interchange. For this purpose, we performed thorough fractional distillation of HMD prepared from glycerol and propionaldehyde under

1070-4272/01/7403-0522$25.00

reduced pressure in a nitrogen atmosphere on a 60-cm column. Separation gave two low-boiling fractions (68–70°C at 5–7 mm Hg and 72–74°C at 5–6 mm Hg) and bottoms.

Chromatographic analysis of the fractions performed on two different stationary phases showed that the first fraction was a practically individual substance (92–95% purity). The second fraction was, apparently, a mixture of *cis* and *trans* isomers (approximately 66 and 28%) with an impurity of a third isomer. Published data on isomerism of heterocyclic compounds suggest the possibility of formation of *cis* and *trans* isomers; with different substituents, the number of isomers increases to four (two isomers for each of the *cis* and *trans* forms) [3, 4]. The first fraction, practically consisting of a single isomer, was analyzed by ^{1}H NMR spectroscopy (Tesla BS-567 spectrometer, 100 MHz). The spectrum was consistent with the structure of 1,3-dioxolane containing one hydroxy group. The signal at 3.4 – 4.2 ppm (relative to HMDS) corresponds to the 1,3-dioxolane ring [5]. Thus, the ^{1}H NMR and GLC data showed that a rather complex mixture of isomers was formed. Detailed study of its composition is beyond the scope of this work.

The second stage involving reaction of HMDs with methyl methacrylate (MMA) was performed under conditions of ester interchange with HMDs based on ketones [1]. The reaction vessel was equipped with a distillation column. HMD was taken as a single isomer and as an isomeric mixture. The results were as follows. After removal of unchanged reactants by distillation under reduced pressure in a nitrogen atmosphere, DMM was obtained as a mixture of two isomers, irrespective of whether the initial HMD was an individual isomer or an isomeric mixture. It should be noted that the ratio of the HMD isomers is determined by reaction conditions, mainly by the nature of the acid catalyst. Thus, to prepare dioxolanylmethyl methacrylates from glycerol, MMA, and aldehydes, there is no need to separate the isomers formed in the first stage. The yield of DMM based on glycerol is about 60%. The physicochemical characteristics of one of DMMs, 2-methyl-1,3-dioxolan-4-ylmethyl methacrylate, are as follows: colorless transparent liquid; bp 84–86°C at 5–6 mm Hg; d_4^{20} = 1.079 g cm^{-3}; n_D^{20} = 1.4540; molecular refraction: calculated 46.35, found 46.40.

CONCLUSIONS

(1) Dioxolanylmethyl methacrylates are formed from aldehydes, glycerol, and methyl methacrylate as mixtures of two isomers, irrespective of whether the intermediate 4-hydroxymethyl-1,3-dioxolane was taken as individual isomer or isomeric mixture.

(2) 1,3-Dioxan-5-ol is not formed in reaction of aldehydes with glycerol.

Feasibility of Depth Processing of Astrakhan Condensate

N. A. Strakhova, D. A. Rozental', L. P. Kortovenko, and G. I. Litvinova

Astrakhan State Technical University, Astrakhan, Russia
St. Petersburg State Technological Institute, St. Petersburg, Russia

Received July 10, 2000; in final form, December 2000

Abstract—The fractional composition of black oil from Astrakhan condensed gas was studied with the aim of its processing to produce commercial fuel.

The Astrakhan Gas Complex is the leading gas-processing plant in the lower Volga region. The rated annual production of separation gas is 12.0×10^9 m^3. Also, commercial petroleum products are produced: gas sulfur, gasoline, diesel fuel, and black oil. The Astrakhan Gas-Processing Plant (AGPP) sells black oil containing 2.8–3.2 wt % sulfur as M-100 boiler fuel. Because of high sulfur content, the demand for such fuel is limited, and it is sold at a low price, since the majority of heat and electric power plants in the region tend to use gas as environmentally cleaner fuel. The physicochemical characteristics of two samples of black oil taken in different times are listed in Table 1.

As seen from Table 1, black oil from the Astrakhan condensed gas deposit is characterized by a high congealing point (30–31°C) and a low coking capacity (1.05–1.11%); it contains three groups of compounds in comparable amounts: (1) paraffins and naphthenic compounds, (2) aromatic compounds, and (3) resins and asphaltenets. The content of solid paraffins is about 18%, and the sulfur content, 3%.

To examine the feasibility of depth processing of the black oil, we obtained and examined its close-cut fractions. Deep-vacuum distillation of the residual components of the condensate under laboratory conditions was performed with a Manovyan flask [1] allowing distillation at temperatures up to 560–580°C at a residual pressure of 40–70 Pa without noticeable decomposition. We also used a MINITOP automated installation, following the ASTM D 2892–90 testing procedure. The characteristics of close-cut (10°C) fractions of averaged black oil samples are listed in Table 2.

It is seen that the content of sulfur in fractions is approximately equal, being within 2.8–3.4 wt %. Solid paraffins are distributed nonuniformly. For example, in the 320–400°C fraction the content of C_{20}–C_{25} is 8.77 wt % relative to black oil; the content of C_{26}–C_{28} in the 400–430°C fraction, C_{29}–C_{31} in the 430–450°C fraction, and C_{32}–C_{36} in the 450–500°C fraction is 29.94, 17.94, and 37.20 wt %, respectively. Oil distillates (320–500°C fraction) amount to 13.5 wt % of stable condensate. They are characterized by a high viscosity index; however, the necessity of labor-consuming removal of sulfur and paraffins makes unfeasible production of base oils in the course of processing of condensed gas. The most

appropriate way to utilize wide-cut vacuum gas oil and its close-cut fractions is production of high-viscosity and motor fuel for low- and medium-speed ship engines, since the requirements to the quality of such fuel are less stringent.

As components of ship fuel we used black oil of grade 100, wide-cut vacuum gas oil (320–500°C fraction), and its close-cut fractions (320–400, 400–450, and 450–500°C); for dilution and modification of the structure and properties of petroleum residues, we used straight-run and hydrorefined diesel fraction from AGPP. The compounds prepared ensured the optimal conditions of transportation and pumping of the fuel; the sulfur content did not exceed the level permitted by the standard [2].

The ship fuel compounds contained, along with diesel fuel, 60% vacuum gas oil (320–400°C), 60 or 50% wide-cut distillate (320–500°C), or 20% black oil and 40% 320–500°C fraction. The quality of these compounds met the requirements imposed on high-viscosity ship fuels [TU (Technical Specifications) 38.1 011 314–90] of the following grades: light high-viscosity SL, high-viscosity SVL, and also on DT and DM motor fuels [GOST (State Standard) 1667–68].

At present, AGPP has no facilities for vacuum distillation; therefore, we examined the possibility of preparing ship fuel by compounding black oil with diesel fuel in a vortical-bed apparatus (VBA) of V-105K-04 type. Compounds were prepared by the vigorous stirring and dispersion in combination with acoustic and electromagnetic treatments [3].

The compound containing 35% black oil and 65% diesel fuel, prepared in a VBA at 140°C and treatment time of 30 s, shows a high resistance to phase separation and a congealing point as low as –10°C, whereas the mechanical stirring as the only kind of treatmnent, performed for 30 min, gives a product with a congealing point of –5°C. Because of improved low-temperature properties of the fuel, the weight fraction of high-paraffin black oil could be increased to 45%. In this case, the congealing point of the fuel was –7°C. The total sulfur content in the fuel was 1.5%, which met the requirements of the standard.

The decreased congelaing point of the ship fuel is apparently due to favorable conditions for dispersion of black oil components in the bulk of the diesel fuel, provided in VBA, so that the sizes of crystallizing paraffins decrease and the structure of the compound becomes more uniform and cross-linked.

CONCLUSIONS

(1) From black oil of stable condensate from the Astrakhan Gas-Processing Plant, it is feasible to produce standard fuel for low-speed diesels by its compounding with diesel fuel, followed by treatment in a vortical-bed apparatus.

(2) Using vacuum distillation facilities, it is feasible to produce from this black oil, by direct compounding with diesel fuel, commercial fuel of the SL and SVL grades according to TU 38.1 011 314–90 and motor fuels of the DT and DM grades according to GOST 1667–68.

Abstract—The feasibility was examined for improving the quality of commercial bitumen by its plasticization with high-paraffin black oil and sulfur from the Astrakhan Gas-Processing Plant, with treatment of the mixed components in a vortical-bed apparatus at 130–140°C for 25 s.

In the context of urgent problems of improving the quality of bitumens produced in Russia, finding new ways to involve sulfur in industrial processes, and developing new sulfur-containing products, we performed studies on modification of commercial bitumens with sulfur. It is known that the influence of sulfur on the structure of petroleum bitumens is the most pronounced when sulfur is present as a condensation structure and sulfur-containing asphaltenes are formed at relatively low mixing temperatures (140°C). Sulfur–bitumen binder was prepared by continuous stirring of the components with a mechanical stirrer for an optimal time [1, 2].

It is interesting to study the effect of electromagnetic field in combination with mechanical treatment on activation of compounding of the sulfur–bitumen binder in a V-150K-04 vortical-bed apparatus. No data are available on the combined effect of mechanical treatment and electromagnetic field, in particular, on preparation of sulfur-containing bitumens. Therefore, we examined the feasibility of obtaining, using a combined effect of electromagnetic field and mechanical activation, the optimal disperse structure of sulfur-containing bitumens by compounding viscous bitumens with residual components of stable condensate and sulfur from the Astrakhan Gas-Processing Plant (AGPP).

As components of sulfur–bitumen binders we used samples of viscous bitumen of the BND 60/90 grade from West-Siberian oils, technical-grade sulfur, and high-paraffin black oil from AGPP. Commercial BND 60/90 bitumen exhibits insufficient adhesion and practically no margin with respect to the softening point. The residual components of the stable condensate from AGPP were used as diluents for the viscous bitumen and plasticizers for the petroleum sulfur–bitumen binder. Sulfur acts as a bitumen modifier owing to interaction with active groups of asphaltenes [2]; it also acts as a filler enhancing the heat resistance of the compound.

Mechanochemcial activation of compound components was performed in a vortical-bed apparatus (VBA) with application of the rotating electromagnetic field at the melting point of sulfur. As grinding bodies were used iron needles. The sulfur–bitumen compound was prepared as follows. A VBA ampule was charged with BND 60/90 bitumen and black oil in various proportions. The mixture was kept for several minutes at 130–140°C. Then sulfur was added in the molten or finely divided form. Electromagnetic treatment of the mixture in VBA was performed at 130°C for 5–25 s depending on the amount of the added sulfur. At the mixing temperature, sulfur melts and, under vigorous stirring, is uniformly dispersed in the bulk of the binder.

Data on the influence of sulfur on commercial characteristics of sulfur-containing bitumens with various ratios of the dispersed phase to dispersion medium are listed in the table. It is seen that the compound prepared from BND 60/90 bitumen and black oil in a 4 : 1 ratio exhibits a relatively narrow plastic range, which is due to high concentration in high-boiling black oil fractions of paraffins and naphthenic hydrocarbons, including solid paraffins with a high melting point (52–70°C). Addition of sulfur (up to 5 wt %) increases the softening point and decreases

	60	78	49.5	–21.0

penetration, which is due to increase in the heat resistance and viscosity of the medium as a result of partial dissolution of sulfur in the dispersion medium and formation of an additional disperse phase of sulfur particles. Low brittle points are due to relative increase in the content of oil fractions of the compounds as a result of partial dissolution of sulfur. As the sulfur concentration is increased further (>10 wt %), the plastic range of bitumens increases. However, simultaneously the frost resistance gets worse, and with respect to the brittle point such sulfur–bitumen binders no longer meet the requirements of the standard. Such a behavior is apparently due to separation of sulfur from oil fractions.

As the amount of the dispersion medium is increased, it becomes feasible to introduce sulfur in high concentrations. For example, in compounds of bitumen with black oil at 3 : 1 and 2 : 1 ratios the optimal concentration of sulfur is 30 wt %, and at a 1 : 1 ratio, 50 wt %. As seen from the table, the low-temperature properties of the binders at various ratios of the components (bitumen, black oil, and sulfur) are improved, with the penetration (0.1 mm) being in the range 72–89 and the softening point, in the range 45.5–47.5°C. This is apparently due to treatment conditions in VBA, providing the favorable structure of the binder at optimal ratio of the components (oils, resins, and asphaltenes).

Microscopic studies of the compound structure show that sulfur is uniformly distributed in the bulk of the binder, with colloidal size of sulfur crystals. Thus, by adding 10–50 wt % gas sulfur, it is feasible to prepare high-quality sulfur–bitumen binders operating in a wide temperature range and meeting the main requirements of GOST (State Standard) 22 245–90 to BND 60/90 paving bitumens.

CONCLUSIONS

(1) Electromagnetic and mechanochemical treatment of compound components in a vortical-bed apparatus at 130–140°C for 25 s allows preparation of a sulfur–bitumen binder resistant to phase separation.

(2) Addition of finely dispersed gas sulfur and residual components of the condensate from the Astrakhan Gas-Processing Plant improves the frost-resistant properties and plasticity of commercial BND 60/90 paving bitumen.

(3) With increasing ratio of the dispersion medium to the dispersed phase in the compounds, the concentration of gas sulfur can be increased to 50 wt %.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Academician V. A. Kistyakovskii's Works in the Theory of Passive State and Corrosion of Metals (To 250th Anniversary of the Discovery of Metal Transition into Passive State)

The first scientific description of the transition of a metal into passive state was given by M.V. Lomonosov (1711–1765) in the paper *O deistvii khimicheskikh rastvoritelei* (On the Action of Chemical Solvents), published 250 years ago in 1750. Unfortunately, this work, and also other scientist's works in the field of physics and chemistry, written in Latin, had been little known to the scientific community till the early XX century. Lomonosov observed and described fast termination of the dissolution of iron in concentrated nitric acid, and attributed this to a change in the solvent properties [1]. Later, the behavior of iron in nitric acid solutions was studied by quite a number of other researchers [2, 3]. In 1836, a Swiss scientist C. Schonbein (1799–1868) was, probably, the first to name "passive" the state of iron appearing on its being immersed in a sufficiently concentrated (50%) solution of HNO_3. In Schonbein's opinion, "the anomalous behavior of iron has nothing to do with its affinity for oxygen, but, rather, is based on something else." In the same year, by Schonbein's initiative, M. Faraday (1791–1867) repeated and extended his experiments. Faraday came to a conclusion that the reason for passivation is the formation on the metal surface of a very thin invisible film. The argument between Faraday and Schonbein was considered in sufficient detail by A.M. Sukhotin in his monograph [3].

In the beginning of the XX century, a great contribution to investigations of the passivity and corrosion of metals was made by V.A. Kistyakovskii, an outstanding Russian scientist.

Vladimir Aleksandrovich Kistyakovskii was born on October 12, 1865, in Kiev, into a family of intellectuals, whose representatives gained wide acceptance. His father, A.F. Kistyakovskii (1833–1885), was a professor of criminal law at Kiev University, the author of scientific works on the history of law and justice in the Ukraine. Vladimir Aleksandrovich's younger brother, B.A. Kistyakovskii (1868–1920), who also went into law, was a doctor of law, public figure, and minister of the Ukrainian government in 1918. B.A. Kistyakovskii's son, Georgii (George) Kistyakovskii (1900–1982), a known chemist, professor of Harvard University, held a number of positions of responsibility in the United States, and was an advisor in science and technology to President Dwight Eisenhower (1890–1969) [4, 5].

Academician V.A. Kistyakovskii (photo taken in 1945–1946)

In 1883, V.A. Kistyakovskii finished Second Kiev Gymnasium and entered the physicomathematical faculty of Kiev University. In 1885, he went to the natural department of the physocomathematical faculty at St. Petersburg University, having a very highly skilled teaching staff at that time. Among the professors of the natural department were chemists D.I. Mendeleev (1834–1907) and N.A. Menshutkin (1842–1907), physiologist I.M. Sechenov (1829–1905), soil scientist V.V. Dokuchaev (1846–1903),

1070-4272/01/7403-0530$25.00

and biologists A.O. Kovalevskii (1840–1901) and A.N. Beketov (1825–1902). When being a senior student, V.A. Kistyakovskii worked under direct supervision of Professor M.D. L'vov (1848–1899), an organic chemist and A.M. Butlerov's (1828–1886) pupil. The first Vladimir Aleksandrovich's scientific work *Deistvie vodnykh rastvorov mysh'yakovoi kisloty na zhidkii izobutilen i amilen* (The Action of Aqueous Solutions of Arsenic Acid on Liquid Isobutylene and Amylene), published in 1899, was his only study in the field of organic chemistry. Already his diploma work was devoted to analysis of modern concepts in the field of chemistry of solutions: *Gipoteza Planka–Arreniusa* (Planck–Arrhenius Hypothesis) [6, 7]. This was one of the first works in Russia, which presented the standpoints of S. Arrhenius (1859–1927), J. van't Hoff (1852–1911), W. Ostwald (1853–1932), and M. Planck (1858–1947) concerning the nature of electrolyte solutions and dissociation processes. In the final part of the work V.A. Kistyakovskii discussed the possibility of bringing into accord various theories of solutions by introducing the concept of ion hydration. In 1889, he graduated from the university with a candidate degree awarded by the physicomathematical faculty.

In 1889–1890, V.A. Kistyakovskii continued, by his own initiative, his education at Prof. Ostwald's laboratory in Leipzig (Germany), the center of the nascent new disciplines, physical chemistry and electrochemistry [7–9]. W. Nernst (1864–1941) and Arrhenius worked together with Ostwald at that time. All the three scientists were later awarded, in different years, Nobel Prizes (in, respectively, 1903, 1909, and 1920). The work at Ostwald's laboratory was very important for the entire subsequent scientific activities of Vladimir Aleksandrovich. He became particularly closely associated with Arrhenius, having lived with him for more than a month in Paris in 1889, during the World Exhibition; their friendly relationship had been preserved for years. Arrhenius became a foreign corresponding member of the St. Petersburg Academy of Sciences in 1903, an honorary member of the Russian Physicochemical Society in 1909, and an honorary member of the Academy of Sciences of the USSR in 1926.

Having returned to Russia, V.A. Kistyakovskii became, together with I.A. Kablukov (1857–1942), a professor of Moscow University, a convinced supporter and propagandist of new concepts concerning the theory of solutions, not supported at that time by leading Russia's chemists. In 1890, Vladimir Aleksandrovich published an important work concerned with the theory of aqueous solutions of double salts [10], in which he considered complicated cases of electrolytic dissociation and introduced the concept of complex compounds into the Russian chemical literature. Results of more detailed physicochemical and electrochemical studies of double salt solutions were published by the scientist in 1901–1902.

In December 1901, V.A. Kistyakovskii presented a large report *Razbor vozrazhenii na teoriyu elektroliticheskoi dissotsiatsii* (Analysis of Objections to the Theory of Electrolytic Dissociation) at the XI Congress of Natural Scientists and Physicians in St. Petersburg. Vladimir Aleksandrovich demonstrated once more his adherence to modern concepts of the nature of electrolyte solutions and emphasized that "it will be possible in the future to reveal the close relationship between the chemical nature and electrolytic dissociation" [5, 11].

In 1891–1895, V.A. Kistyakovskii was compelled to teach in schools (gymnasiums), and only in 1896 he became privatdocent of St. Petersburg University and delivered courses of lectures on physical chemistry, electrochemistry, and photochemistry. Only in August 1902, for the first time after graduating from the university, V.A. Kistyakovskii was appointed regular lecturer at a higher school institution: He was invited to occupy the position of a senior laboratory assistant in the newly formed St. Petersburg Polytechnic Institute [12, 13]. In June 1903, having backed his master's dissertation at Moscow University, he was elected professor, and backed his doctoral dissertation in chemistry at the same place in 1910.

Vladimir Aleksandrovich created at the Polytechnic Institute the first Russia's laboratory of physical chemistry and theoretical chemistry, with excellent, by that time, equipment. He delivered lectures on physical chemistry and electrochemistry, himself did laboratory with students, and supervised diploma works. The central position among quite a number of research directions pursued by V.A. Kistyakovskii was held by investigations of the electrochemical behavior of metals in aqueous media. Being an excellent experimenter himself, Vladimir Aleksandrovich got a chance to perform various electrochemical investigations.

As far back as 1901, when determining the electrode potential of magnesium in a potassium cyanide solution, V.A. Kistyakovskii observed the passivity phenomenon in this metal for the first time. In more detail, he studied the electrochemical behavior of magnesium in various media in 1907 [14]. Originally, the passive behavior of magnesium was only attributed to the formation of an invisible oxide film.

Professor V.A. Kistyakovskii with a group of young lecturers of St. Petersburg Polytechnic Institute (from left to right): sitting: I.I. Zhukov, V.A. Kistyakovskii, and F.E. Dreier; standing: F.F. Rotarskii and L.A. Rotinyants (photo taken in 1909).

Later, Vladimir Aleksandrovich interpreted this process as formation of magnesium oxide hydrate. This initiated analysis of thin films from the colloid-electrochemical standpoint. Beginning in 1909, the scientist developed his own original film theory of metal passivity and corrosion as applied to magnesium, iron, chromium, and, in part, aluminum. The obtained experimental data were first summarized in V.A. Kistyakovskii's doctoral dissertation, which, in conformity with the regulations of that time, was published in full as a separate book [15].

The developed theory is based on the concept that the electrodes under study are covered with an oxide film both in active and in passive states. In the passive state, this film has amorphous glassy structure, and in the active, partly disintegrates through corrosion. V.A. Kistyakovskii particularly emphasized (1912) that the amorphous passivating film is also present on iron, nickel, and chromium surfaces showing metallic luster. The potentials of the passive electrodes are regarded as oxygen potentials.

In studying the electrode processes, Vladimir Aleksandrovich discovered and explained a number of phenomena named by motor chemical or motor electric effects. These phenomena are based on the influence exerted by fluid motion on the transition of a metal from the active into passive state. The concepts of metal and passivity put forward by V.A. Kistyakovskii were developed to a full extent only in the second half of the 1920s.

In 1912–1916 was published in several parts a comprehensive course of electrochemistry, actually the first textbook on this subject in Russia, written by the scientist. The course also included the basic concepts of the film theory of the passive state of metals. In the summer of 1918, in connection with his mother's illness, Vladimir Aleksandrovich went to Kiev, where his mother and brother lived. After Soviets came to power in February 1919 and the Ukrainian Academy of Sciences was organized in March of the same year, V.A. Kistyakovskii was elected its member. He became the chairman of the Chemical Committee intended to fulfil tasks assigned by the Red Army. However, in view of deteriorating health, he was forced to go away for medical treatment to the North Caucasus already in January 1920. All difficulties associated with his stay there were described in detail in the scientist's autobiography, which became open to public only recently (publication by Yu.I. Solov'ev [5]). Only in the autumn of 1922 V.A. Kistyakovskii could return to St. Petersburg and resume his pedagogical and research activities at the Polytechnic Institute, interrupted for four years and later continued till 1934, the time of his moving to Moscow.

Beginning in 1925, the concepts of the film theory of passivity took their final shape in V.A. Kistyakovskii's works, and the relationship of the theory with corrosion processes was underlined [16–19]. The scientist considered the film theory to be a variant of the electrochemical theory of metal corrosion. The reason for the occurrence of the passive state is the formation of an amorphous, glassy electrically conducting film of oxides, covering the metal with a continuous layer. The passivity effect can be observed both in aqueous solutions and in air. The formation of such a film, e.g., on iron placed in humid air, occurs in three stages. The first, obligatory stage is the formation of an amorphous film, in all probability having a structure of colloid type, under the action of oxygen. The second stage consists in the thickening of the film, becoming pseudoamorphous, composed of crystallites. In the third stage, certain crystallites of iron oxides are formed. The second and third stages may be more or less pronounced, depending on the corrosion conditions. According to the film theory, the surface of metals that can become passive (Mg, Fe, Cr, Ni, Co, Al, etc.) in humid air is covered with a film of the corresponding metal oxides. The film structure strongly affects the corrosion processes. Disintegration of the film, its "solidation" (the term introduced by V.A. Kistyakovskii, with broader sense than crystallization), leads to metal corrosion. The film theory of corrosion was at that time a major contribution to the theory of electrode potentials, serving as a basis for the development of the theory of metal corrosion [20].

The many-year's all-round scientific activities of V.A. Kistyakovskii were highly appreciated in our country and abroad. In 1925, he was elected a corresponding member, and in 1929, a full member of the Academy of Sciences of the USSR. He was also a member of the Paris Physicochemical Society and Electrochemical Society of New York.

In 1930, V.A. Kistyakovskii organized in Leningrad, at the Academy of Sciences of the USSR, the Colloid-Electrochemical Laboratory (LAKE) [21]. The laboratory had the minimum number of staff members (2 in 1930 and 7 in 1934) and several postgraduate students and occupied part of a building on Vasilyevsky Island (Volkhovskii lane, 1). The same building housed quite a number of other scientific institutions of the Academy of Sciences of the USSR. The laboratory was aimed to study colloid-electrochemical phenomena and, in particular, to investigate disperse systems, thin films, problems of metal corrosion at temperatures of up to 50°C, and electrocrystallization of metals. The closest associates of V.A. Kistyakovskii at LAKE were A.N. Strel'nikov (department of disperse chemistry), I.V. Krotov (metal corrosion), and K.M. Gorbunova (electrochemistry). There is no escape from mentioning that the presently widely accepted term "electrocrystallization" was introduced by Vladimir Aleksandrovich. Among V.A. Kistyakovskii's pupils at LAKE were also P.D. Dankov, A.T. Vagramyan, Ts.A. Adzhemyan, and others.

In 1934 (May 30–June 3) was held the 1st conference on metal corrosion at the Academy of Sciences of the USSR. V.A. Kistyakovskii was elected its chairman and presented a large report concerned with the problems of passive state and metal corrosion [22].

After the laboratory was transferred from Leningrad to Moscow, together with a number of other institutions of the Academy of Sciences, LAKE was much expanded by V.A. Kistyakovskii's initiative and transformed into the Colloid-Electrochemical Institute (KEIN), Academy of Sciences of the USSR, and the total number of staff members increased from 10–12 to 70 by 1936. Among those who worked at KEIN were A.N. Frumkin (1895–1976), P.A. Rebinder (1898–1972), N.A. Izgaryshev (1884–1956), B.V. Deryagin (1902–1994), and other known scientists. The scope of the institute covered a wide variety of problems [13]. Academician Frumkin became director of the Institute in 1939; in 1945, he initiated transformation of KEIN into the Institute of Physical Chemistry, Academy of Sciences of the USSR.

In 1937, V.A. Kistyakovskii formulated rather clearly the goals of the science he was developing, colloid electrochemistry [23, 24]. It is based on the hypothesis that the phase boundary is a transition layer composed of mutually penetrating, by diffusion, molecules, or adsorbed molecules, or a layer of chemical reaction products (oxide, oxide–adsorption, or other films). The description of these transition layers involves, in close association, concepts of colloid chemistry and electrochemistry. Faraday's idea, accounting for the passive state of iron and steel, was extended by V.A. Kistyakovskii to other metals subject to passivation, with much attention given to the nature of a film. The colloid electrochemistry includes the theory of electrocrystallization of metals as processes related to the corrosion of these metals. The film concept of the passive state, and the adsorption concept which appeared later, do not contradict, but only supplement each other [25].

In 1945, Vladimir Aleksandrovich's 80th birthday anniversary was celebrated. Reports concerned with the life and activities of the scientist, his contribution to the development of electrochemistry and the theory

of metal passivity were delivered by Frumkin [26], Izgaryshev [27], and Dankov [28]. V.A. Kistyakovskii's achievements in studying the passive state of metals were also noted in a monograph by Frumkin and co-authors [29].

In a very brief review we in the first place dwelled upon V.A. Kistyakovskii's electrochemical investigations, leaving aside his works in the field of thermodynamics of fluids, chemical kinetics, photochemistry, and general problems of physical chemistry. We did not consider the intensive scientific-organizational activities of the scientist in the field of corrosion protection of metals.

V.A. Kistyakovskii died in Moscow on October 19, 1952, at the age of 86. He devoted more than sixty years of his life to research and teaching. These 60 years made an epoch in the development of physical chemistry, electrochemistry, and theory of corrosion and corrosion protection of metals. Academician V.A. Kistyakovskii made a major contribution to the coming-to-be and advances of these scientific disciplines in Russia.

========== INFORMATION ==========

IV International Conference "Polymeric Materials of Decreased Combustibility"

The IV International Conference "Polymeric Materials of Decreased Combustibility" took place on November 17–18, 2000 in Volgograd on the base of the Volgograd State Technical University (VGTU). The conference was supported by the Russian Foundation for Basic Research (RFFI). The co-chairmen of the conference were Corresponding Member, Russian Academy of Sciences, Director of the Institute of Chemical Physics, Russian Academy of Sciences (IKhF) A.A. Berlin and Dr. Sci. (Chem.), Head of VGTU, Prof. I.A. Novakov. The members of the Organizing Committee were well-known Russian scientists in the field of polymer combustion: R.A. Andrianov (Moscow State Building University, MGSU), A.N. Baritov (MGSU), G.E. Zaikov (Institute of Biochemical Physics, Russian Academy of Sciences, IBKhF, Moscow), A.D. Kuntsevich (IKhF), A.M. Lipatov (Udmurt State University, Izhevsk), A.M. Merzhanov (Institute of Macrokinetics, Russian Academy of Sciences, Chernogolovka, Moscow oblast), A.I. Rakhimov (VGTU), and Tsyganov (RFFI).

About 400 scientists from 30 research centers of Russia, Uzbekistan, South Korea, Ukraine, the United States, and Belarus took part in the conference. The program included 17 plenary lectures and 50 poster presentations. The conference was opened by Berlin and Novakov who emphasized the urgency and the scientific and practical importance of the conference subject field.

The scientific program of the conference was opened by the N.A. Khalturinskii's (IKhF) report *Physical Aspects of Polymer Combustion and the Mechanism of Inhibitor Action*. Problems of using nanocomposites as fireproofing compounds for polymers and composite materials were discussed in the report made by Zaikov. O.I. Tuzhikov (VGTU) reported on recent achievements of VGTU in the field of using phosphorus-containing compounds as fireproofing compounds for polymers and polymeric compositions (phosphorus-containing polymers and low-molecular-weight additives to polymers). An active interest was taken in results of development of difficultly combustible foamed plastics for building (Andrianov). The L.G. Panova's (Saratov State Technical University) report was devoted to physicochemical principles of fabrication of blended textiles of decreased combustibility and of hybrid composite materials based on them. P.M. Vasil'ev (Splain Research and Production Center, Volgograd) reported on the use of the Mikrokosm integrated computer system for predicting the properties of fireproofing compounds for polymeric compositions. R.M. Aseeva (IBKhF) made two reports one of which was devoted to carbooligoarylenes for composite materials of decreased combustibility and the other, to new environmentally safe fireproofing coatings based on oxidized polysaccharides. G.D. Bakhtina (VGTU) reported on the use of phosphorus-containing methacrylates for preparing polymeric materials of decreased combustibility. Kim Von Duk (Samchok National University, Samchok, South Korea) reported on synthesis of new organosilicones of decreased combustibility for industry. Advances in the field of modified intumescent epoxy compounds were discussed by S.G. Shukman (Research and Educational Center of Chemical Physics, Udmurt Scientific Center, Ural Division, Russian Academy of Sciences, Izhevsk). Yu.M. Evtushenko (Elektroizolit Joint-Stock Company, Moscow) reported on modification of epoxy resins with methylphosphonoamidic acid. The problem of preventing migration of fireproofing compounds in polymers was discussed by A.Ya. Korol'chenko (MGSU). The last three plenary lectures concerned development of processes for production of new fireproofing compounds (F.M. Mudryi, Khimprom Joint-Stock Company, Volgograd), certification of polymeric materials for aircraft interior with respect to fire safety (Barbot'ko, Russian Institute of Aviation Materials, Moscow), and modification of elastic polyurethanes with phosphorus- and boron-containing compounds (S.N. Bondarenko, Volzhskii Polytechnic Institute, Volzhskii, Volgograd oblast).

Among poster presentations, studies on the following subjects should be mentioned above all: features of flame distribution over the surface of thin polymer films containing microencapsulated fireproofing compounds; structure of the surface of epoxy polymers containing microencapsulated fireproofing compounds under thermal impact, physical aspects of combustion, and ways to optimize the composition of fireproofing

1070-4272/01/7403-0535$25.00 © 2001 MAIK "Nauka/Interperiodica"

mixtures with a synergistic effect; coking, structure and properties of the carbonized layer formed in the course of thermal oxidative degradation and combustion of highly reinforced composite materials. Also presented were poster reports concerning the mechanism of coking in the presence of various additives, theory of combustion of polymeric materials, synthesis of new high-performance inhibitors of polymer combustion, mechanism of the action of combustion inhibitors, development of new polymeric materials and compositions of decreased combustibility, toxicity, and fuming in the course of combustion, equipment and procedures for evaluating the fire resistance of polymeric materials.

The conference demonstrated undoubted theoretical and practical interest in the problems of combustibility of polymeric materials. Combustibility of polymers is a cause of many fires, and polymer combustion is accompanied by release of large amounts of toxic substances.

The next International Conference "Polymeric Materials of Decreased Combustibility" will be held in 2002.

The conference proceedings are available from the library of the Institute of Chemical Physics, Russian Academy of Sciences.

INFORMATION

Addcon World 2000: Plastics Additives and Modifiers Conference

The 6th International Plastics Additives and Modifiers Conference took place on October 25–26 in Basel, Switzerland. It was organized by Rapra Technology and financially supported by Ciba Specialty Chemicals, Clariant Huningue, DSM, Lonzagroup, and Uniqema. The conference continued a series of annual meetings held previously in Switzerland, Belgium, Singapore, the United Kingdom, and Czechia.

Every year Addcon brings to participants' notice from 20 to 30 reports made by the leading companies and worldwide known scientists on recent achievements in the field of development and practical use of additives to polymers. Recently, cardinal changes occurred in this field. Thanks to efforts of environmental protection movement, the use of polyvinyl chloride (PVC) was significantly restricted, which had an effect on the use of the corresponding additives. It should be noted, however, that rigid vinyl polymers are still widely used in the building industry.

First and foremost, active attempts are made in Europe to replace halogen-containing fire retardants with environmentally clean fireproofing agents. Novel stabilizers are being developed; nanocomposites gradually gain the market.

Naturally, the producers of additives make efforts to improve their products, facilitate their use, and decrease the production cost. The goal of this (and previous) conference was to aid in improving the quality and performance of additives.

The conference program included 26 reports made by scientists from the United States, Europe, Asia, and Australia. The opening speech was made by Vice President of the Great Lakes Chemicals corporation (the United States) J. Teat who emphasized the urgency and prospects of the conference.

R. Adams, a representative of BP Amoco Chemicals (the United States) reported on parameters of some plasticizers for flexible vinyl compounds and actually initiated a discussion on the use of stabilizers in various materials. Representatives of the British and American Divisions of Velsicol Chemical (T. Bohnert *et al.*) reported on development of an aromatic plasticizer reducing the viscosity of plastisol. The use of a model oxidation reaction for quantitative evaluation of the performance of a stabilizer based on a phenolic antioxidant in polypropylene was reported in a joint presentation by E. Zeinalov (Institute of Problems of Chemical Physics, Academy of Sciences of Azerbaijan) and H. Schroeder (BAM Company, Germany). Unfortunately, this was the only report made by CIS scientists. The Belgian division of Great Lakes Chemicals (C. Callierotti *et al.*) reported on achievements in the use of physical methods for improving the performance of additives. J. Malik and I. Bachert (Clariant Huningue SA, France) proved that the package of stabilizers developed by them is useful for development of new criteria for testing materials.

Consideration of environmental aspects of using additives was initiated by the survey report made by T. Galvanek (BRG, the United States). Successful cooperation of basic and applied science was demonstrated by representatives of the University of Sussex (the United Kingdom) and divisions of EPI in the United Kingdom, Canada, the United States, and Malaysia, who reported on environmentally clean degradable plastics based on polyethylene. J. van Haveren (Agrotechnological Research Institute, the Netherlands) discussed the possibilities and trends in using additives based on renewable materials.

A. Litzenberger (DSBG BV, Germany) discussed the criteria of optimal choice of flame retardants for plastics. R. Herbiet (Alusuisse Martinswerk GmbH, Germany) described in detail new metal hydroxides which proved to be highly efficient as fireproofing compounds. D. Eisermann (Ciba Specialty Chemicals, Switzerland) reported on increase in productivity of polypropylene film production through stabilization with lactone technology. The first day of the conference was completed with a report made by R. Beswick (BMS AG, Switzerland) on the role of market research in development of the additives business.

The second day of the conference was opened with a report of I. Wheeler (Silberline) on the properties of metal pigments. Then D. Deutsch and J. Catino (Specialty Minerals, the United States) presented a method for quick electron-microscopic analysis of service properties of hybrid antiblocks. R. Rangaprasad and Y. Vasudeo (Reliance Industries, India) reported on

1070-4272/01/7403-0537$25.00

studies of the efficiency of using special additives in production of linear polyethylene.

S. Al-Malaika (Aston University, the United Kingdom) reported on an effective bioantioxidant for polymer stabilization and brilliantly demonstrated the significance of basic research for development of new products. The results of cooperation of scientists from different countries were presented in reports made by staffmembers of the University of Sussex (the United Kingdom) and Victoria University of Technology (Australia) (N. Billingham *et al.*, *Evaluation of the Stabilizer Performance in Polymers*) and of the Institute of Macromolecular Chemistry (Czechia) and Institute of Organic Chemistry (Germany) (J. Pospišil *et al.*, *Optimization of Activity, Performance, and Durability of UV Absorbers*).

However, the majority of reports, as follows from the conference goals, were devoted to commercial systems and products. J.-M. van Maren (Bennet Europe, the Netherlands) reported on composites prepared from polymer solutions. Compatible block copolymers of PVC with polyolefins developed by BF Goodrich Performance Materials were described by N. Pourahmady *et al.* J. Williams and K. Geick (Lonzagroup, the Netherlands) described the effect of the plasticizer on the properties of low-density polyethylene films. Additives used in polymer processing were considered by D. De Corte (Dyneon, Belgium).

The most recent advances were discussed by J. McGowan (General Electric Specialty Chemicals Europe, the Netherlands) in the report *A New Class of Polyolefin Process Stabilizer*; N. Ergenc (Ciba Specialty Chemicals, Switzerland) in the report *New Effect Additives*; I. Vulic (Cytec Industries, the Netherlands) in the report *UV Stabilisation of Pigmented Systems*; J. Ehretsmann (Aptechnologies, Switzerland; Propension, France) in the report *Novel Additives for Improvement of Polymer Properties.*

In the concluding speech, the conference chairman D. Pritchard (the United Kingdom) emphasized that the conference was successful and announced that the next conference will take place in 2001 in Berlin.

BOOK REVIEWS

Nikolaev, V.M., Karelin, E.A., Kuznetsov, R.A., and Toporov, Yu.G., *Tekhnologiya transplutonievykh elementov* (Technology of Transplutonium Elements)

Dimitrovgrad: Nauchno-Issled. Inst. Atomnykh Reaktorov, Gos. Nauchn. Tsentr RF, 2000

Discovery of the phenomenon of radioactivity in the very end of the XIX century has produced a very striking effect on the progress of science in the XXth century, becoming one of the most important factors determining the major research lines in physics, chemistry, and chemical technology all over the world. Among the most distinguished achievements of the XXth century is discovery, characterization, and development of production processes of near transuranium elements, neptunium and plutonium. Of a great interest are also the transplutonium elements (TPEs) (americium, curium, berkelium, californium, and einsteinium). It is worth noting that the technology of TPEs is closely related to the problem of nuclear waste management.

The monograph written by a group of expert researchers from the Research Institute of Nuclear Reactors, Russian State Scientific Center, summarizes and critically evaluates the methods for preparation, separation, and use of TPEs (including the methods used in spent fuel reprocessing). Also a wide spectrum of technological, economic, and environmental problems is discussed. The book includes an introduction and six chapters. Each of them is supplemented with vast bibliography (677 references on the total).

In the introduction (pp. 3–6) the authors justify the urgency of the problems discussed in the book, noting the point that no monograph dealing with the technological aspects of production, separation, purification, and practical applications of TPEs was published in Russia till now.

The first chapter (pp. 7–24) is devoted to the physical principles of production of TPEs. By the essence successive neutron capture in nuclear reactors is the only method for production of practically significant amounts of TPEs. The authors examine physical principles of formation of TPEs by irradiation and the methodology of estimating the yield of the resulting nuclides as well as accumulation of actinides in the irradiated fuel of power reactors.

In the second, central chapter (pp. 25–152) are examined the existing methods for TPE separation and purification to remove fission products and nonradioactive elements. It is indicated that in the chemical technology of TPEs a preference is given to the extraction and chromatographic methods as the most suitable for organization of remote-controlled processes providing high partition coefficients. For concentration and isolation of TPEs the precipitation methods are mostly used. In this chapter extraction of TPEs with neutral extractants, amines, and organophosphorus acids is reviewed.

The third chapter (pp. 153–195) represents data on partitioning of TPEs. The complexity of this problem is caused by the similarity in the properties of TPEs in their typical oxidation state (III) and difficulties in preparation of TPEs in oxidation states other than III because of their low stability.

In the fourth chapter (pp. 196–226) a comparative analysis is made of the existing methods of separation of TPEs from irradiated targets.

The fifth chapter (pp. 226–257) is devoted to the urgent problem of separation of TPEs from spent nuclear fuel. The authors indicate that at present only a few countries (France, the Great Britain, Russia, and Japan) regenerate uranium and separate plutonium from spent fuel. At the same time the United States, Germany, Sweden, Spain, and other countries prefer long cooling of spent fuel followed by its disposal in geological formations. In the chapter are discussed the processes for recovery of actinides from high-level radioactive waste, including wet and molten salt processes.

The concluding sixth chapter (pp. 258–355) summarizes data on ionizing radiation sources based on TPEs. Production of such sources is presently the major practical application area of TPEs.

The book is of indisputable interest for a wide spectrum of specialists working in the field of radiochemistry. The style of rendering makes the monograph intelligible enough to be used as a handbook for teaching staff and students specialized in chemistry and chemical technology

BOOK REVIEWS

Geiss, F., *Osnovy tonkosloinoi khromatografii (planarnaya khromatografiya)*

Moscow, 1999, Russian translation of *Fundamentals of Thin-Layer Chromatography*, Mamaroneck, NY: Huethig, 1987

Thanks to an open sorbent layer, thin-layer chromatography (TLC) is more simple and versatile technique as compared to other chromatographic methods. At the same time the fact that in TLC a sorbent is in contact with the gas phase makes it more difficult to describe the partition processes. Because of their complexity the molecular interactions between a sorbent, sorbate, and solvent in TLC systems are poorly understood, which does not allow formulation of criteria for *a priori* decision on optimal solvents and sorbents for solving a given task. Therefore, knowledge of TLC fundamentals as well as of the principles common for all the chromatographic techniques is the necessary condition for successful application of TLC.

The translation of the worldwide known monograph by Geiss became the first book in Russian devoted to the principles of TLC, including new techniques, sorbents, solvents, and methods for optimization of TLC procedure.

Russian translation of the monograph was initiated by V.G. Berezkin. The book was submitted for publishing in 1989. However, only in 1998 V.G. Berezkin and L.N. Kolomiets succeeded (after changing the publishing house) in organization of printing the monograph. Conscientious and competent translation of the book was made by B.P. Lapin and M.A. Koshevnik.

The first chapter of the monograph represents the guidance to the monograph and comparative examination of advantages and drawbacks of TLC and liquid column chromatography.

The second chapter gives the background of TLC, emphasizing the solvent flow in a porous medium under the action of capillary forces. The factors responsible for erosion of chromatographic bands are analyzed. With reference to the works by Giddings and Guiochon the author examines various methods for estimating the layer efficiency (mean theoretical plate height, separation number).

The third chapter is important from the practical standpoint. It is devoted to representation and analysis of the TLC data. Attempts are made to assess the applicability of various methods for correcting R_f. A particular attention is paid to the resolving power equation. To compare the applicability of different multicomponent eluents to separation of the same test mixture, the author recommends to use the discriminating power equation. Also a comparative analysis is given of the potentialities of various elution modes.

With the advent of chemically grafted phases, particularly reversed phases, the requirements to the layer activity control became less strict. However, the traditional sorbents such as silica gel and alumina remain the most widely popular because of their low cost. Therefore, the separation quality may depend on the sorbent activity. In this connection the fourth chapter, reviewing the properties of TLC sorbents and the methods for activity control of hydrophilic sorbents, is interesting and important for understanding the processes occurring in TLC separations.

The fifth chapter deals with the problems of optimization of R_f and the selectivity, i.e., the parameters characterizing solvents and eluents. The methods for characterization of the eluting power are examined.

The system solvent–gaseous phase–sorbent is examined in the sixth chapter, including such topics as saturation of a TLC box, presaturation of a sorbent layer and its consequences, and changing composition of the moving phase. The effects of the temperature, pH, sorbent layer thickness, quality of a solvent, etc. are discussed in the seventh and eighths chapters.

The theoretical and practical aspects of gradient TLC are examined in the ninth chapter.

In the tenth chapter the points considered in the fourth chapter are analyzed as applied to the problem of how the results obtained in TLC separations can be used for optimization of liquid column chromatography separations. The author formulates the criteria of successful application of TLC data to liquid column chromatography separations and analyses the commonly spread sources of failure on this way.

1070-4272/01/7403-0540$25.00

The eleventh chapter entitled *Quantitative Processing of TLC Data* is written by S. Ebel. The chapter outlines briefly the basic principles and methods of quantization of TLC data.

In the twelfth chapter an algorithm is given for optimization of separation conditions, and also recommendations how to eliminate the typical errors.

Finally, in the Appendix are given the basic equations used in TLC, brief glossary of terms, and tables for recalculation of the retention factors.

The book is of indisputable interest for a broad spectrum of specialists working in the field of chromatography, including organic and medical chemists, biologists, criminalists, and also analysts dealing with analysis of drug preparations, environmental objects, and foods.

Abstract—Specific features of the hydrolysis of polyacrylamide and its derivatives under various conditions are characterized. The most efficient procedures for performing hydrolysis in dilute and concentrated aqueous solutions and suspensions, as well as during acrylamide polymerization in aqueous solutions and emulsions, are discussed.

Polymer-analogous transformations involving a low-molecular-weight reagent are successfully employed for modification of natural and synthetic polymers with the aim to prepare products with improved set of performance characteristics [1, 2]. A good example of this is the hydrolysis of polyacrylamide (PAA) and its derivatives, yielding partially hydrolyzed polymers with greater application potential, compared with the initial polymers. Such hydrolyzed polymers differing in the molecular weight M and MWD pattern, chemical composition, and distribution of the hydrolyzed units along the chain (linear, branched, and cross-linked) have different functional purposes and different application fields (water treatment, flocculation of the raw material flotation residue, concentration and recovery of minerals, intensification of petroleum production, paper and textile processing) [3–6]. For example, high polymers [$M = (2–18) \times 10^6$], whose efficiency grows with increasing M, serve as flocculants, thickeners, structure- and film-forming agents and lubricants, and low-molecular-weight polymers [$M = 5 \times 10^3–4 \times 10^5$] can be used as petroleum thinning agents, dispersing and stabilizing agents for muds, and additives for hermetic sealing and for decreasing the loss of cement slurries [3–9]. With regard to preparing partially hydrolyzed polymers with various molecular characteristics, it is worthwhile to consider the potentialities of the chemical modification of PAA and its derivatives by various methods. The relationships in acid and alkaline hydrolysis of polyvinylamides were discussed in review [10] and monograph [6]. In view of these data, supplemented by more recent publications, we consider in this work the specific features of hydrolysis of PAA and its derivatives and the most efficient hydrolysis procedures in dilute and concentrated aqueous solutions and suspensions and during polymerization of acrylamide (AA) in the presence of hydrolyzing agents in aqueous solutions and emulsions. We do not consider copolymerization of AA and other unsaturated amides with acrylic (AAc) and methacrylic acid, since various aspects of copolymerization in the systems of interest have been discussed in monographs [6, 11, 12].

SPECIFIC FEATURES OF HYDROLYSIS OF POLYACRYLAMIDE IN AQUEOUS SOLUTIONS

Without hydrolyzing agents, polyacrylamide is resistant to hydrolysis in aqueous solutions at room temperature [13, 14], and at high temperatures (93°C) it is hydrolyzed at an appreciable rate [15–19]. The chemical stability of aqueous solutions of PAA at 60 and 100°C at pH 4–10 was studied in [20, 21]. The hydrolysis rate is at a maximum at pH 4, and at a minimum at pH ~ 10. Hydrolysis of PAA in the presence of acid catalysts yields AA–AAc copolymers:

$$-(-CH_2-\underset{\displaystyle CONH_2}{\underset{|}{CH}}-)_n- \;+\; mH_2O$$

$$\rightarrow\; -(-CH_2-\underset{\displaystyle CONH_2}{\underset{|}{CH}}-)_{n-m}-(-CH_2-\underset{\displaystyle COOH}{\underset{|}{CH}}-)_m- \;+\; mNH_3.$$

As hydrolysis catalysts are used strong mineral acids (hydrochloric, sulfuric, phosphoric, etc.) and polysulfonic acid [20, 21]. Acid hydrolysis of PAA is

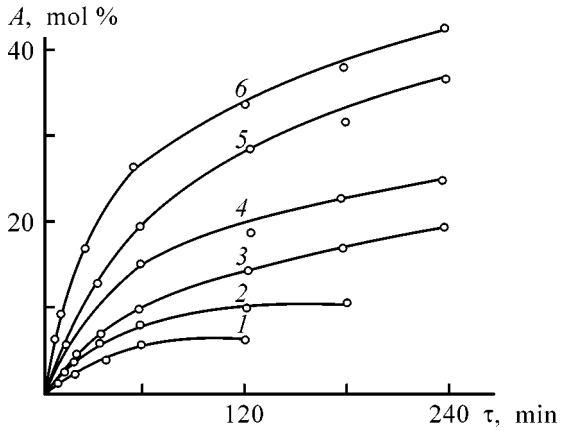

Fig. 1. Variation of content of SA units in copolymer *A* with time τ in hydrolysis of PAA with $M_\eta = 3.2 \times 10^6$ at different NaOH concentrations. [PAA] = 0.14 base-mol l^{-1}, T = 50°C. [NaOH] (M): (*1*) 0.014, (*2*) 0.042, (*3*) 0.070, (*4*) 0.097, (*5*) 0.14, and (*6*) 0.278.

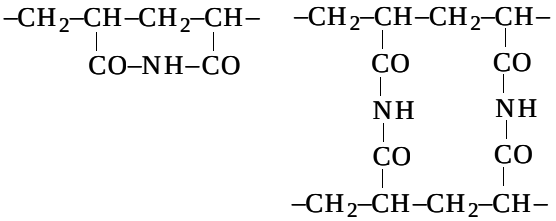
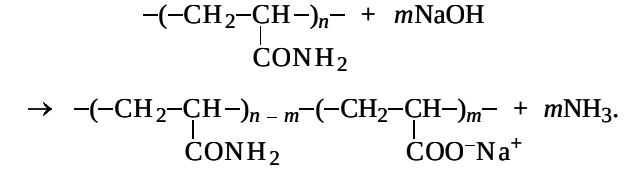
typically accompanied by intra- and intermolecular imidization yielding the following structures:



Imidization yields partially or completely insoluble products. The lost solubility can be recovered by treating the polymer with weakly alkaline solutions to break down the secondary amide bridges between the macromolecules:

Imidization of PAA in acidic media occurs at an appreciable rate at 75, accelerates at 85, and is very fast at 110°C [21] and at high polymer concentrations. Polymethacrylamide (PMAA) undergoes exhaustive imidization at 65°C [3]. In contrast to PAA, *N*-alkylacrylamide polymers do not undergo imidization. Because of the occurrence of imidization, acid hydrolysis of the polymer has not found application in preparing hydrolyzed derivatives of polyvinylamides. Therefore, alkaline hydrolysis seems to be more suitable for these purposes.

Hydrolysis of PAA in the presence of base catalysts (alkalis, carbonates and bicarbonates of alkali metals, etc.) yields random copolymers of AA and AAc salts whose macromolecules contain no block structures [21]:



The kinetics of alkaline hydrolyis of PAA in aqueous solutions has been extensively studied [20, 22–30]. The reaction proceeds at a higher rate compared with low-molecular-weight amides, but, in contrast to them, it involves two stages. The first stage is characterized by the highest rate and is complete at a degree of hydrolysis equal to 40 mol %. This is a first-order reaction with respect to PAA and alkali. The second stage of hydrolysis proceeds at a 10 times lower rate, compared with that in the first stage and is complete at a degree of hydrolysis equal to 70%. The high initial rate of the reaction is due to the fact that the carboxylate groups formed in hydrolysis accelerate the hydrolysis of the neighboring amide groups (anchimeric contribution) [2]. The deceleration with increasing conversion is due to the enhanced electrostatic repulsion between the OH^- ions and the accumulating carboxylate anions $-COO^-$. Deceleration is also due to the growing size of the macromolecular globules, making higher the viscosity of the solutions and hindering the diffusion of the reacting species. Raising the NaOH concentration accelerates the hydrolysis and enriches the forming copolymer in sodium acrylate (SA) units (Fig. 1) [31]. Raising the temperature also accelerates the PAA hydrolysis. The activation energy of PAA hydrolysis grows with increasing conversion and is estimated at 59.5, 74.0, 81.5, and 99.5 kJ mol^{-1} for degrees of hydrolysis equal to 2, 8, 12, and 19 mol %, respectively [32]. A similar pattern of variation of the activation energy with conversion in the alkaline hydrolysis of PAA was observed in [29]. Along with the regular influence of the temperature on the hydrolysis rate, the temperature-related changes in the degree of dissociation of carboxylate groups, in the character of the electrostatic interaction between the carboxylate anions and OH^- ions, and in the conformation taken by the macromolecules, affected the activation energies of hydrolysis.

Hydrolysis in dilute aqueous solutions (0.05–0.2%) of PAA with $M_\eta = 5.7 \times 10^6$ under the action of NaOH was studied in [33]. The reaction was carried out at 3, 25, and 50°C for a period of time ranging from 3 h to 20 days. Lowering the polymer concentration (at [NaOH] = const) made higher the initial rate and degree of hydrolysis of PAA owing to an increase in the [NaOH]/[PAA] ratio. The hydrolysis was intensified by raising the temperature and NaOH concentration (at [PAA] = const). The experiments showed that

low-temperature hydrolysis of PAA in dilute aqueous solutions is suitable for preparing copolymers with controllable content of the SA units, which can be used, e.g., for treatment of natural water.

Influence of the neighboring units. The influence of the hydrolyzed groups on hydrolysis of the neighboring amide groups in alkaline hydrolysis of PAA was studied by Higuchi and Senju [25]. They analyzed the reactivity of the amide units (B) of the macromolecules with zero, one, or two neighboring carboxylate units (A), characterized by hydrolysis rate constants k_0, k_1, and k_2, respectively. For the initial rate of hydrolysis, Higuchi and Senju proposed the equation

$$dx/d\tau = k_0[a - (3 - 2k_1/k_0)x][OH^-], \quad (1)$$

where x is the concentration of the hydrolyzed groups at the instant τ, and a is the initial concentration of the amide groups.

In the course of the reaction, the amide groups having no neighboring carboxylate groups disappear at a degree of hydrolysis equal to 43 mol %, and the amide groups with one carboxylate neighbor at a degree of hydrolysis equal to 57 mol %. At a degree of hydrolysis within 43–57 mol % the reaction rate can be described by the equation

$$dx/d\tau = 2k_2(0.57a - x)[OH^-]. \quad (2)$$

The experimental data on the PAA hydrolysis are adequately described by the relation $k_0 : k_1 : k_2 = 1 : 0.2 : 0$ [25] and indicate a decelerating (with increasing conversion) effect of the $-COO^-$ groups (repulsion of OH^- ions) on the hydrolysis of the neighboring amide groups. For describing the rate of alkaline hydrolysis of PAA with account of the influence exerted by the neighboring groups, Fuoss *et al.* [34] proposed the equation

$$dx/[(a - x)(b - x)] = [k_0 e^{-\alpha\tau} + k_2(1 - e^{-\alpha\tau})]d\tau, \quad (3)$$

where a and b are the initial concentrations of PAA and NaOH, respectively, and α is the probability factor.

Data comparison made by Truong *et al.* [35] showed that the kinetics of alkaline hydrolysis is adequately described by Eqs. (1) and (2). It was also found that the experimentally established (by NMR spectroscopy) pattern of distribution of the carboxylate units in the macromolecules of the hydrolyzed polymer is in good agreement with that calculated for the $k_0 : k_1 : k_2 = 1 : 0.2 : 0$ ratio (Fig. 2). This suggests the decisive role played by the effect of neighboring groups in the kinetics of alkaline hydrolysis of PAA.

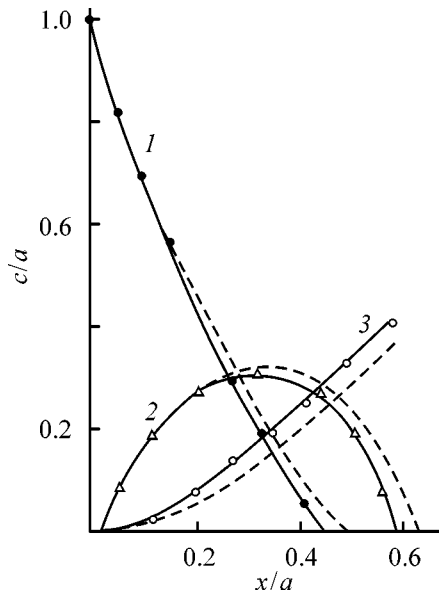


Fig. 2. Relative content of triads in hydrolysis of PAA. (c, a, x) Concentrations of the triads and amide and carboxylate groups, respectively. (*1*) BBB, (*2*) (BBA + ABB); and (*3*) ABA. (*Points*) Experimental data and (*dashed lines*) calculation for $k_0 : k_1 : k_2 = 1 : 0.2 : 0$.

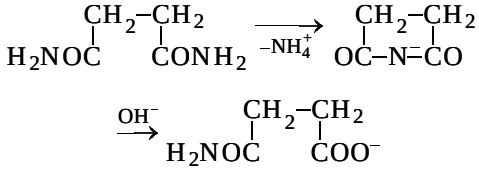
Influence of the macromolecule structure. The hydrolysis reaction is affected by the structure of the polymer molecule. As shown in [36, 37], hydrolysis of PAA and PMAA, similarly to that of low-molecular-weight amides, involves an intermediate imidization stage. This was confirmed by spectral studies: The characteristic absorption band of imide at $\lambda = 235$ nm appeared and subsequently disappeared during hydrolysis. The transformations of low-molecular-weight amides in alkaline hydrolysis can be represented as



The rate constants of imidization, k_i, and hydrolysis, k_h, for low-molecular-weight amides, such as succinimide, glutarimide, and PAA, are estimated at 25°C as follows: $k_i \times 10^{-4}$ (s^{-1}): 2.7, 0.62, 4.4; $k_h \times 10^{-4}$ (s^{-1}): 1.03, 1.78, 1.06 [38]. These constants evidence that the PAA macromolecules contain "head-to-head" linked units that underwent imidization and subsequent hydrolysis. The imidization and hydrolysis become faster with increasing temperature, with the activation energy of imidization exceeding that of hydrolysis [22].

Unlike low-molecular-weight amides that can be hydrolyzed quantitatively [39], PAA is hydrolyzed in

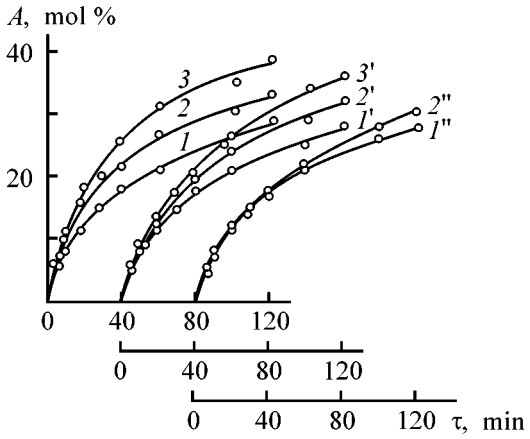


Fig. 3. Variation of the content of SA units in copolymer *A* with time τ in hydrolysis of PAA with $M_\eta = 3.2 \times 10^6$ for various concentrations of NaCl. [PAA] = 0.14 base-mol l^{-1}, [NaOH] = 0.14 M, *T* = 60°C. [NaCl], M: (*1*, *1*', *1*'') 0, (*2*, *2*') 1.71, and (*3*, *3*', *2*'') 3.42. $M_\eta \times 10^{-6}$: (*1*–*3*) 9, (*1*'–*3*') 3.42, and (*1*'', *2*'') 0.4.

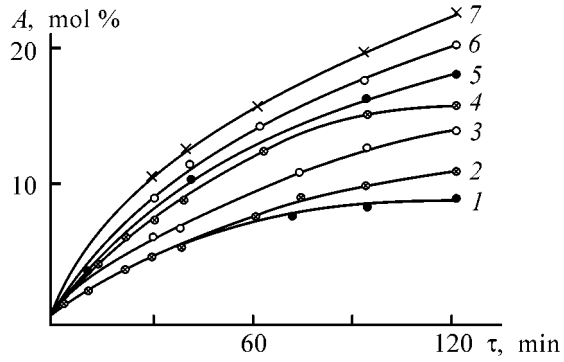

Fig. 4. Variation of the content of Li (Na, K) acrylate units in copolymer *A* with time τ in PAA hydrolysis for various concentrations of (*1*, *3*, *5*) LiOH, (*2*, *4*, *6*) NaOH, and (*2*, *4*, *7*) KOH. [PAA] = 0.14 base-mol l^{-1}, *T* = 50°C. [Alkali], M: (*1*, *2*) 0.07, (*3*, *4*) 0.096, and (*5*–*7*) 0.139.

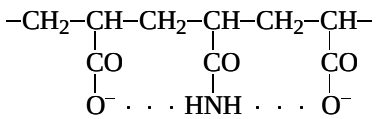
the presence of base catalysts to typically no more than 70 mol %. This is due to the fact that the amide groups blocked by two neighboring carboxylate groups become inactive [24], which can be represented schematically as



Copolymers of AA with AAc and AA with allyl alcohol [20], polymethacrylamide, as well as copolymers of methacrylamide with methacrylic acid, are also hydrolyzed incompletely [38, 40]. The degree of PAA hydrolysis can be increased by carrying out the reaction in 10 M NaOH at 100°C [20]. Also, the degree of hydrolysis can be brought to 96% in a two-stage reaction, with the hydrolysis initially carried out in the presence of NaOH at 20°C to the degree of hydrolysis equal to 67 mol % and then in the presence of HCl at 100°C [41]. Similar results were obtained when PAA was initially hydrolyzed at 95–97°C for 2 h to 60 mol % conversion and then at 100–210°C [42]. It should be noted that at high temperatures the hydrolysis may be accompanied by degradation of the macromolecules [20, 43].

Influence of the ionic strength. The influence of salt additives on the alkaline hydrolysis of PAA in aqueous solutions was discussed in a number of works. It was found that these additives accelerate hydrolysis at 50 [29, 33] and 93°C [44]. In [31], alkaline hydrolysis of PAA with different molecular weights in 1% aqueous solutions at 20–60°C was studied as influenced by addition of NaCl. In [45], the kinetics of the process was studied potentiometrically. As seen from the kinetic curves shown in Fig. 3, the initial rate of hydrolysis of PAA remains unchanged with M_η varied within $(0.4–9.2) \times 10^6$ and upon addition of NaCl. With increasing conversion, the influence of NaCl on hydrolysis becomes appreciable, (compare curves *1* and *3*, *1*' and *3*', and *1*'' and *2*''), and this effect is enhanced with increasing *M*. This follows from the changes with conversion in the electrostatic interactions in the system and in the conformation taken by the macromolcules, as indicated by measurements of the dynamic viscosity of the reaction solutions.

The above data show that the degree of PAA hydrolysis grows with increasing ionic strength of the solutions and molecular weight *M* of the initial polymer.

Kurenkov *et al.* [31] studied the influence of the ammonium sulfate impurity on the alkaline hydrolysis of PAA, this impurity being typical of PAA produced by ammonia procedure. The experiments showed that the initial rate of the reaction and the degree of hydrolysis of the polymer decrease with increasing concentration of the added ammonium sulfate. This is due to the decrease in the concentration of NaOH consumed in the reaction with ammonium sulfate. Thus, the degree of hydrolysis of the forming copolymer may decrease in the presence of impurities contained in PAA produced by ammonia procedure.

Influence of the nature of hydrolyzing agents. The kinetics of hydrolysis of PAA with $M_\eta = 6.5 \times 10^6$ in 1% aqueous solutions in the presence of LiOH, NaOH, and KOH at 50°C was studied in [46]. The kinetic curves of hydrolysis are shown in Fig. 4. It is

seen that the initial rate and degree of hydrolysis of the polymer grow with increasing concentration of the hydrolyzing agent (going from curves *1*, *2* to curves *3*, *4* and *5*–*7*). Data in Fig. 4 for fixed concentrations of added alkali show that the initial rate and degree of hydrolysis of the polymer in the region of low alkali concentrations increase in the order LiOH < NaOH (KOH) (curves *1*, *2* and *3*, *4*), and at higher alkali concentrations, in the order LiOH < NaOH < KOH. According to the findings of Marina and Monakov [47] and the measured dynamic viscosities of the reaction solutions, the degree of binding of the cations to the copolymers of AA with AAc salts increases in the order $Li^+ < Na^+ < K^+$. Therefore, the electrostatic repulsion between the carboxylate anions and OH^- ions, which enhances the catalytic activity of the alkalis, must weaken in the order LiOH > NaOH > KOH. This dependence becomes more pronounced with increasing alkali concentration and time of hydrolysis.

The PAA hydrolysis can be carried out in the presence of sodium silicate—liquid glass which is an aqueous solution of oligomers of general formula $[Na(OH_2)_x]_2Si_mO_{2m+1}$, where m is the silicate modulus ($m = [SiO_2] : [Na_2O] \times 1.032$). Sodium silicate exhibits strong alkaline properties: pH 13–14 and alkalinity corresponding to 3–4 N NaOH [14, 48]. This is due to dissociation of the oligomers in water

$$[Na(OH_2)_x]_2 Si_mO_{2m+1} \rightleftarrows (Si_mO_{2m+1})^{2-} + 2Na(OH_2)^+$$

and the subsequent hydrolysis of the oligomer ions

$$(Si_mO_{2m+1})^{2-} + 2H_2O \rightleftarrows 2OH^- + H_2Si_mO_{2m+1}.$$

As known [49], alkaline hydrolysis of polyacrylonitrile at 92–96°C yields AA–SA copolymers. As hydrolyzing agent can serve sodium silicate [50]. However, high-temperature hydrolysis of polyacrylonitrile is a multistage reaction complicated by the heterophase nature of the process and degradation of the macromolecules [51]. Therefore, it is more advisable to prepare AA–SA copolymers by hydrolysis of PAA at moderate temperatures (20–50°C), which was studied in [52, 53]. In these works, hydrolysis was carried out in 0.5% aqueous solutions at 50°C for 1.5 h. It was shown that the initial rate and degree of hydrolysis increase with growing silicate modulus of sodium silicate owing to the increasing alkalinity and, hence, hydrolyzing power. Raising the sodium silicate concentration within 0.3–1.0% accelerated the reaction and increased the degree of PAA hydrolysis. Similar trends were observed on raising the polymer concentration within 0.05–0.5% [52], as well as on elevating the temperature from 20 to 50°C [53].

Table 1. Characterization of hydrolyzing agents

Hydrolyzing agent	Density at 20°C, g cm^{-3}	Akali content, %
Etching bath effluent	1.435	40.0
Solid alkali wastes	1.020	1.94
Degreasing solution	1.023	2.03

This is the first-order reaction with respect to PAA and sodium silicate, which is in agreement with the data on the hydrolysis under the action of NaOH [22, 24]. The results cited above confirmed the suitability of sodium silicate for preparation at an acceptable rate of efficient flocculants with various degrees of hydrolysis [48].

Partially hydrolyzed PAA with various molecular weights can be prepared by a two-stage procedure, when hydrolysis under the action of sodium silicate is followed by partial degradation of the polymer in 0.4% aqueous solutions under the action of potassium peroxosulfate (5% relative to the polymer) at 50°C for 4 h [54]. It was shown that M can be lowered by factors of 2.3 and 3.5, compared with the initial PAA, the degree of hydrolysis of the products being 42.0 and 16.2 mol %, respectively.

As hydrolyzing agents for PAA can serve various alkaline process wastes. In [55, 56], hydrolysis of PAA in 0.5% aqueous solutions at 30–70°C under the action of alkaline electroplating wastes was studied (these wastes are characterized in Table 1). It was shown that PAA samples with different molecular weights M_η within $(0.9–5.3) \times 10^6$ can be hydrolyzed at room temperature to a degree of 30 mol %. Figure 5 illustrates how the hydrolysis is influenced

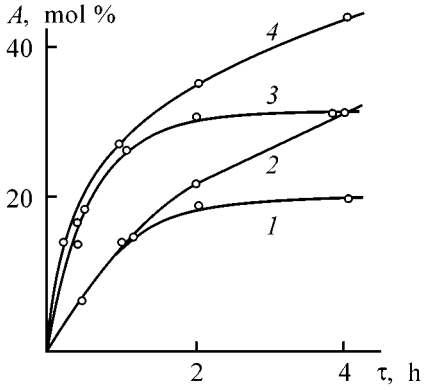


Fig. 5. Variation of the content of acrylate units in copolymer A with time τ in hydrolysis of PAA with $M_\eta = 5.3 \times 10^6$ for various hydrolyzing agents. [PAA] = 0.07 base-mol l^{-1}, T = 21°C. Hydrolyzing agent (0.01%): (*1*) solid alkali wastes, (*2*) sodium hydroxide, (*3*) degreasing solution, and (*4*) etching bath effluent.

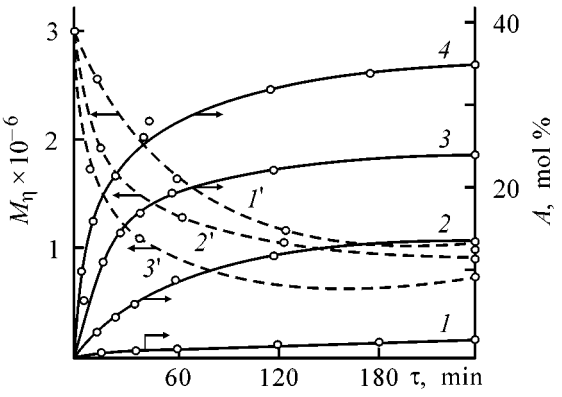

Fig. 6. Variation of (*1*–*4*) content of SA units in copolymer *A* and (*1*'–*3*') M_η with time τ in PAA hydrolysis at various concentrations of NaOH. [PAA] = 0.343 base-mol l^{-1}; $[K_2S_2O_8]$ = 0.033% of [PAA], T = 60°C. [NaOH], M: (*1*, *1*') 0, (*2*) 0.116, (*3*, *2*') 0.437, and (*4*, *3*') 0.734.

by various hydrolyzing agents. It is seen that all the hydrolyzing agents exhibit high catalytic activity with respect to PAA. In the order of increasing catalytic activity, the reagents can be arranged as follows: solid alkali wastes (sodium hydroxide) < degreasing solution < etching bath effluent. The difference between the efficiencies of the hydrolyzing agents is evidently due to the impurities contained in the wastes.

The aforesaid suggests that alkaline electroplating wastes are suitable for preparing partially hydrolyzed PAA, a promising reagent for intensifying the treatment of process wastewater and, in particular, electroplating effluents [57, 58].

METHODS FOR PREPARATION OF ACRYLAMIDE–SODIUM ACRYLATE COPOLYMERS

Hydrolysis of PAA in aqueous solutions in the presence of destructive agents. Alkaline hydrolysis of PAA in the presence of minor amounts of destructive agents is suitable for controlling the chemical composition and molecular weight M of the forming products. The hydrolysis of PAA, combined with its degradation, was studied in [59]. The reaction was carried out at 30–70°C in 2.4% aqueous solutions of PAA with M_η 3×10^6 in the presence of $K_2S_2O_8$ as degradative agent. Hydrolysis was monitored potentiometrically [45], and degradation, viscometrically. Alkaline hydrolysis of PAA [60] and partially hydrolyzed PAA [61] in the absence of $K_2S_2O_8$ did not involve degradation, which is consistent with published data [62]. Introducing $K_2S_2O_8$ and raising its concentraiton did not affect the hydrolysis but were accompanied by a decrease in M as a result of degradation of the macromolecules. Figure 6 illustrates how the NaOH concentration affects the process. Without NaOH, hydrolysis does not occur (curve *1*), whereas with increasing NaOH concentration, the hydrolysis becomes faster (going from curve *2* to curve *4*). It is seen that the degradation reactions are intensified with increasing NaOH concentration (going from curve *1*' to curve *3*'). Raising the temperature affected the degradation in a similar way. In the 30–70°C range, the activation energy of alkaline hydrolysis of PAA in the presence of the destructive agent is estimated at 46.3 kJ mol^{-1}. The studies described demonstrated the possibility of preparing partially hydrolyzed polymer with controllable molecular weight M and chemical composition of the macromolecules.

PAA hydrolysis in suspensions. This method is based on hydrolysis of the already prepared PAA in a concentrated aqueous solution dispersed in a water-immiscible organic solvent (benzene, toluene, heptane, hexane, cyclohexane, etc.). First, a suspension of an aqueous PAA solution is prepared (20–50% water + 20–50% PAA) in an organic liquid containing 0.1–30% of an oil-soluble emulsifying agent with low hydrophilic–lipophilic balance. Also, an alkali-resistant surfactant and 0.2–30% (relative to the suspension mass) of 50% aqueous solution of the hydrolyzing agent (NaOH, KOH, Na_2CO_3, K_2CO_3, etc.) are introduced into the suspension. The reaction is run at 10–70 [63–65] or 125°C under pressure to prevent boiling of the reaction mixture [66]. Also, the hydrolyzing agent can be added in the form of an alkali suspension in a hydrophobic organic liquid [63, 64]. As stabilizing additives can serve oxyethylated alcohols (oleyl and lauryl) [63, 65, 66] and oleic acid isopropylamide [67].

Also described was hydrolysis of a PAA suspension with particle size of 0.001–1.0 cm under the action of alkaline agents in the form of solutions [68, 69] or emulsions [68]. The degree of hydrolysis of the polymer is controlled by varying the concentrations of the hydrolyzing agents, temperature, and reaction time.

Powdered PAA can be hydrolyzed in aqueous-organic media in the presence of an alkali with such organic liquids as C_{4-6} alcohols [69–72], ketones, ethers, and nitriles readily miscible with water [71].

The reaction rate and the degree of hydrolysis of the polymer are governed by the ratio of the aqueous and organic phases. Raising the fraction of water in the mixture leads to higher degree of swelling of the polymer particles and makes the amide groups of the macromolecules more accessible to OH^- ions [73].

The kinetic features of alkaline hydrolysis of PAA with $M_\eta = 3.4 \times 10^6$ and uniform particle size (average size 0.04 cm) have been studied in water–toluene suspensions ([PAA] = 14.2–71.0%, water : toluene volume ratio 1 : 8) at 60°C [45, 74]. NP-3 Sulfonol (sodium alkylbenzenesulfonate of general formula $C_nH_{2n+1}C_6H_4SO_3Na$ with n = 10–12) in amount of 0.5% relative to that of toluene served as stabilizing agent. The data reported in [45, 74] suggest the possibility of changing the degree of hydrolysis of the polymer by varying the NaOH concentration. It was shown that alkaline hydrolysis in suspensions, similarly to that in aqueous solutions, is a second-order reaction (first-order with respect to the alkali and PAA). Hydrolysis is accelerated by raising the temperature; the activation energy is estimated at 63 kJ mol^{-1}.

In [45], the inflence of nonuniform particle-size distibution pattern on alkaline hydrolysis of PAA was studied. Figure 7 presents the kinetic curves of hydrolysis of a PAA sample with nonuniform particle size (particle size 0.015–0.24 cm) and fractions with uniform particle size. In the initial stage of hydrolysis, the PAA samples with nonuniform and uniform particle sizes differ in the degree of hydrolysis. For samples with uniform particle size the initial rate of hydrolysis increases with decreasing particle size. This is due to increase in the degree of swelling of PAA and easier accessibility of the amide groups of the polymer to OH^- ions. As seen from Fig. 7, at high conversions (>40 mol %) the samples with nonuniform and uniform particle sizes exhibit identical degrees of hydrolysis. This is evidently due to the fact that the swelling degree in the aqueous phase of the polymer attained the limiting value for all the samples and the amide groups became equally accessible to the hydrolyzing agent. This demonstrates the possibility of preparing polymers with controllable degree of hydrolysis by PAA hydrolysis in suspensions.

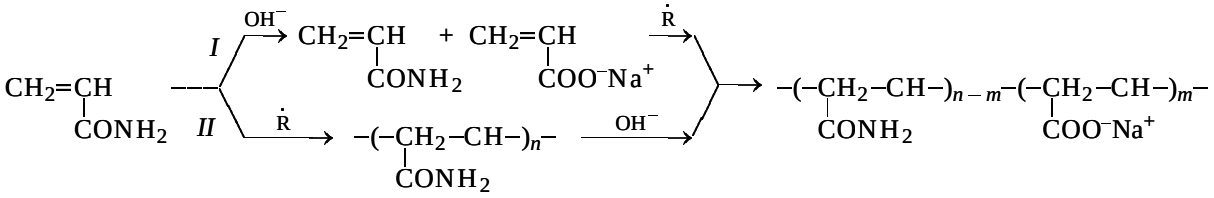
Polymerization of AA in concentrated aqueous solutions in the presence of hydrolyzing agent. In review [75], the AA polymerization in aqueous solutions was studied as influenced by the pH of the medium. Various procedures for AA polymerization in the presence of hydrolyzing agents were described in patents [76, 77]. This process occurs in the presence of free radicals $R^\cdot$ and the OH^- ions, originating from NaOH dissociation and catalyzing the hydrolysis. The process can be represented by the general scheme



Of the two possible reaction routes *I* and *II*, the main route is copolymerization *I*. Only at low conversions (<3%) the contribution from route *II* is comparable with that from route *I*; for high conversions (>30–40%) the contribution from route *II* is negligible. The reaction is carried out with concentrated solutions of monomers to prepare macromolecular products. However, it is accompanied by cross-linking as a result of imidization coused by hydrogen ions present in aqueous solutions. Adding alkali to an aqueous monomer solution makes imidization and cross-linking of the polymer less probable but decreases the molecular weight of the polymer. Formation of water-soluble products is also favored by tris(2-carbamoylethyl)amine (CEA), characterized by high proton-accepting power. Under the polymerization conditions,

* [AA] = 0.704 M, $[(NH_4)_2S_2O_8]$ = 0.1% of AA, 50°C, 5 h.
** [AA] = 0.625 M, $[K_2S_2O_8]$ = 0.1% of AA, 40°C, 2 h.

CEA is formed in the reaction of AA with sodium hydroxide and ammonia by the scheme

$$CH_2{=}CHCONH_2 \xrightarrow{OH^-} CH_2{=}CHCOO^- + NH_3,$$

$$3CH_2{=}CHCONH_2 + NH_3 \rightarrow (CH_2CH_2CONH_2)_3N.$$

CEA forms redox systems with persulfates and affects the initiation rate of polymerization [78]. Also, CEA is a chain-transfer agent, and low-molecular-weight products are formed in its presence, even in concentrated monomer solutions [78–80]. For example, the intrinsic viscosity of the polymers produced by radiation-induced polymerization of AA ([AA] = 70%) in binary eutectic systems (AA + H_2O) decreases from 1350 to 400 $cm^3\ g^{-1}$ with the NaOH concentration increasing from 0.45 to 1.46% [81].

Kurenkov *et al.* [82] studied the AA polymerization in 20% aqueous solutions in the presence of Na_2CO_3 and NaOH under adiabatic conditions (initial temperature 25°C), with peroxosulfate-hydrosulfite as initiating system. The heat released in polymerization decreases the viscosity of the system and shifts the gel effect to high temperatures. The decrease in the viscosity of the reaction mixture facilitates diffusion of the hydrolyzing agent toward the amide groups of the macromolecules and makes the hydrolysis of the polymer more efficient. It was found under conditions simulating the polymerization [82] that CEA is not formed in the presence of Na_2CO_3 and the degree of hydrolysis of AA is not high. The initial polymerization rate tends to decrease with increasing concentration of CEA, NaOH, and Na_2CO_3 additives in the order CEA < NaOH < Na_2CO_3 (at fixed concentration of the additives). The reaction order with respect to CEA, NaOH, and Na_2CO_3 is 1.0, 0.8, and 0.1, respectively. The molecular weight M of the resulting copolymers tends to decrease in the presence of CEA and NaOH additives. In contrast to NaOH, raising the Na_2CO_3 concentration is not accompanied by any increase in the CEA concentration or the molecular weight M of the copolymer. The copolymers prepared in the presence of Na_2CO_3 are characterized by $M < 4.2 \times 10^{-6}$ and content of the SA units of up to 15 mol %.

In [83, 84], AA copolymers with SA or AAc were prepared under the conditions of adiabatic polymerization of AA in 28% aqueous solutions in the presence of alkalis (pH < 13.5) and acids (boric, phosphoric). On introducing radical initiators, the temperature increased from 27 to 92°C owing to the exothermic character of polymerization. Polymerization yielded high copolymers containing 13 mol % ionic units. To increase their content to 30–35 mol %, the reaction mass after polymerization was kept at elevated temperature for 4–20 h.

In [85], synthesis of macromolecular AA–SA copolymers in AA polymerization in 40% aqueous solutions at initial temeprature of 20–50°C [85] was described. The reaction was run in buffer solutions of a mixture of sodium tertraborate and sodium hydroxide (molar ratio 1 : 3) or disubstituted sodium orthophopshate with sodium hydroxide (molar ratio 1 : 1), or sodium carbonate with sodium hydroxide (at salt concentration in the buffer solution of 0.02–0.36 and sodium hydroxide concentration of 0.04–0.5 M) at pH 12.0–12.4. The resulting reaction mass was kept at 60–75°C for 5 h in a vacuum or inert medium. Drying yielded powdered AA–SA copolymer with particle size of 0.01–0.5 cm.

The AA–SA copolymers with content of SA units of 30 mol % and $M = 12 \times 10^6$ can be prepared by radiation-induced polymerization of AA in the presence of sodium hydroxide and boric acid [86]. Polymerization of AA in 20–50% aqueous solutions in the presence of a buffer mixture (pH > 12) under the action of ionizing radiation (^{60}Co) and with chem-

ical initiation can yield AA–SA copolymers of various compositions [87]. At low NaOH concentrations, hydrolysis of the salt component of the buffer mixture increased the alkali content in the reaction mixure and enabled control over the composition of the forming copolymer.
