Of indubitable interest is the possibility of preparing AA–SA copolymers in inverse emulsions. To this end, a concentrated aqueous solution of the monomer, with a hydrolyzing agent as additive, is dispersed in a hydrophobic organic liquid (benzene, toluene, xylene, cyclohexane, etc.) in the presence of a water-in-oil emulsifying agent [88]. Polymerization is initiated by an oil- or water-soluble initiator. In this case, polymerization and hydrolysis proceed in the aqueous phase. The advantages of this method are the facile heat removal and the occurrence of the reaction in low-viscosity media (viscous aqueous solution of the forming copolymer is the internal phase). The reaction yields a latex suitable as a ready-to-use product. The latex can easily be concentrated by azeotropic distillation; if followed by drying, this yields a powdered polymer [6, 88]. Various aspects of the AA polymerization in the presence of hydrolyzing agents in inverse emulsions with various organic solvents, emulsifying agents, and initiators have been discussed [89–98]. It was shown that the polymerization can be accelerated by raising the NaOH concentration. This is due to the enhanced influence of the SA monomer yielded by hydrolysis, whose polymerization is accelerated by the increasing NaOH concentration [11]; the AA polymerization rate in alkaline media is independent of pH [99]. Raising the NaOH concentration results in enrichment of the copolymer in the SA units and a decrease in M (Table 2). The observed decrease in M was ascribed to the increasing contribution of chain transfer to CEA, whose content in the reaction mixture increased with growing NaOH concentration. The data in Table 2 show that the characteristics of the copolymers in inverse emulsions are in agreement with those in aqueous solutions under comparable conditions. The investigations demonstrated the possibility of preparing high AA–SA copolymers of various compositions in inverse emulsions.

Polymerization of AA in concentrated aqueous solutions with subsequent hydrolysis of the polymer. A two-stage procedure for preparing partially hydrolyzed PAA was described in the patents cited in [76, 78]. Initially, AA is polymerized or copolymerized with vinyl monomers in 10% aqueous solutions in the presence of a radical initiator, and the resulting viscous mass of the (co)polymer is treated with alkali at 50–90°C [100, 101]. In other cases [102–109], polymerization is carried out in 10–50% aqueous solutions, predominantly under adiabatic conditions. To facilitate the subsequent hydrolysis, the viscous polymer mass is treated after polymerization in an extruder to obtain particles of size 0.2–2.0 cm, and the resulting granules are treated with solutions of alkalis [102–109], alkali metal carbonates [103, 109, 110], or sodium or potassium hydrocarbonates [110]. Next, the hydrolyzed polymer is once again granulated to particle size of 0.2–0.5 cm, dried at 40–130°C, and crushed to particle size of 0.01–0.1 cm [103, 106, 107]. This yields a copolymer with varied content of SA units and water content of 10–15%. Polymer samples can be uniformly hydrolyzed without mechanical degradation of macromolecules by mixing the gel-like polymer mass with a solid alkali in a screw extruder [101]. A specially designed mixer [110] can be used for preventing agglutination of the polymer granules during mixing with the hydrolyzing agent.

In [111], a procedure was described for preparing products with degree of hydrolysis 1.3–3 times exceeding that calculated for the taken NaOH amount. This procedure involves treatment of the PAA granules with an alkali solution at 55–99°C for 12 h, followed by drying of the polymer. NaCl and KCl can serve as hydrolysis activators [110].

Another two-stage procedure for preparing hydrolyzed polymers [112] deserves attention. Initially, a 35–50% aqueous solution of the monomer (AA, 2-acrylamido-2-methylpropanesulfonic acid, etc.) is prepared, which is poured onto a moving infinite band cooled from the back side with a liquid cooling agent. Thus, a 0.5–1.5-cm thick solution layer is created. This is followed by polymerization in an inert atmosphere at a temperature <80°C under UV irradiation with λ = 300–400 nm or with the use of radical initiators. This yields within 15–60 min a gel-like polymer containing 50–65% water. It is reduced to 0.05–0.2-cm particles and mixed at 10–40°C with alkaline-earth metal (Ca, Mg) oxides taken in amount of <30 mol % relative to that of the polymer unit. Hydrolysis is carried out at 60–80°C for 12 h. The resulting polymer is dried at 80–100°C to a residual moisture content of under 10%, which yields 0.03–0.1-cm granules.

Preparation of hydrolyzed PAA was also described in [113]. First, AA is polymerized in 25% aqueous solutions at 20°C for 5 h, yielding PAA solutions with viscosity of 125 cP. These are granulated in a screw extruder to 0.25-cm particles. The resulting particles are mixed with 20% aqueous NaOH and

dried with hot air for 3 h, which yields a polymer with a degree of hydrolysis of 95 mol % and viscosity of 145 cP.

The reviewed studies show that alkaline hydrolysis of PAA and its derivatives is strongly affected by the characteristics of the initial polymers and hydrolyzing agents, as well as by the reaction conditions. This is manifested in the effect of the neighboring groups, as well as electrostatic, conformational, and concentration effects influencing the kinetics of chemical transformations of polymers and the structure of the forming products. Undoubtedly, with these factors taken into account, it is possible to carry out controllable hydrolysis of polyvinylamides and prepare products with various molecular characteristics and, therefore, various properties.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Manufacture of High-Purity Sodium by Distillation

E. P. Lokshin

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received January 31, 2000; in final form, May 2000

Abstract—The efficiency of purification of technical-grade sodium to remove potassium impurity by distillation is evaluated theoretically. A technology and apparatus for obtaining high-purity sodium by high-vacuum distillation were developed. The metal quality was assessed by means of a variety of chemical and physical methods.

High-purity sodium is necessary for precision studies of its physical properties, synthesis of some special-purity compounds of sodium, and manufacture of high-capacitance tantalum and niobium capacitor powders [2, 3], photoelectric devices [4, 5], illuminating lamps, high-temperature heat pipes, etc.

A number of methods have been proposed for purification of sodium, relying upon the difference in physical and chemical properties between sodium and impurities contained in it. The methods based on low solubility of some impurities in the metal being refined (filtration, melting with settling, purification with cold traps), are suitable for rough purification, e.g., to remove stock particles or a major part of oxygen [6, 7]. It has been reported [8] that the content of Fe, Si, Al, and Cr impurities can be lowered by filtration of sodium heated to 200–500°C from, respectively, 0.003, 0.03, 0.01, and 0.001 wt % to 0.001, 0.001, 0.003, and 0.0001 wt %. These methods failed to ensure the required degree of purification to remove poorly soluble impurities and could not separate soluble impurities. Attempts have been made to improve their efficiency through chemical binding of impurities into compounds having low solubility [9–27]. The chemical binding techniques markedly extended the number of separable impurities; however, special reagents and conditions of chemical binding reactions should be selected for each impurity or group of impurities, which complicates practical use of these approaches.

A technology for manufacture of "reactor" purity sodium has been proposed [9], according to which the technical-grade metal obtained by electrolysis is purified by combined application of methods for oxidative binding of impurities and two-stage filtration; however, no quality characteristics of the obtained metal have been reported. The characteristics of the purification methods used for obtaining the metal make it possible, however, to maintain that for a number of impurities (potassium, gas impurities, calcium, iron, etc.) the achieved purification level was insufficiently high for some fields of application. Also inefficient were electrochemical [28, 29] and crystallization [30] purification techniques.

High-quality sodium can be obtained by reduction of its special-purity compounds. This technique is commonly used to produce small amounts of sodium directly in photoelectric devices [4]. The most frequently used salts are chlorides, chromates, and dichromates, among the commonest reducing agents are calcium, aluminum, titanium, and zirconium. The high-temperature processes employed in this case hinder the development of large-scale apparatus. The obtained metals require further purification, since during the purification process the metal vapor carries away stock particles and gas impurities are evolved, both of these being absorbed by the condensing metal [4]. The metal quality decreases dramatically with increasing scale of the process.

The aim of the present study was to develop a technology for obtaining high-purity sodium from the commercially produced technical-grade metal by the vacuum distillation method.

EXPERIMENTAL

Impurities in sodium can form chemical compounds and be present as true solutions or mechanical inclusions. According to GOST (State Standard) 3273–63, sodium used in the study could contain up to (wt %): 0.25 K, 0.2 Ca, and 0.005 Fe. The technical-grade metal was also contaminated with oxygen, lead ($<5 \times 10^{-3}$%), copper ($>3 \times 10^{-5}$%), bound chlorine and sulfur, organic compounds. Some impurities are present as various compounds, e.g., oxygen may enter into the composition of oxides, hydroxides, or carbonates. The potassium impurity must be the most difficultly separable in distillation of sodium, since the equilibrium pressures of sodium and potassium vapors are close. Therefore, it is necessary to study in the first place the conditions for effective sodium purification to remove potassium.

The possible efficiency of sodium purification to remove potassium by single-stage distillation was evaluated using Rayleigh's equation [31]

$$\ln \frac{W_2}{W_1} = \int_{x_1}^{x_2} \frac{dx}{y - x}, \quad (1)$$

where indices 1 and 2 refer to the intial and current instant of distillation, W is the amount of fluid distilled in the still, and x and y are the concentrations of the volatile component in, respectively, fluid and vapor.

The concentration of the volatile component in vapor and fluid are related by the known expression

$$y = \frac{\gamma_K x P_K^0}{\gamma_K x P_K^0 + \gamma_{Na}(1 - x) P_{Na}^0}, \quad (2)$$

where γ_K, γ_{Na} are the activity coefficients of potassium and sodium; P_K^0, P_{Na}^0 are the equilibrium vapor pressures over pure potassium and sodium.

Theoretically possible yield of pure sodium in equilibrium single-stage distillation of technical-grade sodium (x_1 = 0.25 wt %)

T, K	b_T	Yield (%) of fraction with indicated upper limit of potassium content, wt %			
		0.01	0.005	0.001	0.0005
523	0.0201	93.6	92.3	89.3	88.0
573	0.0305	90.4	88.4	84.1	82.2
623	0.0442	86.2	83.4	77.5	75.0
673	0.0491	84.7	81.7	75.2	72.5

At low impurity concentration the activity coefficient of potassium was considered independent of its concentration in melt. Then, introducing designation

$$b_T = \frac{P_{Na}}{\gamma_K P_K} \quad (3)$$

and taking into account that $\gamma_{Na} \approx 1$ at $x \to 0$, we obtain from (2)

$$y = \frac{x}{x + b_T}, \quad (4)$$

where b_T is independent of the composition of the metal being distilled, but depends on temperature.

Substituting (4) into Eq. (1) and taking into account that $b_T \ll 1$ for the sodium–potassium system, we finally obtain upon integration the following expression

$$\ln \frac{W_2}{W_1} = \frac{b_T}{1 - b_T} \ln \frac{x_2}{x_1}. \quad (5)$$

The activity coefficients at 523, 573, 623, and 673 K were calculated from the experimental activity coefficient at 473 K [32] on the assumption that the entropy of mixing is equal to its ideal value, which gives the equation

$$\ln \gamma_i^{T_1} = \left(\frac{T}{T_1}\right) \ln \gamma_i^T, \quad (6)$$

where $\gamma_i^{T_1}$, γ_i^T are the activity coefficients of i-th component at, respectively, temperatures T_1 and T.

The results of calculation by Eq. (5), presented in the table, indicate that, theoretically, single-stage distillation can ensure deep purification of sodium to remove potassium.

The purification of technical-grade sodium by distillation was studied on a setup shown schematically in Fig. 1. The setup comprised a Kh18N9T steel distillation still *1* with a condensation pipe *2*, charging pipe *3*, evacuation pipe *4*, cover *5* with a pocket for thermocouple *6*, still-heating furnace *7*, S52-1 glass receiving ampules *8*, and an evacuating system (not shown in the figure) comprising a forevacuum and oil-diffusion pumps, a liquid nitrogen trap, transducers, and vacuum meter for measuring the residual gas pres-sure. The bell nipple *9* in the unit connecting the steel condenser and glass members precluded any contact between molten sodium and the metal (Kovar alloy)–glass joint, improving the reliability of the set-up operation.

Sealed containers with technical-grade sodium stored under a layer of paraffin–Vaseline mixture were

opened, metal ingots were extracted, washed with naphtha, and placed in a melting vessel, and the vessel was then evacuated. Sodium was melted and poured through pipe *3* into a pre-evacuated, and tested for air-tightness, distillation setup, with excess pressure of inert gas created over the sodium surface. The major part of oxide films was detained by a steel grid installed at the melting vessel bottom. The melting vessel was disconnected, and the poured-in metal was rapidly heated to a prescribed temperature, with the residual gas pressure maintained at $\leq 6.7 \times 10^{-3}$ Pa. Separate fractions of the distillate were collected into ampules, which were sealed-off when filled. The performed corrosion tests [33] made it possible to establish the conditions under which S 52-1 glass should be used in working with high-purity sodium.

At 573–593 K, the distillation was slow, since the equilibrium pressure of saturated vapor pressure of sodium did not exceed 4 Pa. On raising the distillation temperature to 603 K, the distillation rate was 0.8 g $cm^{-2} h^{-1}$. Although the first fractions of the condensate were enriched in potassium impurity (the potassium content was determined by the atomic-absorption method), sodium containing less than 0.01% potassium could not be obtained. This can be accounted for by fast depletion in potassium of the surface layer of the melt, resulting from metal evaporation from only a thin surface layer [34]. Vapor formation in the bulk of a metallic melt is hindered, since, the metals having high heat conductivity, it is difficult to create the necessary temperature gradient along the melt height. Because of the high heat conductivity and absence of regions with markedly different densities, the role played by convective flows in the agitation of the metal being distilled is also unimportant. Thus, the purification process is limited by potassium diffusion from the bulk toward the surface layer. When the surface layer is depleted of potassium, the process of equilibrium distillation is disrupted and the efficiency of separation markedly decreases.

An acceptable degree of purification can be achieved if distillation of a minor amount of sodium is performed in two stages: first at 523–563 K, with the main amount of potassium and organic compound impurities removed, and then at 623–633 K, to remove difficultly volatile impurities (calcium, heavy metals, sodium oxide, etc.). Two-stage distillation gave metal containing less than 0.01% potassium; however, the duration of the first stage was 48 h at metal height of 10 cm in the distillation still.

Fabrication of reliable and safe stirring devices suitable for operation with alkali metals at high temperature is a complicated task. To ensure effective melt stirring, a distillation apparatus shown schematically in Fig. 2 has been developed [35]. It comprised a distiller *1* with an extension *2*; central tube *3* with vertical slits *4* for metal circulation; and cover *5* with welded-in pipes *6* and *7* for, respectively, pouring-in black metal and condensing vapor. To extensions of the condensation pipe were connected an evacuating system and vessels-receivers for the evaporated metal (not shown in Fig. 2). A filling *8*, made of perforated steel disks, was fixed inside the central tube. An entrainment trap *9* was mounted above the central tube. The distiller was heated with a furnace *10*, and the extension *2*, with an independent electric heater *11*, with the power of both controlled by varying the applied voltage by means of autoformers.

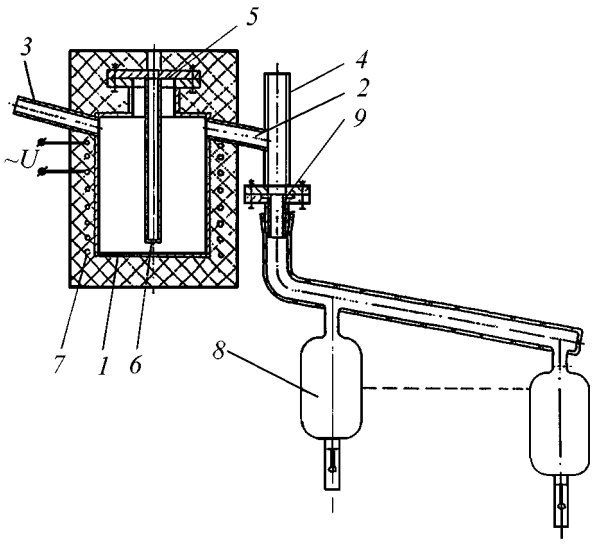

Fig. 1. Schematic of high-vacuum distiller.

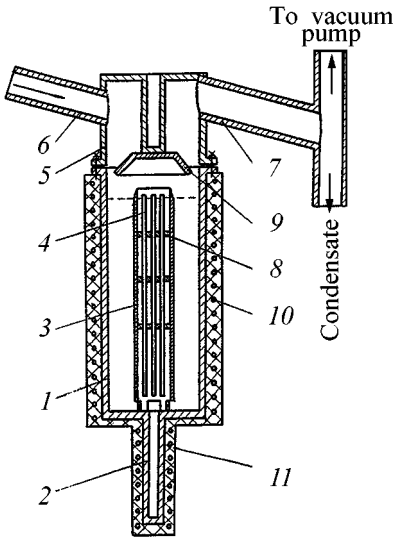

Fig. 2. Schematic of a device for metal distillation in the boiling mode.

The distillation was done as follows. An assembled apparatus was evacuated and heated to 400–410 K, and technical-grade sodium was poured-in. The extension whose length exceeded approximately 20-fold its diameter was heated with the furnace, which allowed sodium overheating in the extension to 1030–1050 K, with the temperature of sodium in the distiller being 510–550 K. A vapor was formed in the extension, whose pressure exceeded the hydrostatic pressure of the column of sodium poured into the distiller. The vapor moved along the central tube upwards, with the vapor flow disintegrated in the filling into fine bubbles and intensively agitating the melt. After potassium-rich fractions were evaporated, the distiller was cooled and fractions of the condensate and still bottoms were fractionated.

Upon 2-h distillation of 5500 g of technical-grade sodium containing 0.28% potassium, 95.5% of the metal remaining in the still contained 0.007% potassium. Potassium was concentrated in two fractions, 125 g each, containing 11.4 and 0.52% potassium, respectively. On making the distillation longer (5 h), the content of potassium impurity in the still bottoms decreased to 0.0015–0.003%, with 88.5–90% of sodium obtained as purified product. At distillation duration of 7 h, the potassium impurity became 0.0006% with 85% of sodium obtained as purified product. Organic residues were distilled off simultaneously with potassium.

Final purification of sodium was carried out by means of repeated distillation in the setup shown in Fig. 1 at a temperature of 650–690 K and residual gas pressure of no more than 6.7×10^{-3} Pa. With this done, the most difficultly volatile impurities—calcium, heavy metals, chlorides, oxides, etc.—were separated. The purified metal was analyzed by atomic-absorption and spectral methods. Below is given the content of impurities in high-purity sodium purified by the developed technique:

Impurity	K	Rb	Cs	Cu	Ag	Mg
Content, wt %	6×10^{-4}	$<1 \times 10^{-3}$	$<1 \times 10^{-3}$	$<5 \times 10^{-6}$	$<5 \times 10^{-7}$	$<2 \times 10^{-5}$
Impurity	Ca	Zn	Al	Ga	In	Tl
Content, wt %	2×10^{-5}	1×10^{-5}	$<1 \times 10^{-5}$	$<5 \times 10^{-6}$	$<5 \times 10^{-6}$	$<8 \times 10^{-6}$
Impurity	Ti	Sn	Pb	Sb	Bi	V
Content, wt %	$<9 \times 10^{-6}$	$<5 \times 10^{-6}$	$<5 \times 10^{-6}$	$<5 \times 10^{-5}$	$<5 \times 10^{-6}$	$<5 \times 10^{-7}$
Impurity	Cr	Mo	Mn	Fe	Co	Ni
Content, wt %	$<5 \times 10^{-6}$	$<5 \times 10^{-6}$	$<5 \times 10^{-6}$	$<1 \times 10^{-5}$	$<2 \times 10^{-6}$	1×10^{-6}

The quality of sodium obtained using the developed technology exceeds that of the best of the known foreign samples [36, 37].

The content of oxygen, found by vacuum evaporation of sodium from a sample, with subsequent titration of unevaporated residue, was not higher than 2×10^{-4} wt %.

The ratio of the residual electrical resistance ρ_0 (at $T \to 0$) of high-purity sodium to the resistance at 293 K was 1.54×10^{-4}, which corresponds to a total impurity content of about 0.001 wt %.

CONCLUSIONS

(1) It was shown theoretically and experimentally that vacuum evaporation of a minor amount of technical-grade sodium can yield metal with impurity content of less than 0.01 wt %. The rate-limiting stage of the process is potassium diffusion from the bulk toward the surface layer of the melt being refined. A distiller design and a process regime were developed, making it possible to overcome kinetic hindrances.

(2) Final purification of sodium to remove alkalineearth and heavy metals, oxygen, organic and other impurities is achieved by its additional high-vacuum distillation. A distiller design and regimes of finishing sodium purification were developed.

(3) The developed technology and equipment were used in commercial manufacture of high-purity sodium in conformity with TU (Technical Specification) 48-4-475–86.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Influence of Intensive Mechanical Treatment on Decomposition of Barium Peroxide

I. A. Massalimov and Yu. A. Sangalov

Research Institute of Low-Tonnage Chemical Products and Reagents, Ufa, Bashkortostan, Russia

Received May 11, 1999; in final form, November 1999

Abstract—The effect of mechanical treatment on the properties of barium peroxide—high-temperature source of oxygen—is considered.

Peroxide compounds of alkaline-earth metals attract attention of researchers and technologists as a source of chemically bound and readily evolved oxygen. These compounds have pronounced thermal stability and are widely used in metallurgy, polymer chemistry, medicine, etc. [1]. The basic technological parameter ensuring the possibility of using the peroxides is the temperature of their decomposition into an oxide and active oxygen. The most stable of the known metal peroxides—barium peroxide, starts to actively evolve oxygen at 500°C, with complete loss of oxygen at 900°C [2]. The change in enthalpy in the process is 75 kJ mol^{-1} {$\Delta H_f(BaO_2)$ = –623, $\Delta H_f(BaO)$ = –548 kJ mol^{-1} [3]}. BaO_2 decomposition is accompanied by rupture of the peroxide bond and liberation of oxygen [4].

The kinetics of BaO_2 dissociation depends on external pressure and atmosphere composition. In the atmosphere of oxygen, BaO_2 is more thermally stable, as would be expected, whereas in the atmosphere of water vapor or carbon dioxide it starts to decompose already at 200°C [5]. However, the presence of water vapor or carbon dioxide in the reaction volume is not always desirable or acceptable. The synthesis temperature (with peroxide used) may be lower than the temperature at which intensive oxygen evolution occurs. In such cases, modification of barium peroxide is desirable, lowering the temperature of its dissociation.

In the present communication, a method for controlling the temperature of barium peroxide decomposition in air under normal pressure is proposed, relying upon intensive mechanical treatment.

Barium peroxide [GOST (State Standard) 6054–75] was preliminarily dried at 105°C. Barium peroxide powders—both initial and mechanically treated—were stored in a desiccator over calcium chloride. An analysis of the IR spectra of the samples demonstrated the absence of water and carbon dioxide adsorbed from air.

The mechanical treatment of barium peroxide was done in the working chamber of a D-109 disintegrator. Powders mechanically treated to varied extent were obtained by repeated or multiple grinding in the same apparatus. Sedimentation, thermal, and X-ray diffraction analyses of the initial and mechanically treated BaO_2 samples were made under identical conditions.

The sedimentation analysis was made on a Retsch Lumosed photoelectric instrument (Germany). A 2-g sample was placed in a chamber filled with cyclohexanol, thoroughly stirred, and the chamber was mounted on the analyzer. In the course of particle settling, the intensity of a light beam passing through the chamber changed, which was recorded by the analyzer. A computer connected to the analyzer calculated by means of appropriate software the size distribution of the particles.

Thermal analysis was done on a Q-1000 derivatograph (Hungary), with differential-thermal (DTA) and thermogravimetric (TG) curves recorded. The thermal effects were evaluated from the DTA curves, using reference samples.

X-ray analysis was made on a DRON-2.0 diffractometer. The BaO_2 unit cell is tetragonal, with two molecules and each barium ion surrounded by six peroxide ions forming an octahedron. The unit cell parameters of the initial powder were as follows: a = 3.818 and c = 6.854 Å.

1070-4272/01/7404-0560 $25.00 © 2001 MAIK "Nauka/Interperiodica"

A sedimentation analysis of BaO_2 samples mechanically treated to varied extent demonstrated that considerable changes in particle size are only observed after the first two treatments: the broad asymmetric particle size distribution lying in the interval 0.05–0.30 mm (Fig. 1a) is transformed into a narrow peak with maximum corresponding to particle size of 0.005–0.010 mm (Fig. 1b). Further multiple treatment of the powder did not lead to any significant changes in the curve (Fig. 1b).

Intensive mechanical treatment of peroxide powders leads to the appearance in the DTA curves (Fig. 2) of new exothermic peaks in the temperature range 240–350°C, with the height and shape of the peaks dependent on the extent of mechanical treatment. The appearance of these peaks upon mechanical treatment indicates the occurrence of some changes caused by mechanical impact. In mechanochemistry, the additional energy imparted to a substance by mechanical treatment is conventionally named excess enthalpy

$$\Delta H_{ex} = H_T^* - H_T,$$

where H_T^* is the enthalpy of a mechanically treated active solid, and H_T is the enthalpy of the same substance in the initial equilibrium state at temperature T.

The energy is accumulated in distorted chemical bonds appearing as a result of atomic displacements relative to regular crystal lattice sites. Since the excess enthalpy affects both the equilibrium and the rate of the solid-state reaction, it is a rather important quantitative characteristic of the reactivity of a substance. The excess enthalpy is determined by measuring the area under the peak in the DTA curve corresponding to annealing of defects formed in the solid as a result of mechanical treatment. To compare ΔH_{ex} values obtained in different stages of mechanical treatment with the energy of barium peroxide decomposition equal to 75 kJ mol^{-1} [3], ΔH_{ex} was evaluated for reference samples: $AgNO_3$, Sn, $LiNO_3$, $NaNO_3$, and KNO_3 characterized by heat effects in the range 200–350°C. In the initial stage of mechanical treatment, ΔH_{ex} grows, but then decreases despite the continued intensive treatment. This fact indicates that, in a certain stage, part of energy accumulated in the preceding treatment is released.

An analysis of curves describing the loss of mass of peroxide samples as a function of temperature demonstrated that the curves are shifted to lower temperatures, i.e. oxygen evolution starts at lower temperatures. For clarity, points corresponding to 50% loss of active oxygen were chosen in these curves and

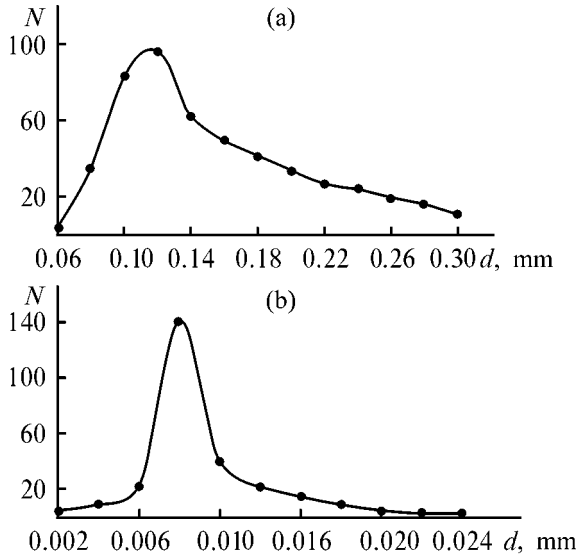

Fig. 1. BaO_2 particle size distribution functions. (N) Number of particles and (d) particle diameter. Powder: (a) initial and (b) twice treated.

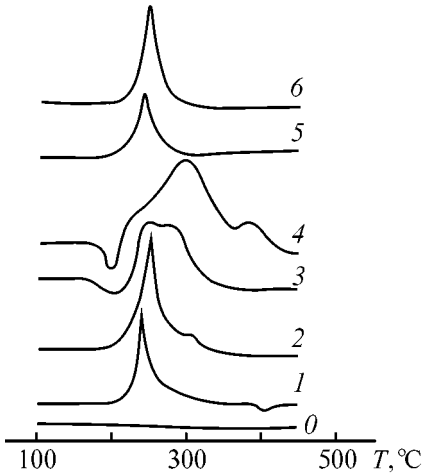

Fig. 2. DTA curves for mechanically treated barium peroxide powders. (T) Temperature. *Digits* at curves indicate the number of treatments; curve *0* is for the initial sample.

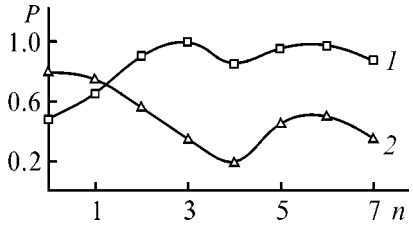

Fig. 3. Parameters P of BaO_2 samples vs. the number n of mechanical treatments. Parameter P: (*1*) S/S_{max} (for explanation see text), (*2*) $T \times 10^{-3}$ (°C) corresponding to liberation of 50% of active oxygen.

the corresponding temperatures were calculated for these points for each sample treated to varied extent. Figure 3 (curve *2*) presents the dependence of this temperature on the extent of treatment.

X-ray studies of samples subjected to varied extent of mechanical loading demonstrated that their crystal structure undergoes noticeable changes. X-ray diffraction patterns measured under identical conditions revealed changes in reflection intensity ratios. For example, for certain samples the intensity of the reflection (101) becomes equal or even smaller than 59% of the intensity of the reflection (002). Changes in the intensities of the reflections from different planes indicates varied degree of disordering of their constituent atoms under the action of mechanical treatment of varied intensity. The increase in the intensity of (002) reflections with respect to other reflections indicates that the employed extent of mechanical treatment does not cause any significant shifts from the (002) plane containing barium atoms. Presumably, the role of a stabilizing factor is played in this case by the presence of a pair of oxygens between barium atoms from different planes, contributing to the (002) reflections. At the same time, it is easier to cause disordering of atoms from the (101) plane by mechanical treatment. The process of a general decrease in intensity with its subsequent growth is observed several times with increasing duration of mechanical treatment.

The periodically observed general decrease in reflection intensity is due to partial disordering of atoms throughout the crystal lattice, giving way, in the course of subsequent mechanical treatment, to ordering of lattice atoms.

It should be noted that, despite the significant changes in X-ray reflection intensities, no already present peaks disappear and no new peaks appear in the X-ray diffraction patterns. No significant broadening of X-ray profiles is observed either.

For quantitative comparison of changes in X-ray diffraction patterns, the quantity

$$S = \sum_{hkl} I(hkl)$$

was calculated, where $I(hkl)$ is the intensity of an X-ray reflection with Miller indices (hkl).

S values were calculated for each sample. For convenience of presentation of S in relation to treatment duration, the maximum value, S_{max}, was chosen among all the S values corresponding to each sample, and all these values were normalized to it.

The effect of mechanical loading on the S/S_{max} value is illustrated in Fig. 3 (curve *1*).

An analysis of how the BaO_2 lattice constants depend on mechanical loading demonstrated that the parameters a and c change insignificantly with loading, except in the case of a fourfold treatment for which the microstrain $\Delta a/a$ is 1%.

Mechanically treated barium peroxide was used to perform solid-state synthesis of a high-temperature superconductor, $Y_1Ba_2Cu_3O_y$. As a result, the synthesis temperature was lowered by 150°C and more homogeneous samples were obtained, having no inclusions of the undesirable "green" phase of $BaCuO_2$. Thus, mechanical treatment made "milder" the synthesis conditions and improved the product quality even at higher temperatures, where the common untreated barium peroxide yields better results, compared with barium oxides.

Use of mechanically modified barium peroxide could produce even greater effect in polymer chemistry and organic synthesis, in purification of wastewater and organic and inorganic materials, in metallurgy, etc.

CONCLUSIONS

(1) Application of considerable mechanical loads leads to noticeable structural rearrangements in barium peroxide. The effect of periodic changes in reflection intensity with mechanical load points to relaxation of a deformed crystal into its initial state under mechanical impact. The doses of mechanochemical action leading to the highest microstrains were determined.

(2) Mechanical activation of barium peroxide gives rise to a number of new thermal effects in the temperature range 200–350°C and also leads to a significant change in the dynamics of liberation of active oxygen. The areas under exothermic peaks in DTA curves change nonmonotonically with applied load.

(3) To the maximum values of the exothermic peaks in the DTA curves correspond minimum reflection intensities in X-ray diffraction patterns, indicating the most disordered state with the maximum microdeformation parameter. To these values correspond the lowest temperatures of BaO_2 decomposition.

(4) The existence of a correlation between X-ray and thermal data points to the bulk nature of crystal-structure changes occurring in the substance in the course of its mechanical treatment and to the possibility of lowering substantially the BaO_2 dissociation temperature.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Analysis of Alloying in the System Lithium–Tellurium

A. G. Morachevskii

St. Petersburg State Technical University, St. Petersburg, Russia

Received January 16, 2001

Abstract—Data on thermodynamic properties of alloys of the system lithium–tellurium in liquid and solid states are compared and analyzed.

Tellurium forms with all alkali metals intermetallic compounds commonly possessing very narrow homogeneity regions. In addition, formation of tellurium-based solid solutions is uncharacteristic of these systems [1–4]. The lack of solid solutions allows use of polarization measurements for estimating the thermodynamic properties of the solid phases and makes simpler the necessary calculations.

In the system Li–Te, congruently melting compounds Li_2Te (mp 1477 ± 10 K) and $LiTe_3$ (mp 733 ± 1 K) are formed, with the latter compound characterized by a very flat maximum [1, 5]. The optimized phase diagram of the system (Fig. 1), presented by Sangster and Pelton [6], is very close to the data of [5].

The first data on thermodynamic properties of the system Li–Te were presented by Foster and Liu [7] who measured the potentials of lithium alloys with tellurium in the melt LiF–LiCl relative to a lithium–bismuth reference electrode (Li–Bi alloy saturated with Li_3Bi). The authors studied the lithium-lean part of the system ($0.056 \le x_{Li} \le 0.520$, x_{Li} is the molar fraction of Li in the alloy, 14 compositions) at a single temperature (798 K). The excess partial molar Gibbs energy of lithium ΔG_{Li}^{exc} (J mol^{-1}) at this temperature as a function of composition can be represented as

$$\Delta G_{Li}^{exc} = -153000 - 24000x_{Li} + 48850x_{Li}^2. \quad (1)$$

Equation (1) covers solely the region of liquid alloys of the system Li–Te at 798 K ($x_{Li} \le 0.38$). At infinite dilution ($x_{Li} \to 0$) ΔG_{Li}^{exc} is –153.0 kJ mol^{-1}, and the activity coefficient of lithium, γ_{Li}^{∞}, 9.6×10^{-11}. It follows from Eq. (1) that the ΔG_{Li}^{exc} value varies only slightly with increasing lithium content in the alloy: –154.9 (x_{Li} = 0.10), –155.8 (x_{Li} = 0.20) and –155.8 kJ mol^{-1} (x_{Li} = 0.30). The average value of ΔG_{Li}^{exc} in the region of liquid alloys is -155.4 ± 0.6 kJ mol^{-1} [7].

At 798 K and $x_{Li} > 0.38$ the process in the cell is associated with the reaction

$$Li(l) + 0.5Te(l) = 0.5Li_2Te(s). \quad (2)$$

The change in the standard Gibbs energy ΔG_{798}^0 upon formation of 1 mole of Li_2Te is -325.9 ± 1.7 kJ mol^{-1} [7]. The same value is given in the reference book compiled by Mills [8]. The standard entropy of Li_2Te, found by approximate calculation, is $S_{298}^0 = 77.4 \pm 12.6$ J mol^{-1} K^{-1} [8]. A close value, $S_{298}^0 = 80.8 \pm 12.6$ J mol^{-1} K^{-1}, was obtained using a different calculation procedure by Voronin [9]. The standard enthalpy of Li_2Te formation, ΔH_{298}^0, was estimated to be -355.6 ± 20.9 kJ mol^{-1}, using the

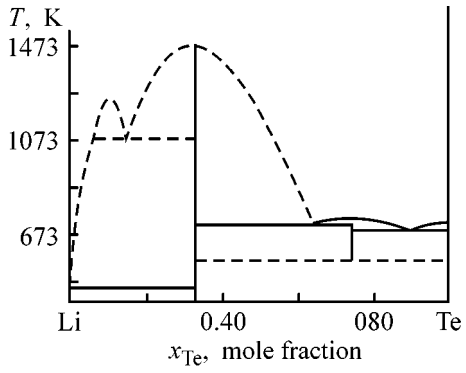

Fig. 1. Phase diagram of the lithium–tellurium system [6]. (T) Temperature and (x_{Te}) tellurium content in the system.

1070-4272/01/7404-0564 $25.00 © 2001 MAIK "Nauka/Interperiodica"

standard entropy and ΔG^0_{298} from the reference book [8]. The same values of ΔH^0_{298} and S^0_{298} were used by Barin *et al.* [10] to estimate the thermodynamic functions of Li_2Te in a wide temperature range (298–1100 K).

For liquid lithium–tellurium alloys, close results were obtained in [11]. In a set of systematic investigations concerned with thermodynamic properties of liquid alloys formed by lithium and Group III–V elements of the periodic system, alloys of the system Li–Te ($0.016 \le x_{Li} \le 0.222$, 7 compositions, 823 K) were studied by the emf method [12, 13]. As electrolyte served a eutectic mixture LiF–LiCl. The limiting value of ΔG^{exc}_{Li} at infinite dilution is –154.3 kJ mol^{-1} and $\gamma^{\infty}_{Li} = 1.6 \times 10^{-10}$. In the composition range studied here, ΔG^{exc}_{Li} is virtually constant (–154.3 kJ mol^{-1}) [11].

In a more recent study [14], a lithium–fluoroborate glass was used in emf measurements to avoid interaction of Li–Te alloys with molten electrolyte. Li_2Te is possibly soluble in molten salts [15–17]. On the basis of the whole set of properties, the following glass composition was taken to be the optimal (mol %): 15.9 Li_2O, 69.0 B_2O_3, and 15.1 LiF [18, 19]. The lithium–tellurium alloys under study were prepared electrochemically [20].

In [14], the alloys were studied in the range 733–803 K ($0.008 \le x_{Li} \le 0.283$, 10 compositions) and the partial and integral thermodynamic characteristics at 785 K were given. The activity coefficient of lithium is virtually constant in the composition range studied [$(3.44 \pm 0.39) \times 10^{-11}$ at 785 K]. The dependence of the emf on $\log x_{Li}$ is nearly linear (Fig. 2). In this case, the expression

$$E = -2.303 \frac{RT}{F} \log x_{Li}\gamma_{Li}$$

can be represented as

$$E = a - b\log x_{Li}.$$

The least-squares processing of the data reported in [14] yields the dependence

$$E = 1.661 - 0.124\log x_{Li}.$$

The correlation coefficient is 0.993, and the root-mean-square error, 0.35%. It should be noted that the obtained coefficient of the logarithm in the above expression slightly differs from the theoretical value (0.156 at 785 K).

The activity coefficient of tellurium was determined by integrating the Gibbs–Duhem equation in the form

$$\ln \gamma_{Te} = -\alpha_{Li}x_{Li}x_{Te} + \int_0^{x_{Li}} \alpha_{Li} dx_{Li},$$

where $\alpha_{Li} = \ln \gamma_{Li}/(1 - x_{Li})^2$.

Below, the activities and activity coefficients of lithium and tellurium in liquid alloys at 785 K are given for the composition interval ($0.08 \le x_{Li} \le 0.28$) with a step of 0.04 molar fraction:

x_{Li}	$a_{Li} \times 10^{12}$	$\gamma_{Li} \times 10^{11}$	a_{Te}	γ_{Te}
0.08	2.67	3.34	0.957	1.04
0.12	3.57	2.97	0.928	1.06
0.16	5.30	3.31	0.876	1.04
0.20	7.08	3.54	0.821	1.03
0.24	7.85	3.27	0.798	1.05
0.28	8.23	2.94	0.793	1.10

The average activity coefficient, as determined from smoothed data, is $(3.23 \pm 0.14) \times 10^{-11}$ for lithium and -1.05 ± 0.02 for tellurium. If Henry's law is fulfilled for a solute (lithium in the given case), then Raoult's law must be fulfilled for the solvent (tellurium) in the same range of compositions [21].

According to [14], the ΔG^{exc}_{Li} value in the concentration range ($0.008 \le x_{Li} \le 0.280$) at 785 K lies within the range from –152.8 to –158.5 kJ mol^{-1}, which is close to the previously obtained results [7].

In [22], the vapor pressure of Te_2 over molten $LiTe_3$ at 733–1030 K was measured by absorption spectrometry. In this case, the temperature dependence of tellurium activity is expressed by the equation ($x_{Te} = 0.75$)

$$\log a_{Te} = -0.471 + 296.5T^{-1}.$$

At 785 K the tellurium activity is 0.807 and its activity coefficient, 1.08, in good agreement with the above data obtained on the basis of [14].

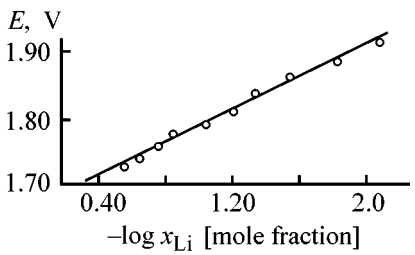

Fig. 2. Electromotive force E vs. lithium concentration x_{Li} in the alloy at 785 K.

In the same study [22], the vapor pressure of tellurium over a $LiTe_3$–Li_2Te mixture in solid state at 653–722 K was also determined. For the equilibrium

$$4LiTe_3(s) = 2Li_2Te(s) + 5Te_2(g)$$

$\log P_{Te_2} = 5.326 - 6726/T$, where P is pressure (atm).

For the reaction

$$0.5Li_2Te(s) + 2.5Te(s) = LiTe_3(s) \quad (3)$$

the change in the Gibbs energy (kJ) is given by

$$\Delta G_T^0 = 30.51 - 5.293 \times 10^{-2}T. \quad (4)$$

The authors of [22] emphasize that the ΔG_T^0 value becomes positive below 577 K and the compound $LiTe_3$ decomposes into two phases: Li_2Te and Te [22]. This fact is reflected in the phase diagram of the Li–Te system (Fig. 1).

In [23–28], the thermodynamic properties of the compounds formed by lithium and other alkali metals were determined by means of polarization measurements, with polarization curves measured in pulsed galvanostatic mode and switching-off curves recorded on a specially designed setup [29, 30]. The method consists in that the potential of tellurium electrode polarized by dc rectangular pulses of increasing amplitude is recorded at the moment when the circuit is broken. The setup allowed switching-on the polarizing current for a prescribed time (from 1 to 32 s), turning-on the tape drive of the recorder 1 s before the polarization circuit is broken, current switching-off, and delivery of a pulse to a digital voltmeter. Measurements in the potentiodynamic mode could be used for obtaining preliminary results and estimating the number of phase regions in alloying.

The above technique for measuring polarization curves in pulsed galvanostatic mode is fast and, at the same time, ensures high accuracy (not worse than ±1%) in determining the phase-region potential. However, the interpretation of results depends on the reliability of data obtained in studying a particular phase diagram. In the Li–Te system, only two compounds are formed whose compositions are beyond any doubt. Consequently, polarization measurements yield rather reliable results in this case.

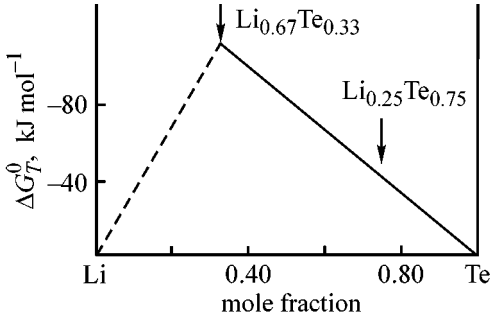

Fig. 3. The integral molar Gibbs energy ΔG_T^0 vs. alloy composition in the system lithium–tellurium at 650 K.

The Li–Te system was studied at 650 K, with a LiF–LiCl–LiI melt as electrolyte [25]. Two regions with constant potentials relative to lithium reference electrode (1.774 ± 0.002 and 1.721 ± 0.002 V), attributable to the phase regions Te + $LiTe_3$ and $LiTe_3$ + Li_2Te, were clearly revealed in the polarization and switching-off curves. The first phase region is related to the reaction

$$Li(l) + 3Te(s) = LiTe_3(s). \quad (5)$$

In accordance with reaction (5), the standard changes in the Gibbs energy in the formation of $LiTe_3$ and $Li_{0.25}Te_{0.75}$ from pure components are -171.2 ± 0.2 and -42.8 ± 0.1 kJ mol^{-1}, respectively.

The second phase region corresponds to the occurrence of the reaction

$$LiTe_3(s) + 5Li(l) = 3Li_2Te(s). \quad (6)$$

The change in the Gibbs energy at 650 K for this reaction is -830 ± 0.2 kJ. Taking into account the ΔG_{650}^0 value for $LiTe_3$, we have -333.8 ± 0.4 and -111.3 ± 0.2 kJ mol^{-1} for the change in the Gibbs energy in the formation of, respectively, Li_2Te and $Li_{0.67}Te_{0.33}$ from pure components. These values are close to those obtained previously by Foster and Liu [7] at 798 K. For reaction (3) at 650 K, Eq. (4) gives, on the basis of data reported in [22], $\Delta G = -3.89$ kJ; according to our data, $\Delta G = -1.30$ kJ.

The dependence of the Gibbs energy on composition for the Li–Te system at 650 K [25] is presented in Fig. 3. As seen, there is virtually no clearly visible break in the curve at $LiTe_3$ composition. Indeed, it follows from the obtained potentials that the partial molar Gibbs energy of lithium ΔG_{Li}, determining the slope of the straight lines, is –166.1 and –171.2 kJ mol^{-1} at 650 K in the phase regions $LiTe_3$ + Li_2Te and Te + $LiTe_3$, respectively. With the adopted scale of the ordinate axis in Fig. 3, this difference is very small.

Data on integral molar Gibbs energy ΔG (kJ mol^{-1}) at 798 K, obtained in [7, 14], are close in the comparable part of the homogeneity region:

x_{Li}	ΔG_{798} [7]	ΔG_{798} [14]	Discrepancy, %
0.04	–7.31	–7.32	0.14
0.08	–14.22	–14.41	1.32
0.12	–20.97	–21.90	4.20
0.16	–27.63	–28.30	2.37
0.20	–34.23	–35.11	2.51
0.24	–40.79	–41.87	2.58
0.28	–46.99	–48.52	3.15

In studying the tellurium cathode polarization, we used, along with the halide electrolyte, a nitrate–nitrite electrolyte with addition of lithium hydroxide ($LiNO_3$–$LiNO_2$–LiOH, 423 K) and also electrolytes with dissimilar cations, LiCl–KCl (650 K) and $LiNO_3$–KNO_3 (423 K). No significant differences between the potentials of the two-phase regions of interest were revealed; however, in electrolytes with dissimilar cations, a region with constant potential relative to the lithium reference electrode (1.959 ± 0.008 V at 423 K and 1.896 V at 650 K) was additionally observed. Most likely, this is due to the involvement of potassium ions in alloying.

It should be particularly emphasized that, in an electrolyte with a single kind of cations, both two-phase regions are recorded at 423 K, although the difference between the potentials corresponding to these regions does not exceed 0.02 V (1.770 ± 0.010 and 1.751 ± 0.002 V).

The potential of the Te + Li_2Te two-phase region relative to lithium reference electrode (1.779 ± 0.003 V), determined in [31] at 298 K by the electrochemical method (coulometric titration) with the use of a propylene–carbonate electrolyte containing LiF_6As, corresponds to the standard Gibbs energy of Li_2Te formation from pure solid components (-343.5 ± 1.3 kJ mol^{-1}). The obtained potential of the phase region at 298 K [31] is close to the potentials of the phase regions at 423 K [25].

Data on the potential of lithium reduction from molten electrolytes on a liquid tellurium cathode are available [23, 32]. The discharge of lithium ions with the formation of an alloy on both solid and liquid cathodes should be considered a single electrochemical process [33]. This concept is of fundamental importance and governs the thermodynamics of alloying. Not only electron transfer occurs, but also a simultaneous interaction of the reduced metal with the cathode material. In reduction of lithium on a liquid tellurium cathode, the observed value of the potential cannot serve as a basis for any thermodynamic calculation because of the undetermined lithium content in the surface layer of the liquid alloy. Nonetheless, the depolarization value and the difference between the potentials of lithium reduction on an inert solid cathode and a liquid cathode allow qualitative estimation of the degree of component interaction in the liquid alloy. It should be kept in mind, however, that the depolarization depends, to a certain extent, on the measurement technique. For this reason, the potentials of lithium reduction on various liquid cathodes can be compared solely under identical measurement conditions. The depolarization value in lithium reduction on the liquid tellurium cathode lies within 1.95–2.10 V. For comparison, this value is 0.94 V for bismuth and 0.68 V for lead at 723 K [34].

The switching-off curves measured at 823 K, after polarizing the liquid tellurium cathode with 2–3 A cm^2 current density for 1 h, show two plateaus of potential decay. In the LiF–LiF electrolyte, the plateau potentials, averaged over 30 tests, are 0.72 ± 0.05 and 1.64 ± 0.01 V relative to a lithium reference electrode [32]. The latter potential is close to the potential corresponding to liquid lithium–tellurium alloy saturated with Li_2Te (1.67 V, 798 K) [7]. The plateau in potential decay at 0.72 ± 0.05 V cannot be explained yet, since part of the system Li–Li_2Te has virtually not been studied at all.

The aforesaid suggests that there is rather good agreement between the results obtained in studying the thermodynamic properties of liquid alloys and solid phases in the system Li–Te by different methods.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Analysis of Alloying in the System Lithium–Selenium

A. G. Morachevskii

St. Petersburg State Technical University, St. Petersburg, Russia

Received January 16, 2001

Abstract—Data on the thermodynamic properties of liquid alloys and the solid phase in the system lithium–selenium are compared and discussed.

Lithium and selenium form only a single compound, Li_2Se (mp 1575 ± 5 K), and there exists a separation region in the selenium-rich part of the system [1]. The optimized phase diagram of the system is presented in Fig. 1 [2]. Other properties of lithium–selenium alloys are considered in a review [2]. However, it seems reasonable to discuss results obtained in thermodynamic studies of the alloys in more detail.

First data on thermodynamic properties of liquid alloys of the system Li–Se were obtained in [3] by measuring the emf of concentration cells with lithium–selenium alloys ($x_{Li} \le 0.464$, x_{Li} is the molar fraction of lithium in the alloy) in contact with molten LiBr–RbBr (mp 540 K) or LiF–LiCl–LiI electrolyte (mp 614 K), and experimental data were represented as graphs. The interaction of lithium–selenium alloys with salt melts [4] makes interpretation of the emf measurements rather complicated.

In [5], thermodynamic properties of liquid lithium–selenium alloys ($0.002 \le x_{Li} \le 0.159$, 12 compositions) were studied by the emf method, with glass ($Li_2O : B_2O_3 : LiF = 8.3 : 84.7 : 15.3$ wt %) used as solid electrolyte to prevent interaction of Li–Se alloys with molten electrolyte LiCl–KCl. All the compositions studied lie within the separation region. The average cell emf is 2.085 ± 0.002 V at 693 K. In the separation region of the Li–Se system, where a mixture of molten salts is additionally present as a third phase, the emf is 2.10 V at both temperatures (633 and 663 K) [4], which is close, within 0.7%, to the above value. This suggests that the influence exerted by the interaction with the salt phase on the thermodynamic properties of the Li–Se itself is insignificant. The average partial molar Gibbs energy of lithium ΔG_{Li} at 693 K in the separation region is (201.2 ± 0.2) kJ mol^{-1} [5]. The average Li activity, a_{Li}, at this temperature is $(6.83 \pm 0.24) \times 10^{-16}$.

It was indicated in [4] that the interaction of lithium with selenium in the liquid state should be described by the reaction

$$2Li + xSe = Li_2Se_x.$$

For this reason, the activity coefficient and activity of Li_2 are used. This approach seems to be inconvenient for systematic studies of the thermodynamic properties of liquid lithium alloys [6] and is not substantiated to a sufficient extent.

In the composition range studied [5], the integral molar Gibbs energy ΔG of the system Li–Se can be estimated with regard to the constant ΔG_{Li} value by taking into account that virtually pure selenium (ΔG_{Se} approaches zero) is in equilibrium with the lithium alloy at 693 K. This energy can also be calculated in the conventional manner without taking into account the specificity of interaction between the components:

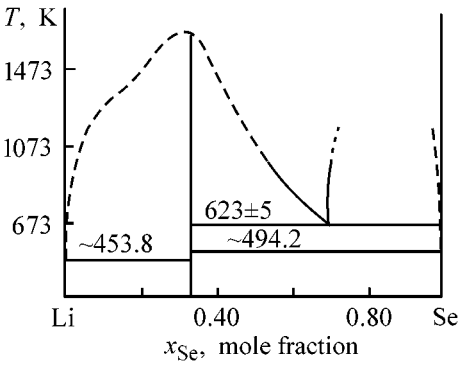

Fig. 1. Phase diagram of the lithium–selenium system according to [2]. (T) Temperature and x_{Se} selenium content in the alloy.

1070-4272/01/7404-0569 $25.00 © 2001 MAIK "Nauka/Interperiodica"

$$\Delta G = (1 - x_{Li})\int_0^{x_{Li}} \frac{\Delta G_{Li}^{exc}}{(1 - x_{Li})^2}\, dx_{Li} + \Delta G^{id},$$

where ΔG_{Li}^{exc} is the partial excess Gibbs energy of lithium and ΔG_{Li}^{id} is the change in the Gibbs energy for the ideal solution at a given composition and temperature.

Both the approaches give similar results (693 K, ΔG, kJ mol^{-1}):

x_{Li}	ΔG	x_{Li}	ΔG	x_{Li}	ΔG
0.02	–4.06	0.08	–16.11	0.14	–28.17
0.04	–8.06	0.10	–20.16	0.16	–32.20
0.06	–12.08	0.12	–24.21	0.18	–36.22

As shown above, only a single, rather stable compound Li_2Se is formed in the Li–Se system. This fact and the constant ΔG value in the composition range studied enable an approximate estimate of the change in the Gibbs energy for the reaction

$$0.667Li(l) + 0.333Se(l) = Li_{0.667}Se_{0.333}(s). \quad (1)$$

The point of intersection of the dashed straight lines in Fig. 2 corresponds to the limiting Gibbs energy for reaction (1) at a given temperature (–134.1 kJ mol^{-1}). The true value of ΔG must be somewhat lower in absolute value (probably, -131 ± 2 kJ mol^{-1}). The change in the Gibbs energy of reaction (1) at 633 K, calculated from the results of emf measurements for compositions in equilibrium with the solid phase Li_2Se, is –131.1 kJ mol^{-1} [4]. With the slight difference in measurement temperatures (693 and 633 K) disregarded, these results agree quite satisfactorily. The corresponding value for Li_2Se is –393.3 kJ mol^{-1}.

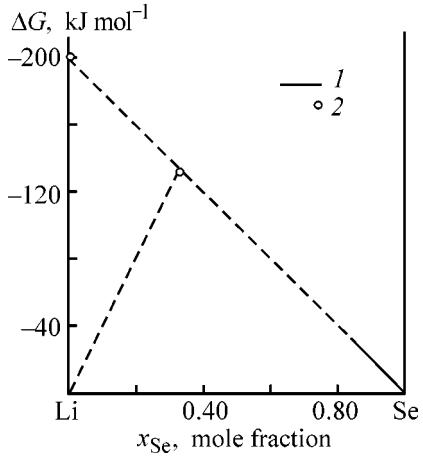

Fig. 2. Integral molar Gibbs energy ΔG vs. composition. (x_{Se}) Selenium content in the alloy. Data, temperature (K): (*1*) [5], 693 and (*2*) [3], 633.

In a study [7], not mentioned in review [2], the polarization of a solid selenium electrode in the $LiNO_3$–$LiNO_2$–LiOH melt was studied at 423 K. The polarization curve measured in pulsed galvanostatic mode has a clearly pronounced portion of constant potential (2.098 ± 0.002 V) relative to a solid lithium reference electrode. This potential is associated with the presence of a two-phase mixture Se + Li_2Se in the surface layer of the electrode being polarized. Thus, for the reaction

$$2Li(s) + Se(s) = Li_2Se(s) \quad (2)$$

the change in the Gibbs energy at 423 K is –404.9 kJ mol^{-1}. Correspondingly, ΔG = 135.0 kJ mol^{-1} in the case of formation of the $Li_{0.667}Se_{0.333}$ compound by reaction (2). Recalculation to the liquid supercooled state of the initial components, corresponding to reaction (1), yields –135.6 and –406.8 kJ mol^{-1} for $Li_{0.667}Se_{0.333}$ and Li_2Se, respectively (at 423 K).

The standard entropy S_{298}^0 of lithium selenide is estimated unambiguously. Calculation by Latimer's method [8] yields 96.2 ± 20.9 J mol^{-1} K^{-1}, and that by Voronin's method, 69.9 ± 12.6 J mol^{-1} K^{-1} [9]. In Mills's handbook [10], the S_{298}^0 value of 71.1 ± 12.6 J mol^{-1} K^{-1} is reported. The same value (with unspecified error) is used as a basis for calculations in the reference book [11].

The change in the enthalpy in Li_2Se formation from pure solid components at 423 K can be calculated with reasonable accuracy by means of the equation

$$\Delta H_T = \Delta G_T + T\Delta S_{298}^0 + T\Delta C_p \ln(T/298),$$

where ΔS_{298}^0 characterizes the enthalpy change under the standard conditions and ΔC_p is the change in the average heat capacity in the temperature range under consideration.

According to the data presented in the reference book [11], S_{298}^0 = 29.08 J mol^{-1} K^{-1} for Li(s) and 42.26 J mol^{-1} K^{-1} for Se(s). Closely similar values (29.10 and 42.43 J mol^{-1} K^{-1}, respectively) were used in calculations in [8]. If we accept S_{298}^0 = 96.2 J mol^{-1} K^{-1} for Li_2Se, then the ΔS_{298}^0 value for the process considered will be –4.22 J mol^{-1} K^{-1}. In its turn, the other S_{298}^0 values given above for Li_2Se yield ΔS_{298}^0 –30.52 and –29.32 J mol^{-1} K^{-1}. The average heat capacities of the components in the range 298–623 K are (J mol^{-1} K^{-1}): 17.1 (Li_2Se), 6.21 (Li), and 6.38 (Se) [11]. With these values taken into account by using equation (3) for 423 K at ΔG_{423} = –404.9 kJ mol^{-1}, we obtain, depending on ΔS_{298}^0, the following ΔH_{423} values (kJ mol^{-1}): –406.9, –418.0,

and –417.5. The last two values are preferable, and they are close to the ΔH^0_{298} value for Li_2Se (-425.9 ± 8.4 kJ mol^{-1}), obtained by fluorine calorimetry in [8].

Thus, the results of electrochemical measurements yield the following values of the integral molar parameters for compounds Li_2Se (kJ mol^{-1}): 404.9 (ΔG_{423}), –418.0 (ΔH_{423}), and –393.3 (ΔG_{633}). The changes in the Gibbs energy are obtained on the basis of a series of experimental studies [3, 5, 7]. The enthalpy change depends on the method chosen for estimating the standard energy of lithium selenide, but seems to be rather reasonable.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Improvement of the Procedure for Thermodynamic Calculation of the Equilibrium Composition of Gas Mixture Formed in Concurrent-Consecutive Reactions

N. V. Trusov

Kharkov State Polytechnic University, Kharkov, Ukraine

Received May 12, 2000; in final form, September 2000

Abstract—Criteria are proposed that make it possible to exclude interactions distorting the results that can be obtained in a thermodynamic calculation of the equilibrium composition of the gas mixture formed in concurrent-consecutive reactions. The proposed improvement is verified on the basis of the available experimental data.

In [1], a thermodynamic calculation of the equilibrium composition was performed using the modified Hook–Jeaves method [2]. The choice of a process for catalytic oxidation of ammonia as a test object of study can be attributed to the exhaustive scientific substantiation of this technology [3–7] allowing precise evaluation of the validity of calculated data.

The calculation of the equilibrium composition formed in ammonia oxidation, performed in [1], made it possible to ascertain some specific features of the process, on the one hand, and clearly established the possibility of using the proposed technique for thermodynamic analysis of processes occurring in complex chemical systems, on the other. However, there was evidence indicating the insistent need for further improvement of this method.

For example, a completely unacceptable circumstance was revealed in solving the test problem, namely, the reactions of nitrogen(II) oxide oxidation to NO_2 and NO_x hydrogenation were included into the set of reactions under consideration. This was done because the change in the Gibbs energy gave no reason to exclude these reactions. Both the reactions occur in the industrial process for nitric acid production, but take place in the stages of afteroxidation–absorption of nitrose gas and in purification of the discharged flow to remove nitrogen oxides. In the stage of ammonia oxidation, these reactions do not occur [3, 4] and the problem in question can only be solved with the given stage modeled as precisely as possible by means of a thermodynamic calculation.

Noteworthy in this connection is the influence exerted by the number of reactions taken into account on the calculated composition of the equilibrium gas. For example, if only the following reactions are considered

$$4NH_3 + 5O_2 = 4NO + 6H_2O, \quad (1)$$

$$2NH_3 = 3H_2 + N_2, \quad (2)$$

$$4NH_3 + 3O_2 = 2N_2 + 6H_2O, \quad (3)$$

$$4NH_3 + 4O_2 = 2N_2O + 6H_2O, \quad (4)$$

then the obtained equilibrium composition (Table 1) is in rather good agreement with experimental data [3, 4]. However, if only the reaction

$$2NO + O_2 = 2NO_2 \quad (5)$$

is added, the calculated composition of the nitrose gas changes dramatically (Table 1). It can be seen that it is reaction (5) that is the reason for the discrepancy between the calculated thermodynamic data and experimental results. This evidence required thorough analysis.

Table 1. Equilibrium composition of nitrose gas in relation to the number of reactions considered (T = 1200 K, P = 0.1 MPa, initial ratio O_2/NH_3 = 2 mol mol^{-1})

Set of reactions	Production gas component, vol %						NO_x yield, %
	N_2	O_2	H_2O	NO	N_2O	NO_2	
(1)–(4)	70.0	7.1	13.9	8.9	0.1	–	95.3
(1)–(5)	74.3	8.5	11.1	0.4	0.43	5.28	86.9

1070-4272/01/7404-0572 $25.00 © 2001 MAIK "Nauka/Interperiodica"

It was evident that, despite the thermodynamic probability, there exists a group of reactions (*n*) that cannot be included into the set of concurrent-consecutive chemical interactions (*m*). The reason is that they have different durations τ, which cannot be accounted for by a thermodynamic analysis by definition. With the reaction duration $\tau(m) << \tau(n)$, the calculated equilibrium composition is the composition that could be formed in a real process at infinitely long exposure.

In the system under study, $NH_3 + O_2$, reactions of this kind can be revealed and excluded from consideration on the basis of extensive published evidence [3–7]. However, on passing to a less studied system of reagents and chemical processes, such an operation might prove impossible or erroneous, which would naturally distort the final calculated result, and to such an extent that its practical value would be completely depreciated. Therefore, the problem of finding a criterion that would reveal such reactions already in the preliminary stage is of primary importance. The present communication reports the results of this search.

To solve the problem, it is in the first place necessary to select reactions reliably known to proceed (A) or not proceed (B) in the real process of catalytic oxidation of ammonia.

Group A includes reactions (1)–(4). This choice was substantiated using the results obtained in [3, 4]. As for group B, it comprises reaction (5) and

$$5H_2 + 2NO = 2NH_3 + 2H_2O, \quad (6)$$

$$2H_2 + 2NO = N_2 + 2H_2O. \quad (7)$$

As would be expected, the subsequent direct comparison between the thermodynamic potentials of the chosen reactions (Gibbs energy ΔG_T^0 and enthalpy ΔH_T^0) failed to reveal in both the groups any common pattern that would allow identification of those of the reactions that distort the results of thermodynamic calculation as compared with experimental data. However, relating the thermodynamic potentials of a particular reaction (*i*) to the ΔG_T^0 and ΔH_T^0 of reaction (1) governing the composition of the equilibrium gas [i.e. is basic[1] (b)] revealed an interesting pattern. The characteristics presented in Table 2 require some explanation.

The ratios $\Delta G_T^0(i)/\Delta G_T^0(b)$ and $\Delta H_T^0(i)/\Delta H_T^0(b)$ used for criterial evaluation and denoted, respectively, by $\mathrm{Rel}[\Delta G_T^0(i)]$ and $\mathrm{Rel}[\Delta H_T^0(i)]$ vary differently with increasing reaction temperature for reactions belonging to groups A and B. A typical pattern demonstrating the difference between the two groups of reactions with regard to one of the criteria is shown in Fig. 1. This difference is reflected by the schematic representation of the obtained correlation with indication of the sign of criterion application within the temperature interval under study (900–1400 K).

Table 2. Behavior with temperature of the criteria $\mathrm{Rel}[\Delta G_T^0(i)]$ and $\mathrm{Rel}[\Delta H_T^0(i)]$ for some reactions (T = 900–1400 K, P = 0.1 MPa)

Reaction *i*	Criterion	
	$\mathrm{Rel}[\Delta G_T^0(i)]$	$\mathrm{Rel}[\Delta H_T^0(i)]$
Proceeding reactions		
(2)	+\+	+\+
(3)	+\+	+\+
(4)	+\+	+\+
Non-proceeding reactions		
(5)	+\−	+\+
(6)	+\+	+/\+
(7)	+\+	+/\+

There is no escape from noticing the fact that, for all reactions whose occurrence under conditions of catalytic oxidation of ammonia has been confirmed experimentally, the behavior of the functions $\mathrm{Rel}[\Delta G_T^0(i)]$

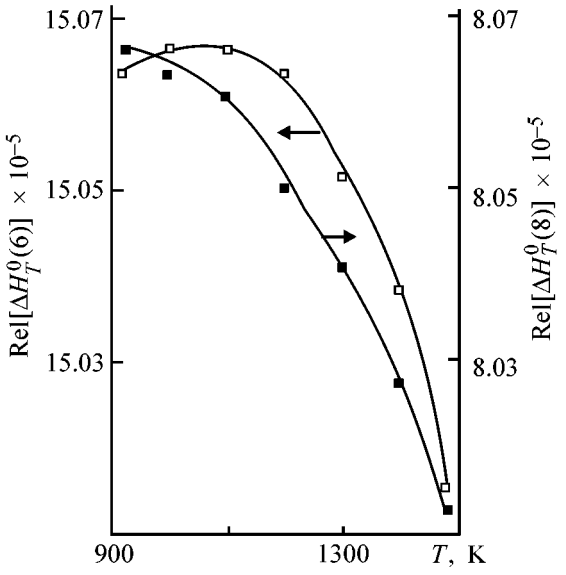

Fig. 1. Typical behavior with temperature T of the criterion $\mathrm{Rel}[\Delta G_T^0(i)]$ for reactions (6) and (8).

[1] In the given case, the choice of the gas reaction is unambiguously predetermined a priori [3–7]. However, in the general case, a search for such a reaction is an independent scientific problem.

Table 3. Effect of the AAM composition and reaction temperature on ammonia conversion into NO_x, γ (P = 0.1 MPa)

O_2/NH_3, mol mol^{-1}	γ (%) at indicated temperature, K		
	1100	1200	1300
1.00	74.1	75.0	75.0
1.25	78.5	78.5	78.9
1.50	85.1	85.1	94.3
1.75	94.0	94.0	89.1

and Rel[$\Delta H_T^0(i)$] with T and their sign remain invariable over the entire temperature range studied. This circumstance cannot be understood as a mere coincidence, as it is equally impossible to consider accidental the fact that at least a single characteristic for all reactions of group B (run of the curve or the sign of the criterion at the boundary of the temperature interval) differs from that for group A.

Detailed theoretical substantiation of the revealed pattern is far beyond the scope of the present study. It should be noted that this would require a special analysis including as a not the least important part a mathematical approximation to the Le Chatelier principle as applied to the set of the reactions under study. However, even a formal application of the revealed relationship allows successful solution of the problem at hand—to reveal and exclude already in the preliminary stage the reactions distorting the results of a thermodynamic calculation of the equilibrium composition.

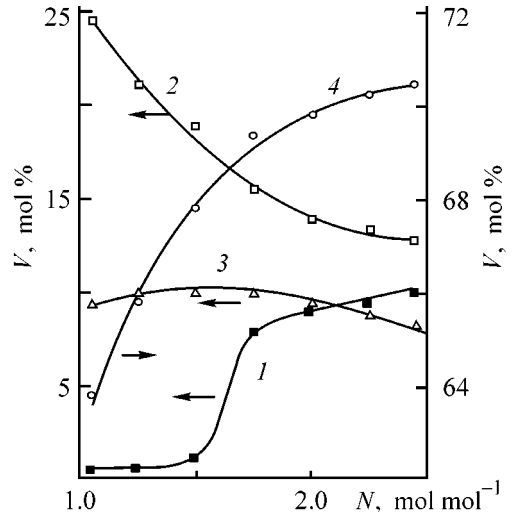

Fig. 2. Content V of a component in the equilibrium mixture vs. the initial ratio O_2/NH_3 N in the AAM. T = 1200 K, P = 0.1 MPa; calculation after a criterial estimate of the entire set of reactions. Component: (*1*) O_2, (*2*) H_2O, (*3*) NO, and (*4*) N_2.

To verify the possibility of using the proposed characteristics, a criterial analysis was made of the entire set of reactions considered in [1]. It was found that only four more reactions should be added to reactions (1)–(4)

$$4NH_3 + 6NO = 5N_2 + 6H_2O, \quad (8)$$

$$2NO = N_2 + O_2, \quad (9)$$

$$4NH_3 + 7O_2 = 6H_2O + 4NO_2, \quad (10)$$

$$4NO = N_2 + 2NO_2. \quad (11)$$

The criterial characteristics of the reaction

$$H_2 + 2NO = H_2O + N_2O \quad (12)$$

seemingly allow its inclusion into the set of the considered interactions; however, none of the selected 11 reactions proceeds to give hydrogen.

The last circumstance indicates that formal use of the proposed criteria in no way rules out a chemical-technological assessment of information. It is quite evident that a meaningless set of concurrent-consecutive reactions would be obtained without taking this aspect into account. In the given case, an absurd member of the set would be hydrogenation of nitrogen(II) oxide in the absence of at least a single reaction leading to appearance of hydrogen in the gas mixture.

A part of the results obtained in a thermodynamic calculation is presented in Table 3.

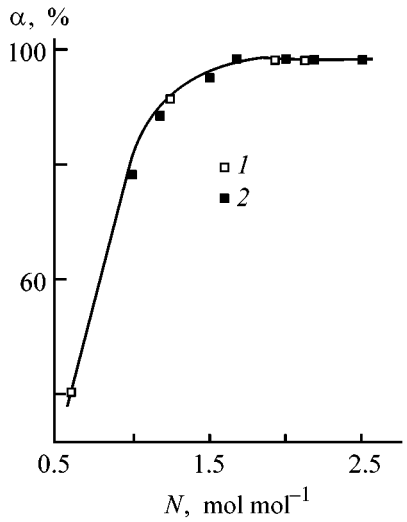

Fig. 3. Yield α of nitrogen oxides NO_x vs. initial O_2/NH_3 ratio N in AAM. Data: (*1*) [3] and (*2*) present study.

It can be seen that temperature has practically no effect on the yield of NO_x at O_2/NH_3 ratios less than the stoichiometric value for reaction (1). Raising the content of oxygen has positive effect on the NO + NO_2 yield, which points to the necessity for preliminary heating of the initial air–ammonia mixture (AAM). However, at $O_2/NH_3 > 1.75$ (mol mol^{-1}), temperature becomes an adversely affecting factor. A detailed analysis of the results obtained in a thermodynamic calculation of the equilibrium composition demonstrated that the reason is that thermal dissociation of nitrogen(II) oxide by reaction (11) is markedly intensified, causing unavoidable partial loss of the forming target product. All this is in good agreement with Atroshchenko's opinion [3] that, in some cases, temperature may be a more important factor than the initial mixture composition, and its influence may be both positive and negative.

As for the "straight" (i.e. that at fixed temperature) effect of the AAM composition, it is evident from the analysis in Fig. 2.

Figure 2 more precisely corresponds to experimental data of various authors [3–7] than the results presented in [1]. It should be emphasized that the coincidence of the calculated thermodynamic characteristics with experimental results [3] is virtually ideal for the dependence of the NO_x yield on the initial gas composition (Fig. 3).

The presented results can serve as direct proof of the adequacy of the proposed technique for revealing reactions that distort results obtained in thermodynamic calculations of the equilibrium composition as compared with the actual process. All this makes it possible to pass to considering more complicated tasks. In particular, a direct possibility opens up of studying whether or not application of Andrussow's nitroxyl theory [8] and Wendlandt's hydroxylamine mechanism [9] to the mechanism of catalytic ammonia oxidation is justified. This is all the more important as the first theory was created at the time when the very existence of HNO was purely hypothetical (no experimental evidence in favor of the existence of this compound existed), and the presence of NH_2OH as an intermediate in catalytic oxidation of ammonia has not been confirmed experimentally up to now [10].

CONCLUSION

Based on a comparative analysis of experimental results obtained by different researchers, criteria are proposed allowing exclusion of reactions distorting the results of thermodynamic calculations of the equilibrium composition. The coincidence of the obtained calculated results with experimental data is virtually ideal.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Physicochemical Properties of Lithium Perchlorate Solutions in Mixtures of Sulfolane with 1,3-Dioxolane

V. S. Kolosnitsyn, N. V. Slobodchikova, N. V. Karichkovskaya, and L. V. Sheina

Institute of Organic Chemistry, Ural Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Received March 22, 2000; in final form, July 2000

Abstract—The electrical conductivity, viscosity, and density of sulfolane–1,3-dioxolane mixtures and 1 M lithium perchlorate solutions on their base were studied. The activation energies of viscous flow and electrical conductivity were calculated. Departures of some of the measured values from additivity are demonstrated.

It is known that individual highly polar solvents are strongly associated because of the formation of hydrogen bonds and dipole–dipole and electron-donor–acceptor (EDA) interactions. The extent of association reaches tens and, occasionally, hundreds of units. This leads to an increase in viscosity and, thereby, impairs the transport properties of polar solvents, which is extremely undesirable when high-conductivity electrolyte solutions are to be obtained. Mixtures of solvents, as a rule, have lower viscosity that it would be expected on the basis of their composition. The reason is that heteromolecular associates are formed, with molecular weight lower than that of homomolecular associates existing in individual solvents. It could be assumed that the composition of heteromolecular associates and their strength are in the first place determined by the EDA properties and stereochemistry of interacting molecules. However, it is difficult to make *a priori* an unambiguous conclusion about the composition of heteromolecular associates formed in one or another system on the basis of the available reference data. Therefore, investigations are necessary, aimed to elucidate the stereochemistry of associates formed in various systems and to relate the EDA and structural properties of interacting molecules to the composition and strength of heteromolecular associates being formed.

To obtain high-conductivity electrolyte solutions, solvents are prepared on the basis of mixtures of highly polar compounds, having high solvating power, with low-polar compounds having low viscosity. Most frequently, propylene carbonate [1, 2] and ethylene carbonate are used as highly polar components, and tetrahydrofuran (THF), dimethoxyethane (DME), and dioxolane, as low-polar components. A promising group of highly polar solvents is formed by sulfolanes [3]. However, the physicochemical properties of mixed solvents on their base are little studied. Previously, electrolyte systems based on a mixture of sulfolane (Sl) with THF and DME have been studied [4].

The aim of the present study was to analyze in detail the physicochemical properties of lithium perchlorate solutions in mixtures of sulfolane with 1,3-dioxolane.

EXPERIMENTAL

The solvents and lithium perchlorate were thoroughly purified and dried. According to gas-liquid chromatography, the purity of the solvents was no less than 99.5–99.8%. The solutions used were prepared in a box dried with phosphorus(V) oxide. The content of water in the electrolyte solutions, found by biamperometric titration in Fischer's reagent, did not exceed 0.03%. The electrical conductivity χ was measured with an E7-8 ac bridge in capillary cells with platinum-plated electrodes. The solution viscosity η was measured in Ubbelohde viscometers with suspended level of closed type, and the density ρ was found picnometrically. The errors in determining the viscosity and electrical conductivity did not exceed 0.2%, the error in density was 0.02%, the temperature was maintained to within ±0.01°C. The molar volume V_m was calculated as described in [5].

A study of the physicochemical properties of sulfolane mixtures with dioxolane demonstrated that the dependence of their viscosity on composition is strongly non-linear (Table 1). The composition dependence of the mixture density is also nonlinear, but to a much lesser extent. For example, the departure of molar volumes from additivity does not exceed 1%. The significant negative deviations from linearity, observed for viscosity isotherms, indicate a manifestation of specific intermolecular interactions in the solvents. The weakly pronounced deviations of the molar volume from additivity are in all probability due to the close molar volumes of homo- and heteromolecular associates in the solvents.

The physicochemical properties of lithium perchlorate solutions in sulfolane–dioxolane mixtures are presented in Table 2. The isotherms of electrical conductivity of 1 M solutions of lithium perchlorate solutions in solvent mixtures pass through a maximum at a 1 : 1 molar ratio of components. This indicates that the specific interactions between sulfolane and dioxolane are preserved in the presence of lithium perchlorate.

The increase in the electrical conductivity may be due to a decrease in the solution viscosity or to a change in the degree of salt association. To reveal the factors responsible for the change in electrical conductivity, the correlated electrical conductivity $\chi\eta$ was calculated. It was found that the isotherms of correlated electrical conductivity are convex with respect to the mixture composition axis (Fig. 1). The correlated electrical conductivity decreases with increasing temperature.

It is known [6] that the dependences of the correlated electrical conductivity of salt solutions in solvent mixtures on their composition are linear only in those cases when the solvating powers of the solvents are the same or differ widely, which is due to the invariable composition of the solvation shells of the salts. The positive deviations of the $\chi\eta$ isotherms from linearity are observed in the case of preferential solvation of lithium ions by molecules of solvents with large molar volume. The preferential solvation is done by solvents possessing high donor properties. For example, the authors of [7] attributed the positive deviations of the correlated electrical con-

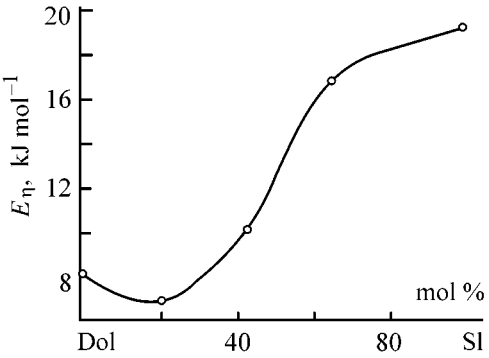

Fig. 2. Concentration dependence of the activation energy E_η of viscous flow of sulfolane–dioxolane mixtures.

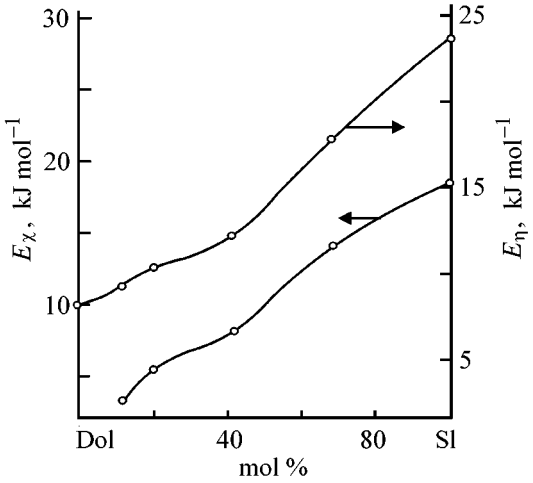

Fig. 3. Concentration dependences of the activation energy of electrical conductivity, E_χ, and viscous flow, E_η, of 1 M lithium perchlorate solutions in mixtures of sulfolane with dioxolane.

ductivity of lithium tetrafluoroborate solutions in mixtures of propylene carbonate with dimethoxyethane from linear concentration dependence to preferential solvation of lithium ions by dimethoxyethane molecules, possessing higher donor properties than propylene carbonate.

The negative deviations of the correlated electrical conductivity from a linear concentration dependence indicate a higher degree of lithium perchlorate association in mixtures of sulfolane with dioxolane than it would be expected on the basis of the solvent mixture composition. The decrease in the χη value with growing temperature points to an increase in the degree of lithium perchlorate association.

The higher degree of salt association in solvent mixtures is due to the fact that the solvate shell of lithium perchlorate is mainly composed of dioxolane molecules. Since the molar volume of dioxolane (68.6 $cm^3\ mol^{-1}$) is much smaller than that of sulfolane (95.2 $cm^3\ mol^{-1}$), resolvation leads to a decrease in the interionic distance, because of the decreasing size of the solvate shell of the lithium ion, and thereby makes higher the degree of lithium perchlorate association.

The activation energy of viscous flow of solvent mixtures exhibits a minimum as a function of concentration at a sulfolane : 1,3-dioxolane molar ratio of 2 : 1 (Fig. 3) and an inflection point at 1 : 2 molar ratio of the components. Since the activation energy is a structure-sensitive parameter, such a behavior of the activation energy as a function of concentration suggests that sulfolane : 1,3-dioxolane molecular associates of compositions 1 : 2 and 2 : 1 exist in solvent mixtures. The concentration dependences of the activation energies of viscous flow and electrical conductivity are also nonlinear, but to a much lesser extent, compared with solvent mixture. Only slight negative deviations from linearity are observed at a sulfolane : 1,3-dioxolane ratio close to 1 : 1. Probably, binding of most part of 1,3-dioxolane molecules in the solvate shell of a lithium ion leads to disintegration of sulfolane–1,3-dioxolane intermolecular associates.

CONCLUSION

The the isotherms of electrical conductivity of lithium perchlorate in mixtures of sulfolane with 1,3-dioxolane exhibit a maximum at a molar ratio of the components close to 1 : 1. The appearance of the maximum is due to a decrease in the solution viscosity, resulting from the formation of heteromolecular associates with lower degree of association, compared

with homomolecular associates. The degree of lithium perchlorate association in mixtures of sulfolane with 1,3-dioxolane is lower than it would be expected judging from the composition of the system. This is attributed to a decrease in the volume of the solvate shell of a lithium ion as a result of preferential solvation by 1,3-dioxolane.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Lanthanum(III) by Natural Mordenite-containing Tuff

Abstract—The equilibrium in the mordenite-containing tuff–lanthanum(III) solution system was studied within a wide metal concentration range (1–2000 μg ml^{-1}). Kinetic parameters of La(III) sorption were determined.

Rare-earth elements, exhibiting high biological activity, are widely used as microfertilizers [1–4]. Lanthanum(III) sulfate catalyzes the fixation of atmospheric nitrogen by nitrogen-fixing bacteria [3]. Lanthanum, cerium, and samarium nitrates are efficient microfertilizers improving the germination of seeds of wheat, pea, corn, and sugar beet and raising their productivity by 22–40% and dry substance gain by 11–14% [1–3]. Acceleration of bean crops ripening by 4–6 days has also been observed [1].

To obtain REE-based microfertilizers, it is appropriate to use the sorption technology, with natural zeolites as sorbents. Zeolites are prolonging carriers of microelements, releasing them into the soil solution during a long period of time. Published data on the kinetics of REE sorption by natural zeolites and on the solution–zeoilite equilibrium, which are necessary for preparing and using new microfertilizers, are lacking.

EXPERIMENTAL

A mordenite-containing tuff from Mukhor-Talin perlite–zeolite deposit (Buryatia) with the composition (wt %): SiO_2 70.96, Al_2O_3 11.97, MgO 0.18, CaO 0.92, Na_2O 2.38, and K_2O 5.22, and Si/Al molar ratio of 5.2, was used as a sorbent. The content of zeolite in the rock determined with a PTsL-2 zeolite portable laboratory [5] was 62%. To analyze the sorption kinetics and equilibrium sorption of lanthanum ions, the mordenite-containing tuff was crushed, with 0.25–0.5- and 1–2-mm fractions separated from the dust and dried at room temperature for 24 h. The sorption equilibrium was studied under static conditions. Solutions of lanthanum sulfate and nitrate with La^{3+} concentrations from 1 to 2000 μg ml^{-1} and the solid-to-liquid (s : l) ratios of 1 : 10 and 1 : 50 were taken. The lanthanum content was determined photometrically with arsenazo III, which is a very sensitive and selective procedure [6]. The sorption capacity was calculated as the difference of the lanthanum concentrations before and after sorption (average of three measurements); the relative determination error was no more than 3%.

The kinetics of lanthanum sorption from solutions with lanthanum concentrations of 0.01, 0.02, 0.005, and 0,007 g-ion l^{-1} was also studied under static conditions. The time of sorbent–solution contact was varied from 5 min to 6 days. The kinetic curves were plotted in the Q–τ coordinates, where Q is the amount of lanthanum ions sorbed and τ is the time of the contact between solution and sorbent. The kinetic parameters were calculated by the method described in [7]. During the initial period, when lanthanum sorption proceeds on the sorbent surface and the process is controlled by external diffusion, the rate constant R was calculated by the equation

$$R = \frac{dQ}{d\tau}\frac{1}{CK}, \quad (1)$$

where C is the lanthanum concentration in the solution and K is the equilibrium distribution coefficient.

With increasing contact time, the amount of the metal ion sorbed is determined by the rate of exchange inside the sorbent grain. To calculate the effective diffusion coefficient D and the exchange rate constant B characterizing the internal-diffusion mech-

1070-4272/01/7404-0580 $25.00 © 2001 MAIK "Nauka/Interperiodica"

anism, the equation derived for spherical particles was used:

$$F = Q_\tau/Q_\infty = (6/r)\sqrt{D\tau/\pi}, \quad (2)$$

$$B = \pi^2 D/r^2, \quad (3)$$

where Q_τ/Q_∞ is the degree of ion exchange and r is the average radius of sorbent particles.

The obtained data are presented in the table and in Figs. 1–3. In spite of the wide concentration range (1–2000 μg ml^{-1}), all isotherms of equilibrium sorption are similar. Figures 1a and 1b show the isotherms of lanthanum sorption from solutions of lanthanum nitrate and sulfate by mordenite tuff with grain size of 0.25–0.5 and 1–2 mm at s : l ratios of 1 : 10 and 1 : 50.

As seen, all isotherms have three portions: (1) the initial portion, whose points lie on the ordinate axis; which means quantitative (100%) recovery of lanthanum from dilute solution; (2) portion ascending to the maximum, and (3) descending portion. The lanthanum recovery depends on the anion nature: it is somewhat higher for nitrate than for sulfate.

With increasing lanthanum concentration, isotherms pass through maximum and then sorption starts to decrease. Thus, the study performed in a wide range of La(III) concentration revealed complex character of lanthanum sorption by mordenite tuff, from complete recovery to drastic decrease of sorption.

The maximum in the isotherm may be associated with the existence in solution of intermediates with enchanced chemical affinity for tuff [8]. The REE ions are strong complex-forming species. In the neutral and acid aqueous solutions, lanthanum ions exist as aqua complexes $[La(H_2O)_n]^{3+}$ or $[La(H_2O)_n(OH)]^{2+}$, where n = 5–8 [9, 10]. In sulfate solutions, complexes $[La(SO_4)_n]^{3-2n}$, where n = 1–3, are also found. At low sulfate ion concentrations (<0.1 g-ion l^{-1}), $[La(SO_4)]^+$ cations prevail [11], although anionic complexes may also be formed under the same conditions [12]. In aqueous solutions of lanthanum nitrate, complexes $[LaNO_3]^{2+}$, $[La(NO_3)_2]^+$, and $[La(H_2O)_nNO_3]^{2+}$ with n = 5–6 exist [13, 14].

Probably, at concentrations below that corresponding to the sorption peak, lanthanum aqua and hydroxo complexes are sorbed, since the enhanced zeolite selectivity with respect to lanthanum ions in the initial portion of the isotherm (where they are sorbed completely) can be accounted for by the large charge of the ion. The mechanism of sorption of the lanthanum aqua complex by a synthetic zeolite is described in [15]. The inversion of the sorbent selectivity after

$B \times 10^{-5}$, s^{-1}	67	1.7	55	1.0

reaching a certain lanthanum concentration, which is a manifestation of electroselectivity, supports this mechanism: upon dilution, the equilibrium is shifted toward stronger sorption of ions with larger charge, whereas in concentrated solutions the opposite trend is observed [8].

The grain size and the s:l ratio affect the position of the isotherm peak. At d = 0.25–0.5 mm and s : l ratio of 1 : 50 (Figs. 1a, 1b, curves *1*) the maximum exchange capacity (EC) is observed at lower equilibrium concentrations than in the case of larger grain size and s : l ratio of 1 : 10 (Figs. 1a, 1b, curves *2*), i.e., on small tuff grains the maximal *EC* is reached at lower sorbent consumption. This result was used in selecting the regime of saturation of mordenite-containing tuff with lanthanum salts.

The kinetic curves of lanthanum sorption by mordenite-containing tuff are similar (Fig. 2). The degree of filling of the zeolite phase, F, is in all cases a linear function of $\tau^{1/2}$ up to high values of F (Fig. 3). This confirms the fairly high contribution of the internal-diffusion mechanism of sorption [16]. The kinetic parameters listed in the table show how the rate of lanthanum sorption depends on the tuff grain size, lanthanum concentration, and nature of anion.

With decreasing grain size, the sorbent surface area grows and, hence, the rate of sorption controlled by external diffusion $dQ/d\tau$ increases. With increasing concentration of lanthanum sulfate, the time of half-exchange $\tau^{1/2}$ and the time of attaining the equilibrium, τ_∞, become shorter. The rate of sorption of the lanthanum ion by the external-diffusion mechanism $dQ/d\tau$, the rate constant of external-diffusion sorption R, and the distribution coefficient K are also higher in sorption from more concentrated solutions. The metal concentration also affects the parameters of the internal-diffusion process: the rate constant B and effective diffusion coefficient D increase with concentration. The B value is of the same order of magnitude as R. Hence, the sorption of lanthanum ions from the sulfate solution occurs by the mixed mechanism.

Let us consider the effect of the anion nature on the kinetic parameters. The data in the table show that the distribution coefficient K for sorption from a nitrate solution is greater than that for a sulfate solution. The sorption proceeds with lower rate both across the grain–solution boundary and within the grain itself, which is caused by lower mobility of nitrate ions, compared with that of sulfate ions [17]. The internal diffusion is the limiting stage of the lanthanum sorption from a nitrate solution, because R is an order of magnitude lower than B.

CONCLUSIONS

(1) The sorption equilibrium in the mordenite-containing tuff–lanthanum(III) system was studied. The sorption isotherms show a maximum, suggesting complex interactions in the system.

(2) The rate of lanthanum(III) sorption depends on the nature of anion, grain size, metal concentration, and s : l ratio and is described by the mixed mechanism in sorption from sulfate solutions and by the external-diffusion mechanism for nitrate solution.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Copper(II) from Chloride Solutions by Carbonate-containing Technological Waste

T. G. Lupeiko, T. I. Ivleva, and L. A. Solov'ev

Rostov State University, Rostov-on-Don, Russia

Received December 17, 1999; in final form, October 2000

Abstract—Absorption of copper(II) ions from copper chloride solutions by a technological carbonate-containing waste was studied in relation to concentration of starting solutions (1–25 wt %), amount of sorbent added, and time.

The problem of industrial waste purification to remove heavy metals and, in the future, recovery of these metals from natural water and contaminated soil, have been and will be a major problem of importance increasing year after year. Tackling with this problem requires a large amount of relatively low-cost and readily available sorbents. Of particular interest in this connection is the possibility of using as sorbents technological wastes with appropriate properties.

There is published evidence that calcium carbonate [1] or calcium and magnesium carbonates [2] can be used as sorbents removing heavy metals from water. The sorption capacity of calcium (magnesium) carbonate is associated with the exchange of calcium (magnesium) ion for a heavy metal ion in aqueous solutions. Since the effectiveness of ion exchange of a solid carbonate-containing product is the higher, the larger its solubility product (SP), it would be expected that a mixture of calcium and magnesium carbonates is a more effective sorbent than pure calcium carbonate in view of the fact that the SP ($CaCO_3$) is 9.9×10^{-9}, and SP ($MgCO_3$), 4×10^{-5} [3].

The present communication reports on a study of copper(II) sorption from copper chloride solutions by activated technological waste containing calcium and magnesium carbonates (for brevity, henceforth—sorbent).

EXPERIMENTAL

For experiments, copper(II) chloride dihydrate of chemically pure grade was used to prepare 20 ml of copper chloride solutions of the following concentrations: 1.02, 2.05, 4.13, 8.38, 12.70, 16.37, 20.43, 25.24 wt % or, respectively, 0.0103, 0.0208, 0.0427, 0.0903, 0.1423, 0.1908, 0.2477, 0.3200 g cm^{-3} (solutions nos. 1–8, respectively). To these solutions was added 1 g of sorbent predried to constant weight at 100°C and the mixtures were kept at 20°C with stirring at regular intervals. After a certain time elapsed, the liquid phase was filtered and analyzed for the content of residual copper. Copper was determined complexometrically with murexide [4] or, at low concentrations, by spectrophotometry of ammonia complexes [5]. The error was not higher than 0.5%. To eliminate

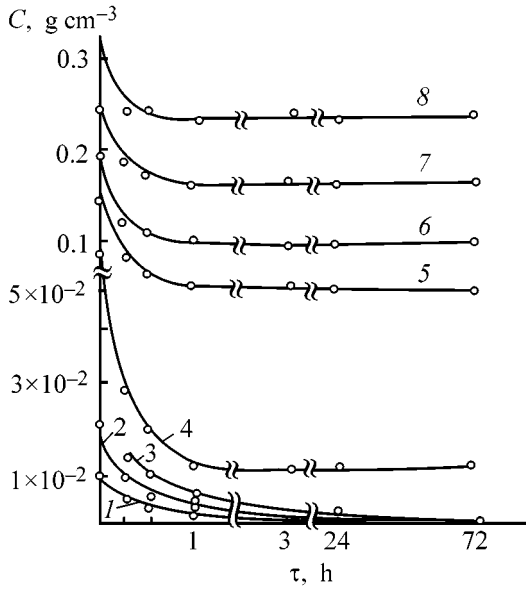

Fig. 1. Variation of copper(II) concentration C in copper chloride solutions nos. 1–8 in the course of sorption. (τ) Time. Digits *1–8* at the curves denote solution numbers; the same for Fig. 2.

the interference of calcium and magnesium ions, these were masked by adding sodium fluoride prior to titration. Also, the pH of the starting solutions and solutions was measured in the course of sorption (PRL no. 517 pH-meter with silver chloride and glass electrodes; accuracy of pH measurement in the optimal mode ±0.01 pH units). The solution density, necessary for calculations, was found picnometrically. The error in determining the solution density was ±0.0005 density measurement units [6]. To ascertain the composition of the product obtained as a result of sorption, it was subjected to X-ray phase analysis on a DRON-2 installation with Cu_{K_α} radiation. The error in determining the interplanar spacings was not higher than 0.01 Å. The common feature of all experiments is that carbon dioxide evolution was observed upon addition of sorbent to the solutions under study, becoming more pronounced with increasing concentration of the initial solution.

As it can be seen from Fig. 1, the process of copper sorption from copper(II) chloride solutions proceeds intensively, being complete in approximately 1 h. However, sorption from solutions nos. 1–3, also proceeding intensively during the first hour, is not complete, but continues further, although being much slower. For example, in the case of starting solution no. 2, the concentration of copper(II) chloride decreases to 0.0036 g cm^{-3} 1 h after the beginning of sorption, and becomes an order of magnitude lower in 3 days. The specificity of sorption from solutions nos. 1–3 is apparently associated with their comparatively high dilution resulting in that the amount of copper ions contained in these solutions is insufficient for saturating the added sorbent. This conclusion is especially clearly confirmed by Fig. 2. Indeed, it can be seen that the maximum amount of copper sorbed per 1 g of sorbent grows steadily with increasing copper content in the starting solution. The highest value (~0.83 g g^{-1}) is reached for solution no. 5, initially containing approximately 1.34 g of copper. Hence follows that solutions nos. 1–3, containing in 20 ml of solution about 0.1, 0.2, and 0.4 g of copper, respectively, cannot ensure saturation of the added 1 g of sorbent.

It can also be seen from Fig. 3 (curve *1*) that, on reaching a value of 0.83 g g^{-1} for solution no. 5, the specific amount of sorbed copper starts to decrease. This tendency is more pronounced in the case of a more prolonged contact between the sorbent and solution (Fig. 2). No unambiguous explanation has been given for this fact, but it should be taken into account to ensure effective use of the sorbent.

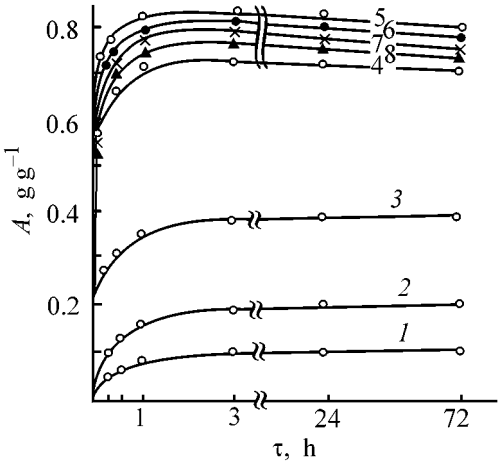

Fig. 2. Amount *A* of copper bound with sorbent in solutions nos. 1–8 vs. time τ.

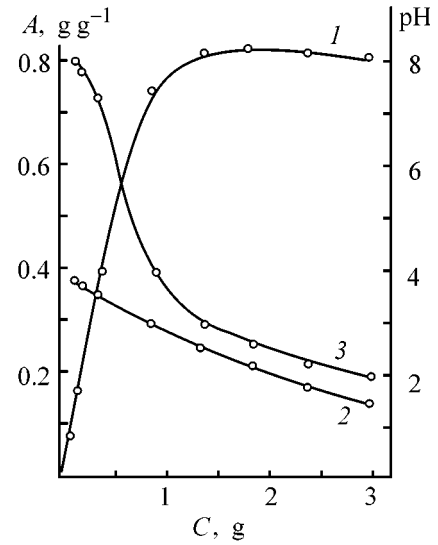

Fig. 3. (*1*) Amount A of copper bound by 1 g of sorbent in 1 h, (*2*) pH of the starting solutions, and (*3*) that in 72 h vs. copper content *C* in the starting solutions nos. 1–8.

The obtained data suggest that the processes of sorption from solutions nos. 5–8, on the one hand, and nos. 1–4, on the other, are markedly different. In the first case, the process ends with sorbent saturation in approximately 1 h, whereas in the second, the sorption, also being intensive during the first hour, later passes into a slowed-down phase continuing for days and presumably terminating only after formation of an equilibrium copper-containing sorption product.

Since the sorption process, consisting in an exchange interaction of calcium and copper carbonates in the sorbent with copper(II) ions in solution, is associated with hydrolysis, the possible final products of interaction between the carbonates and copper ions are hydrolysis products—basic salts and even copper(II)

hydroxide. The apparent key factors in the given case are their solubility products and changes in solution pH in the course of sorption. As indicated by the obtained results, the behavior of the solution pH (Fig. 3, curves *2* and *3*) strongly depends on the copper(II) content in the starting solutions. In solutions nos. 4–8, the change in pH is relatively small and terminates in approximately 1 h. In the case of starting solutions nos. 1–3, the pH changes during much longer time and to a greater extent. For example, the pH reaches a value of 7.45 in solution no. 3 and 7.75 in solution no. 2. These data are in good agreement and confirm the fact that 1 g of sorbent is insufficient for neutralizing initial acid solutions in copper sorption from solutions nos. 5–8. At the same time, in sorption from solutions nos. 1–3, the amount of copper in these solutions is not enough for saturating the sorbent. Sorbents binds hydrogen ions by the reaction

$$2H^+ + MCO_3 \rightarrow M^{2+} + H_2O + CO_2$$

thereby shifting to the right the hydrolysis reaction

$$Cu^{2+} + nH_2O \rightleftarrows [Cu(OH)_n]^{2-n} + nH^+.$$

An indirect evidence in favor of the occurrence of this reaction is the intense evolution of carbon dioxide upon addition of sorbent to copper(II) chloride solutions. The equilibrium of hydrolysis reactions is shifted in solutions nos. 1–3 to such an extent that the initially acid solutions become neutral or even weakly alkaline. It would be expected, with account of the fact that the reached pH values exceed the pH of the onset of copper(II) hydroxide precipitation (5.5) and approach the pH of its complete precipitation (8–10) [7], that even copper(II) hydroxide ($n = 2$) may be the final product of sorption in the case of an excess of sorbent.

In this connection, with an excess of sorbent, the residual concentration of copper may reach values determined by the solubility product of copper hydroxide. In particular, at pH 8 this concentration is 6.03×10^{-9} g cm^{-3}. Presumably, just this value is that final concentration to which tends in the course of time the residual concentration of copper in a solution treated with an excess of sorbent. However, products with $n < 2$ can be formed in intermediate stages. Indeed, according to X-ray phase analysis of sorption products [8] (see the table), the main phase

formed in sorption from dilute solutions nos. 1–3 is $Cu_2Cl(OH)_3$. This phase is detected in corresponding sorption products after both 1h and 3 days of contact between the sorbent and solution. This may be due to either lower solubility of $Cu_2Cl(OH)_3$, compared with the solubilities of other possible phases (including copper hydroxide), or to the fact that this phase is originally formed in sorption and its subsequent transformation into products of deeper hydrolysis is rather slow. The last variant (possibly combined with the first) is indirectly confirmed by the presence of reflections corresponding to this phase also in X-ray diffraction patterns of sorption products formed in more concentrated solutions.

CONCLUSIONS

(1) Carbonate-containing sorbent of technological origin can be used to sorb copper(II) from chloride solutions. Addition of the sorbent to solutions of this kind leads to intense evolution of carbon dioxide, accompanied by a decrease in the acidity of the starting solutions. With solutions originally containing more than 1.3–1.5 g of copper per 1 g of sorbent added, the sorption process ends with sorbent saturation in approximately 1 h. The maximum sorbent capacity is in this case 0.83 g g^{-1}.

(2) With an excess of sorbent, the sorption process is vigorous initially and then becomes slower, with the latter stage not complete even after 3 days. The solution pH becomes in this case equal to, or greater than 7, with the $Cu_2Cl(OH)_3$ phase being the main product of copper precipitation.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Cations of the Zn^{2+}–Hg^{2+}–NO_3^-–H_2O System by Biomass of Ostreatus Agaricaceae Basidiomycete and KB-4(H^+) Cation Exchanger

T. L. Zalevskaya and E. V. Radion

Belarus State Technological University, Minsk, Belarus

Received February 3, 2000; in final form, October 2000

Abstract—Sorption of cations of the Zn^{2+}–Hg^{2+}–NO_3^-–H_2O system by the biomass of basidiomycete (line 21 *Pl. ostreatus f. florida*) and by KB-4(H^+) cation exchanger at pH 1.00 was studied. The results are discussed with regard to the state of cations in the solution before contact with the sorbent, sorbent properties, and sorption behavior of cations.

Previously, we studied the sorption of Cu(II), Pb(II), Hg(II), or Fe(III) by the biomass of *Pl ostreatus f. florida* basidiomycete from nitrate solutions containing a single cation or two metal cations simultaneously [1, 2]. The results were considered from the viewpoint of hydrolytic properties of metal ions. Proceeding with these studies, we examined the sorption of Hg(II) by a basidiomycete biomass from 0.1 M solution in the presence of 0.1 M Zn(II).

To examine the nature of sorption bonds, we also studied the sorption of Hg(II) and Zn(II) by carboxylic cation exchanger KB-4(H^+) whose functional groups can act as centers of electrovalent interaction and are able to participate in ion-dipole interaction, H-bond formation, and complexation [3].

EXPERIMENTAL

Analytically pure zinc nitrate and the solution of Hg(II) nitrate prepared by dissolution of metallic mercury in chemically pure nitric acid (1 : 1) were used. The fruit bodies of basidiomycete *Pl. ostreatus f. florida*, line 21 were provided by the Wood Institute, Belarussian National Academy of Sciences. Samples of air-dry basidiomycete biomass crushed to 0.5-mm particles were brought in contact with metal salt solution in hermetically sealed vessels for one day. Preliminary kinetic experiments showed that this the time is enough for equilibrium to be attained in the system [1]. The required solution pH was adjusted by adding chemically pure KOH or HNO_3. The solution pH was measured on an EV-74 universal pH meter with an error of 0.05 pH units. In blank tests performed for each system, a biomass sample was brought in contact with a zinc- and mercury-free solution at a given pH.

Mixtures were kept in a TS-80 M-2 air thermostat with intermittent agitation. After one day, equilibrated solutions were separated from the basidiomycete biomass, and the content of metal ions in them was determined.

The cation exchanger was pretreated by the method described in [4]. Its moisture content, determined as in [5], was 16.22%. The sorption was studied at 25 ± 0.1°C under static conditions; the attainment of the equilibrium distribution of metal ions between the solution and cation exchanger was proved in all runs.

To determine the effect of metal ion concentration, the sorption was studied at Hg(II) and Zn(II) concentrations of 0.01 and 0.1 M. The solutions prepared were kept for 7 days at 25 ± 0.1°C to attain equilibrium. The effect of pH could not be studied, because HgO deposition begins even at pH > 1.20. Therefore, all studies were done at pH 1.00.

The amounts of Hg(II) and Zn(II) simultaneously present in the solution were determined complexometrically. Initially the total metal content was determined by back-titration with a standard solution of zinc salt with eriochrome black T in ammonia buffer, then potassium iodide was added to displace equivalent amount of EDTA from its mercury complex, and the displaced EDTA was titrated with the zinc salt. The Zn(II) content in the mercury-free solution was

* (V) solution volume and (m_0) sorbent sample weight.

determined by direct complexometric titration with eriochrome black T in ammonia buffer at pH 10 [6].

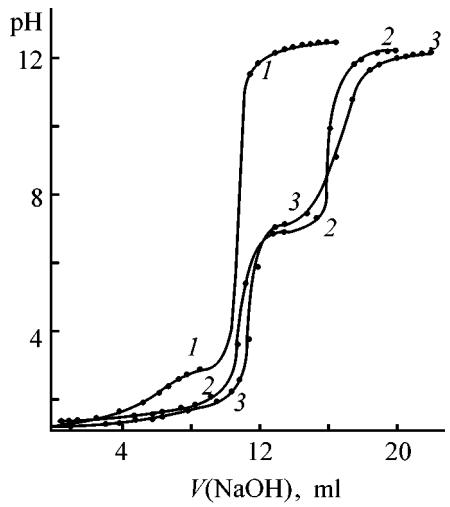
The metal sorption by the sorbent, S (mmol and mg per g of absolutely dry sorbent), and distribution coefficients K_d between the sorbent and solution were calculated from the chemical analysis data (table).

In discussing the sorption of simultaneously present metals, we should take into account the action of many factors: (1) the state of metal ions in the solution before coming in contact with the sorbent, which is determined by the hydrolytic behavior of each ion, by mutual influence of ions on their hydrolysis, and by probable interaction of hydrolyzed species of different metals; (2) the ion-exchange properties of the sorbent, determined by the number of ionogenic groups, degree of their dissociation at given pH, and the nature of exchanging ion [5]; and (3) the sorption behavior of metal ions, which is individual and depends on the chemical nature of the metal ion and sorbent.

We determined the pH at which HgO and $Zn(OH)_2$ start to precipitate (>1.20 and >5.50, respectively) from 0.1 M metal ion solution. At the same time, the solution containing 0.1 M Hg(II) and 0.1 M Zn(II) cannot be prepared at pH > 1.00 because of the precipitate formation. It is this fact that determined the pH at which we studied the metal sorption in the Hg(II)–Zn(II)–NO_3^-–H_2O system. As seen, the Hg(II) hydrolysis is facilitated in a mixed Hg(II)–Zn(II) solution, i.e., Zn(II) affects the hydrolytic behavior of Hg(II).

To obtain preliminary data on the possible hydrolytic interaction of Hg(II) with Zn(II), we performed pH-metric titration of solutions by the method described in [7] (see figure). Two titration jumps in curve *3* are observed after the onset of precipitation. To find whether HgO and $Zn(OH)_2$ coprecipitate, we performed some calculations [7]. In accordance with the solubility products SP(HgO) 3.0×10^{-26} and SP($Zn(OH)_2$) 1.4×10^{-17} [8], at the instant when $Zn(OH)_2$ starts to precipitate, the concentration of untitrated Hg(II) is

$$C(\mathrm{Hg}) = \frac{\mathrm{SP(HgO)}}{\mathrm{SP[Zn(OH)_2]}}\, C_{in}(\mathrm{Zn}) \approx 2 \times 10^{-11} C_{in}(\mathrm{Zn}).$$



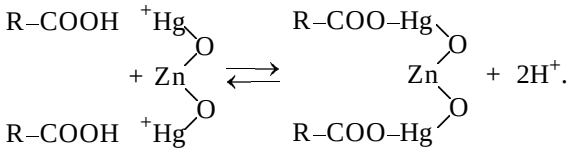
Curves of potentiometric titration of (*1*) Hg(II), (*2*) Zn(II), and (*3*) Hg(II)–Zn(II). $C_{Hg} = C_{Zn} = 0.01$ M. (*V*) Volume.

Thus, at practically any initial concentration of metal ions, two jumps corresponding to successive precipitation of HgO and $Zn(OH)_2$ must be observed in the curve of titration of an Hg(II)–Zn(II) solution with alkali in the absence of chemical interaction between Hg(II) and Zn(II). This is, indeed, observed in the experiment (curve *3*). However, the curve shape suggests that certain interaction between Hg(II) and Zn(II) does occur, because the curve contains no titration jump related to titration of pure Hg(II) in the acid medium (curve *1*), and the second jump is distorted and shifted to the right relative to curve *2* owing to superposition of some other process. Hence, Hg(II) and Zn(II) ions affect the hydrolysis of each other, with Hg(II) hydrolysis facilitated. Interaction of these ions in the solution is also possible.

At pH 1.00, when the degree of cation exchanger ionization is negligible, we should expect negligible sorption of Hg(II) and Zn(II) with KB-4 ion exchanger (pK ≈ 7 [3]. Indeed, only Zn(II) is not sorbed from solutions free of the other metal (see table), i.e., the ion exchange properties of KB-4 resin depend on the nature of the exchanging ions. The higher affinity of KB-4 for Hg(II) may be due to a number of specific properties of Hg^{2+} ion distinguishing it from the other metal ions. Firstly, no hydroxides are known for Hg^{2+}, with HgO directly precipitated instead. Secondly, Hg^{2+} shows low hydrolysis susceptibility; nevertheless, HgO is precipitated from strongly acidic solutions. Thirdly, a number of Hg^{2+} compounds are covalent (they are weak electrolytes), which is due to the strong polarizing effect of Hg^{2+}. It is known that the bond covalence grows with increasing polarization and the H^+ ion exhibits a particularly high polarizing effect. Since H^+ and Hg^{2+} ions participate in the ion exchange:

$$\begin{matrix}\text{R–COOH}\\ \text{R–COOH}\end{matrix} + Hg^{2+} \rightleftharpoons \begin{matrix}\text{R–COO}\\ \text{R–COO}\end{matrix}\!\!\!

Zn(II). Since the Hg(II) sorption by the cation exchanger is the ion-exchange process and Zn(II) is sorbed only via interaction with Hg(II), we can suggest that the sorption of heteronuclear oxocompound Hg(II)–Zn(II) proceeds in accordance with the scheme



(Fragment of heteronuclear oxocompound)

The data in the table also show that, in the absence of the other metal, Zn(II) is sorbed by the basidiomycete biomass to a greater extent than Hg(II). When these metals are present simultaneously, their sorption behavior changes: the Zn(II) sorption stops, while the Hg(II) sorption increases somewhat.

The high K_d values for Zn(II) in the mercury-free solution deserve attention. To clarify whether ionic or nonionic forms of metals are sorbed by the basidiomycete biomass, we varied the V/m_0 ratio. In this case, for Zn(II) in a mercury-free solution, K_d changes (see table), and we can suggest in accordance with Schubert's rule that nonionic forms of Zn(II) are sorbed [9]. For Hg(II) in a zinc-free solution, K_d is constant at varied V/m_0. Hence, ionic forms of Hg(II) are sorbed. As shown in [2], these are Hg^{2+} ions. In solutions containing both ions, K_d for Hg(II) changes somewhat with V/m_0. This indicates a change in the Hg(II) sorption behavior (as compared with zinc-free Hg(II) solutions), caused by the formation of a heteronuclear Hg(II)–Zn(II) compound.

Comparison of the metal ion sorption by the basidiomycete biomass and KB-4 under the same conditions allows a conclusion that sorption by the KB-4 ion exchanger of Hg(II), Hg(II) in the presence of Zn(II), and Zn(II) in the presence of Hg(II), is greater than sorption by the basidiomycete biomass. The mechanism of Hg(II) sorption is the same in all cases: the ion exchange of Hg^{2+} for H^+. The Zn(II) sorption from mercury-free solution cardinally differs for the examined sorbents. Zn(II) is not sorbed by the cation exchanger at all and strongly sorbed by the basidiomycete biomass. As shown above, nonionic forms of Zn(II) are sorbed. The nature of the Zn(II)– biomass bonds remains unclear, and further studies are required to reveal the role of various functional groups in the interaction of Zn(II) with the basidiomycete biomass.

Since the sorption behavior of Hg(II) and Zn(II) in their sorption by the basidiomycete biomass are strongly different, we can suggest that the heteronuclear Hg(II)–Zn(II) compound existing in the solution decomposes upon sorption, and preferential Hg^{2+} sorption occurs because of the above-mentioned features of this ion.

CONCLUSIONS

(1) In the Hg(II)–Zn(II) solution, the mutual influence of the metals on their sorption and hydrolytic behavior is observed.

(2) The heteronuclear Hg(II)–Zn(II) compound formed in the solution is strongly sorbed by the KB-4 ion exchanger, but decomposes when brought in contact with the biomass of *Pl. ostreatus f. florida* basidiomycete.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Characteristics of "Food Fibers" in Secondary Products of Processing of Vegetable Raw Materials

S. S. Stavitskaya, T. I. Mironyuk, N. T. Kartel', and V. V. Strelko

Institute of Sorption and Endoecological Problems, National Academy of Sciences, Kiev, Ukraine

Received May 30, 2000; in final form, November 2000

Abstract—Some structural-sorption characteristics of a series of secondary products (wastes) obtained in processing of vegetable raw materials, such as wheat straw, buckwheat peel, sunflower husk, and beet pulp, containing fibrous cellulose skeleton ("food fibers"), were determined. The effect of chemical and mechanochemical modification of these products on the characteristics of their pore structure and sorption activity with respect to organic substances, heavy metal ions, and ^{90}Sr radionuclides was studied.

Previuos studies [1, 2] have shown that linear regular homopolysaccharides (cellulose, mannans, and chitin), contained in products of vegetable origin (grasses, legumes, vegetables, fruits, berries, algae, mushrooms, etc.) and also called "food fibers" (FFs), which are insoluble in water owing to strong intramolecular association, have noticeable binding ability with respect to a number of heavy metals and radionuclides, among them transuranium elements. It has been found experimentally that, in human and animal gastrointestial tracts, FFs are able to sorb calcium, copper, zinc, and iron ions, and also cholic acids, nitrous slags, phenols, and other toxic substances and to detoxicate the organism [3–5]. Medical and biological studies indicate that FFs used as sorbing food additives facilitate removal of various toxicants from the organism in curing many diseases, which appreciably increases the efficiency of therapeutic procedures and reduces their duration.

Because of the need for widening the assortment of sorbents (enterosorbents and food additives), it is an urgent task to study sorption, ion-exchange, and complexing characteristics of a number of vegetable products, which appear most often as nonutilizable wastes of agricultural industry.

The aim of this work was to study comprehensively the sorption characteristics of some FF-containing products, such as wheat straw, buckwheat peel, sunflower husk, and beet pulp. These products were subjected to chemical or mechanochemical modification: (1) lyophilic drying of the product after treatment with buffer solutions of varied acidity and (2) thermal extrusion of a moistened product.

Lyophilic drying (cold vacuum dehydration) of the products was carried out on a laboratory setup at temperatures ranging from –10 to –15°C after swelling of these products during boiling in buffer solutions with pH 3.56 ($KC_4H_5O_6$), 7.05 (KH_2PO_4 + Na_2HPO_4), and 9.18 (K_2HPO_4) for 1 h and keeping the resulting suspensions at room temperature for 7 days, washing of the solid phase with distilled water to neutral wash water pH, and filtration.

The mechanochemical treatment of the samples was carried out on a pilot two-worm extruder.[1] Its technical characteristics were as follows: length 1.5 m, outlet diameter 63 mm, rotation speed of the worms 30–45 rpm, and temperature in the area of maximum compression 160–180°C. The initial product fed into the extruder had moisture content of 25%.

The main goal of the modification of these products was to raise their internal adsorption surface area and facilitate the access to active centers of FF-containing materials. Therefore, it was of interest to estimate the sorption characteristics of the modified products with respect to organic substances, toxic metals, and radionuclides.

The features of the pore structure of the products and their capacity for molecular and ion-exchange sorption were studied by common procedures [6, 7]. The specific surface area S_{sp} was measured gas-chromatographically from the thermal desorption of argon. The volume of sorption pores, W_s, was de-

termined by the dessicator technique from the sorption of benzene, methanol, and water vapor.

The sorption capacity of the sorbents under consideration was estimated from the isotherms of adsorption from aqueous solutions of substances-markers with various molecular weights, such as Methylene Blue (M = 319) and vitamin B_{12} (M = 1355), representing groups of organic compounds with, respectively, low and medium molecular weight. In doing so, we used the method of individual weighed portions; the solid phase to solution weight ratio was 1 : 2000, and the contact time of the material with solutions of various initial concentrations, 4 h.

The ion-exchange characteristics of the samples (static exchange capacity) were judged from the sorption of acid and alkali from 0.01 M HCl and 0.1 M NaOH solutions.

The structural changes in the products (degradation of polysaccharide chains) upon mechanochemical modification were estimated from the concentration of paramagnetic centers, determined by ESR. The ESR spectra of dry sorbent samples were recorded on an SEPR-03 radiospectrometer (Svetlana Production Association, Russia) in air at room temperature.

The limiting sorption capacity of the samples for heavy metal cations was determined from the corresponding plateaus in the isotherms of sorption from solutions of lead acetate and strontium chloride. The equilibrium concentrations of metals in the solutions were measured by the atomic-absorption spectroscopy on a KAS-120.1 device (Elektropribor Production Association, Ukraine).

The sorption selectivity with respect to radiostrontium was estimated from the distribution coefficient K_d of the isotope between the sorbent and radioactive solution. The initial activity of the solution was 1.6×10^{-5} Ci l^{-1}. The specific activities were measured by the standard procedure [8]: after evaporation of 1 ml of an aliquot, the dry residue was analyzed with a 1211 RackBeta liquid scintillation β-counter (Finland) tuned to the ^{90}Sr emission energy.

Table 1 presents data characterizing the porosity of lyophilized materials treated with buffer solutions. The initial products were practically nonporous. Swelling in the electrolytes and subsequent lyophilic drying resulted in the appearance of sorption pores and development of the specific surface area of the materials. In acidic media, the porosity develops considerably more slowly than in neutral and alkaline solutions. The S_{sp} values for products treated with acidic and alkaline buffer solutions differ by a factor as large as 3–5. In addition, the samples treated with alkaline solutions have fairly high adsorption activity with respect to organic substances in aqueous solutions. For example, it follows from the isotherms of Methylene

Table 1. Characteristics of porosity of FF-containing lyophilized materials treated with buffer solutions with various acidities

Parameter	pH of suspension	Material		
		wheat straw	buckwheat peel	sunflower husk

	After extrusion	3.1	0.5	2.0	2.3	3.1	270

Blue adsorption (see Fig. 1a) that the adsorption capacity of these samples reaches 150–200 mg g^{-1}, which is comparable with some classic sorbents (activated carbons, silicas, clays, and others) recommended as adsorbents for medicine.

However, the sorption activity of the resulting samples with respect to medium-molecular-weight molecules, represented by vitamin B_{12}, is lower than that of activated carbons (Fig. 1b) with a broad pore-size distribution. It is likely that the resulting FF-containing materials have ultramicroporous structure accessible to small polar molecules (water, methanol), but the access is hindered for larger nonpolar molecules of benzene and impossible at all for large molecules of vitamin B_{12}. This is evident from the data on W_s for various adsorbates (Table 1): the values determined for comparatively small molecules of methanol and water (critical size of up to 0.3 nm) are higher by a factor of 2–2.5 that those for benzene (critical size of up to 0.6 nm). Medium-sized and large molecules are most probably sorbed in macropores whose contribution to the specific surface area of the sorbent sample is, as a rule, insignificant (no more than 1 $m^2 g^{-1}$).

The results of titrations of FF-containing materials with 0.1 N NaOH and 0.01 HCl show rather strong sorption of alkali metal cations. Their static exchange capacity (SEC) with respect to Na^+ cations is 0.8–1.8 mg-equiv g^{-1} even for the initial materials, which suggests the presence of proton groups, most probably of alcohol type (as suggested by the structure of the cellulose skeleton). This is responsible for the ion-exchange and complexing sorption of multicharged alkali and transition metal cations.

It was of interest to improve the sorption characteristics of FF-containing materials by thermal extrusion treatment, which, in our opinion, must result in an increase in the accessibility to ions of active centers in a rather rigid three-dimensional skeleton of the material. It is well known [9] that the mechanochemical treatment of the material in extrusion may result in numerous ruptures (degradation) of polysaccharides chains, indicated, e.g., by an increase in the concentration of defective structures of the free-radical type, i.e., paramagnetic centers (PCs). Actually, an abrupt increase (by a factor of 2–2.5) in the concentration of PCs in FF-containing materials is registered after extrusion in the ESR spectra (Table 2). It is evident that the presence of PCs of the macroradical type should be considered a positive factor for food additive or enterosorbent, since macroradicals can inhibit free-radical chain processes at the cell level, initiated by both external ionizing radiation and internal radiation caused by incorporated radionuclides.

It was found that, upon extrusion, the SEC of the materials with respect to Cl^- anions increases insignificantly, while the SEC with respect to Na^+ cations grows noticeably (by 0.2–0.6 mg-equiv g^{-1}). This treatment of the materials has positive effect on their binding power with respect to multicharged metal cations: the sorption capacity of the materials with respect to Pb^{2+} and Sr^{2+} increases by 30–40% (Table 2).

Still more interesting are data on changes in the selectivity of radioactive strontium sorption by FF-containing materials after thermal extrusion. The resulting distribution coefficients K_d with respect to ^{90}Sr suggest that the mechanochemical treatment of these ma-

terials increases their sorption selectivity practically by an order of magnitude. In other words, modified FF-containing materials can be compared, as radioactive strontium sorbents, with adsorbents of the ion-exchange type, e.g., oxidized carbons [10].

CONCLUSIONS

(1) After proper chemical or mechanochemical modification, secondary products of processing of agricultural plants can be considered fairly efficient adsorbents in molecular or ion-exchange sorption. Their sorption characteristics with respect to organic substances (e.g., Methylene Blue and vitamin B_{12}), heavy metal ions (e.g., lead and strontium), and strontium radionuclide compare well with those for classic adsorption materials based on carbons, silica, aluminosilicates, etc.

(2) Modified materials based on secondary vegetable products and containing food fibers can be considered potential food additives with therapeutic and prophylactic effect or as components of enterosorbents.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Voltammetry with a Fluoride-Selective Electrode with Solid-Phase Reference System

Abstract—Experimental results obtained in a study of the voltammetric response of an all-solid fluoride-selective electrode based on LaF_3 (Eu^{2+} 0.8 mol %), LaF_3 (Sr^{2+} 5 mol %) and CeF_3 (Sr^{2+} 5 mol %) single crystals brought in contact with Ag, Bi, and Sn metal samples are presented. The method of cathodic inversion voltammetry was applied to study the reduction of La^{3+} and Ce^{3+}—cations from the rigid sublattice of solid electrolytes, which determines the threshold of the electrochemical stability of a membrane. Anodic inversion voltammetry was used to investigate the characteristics of solid-phase generation of metal fluorides at the interface between the fluoride-selective electrode and metals.

The fluoride-selective electrode (FSE) with a single-crystal membrane of LaF_3 solid electrolyte activated with Eu^{2+} (0.8 mol %), one of the most specific ion-selective electrodes, is widely used for measuring the activity of the fluoride ion in solutions [1]. In addition, it has been proposed to use FSE in an electrochemical cell with a metal working electrode as voltammetric sensor (VAS) sensitive to changes in the elemental composition of solid surfaces [2, 3]. The operation of FSE and VAS is based on different processes. In FSE, the potential-determining process is the reversible transfer of the fluoride ion at the solid electrolyte–solution interface

$$F^-_S \leftrightarrow F^-_{s.e} \text{ (FSE)}. \quad (1)$$

In VAS, the voltammetric response is due to solid-phase reactions of metal fluoride formation, proceeding at the interface between the FSE membrane and metal and involving mobile ions of the solid electrolyte, $F^-_{s.e}$:

$$nF^-_{s.e} + M \leftrightarrow MF_n + ne\text{(VAS)}, \quad (2)$$

whose reduction is characterized by curves with a single peak [2–4]. It is proposed to use the output signals of the sensor: peak current and potential and stationary potential, to determine the nature of a metal and its content [2, 3].

The present communication reports on a study of the voltammetric response of FSE with a solid-state reference system in the case of contact between LaF_3 single-crystal membrane (Eu^{2+} 0.8 mol %) and metals. The study was undertaken in order to expand the use of FSE and single-crystals of other nonstoichiometric fluorides with tysonite structure [LaF_3 (Eu^{2+} 0.8 mol %), LaF_3 (Sr^{2+} 5 mol %), and CeF_3 (Sr^{2+} 5 mol %)] in detection of metal impurities on the surface of solids without aqueous or nonaqueous solutions and without reagents. Previously, all-solid FSEs with LaF_3 membrane (Eu^{2+} 0.8 mol%), and single crystals of LaF_3 (Sr^{2+} 5 mol%) and CeF_3 (Sr^{2+} 5 mol %), have not been considered in the voltammetric mode.

EXPERIMENTAL

Two types of FSE were fabricated, with liquid and solid inner reference systems. Polished membranes made of a lanthanum fluoride single crystal activated with Eu^{2+} (0.8 mol %) were 10 mm in diameter and 1–1.5 mm thick. Some experiments were done with all-solid FSEs based on LaF_3 (Sr^{2+} 5 mol %) and CeF_3 (Sr^{2+} 5 mol %) single crystals.

The electrochemical behavior of the interface between the solid electrolyte and metal can be strongly affected by structural defects and crystallographic in-

1070-4272/01/7404-0596 $25.00 © 2001 MAIK "Nauka/Interperiodica"

homogeneities of the solid electrolyte. Since preliminary experiments revealed that the voltammetric signal intensity depends on the conductivity-related properties of the single-crystal solid electrolyte, membranes with resistance not exceeding 50 kohm were chosen.

Particular attention was given to pretreatment of the FSE membrane surfaces and metallic electrodes, since dynamic voltammograms are exceedingly sensitive to contamination of contact surfaces and reflect the presence of uncontrollable impurities in trace amounts. The procedure for treatment of the solid electrolyte surface and preparation of metal samples for experiments was described in [2].

The study was performed in two-electrode electrochemical cells FSE | M

$$\text{Sn, SnF}_2 \,|\, \text{LaF}_3 \,|\, \text{M} \qquad (3)$$

using a PU-1 polarograph or PI-50-1.1 potentiostat with PR-8 programming unit. The metal served as working electrode with area varied in the experiment between 0.05 and 1 mm^2. The fluoride-selective electrode with a solid-phase reference system served in voltammetric measurements as auxiliary and reference electrodes. Solid-phase Sn, SnF_2 electrodes, commonly used in LaF_3-based gas sensors [5, 6], were fabricated by mixing Sn and SnF_2 powders and compacting the mixture, with subsequent fusion.

The emf was measured with an I-120 ion meter or ITN-7 electrometer (R_{in} = 10^{16} ohm).

The operation of an all-solid FSE in contact with metal electrode was studied in the inversion voltammetry mode. As experimental metal samples were tested Ag, Sn, and Bi, whose electrochemical behavior has been considered previously for an FSE with liquid inner reference system [7, 8].

A most important condition for studying the response of the interface between the FSE membrane and metal is the descrimination of the processes occurring in half-cells of the cell with solid electrolyte. It is more difficult to ensure nonpolarizability of the interface between the solid electrolyte and the solid-phase reference system in voltammetric measurements, compared with the case of potentiometry [9], especially with anionic conductors. The requirements to the solid-phase reference systems can be formulated as follows: (i) the reference system must contain a sufficient number of active ions ensuring charge transfer across the interface between the reference electrode and the solid electrolyte, (ii) metal particles must form an electrically conducting network, (iii) large contact surface area between the ionic and electronic conductors is necessary for diminishing the polarization at the metal–salt interface, (iv) it is advisable to make as thin as possible the salt layer between the surface of the single-crystal solid electrolyte and metal particles for reducing the ohmic polarization of the layer, and (v) it is necessary to ensure high rate of exchange at the metal–salt and salt–solid electrolyte phase boundaries of the reference half-cell.

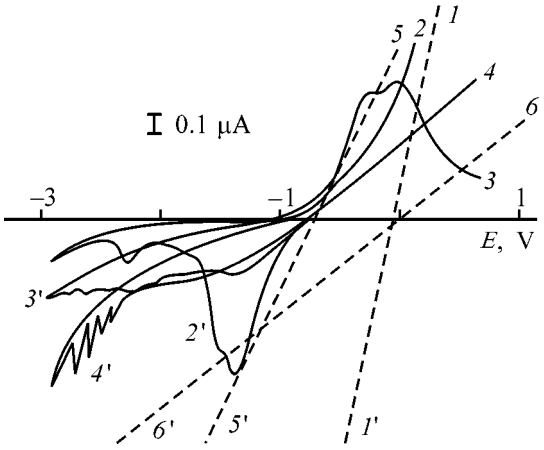

Fig. 1. Dynamic voltammograms of cells. Potential sweep rate V = 0.03 V s^{-1}; the same for Fig. 2. (E) Potential; the same for Fig. 2. Cell: (*1*, *1'*) (4), (*2*–*5*, *2'*–*5'*) (5), and (*6*, *6'*) (6). For explanation see text.

The choice of a solid-phase reference system based on SnF_2 is governed by the sufficiently high ionic conductivity of SnF_2 ($\sigma \approx 2 \times 10^{-7}$ S cm^{-1} at 20°C) and by the fact that the reaction $SnF_2 + 2e \leftrightarrow Sn + 2F^-$ is reversible under certain conditions [4, 7]. The fabricated solid Sn, SnF_2 electrodes were tested by successive comparison of voltammograms of the cells

$$\text{Ag, AgCl} \,|\, \text{KCl 1 M, KF 1 M} \,|\, \text{LaF}_3 \,|\, \text{KF 1 M, KCl 1 M} \,|\, \text{AgCl, Ag;} \qquad (4)$$

$$\text{Ag, AgCl} \,|\, \text{KCl 1 M, KF 1 M} \,|\, \text{LaF}_3 \,|\, \text{SnF}_2\text{, Sn;} \qquad (5)$$

$$\text{Sn, SnF}_2 \,|\, \text{LaF}_3 \,|\, \text{SnF}_2\text{, Sn,} \qquad (6)$$

measured at potential sweep rates in the range 0.02–0.05 V s^{-1}.

The current–voltage (I–E) characteristic of the symmetric cell (4), linear within ±3 V and independent of the potential sweep rate (Fig. 1, curves *1* and *1'*), was used for evaluating the ohmic voltage drop in the solid electrolyte [7].

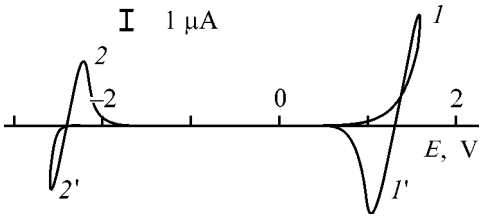

Fig. 2. Cyclic voltammogram of the Sn, $SnF_2|LaF_3|Ag$ cell. For explanation see text.

It was found that the voltammograms of cell (5), comprising two types of reference electrodes: silver chloride electrode in an aqueous solution and a solidphase electrode, measured at potentials ranging from –2 to +2 V, were different for different samples. With some solid electrodes, a single-peak SnF_2 decomposition curve was observed at E = –0.6 V after anodic polarization of the $LaF_3|SnF_2$, Sn contact in the range from –0.5 to +1.5 V and subsequent cathodic sweep (Fig. 1, curves *2* and *2*'). With other solid electrode samples, an anodic peak was clearly manifested at E = 0.05 V, associated with the reaction of tin fluoride formation (Fig. 1, curves *3* and *3*'). In other cases, irregular current fluctuations appeared in the cathodic region, indicating, in all probability, a poor contact between the reference electrode and the surface of the single-crystal membrane. The observed diversity of voltammetric responses does not always affect the cell emf, i.e., the stationary potential of the Sn, SnF_2, LaF_3 electrode was reproducible, E_{st} = –(0.621 ± 0.003) V. However, when effects of this kind did appear, interpretation of processes at the $LaF_3|M$ interface was either strongly hindered or at all impossible. In this connection, attention was paid to the technology of fabrication of the solid-phase reference system whose efficiency was verified by measuring voltammograms of cell (5). The fabrication technology of the Sn, SnF_2 electrodes was modified so as to ensure, by changing the salt to metal ratio, compaction pressure, and time and temperature of fusion, a linear *I–E* characteristic of cell (5) at potentials ranging from E = –2.0 to E = +2 V (Fig. 1, curves *5* and *5*'). It was found that raising the potential sweep rate ($dE/dt > 0.06$ V s^{-1}) led to the appearance of a hysteresis in the dynamic *I–E* curve. Therefore, voltammetric testing of solid-phase electrodes was also used to select the working range of potential sweep rates. A comparison of the *I–E* curves for cells (1) and (5) revealed an additional polarization resistance that remained unchanged under the experimental conditions.

The voltammogram of cell (6) with two solid-phase contacts (Fig. 1, curves *6* and *6*') is characterized, as would be expected, by an increase in polarization resistance, but remains linear in the range of potentials in question and exhibits no hysteresis at sweep rates of 0.01 to 0.04 V s^{-1}. Similar behavior is observed with $LaF_3:Sr^{2+}$ and $CeF_3:Sr^{2+}$ single crystals. All-solid FSEs, ensuring this type of dynamic *I–E* curves in contact with Sn, SnF_2, were used to study the $LaF_3|M$ interface, with the *I–E* curve of cell (5) monitored at regular intervals, in the case when there occurred a Nernst dependence of the FSE emf on the activity of the fluoride ion in solution in the range 1–5 pF^-.

The working range of potentials at which solid-phase reactions at the $LaF_3|M$ interface (M = Ag, Bi, or Sn) was verified using the cyclic voltammogram of the Sn, $SnF_2|LaF_3|Ag$ cell (Fig. 2), since the potential of silver fluoride formation is the most positive among the metal electrodes under study: E^0 (Ag|AgF) = 0.95 V [7]. After anodic charging of the interface from E = 0.5 to E = 2 V, a current appears at E > +1 V as a result of AgF formation. A single-peak curve of silver reduction is observed in subsequent cathodic potential sweep (Fig. 2, curves *1* and *1*'). Further shift of the potential in the negative direction gives rise to a current at E = –2.35 V (Fig. 2, curve *2*'). Changing the sweep direction to anodic is accompanied by the appearance of curves with a single peak (Fig. 2, curve *2*). The nature of the curves depends on the contact zone area, potential sweep rate, and interface potential in inversion. In cathodic polarization of the $LaF_3|M$ interface at –2.35 V, cations belonging to the rigid sublattice of the single crystal are reduced to form $LaF_3|La|Ag$ electrodes, and potential inversion in the anodic direction leads to La oxidation and regeneration of the solid electrolyte. A similar behavior is characteristic of an FSE with liquid inner reference system the case of contact between a $LaF_3:Eu^{2+}$ membrane and metals [4, 9]. The redox reactions involving lanthanum contained in the solid electrolyte are important as regards the possible use of nonstoichiometric fluorides in analytical practice, since they determine the working range of potentials.

The reactions limiting the cathodic region of electrochemical stability of the solid fluorine-conducting electrolyte were analyzed using LaF_3 (Eu^{2+} 0.8 mol %), LaF_3 (Sr^{2+} 5 mol %), and CeF_3 (Sr^{2+} 5 mol %) single crystals in the cathodic inversion voltammetry mode. It was found that the voltammograms of the contact between Ag and the single crystals used were similar, but the reduction potential was dependent on the cations of the rigid sublat-

tice. The initial portions of the dynamic voltammograms, reflecting the transition to a Faraday cathodic process, were, as a rule, independent of the potential sweep rate. (dE/dt = 0.02–0.05 V s^{-1}). Further, the slope of the *I–E* curves coincided with the ohmic polarization of the contact FSE membrane–Ag. The dynamic anodic curves measured from the level of the stationary potential were characterized by a single peak and reflected the transition from the $LaF_3|La|Ag$ electrode to a $LaF_3|Ag$ one with regeneration of the FSE|Ag interface. Figure 3 presents $CeF_3:Sr^{2+}|Ag$ interface regeneration curves taken after cathodic forming of the $CeF_3:Sr^{2+}|Ce|Ag$ cell at generation potential $E_{g.c}$ = –2.6 V and Q_c = 8.36 μC.

Reduction of La^+ in $LaF_3:Eu^{2+}$ and $LaF_3:Sr^{2+}$ single crystals and Ce^{3+} in $CeF_3:Sr^{2+}$ single crystal was studied by analyzing the influence exerted on the characteristics of anodic processes by the potential of cathodic charging of the interface to form $LaF_3:Eu^{2+}|La|Ag$, $LaF_3:Sr^{2+}|La|Ag$, and $CeF_3:Sr^{2+}|Ce|Ag$ electrodes. It was found that at generation potentials ranging from $E_{g.c}$ = –2.5 to $E_{g.c}$ = –2.7 V the current of the peak in the anodic curves linearly depends on the square root of the potential sweep rate $I_{a.p} = f(V^{1/2})$ in the range 0.01–0.05 V s^{-1} for all of the interfaces studied (Fig. 4a). The same dependence is preserved when the data are corrected for the ohmic polarization of the contact [10]. The accumulation potential exerts only slight influence on the slope of the $\log I_{a.p} = f(\log V)$ dependence, varying between 0.5 and 0.6 for the experimental data and those corrected for the ohmic polarization. Probably, the interface regeneration process is of diffusion nature. A linear dependence of the anodic peak current on the amount of passed electricity, $I_{a.p} = f(Q_c)$ (Fig. 4b) is observed at Q_c ranging from 7.27 to 23.4 μC for the $LaF_3:Eu^{2+}|Ag$ interface (curves *1–3*) and from 8.36 to 17.6 μC for the $CeF_3:Sr^{2+}|Ag$ interface (curve *4*). The emf of the formed cells is within –(2.380 ± 0.005) V for the Sn, $SnF_2|LaF_3:Eu^{2+}|La|Ag$ cell, –(2.370 ± 0.005) for Sn, $SnF_2|LaF_3:Sr^{2+}|La|Ag$, and –(2.340 ± 0.005) for Sn, $SnF_2|CeF_3:Sr^{2+}|Ce|Ag$.

The reactions of metal fluoride formation at the $LaF_3:Eu^{2+}|M$ interface in the solid-phase cell (3) (M = Ag, Bi, or Sn) were studied in the anodic inversion voltammetry mode. Previously, it has been shown in studying an FSE with water reference system that the nature of the decomposition curves of anodically generated compounds depends on the generation potential $E_{g.a}$, and, after the formation of an intermediate phase of metal fluorides at the op-

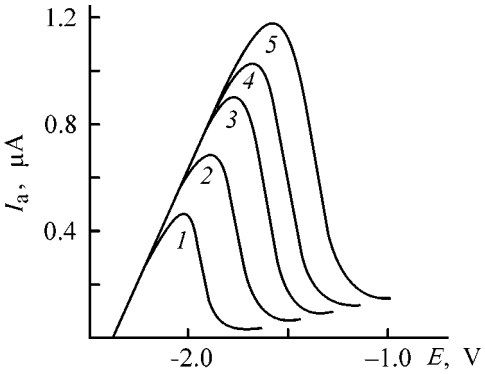

Fig. 3. $CeF_3:Sr^{2+}|Ag$ interface regeneration (*I–E*) curves taken after cathodic forming of the $CeF_3:Sr^{2+}|Ce|Ag$ cell at $E_{g.c}$ = –2.6 V (Q_c = 8.36 μC). Potential sweep rate *V* (V s^{-1}): (*1*) 0.01, (*2*) 0.02, (*3*) 0.03, (*4*) 0.04, and (*5*) 0.05; the same for Fig. 5.

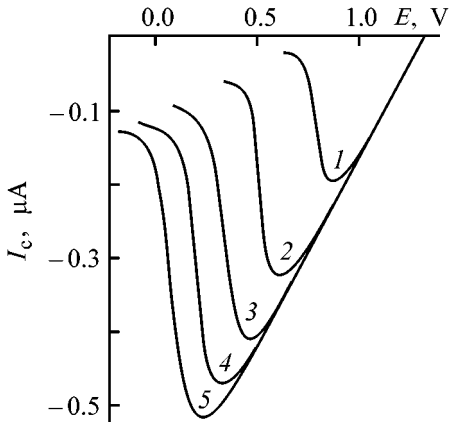

Fig. 5. $LaF_3:Eu^{2+}|Ag$ interface regeneration curves I_c–E after anodic formation of AgF at $E_{g.a}$ = 1.9 V.

timal potential $E_{g.a}$, the cathodic curves are characterized by a single peak [2, 7]. Guided by the prospects for use of this kind of curves in analytical practice, the authors of the present study paid primary attention to data analysis allowing the most adequate assessment of the chosen optimal potential $E_{g.a}$ of compound accumulation in studying the processes at the interface between M and FSE membrane with a solid-phase reference system.

For this purpose, the effect of $E_{g.a}$ on how the cathodic peak current $I_{c.p}$ and peak potential $E_{c.p}$ depend on the potential sweep rate V and amount of electricity Q_a consumed for generation of metal fluorides in potentiostatic charging of the $LaF_3:Eu^{2+}|M$ interface was studied. It is known that the conditions of electrolysis in aqueous and nonaqueous solutions affect the properties of a deposit at its equal amounts. Deviation from the optimal accumulation potential leads to a change in the run of dynamic I–E characteristics, e.g. affects the peak width [11]. Possibly, the mechanism by which the nucleation and growth of a deposit of metal fluorides occur at the interface between the FSE membrane and metal in air medium is manifested in a change in relative rates of separate stages of the multistage solid-phase process. As a criterion for optimizing the electrolysis conditions in order to decrease the number of stages limiting the rate of the solid-phase process is chosen the potential of the cathodic charging of the interface, at which the $I_{c.p}$ of the anodic curve is a linear function of V^n with n close to 0.5. In the voltammetry of aqueous solutions, such a behavior is characteristic of processes controlled either by the rate of mass transfer under linear diffusion conditions [12] or by the ohmic resistance of passive films [13, 14].

Preliminary choice of nearly optimal potentials $E_{g.a}$ was done with regard to the $E_{g.a} - E_{st}$ values obtained previously [8, 10]. A linear dependence of the peak current of cathodic curves on $V^{1/2}$ in the range 0.01–0.04 V s^{-1} was observed at the chosen $E_{g.a}$ for the contacts under consideration. Experiments demonstrated that changes in $E_{g.a}$ affect in different ways the characteristics of the cathodic processes, namely, the behavior of $E_{c.p}$ and slope of the $\log I_{c.p} = f(\log V)$ dependence and also exert influence on the emf of the formed cells.

As shown by investigations of anodic processes at the $LaF_3:Eu^{2+}|Ag$ interface, the cathodic curves recorded from the level of the stationary potential after accumulation of an intermediate compound exhibit a single peak. Figure 5 presents cathodic curves taken at potential sweep rates in the range 0.01–0.05 V s^{-1} after anodic polarization of the $LaF_3:Eu^{2+}|Ag$ interface at $E_{g.a}$ = 1.9 V (Q_a = 32.16 μC). The ratio $\Delta\log I_{c.p}/\Delta\log V$ for the $LaF_3|Ag$ interface is independent of the accumulation potential and approximately equal to 0.5 for experimental and ohmic-polarization–corrected data, which confirms the diffusion nature of the solid-phase process [10, 12]. With increasing potential sweep rate, the peak potential is shifted in the negative direction and linearly depends on $V^{1/2}$. Such a behavior is characteristic of processes controlled by the ohmic resistance of passive films [12, 14]. The peak potential corrected for the ohmic polarization of the solid electrolyte remains constant. With correction made for the ohmic polarization of the contact, the potential difference between the half-peak potential and the current peak potential ($E_{c.p/2} - E_{c.p}$) = 0.06 V, which corresponds to a reversible process with transfer of a single electron. The emf of the cells formed at accumulation potentials of 1.9, 2.0, and 2.1 V is in the range (1.345 ± 0.003) V.

It is important to note that a deviation of $E_{g.a}$ from the optimal value within ±0.1 V is tolerable for the given structure does not lead to any significant change in its characteristics. Attention should be paid to the fact that insufficient treatment of the interfacial surface exerts much more pronounced influence on the properties of cathodic curves, with the half-peak potential becoming more negative than the stationary potential ($E_{c.p/2} \neq E_{st}$), the dependence of the peak potential $E_{c.p}$ on $\log V$ turning linear, and processes at the interface becoming irreversible even upon generation of compounds at the optimal $E_{g.a}$.

Upon generation of an intermediate phase at the $LaF_3:Eu^{2+}|Sn$ interface at $E_{g.a}$ = 0.9 and $E_{g.a}$ = 0.8 V, the cathodic curves measured from the level of the stationary potentials, with V varied between 0.01 and 0.05 V s^{-1}, are also characterized by a single peak. However, the generation potential affects the way in which in fluoride is formed and the $LaF_3:Eu^{2+}|Sn$ regenerated, making $\Delta\log I_{c.p}/\Delta\log V$ increase from 0.60 (for $E_{g.a}$ = 0.9 V) to 0.637 (for $E_{g.a}$ = 0.8 V), which is accompanied by peak broadening. The peak potential $E_{c.p}$ shows a linear dependence on log *V*, which is a criterion of process irreversibility and disagrees with the data obtained for an FSE with aqueous reference system. Also, a change in the emf of the formed Sn, $SnF_2|LaF_3|SnF_2$, Sn cells is observed (0.03 V for $E_{g.a}$ = 0.8 V and 0.01 V for $E_{g.a}$ = 0.09 V).

The $LaF_3:Eu^{2+}|Bi$ interface regeneration curves obtained after potentiostatic charging at $E_{g.a1}$ = 1.1, $E_{g.a2}$ = 1.2, $E_{g.a3}$ = 1.28, and $E_{g.a4}$ = 1.3 V, all exhibiting a single peak, strongly differ from the dynamic voltammograms of the FSE|Ag interface. The initial portion of the cathodic polarization curve is independent of the potential sweep rate and has a shape characteristic of charge-transfer-controlled processes. The peak potentials $E_{c.p}$ show linear dependence on log *V*, similarly to the FSE|Sn interface. The slope of the linear dependence $\log I_{c.p} = f(\log V)$ grows from 0.72 to 0.83 as $E_{g.a}$ is changed from 1.2 to 1.3 V, with the peak in the cathodic curves broadening and the ratio of the area under the cathodic peak to amount of charge consumed in deposit accumulation increasing. Presumably, the reaction of bismuth fluoride formation at the contact of the FSE membrane with Bi and the cathodic regeneration of the interface are irreversible. The emf of formed cells is within (0.400 ± 0.010) V.

Figure 6a presents linear dependences of the peak current $I_{c.p}$ on $V^{1/2}$ for the interfaces $LaF_3:Eu^{2+}|Ag$ ($E_{c.p}$ = 1.9 V, Q_a = 5.12 μC), $LaF_3:Eu^{2+}|Bi$ ($E_{g.a}$ = 1.3 V, Q_a = 54 μC), and $LaF_3:Eu^{2+}|Sn$ ($E_{g.a}$ = 0.8 V, Q_a = 18.7 μC) for data obtained in experiment and those corrected for the ohmic polarization of the contact by means of approximate equations [12].

For solving analytical problems, it was of interest to study the dependence of $I_{c.p}$ on the amount of charge consumed for generation of metal fluorides. It was found that the dependence $I_{c.p} = f(Q_a)$ measured upon AgF accumulation at E_g = 2.0 V is linear within the range from 1.5 to 7 μC (Fig. 6b, curve *1*) and

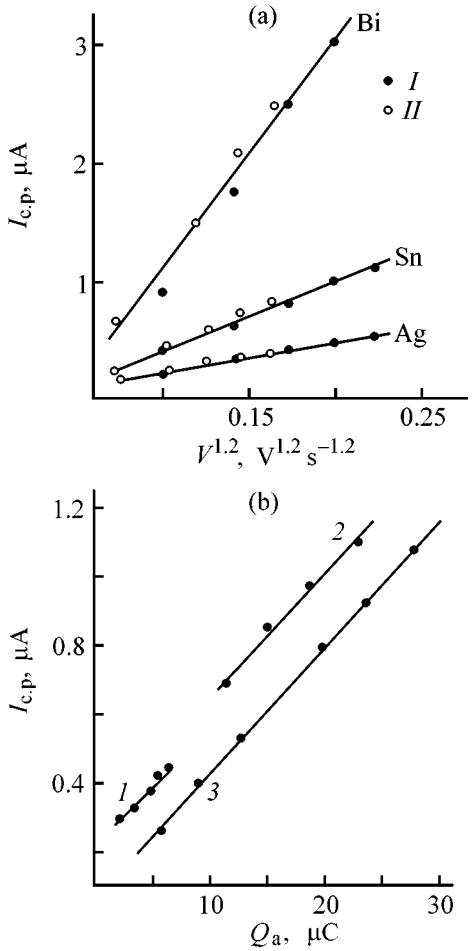

Fig. 6. Cathodic current peak $I_{c.p}$ after anodic charging of the FSE|M (+) interface at $E_{g.a}$ vs. (a) potential sweep rate *V* and (b) amount of passed electricity Q_c. (a) M: Ag: $E_{g.a}$ = 1.9 V, Q_a = 5.12 μC; Sn: $E_{g.a}$ = 0.8 V, Q_a = 18.7 μC; Bi: $E_{g.a}$ = 1.3 V, Q_a = 54 μC. (b) Potential sweep rate *V* (V s^{-1}): (*1*) 0.04 (Ag, $E_{g.a}$ = 2 V), (*2*) 0.03 V (Bi, $E_{g.a}$ = 1.28 V), and (*3*) 0.02 (Bi, $E_{g.a}$ = 1.1 V). For explanations see text.

25 to 95 μC at larger area of contact between silver and the FSE membrane. Interestingly, despite the irreversible nature of the process of $LaF_3:Eu^{2+}|Bi$ interface regeneration, the dependence of $I_{c.p}$ on Q_a measured after polarization of a contact between the membrane and bismuth is also linear in the Q_a range from 5.8 to 27.7 μC at E_g = 1.1 V (Fig. 6b, curve *3*) and 11.6 to 23 μC at E_g = 1.28 V (Fig. 6b, curve *2*).

CONCLUSIONS

(1) In studying the voltammetric behavior of an all-solid fluoride-selective electrode based on LaF_3 (Eu^{2+} 0.8 mol %), LaF_3 (Sr^{2+} 5 mol %), and CeF_3 (Sr^{2+} 5 mol %) single crystals, it is advisable to

verify the *I–E* characteristic of the Sn, SnF_2|FSE membrane|aq F^-, Cl^-|AgCl, Ag cell. Provided that it is linear in the working range of potentials and potential sweep rates, the voltammetric response of an all-solid fluoride-selective electrode in contact with metal is similar to that of the commercial fluoride-selective electrodes.

(2) The threshold of electrochemical stability of a solid fluorine-conducting electrolyte was determined, characterizing the cathodic part of the working range for voltammetry of an all-solid fluoride-selective electrode in contact with metals.

(3) The influence exerted by the potential of anodic accumulation of metal fluorides at the interface between an all-solid fluoride-selective electrode and metal (Ag, Bi, Sn) on the dependence of the peak current of interface regeneration processes on the potential sweep rate was considered. The revealed pattern is also characteristic of redox reactions involving cations from the rigid sublattice in the membrane of a fluoride-selective electrode; these reactions occur on the surface and in the bulk of the solid electrolyte without involvement of the contact metal in the electrode reaction.

(4) The obtained dependences of the stationary potential and peak potential on the nature of metal, and also the linear dependence of the peak current on the amount of charge consumed for product formation, are of interest for analytical practice, since these results can be used for voltammetric detection of the metals considered in this study with all-solid cells in the air medium.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of Anodic Polarization of Fibrous Carbon Electrode in Alkaline and Acid Solutions on the Distribution of Electrical Conductivity across the Electrode Thickness

V. K. Varentsov and V. I. Varentsova

Institute of Solid-State Chemistry and Mineral Processing, Siberian Division, Russian Academy of Sciences, Novosibirsk, Russia

Received May 5, 2000; in final form, June 2000

Abstract—The effect exerted by anodic treatment of electrodes with varied thickness, made of NT-1 low-conductivity carbonized material, in 0.07 M KOH and 0.25 M H_2SO_4 solutions on the distribution of the electrical conductivity across the electrode thickness at various anodic polarization conditions was studied.

It has been shown previously that cathodic treatment of electrodes of varied thickness, made of a high-resistivity NT-1 carbonized material, in solutions of sulfuric acid and potassium hydroxide yields electrodes with electrical conductivity varying across the electrode thickness [1]. The conductivity profile depends on polarization conditions and electrode thickness. It has been established that anodic treatment of electrodes made of fibrous carbon materials (FCM) in acid and alkaline solutions can be used to change the electrical conductivity of FCMs [2]. The most pronounced changes are observed for carbonized FCMs—depending on anodic polarization mode their conductivity may vary within a factor of several tens. This suggests that anodic treatment of FCM can serve as efficient method for obtaining non-isoconducting electrodes.

The present communication reports on a study of the influence exerted by anodic polarization of NT-1 FCM electrodes in potassium hydroxide and sulfuric acid solutions on the distribution of electrical conductivity across the electrode thickness.

EXPERIMENTAL

The experimental procedure was identical to that described previously [1]. The anodic polarization was performed using a B5-49 dc power source with solutions containing (M): (1) 0.07 KOH, (2) 0.1 KOH and 1.5 $(NH_4)_2SO_4$, and (3) 0.25 H_2SO_4 circulated through the electrode at a rate of 0.18 ml cm^{-2} s^{-1}. A cell of special design, described in [3], was equipped with a special insert allowing measurement of the electrode thickness. The study was carried out with electrodes consisting of several layers of NT-1 FCM with electrical conductivity of 0.04 Ω^{-1} cm^{-1}. After anodic treatment the electrode was thoroughly washed with distilled water and dried to constant weight, and then the electrical conductivity of each of the FCM layers was measured [1].

The theory of flow-through three-dimensional electrodes shows that the polarization profile across the electrode thickness, determining the electrode efficiency, largely depends on the relative electrical conductivities of the electrode material and the solution. In this connection, it is of importance to consider the effect of this factor on the possible electrical conductivity profile across the electrode thickness. These studies were performed with a 0.07 M KOH solution with electrical conductivity lower than that of NT-1. To raise the electrical conductivity of the KOH solution, 1.5 M of NH_4NO_3 salt was added, with the electrical conductivity of the resulting solution exceeding that of NT-1.

Figures 1 and 2 present the distributions of the electrical conductivity of the electrode across its thickness L for varied conditions of its anodic polarization in the above alkaline solutions. For convenience of comparison of the obtained results, the ratio of electrical conductivities of the fibrous carbon electrode (FCE) before, χ_{in}, and after, χ_t, its anodic treatment is plotted along the ordinate axis. It can be seen from Figs. 1

and 2 that different χ distributions across the electrode thickness can be obtained with alkaline solutions having different electrical conductivities. Figure 1 demonstrates the effect exerted by anodic polarization of FCE in an alkaline solution whose electrical conductivity exceeds χ_{NT-1} fivefold. The dependence χ_{in}/χ_t–L shows an extremum, the largest changes in electrical conductivity are observed at the backside of the electrode. The electrical conductivity profile depends on the anodic polarization conditions. Raising the anodic treatment current density makes the electrical conductivity profile more pronounced, with the FCM resistivity increasing not only in the back (B), but also in the front part (F) of the electrode. The electrical conductivity at the electrode edges and in its middle part differ 1.6–3.5-fold (Fig. 1a). The electrode thickness is important—the extremum in the χ_{in}/χ_t–L curve is more pronounced for a thinner electrode and tends to disappear with increasing electrode thickness (Fig. 1b).

Another situation is observed in performing anodic treatment of FCE in an alkaline solution with electrical conductivity 3 times lower than that of FCE (Fig. 2). The most pronounced change in the electrical conductivity is observed at the front side of the electrode. Varying the conditions of anodic polarization and the electrode thickness affects the slope of the ascending portion of the χ_{in}/χ_t–L curve. It should be noted that the electrical conductivities at the front side of the electrode and in its middle part differ by more than a factor of 40.

The observed changes in the electrical conductivity profile in the electrode, depending on the relative initial electrical conductivities of the electrode material and the solution, electrode thickness, and overall anodic treatment current density are in good agreement with the theoretically predicted and experimentally confirmed distribution of polarization across the electrode thickness, depending on the above-mentioned factors [4–8]. For example, it is known that, in the case when the electrical conductivity of FCM, χ_{FCM}, exceeds that of the solution, χ_s, the process is localized at the front side of the electrode. In the opposite case, at $\chi_{FCM} < \chi_s$, the process is localized at the back side of the electrode [4, 8]. Raising the current density favors stronger polarization at the electrode edges, in good agreement with the data presented in Fig. 2.

Anodic polarization on NT-1 in sulfuric acid solutions does not lead to such pronounced changes in the electrical conductivity across the electrode, compared with that in alkali solutions. In contrast to the results presented above, the variation of χ_{FCM} across the electrode (Fig. 3) and the change in χ_t relative to χ_{in} are much weaker as compared with the case of FCM treatment in alkaline solutions. The electrical conductivities in the middle part of the electrode and at its edges differ by no more than a factor of 1.1–1.5. The most pronounced changes in χ_{FCM} are observed at the front side of the electrode, and not at its back side as it would be expected on the basis of the fact that $\chi_s > \chi_{FCM}$ ($\chi_s = 0.12\ \Omega^{-1}\ cm^{-1}$). The conceivable reason for such a change in the electrical conductivity of NT-1 is that FCM intercalation compounds are formed with sulfuric acid, with the electrical conductivity of graphite even possibly growing somewhat [9–11]. It is known that the forming compounds are unstable and decompose already at room temperature both in solution and in air. The experimental procedure included sample drying at 80–100°C, which favored decomposition of these intercalation compounds. As a result, the obtained χ_{in}/χ_t–L dependences deviate from the expected dependences and theoretical polarization profiles, even though the occurrence of a minimum in the middle part of the electrode is in agreement with the polarization distribution across its thickness. No data on how χ_{FCM} changes in the course of decomposition of intercalation compounds could be found in the literature. Apparently, more adequate interpretation of the obtained dependences requires special additional investigations, which are beyond the scope of the present study.

It should also be noted that comparison of the results reported in this communication and those obtained in [1] indicates that changes in χ_{FCM}, measured on a single-layer electrode 2–3 mm thick and multilayer electrode are about the same under comparable conditions. For example, the $\chi_{NT\text{-}1}$ decreases upon anodic polarization in a KOH solution 50–80-fold for a single-layer electrode 3 mm thick [1]. It can be seen from Fig. 1 that the electrical conductivity of the front part of the electrode decreases 45–50-fold as compared with the starting material. These results also confirm the adequacy of representing a single-layer electrode as a multilayer electrode composed of FCMs of the same type. This approach has been successfully used in studying FCM operation by means of numerical and experimental methods [5–8].

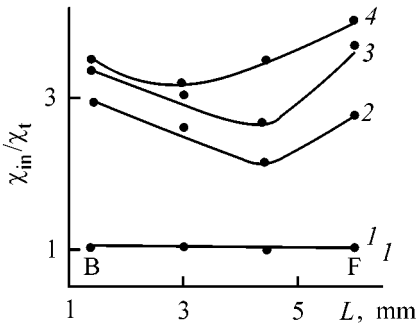

Fig. 3. Distribution of electrical conductivity χ_{in}/χ_t across the electrode thickness L after anodic polarization in a 0.25 M H_2SO_4 solution. Electrode thickness 6 mm. Current density (A m^{-2}): (*1*) 0, (*2*) 1000, (*3*) 250, and (*4*) 2500. Treatment duration (min): (*1*) 0, (*2*, *3*) 15, and (*4*) 5.

Thus, the results obtained in studying the influence exerted by anodic polarization on the electrical conductivity of FCM and its distribution across the electrode allow tentative assessment of the promise of electrolysis as a method for creating fibrous carbon electrodes with electrical conductivity varying across the electrode thickness. The variation of the electrical conductivity across an electrode subjected to anodic treatment in an alkaline solution is in qualitative agreement with the theoretically predicted polarization profile. This allows fabrication of nonisoconducting electrodes with prescribed electrical conductivity profile across the electrode thickness.

CONCLUSIONS

(1) Anodic treatment of electrodes made of high-resistivity carbonized fibrous carbon material NT-1 in alkaline and acid solutions changes the electrical conductivity of the electrode across its thickness. Depending on the solution composition, relative initial conductivities of the electrode material and the solution, and anodic polarization current density, different

electrical conductivity profiles across the electrode can be obtained.

(2) In the case of treatment in alkaline solutions, the experimentally obtained electrical conductivity profiles across the electrode thickness are in qualitative agreement with the theoretical polarization profile.

(3) The lack of correspondence between the polarization profile and electrical conductivity profiles across a fibrous carbon electrode treated in sulfuric acid solutions is probably due to formation of intercalation compounds of sulfuric acid and graphite.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Participation of Zincate Ions in Processes Occurring on Nickel Oxide Electrode of Nickel–Zinc Battery

Z. P. Arkhangel'skaya, R. P. Ivanova, T. B. Kas'yan, and L. B. Raikhel'son

Rigel' Joint-stock Company, St. Petersburg, Russia

Received May 12, 2000; in final form, October 2000

Abstract—A mechanism of zinc transfer from the negative to the positive electrode of a nickel–zinc battery was studied.

A study of the distribution of components in a nickel–zinc (NZ) battery under cycling has shown that approximately 20% of the active material in the negative electrode is transferred to the nickel oxide electrode (NOE) in the initial cycles [1]. According to X-ray data, the active material is present in NOE pores as zinc oxide, forming no compounds with nickel oxides. The dynamics of its accumulation corresponds to the loss of weight by the negative electrode.

The mechanism of transfer of zinc compounds has not been established. This issue was considered in [2] with the purpose to reveal the reasons for NOE "poisoning" in NZ batteries. The authors assumed that the observed reduction in the electrode capacity is due to zinc oxide precipitation in its pores, caused by a decrease in the KOH concentration in the electrolyte, associated with oxygen evolution in charging.

The precipitation of zinc oxide in NOEs with a cermet base hardly affects the efficiency of such electrodes at moderate discharging rates, but impairs the specific characteristics of the NZ battery, because part of the active material of the negative electrode is not used properly. Therefore, elucidation of the reasons for the interelectrode zinc transfer in NOEs is of considerable interest.

EXPERIMENTAL

We studied processes in ventilated NZ-25, NZ-80, and NZ-180 batteries with rated capacity of 25, 80, and 180 A h, respectively. Paired cermet nickel-oxide electrodes of thickness 1 mm and zinc electrodes with active material consisting of zinc oxide, metallic zinc, and inhibitors and surfactants as additives were used in the batteries. The ratio of the initial capacities of the negative and positive electrodes in all the batteries was 3 : 1. Hydrated cellulose and nonwoven polypropylene were used as separators.

The electrolyte in the NZ-25 and NZ-180 batteries contained 480 and 15 g l^{-1} of KOH and LiOH, respectively, and that in the NZ-80 batteries, 380 and 25 g l^{-1}, respectively. The volume of the electrolyte was 4 cm^3 per 1 A h of rated capacity, which corresponds to the total volume of pores in the electrodes and separators.

The batteries were charged during 8–10 h with stepwise decreasing currents (A) to a voltage of 1.98 V in each stage: NZ-25: I_1 = 5, I_2 = 3, I_3 = 1.5; NZ-80: I_1 = 10, I_2 = 5; and NZ-180 I_1 = 20, I_2 = 10. The imparted capacity was 25, 80, and 150 A h, respectively. The current expenditure for oxygen evolution did not exceed 1–2% per cycle. This hardly affected the KOH concentration, and only resulted in its gradual decrease because of the accumulation of carboxylic ions in the electrolyte. In this connection, we reduced after 100–200 cycles the capacity supplied to the batteries in charging. The discharge currents corresponded to a 5-h mode (5, 16, and 40 A, respectively), i.e., the conditions of electrolyte diffusion and convection were the same for all the batteries.

In the course of the tests, some batteries were periodically disassembled in charged or discharged state, and the content of ZnO and Zn_{met} in zinc electrodes and also that of KOH, K_2CO_3, LiOH, and Zn^{2+} in free electrolyte, zinc electrodes, and NOEs were determined.

The transfer of zinc compounds from the negative electrode to the NOE in battery cycling is character-

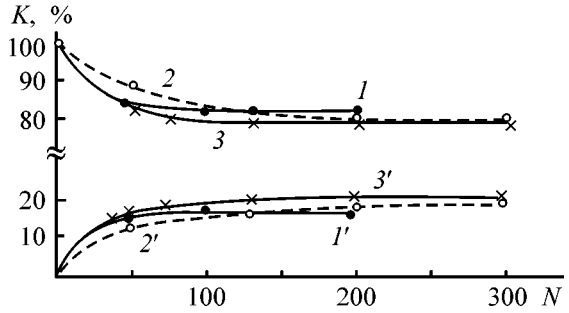

Fig. 1. Variation of the zinc content in (*1*–*3*) negative and (*1*′–*3*′) positive electrodes in cycling of (*1*, *1*′) NZ-25, (*2*, *2*′) NZ-80, and (*3*, *3*′) NZ-180 batteries. (*K*) Ratio of the zinc weight to its initial amount and (*N*) number of cycles.

ized by correspondence between the loss of Zn weight from the negative electrode and its accumulation in the positive electrode (Fig. 1). Approximately 10% of zinc is transferred during the first 10 cycles from the negative electrode to the NOE, which corresponds to 1.2 g per cycle for the NZ-25 battery. Then the transfer slows down and stops by 50–70th cycle. The total amount of zinc accumulated in the NOE was 20–22%.

The concentration of zincate ions in the electrolyte of charged NZ-25 and NZ-80 batteries was 10–15 g l^{-1}, whereas in discharged batteries it decreased with increasing number of cycles, from 50 to 30 g l^{-1}, in contrast to silver-zinc batteries (having no nickel oxide electrode) where it was 80–100 g l^{-1} under the same conditions [3] and changed only slightly in cycling.

These results confirm the pattern established in [1], and demonstrate that fundamental changes in macrokinetic processes occurring at zinc electrodes are associated with the operation of the NOE in the alkaline battery.

The limiting concentration of zincate ions formed in anodic zinc dissolution in KOH solutions depends on the KOH concentration:

$$Zn + 4OH^- - 2e = [Zn(OH)_4]^{2-}. \quad (1)$$

When hydroxide ions are deficient in the zone of the electrochemical process, the hydroxo complex is decomposed to liberate these ions, which serves to prolong the discharge of the zinc electrode:

$$[Zn(OH)_4]^{2-} \rightarrow ZnO + H_2O + 2OH^-. \quad (2)$$

In the process, the consumption of hydroxide ions decreases from 2 to 1 mol per faraday (26.8 A h) of electricity. Reverse reactions occur in the cathodic process. The redox reaction on NOE proceeds as follows

$$Ni(OH)_2 + OH^- - e \rightarrow NiOOH + H_2O. \quad (3)$$

Oxides with higher oxygen content are scarcely formed under the considered conditions (charging to no more than 80% of the maximum NOE capacity), which allows us to determine the consumption of hydroxide ions with sufficient accuracy. The following reaction may occur in parallel with reaction (3)

$$2OH^- - 2e \rightarrow H_2O + 1/2O_2. \quad (4)$$

To reduce the fraction of current consumed for reaction (4), we limited the final charging voltage. In the case when the main processes occur without side reactions, the consumption and formation of OH^- ions at the electrodes are counterbalanced during both charging and discharging of NZ batteries. Since this compensation is provided by reactions at the opposite electrodes, it depends on the conditions of OH^- ion delivery to the reaction zones.

The correspondence between the loss of zinc from the negative electrode and the accumulation of zinc in the NOE (Fig. 1) means that these processes are closely related in the NZ battery. To elucidate the transfer mechanism, it is necessary to determine this relationship.

The OH^- ions participating in the reaction migrate and diffuse under the influence of KOH concentration gradient directed from the negative to the positive electrode in charging a battery, and in the opposite direction during its discharge. Correspondingly, the concentration gradient of zincate ions has the same direction. In both cases, the appearance of a considerable concentration gradient is due to the occurrence of migration processes under the conditions of slowed-down diffusion of reagents, which is unable to compensate for concentration changes occurring in porous electrodes when a complicated system of separators is used [4].

The second feature of the observed transfer consists in that the kinetics of zinc oxide accumulation in the NOE (percentage of zinc weight in the negative electrode) is similar in all the batteries under study, in spite of their different sizes and capacities (Fig. 1). Thus, under identical polarization conditions, the change in the concentration of zinc oxide in NOE pores depends not on its surface area, but on the capacity per unit of its volume [5], i.e., on the NOE thickness, equal for all the batteries under study.

Change in component weights and electrolyte concentration in NOE pores in charging an NZ-25 battery {initial concentration: KOH 8.03 M, $[Zn(OH)_4]^{2-}$ 0.93 M; charging capacity 25 A h (0.93 faraday); volume of pores in NOE 33 cm^3}

Process stage	Contents of components, mol				Concentration, g l^{-1}

* Replenishment with hydroxide ions liberated upon hydroxo complex decomposition.

The analytically determined electrolyte compositions in charged and discharged NZ batteries (Fig. 2) are diffusion-averaged. However, these data indicate that the concentrations of KOH and zincate ions in the electrolyte of the charged and discharged batteries are not completely equalized, which results from changes occurring in NOE pores. In this case, the content of zincate ions in the electrolyte of a charged battery is low (approximately 15 g l^{-1}), and that in a discharged battery, 25–30 g l^{-1}, i.e., it does not exceed 50 g l^{-1} even in the initial cycles.

On the basis of the obtained data and taking into account the data of [5] on changes in the electrolyte composition under charging conditions, we calculated the amount of KOH in NOE pores by the end of charging of an NZ-25 battery in the third cycle (see the table). It was assumed that only NiOOH is formed in the NOE and no oxygen is evolved. The component diffusion was disregarded, being suppressed in the given case because of liberation of OH^- ions directly within NOE pores.

The decrease in the KOH content was determined using Eq. (3) in view of its being equal to K mol per faraday of passing current. Here K is the potassium transfer number equal to 0.27 [6], as calculated from the limiting equivalent electric conductivity of K^+ and OH^- ions. The increase in the amount of water by reaction (3), namely, 1 mol per faraday, was disregarded, since the excess water is displaced from the pore space [5].

In the calculations, account was taken of the electrolyte replenishment with hydroxide ions liberated upon decomposition of the hydroxo complex in the NOE pores (see the table). Their amount was determined on the assumption that $[Zn(OH)_4]^{2-}$ ions do not participate in the reactions occurring in NOE in battery charging. Therefore, changes in the content of hydroxide ions are only related to a decrease in the $[Zn(OH)_4]^{2-}$ solubility with diminishing KOH concentration.

Comparison of the data in the table and Fig. 2 shows that the KOH concentration in NOE pores decreases by approximately a factor of 2.5 in the course of charging, compared with the averaged electrolyte concentration. These data reflect the slowing down of the diffusion processes in the battery's electrolyte.

The variation of the concentrations of KOH and zincate ions in NOE pores in the third charging–discharge cycle, determined from the experimental data

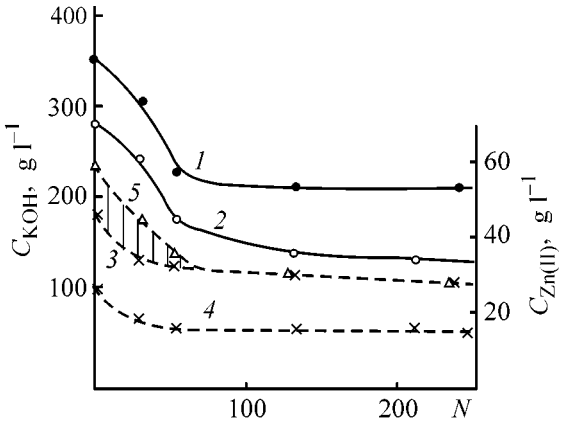

Fig. 2. Variation of the concentration C of (*1, 2*) KOH and (*3–5*) zincate ions in terms of Zn(II) in the electrolyte of an NZ-80 battery in cycling of (*1, 3, 5*) discharged battery [(*5*) at the negative electrode] and (*2, 4*) charged battery. (*N*) Number of cycles.

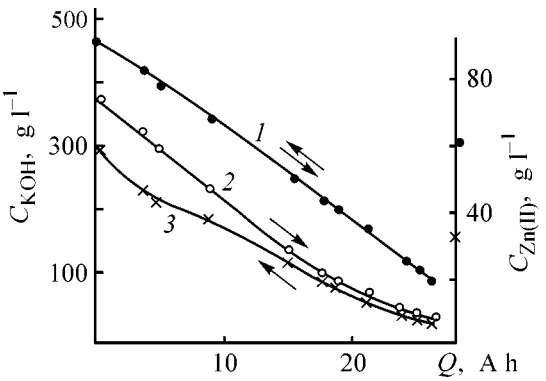

Fig. 3. Changes in concentration *C* of (*1*) KOH and (*2, 3*) zincate ions in terms of Zn(II) in NOE pores in the course of (*1, 2*) charging and (*1, 3*) discharge of an NZ-25 battery. (*Q*) Capacity.

obtained in this study and those reported in [3, 7], in good agreement with our data, is illustrated in Fig. 3. The curves describing the variation of the KOH concentration in charging and discharge coincide in accordance with the reversibility of reaction (1), and the plots for zincate ions disagree owing to the low solubility of zincates formed in chemical dissolution of ZnO.

Thus, the per-cycle loss of zinc from the negative electrode results from the transition of such an amount of zincate ions from it into the electrolyte, which is necessary to maintain the level characteristic of the processes occurring at this electrode. This amount corresponds to that of zinc remaining in the NOE in the form of ZnO.

Zincate solutions being unstable, the scheme in Fig. 3 is unsuitable for precise quantitative determinations. However, it gives basic notion of the processes resulting in the transfer and accumulation of zinc oxide in NOE pores. It also shows that, with decreasing KOH concentration in the electrolyte, the transfer of zinc falls, since in this case the limiting concentrations of zincate ions formed in electrochemical and chemical dissolution approach each other.

Comparison of Figs. 2 and 3 allows assessment of the influence exerted by diffusion processes on the variation of the content of the electrolyte components. It is evident that the averaged concentrations of KOH and zincate ions in a charged battery are greater by approximately a factor of 2.5 than the calculated minimum concentrations in pores shown in Fig. 3. Since the volume of the electrolyte in the NOE pores corresponds to 1/3 of its total volume in the battery, the calculated change in the concentration in pores is close to the actual value, i.e., the effect of the diffusion of OH^- ions into the pore space of NOE during charging and discharge of the battery is insignificant, and their formation directly in the NOE pores upon decomposition of hydroxo complexes contained in the pores is of greater importance.

The run of curves *3* and *5* in Fig. 2 shows that at number of cycles less than 70 the region between them reflects the kinetics of zinc oxide accumulation in the NOE, and the approach of these curves to each other is related to a decrease in the KOH content in the electrolyte.

CONCLUSIONS

The transfer of zinc from the negative electrode to the nickel oxide electrode in a nickel–zinc battery is associated with the formation of electrolyte flows oppositely directed in charging and discharge. A greater concentration of zincate ions is established at the negative electrode, compared with the concentration reached upon chemical dissolution of zinc oxide precipitated in the nickel oxide electrode. The deficiency in zincate ions returning to the zone of the negative electrode in discharge of the nickel oxide electrode is compensated for by the anodic process at the zinc electrode, maintaining equilibrium with respect to hydroxide and zincate ions.

The transfer of zinc is slowed down as the KOH concentration in the electrolyte decreases, because the solubilities of the zincate ion in electrochemical and chemical processes approach each other.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Kinetics of Sn(II) Contact Reduction in Alkaline Solutions with Compact and Dispersed Aluminum

A. F. Dresvyannikov and I. O. Grigor'eva

Kazan State Technological University, Kazan, Tatarstan, Russia

Received September 19, 2000

Abstract—The kinetics of contact reduction of tin on aluminum from alkaline stannite solutions was studied by atomic absorption analysis, iodometry, gravimetry, X-ray phase analysis, and method of polarization diagrams.

Tin finds wide application in various industries. Since the cost of tin is rather high, a necessity arises to recover it from spent industrial solutions. The known methods of tin recovery in the form of metal from aqueous solutions are rather few in number and mainly performed in acid media. These are electrolytic reduction, characterized by low current efficiency owing to the low concentration of tin ions in solution, and also cementation (contact reduction). For example, it was proposed in [1] to recover tin by the contact reduction on aluminum or aluminum alloys from wastewater by its acidification with hydrochloric, sulfuric, or nitric acid to pH ≤ 4. Tin of more than 99% purity is precipitated from solutions within 1–4 h as a powder or granules.

It is necessary to note that the contact reduction process is widely applied in electroplating of coatings onto aluminum. In this case [2], stannate alkaline solutions are used in which aluminum articles are covered with a film of contact tin serving as an independent coating improving the antifriction properties of the surface [3]. During the first 10–20 s after the onset of the reaction, there are about 2000 atoms of dissolved aluminum [4, 5] per single deposited atom of tin; further, this ratio changes sharply, reaching a value of 6 : 1. Simultaneously, the rate of aluminum dissolution and hydrogen evolution decrease because of the blocking of the main part of the surface area of the base metal by the contact deposit.

The contact reduction of tin(IV) in alkaline solutions has been studied in sufficient detail [3–5], whereas there are scarcely any data on the contact reduction of tin(II).

Previously, it has been proposed to use dispersed aluminum for recovery of tin from solutions of its compounds [6]. Therefore, the aim of this work was to study the contact reduction of tin (II) ions in alkaline solutions by compact and dispersed aluminum.

Polydisperse aluminum of PA-1, PA-3, and ASD-0 grades (as-delivered) with average particle size of 343, 169.5, and 77.8 μm and variation factor of, respectively, 0.31, 0.48, and 0.29 was used. The content of the main component was determined from the volume of hydrogen evolved upon dissolution of aluminum in alkali. Chemically pure $SnSO_4$ and NaOH were used. The compositions of the reaction mixture are given in Table 1.

The procedure of Sn(II) reduction by suspended aluminum was described in [7, 8].

The content of Sn(II) ions was determined by iodometric titration of reaction mixture aliquots taken at certain time intervals. In addition, the content of tin ions in the reaction mixture was monitored at regular intervals by atomic absorption spectrometry (AAS-1N spectrometer, Carl Zeiss). The evolved hydrogen was determined volumetrically.

The content of the main component and additives in the deposit was determined by X-ray fluorescent (VRA-20L spectrometer, Carl Zeiss) and X-ray phase analyses (DRON-3M installation) with the use of long-wavelength Fe_{K_α} radiation with a β-filter.

Electrochemical studies were carried out with A999 aluminum samples of 99.8% purity [TU (Technical Specification) 6-09-2705–78]. Cathodic polarization curves (2 mV s^{-1}) were measured on tin in solutions under study with a P-5848 potentiostat (Table 2), and the anodic curves, on aluminum in similar electrolytes containing no tin ions. The potentials are given relative to a silver chloride reference electrode. Aluminum samples, dried in a drying box and cooled to constant weight, were weighed before and after obtaining a deposit, and also after its dissolution in dilute HNO_3 (1 : 1).

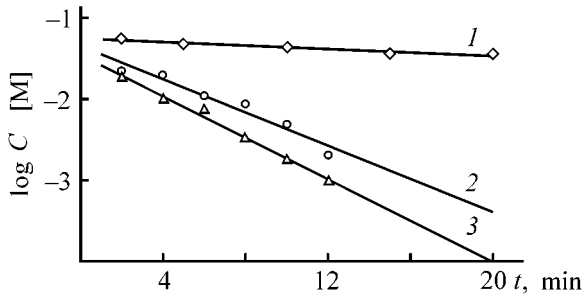

Fig. 1. Kinetics of Sn(0) deposition on aluminum of varied dispersity. C_{Sn} = 0.069 M. (*C*) Current Sn(II) concentration and (*t*) time. Aluminum: (*1*) PA-1, (*2*) PA-3, and (*3*) ASD-0.

The difference between standard potentials of aluminum and tin in alkaline stannite solutions is rather significant (approximately 1.4 V [9]), and, therefore, intensive contact exchange of the Al–Sn(II) pair is thermodynamically possible.

When aluminum is brought in contact with an alkaline stannite solution, first the natural oxide film on its surface is dissolved, and then there occurs contact reduction of tin, followed by dissolution of aluminum with hydrogen evolution:

$$Al_2O_3 + 2OH^- + 3H_2O = 2[Al(OH)_4]^-,$$

$$3[Sn(OH)_4]^{2-} + 2Al = 3Sn + 2[Al(OH)_4]^- + 4OH^-,$$

$$2Al + 2NaOH + 6H_2O = 2Na\,[Al\,(OH)_4] + 3H_2.$$

The experiments demonstrate that about 90% of metallic tin is precipitated with PA-3 or ASD-0 dispersed aluminum within the first 5–8 min (Fig. 1). The use of sufficiently dispersed aluminum powders (d_{av} < 200 μm) results in the loss of suspension's aggregate stability in the course of tin deposition and in the association of its particles into large formations (granules) from several fractions of millimeter to several millimeters in size, with shape from flat, "tablet-like" to spherical. These granules have high mechanical strength, which points to considerable interaction forces between the particles.

The kinetics of tin(II) reduction by dispersed aluminum is described by a first-order equation (Fig. 1), in agreement with the general concept of the process of contact exchange: the deposition occurs under diffusion control of metal ions being reduced, following the law of a monomolecular reaction on the outer surface of a deposit with approximately constant surface area [10, 11]. In view of the aforesaid, we calculated the apparent rate constants K_{app} of tin(II) reduction as follows [8]:

$$K_{app} = \frac{2.303}{t}\frac{V}{S}\log\frac{C_0}{C}.$$

Here *S* is the metal surface area (cm^2), *V* the volume of the reaction mixture (cm^3), C_0 the initial tin(II) concentration (M), *C* the current tin(II) concentration (M), and *t* the process duration (s).

In doing so, it was accepted that the surface area, on which tin is reduced, is invariable for each particular type of aluminum powder.

The experiments show that K_{app} decreases with increasing amount of aluminum and concentration of Sn(II) ions and increases with growing concentration of alkali and degree of aluminum dispersion:

Composition no.	K_{app}, cm s^{-1}
1	0.0063
2	0.0192
3	0.0283
4	0.0184
5	0.020
6	0.044
7	0.987
8	2.256
9	0.0157

The experimental data are in complete agreement with the concept of the related chemical activity of dispersed aluminum and the thickness of the oxide layer on its surface, which is, in turn, determined by particle size [12].

Since the process under consideration is of electrochemical nature, we calculated by Faraday's law from titrimetric data the apparent current density for the contact exchange:

$$j = m/qSt.$$

Here m is the weight of tin reduced by instant of time t, q is the electrochemical equivalent of tin, and S is the surface area of aluminum particles.

The apparent current density corresponding to this process was calculated from the volume of evolved hydrogen. These experiments show that not only the current density of hydrogen evolution (Fig. 2a), but also its ratio to the current density of the contact exchange (Fig. 2b) changes with time. Both curves exhibit a maximum, which is characteristic of topochemical transformations [11]. It is believed that the occurrence of a maximum is related to the increase in the surface area of precipitated metal (tin) and in the current density of partial reaction of tin reduction. The fast growth of the tin surface area in the initial stage results in that the rate of contact exchange increases with time. However, owing to a decrease in the concentration of tin(II) ions, the contact exchange current also decreases. The surface area becomes constant, since the rate of contact exchange decreases.

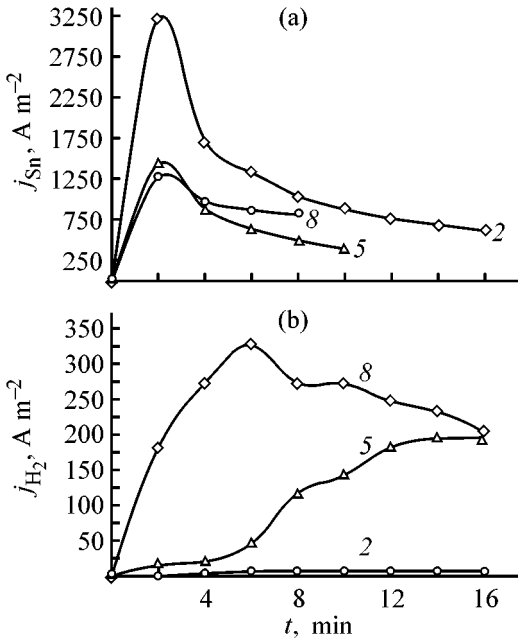

Fig. 2. Kinetics of (a) tin deposition and (b) hydrogen evolution on PA-3 aluminum particles. (j) Current density and (t) time. Numbers at the curves correspond to the numbers of compositions in Table 1.

In concentrated tin(II) solutions ($C_{Sn} \geq 10^{-2}$ M), the rates of metal deposition and hydrogen evolution differ by more than two orders of magnitude, and in dilute solutions ($C_{Sn} \leq 10^{-3}$ M), by a factor of 2–3.

The behavior of compact aluminum under similar conditions is different: at $C_{Sn} \geq 10^{-1}$ M the rates of tin reduction and hydrogen evolution are comparable, whereas in dilute ($C_{Sn} \approx 10^{-3}$ M) solutions the rate of metal reduction is almost two orders of magnitude less than the rate of hydrogen evolution (Table 3). This fact confirms the assumption that the physicochemical properties of compact and dispersed aluminum are essentially different. According to the data reported in [13, 14], compact and dispersed kinds of aluminum have different structures of surface oxide layers, and also clear distinctions in crystal lattice characteristics (unit cell parameters, sizes of mosaic units, microstresses, etc.).

Since the reaction of hydrogen liberation makes lower the current efficiency of the cathodic reduction of tin in dilute solutions (10^{-3}–10^{-2} M) at sufficiently high current densities of aluminum dissolution, the compromise electrode potential is frequently close to the corrosion potential of aluminum in the supporting solution. This fact suggests that the reaction of hydrogen reduction, occurring simultaneously with the reduction of tin complexes on the surface of a freshly

precipitated metal, substantially affects the contact exchange (Fig. 3).

The compromise potential of such a composite electrode first shifts in the positive direction, which is associated with the blocking of the aluminum surface by reduced tin (Fig. 4). The range of potentials at which contact exchange occurs corresponds to the cathodic reduction of tin in diffusion mode (Fig. 3) and, therefore, this reaction is rate-determining.

With increasing alkali concentration, the potential of the aluminium electrode shifts to a more positive region, which is attributable to the formation of a more compact layer of the deposit. Comparison of the currents of cathodic reduction of tin and anodic dissolution of aluminum shows that the contact deposition of tin from concentrated solutions involves a minor fraction of side reduction of hydrogen. The process of contact exchange in these conditions can be approximately described by polarization (corrosion) diagrams. For a specified concentration of tin ions the limiting current of 30–40 A m^{-2} in run no. 1 (Table 2) is reached at potentials of –1.2…–1.6 V (Fig. 3).

At a sufficiently high concentration of tin(II) ions (≥10 M), tin is precipitated as a dense spongy deposit poorly adherent to the compact base metal and periodically detached from the surface. Such a deposit does not preclude electrolyte access to the aluminum surface, and, therefore, the contact exchange can theoretically occur to the point of complete dissolution of aluminum or complete precipitation of tin. The reduction of tin ions at the limiting diffusion current under a considerable cathodic polarization may be the reason for tin precipitation as a spongy deposit [10, 11]. The gravimetric data (Table 3) show that the rate of hydrogen evolution in dilute solutions essentially grows, reaching a value that exceeds severalfold the rate of tin reduction j_c(Sn):

$$j_a(\mathrm{Al}) = j_c(\mathrm{Sn}) + j_c(\mathrm{H}),$$

$$j_c(\mathrm{H}) = j_a(\mathrm{Al}) - j_c(\mathrm{Sn}).$$

The intensity of aluminum dissolution grows, in accordance with its anodic behavior, with increasing NaOH concentration (Table 3). The evolution of hydrogen in dilute solutions leads to a dramatic decrease

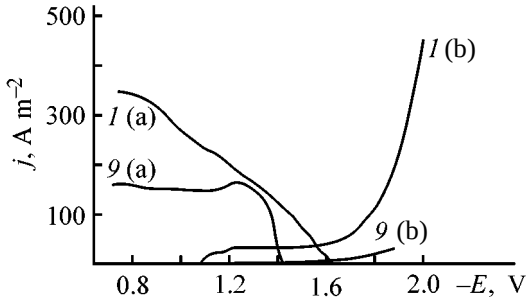

Fig. 3. (a) Anodic and (b) cathodic polarization curves for precipitation of tin on aluminum at varied concentration of tin(II) ions in solution. (j) Current density and (E) potential. The numbers at the curves correspond to run numbers in Table 2; the same for Fig. 4.

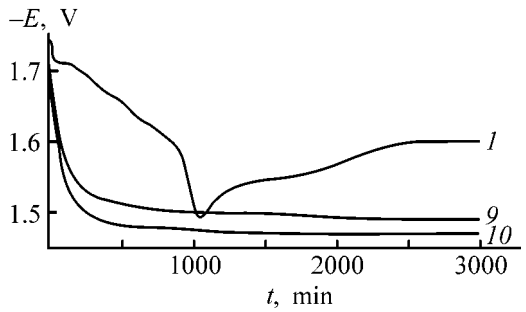

Fig. 4. Chronopotentiograms of A999 aluminum in solutions with varied concentration of tin(II) ions. (E) Potential and (t) time.

in the cathode current efficiency by tin at rather high current density of aluminum dissolution (Fig. 3), with the compromise electrode potential frequently being lower than the potential of "free" aluminum corrosion in a supporting solution (Table 3). This fact points to a complicated relationship between all the three reactions and, in particular, to the overall effect of aluminum surface activation, e.g., owing to its development, accumulation of alkali in the cathode layer, intensification of dissolution product removal, etc. (Fig. 4).

The aforesaid shows that the method of polarization diagrams is inapplicable in its frequently used simplified version to determination of the contact exchange current in those systems in which the current corresponding to side reactions is comparable with this current. This is rather evident, because the polarization curve of corroding metal reflects not the anode current of metal dissolution, but the difference between this parameter and the cathode current of oxidant reduction.

Thus, the behavior of the aluminum electrode in stannite alkaline solutions is determined by a combination of reactions: anodic dissolution of aluminum, cathodic reduction of tin, and, finally, cathodic evolution of hydrogen, which proceeds on both aluminum and tin. In this case, the total rate of the process is determined by the anodic dissolution of aluminum and depends at any instant of time on the current values of the electrode potential and the state of the electrode surface.

It is necessary to note that a coarse fern-shaped deposit is formed on compact aluminum at sufficiently high Sn(II) concentrations in solution ($\geq 10^{-2}$ M). According to the data of X-ray diffractometry, this deposit is identified as β-tin ("white" tin) with minor admixture of SnO_2. A similar pattern is also observed in reduction of Sn(II) with dispersed aluminum. In this case, weak lines of residual aluminum are observed in the X-ray diffraction patterns.

The purity of the deposited tin can be improved by additional treatment of the deposit with a concentrated alkali solution removing residual aluminum or its oxo and hydroxo compounds.

Our experiments and their theoretical interpretation suggest that the reduction of tin(II) ions to free metal on compact and dispersed aluminum has both common features and certain distinctions resulting from the dissimilar nature and structure of the outer layer of natural aluminum oxide, and also from different diffusion conditions on a flat electrode and suspension metal particles.

CONCLUSIONS

(1) Tin can be deposited as metallic granules or powder from stannite solutions in a wide concentration range (10^{-1}–10^{-3} M) via reduction with compact and dispersed aluminum.

(2) The process kinetics is of diffusion nature, which is caused by the formation of a continuous layer of tin on aluminum in the initial stage of the process.

(3) The resulting deposits mainly consist of β-tin with minor admixture of aluminum metall and SnO_2.

(4) The method of polarization curves is inapplicable in its traditional version to the determination of the contact exchange current in the systems in which the current of side reactions is comparable with the contact exchange current.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Transport Limitations on Anodic Dissolution of Steels in Phosphoric Acid Electrolyte with Conditioning Additives

E. A. Fedorova

Nizhnii Novgorod State University, Nizhnii Novgorod, Russia

Received July 5, 2000; in final form, January 2001

Abstract—Transport limitations on anodic dissolution of steels with varied level of alloying were studied in the repassivation region in modified electropolishing solutions with addition of alkali metal sulfates, glycerol, adamantane, and remantadine.

Good performance in the practice of electrochemical treatment of steel and alloy surfaces has been exhibited by modified solutions for electrochemical polishing with conditioning additives of the type of adamantane [1], possessing a number of advantages over the conventional sulfuric–phosphoric–chromic acid electrolyte [2]. A most important information, necessary for selecting optimal solution compositions and electrochemical polishing modes for alloys with varied degree of alloying can be obtained by studying the kinetics and revealing the limiting stages of anodic oxidation of alloys in the transpassive state.

If oxygen is evolved in the course of anodic polishing, which is characteristic of steels [3, 4], this unambiguously indicates that a continuous solid (apparently of oxide nature) film is formed on the anode surface. This film possesses ionic conductivity and *p*- or *n*-type semiconductivity. The rate of anodic oxidation of the alloy is determined in this case by three components of potential drops across the alloy–film and film–electrolyte interfaces and the film itself. It is still a matter of discussion which one of these plays the decisive role and what is the driving factor of the process—ion migration within the anodic oxide film (AOF) under the action of electric field, diffusion mass transfer of reagents in the near-electrode layer [5], acceptor mechanism of control, or the mechanism of salt film formation [6, 7].

The kinetics of anodic dissolution of transpassive steel anodes was studied for the example of 12Kh18N10T, 20Kh13, 95Kh18, and 08kp steels with varied degree of alloying and diffusion coefficients were evaluated for phosphoric acid (PhA) electrolytes with alkali metal sulfates (and K_2SO_4 [4] in the first place), glycerol $C_3H_8O_3$, adamantane (Ad), and its derivative—remantadine (Re) as conditioning additives.

EXPERIMENTAL

Electrochemical measurements were carried out with a P5848 potentiostat and KSP-4 recorder in a three-electrode cell with separated electrode spaces and saturated silver chloride reference electrode. The potentials are given relative to the standard hydrogen electrode. The steel working electrodes, fabricated in the form of disks with reactive surface area of 0.2–0.5 cm^2, were cleaned mechanically and weighed prior to each experiment. All the experiments were done at 323 K.

Partial polarization curves were plotted with account of the current efficiencies of ionization of steel components, determined gravimetrically and by quantitative analysis of anolytes in an electrolyzer with separated electrode spaces. The electrochemical equivalents of the steels were calculated with account of the percentage content of components and their final oxidation states. The fraction of current consumed for evolution of oxygen gas was evaluated volumetrically. The quantitative content of metal ions of the dissolving components of a steel in the anolyte was determined by atomic-absorption analysis on an AAS-1 spectrophotometer with detection limit of 0.05–0.1 mg l^{-1} [8]. Voltammograms were measured at potential sweep rates V_s (V s^{-1}): 0.01, 0.02, 0.05, 0.1, and 0.2. Measurements on a rotating disk electrode were done at rotation velocities w = 25–324 rad s^{-1}.

It has been shown previously that, in the case of joint use of adamantane and potassium sulfate con-

1070-4272/01/7404-0616 $25.00 © 2001 MAIK "Nauka/Interperiodica"

ditioning additives to a PhA electrolyte, the current efficiencies of anodic dissolution of the components of 12Kh18N10T steel decrease, making the service life of polishing solutions 1.5 times longer. Replacing water with glycerol in electrolytes of this kind ensures the necessary smoothing of the surface of steels with heterogeneous structure (20Kh13, 95Kh18, and 08kp), with the rate of their anodic dissolution becoming lower.

Figure 1 presents the experimental data obtained in studying the factors retarding the oxidation of steel components in the presence of conditioning additives to a PhA solution for the example of 12Kh18N10T steel at current peak (j_p) potentials and limiting currents j_l at the inflection point of current–voltage (*I–E*) curves. Figure 2 shows the results of partial-current measurements on a rotating disk electrode. The initial portions of the j_p–$V_s^{1/2}$ and j_p–$w^{1/2}$ curves were approximated in all solutions by straight lines corresponding to a diffusion-controlled process. With increasing V_s and w, the anodic dissolution process first passes into the region of mixed diffusion-activation–controlled kinetics and then into that of purely activation control, where mixing already has no effect on the process rate (Fig. 2a).

With the anodic polarization increasing further, when two processes—ionization of steel components and oxygen evolution at the AOF–electrolyte interface—occur in parallel, the portion intercepted on the ordinate axis by the straight line plotted in the j_p–$w^{1/2}$ coordinates is equal [9] to the fraction of current consumed for oxygen evolution (Fig. 2b). In the transpassive region, with increasing V_s, the process becomes irreversible (Fig. 2b).

According to the theory of thin-film voltammetry applied to quasi-reversible and irreversible electrochemical processes [9–12], including anodic oxidation [10, 11], the peak currents j_p in the *I–E* curves can be used to evaluate the diffusion coefficients of ions in anodic dissolution of metallic electrodes.

About the same peak currents were observed in voltammetric curves obtained with 08kp, 20Kh13, and 95Kh18 steel electrodes in PhA solutions with conditioning additives. For the 95Kh18 alloy the currents were higher than those with other steels at one and the same anode potential. The same pattern was observed in constructing anodic partial curves $\log j_{st}$–*E* (Fig. 3).

The obtained voltammetric characteristics of steel electrodes were used to find the diffusion coefficient *D* of ions, with account of the procedures for cal-

culation of diffusion and kinetic parameters of irreversible processes [9], by means of the equation

$$J_p = 3.0 \times 10^5 n(\alpha n)^{1/2} SCD^{1/2} V_s^{1/2}, \quad (1)$$

where J_p is the experimental peak current in the voltammetric curve (A), S the electrode area (cm^2), C the concentration of dissolving ions of steel components in the anolyte (M), V_s the potential sweep rate (V s^{-1}), n the number of electrons exchanged in an elementary process, and α the transfer coefficient for electrons.

The αn values were calculated using a quantity that is a reciprocal of the slope of the linear dependence of the peak potential $E_p = f(\ln V_s)$ and the Delahey equation [9] for the irreversible process:

$$dE_p/d\ln V_p = 2.303RT/2\alpha nF. \quad (2)$$

The diffusion coefficients of iron ions, mainly contained in the alloys under study, in the anodic dissolution of the alloys in a PhA electrolyte with conditioning additives in the range of electropolishing potentials are listed in Table 1. The obtained values of diffusion coefficients reflect the occurrence of an intermediate state between the liquid- and solid-phase diffusion of ions of components of the dissolving steels [13]. Of the two main driving factors of the process—ion migration under the action of electric field within AOF and diffusion of products formed in anodic dissolution of the steel components under the action of the concentration gradient—the first is apparently the limiting factor. In this case it becomes possible to account for the observed increase in the rate of anodic dissolution of steels with the growing extent of their alloying with chromium in the order 95Kh18 > 20Kh13 > 08kp (Fig. 3). Easier migration of ions through the AOF (γ-Fe_2O_3) exhibiting semiconducting properties with *p*-type conduction is possible if the motion of ions (Fe^+) of one of the two main components of chromium steels—iron and chromium—is slower. Cr^{6+} ions, being incorporated into the semiconducting γ-Fe_2O_3 film will increase the number of cationic vacancies and, as a result, make higher the rate of iron ionization. The incorporation of chromium ions in the γ-Fe_2O_3 oxide layer is possible since the difference between the atomic radii of Fe (r_{Fe} = 1.26 Å) and Cr (r_{Cr} = 1.30 Å) [16] does not exceed 15%.

The partial dependences $\log j_{st}$–E reflecting the anodic dissolution of iron, the dominant component of 08kp, 20Kh13, and 95Kh18 steels, show a break (Fig. 3). The slope of the semilogarithmic curves is greater after the break, which corresponds to the stage mechanism of metal ion ionization [17] and is due to the dissimilar dependences of the rates of these stages on potential.

With multicharge ions (Fe^{2+}, Fe^{3+}, Cr^{3+}, Cr^{6+}) formed in the end, abstraction of electrons from metal ions presumably occurs in stages. The initially formed subions (Fe^+ and, possibly, Cr^{2+}) will overcome the potential barrier at the metal–oxide interface and then potential barriers inside the forming oxide film, migrating via cationic vacancies and, possibly, being in part additionally oxidized inside the film. The subions going out of the film must react with atomic oxygen. Therefore, the rate of the oxygen process must be determined by two processes—evolution of oxygen

gas and oxygen consumption for additional oxidation of the products formed in anodic oxidation of steel components.

Experiments on collection of gas evolved from the surface of 12Kh18N10T steel anodes in a PhA solution with conditioning additives (Table 2) confirmed the assumption made.

The fraction of current consumed for oxygen gas evolution, Q_{O_2}, was smaller than the theoretically calculated current efficiencies by O_2 [$CE^{O_2} = 100 - CE^{st}$ (%)] in solutions containing either K_2SO_4 or glycerol and adamantane. Therefore, the observed inequality $Q_{O_2} < CE^{O_2}$ cannot be accounted for only by the possible oxidation of organic additives in the course of electrolysis.

The conditioning additives to the PhA solution affected the kinetics of anodic dissolution of steels in different ways (Table 2). Raising the content of cations K^+ and adamantane in a wide range of concentrations in an aqueous PhA solution makes lower the current efficiencies by the steels under study, which is due, as shown in [18], to their adsorption onto the steel anode surface.

In the case of simultaneous presence of glycerol and adamantane additives in a conditionally nonaqueous phosphoric acid solution, the rates of ion migration in the film (Table 1) and current efficiencies by steel increased somewhat, and the fraction of oxygen gas decreased (Table 2).

It may be assumed that, since the surface anodic film must be in dynamic equilibrium with the solution, unstable subions going out of the film will transform into stable ions under the action of oxygen and solution, with precipitation of the solid phase. If this occurs in the close vicinity of the film, it grows somewhat. Under the action of additives (adamantane and remantadine in the first place), subions probably acquire a certain extent of stability and may pass into solution, being preserved for a certain time and forming supersaturated solutions. According to the Schottky mechanism [19], this must make the film thinner, facilitate somewhat the anodic process, especially at

microscopic projections, and accelerate the smoothing of the microscopic roughness, and this was actually observed in practice (Table 3).

CONCLUSIONS

(1) Anodic dissolution of steels in phosphoric acid electrolyte with such conditioning additives as potassium sulfate, glycerol, and adamantane (or remantadine) proceeds in the transpassive region in stages, with ion migration in the AOF under the action of electric field as limiting factor, film thinning, and accelerated smoothing of the surface microroughness.

(2) It is recommended to use remantadine [$(2.0–4.0) \times 10^{-2}$ M], lowering the rate of anodic dissolution of steels as compared with adamantane, in electrochemical treatment of chromium and carbon steels as an additive to a solution of composition (M): H_3PO_4 13.5, H_2SO_4 0.5, $C_3H_8O_3$ 2.0, with the required quality of surface treatment preserved.

CATALYSIS

Synthesis of Monosilane by Catalytic Disproportionation of Trichlorosilane in a Reaction-Rectification Apparatus with Recycle

V. M. Vorotyntsev, G. M. Mochalov, and O. V. Nipruk

Nizhnii Novgorod State Technical University, Nizhnii Novgorod, Russia

Received February 21, 2000; in final form, October 2000

Abstract—Basic principles of a procedure for calculating a reaction-rectification apparatus for synthesizing silane by catalytic disproportionation of trichlorosilane are presented. Technological parameters are substantiated and the process of silane synthesis in the reaction-rectification apparatus is optimized.

Silane is one of the most important starting materials used to manufacture semiconducting silicon and epitaxial structures on its base. The quality of semiconducting silicon is mainly determined by the purity of silane, and, therefore, the use of silane in microelectronics imposes strict requirements on its purity. Since the impurity composition of silane is formed in the stage of its synthesis, much attention is paid presently to selecting a synthesis technique allowing easy purification of the obtained product.

Until recently, disproportionation of organosubstituted silanes [1], namely, that of triethoxysilane, has been the main industrial method for silane synthesis. However, silane obtained in this way contains difficultly removable impurities of organic substances and, therefore, fails to satisfy the growing requirements of microelectronics.

The highest-purity silane can be obtained by disproportionation of trichlorosilane in the presence of a catalyst [2–7]. However, the proposed method has long been in disuse in the industry because of the lack of catalyst that would not contaminate the product and could retain its activity for a sufficiently long time. According to the patent literature, the best catalysts for disproportionation of trichlorosilane are anion-exchange resins combining high activity of functional groups and ability to bind molecules containing electroactive atoms—As, B, and P. The highest catalytic activity is exhibited by resins of the following types: Amberlyst A-21, Amberlyst-26, gel quaternary-ammonium resin IRA-400, AN18-12P, and AV27-12P.

Synthesis of silane by disproportionation of trichlorosilane has not been used in Russia until now, and, therefore, calculation and optimization of the technological scheme and of the procedure for synthesizing silane by this method are of interest.

When reactions of redistribution of hydrogen and chlorine atoms among molecules of chlorosilanes from the series $SiCl_4$, $SiHCl_3$, SiH_2Cl_2, SiH_3Cl, SiH_4 proceed in the course of catalysis on anion-exchange resins at nearly normal temperature, bimolecular interactions may occur simultaneously, described by the following equations of reversible reactions [1]:

$$2SiHCl_3 \rightleftarrows SiCl_4 + SiH_2Cl_2, \quad (1)$$

$$2SiH_2Cl_2 \rightleftarrows SiHCl_3 + SiH_3Cl, \quad (2)$$

$$2SiH_3Cl \rightleftarrows SiH_2Cl_2 + SiH_4, \quad (3)$$

$$2SiH_2Cl_2 \rightleftarrows SiCl_4 + SiH_4, \quad (4)$$

$$SiCl_4 + SiH_3Cl \rightleftarrows SiHCl_3 + SiH_2Cl_2, \quad (5)$$

$$SiHCl_3 + SiH_4 \rightleftarrows SiH_2Cl_2 + SiH_3Cl. \quad (6)$$

Reactions (1)–(4) involve disproportionation; reactions (5) and (6) are of dismutation type.

Thus, synthesis of silane by disproportionation proceeds in stages, with dichlorosilane and monochlorosilane formed as intermediates. Therefore, it is advisable to synthesize silane in the recycle mode, i.e., with separation of target products and recycling of intermediates into the reactor. A reaction-rectification apparatus described in [8] (Fig. 1) was used for this purpose.

1070-4272/01/7404-0621 $25.00 © 2001 MAIK "Nauka/Interperiodica"

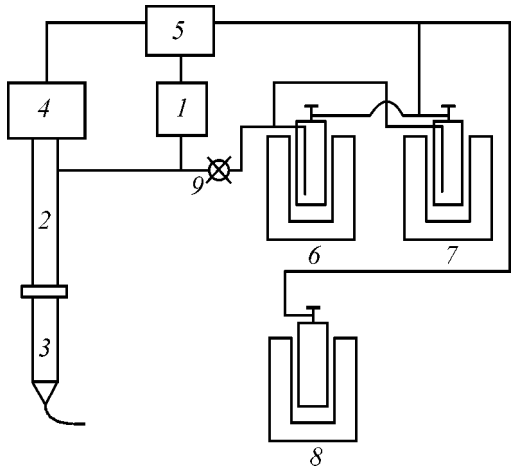

Fig. 1. Schematic of a reaction-rectification apparatus for synthesizing silane by catalytic disproportionation of trichlorosilane: (*1*) Vessel, (*2*) rectification column, (*3*) evaporator, (*4*) reactor, (*5*) dephlegmator, (*6, 7*) condensers, (*8*) silane receiving vessel, and (*9*) cock.

The starting trichlorosilane is fed from vessel *1* into the upper part of the separation section of rectification column *2* and then into condenser *3*. Trichlorosilane vapor is delivered from the evaporator into the lower part of the separation section of rectification column and then into reactor *4*. The reactor has the form of a thermostated vessel charged with a catalyst. In the reactor occurs the disproportionation of silane, with the composition of the mixture of reaction products close to the equilibrium composition at the reactor temperature.

Synthesis gas is fed into dephlegmator *5* where partial condensation of reaction products occurs. The condensate, containing trichlorosilane, silicon tetrachloride, and other chlorosilanes, is returned into vessel *1*, being mixed there with the starting trichlorosilane. As a result, the reaction products are accumulated in vessel *1*. A mixture of chlorides is delivered from the vessel into the separation section of the rectification column whose operation results in that silicon tetrachloride is concentrated in the evaporator and discharged from the apparatus. The process of silicon tetrachloride accumulation in vessel *1* continues until the rates of its synthesis in the reactor and discharge from the evaporator become equal. After this occurs, the apparatus is operating further in the stationary mode. The vapor not condensed in dephlegmator *5*, enriched in silane and light chlorosilanes, is discharged from the apparatus and condensed in receiving vessel *6* or *7* at liquid nitrogen temperature. At regular intervals, silane is evaporated from the receiving vessel into vessel *8*, and light chlorosilanes are returned through cock *9* into the apparatus and, arriving at the reactor, are again involved in the reaction of disproportionation. The products of this reaction are again subjected to partial condensation in dephlegmator *5*. Thus, the apparatus is operating in a closed cycle.

It can be seen from the described technological cycle that an important condition for operation of the apparatus is the concerted action of the reactor and the rectification column. The rate of silicon tetrachloride discharge depends on the degree of extraction, separation factor, and silicon tetrachloride concentration in the upper part of the rectification column. In its turn, the rate of synthesis of silicon tetrachloride is determined by the difference in its concentrations before and after passing through the reactor, and the concentration at the reactor inlet coincides with that in the upper part of the rectification column. In accordance with the equations of reactions (1)–(6), the content of silicon tetrachloride in the starting mixture fed into the reactor affects the concentration of silane and chlorosilanes in the gas mixture discharged from the reactor. Consequently, the concentration of silicon tetrachloride at the reactor inlet and in the upper part of the rectification column determines the efficiency of both the reactor and the rectification column. Therefore, the algorithm for calculation of the above technological cycle is aimed to search for the concentration of silicon tetrachloride at the reactor inlet and the upper part of the rectification column. This problem was solved as follows.

(1) Controllable parameters of the process were set: reaction temperature T_r; dephlegmator temperature T_d; pressure in the apparatus, P_0; $SiCl_4$ concentration in the lower part of the column, X_l; separating capacity of the rectification column, represented by the number n of theoretical plates in the zero-takeoff mode.

(2) The composition of the starting mixture fed in the reactor was introduced: $DI(1)$, $DI(2)$, $DI(3)$, $DI(4)$, and $DI(5)$—concentrations of, respectively, silane, mono-, di-, and trichlorosilane, and silicon tetrachloride.

(3) The composition of the equilibrium mixture discharged from the reactor at T_r was calculated using the following algorithm.

(a) The equilibrium constants were calculated from the Gibbs energies; the thermodynamic constants necessary for calculations were taken from [9, 10].

(b) The equilibrium concentrations of the components in reaction (1) were calculated by passing to a three-dimensional coordinate system and introducing a variable reaction coordinate z reflecting

changes in component concentrations in the course of the reaction:

$$X(3) = DI(3) + 0.5z,$$

$$X(4) = DI(4) - z,$$

$$X(5) = DI(5) + 0.5z,$$

where $X(3)$, $X(4)$, and $X(5)$ are, respectively, the equilibrium concentrations of di- and trichlorosilane and silicon tetrachloride.

The solution was found in the form of the following quadratic equation

$$K_{eq}1 = X(5)X(3)/X(4)^2.$$

The physically realizable solution must satisfy the condition $0 \le X(4) \le 1$, $0 \le X(3) \le 1$, $0 \le X(5) \le 1$.

(c) Using the obtained z value, the equilibrium concentrations of the reactants of reactions (1)–(6) were calculated at appropriate equilibrium constants, with the z value and the mixture composition corrected each time. The calculation was repeated until the quasi-equilibrium composition of the system stabilized at the values corresponding to the chosen convergence criterion. This gave a set of equilibrium concentrations of all the components of the system: $X(1)$ silane, $X(2)$ monochlorosilane, $X(3)$ dichlorosilane, $X(4)$ trichlorosilane, and $X(5)$ silicon tetrachloride.

(4) The saturated vapor pressure was calculated for each component of the system at T_d by the following equations [9–11]:

$$\mathrm{SiH_4} - \log P_1 = 68.07 - 2020/T + 5.1847 \times 10^{-5}T^2 - 25.771 \log T,$$

$$\mathrm{SiH_3Cl} - \log P_2 = 7.3948 - 1095.7/T,$$

$$\mathrm{SiH_2Cl_2} - \log P_3 = -1297.2T + 1.75\log T - 2.4827 \times 10^{-3}T + 3.9022,$$

$$\mathrm{SiHCl_3} - \log P_4 = -1170/(T + 246) + 7.09119,$$

$$\mathrm{SiCl_4} - \log P_5 = 7.6414 - 1572.3/T.$$

(5) The separation factor defined as the ratio of the $SiCl_4$ concentrations at the top and bottom of the column; degree of extraction, p; rate of synthesis in the reactor; and rate of $SiCl_4$ discharge from the apparatus were calculated. The degree of extraction was found using the equation [12]

$$F = \frac{1 - \alpha\theta}{(1 - p)F_0^{-(1 - \alpha\theta)/(1 - p)} - \theta},$$

where $\theta = p(\alpha - 1)$, F is the separation factor in the takeoff mode, F_0 the separation factor in the zero-takeoff mode, $F_0 = \alpha^n$, n the number of theoretical plates, p the degree of extraction, and α the separation coefficient.

The following comparison was made: if the rate of discharge was lower than the rate of synthesis, then the concentration of silicon tetrachloride at the inlet of the reactor and the separation section was raised: otherwise, it was reduced and step 3 was executed again. The calculation procedure was repeated until the rates of synthesis and discharge of silicon tetrachloride became close, to satisfy the chosen convergence criterion.

(6) The saturated vapor pressure was calculated for the equilibrium mixture, liquefied at T_d and having concentrations $X(1)$–$X(5)$ (steps 3b and 3c) of the components discharged from the reactor, using the equation

$$P = P_1X(1) + P_2X(2) + P_3X(3) + P_4X(4) + P_5X(5).$$

(a) In the case of $P < P_0$, the composition $X(1)$–$X(5)$ was used in step 3 [instead of $DI(1)$–$DI(5)$] and the calculation procedure was repeated until condition 6b was satisfied.

(b) At $P > P_0$, the procedure went to calculating by the method of iterations the degree of extraction of light fractions from dephlegmator *5*.

(7) The composition of equilibrium liquid and vapor phases in dephlegmator *5* at temperature T_d and pressure P_0 was calculated using a set of equations for i components, having the form

$$x_0(i) = y_0(i)P_0/[P_0(1 - S) + SP_1],$$

where i is the number of a mixture component, S the degree of extraction of light fractions, P_0 the working pressure, P_i the equilibrium pressure at T_d, $x_0(i)$ the concentration of ith component in the liquid phase, and $y_0(i)$ the same in the vapor phase.

(8) The system of equations was solved by iterations of the degree of extraction.

(9) Since the liquid of composition $x_0(i)$ comes from dephlegmator *5* into the feeding vessel *1* and thence arrives at the reactor inlet and the upper part of the rectification column, this composition was used in passing to step 3.

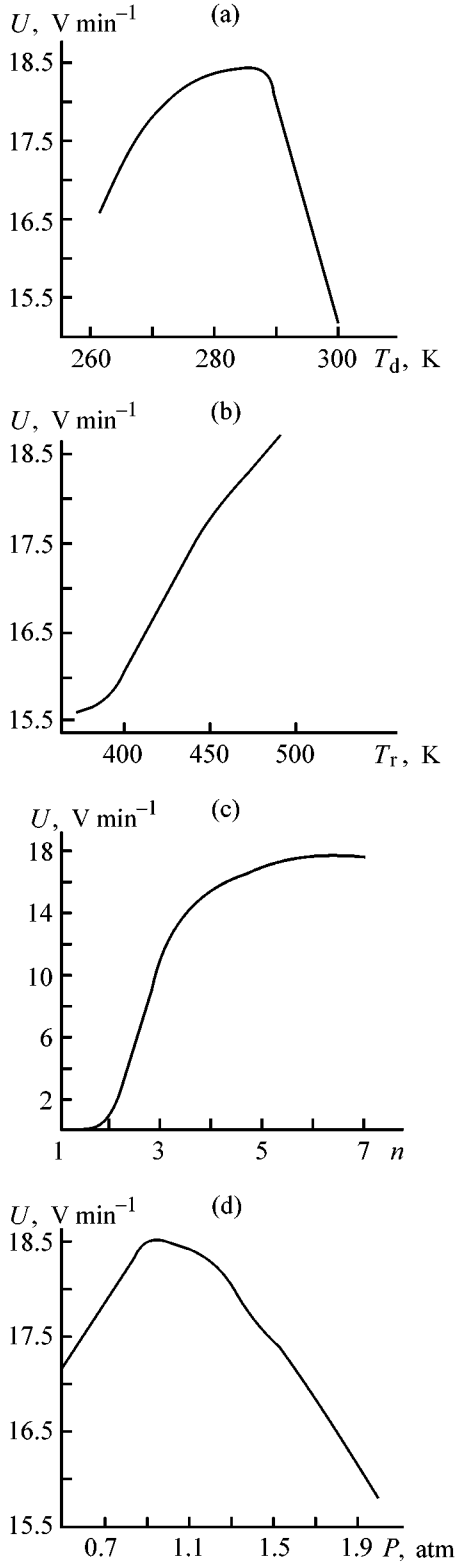

Fig. 2. Calculated dependences of the output capacity U of the apparatus on (a) dephlegmator temperature T_d, (b) reactor temperature T_r, (c) number n of theoretical plates in the rectification column, and (d) pressure P in the column.

(10) The calculation procedure was repeated until stationary values of S, $x_0(i)$, and $y_0(i)$ were obtained with the satisfied condition for equal rates of synthesis and discharge of silicon tetrachloride.

(11) Since the vapor of composition $y_0(i)$ is discharged from dephlegmator *5* and condensed in receiving vessel *6* or *7*, light chlorosilanes remaining in the receiving vessels after silane is evaporated therefrom into vessel *8* are returned into the reactor (recycled). The $y_0(i)$ values were used to calculate the composition of the liquid in vessels *6* and *7* after the evaporation of silane. This composition was used in step 3 to calculate the concentration of silane in the mixture discharged from the reactor; degree of vapor mixture extraction from dephlegmator *5* in recycle, S_r; and concentration of silane in the mixture, y_{1r}.

(12) Then the output capacity U (g g^{-1}) of the apparatus was found for a conventional reactor load of 1 mol min^{-1}:

$$U = [Sy_1 + (S_rSy_{1r})(1 - y_1)][1 + S(1 - y_1)] \times 32 \times 60,$$

where Sy_1 is the amount of silane taken-off in 1 min, y_r the concentration of silane in the vapor in a recycle, $S_rS(1 - y_1)y_{1r}$ the amount of silane taken-off during a recycle, and 32 the molecular weight of silane (g mol^{-1}).

The data obtained in the calculations are graphically in Figs. 2a–2d.

It can be seen from Fig. 2a that, with the dephlegmator temperature increasing to 278 K, the output capacity of the apparatus grows. It may be assumed that this is due to the fact that the solubility of silane in the condensate decreases with increasing temperature. This prevents silane from coming back to the reactor, which diminishes the influence exerted by the reverse reaction of dismutation. At higher temperatures (T > 285 K), a greater amount of light chlorosilanes is discharged from the apparatus instead of being returned into the reactor, which impairs the output capacity of the apparatus.

It is seen from Fig. 2b that the output capacity of the apparatus grows steadily with increasing reactor temperature, since the reaction equilibrium is shifted toward formation of light products, this reaction being endothermic.

The influence of the number of theoretical plates, n, is illustrated in Fig. 2c. It can be seen that, at n < 3 and $SiCl_4$ concentration in the lower part of the column equal to 99%, the output capacity of the apparatus is nearly zero. This is due to the low efficiency of

the column in $SiCl_4$ removal from the reaction zone. Then the output capacity increases and, having reached the maximum value at $n = 6$, remains further unchanged, since the rectification column already shows its maximum separation efficiency in the technological process in question. Consequently, raising the number of theoretical plates to more than six is inexpedient.

Elevating the pressure in the apparatus to 1.2 atm leads to an increase in output capacity because of the higher concentration of light chlorosilanes in the condensate and to their recycling into the reactor, with the result that the rate of silane synthesis becomes higher (Fig. 2d). Raising the pressure to more than 1.2 atm makes the output capacity lower because of the increasing solubility of silane in the condensate and its penetration into the reactor where it is involved in the reverse reaction of dismutation.

The described technological scheme for manufacture of silane was implemented in a pilot installation. An experimental study of the silane synthesis demonstrated that the calculated dependence of the output capacity of the installation on the dephlegmator temperature, pressure, and number of theoretical plates is in agreement with the experiment, with, however, the experimental output capacity constituting only 70% of the calculated value. Possibly, this is due to kinetic limitations affecting the attainment of chemical equilibrium in the reactor, disregarded by the calculation procedure (step 3c). A gas-chromatographic analysis of a mixture of chlorosilanes before and after the reactor confirmed this assumption. The kinetic limitation on the reaction is associated with the fact that only the first disproportionation reaction is kinetically unhindered in the multistage consecutive-concurrent process of trichlorosilane disproportionation to silane [see reactions (1)–(3)]. The same effect was observed in a laboratory study of the kinetics of trichlorosilane disproportionation [13]. Probably, the kinetic limitation is associated with hindrances to desorption of a higher-boiling reaction product from the catalyst surface.

CONCLUSIONS

(1) The calculations demonstrated that the most expedient way to synthesize silane is in a reaction-rectification apparatus at the maximum possible reactor temperature (limited by the thermal stability of the catalyst used and of intermediate reaction products), dephlegmator temperature T_d = 278–285 K, pressure P = 1–1.2 atm, and number of theoretical plates in the rectification column of no less than six.

(2) An experimental study of the silane synthesis by the proposed technological scheme established that the experiment is in good agreement with the calculations.

(3) The practical implementation of this technology and synthesis conditions made it possible to create the first Russia's facility for manufacture of monosilane satisfying the requirements of microelectronics.

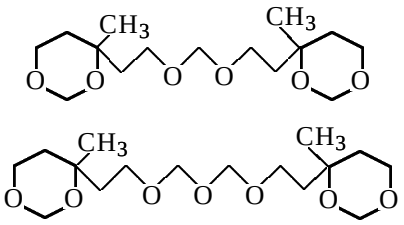
Received June 23, 2000; in final form, February 2001

Abstract—The kinetic parameters of liquid-phase oxidation of dioxane alcohol formals were determined. The inhibiting activity of a number of phenol and organophosphorus antioxidants is evaluated and methods are proposed for decelerating the destruction of dioxane alcohol formals, occurring via thermal oxidation.

High-boiling by-products of isoprene synthesis by the dioxan method are multicomponent mixtures [1]. After evaporation of light fractions, the products are mainly composed of dioxane alcohol formals (DAF) of the following composition [1]:



At present, DAFs find application as plasticizers in polyvinylchloride-based formulations [2]. However, wide use of DAF is hindered by their poor thermal oxidation stability.

The aim of the present study was to analyze the autooxidation and initiated oxidation of DAF and to choose on this basis antioxidants able to hinder undesirable processes of thermal-oxidation destruction.

EXPERIMENTAL

The rate of O_2 uptake in DAF oxidation was studied on a gasometric setup of static type [3]. A thermostated glass reactor of conical shape, equipped with a magnetic stirrer, was charged with 5 ml of DAF and purged with oxygen for 10 min. The amount of absorbed oxygen $\Delta[O_2]$ (mol l^{-1}) was calculated using the formula

$$\Delta[O_2] = V_{O_2}/V_s \times 22.4,$$

where V_{O_2} is the amount of absorbed oxygen (ml), and V_s is the sample volume (ml).

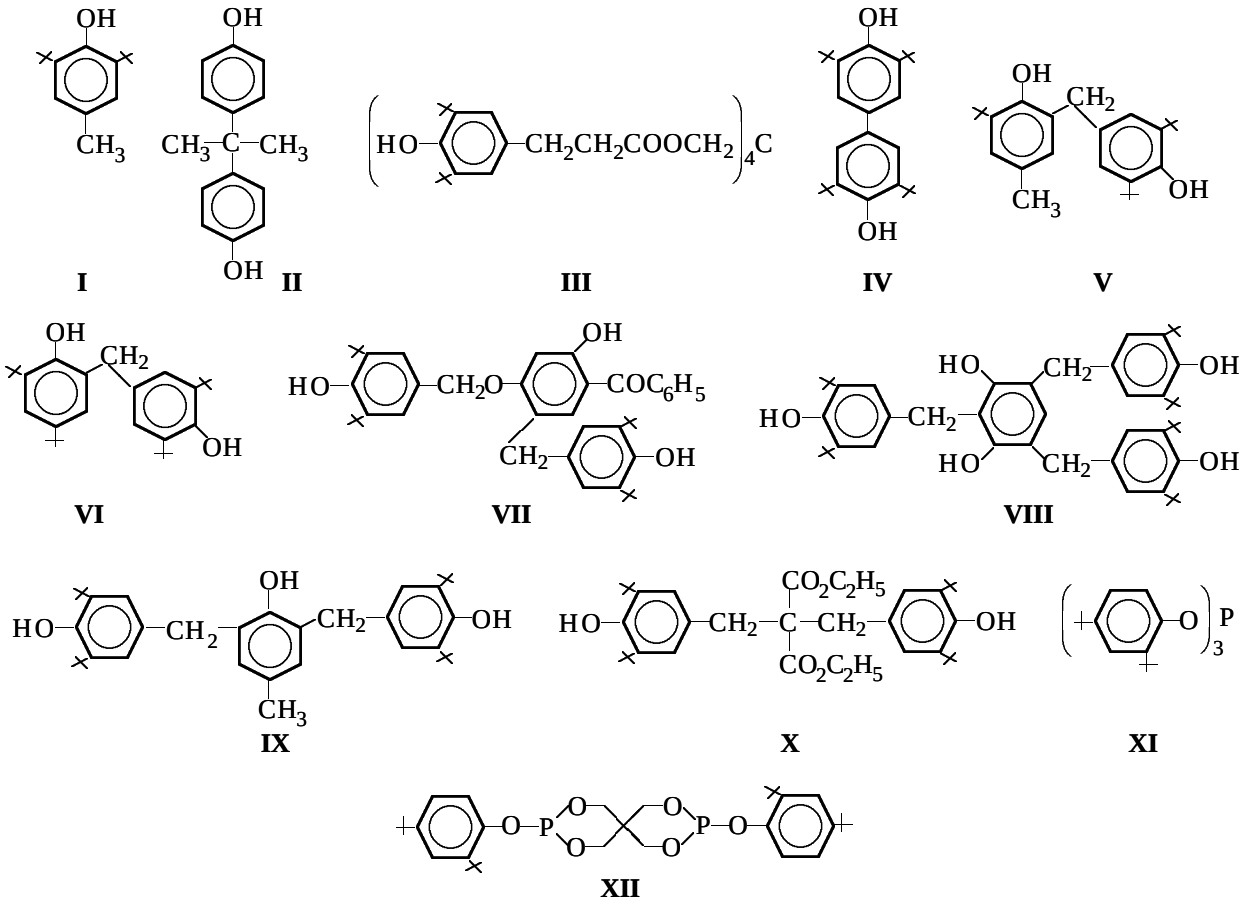
The rate of oxidation $V_{O_2} = \Delta[O_2]/t$ was determined as the slope of the straight line in the coordinates $\Delta[O_2]$–time.

The temperature range of DAF oxidation, ensuring the occurrence of the process in the chain mode, is 100–130°C. To this interval of working temperatures corresponds the initiator *tert*-butyl peroxide (TBP) with rate constant of decomposition equal to $\log k_d = 14.9 - 146.300/19.15T$ [4]. The TBP concentration was varied within the range $(2–30) \times 10^{-3}$ M.

The parameter a, characterizing the oxidability of a DAF ($a = k_d[DAF]/2k_t^{1/2}$) containing a DAF hydroperoxide (DAFHP) with unknown initiation rate $v_{i,DAF}$, was determined by the method of mixed initiation. According to this technique, a DAF with chains generated at an unknown rate $v_{i,DAF}$ was oxidized in the presence of TBP initiator for which the rate constant of initiation, k_i, is known [4]. For this purpose, the initial rate of oxidation, v_{O_2}, was measured in a set of experiments with different TBP concentrations, and the parameter a and $v_{i,DAF}$ were found from the dependence of v_{O_2} on [TBP], using the expression $v_{O_2} = a^2/v_{i,DAF} + a^2k_i[TBP]$ [4].

The parameter b characterizing the susceptibility of DAF to auto-oxidation is a combined factor [$b = (1/2)ak_i^{1/2}$] including the parameter a determining the rate of chain oxidation at v_i = const and $k_{i,DAF}$—the effective rate constant of auto-oxidation [4]. The autooxidation of DAF proceeds with acceleration, and the kinetics of O_2 absorption is described by the known expression $(\Delta[O_2])^{1/2} = bt$, characteristic of hydrocarbons, fuels, and acetals [3, 4]. In the coordinates $\Delta[O_2]^{1/2}$–t, the experimental points fall on a straight line. The parameter b is determined as the slope of the experimental straight line, with the upwards shift

1070-4272/01/7404-0626 $25.00 © 2001 MAIK "Nauka/Interperiodica"



of the straight line away from the origin of coordinates related to the presence in DAF of hydroperoxides accumulated in storage.

DAF hydroperoxides were analyzed using a iodometric method based on reduction of the peroxide group by the iodide ion [5]. Oxidants of phenol type **I**–**X**, used to suppress autooxidation of DAF, were synthesized by the method described in [6]; organophosphorus compounds **XI** and **XII**, tested as DAF oxidation inhibitors, were obtained as described in [7].

In manufacture and storage of DAF in contact with atmospheric oxygen, the corresponding hydroperoxides (DAFHP) are accumulated, with their concentration in some samples equal to $(2–4) \times 10^{-3}$ M. The auto-oxidation of DAF at elevated temperature (>120°C) is accompanied by intensive absorption of oxygen to give DAFHP (Table 1). The yield of DAFHP per absorbed oxygen is nearly quantitative in the initial stage of autooxidation (ca. 90% at $\Delta[O_2] \le 1 \times 10^{-2}$ M). With increasing extent of the process, the DAFHP yield decreases to become about 30% by the end of experiment, with the decomposition rate much exceeding under these conditions the rate of DAFHP formation. With increasing temperature, the parameter b characterizing the rate of auto-oxidation grows from 4×10^{-5} to 27×10^{-5} $(M\ s^{-2})^{1/2}$; the Arrhenius dependence has the form $\log k = 6.36 - 76\,500/(19.5T)$. The activity of DAF in auto-oxidation (Table 2) is comparable with that for individual cyclic acetals [1,3-dioxane (DO) and 4,4-dimethyl-1,3-dioxane (DMDO)]—$b_{DO} : b_{DMDO} : b_{DAF} = 18.9 : 14.7 : 11.5$ (120°C).

The dependence of squared rate of initiated DAF oxidation, $v_{O_2}^2$, on the TBP concentration is linear and described by the equation $v_{O_2}^2 = a^2 v_{i,DAF} + a^2 k_i[TBP]$. The chain length, varying within the range 75–200 (Table 3), depends on temperature and initiator concentration. The effect of temperature on the parameter a characterizing the oxidability of DAF is described by the equation $\log a = 6.12 - 58\,200/(19.15T)$. The oxidability of DAF is much lower (Table 2) than that of the compounds DO and DMDO.

However, the high initiating activity of the accumulating hydroperoxides (120°C, $k_i = 4b^2/a^2 = 1.2 \times 10^{-4}$ s^{-1}) is the main reason for the poor oxidation stability of DAF in operation at elevated temperatures.

To suppress the undesirable auto-oxidation and improve the thermal-oxidation stability of DAF, the effect of phenol **I**–**X** and organophosphorus **XI** and **XII** compounds on the rate of O_2 absorption was studied. In the absence of inhibitors, DAFs oxidize at virtually constant rate with slight acceleration in accordance with the expression

$$\Delta[O_2] = b^2 t^2.$$

Introduction into the oxidizing system of ionol **I** makes the rate of O_2 absorption lower, with no induction period observed, which is presumably due to the presence in the mixture of DAFHP accumulated during storage. The kinetic curves of DAF auto-oxidation are linearized in the coordinates $\Delta[O_2]^{1/2}$–t, the auto-oxidation parameter b decreases from 11.5×10^{-5} to 2.2×10^{-5} $(M s^{-2})^{1/2}$ (120°C) with the concentration of **I** increasing from 0.018 to 0.10 wt % (Table 4). The influence exerted by the inhibitors was evaluated on the basis of the auto-oxidation deceleration factor n equal to the ratio of the auto-oxidation rate in the absence of inhibitor to that in its presence ($n = b/b_{InH}$). For example, the process deceleration factor for inhibitor **I** grows with increasing inhibitor concentration to reach the limiting value ($n_\infty = 5.2$) at [InH] $\geq$ 0.1 wt %.

The organophosphorus inhibitor **XII**, taken at concentration of 0.1 wt % (2×10^{-3} M), affects the auto-oxidation of DAF only slightly ($n = 1.5$). Raising the concentration of **XII** to 1.25 wt % (2.5×10^{-2} M; this concentration ensures stability of PVC-based polymer formulation plasticized with DAF) strongly decelerates the auto-oxidation of DAF ($n = 8.8$) and, after absorption of 4×10^{-3} M O_2 in the course of 40 min (120°C) the process virtually terminates. Consequently, the effect of process deceleration under the action of the organophosphorus inhibitor is manifested only in the case of its manyfold excess over the content of

DAFHP accumulated in DAF storage; [DAFHP] = 2×10^{-3} M $[InH]_0 = 2.5 \times 10^{-2}$ M.

Under these conditions, DAFHPs initiating auto-oxidation are presumably transformed into inactive molecular products, with virtually no free radicals formed. Introduction of an organophosphorus inhibitor (0.1 wt %) into the system being oxidized makes the rate of auto-oxidation higher ($n = 3$), presumably because of the catalytic decomposition of DAFHP by the homolytic mechanism.

The inhibitors studied show no synergistic effect. For example, a mixture of two inhibitors, **II + XII**, taken in a 3 : 2 ratio at a total concentration of 0.1 wt %, exhibits antagonism, since the deceleration factor of the mixture of inhibitors ($n = 1.1$) is much lower than that for each of the individual compounds **II** and **XII**. Raising the total concentration of the mixture of inhibitors to 1.25 wt % leads to only a slight increase in the DAF autooxidation deceleration factor ($n = 3.2$).

As already mentioned, use of high inhibitor concentrations ($\geq 10^{-2}$ M) fails to preclude auto-oxidation completely and kinetic curves show no induction period. Therefore, the efficiency of the inhibitors was evaluated on the basis of the parameter $\alpha = k_{InH}/k_d[DAF]$ [4]. According to this expression, the faster the reaction of an inhibitor with peroxy radicals leading the oxidation chain, the greater the α value and the higher the inhibitor's efficiency. If inhibited oxidation proceeds by the chain mechanism and chain termination occurs via reaction between the inhibitor with peroxy radicals, then the oxidation rate is described by the equation [4]

$$v_{O_2} = \frac{k_d[DAF]v_i}{fk_{InH}[InH]} = \alpha^{-1}\frac{v_i}{f[InH]},$$

whence follows that under the conditions of oxidation at $v \leq 30$

$$\alpha = \frac{v_i}{(v_{O_2} - v_i)f[InH]},$$

with $f = 2$ (Table 2).

The above procedure for determining the α value was used to measure the efficiency of the decelerating action of compound **I** and other phenol inhibitors. The obtained data are compared with a similar characteristic for the organophosphorus compound **XII** in Table 5.

It can be seen from the presented data that introduction of inhibitors in the case of DAF auto-oxidation makes the process rate lower, with the chain length decreasing from 54 to 7 units; however the chain mode is preserved even at rather high inhibitor concentrations in the range $(1.2–24.6) \times 10^{-3}$ M. The observed behavior is presumably due to the presence in DAF of DAFHPs effectively stimulating the oxidation. This assumption is confirmed by the low value of the parameter α characterizing the efficiency of inhibitors in DAF oxidation ($\alpha < 10^2$ M^{-1}), much exceeded by those in inhibited oxidation of a mixture of hydrocarbons ($\alpha \geq 10^3$ M^{-1}) [4]. In addition, molecules containing an acetal group form hydrogen bonds with phenol inhibitors, much impairing their activity in the reaction with peroxy radicals, terminating the chains [8].

Table 5. Evaluation of inhibitor efficiency in DAF auto-oxidation (120°C, $v_{i,DAF} = 2.2 \times 10^{-7}$ M s^{-1}, $f = 2$)

Inhibitor	$[InH] \times 10^3$, M	$v_{O_2} \times 10^5$, M s^{-1}	ν	α, M^{-1}
I	0	1.20	54	–
	1.3	0.44	20	19
	2.8	0.35	16	11

VII	1.2	0.32	15	29
VIII	1.4	0.40	18	20
IX	2.0	0.69	31	8
	24.6	0.15	7	3

CONCLUSIONS

(1) A mixture of dioxane alcohol formals intensely absorbs oxygen at elevated temperatures (100–300°C) to form the corresponding hydroperoxides. The parameter characterizing the rate of auto-oxidation of DAFs is close to those for individual 1,3-dioxanes and much exceeds the parameters for hydrocarbons. The high initiating activity of the forming hydroperoxides accounts for the low thermal-oxidation stability of DAFs.

(2) Introduction of phenol inhibitors into the system substantially lowers the rate of auto-oxidation, with the process deceleration factor markedly changed. For organophosphorus inhibitors this parameter is somewhat lower.

Abstract—Electrokinetic technique for soil decontamination to remove hydrophobic organic compounds, based on application of direct electric field to soil sample preliminarily treated with solutions of chelating agent and a nonionic surfactant, was developed. The influence of various factors on electroosmotic flow in soddy podzolic soil sample was studied.

Decontamination of soils to remove organic contaminants is an urgent problem [1, 2]. This problem can be solved with the use of various techniques, including thermal [3] or biological [4] treatment of soil, pumping of solutions containing agents capable of extracting the toxic contaminants throngh soil [5, 6], and application of electric field [7, 8]. However, these techniques are suitable for decontamination of specific objects only. For example, treatment with heated gas is efficient in removal of organic impurities from sandy soil but is unsuitable for decontamination of clay. Furthermore, such techniques are mainly suitable for removal of highly volatile organic compounds [3].

In this work, we studied decontamination of heavy soil containing large amount of clay to remove hydrophobic organic compounds (HOCs). Decontamination of such soils is one of the most difficult remediation problems. The main aim of our experiments was to study on model systems the possibility of increasing the efficiency of electrokinetic decontamination of soil to remove neutral toxic organic compounds with the use of chemical reagents.

The electrokinetic technique for decontamination of soil is based on removal of impurities by electroosmosis, electromigration, electrophoresis, and diffusion. The most efficient among these processes is electroosmosis. The efficiency of impurity removal by this mechanism is mainly controlled by the electrokinetic potential (ζ-potential) [9]. It is known that the surface of soil particles is charged negatively [10] and characterized by relatively low ζ-potential [11, 12]. The ζ-potential can be increased by treatment of soil with aqueous solutions of chelating agents, such as 1-hydroxyethylidenediphosphonic (HEDP), ethylenediaminetetraacetic (EDTA), and citric acids. Introduction of these compounds, especially HEDP, into a soil sample in amount of 1×10^{-2} M leads to an approximately 10-fold increase in the ζ-potential [11–13].

The ζ-potential is also influenced by the pH of solutions of chelating compounds added to soil. It was found that for HEDP and EDTA solutions the maximum ζ-potential is attained at pH 6–8 [13, 14].

To remove HOCs from soil it is necessary not only to increase the electroosmotic flow but also to ensure HOC solubilization in the pore solution. For this purpose, a contaminated soil sample should be simultaneously treated with chelating agent and nonionic surfactant. It should also be taken into account that introduction of nonionic surfactant in the soil can affect the rate of the electroosmotic flow. Therefore, we studied in this work the dependence of soil decontamination on the nature of a nonionic surfactant.

In our experiments, we used nonionic surfactants, since these compounds are to a considerably lesser ex-

tent sorbed on the soil surface as compared with cationic surfactants. Furthermore, in contrast to anionic surfactants, the use of nonionic surfactants is not accompanied by electromigration of micelles in the direction opposite that of the electroosmotic flow, deteriorating electroosmotic transfer of the impurities.

EXPERIMENTAL

Our experiments were performed with a sample of clayey loam soddy-podzolic soil taken from the top soil horizon (0–15 cm) at the divide territory of an experimental field located at the Dokuchaev base station (Zelenograd). The main characteristics of this soil sample were as follows:

Characteristic	Value
pH (salt extract)	5
Hydrolytic acidity, mg-equiv kg^{-1}	17
Exchangeable calcium, mg-equiv kg^{-1}	160
Exchangeable magnesium, mg-equiv kg^{-1}	70
Free iron (by Jackson), %	0.17
Mobile iron (by Tamm), %	0.05
Total organic carbon, %	1.2

The initial soil sample was air-dried, broken down, and sifted through a sieve with 3-mm mesh.

Figure 1 shows schematically the experimental unit. The unit consists of an electroosmotic cell, a dc power supply, and devices for measuring the pH, current strength, and voltage. The electroosmotic cell is divided by perforated membranes into three compartments: cathode, anode, and that for a soil sample. The total surface area of perforations in each membrane is 10 cm^2. The perforated membranes are covered with filter paper. The cross section of the unit is 5.1×5.3 cm^2. The lengths of the soil compartment and electrode compartments are 8.3 and 5.5 cm, respectively. The platinum electrodes are installed at the minimal spacing from the membranes. A constant level of solution in the compartments is ensured by overflow of the excess solution into the receiving flasks through the drain pipes.

In our experiments, we used readily water-soluble nonionic surfactants Triton X-100 (9-10-oxyethylated isooctylphenol $R–C_6H_4–O(C_2H_4O)_mH$, where R is the isooctyl radical, (m = 9, 10), OS-20 [monoalkyl ethers of polyethylene glycol prepared from primary aliphatic alcohols $C_nH_{2n+1}O(C_2H_4O)_{20}H$, n = 14–18], and ALM-10 [monoalkyl ethers of polyethylene glycol prepared from primary aliphatic alcohols $C_nH_{2n+1}O(C_2H_4O)_{10}H$, n = 12–14]. The critical micelle concentration (CMC) of the nonionic surfactants tested were as follows (M): Triton X-100 9×10^{-4} M, OS-20 2×10^{-4}, and ALM-10 1.6×10^{-4} [15, 16].

The effect of nonionic surfactants Triton X-100 and OS-20 on the electroosmotic flow through a soil sample was studied by the following technique. The air-dried soil sample was moistened with aqueous solutions containing chelating agent and nonionic surfactant to moisture-saturated state. The moisture-saturated capacity of the soil sample used in our experiments was 0.47 ml H_2O per 1 g air-dried soil. The pH of the chelating agent (HEDP) solution was adjusted to 6–8 by adding 40% NaOH. The concentration of the chelating agent was 1×10^{-2} M; the surfactant concentration was varied from 0 to 10-fold CMC and higher. The moistened soil sample was allowed to stand in a dessicator for 1 day to attain equilibrium. After equilibration the soil sample was placed in the strictly horizontal soil compartment of the experimental unit. The aqueous solution containing the surfactant and chelating agent in amounts equal to those in the pore solutions (pH 6–8) was poured into the anode compartment. The presence of the surfactant in the anode solution ensures its constant concentration in the soil sample throughout the experiment. The cathode compartment was filled with 1×10^{-2} M HEDP solution with pH equal to that in the anode compartment. The solution volume in both the anode and cathode compartments was 150 cm^3. Under these conditions, the surface of the liquid phase in the electrode compartments coincides with level of the overflow pipes. The weight of the moist soil sample was 445 g (330 g of air-dried soil). The level of the soil surface in the soil compartment exceeds the level of the solution surface in the side compartments by 3–4 mm. The higher level of the soil surface prevents overflow of the anode and cathode solutions above the soil

sample. The cathode solution volume drained into the receiving flask was intermittently balanced by pouring an equal amount of the fresh solution into the anode compartment.

In the course of electroosmosis, the pH in both the anode and cathode compartments was adjusted to 6–8 by adding concentrated sulfuric acid and 40% NaOH. We used the concentrated reagent solutions to eliminate the inaccuracy in determining the rate of the electroosmotic flow V_{eo} due to dilution.

The field strength E between the electrodes was 2 V cm^{-1}. The experiments were carried out at room temperature. Table 1 shows our results concerning the influence of the surfactant concentaration on V_{eo} in the presence of 1×10^{-2} M HEDP.

The electrokinetic treatment was used by us for decontamination of the soil sample to remove both moderately volatile [chlorobenzene (CB)] and highly volatile [trichloroethylene (TCE)] organic compounds. The rate of TCE evaporation exceeds that of CB by more than a factor of 3.5 [17].

In decontamination of the soil sample to remove chlorobenzene, ALM-10 and HEDP were used as nonionic surfactant and chelating agent, respectively. In removal of tricloroethylene, Triton X-100 was used instead of ALM-10 as the nonionic surfactant, all other factors being the same.

The experiments on decontamination of the soil sample to remove HOC were carried out as follows. A certain amount of HOC was added to an air-dried soil sample; the sample was thoroughly mixed and allowed to stand for 1 day for equilibration. Thereafter, the soil sample was treated with an aqueous solution containing nonionic surfactant and chelating agent and kept for 1 day. After electrokinetic treatment, the content of CB and TCE was determined in the electrode and soil compartments. Chlorobenzene and trichloroethylene were recovered from the anode and cathode solutions and soil sample by treatment with hexane at the following ratios of the organic and aqueous phases: anode solution 3 : 1, cathode solution 3 : 1, and soil pore solution 2 : 1. The chlorobenzene content was determined spectrophotometrically on an M 40 UV-VIS spectrophotometer, TEC was determined by gas chromatography on an HP-5890 gas chromatograph with an MSD-5972 mass-selective detector.

Our data on electroosmotic removal of CB from a sample of soddy-podzolic soil preliminarily contaminated with this organic compound are given in Table 2 and Fig. 2.

Table 1. Effect of surfactant concentration on the electroosmotic flow rate V_{eo}

Reagent, M	Surfactant concentration, M	V_{eo}, ml h^{-1}
1×10^{-2} KCl	0	2.0 ± 0.6
1×10^{-2} HEDP	0	6.0 ± 6.0
1×10^{-2} HEDP + OS-20	2×10^{-3}	5.5 ± 0.6
1×10^{-2} HEDP + Triton X-100	9×10^{-3}	5.3 ± 0.6
	2.7×10^{-2}	4.8 ± 0.6

We found that introduction of various surfactants into the soil sample decreases the electroosmotic flow rate. As seen from Table 1, at the same ratios of the surfactant content in the pore solution to CMC, introduction of Triton X-100 decreases V_{eo} to a larger extent than that of OS-20. These results show also that, with the Triton X-100 concentration in the pore solution increasing from 0 to 2.7×10^{-2} M, V_{eo} decreases by approximately 20%. However, although the nonionic surfactant makes lower the electroosmotic flow rate, the acceleration of osmosis under the action of the chelating agent remains significant even at surfactant concentrations substantially exceeding CMC. For comparison it should be noted that for a soil sample treated with 1×10^{-2} M KCl V_{eo} is equal to 2.0 ± 0.6 ml h^{-1}.

In order to intensify the transfer of organic toxic impurities into the pore solution, the nonionic surfactant should be introduced in amounts much exceeding the CMC. Under these conditions, the colloid dissolution of HOCs may occur via both solubilization and formation of microemulsions [18].

We found that, in electrokinetic treatment of the soil sample contaminated with HOCs, the toxic contami-

E, V cm^{-1}	V_{eo}^{av}, ml h^{-1}	N	Chlorobenzene amount (g) and concentration (%) after electrokinetic experiment				Degree of soil decontamination from chlorobenzene
			in cathodic solution	in soil sample	in anodic solution	total	
0	0	0	0.05 (12.5)	0.26 (75)	0.05 (12.5)	0.36 (100)	28
2	5.1	1.6	0.17** (47**)	0.14 (39)	0.05 (14)	0.36 (100)	61

* E field strength; (V_{eo}^{av}) average electroosmotic flow rate; (N) number of volumes of the pore solution transferred from soil sample by osmotic flow during the electrokinetic experiment.

** Chlorobenzene amount (g) and concentration (%) in both cathodic solution and corresponding receiving flask.

nants are transferred not only to the cathode but also to the anode compartment.

This fact shows that, along with the transfer of an HOC with electroosmotic flow into the cathode compartment, HOC also passes into the anode compartment by diffusion. However, it is the electroosmotic flow that contributes to the greatest extent to the total transfer of the contaminants. As seen from Table 2, chlorobenzene is equally distributed between the cathode and anode compartments in the absence of electric current. At the same time, in the presence of the electroosmotic flow, the contaminant concentration in the cathode compartment exceeds that in the anode compartment by a factor of 3.4. For example, at $E = 2$ V cm^{-1} the amount of the contaminant removed mainly by the electroosmotic flow increases by a factor of 2.2 as compared with that via diffusion (at $E = 0$).

Figure 2 shows the time dependence of both the electroosmotic flow rate and the current in electrokinetic treatment of a soil sample contaminated with chlorobenzene. The gradual increase in the current in the course of an electroosmosis under constant voltage is indicative of increase in the conductivity of solutions. With pH maintained at 6–8, we observed an increase in the current in all the experiments on electrokinetic treatment of soddy-podzolic soil. In our opinion, the increase in the current is caused by intermittent neutralization of the cathode and anode solutions in the course of electrokinetic treatment.

In the experiments on soil decontamination to remove TCE and CB, we found that, with increasing surfactant concentration in pore solution, the rate of removal of these contaminants grows. For example, with the Triton X-100 concentration increasing from 9×10^{-3} to 2.7×10^{-2} M, the average rate of contaminant removal increases by approximately a factor of 3.

Our experiments showed (Table 2) that, after an uninterrupted 45-h electrokinetic treatment of soil sample contaminated with chlorobenzene, 61% of this contaminant was removed. In this experiment, the initial chlorobenzene content in the soil sample was 0.12 wt %, and the ALM-10 concentration in pore solution, 2.8×10^{-3} M. The soil sample contaminated with TCE was electrokinetically treated for 34 h in the presence of 9×10^{-3} M Triton X-100 in the pore solution. Such treatment lowered the contaminant content from 0.1 to 0.015 wt %, i.e., 85% of the contaminant was removed. Comparison of our experimental results on TCE removal from soil sample with those reported in [7] shows that the use of a mixed reagent containing chelating agent and neutral surfactant increases the efficiency of electroknetic decontamination of soil to remove this toxic impurity.

Our experiment showed also that TCE is removed from soil faster than CB. We believe that this difference is caused by hindrance to CB solubilization in pore solution.

CONCLUSIONS

(1) Introduction of nonionic surfactants into a soil sample in amounts significantly exceeding the critical micelle concentration in pore solution decreases the electroosmotic flow rate in electrokinetic decontamination of soil to remove organic toxic impurities. However, the overall increase in the volume rate of the electroosmotic flow under the action of HEDP present in solution as the chelating agent remains significant.

(2) Treatment of a soil sample with mixed reagent containing chelating agent and surfactant in the electrokinetic technique for removal of toxic hydrphobic organic compounds substantially raises its efficiency,

as shown by experiments on removal of chlorobenzene and trichloroethylene from soddy podzolic soil.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Monitoring of the Sources of Environmental Pollution with Crude Oil

O. Yu. Begak and A. M. Syroezhko

St. Petersburg State Technological Institute, St. Petersburg, Russia;
Mendeleev All-Russian Research Institute of Metrology, St. Petersburg, Russia

Received December 28, 2000

Abstract—The possibility of preliminary identification of sources of environmental pollution with crude oil was studied by IR Fourier spectroscopy, gamma-ray spectrometry, chromatography–mass spectrometry, and capillary gas-liquid chromatography with oil samples from six fields of the Khanty-Mansi Autonomous District and samples of soil and ground water contaminated with these oils.

Conclusive identification of sources of pollution with oil is the most important environmental problem. At present nearly 160–170 Mt of crude oil is recovered annually in the Khanty-Mansi Autonomous District, which is more than half of the oil production in Russia. At such a scale of oil recovery, environmental pollution due to various accidents on the pipelines is inevitable. However, determining the culprit is rather difficult because of the absence of reliable procedures for identifying the origin of a crude oil. Such a problem is dealt with for the first time for a single geographical region with a large number of oil wells located in rather close proximity.

In this work, we attempted to determine the differences in the composition of six oil samples recovered from various fields of Khanty-Mansi Autonomous District and two samples of contaminated soil and water. It should be noted that, when brought in contact with soil and water, oil undergoes various transformations depending on the temperature gradient, humidity, solar activity, wind rose, etc. (typical of a given geographical region [1]) and proceeding at different rates for different petroleum hydrocarbons. In 1994, the Ministry for Environmental Protection and Natural Resources of the Russian Federation issued an instruction on how sources of water pollution with crude oil are to be identified, based on successive use of IR spectroscopy and gas-liquid chromatography [2]. In addition, in 1993, the Federal Department of Hydrometeorology and Environmental Monitoring brought into use "The System of Identification of Oil Spillages in Sea" [3], based on spectrophotometry and high-pressure liquid and capillary chromatography. The above documents were taken into account in this study.

EXPERIMENTAL

Crude oil samples from six fields (Alekhinskoe, Lyantorskoe, Prirazlomnoe, Priobskoe, Krasnoleninskoe, and Trekhozernoe) and samples of soil (Alekhinskoe field) and water (Petelinskoe filed) contaminated with oil were taken in November 1997 (Table 1).

1070-4272/01/7404-0636 $25.00 © 2001 MAIK "Nauka/Interperiodica"

The samples were studied using IR spectrometry, capillary gas-liquid chromatography (GLC), chromatography–mass spectrometry, and gamma-ray spectrometry.

The IR spectra were recorded on computerized IR Fourier spectrometer (FSL-05 software, SpbInstruments, St. Petersburg) in automated mode in the 650–800 cm^{-1} region (resolving power 1 cm^{-1}) in 80-μm thick cells with KBr windows [4].

The capillary GLC of the oil samples was performed on a Tsvet-500 chromatograph equipped with a flame-ionization detector and a quartz capillary column (0.32 mm in diameter and 50 m long) with OV-101 stationary phase.

The chromatography–mass spectrometry of crude oil, soil, and water samples was carried out on an MD 800 unit with a capillary column and a system for computer processing of the results.

The gamma-ray spectra were registered on a gaged gamma-ray spectrometer with a DGDK-80V-3 Ge(Li) semiconductor detector, equipped with an ES 1840 PC for automated recording and processing of the results. Samples of oil, soil, and flooded oil (300 ml volume) were placed in a special cell on the semiconductor detector. Owing to the low specific activity of the samples, the gamma-ray spectra of the samples were accumulated for 8 h.

The IR spectra of crude oil samples recorded on an IR Fourier spectrometer are presented in Fig. 1. We compared the spectra in the 600–1800 cm^{-1} range by means of computer subtraction of one spectrum from another, with the maximum error in recording the optical absorption of no more than 0.5%. Curve 1 corresponds to the absorption spectrum of sample no. 1. The other curves were obtained by subtraction of the spectra of the other samples from the spectrum of sample no. 1. As seen, the resulting spectra exhibit significant differences in the "fingerprint" area, except the spectrum of sample no. 6 (Table 1) for which the difference in the intensities of most of the bands is smaller than 10%. Nevertheless, the absorption spectra of the samples in question exhibit significant differences in the 650–800 cm^{-1} range in Fourier absorption (Fig. 2). Thus, the Fourier spectrometry allows reliable identification and distinguishing of various sorts of crude oil as environmental contaminants, including oil in soil and water. It was found that a short-term UV irradiation with simultaneous bubbling of oxygen through the samples (artificial aging) did not give rise to any new bands and did not cause significant transformation of the existing bands (Fig. 3).

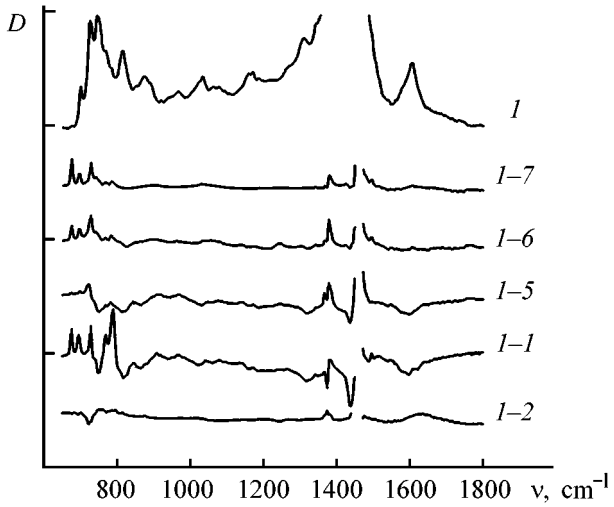

Fig. 1. Spectra of crude oil samples. (*D*) Optical density and (ν) wave number; the same for Figs. 2 and 3. (*1*) Sample no. 1; (*1–1*, *1–2*, *1–5*, *1–6*, *1–7*) the differences of the spectra of sample no. 1 and sample nos. 2, 4, 5, 6, and 7, respectively. Runouts at 1450 cm^{-1} are due to the low transmission of the sample. The distance between the marks on the vertical axis corresponds to a change in *D* by 1; the same for Figs. 2 and 3.

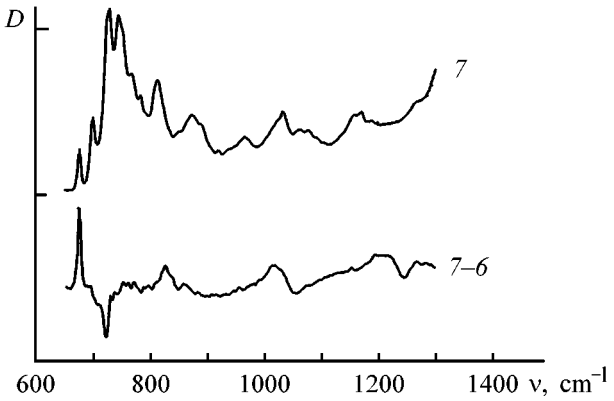

Fig. 2. Comparison of the spectra of sample nos. 6 and 7. (*7*) Sample no. 7; (*7–6*) the differences of the spectra of sample nos. 7 and 6 (Magnification ×5).

The chromatographic data showed that the oil samples from the Lyantorskoe and Petelinskoe fields differ significantly from the other samples, whereas the composition of the other oil samples is nearly the same. We found that the quantitative and qualitative reproduction of chromatograms (peak intensity and retention time) recorded on a Tsvet-500 chromatograph are insufficient for reliable identification of oil samples.

Investigation of the oil samples by chromatography-mass spectrometry before and after aging (heating to 90°C, UV irradiation with a 1000-W lamp) showed

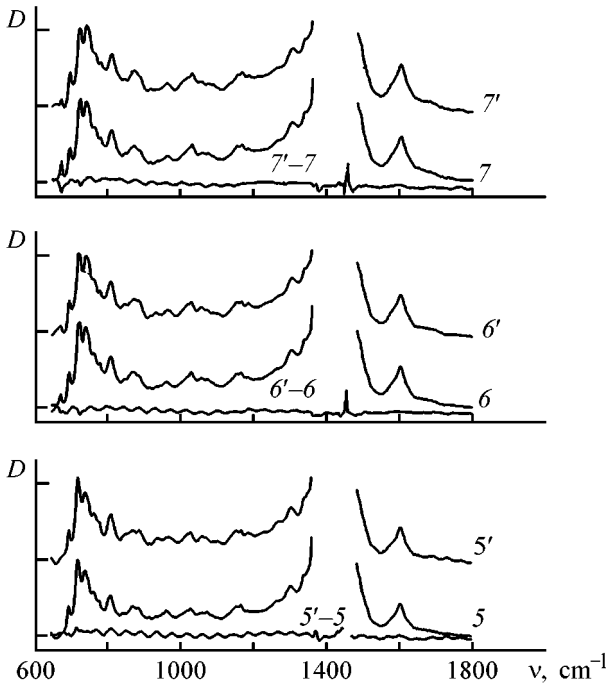

Fig. 3. Comparison of the spectra of sample nos. 5–7. Spectra registered (*5–7*) before and (*5*′*–7*′) after aging; (*5–5*′, *6–6*′, *7–7*′) the difference of the spectra of the corresponding crude oil samples.

that the ratio of ^{12}C and ^{13}C isotopes is nearly constant in all of the oil samples studied. Their hydrocarbon compositions are also similar, with slight difference observed only in the content of isopropenoid alkanes (pristane, phytane, and norpristane). However, these differences are not so significant as to ensure reliable identification of the initial oil samples.

Since the crude oil in each field occurs in rock materials differing in chemical composition and content of natural nuclides (NRNs) [5], the content of NRN in the oil samples taken from different fields must also be different (Table 2). All the samples contain nuclides of the thorium and uranium series, and the soil sample, also potassium-40. The samples differ in qualitative radionuclide composition, except sample nos. 5 and 7 exhibiting nearly twofold difference in the content of bismuth-214. As seen from Table 2, gamma-ray spectrometry only allows identification of the potential source of oil pollution using seven nuclides: four members of the thorium series (thallium-208, bismuth-212, lead-212, and actinium-228), two members of the uranium series (bismuth-214, lead-214), and potassium-40 (for soil samples).

Thus, each crude oil sample taken from a different field is characterized by individual nuclide composition. It should be noted that the total content of radioactive nuclides in the samples of the Khanty-Mansi oil district is relatively low. The highest content of radionuclides was determined for sample no. 3 (soil sample taken from a spillage territory at the Alekhinskoe field), whose specific activity of 23.8 ± 4.2 Bq kg^{-1} is more than an order of magnitude smaller than the maximal permissible level (370 Bq kg^{-1} according to nuclear safety regulations NBR-96). In the other oil samples, the specific activity is even lower and nuclides of the thorium and uranium series were only recorded owing to the high sensitivity of gamma-ray spectrometry (special computer program was used in processing the obtained gamma-ray spectra). Further study of oils by the given method requires wider statistics. It should be noted that this procedure, combined with the other methods, may be promising for oil identification in the case of two and more sources of oil pollution.

Table 2. Data of gamma-ray spectrometric analysis of oil samples

Sample no. (according to Table 1)	Specific activity A_s, Bq kg^{-1}					
	uranium series		thorium series			
	^{214}Bi	^{214}Pb	^{208}Tl	^{219}Bi	^{212}Pb	^{228}Ac
1	–	–	–	–	–	5.3 ± 7.5
2	–	4.8 ± 4.7	–	–	–	8.9 ± 6.0
3*	3.2 ± 2.6	6.0 ± 4.3	3.7 ± 2.0	–	5.3 ± 3.9	13.3 ± 6.0
4	–	–	–	–	–	–

6	11.5 ± 12.5	–	2.7 ± 2.1	–	–	–
7	24.8 ± 10.6	11.8 ± 6.1	–	–	–	–
8	10.9 ± 15.7	15.1 ± 10.1	–	–	–	5.5 ± 4.7

* Potassium-40 was found only in sample no. 3 (soil), its specific activity was 157.5 Bq kg^{-1}.

CONCLUSIONS

(1) A study of six samples from different oil fields of Khanty-Mansi Autonomous District demonstrated that it is advisable to perform preliminary search for the source of oil pollution of soil and water by means of IR Fourier spectroscopy and gamma-ray spectrometry.

(2) Chromatography–mass spectrometry and capillary chromatography are of little use in solving this environmental problem.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Dispersion and Coalescence in Fluid-Gas Jet Apparatus with Elongated Mixing Chamber

A. N. Blaznov, V. A. Kunichan, and D. V. Chashchilov

Biisk Technological Institute of Polzunov Altai State Technical University, Biisk, Russia

Received October 16, 2000

Abstract—The problem of application of fluid-gas jet apparatus with elongated cylindrical mixing chamber as mixers is considered. Results obtained in studying the dispersion and coalescence of bubbles of the gas phase are presented. The obtained experimental data are processed in terms of Kolmogorov's theory of isotropic turbulence.

Fluid-gas jet apparatus can be effectively used as absorbers. Their application in chemical, food, and pharmaceutical industries to remove noxious impurities from gases to be discharged into the atmosphere has been described [1–3]. Fluid-gas jet apparatus with elongated (no less than 30–35 diameters long) cylindrical mixing chamber show promise as absorbers of this kind. Such apparatus are characterized by simple design of the mixing chamber (without confuser or diffuser) and make it possible to achieve high injection coefficients [3]. There exists a procedure for calculating these apparatus as water-jet vacuum pumps [3, 4]. However, the available published data are insufficient for calculating the absorption characteristics of jet apparatus with elongated mixing chamber.

It is known that the intensity of absorption is determined by the interface area and mass-transfer coefficient. In [1, 2], studies were reported concerned with jet-injection shell-and-tube absorbers similar in design to fluid-gas jet apparatus with elongated cylindrical mixing chamber. The presented equations enable calculation of averaged values of the interface surface area at uncontrolled gas content. With fluid-gas jet apparatus allowing control over the injection coefficient and, consequently, over the gas content, evaluation of their mass-exchange characteristics requires such calculation techniques which take into account, together with other factors, the dependence of the interface surface area on the gas content and residence time of the gas-fluid emulsion in the mixing chamber of the absorber.

A schematic of an absorber based on a jet apparatus with elongated mixing chamber is presented in Fig. 1. The working fluid is delivered at high velocity into the mixing chamber and is mixed there with the gas being injected, to form a gas-fluid emulsion. Two zones can be conventionally distinguished in the mixing chamber, differing in the flow motion modes [3, 5]. The first zone is that of unsteady flow, in which the jet of the working fluid expands, is mixed with the gas phase, and fills the entire cross-section of the mixing chamber at some distance L from the nozzle exit. This zone is characterized by enhanced turbulence. At a distance L from the nozzle exit the

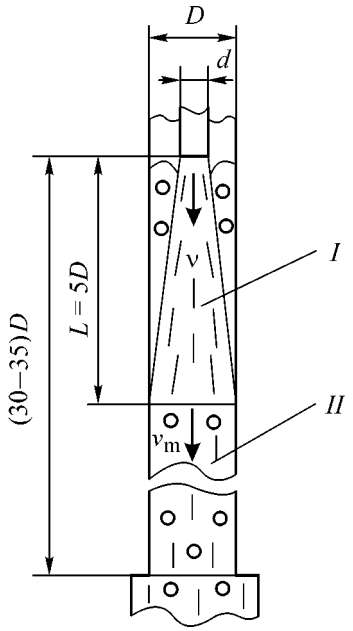

Fig. 1. Schematic of jet absorber. Flow zone: (*I*) unsteady and (*II*) steady.

1070-4272/01/7404-0640 $25.00 © 2001 MAIK "Nauka/Interperiodica"

intensity of agitation decreases and the gas-fluid flow passes into the steady-flow zone in which a homogeneous gas-fluid emulsion moves. Mainly dispersion of gas bubbles in the turbulent flow is observed in zone *I*, and coalescence of these bubbles, in zone *II*.

The process of dispersion in a turbulent flow can be described using Kolmogorov's theory of isotropic turbulence [6]. In this case, the expression for determining the average volume-surface diameter of gas bubbles, $d^0_{32_{\varphi\to 0}}$, at very low content of the dispersed phase ($\varphi \to 0$) has the form

$$d^0_{32_{\varphi\to 0}} = K(\sigma^{3/5}/\rho^{1/5}\varepsilon^{2/5}), \quad (1)$$

where K is a constant, σ the surface tension (N m^{-1}), and ρ the density of the continuous phase (kg m^{-3}).

The parameter ε in (1), named the energy dissipation rate, is calculated as

$$\varepsilon = N/V, \quad (2)$$

where N is the amount of energy dissipated in the turbulent flow per unit time (W), and V is the volume within which this occurs (m^3).

Applying this approach to a jet absorber, we define the energy loss by fluid jet per unit time in the unsteady-flow zone (Fig. 1) as

$$N = Gv^2/2 - Gv_m^2/2, \quad (3)$$

where G is the mass flow rate of the working fluid (kg s^{-1}), v the velocity of the fluid jet at the nozzle exit (m s^{-1}), and v_m the fluid velocity in the mixing chamber (m s^{-1}).

The condition for fluid flow continuity in the nozzle and the chamber gives

$$N = \frac{\rho v^3}{2}\frac{\pi d^2}{4}\left(1 - \frac{d^4}{D^4}\right), \quad (4)$$

where d and D are the diameters (m) of, respectively, the nozzle and the mixing chamber.

The volume of the unsteady-flow zone is approximately equal to the volume of a cylinder of diameter D and length L:

$$V = (\pi D^2/4)L. \quad (5)$$

The length of the mixing chamber can be expressed in terms of the mixing chamber diameter as $L = mD$. The coefficient m varies within the range from 4.5 to 6 [7–9].

Thus, the rate of energy dissipation can be finally found from the expression

$$\varepsilon = \frac{\rho v^3 d^2}{2mD^3}\left(1 - \frac{d^4}{D^4}\right). \quad (6)$$

It is noteworthy that at d/D ratios smaller than 0.5 the numerical value of the expression in parentheses in (6) is close to unity. In this case, expression (6) can be simplified:

$$\varepsilon = \rho v^3 d^2/2mD^3. \quad (7)$$

The effect of gas content φ on the bubble diameter can be taken into account by means of a linear function, $f(\varphi) = 1 + k\varphi$, where k is a proportionality factor [10].

Then, the final expression for determining the diameter of bubbles formed in the unsteady-flow zone takes the form

$$d^0_{32} = K\frac{\sigma^{3/5}}{\rho^{1/5}\varepsilon^{2/5}}(1 + k\varphi). \quad (8)$$

In further motion of the gas-fluid emulsion in the turbulent flow along the mixing chamber in zone *II* (Fig. 1), the interface surface area changes through coalescence of separate bubbles. This phenomenon is due to collisions of bubbles under the action of turbulent pulsation. The process of bubble coalescence in the fluid–fluid systems was described in [11]. A formula was proposed for calculating the drop collision frequency in terms of Kolmogorov's theory of isotropic turbulence. For a monodisperse heterogeneous system the collision frequency can be determined for a particle (drop, bubble) from the expression [11]

$$\theta = \left(\frac{24\varphi w^2}{d_b^2}\right)^{1/2}, \quad (9)$$

where w^2 is the averaged squared rate of turbulent pulsation and d_b is the bubble size (m).

According to Kolmogorov's theory, the averaged squared rate of turbulent pulsation

$$w^2 = C\left(\frac{\varepsilon_{dr} d_b}{\rho}\right)^{2/3}, \quad (10)$$

where C is a constant and ε_{dr} is the rate of energy dissipation in the steady-flow zone.

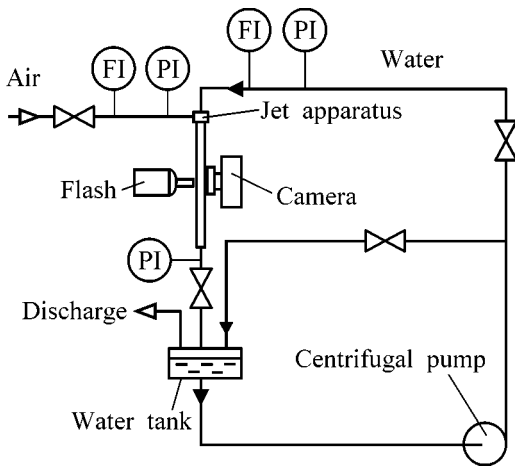

Fig. 2. Schematic of the experimental setup.

For a cylindrical mixing chamber, the following expression can be written for calculating the average ε_{dr} as flow losses in a pipe [12]:

$$\varepsilon_{dr} = \lambda \frac{\rho v_m^3}{2D}, \qquad (11)$$

where λ is the friction coefficient.

The coalescence frequency θ_c is related to the collision frequency θ of a bubble and the collision efficiency factor K_e by [11]:

$$\theta_c = K_e \theta. \qquad (12)$$

If n_τ gas bubbles are present in a unit volume of the flow at a current instant of time, then $n_\tau\theta/2$ collisions occur in unit volume. If the initial number of bubbles in a unit volume is denoted by n_0, and the number of bubbles coalesced by the given instant of time, by n, then the following equation can be written for the frequency of collisions occurring in a unit volume:

$$\theta^V = \frac{(n_0 - n)}{2}\theta. \qquad (13)$$

Then the coalescence frequency in a unit volume can be found from

$$\theta_c^V = K_e \frac{(n_0 - n)}{2}\theta. \qquad (14)$$

Since $\theta_c^V = dn/d\tau$ and the number and diameter of bubbles are related by

$$d_b = \left[\frac{6\varphi}{\pi(n_0 - n)}\right]^{1/3}, \qquad (15)$$

substitution of (9) and (15) into Eq. (14) and integration of the obtained expression from, respectively, 0 to τ and 0 to n yields

$$d_b = d_b^0\left[1 + K_e \frac{\varphi^{1/2}(\varepsilon_{dr}/\rho)^{1/3}\tau}{(d_b^0)^{2/3}}\right]^{3/2}, \qquad (16)$$

where d_b^0 is the bubble diameter at the initial instant of time (m).

Expression (16) can be used for describing the dependence of the bubble diameter on the time of emulsion motion in the mixing chamber of the jet apparatus at a given gas content. For polydisperse systems, the average volume-surface bubble diameter d_{32} is used as a quantity determining the bubble size d_b.

EXPERIMENTAL

With the aim to study experimentally the dispersion and coalescence of gas bubbles and to determine numerically the coefficients K, k, and K_e appearing in (8) and (16), an experimental setup shown schematically in Fig. 2 was developed. The setup comprises a vertical jet apparatus with a replaceable nozzle and an elongated cylindrical glass chamber of the same kind, a water tank, and a centrifugal pump. The setup is equipped with means of control and monitoring of the rate and pressure of the working gas and injected gas flows, and also with a camera and a flash for recording the bubble size.

The setup was used to study the dispersion and coalescence of the gas phase in the mixing chamber of the jet apparatus for the water–air system. The experiments were carried out for nozzles 4, 6, 8, 10, and 12 mm in diameter and mixing chambers of diameter 10 and 15 mm. The jet velocity at the nozzle exit was varied within 0.86–25 m s^{-1}. The temperature of fluid and gas was maintained at 25°C. The average volume-surface bubble diameter d_{32} was determined photographically.

The bubble size at the initial instant of time was determined by taking photographs of the gas-fluid emulsion at a distance $L = 5D$ from the nozzle exit at volume gas content φ of 0.01, 0.1, and 0.2.

Figure 3 shows as points the experimental data obtained in determining the average volume-surface bubble diameter d_{32}^0 at the initial instant of time in relation to the energy dissipation rate calculated using (7). The solid lines represent the results of experimental data processing by the least-squares method with the use of Eq. (8). $K = 1.05$ was found at low gas

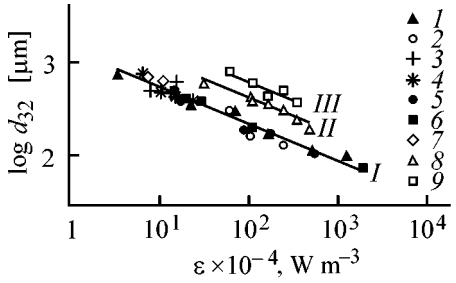

Fig. 3. Bubble size d_{32} vs. energy dissipation rate ε for an apparatus with nozzles of diameter d and mixing chambers of diameter D at gas content φ. d (mm), D (mm), φ: (*1*) 4, 15, 0.01; (*2*) 6, 15, 0.01; (*3*) 10, 15, 0.01; (*4*) 12, 15, 0.01; (*5*) 4, 10, 0.01; (*6*) 6, 10, 0.01; (*7*) 8, 10, 0.01; (*8*) 6, 15, 0.1; (*9*) 6, 15, 0.2. (*I–III*) Calculated curves at gas content φ of, respectively, 0.01, 0.1, and 0.2.

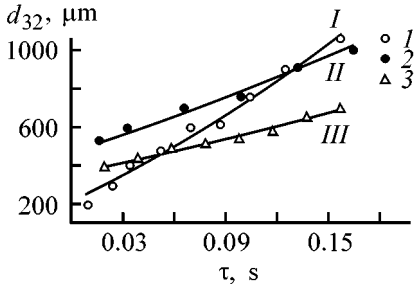

Fig. 4. Bubble size d_{32} vs. residence time τ of bubbles in the mixing chamber for an apparatus with nozzle of diameter d = 4 mm and mixing chambers of diameter D at fluid jet velocity at the nozzle exit v and gas content φ = 0.3. D (mm), v (m s^{-1}): (*1*) 10, 25; (*2*) 10, 13.3; and (*3*) 15, 25. (*I–III*) Calculated curves.

content, and k = 9, at φ = 0.1 and 0.2. The calculated values are in agreement with experiment within ±15%.

The variation of the interface area along the mixing chamber as a result of gas bubble coalescence was studied in several flow motion modes at a gas content that is the maximum possible for the photographic method to be applicable. The results obtained in a number of experiments in a jet apparatus with a nozzle 4 mm in diameter and mixing chambers 10 and 15 mm in diameter at a gas content φ = 0.3 are represented by points in Fig. 4 in the form of the dependence of the bubble size on the time of bubble residence in the mixing chamber. For comparison, the figure shows lines obtained by processing the experimental data by the least-squares method with the use of expression (16). It was found that the collision efficiency factor K_e = 0.014. The maximum difference between the calculated values and experimental data is ±10%.

CONCLUSIONS

(1) An approach to describing the dispersion and coalescence of the gas phase in fluid-gas jet apparatus with elongated mixing chamber, employed as jet absorbers, is proposed on the basis of Kolmogorov's theory of isotropic turbulence.

(2) The adequacy of the proposed approach is confirmed experimentally. Expressions are obtained for determining the average volume-surface diameter of gas bubbles in relation to the rate of energy dissipation in the fluid jet, volumetric gas content, and time of residence of gas bubbles in the mixing chamber of the apparatus. These expressions can be used to calculate mass exchange characteristics of jet absorbers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Synergistic Effects on Ion-Exchange Chromatographic Separation of Proteins

A. A. Demin, K. P. Papukova, E. S. Nikiforova, and E. N. Pavlova

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received June 7, 2000

Abstract—Formation of strong bonds between proteins and polyelectrolyte chains of ion-exchange sorbents gives rise to synergistic effects in multicomponent sorption and chromatographic separation of proteins. A series of heteronetwork-cross-linked polymeric bases with varied content of ionic groups was prepared. Consecutive sorption and cosorption of insulin and α-lactalbumin on these materials were studied.

Correct understanding of the interaction of multicomponent protein mixtures with the sorbent surface is very important in developing chromatographic procedures for recovery and purification of proteins. In most cases, studies of multicomponent sorption and chromatography are based on the concept on competitive sorption of the sorbate molecules on a limited number of sorption centers on the sorbent surface. At the same time, it is known that, at strong interaction of a protein with the sorbent surface, adsorbed protein layers with different structures and energies of intermolecular bonds are formed under certain conditions. Zimina *et al*. [1–2] observed formation of such nonuniform layers during interaction of γ-globulin with polyethylene or polydimethylsiloxane films and of human serum albumin with a film of siloxane-carbonate copolymer. The first, irreversibly or strongly adsorbed layer consists of molecules directly interacting with the surface active centers. The second layer contains molecules adsorbed on the active centers of protein molecules of the first layer.

The energy barrier preventing competitive protein sorption (causing "irreversible protein sorption") is due to either a change in the conformation of an adsorbed protein molecule [3] or multicenter interaction of the macromolecule with the surface [4]. For a protein to be desorbed, external conditions—solution pH, ionic strength, and content of an organic solvent—are to be changed.

Polymeric materials are the most preferable sorbents for recovery and purification of biologically active compounds (BACs). The high sorption capacities of these materials for BACs are due to the polyfunctional nature of the interaction with BACs and to the highly permeable crosslinked structure of the polymers having pores and channels larger than diameters of solvated molecules of a target compound. Ion-exchange sorbents with high capacity for proteins (up to several grams of protein per 1 g of the sorbent) were prepared in the course of studies aimed at improving the selectivity of protein sorption [5–7]. The target component was recovered under conditions providing the strongest sorption of the protein on the sorbent.

Studies of the consecutive sorption and cosorption of model protein pairs on ion-exchange sorbents of different types have shown that multicomponent protein sorption under the conditions of the strongest sorption, determined by pH, is complicated by synergistic effects: there is no desorption of one protein by another and, furthermore, the sorption of one protein grows in the presence of the other under static conditions [8–11]. It has been demonstrated that, at the same ratio between the components of a mixed protein solution and the sorbent, the protein content in the sorbent may depend on the sequence in which the proteins was brought in contact with the sorbent. The selectivity of protein sorption may be reversed during sorption.

The above data show that synergistic effects in multicomponent sorption are caused by strong bonding between a protein and a sorbent. After the sorption centers are filled, further binding is effected by protein–protein interactions. It is clear that synergistic effects deteriorate the protein separation, since fine chromatographic separation is only possible when the sorp-

1070-4272/01/7404-0644 $25.00 © 2001 MAIK "Nauka/Interperiodica"

tion energies of each component of the mixture are different. For efficient separation of the components, competitive sorption conditions are necessary.

Previously [12] we studied sorption of insulin and ribonuclease on Polysorb molecular sorbent as influenced by the degree of its sulfonation. It was found that realization of either synergistic effect or competitive sorption is determined by the number of ionic groups of the sorbent per protein molecule. However, protein separation on the Polysorb sorbent is complicated by strong hydrophobic interaction of the proteins with the sorbent matrix (macroporous copolymer of styrene with divinylbenzene). To determine the influence of synergistic effects on the protein separation, we prepared a series of cross-linked polymeric bases (CPBs) with the following properties: (1) hydrophilicity to prevent hydrophobic interactions, (2) variable content of ionic groups, and (3) heteronetwork-cross-linked structure providing high permeability for protein molecules. In the present study we analyzed the multicomponent sorption of proteins on these CPBs under static conditions and demonstrated how the kinetics of protein separation depends on the mechanism of the multicomponent sorption.

To determine the conditions for synthesis of hydrophilic structurally stable CPBs with varied content of ionic groups, we studied copolymerization of *N*-dimethylaminopropylmethacrylamide (DMAM) with *N*,*N*'-ethylenedimethacrylamide (EDMA) in aqueous solutions. Previously we showed [13] that DMAM copolymerizes with hexahydro-1,3,5-triacryloyltriazine in an aqueous solution under heterogeneous conditions to form structurally stable CPBs with strong swellability. Three-dimensional copolymerization of these monomers in aqueous or aqueous-organic solution yields highly hydrated copolymers. The structure of the resulting CPBs consists of both densely cross-linked regions containing microglobules and loosened regions disappearing on drying. Swollen cross-linked polymeric bases contain a large amount of the solvent, which ensures high permeability for BAC macromolecules.

Copolymerization of DMAM with EDMA in water also occurs under heterogeneous conditions to form CPBs of the ADE type (anion exchangers based on dimethylaminopropylmethacrylamide–ethylenedimethacrylamide copolymers). The monomer concentration in the solution is 20%. The relative swelling K_{rel}, expressed as the ratio of the swelling coefficient K_{swell} of the Cl form of CPB to that of the OH form and characterizing the structural stability of ADE CPBs, remains virtually the same (close to unity) on changing EDMA content in CPB (Fig. 1). Taking into account this fact, structurally similar hydrophilic CPBs with varied content of ionic groups $-N(CH_3)_2$ were prepared by copolymerization of appropriate hydrophylic nonionic amide with DMAM and EDMA [14]. *N*-(2-hydroxypropyl)methacrylamide (HPMA), which is similar in reactivity to DMAM and EDMA, was used as a hydrophilic nonionic monomer. The EDMA content was constant (10 mol %).

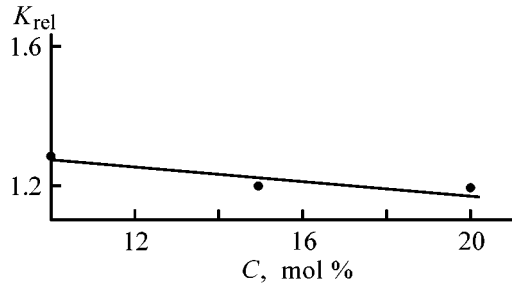

Fig. 1. Relative swelling coefficient K_{rel} of CPB vs. the content of the cross-linking agent *C*.

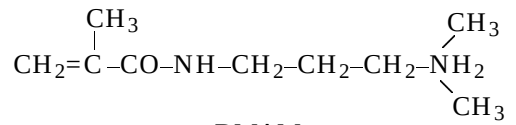
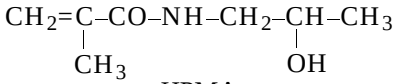
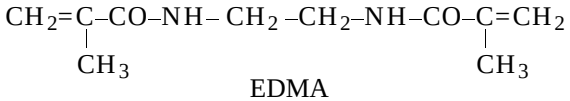


DMAM



HPMA



EDMA

A series of CPBs: ADE-10, ADGE-10-1, ADGE-10-4, and ADGE-10-10 was prepared. The first and the second figures in the CPB name denote the molar percentage of EDMA and the number of HPMA moles per mole of DMAM, respectively. GPE-10 is an EDMA–HPMA copolymer. Some properties of CPBs are summarized in Table 1.

Table 1. Properties of CPBs*

CPB	V_{sp}, ml g^{-1}	EC, mg-equiv g^{-1}	K_{rel}
ADE-10	10.0	5.0	1.3
ADGE-10-1	8.1	2.8	1.2
ADGE-10-4	7.7	1.2	1.2
ADGE-10-10	7.7	0.4	1.0
GPE-10	5.9	–	1.0

* V_{sp} and EC are the specific volume and the exchange capacity for chloride ion, respectively.

Table 2. Selectivity coefficient of protein sorption on CPB at pH 8.0

Sorbent	Selectivity coefficient	
	insulin	α-lactalbumin
ADE-10	2200	460
ADGE-10-1	1100	330
ADGE-10-4	230	90
ADGE-10-10	50	20
GPE-10	1	1

The degree of swelling of CPB weakly changes with the DMAM–HPMA ratio. The structural stability of CPB was estimated from the relative swelling coefficient K_{rel}. As seen from Table 1, K_{rel} changes weakly and approaches unity with decreasing DMAM content. This indicates that the CPB structure is stable during ionization. Thus, copolymerization of DMAM and HPMA with EDMA in a 20% aqueous solution yields structurally stable CPB characterized by strong swellability, irrespective of the terpolymer composition.

The ion-ion interaction between a protein and a sorbent can be controlled by the DMAM–HPMA ratio. Since the selectivity of sorption of model proteins (insulin and α-lactalbumin) on these CPBs at pH 8.0 falls with decreasing content of the ionic monomer and the proteins do not interact with GPE-10 (Table 2), we suggest that the sorption of these proteins on the CPB is mainly due to ion-ion interactions. The selectivity coefficients were calculated from the isotherm sections measured at low degrees of sorption.

The multicomponent sorption of proteins on the tested anion exchangers was studied under static conditions for the example of the insulin–α-lactalbumin pair at pH 8.0 (the conditions providing the maximal insulin sorption). When consecutive sorption was studied, the second protein was introduced after the attainment of equilibrium in the system sorbent–first protein. After the sorption was complete, the protein concentrations in the binary solution were determined by reversedphase high-performance liquid chromatography. Then the protein amount sorbed by 1 ml of the sorbent was calculated. When the cosorption was studied, a binary protein solution with the same weight concentrations of the components was used. The results are presented in the form of histograms (Fig. 2).

As seen from Fig. 2, in the case of the consecutive sorption on ADE-10, the second protein not only does not desorb the first protein but also promotes its additional sorption. In the case of cosorption, the total amount of proteins sorbed on ADE-10 is higher than the sum of the sorption capacities of the anion exchanger for the components, i.e., the proteins are sorbed by the synergistic mechanism. Addition of the second protein to the system comprising ADGE-10-1 and the first protein does not increase the sorption of the first protein. At the same time no desorption of the first protein is not observed either. Consecutive sorption of the proteins on ADGE-10-4 is a competitive process: addition of a solution of the second protein results in desorption of the first protein from the ion exchanger. Similarly, the mechanism of sorption of insulin and ribonuclease on the sorbents with different

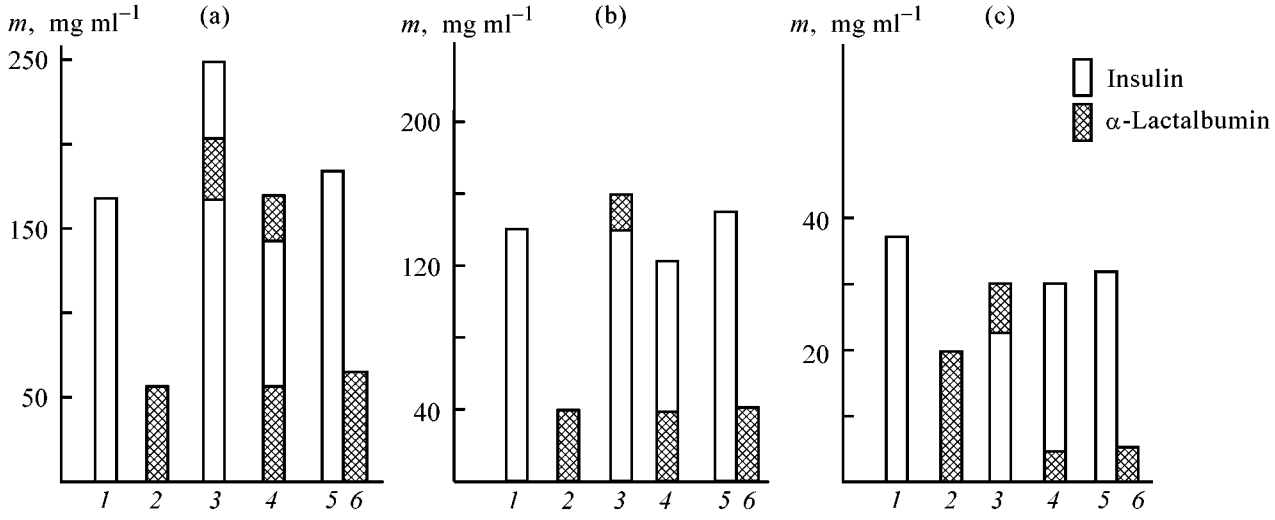


Fig. 2. Consecutive sorption and cosorption of insulin and α-lactalbumin on (a) ADE-10, (b) ADGE-10-1, and (c) ADGE-10-4. (*m*) Amount of protein sorbed by 1 ml of the sorbent. Sorption mode: (*1*, *2*) from separate component solutions, (*3*, *4*) consecutive, and (*5*, *6*) from two-component solution.

degrees of sulfonation goes from synergistic to competitive with decreasing content of the ionic groups in a sorbent.

To accelerate the protein sorption under dynamic conditions and to approach the conditions of equilibrium sorption, we aslo used composites based on the tested CPBs, so-called cellosorbents. Cellosorbents were prepared by impregnation of a highly permeable cellulose hydrate matrix with 3–10 μm sorbent particles in forming spherical cellosorbents granules [15, 16]. We prepared TsS-ADM-10 and TsS-ADG-10-4 cellosorbents with 100–315-μm granules. The exchange capacities of these materials for the chloride ion are 0.78 and 0.24 mg-equiv g^{-1} of dry sorbent, respectively. The water content in the hydrated sorbent is 90%.

In the dynamic experiments, a sorbent tested was placed in a 2×62-mm Milichrom steel column. A 1 mg ml^{-1} protein solution was fed at a 5 μl min^{-1} rate. A solution of the second protein was passed trough the column after the sorbent was saturated with the first protein. Then the column was washed with water and the proteins were desorbed with 0.3% orthophosphoric acid, with the eluate dived into fractions. It was shown preliminarily that the tested proteins are completely desorbed under these conditions. In each fraction, the protein concentration was determined by HPLC. When the cosorption was studied, we used a solution with the same concentrations of insulin and α-lactalbumin and a total protein concentration of 2 mg ml^{-1}.

When a solution of the second protein is passed through a column with ADE-10 and ADGE-10-1 saturated with the first protein, the desorption of the first protein is low. Probably the second protein substitutes only the molecules of the first protein sorbed by the protein-protein interactions. The sorption layer thus formed contains two proteins: the first is bound mainly to the amino groups of the sorbent and the second is sorbed owing to the protein–protein interactions. The content of insulin and α-lactalbumin in ADE-10 and ADGE-10-1 after passing a binary solution containing both the proteins is close to that in the initial solution. The eluate obtained in desorpton with an acid solution contains insulin and α-lactalbumin. The sorption properties of cellosorbents based on ADE-10 and ADGE-10-1 are similar. The composition of the eluate fractions formed in desorption from TsS-ADE-10 cellosorbent is shown in Fig. 3a. Thus, sorbents with high content of ionic groups are inefficient for the most economic frontal displacement processes. In the case of consecutive sorption on the ADGE-10-4 sorbent, the protein sorbed in the first step is completely desorbed with a solution of the second protein. When an insulin–α-lactalbumin solution is passed through a column packed with this sorbent, the sorbent is gradually enriched with insulin selectively sorbed under these conditions. The elution peak obtained after passing 2 ml of an insulin–α-lactalbumin solution through a column with TsS-ADGE-10-4 is shown in Fig 3b.

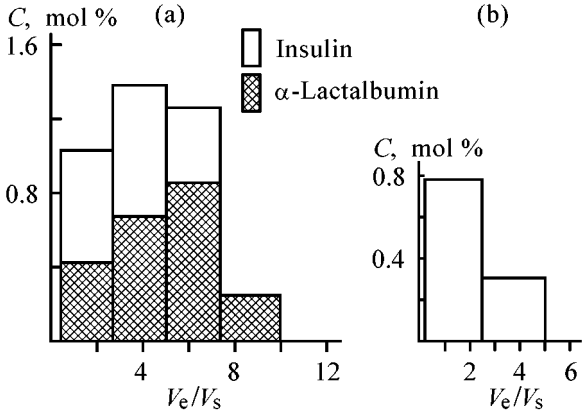

Fig. 3. Elution of proteins sorbed from an insulin–α-lactalbumin solution with equal weight concentrations of the proteins (C_{tot} = 2 mg ml^{-1}) on (a) TsS-ADE-10 and (b) TsS-ADGE-10-4. (V_e) Total eluate volume (ml), and (V_s) sorbent volume.

CONCLUSIONS

(1) Consecutive sorption and cosorption of model proteins (insulin and α-lactalbumin) on specially prepared heteronetwork polymeric bases with varied content of ionic groups (with capacity for Cl^- ranging from 0.4 to 5.1 mg-equiv g^{-1}) was studied under static conditions. With decreasing content of ionic groups in the sorbents, the protein sorption weakens, which leads to a competitive mechanism of multicomponent sorption.

(2) A study of the sorption-desorption kinetics of proteins on sorbents with varied content of ionic groups showed that the efficient frontal displacement process of ion-exchange chromatography is only possible in the case of competitive sorption.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Anion Exchangers Based on Allyl Compounds and Some Nitrogen- and Oxygen-Containing Monomers and Oligomers

E. E. Ergozhin, A. K. Chalov, R. A. Iskakova, and A. I. Nikitina

Abstract—Anion exchangers containing different basic groups and having good physicochemical and sorption properties were prepared by polycondensation of polyallylamine and various allyl halides, diglycidyl ethers of dihydroxybenzenes, and aromatic amines with some aliphatic polyamines.

Synthesis of allyl polymers with high chemical and thermal stability is being extensively studied [1–3]. New ion-exchange resins with high sorption capacity for transition metal ions have been prepared by polycondensation of allyl monomers with epoxy compounds. The kinetics and mechanism of reactions of various allyl compounds have been studied and described quantitatively [4–6]. Abdusattarova *et al*. [5] analyzed the kinetic features of radical polymerization of diallyl monomer formed from allyl bromide and piperidine. Pavlova *et al*. [6] studied the mechanism of intramolecular cyclization in radical polymerization of diallyl isophthalates, preceding gelation.

In this work, we studied the synthesis and properties of polyfunctional anion exchangers based on polyallylamine (PAA), allyl bromide (AB), allyl chloride (AC), diglycidyl ethers of resorcinol (DGER) and hydroquinone (DGEH), and various amines: polyethylenepolyamine (PEPA), polyethylenimine (PEI), and hexamethylenediamine (HMDA). The reaction kinetics were studied by polarography, IR spectroscopy, and chemical analysis.

EXPERIMENTAL

Diglycidyl ethers of resorcinol and hydroquinone were prepared by the procedure described in [7]. The content of epoxy groups, determined by the procedure described in [8], was 31.7 and 30.2%, respectively. The anion exchangers were prepared in dimethylformamide (DMF) at various temperatures. The resulting gel was cured at 80–120°C. Condensation of DGER and DGEH with PAA was performed at a temperature of 40 to 80°C for a time ranging from 1 to 2 h. When AG was used, the temperature and time of the reaction were 13–24°C and 0.5–2 h. The cured polymer was crushed and sifted, with the 0.25-mm fraction taken.

The static exchange capacity (SEC, mg-equiv g^{-1}), moisture content, swellability, and chemical and thermal stability of the anion exchangers were determined by the conventional procedures [9].

The polarographic study was performed on a PU-1 universal polarograph. The parameter $m^{2/3}t^{1/6}$ of the capillary was 4.38 $mg^{2/3}\ s^{-1/2}$. As reference electrode served saturated calomel electrode. As supporting electrolyte was used 0.02 M $(C_2H_5)_4NI$ solution in 50% DMF.

The IR spectra of the initial compounds and intermediate and final reaction products were recorded on a Specord M 80/M 85 spectrophotometer KBr pellets (200 mg KBr + 1 mg of a sample) or thin films between plates.

The IR spectra of DGER and DGEH contain the bands of epoxy groups in the ranges 850–950, 1200–1250, and 3000–3100 cm^{-1}. The bands at 1424 and 1000 cm^{-1} in the spectrum of allylamine are assigned to the double bond of the allyl group.

No bands of epoxy groups or the double bond of the allyl group were found in the IR spectrum of the anion exchanger prepared from PAA, DGER, and DGEH. The bromine number of the allylamine oligomer (6.3) [10] also suggests the opening of the double bonds.

Table 1. Influence exerted by the nature of the starting compounds on the nitrogen content, SEC, and sorption capacity of the anion exchangers

Anion exchanger based on	N, %	SEC, mg-equiv g^{-1}	Sorption capacity, mg-equiv g^{-1}		
			Cu^{2+}	Ni^{2+}	Co^{2+}
PEPA : AB : DGER	12.97	9.9	9.8	4.6	3.9
PEI : AB : DGER	16.55	8.7	7.7	4.1	3.9
HMDA : AB : DGER	6.56	5.0	5.0	3.5	3.1
PEPA : AC : DGER	13.15	10.2	10.2	5.4	5.3
PEI : AC : DGER	16.17	6.6	5.4	3.5	3.1
HMDA : AC : DGER	6.98	5.1	5.0	2.9	2.3
PEPA : AB : DGEH	11.02	8.9	8.6	4.0	3.6
PEI : AB : DGEH	15.40	7.8	7.2	4.0	3.4
HMDA : AB : DGEH	5.62	4.3	4.1	2.8	2.5
PAA : H_2O : DGER	8.57	6.2	4.3	3.1	3.0

Copolymers with the maximum exchange capacity (6.2 mg-equiv g^{-1}) are formed at PAA : DGER : H_2O = 0.3 : 0.7 : 2.5.

Water catalyzes the reaction of epoxy compounds with amines and increases the swellability of the resulting anion exchanger. At a deficiency of water the reaction mixture is overheated in the initial precondensation step, and the reaction becomes less homogeneous.

Copolymers prepared from allyl halides and DGER at high amine content in the reaction mixture are water-soluble or strongly swelling. The physicochemical properties of these anion exchangers deteriorate. For example, the SEC and swellability of the anion exchanger based on PEPA grow from 6.5 to 9.9 mg-equiv g^{-1} and from 6.1 to 8.4 mg l^{-1}, respectively, with the amine concentration increasing from 1 to 2 wt parts. The SEC of the anion exchanger based on PEI increases from 3.5 to 8.7 mg-equiv g^{-1} with increasing amine concentration from 1 to 3.5 wt parts. Copolymerization of HMDA at amine concentrations higher than 1 wt part yields soluble products.

We found that the exchange capacity of the anion exchangers based on PAA decreases to 2.6 mg-equiv g^{-1} with the fraction of the cross-linking agent increasing from 0.7 to 1.0 wt parts. As the DGER content increases from 1 to 2.5 wt parts, the SEC and the swellability of the anion exchangers based on allyl halides (AHs) decrease from 8.9 to 5.9 mg-equiv g^{-1} and from 9.3 to 5.2 mg l^{-1}, respectively, which is probably due to an increase in the cross-linking density. This makes lower the accessibility of the functional groups in ion exchange.

The physicochemical properties of the anion exchangers prepared at the optimal ratio of the starting components were studied as influenced by the temperatures of precondensation and curing. The exchange capacity of the ion exchanger increases from 5.3 to 9.9 mg-equiv g^{-1} on elevating the precondensation temperature from 13 to 24°C. As the curing temperature is raised from 80 to 120°C, the SEC of the anion exchangers decreases from 9.9 to 7.4 mg-equiv g^{-1}, which is probably due to an increase in the cross-linking density owing to deamination and dehydration.

The influence exerted by the nature of the initial components on the static exchange and sorption capacities of the anion exchangers is shown in Table 1.

The static exchange and sorption capacities of the anion exchangers for transition metal ions strongly depend on the amine nature. The SEC of the polymers prepared with PEPA, which is the most effective, is as high as 9.9–10.2 mg-equiv g^{-1}. The capacities are almost independent of the nature of allyl compounds and diglycidyl ethers (DGE).

The sorption capacity of all anion exchangers for copper(II) cations is high. Nickel(II) and cobalt(II) cations are more effectively sorbed by anion exchangers based on PEI, HMDA, and PAA.

Thus, the best preparation conditions of the anion exchangers based on DGER are as follows: PAA : H_2O : DGER = 0.3 : 0.7 : 2.5; precondensation temperature 80°C and time 2 h. The best conditions of condensation of AH with DEG are as follows: PEPA : AH : DGE = 2.0 : 2.0 : 1.5; PEI : AH : DGE = 3.5 : 2.0 : 1; HMDA : AH : DGE = 2 : 2 : 1.5; precondensation temperature 24°C and curing temperature 80°C; preparation time 2 h.

The chemical stability of the anion exchangers was estimated from the change in the exchange capacity in solutions of 5 N sulfuric acid, sodium hydroxide, and 10% H_2O_2. The polymers based on PEPA exhibit the lowest stability with respect to the oxidizing agent and sulfuric acid. A study of the thermal stability of the anion exchangers on heating at 100°C for 12 h in hermetically sealed ampules showed that the decrease in the capacity does not exceed 8%.

It was of interest to study the kinetic features of precondensation of AHs with DGEs and amines. Previously, the mechanism of polycondesation of allyl bromide, DGER, and PEPA has been studied by polarography, IR spectroscopy, and chemical analysis. This reaction has been found [11] to be a two-step process. In the first step, AB reacts with DGER via opening of the epoxy ring and rupture of the C–Br bond in allyl bromide. Addition of PEPA in the second step yields cross-linked anion exchanger owing to

rupture of both the C–Br bond in the intermediate and the N–H bond in the amino group and opening of the double bond of the allyl group.

We studied the kinetics of each step of this reaction by polarography. This method offers a number of advantages in studying the kinetics of homogeneous reactions, one of which is the possibility of an *in situ* study without isolation of the components from the reaction mixture [12]. If during chemical reaction one or several polarographically active compounds are formed or consumed in a solution, the time dependences of their concentration can be followed by polarography.

Among AB, DGER and PEPA, only allyl bromide is polarograpically active. A great number of halogen-containing organic compounds is known to be reduced on a mercury dropping electrode at a half-wave potential $E_{1/2}$ ranging from 0 to –2.5 V. Electrochemical rupture of the carbon–halogen bond in monohalogenated derivatives usually involves two electrons. In this case a halide anion is formed and the position of the halogen atom in the organic molecule is occupied by a hydrogen atom.

$$C_3H_5Br + 2e \rightarrow C_3H_6 + Br^-.$$

This reaction is manifested in polarograms as single-step two-electron diffusion-controlled waves. We used 0.02 M $(C_2H_5)_4NI$ in 50% DMF as supporting electrolyte, since DMF is strongly adsorbed on the surface of a mercury dropping electrode, thus preventing appearance of polarographic maxima [13]. From the polarograms of AB recorded in this electrolyte we determined the half-wave reduction potential of allyl bromide, –1.29 V, which agrees with published data [14].

The kinetic curves describing a decrease in the concentration of AB during its polycondensation with DGER and PEPA at different temperatures were constructed from the results of polarographic analysis (Fig. 1), since the intensity of the polarographic wave *h* is directly proportional to the AB concentration. These curves show that the reaction is accelerated with increasing temperature and is vigorous in both steps during the first 60 min. Thus, the optimal time of precondensation of these monomers is 2 h.

A study of the polycondensation kinetics showed that the rate constants of both steps remain virtually constant. This indicates that the polycondensation of AB, DGER, and PEPA is a first-order reaction [15]. The kinetic parameters of the polycondensation are summarized in Table 2.

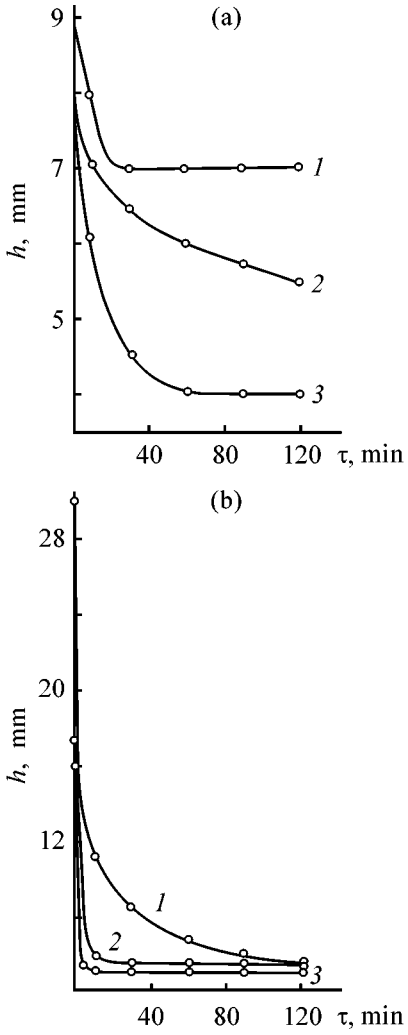

Fig. 1. Kinetics of the (a) first and (b) second steps of AB polycondensation with DGE and PEPA at (*1*) 13, (*2*) 18, and (*3*) 24 °C. (*h*) Intensity of polarographic wave and (τ) time.

As seen from Fig. 2, the fact that the temperature dependences of the rate constants are linear in the Arrhenius coordinates in both steps confirms that the polycondensation can be described by the Arrhenius equation.

Table 2. Kinetic parameters of the first and second steps of polycondensation of AB, DGER and PEPA

Step	*T*, K	log *k*	*E*, kJ mol^{-1}
AB + DGER	286	–3.7	32
	291	–3.4	
	297	–3.2	
AB + DGER + PEPA	286	–8	28
	291	–2.5	
	297	–2.3	

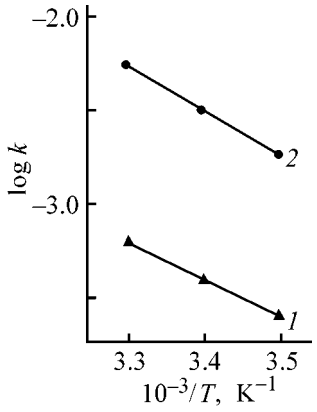

Fig. 2. Rate constants *k* of the (*1*) first and (*2*) second steps of polycondensation of AB, DGER, PEPA vs. temperature *T*.

Thus, new polyfunctional anion exchangers with high exchange capacity and improved physicochemical properties were prepared by polycondensation of allyl compounds and diglycidyl ethers of dihydroxybenzenes with various amines in DMF, followed by curing of the resulting gel. The optimal preparation conditions were determined and some properties of the anion exchangers were studied. As determined by polarography, IR spectroscopy, and chemical analysis, the use of AHs allows preparation of three-dimensional polymers cross-linked not only by amines, but also by the double bonds of allyl groups. Polycondensation of AB, DGER, and PEPA is a first-order reaction. The low activation energies indicate that both the steps are fast at low temperatures, with the second step being faster than the first. This is likely to be due to the exothermic nature of the second step.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Formation, 3D Structure, and Strength Characteristics of Interpenetrating Polymer Networks Based on Cold-Curing Oligomer–Oligomer Systems

Yu. N. Anisimov and S. N. Savin

Mechnikov State University, Odessa, Ukraine

Received September 25, 2000; in final form, December 2000

Abstract—The kinetics of low-temperature formation of interpenetrating polymer networks based on modified epoxy resins and copolymers of unsaturated oligoester resin with oligoether acrylates were studied in relation to the composition of the initial mixture. The influence of the parameters of the three-dimensional structure (cross-linking density, content of lattice points, number of monomeric units in cross-links) on the strength characteristics of the resulting polymer networks was examined, and the best conditions were found for preparing shockproof materials.

The properties and structure of interpenetrating polymer networks (IPNs) of various types are favorable for preparing materials with valuable service characteristics [1, 2]. The three-dimensional (3D) structure and properties of polyurethane-based IPNs are largely influenced by the kinetics of formation of these materials [2]. Curing of a series of modified epoxy resins has been studied, and the main characteristics of their network structure have been determined; the shock resistance of these materials is relatively poor [3, 4]. We have studied previously the 3D structure and physicomechanical characteristics of network copolymers based on unsaturated oligoester resins and oligoether acrylates [5], and also the kinetics of formation, 3D structure, and strength characteristics of semi-IPNs based on modified epoxy resins and oligoether acrylates [6]. In this work we studied the process of formation, 3D structure, and strength characteristics of IPNs based on modified epoxy resins and network copolymers of cold-curing oligoester resins with the aim of preparing polymeric materials with enhanced strength.

EXPERIMENTAL

We studied the kinetics of IPN formation from two network components. The first component was UP-637 epoxy–resorcinol resin [TU (Technical Specifications) 6-05-241–74] containing 32 wt % epoxy groups; for comparison we used ED-20 epoxy–4,4'-isopropylidenediphenol resin [GOST (State Standard) 10587–84] containing 22 wt % epoxy groups. The choice of UP-637 was governed by the higher strength of composites based on it, as compared with other modified resins [3, 6]. The epoxy resins were cured at 20°C with polyethylenepolyamine (PEPA) of B brand (TU 6-02-594–85), taken in amounts of 20 and 14 wt %, respectively, relative to the above-mentioned epoxy resins. The second component of IPN was a network copolymer based on polyethylene glycol maleate phthalate (PGMP) (GOST 27952–88) containing 98.2 wt % main substance and oligoether acrylates (OEAs): triethylene glycol dimethacrylate (TGM) and di(triethylene glycol) phthalate dimethacrylate (MGP) containing 98.6 and 98.2 wt % main substance, respectively. The characteristics of these compounds agree with data reported in [5, 7]. For comparison, we prepared copolymers of PGMP with methyl methacrylate (MMA). Copolymerization was performed at weight fraction of the oligomers in the initial mixtures of 0.45 at 20°C in the presence of the effective initiating system methyl ethyl ketone peroxide (MEKP)–cobalt diacetylacetonate (CDA), proposed in [5].

The kinetics of network formation was studied by two independent methods: IR spectroscopy and measurement of the electrical conductivity of curing systems. In the first case, IPNs were formed in special

* (C_1, C_2) Content of copolymer and gel fraction, respectively; (ρ_{cl}) cross-linking density; (γ) content of chemical lattice points; ($\bar{P}_{cl}$) mean content of OEA units in cross-links; and (ΣF) total cohesion.

cells between NaCl plates directly in the cell compartment of a Specord 75-IR spectrometer. The extent of curing of epoxy resins was determined by measuring the optical density at the absorption peak of the epoxy groups at 930 cm^{-1}, and the degree of copolymerization of the second component, by measuring the optical density at the absorption peak at 1630 cm^{-1}, associated with stretching vibrations of the double bond in PGMP and OEA [6]. The transmission at these wave numbers varied within 15–80% in the course of network formation, which allowed the degree of conversion of the components to be measured with an accuracy of ±0.5%. The advantage of this method as compared with dilatometry and calorimetry is the possibility of monitoring the transformation of each component to high conversions, irrespective of the growing viscosity [6]. The rate of network formation from the epoxy resins, W_1, and the copolymerization rate W_2 were calculated by the least-squares method with error not exceeding 3%. The electrical conductivity of the curing system was measured in a temperature-controlled Teflon cell with an E7–8 digital meter by the previously described procedure [6] allowing calculation of the apparent rate of network formation W_{app}, which includes the overall rate of curing of the epoxy resin and the rate of copolymerization of the second component, with a relative error of 3%.

The formed IPNs were extracted with boiling acetone in a Soxhlet apparatus in the course of 12 h, after which the yield of the 3D-cross-linked gel fraction was determined. The extraction was performed with IPN materials formed by curing at 20°C for no less than 24 h. The strength characteristics of the materials were determined as follows. The breaking compression stress σ_c was measured according to GOST (State Standard) 4861–82 for cylindrical samples 12 mm in diameter and 15 mm high on a TsD-10 testing machine; the relative error did not exceed 2%. The impact resilience of the composites a_{im} was measured for 60 × 5 × 5-mm rectangular samples without notches using an MK-05 pendulum impact machine with distance of 40 mm between the bearings, according to GOST (State Standard) 3458–88; the relative error was 2%.

The kinetic parameters of IPN formation (see table) show that the rates of formation of individual network structures of the first and second components are

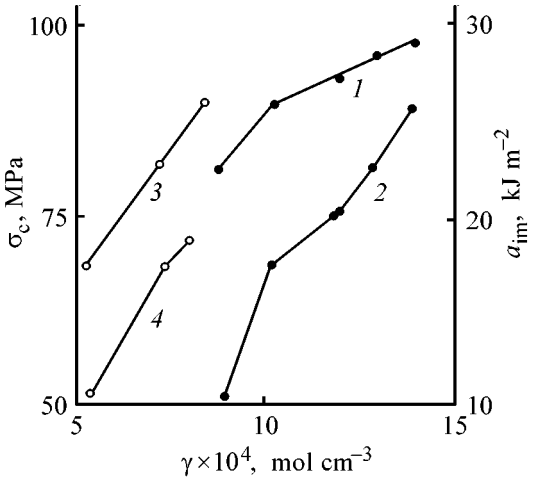
rather close; the curing rate of UP-637 resin and the copolymerization rate in the system PGMP + MGP are somewhat higher. The kinetic parameters of curing of the individual components, determined by IR spectroscopy (W_1) and evaluated from the electrical conductivity (W_{app}), are reasonably consistent. In preparing IPNs from two components, the rates of formation of the networks based on epoxy resin increase in going from ED-20 to UP-637, remaining close to the rates of curing of the individual resins (see table). Copolymerization of the second component occurs under the conditions when a network based on the epoxy resin is formed, with significant increase in the viscosity in the initial period, which favors manifestation of the gel effect; the rate W_2 is higher than that in the absence of the epoxy resin. The rates of formation of the network from the second component increase in going from TGM to MGP, all other conditions being the same, which is consistent with our data [5] on the relative reactivity of these OEAs in copolymerization. It should be noted that the apparent rates of IPN formation, W_{app} are, on the whole, additive with respect to W_1 and W_2 and can be used as a measure of the overall rate of IPN formation. The rates of IPN formation are the highest in formulations based on the epoxy–resorcinol resin and the PGMP–MGP copolymer: The IPN formation is complete at 20°C within 60–100 min.

The 3D structure of the IPNs was characterized by the cross-linking density ρ_{cl} {calculated by Charlesby's formula (1) [7]} and the content of chemical lattice points γ (see table).

$$\rho_{cl} = \frac{1/(\sqrt{m_s} - 1)}{1 - m_s}, \quad (1)$$

where m_s is the content of the soluble sol fraction in the composites, determined by extraction with acetone.

The parameter ρ_{cl} is dimensionless and allows only qualitative evaluation of the cross-linking density in IPNs as influenced by the initial formulation and the curing conditions. It is preferable to use the parameter γ, calculated from the known molecular weights of the IPN components and their content in the composites by the procedure similar to that described in [2, 6]; the relative error does not exceed 3%. Knowing γ and the molecular weights of the corresponding OEAs, we calculated the mean number of OEA units in the cross-links $\overline{P}_{cl}$ of the second IPN component. In total, these parameters characterize the 3D structure of the IPNs and reveal correlations between the structural parameters and



(*1, 3*) Breaking compression stress σ_c and (*2, 4*) impact resilience a_{im} of IPNs vs. the content of chemical lattice points γ in polymeric materials: (*1, 2*) polymeric materials with IPN based on epoxy resin and PGMP–OEA network copolymers; (*3, 4*) PGMP–OEA network copolymers. For compositions, see table.

strength characteristics (see table, figure). We found that both σ_c and a_{im} grow with increasing γ, which agrees with the trends observed previously in semi-IPNs [5, 6]. Among the materials prepared from the individual components, the highest strength is exhibited by the materials based on the epoxy–resorcinol resin and PGMP–MGP copolymers (see figure). As for IPNs prepared from two components, with the weight fraction of the second component (copolymer) raised from 0.3 to 0.6, the parameters ρ_{cl}, γ, and a_{im} first increase, reaching a maximum at C_1 = 0.45, and then decrease (see table). The trend in the variation of $\overline{P}_{cl}$ is the opposite. Estimation of the density of the chemical cross-links in copolymers of the oligoester resin with OEA showed that the content of the chemical lattice points increases in going from TGM to MGP, especially as compared with the copolymers based on MMA. The highest strength characteristics (both σ_c and a_{im}) are exhibited by the IPNs based on the epoxy–resorcinol resin and PGMP–MGP copolymers; the parameters of the 3D network for these IPNs are also the highest.

The physicomechanical properties of 3D-cross-linked polymers are determined by the content of not only chemical network points but also potential physical network points facilitating energy dissipation in mechanical treatment of the polymeric material [1, 8]. At present, there are no experimental procedures for measuring the physical network parameters in network polymers and IPNs [3, 7, 8]. The physical network density in polymers is estimated from the cohesion,

using the molar attraction constants F for various atomic groups in macromolecules, following the recommendations given in [7, 8]. Previously, such calculations of the total cohesion ΣF have been performed for TGM and MGP homopolymers; it was found that ΣF and the impact resilience of the polymers vary in parallel [9]. Using a similar procedure, we calculated the total cohesion both for the individual components and for IPNs prepared from them (see table); the error in calculating ΣF did not exceed 0.1%. It is seen that the strength grows with increasing cohesion, especially the dynamic strength characterized by a_{im}. The higher impact resilience of IPNs based on MGP copolymers, as compared with those based on TGM copolymers, may be due to the higher calculated values of total cohesion of such IPNs, since the MGP copolymers contain atomic groups with high internal rotation barrier—phthalate groups, and hence to larger zone in which cross-links are stabilized. The absolute values of the impact resilience of the resulting IPNs with the optimal composition are 1.5–2 times higher than the similar characteristics of the corresponding individual network components and correspond to the parameters of shockproof polymeric materials [7, 10].

CONCLUSION

The effect exerted by the content and nature of components on the kinetics of low-temperature formation of interpenetrating polymer networks from oligomer–oligomer systems was elucidated.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Directional Synthesis of Hybrid Polymers from 2- and 4-Vinylpyridines

Abstract—Formation of hybrid three-dimensional structures by treatment of copolymers of 2- and 4-vinylpyridine with butyllithium, followed by grafting of *tert*-butyl acrylate molecules, was studied by mass-spectrometric thermal analysis and ^{13}C NMR spectroscopy.

The specific feature of anionic polymerization of 2- and 4-vinylpyridine (2-VP, 4-VP) is the high activity of the pyridine rings in the monomers and polymers in reactions with initiator molecules and active centers (ACs) formed in the course of polymerization. Thanks to this property, it is possible to construct macromolecules of complex "architecture," including hybrid polymers based on copolymers of 2- and 4-VP and *tert*-butyl acrylate (TBA), under the action of butyllithium.

The process of formation of three-dimensional (3D) hybrid structures, which can be transformed into polyelectrolyte networks with predictable parameters, can be monitored by mass-spectrometric thermal analysis (MTA) and solid-state ^{13}C NMR spectroscopy.

Synthesis of homopolymers and hybrid polymers of 2- and 4-VP is of interest as one of possible routes (along with polymerization of some other polar monomers) to polymers that can be functionalized and used in various branches of chemistry, pharmacology, medicine, biology, etc., in particular, in the fields where pH-sensitive polymeric systems are required. A study of the mechanism of anionic polymerization of polar monomers, effected by allyl derivatives of Cr, Mo, and W, and a structural analysis of the resulting macromolecules [1–3] revealed a number of structural forms of the polymers, originating from two types of active polymerization centers that arise on the growing chains: nitrogen–metal and carbon–metal, capable of interconversion in the course of growth of the polymeric molecules. Polymerization of 2- and 4-VP, as well as that of *N*,*N*-dimethylacrylamide [4], yields macrocyclic, network, branched, star-shaped, and linear structures. The revealed relations allow control of the macromolecular architecture within wide limits and construction of polymeric materials with new chemical, mechanical, optical, and hydrodynamic properties. These relations are also to a certain extent applicable to other initiators of anionic polymerization, such as organolithium, -sodium, -potassium, and -magnesium compounds. To reveal the specific features of polymerization under the influence of the above compounds, it is appropriate to examine the results of synthesis of hybrid polymers in the presence of an organolithium compound.

In this work, taking into account the high activity of pyridine rings in reactions with organometallic compounds and different activities of the N–Met bond in 2- and 4-VP polymers, we made an attempt to construct polymeric chains, using as the base element an assembly of characterized 2- and 4-VP copolymers prepared by radical polymerization. The copolymers were treated with butyllithium to generate active centers along the polymer chain for subsequent grafting of pendant chains of poly-*tert*-butyl acrylate (PTBA). We expected that, by varying the molecular weight and composition of the copolymer, it would be possible to change the content of active centers along the copolymer chain and hence the number of pendant chains of the grafted polymer. It would be thus possible to control the parameters of the branched polymer and, in the limiting case, the parameters of the forming 3D network.

To analyze the polymers and reveal the mechanism of the reaction of organometallic compounds with polyvinylpyridines, we used MTA and solid-state ^{13}C NMR spectroscopy.

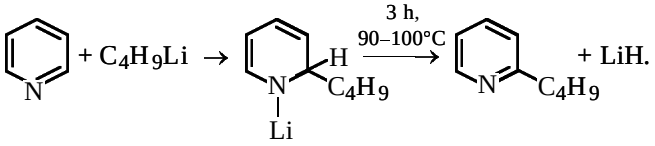
EXPERIMENTAL

Homo- and copolymers of 2- and 4-VP were prepared by polymerization of freshly distilled 2- and 4-VP at 70°C in the bulk in the presence of 0.5% azobis(isobutyronitrile) (AIBN). The polymer was precipitated into petroleum ether, purified by fourfold reprecipitation from chloroform solution into petroleum ether, and vacuum-dried at 50°C for 24 h. Butyllithium was prepared by reaction of Li with C_4H_9Cl in hexane. The reaction of the polymers and copolymers with C_4H_9Li was performed at temperatures from +5 to –65°C, polymer concentration of 0.1 M, and molar ratios C_4H_9Li/monomer unit of 1, 0.8, 0.3, and 0.1. After a definite time (from 1 min to several hours), either the process was stopped by adding 1 ml of a cooled CH_3OH–H_2O mixture (10 : 1), or pendant TBA chains were grafted by adding 1 ml of TBA. The polymer was precipitated by adding water, washed several times with fresh portions of water (until pH of the wash water reached 6–7), and vacuum-dried at 50°C.

Mass-spectrometric thermal analysis of the polymers [3] was performed with an MKh-1320 device. A 0.1–0.2-mg sample was fixed with aluminum foil on a thermocouple placed in the thermal degradation chamber. The sample was heated from 293 to 773 K at a rate of 5 deg min^{-1}. The mass spectra of the thermal degradation products were recorded at 2-min intervals, and a mass thermogram (temperature dependence of the characteristic ion currents) was obtained.

High-resolution solid-state ^{13}C NMR spectra were obtained at room temperature on a Bruker CXP-100 spectrometer (25.18 MHz for ^{13}C) using magic angle spinning (3–4 kHz) and cross polarization techniques. The chemical shifts (ppm) are given relative to TMS.

The reaction of butyllithium with pyridine was described for the first time by Ziegler [5]. Nucleophilic substitution at the α-position yielded 2-butylpyridine. Ziegler also prepared 2,6-dibutylpyridine by reaction of butyllithium with 2-butylpyridine, and also some other related derivatives of pyridine and quinoline [6]:



Reaction of pyridine with C_4H_9Li involves alkylation with the formation of a cyclic diene structure, followed by rearomatization. Much later, Schmitz *et al.* [7] studied by chromatography and mass spectrometry the products of reaction of pyridine, cumyl, and ethylpyridine with C_4H_9Li. Some conclusions of [7] can be applied to reactions accompanying the anionic polymerization of 2-VP. Alkylation of the ring by the nucleophilic attack at the α-position occurred in all cases (at varied component ratio, reaction temperature, chain-terminating agents). In some cases, products formed by attack of C_4H_9Li at the alkyl group of the model compound were detected. The products of ring alkylation undergo rearomatization, but dihydro- and tetrahydroalkylpyridines were also detected.

The first step in the development of a procedure for directional synthesis of hybrid polymers was to reveal specific features of the mechanism by which occurs

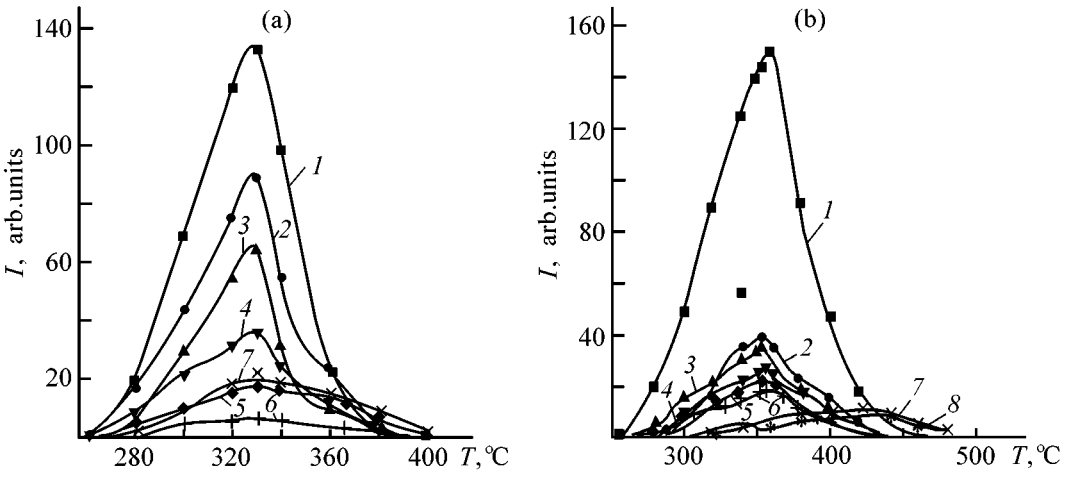


Fig. 1. Curves of evolutiuon of volatile products in thermal degradation of P-2-VP: (a) initial polymer and (b) polymer treated with butyllithium (P-2-VP-1). (*I*) Intensity and (*T*) temperature. Mass of characteristics ions: (a) (*1*) 105, (*2*) 79, (*3*) 104, (*4*) 106, (*5*) 118, (*6*) 119, and (*7*) 132; (b) (*1*) 119, (*2*) 132, (*3*) 175, (*4*) 105, (*5*) 106, (*6*) 79, (*7*) 163, and (*8*) 137.

the reaction of poly-2-vinylpyridine (P-2-VP) with C_4H_9Li. It was of interest to find how readily are the pyridine rings in the polymer chains alkylated:

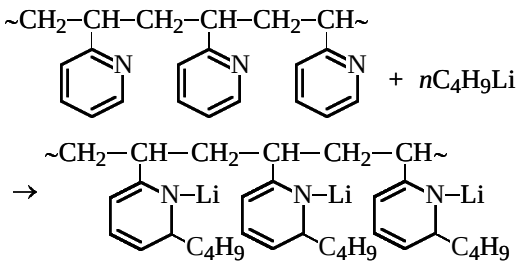

Figure 1a shows a mass thermogram of P-2-VP prepared by radical polymerization of 2-VP in the bulk, initiated by AIBN. Treatment of this polymer in toluene at +5°C with butyllithium (monomer unit : C_4H_9Li = 1 : 0.8) yields a product (P-2-VP-1) whose mass thermogram (Fig. 1b) significantly differs from that given in Fig. 1a both in the set of characteristic peaks and in the temperature dependence of the ion currents. Below are given the mass spectra of the thermal degradation products of the initial P-2-VP at 370°C

m/*e*	105	79	104	106	78

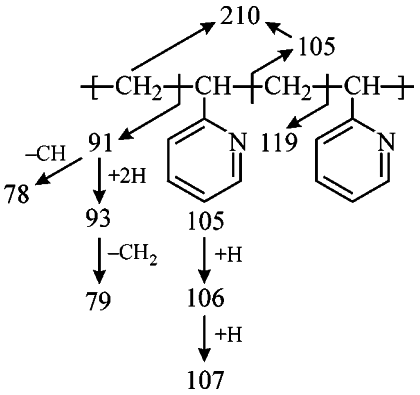
I	133	131	130	79	59	52	

The fragmentation pattern of P-2-VP[1] is shown in Scheme 1.

Scheme 1.



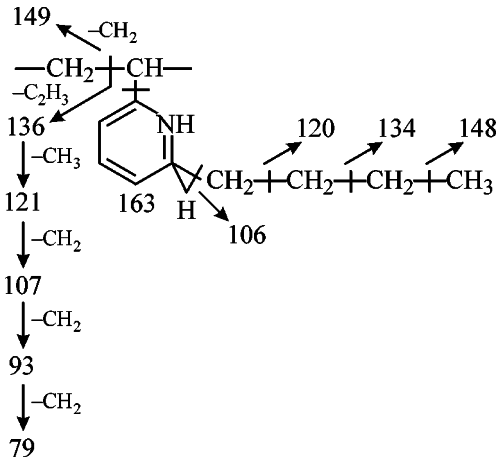
Fragmentation of P-2-VP.

[1] It should be taken into account that the mass spectrum reflects a superposition of two processes: thermal degradation of polymeric molecules and fragmentation of low-molecular-weight degradation products in the ion source.

Since, as already noted, the reaction of P-2-VP with C_4H_9Li can yield both alkylcyclodiene and aromatic products, for we should consider two fragmentation patterns P-2-VP-1 (Schemes 2, 3).

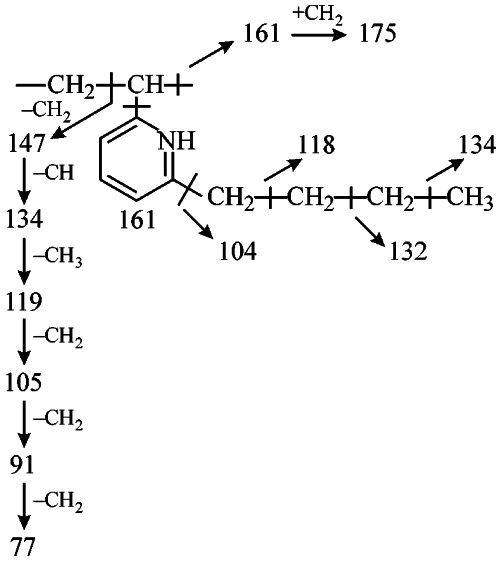
As seen from the mass spectrum of P-2-VP-1, the strongest peak is that at *m*/*e* 119, in contrast to the mass spectrum of the initial P-2-VP with the strongest peak at *m*/*e* 105. Simple fragmentation by Scheme 2 does not produce an ion with *m*/*e* 119 without further additions or rearrangements. Fragmentation by Scheme 3 does produce an ion with *m*/*e* 119, but in this case its peak would hardly be the strongest in the mass spectrum.

Scheme 2.



Fragmentation of P-2-VP-1 (without rearomatization).

Scheme 3.



Fragmentation of P-2-VP-1 (with rearomatization).

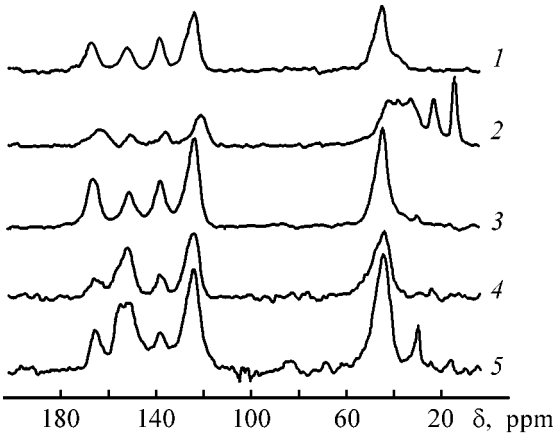


Fig. 2. High-resolution solid-state ^{13}C NMR spectra: (*1*) initial P-2-VP; (*2*) P-2-VP treated with butyllithium (P-2-VP-1); (*3*) P-2-VP treated with butyllithium at 0°C with addition of TBA; (*4*) copolymer of 2-VP and 4-VP (1 : 1); and (*5*) graft copolymer based on 2-VP : 4-VP (1 : 1) and TBA. (δ) Chemical shift.

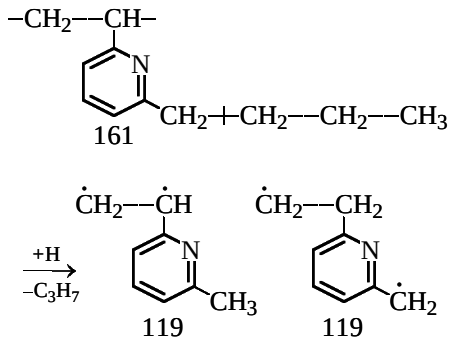
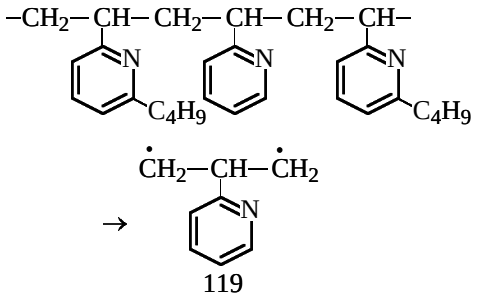
The more probable pathway of formation of the ion with *m*/*e* 119 is the loss of the C_3H_7 group followed by addition of hydrogen to the remaining fragment:



At the chosen ratio of the polymer and C_4H_9Li, the alkylation of P-2-VP occurs to no more than 80%. The P-2-VP units remaining unchanged give the fragmentation peak at *m*/*e* 105. Since depolymerization is hindered by the presence of alkylated units, another pathway of thermal degradation of P-2-VP units may become preferable:



From the two above-given fragmentation patterns of P-2-VP-1, that shown in Scheme 3 is more consistent with the observed set of charactestic ions. In other words, under the chosen conditions, alkylation of the pyridine rings is followed by complete (or considerable) rearomatization of the alkylated cyclodiene fragments.

This conclusion is supported by the fact that ions with *m*/*e* 161 (molecular ion in Scheme 3, one of the strongest peaks in the mass spectrum), 132, 177 ($M + CH_2$) and 189 ($M + C_2H_4$) are present in the mass spectrum.

This result of MTA was confirmed by solid-state ^{13}C NMR spectroscopy. Figure 2 (curve *1*) shows the NMR spectrum of the initial P-2-VP. The signals (ppm) are assigned as follows: 42.7, CH and CH_2 groups of the vinyl chain; carbon atoms of the pyridine ring: 121.7, C^2 and C^4; 136.4, C^3; 149.9, C^5; and 164.9, C^1. The spectrum is fully consistent with the structure of P-2-VP.

Figure 2 (curve *2*) shows an NMR spectrum of the polymer treated with butyllithium (P-2-VP-1). The spectrum contains lines corresponding to the carbon atoms in the chain of the butyl fragment (12.4, 21.2, 30.9, 36.2 ppm). In the downfield region, the positions and shapes of some lines changed. The lack of signals at about 100 and 50 ppm ($C^{2'}$ and $C^{4'}$ atoms in the cyclodiene moiety) suggests a practically complete rearomatization of the pyridine rings alkylated with butyllithium. The signals at 163 ($C^{1'}$, $C^{5'}$), 134 ($C^{3'}$), and 119 ppm ($C^{2'}$, $C^{4'}$) have downfield shoulders, which, in combination with the presence of a signal at 148.5 ppm belonging to the C^5 atom in the intact pyridine ring, suggests incomplete alkylation of the pyridine ring and agrees with our expectations when account is taken of the reaction conditions.

Thus, the MTA and ^{13}C NMR data show that alkylation of the pyridine rings in P-2-VP under the action of C_4H_9Li readily occurs at +5°C; the reaction products contain vinylpyridine and vinylalkylpyridine fragments, whereas fragments with cyclodiene structure are practically absent. However, such structures are detected by ^{13}C NMR spectroscopy in the products of the reaction of P-2-VP with C_4H_9Li, performed at lower temperature (e.g., –65°C); thus, we can conclude that, in the range from +5 to –65°C, rearomatization of cyclodiene structures formed by alkylation of P-2-VP with C_4H_9Li significantly depends on temperature.

The next step in the synthesis of hybrid polymers is the reaction of "living" polyvinylpyridine with TBA at the N–Li bond. It has been noticed [8] that in the case of P-2-VP, active centers show low activity in anionic polymerization, especially at low temperatures; by contrast, in the case of P-4-VP, N–Li

active centers are highly reactive. Therefore, for further directional synthesis of hybrid polymers we decided to use copolymers of 2-VP and 4-VP obtained by radical polymerization in the bulk at 70°C under the action of AIBN. The copolymerization constants were determined by the Fineman–Ross method: r_1 = 0.50 (4-VP), r_2 = 0.79 (2-VP). The composition of the copolymers was determined from the ^{1}H NMR spectra (in $CDCl_3$); the molecular and conformational characteristics of the copolymers were studied by sedimentation–diffusion analysis, viscometry, and light scattering (see table).

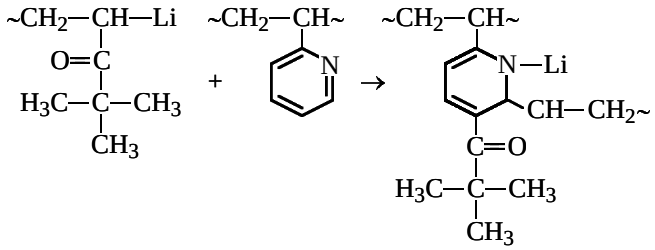
Molecular weight M_{sd} and composition of copolymers

Molar ratio of 4-VP and 2-VP		M_{sd}
in monomer mixture	in copolymer*	
0.80 : 0.20	0.75 : 0.25	20000
0.50 : 0.50	0.42 : 0.58	48000
0.20 : 0.80	0.22 : 0.78	100000

* The composition of the copolymers was determined from the ^{1}H NMR spectra by the intensity ratio of the peaks (ppm) at 8.2 (S_1), 6.8 (S_2), and 6.25 ppm (S_3); content of 2-VP $C = 2S_2/(S_1 + S_2) = 2S_2/(S_2 + S_3)$.

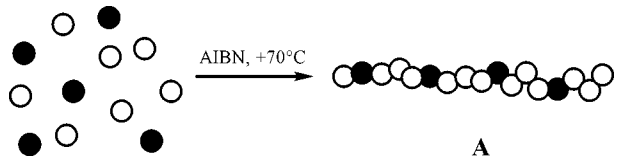
Figure 2 (curve *3*) shows a ^{13}C NMR spectrum of P-2-VP treated with C_4H_9Li at 0°C, with TBA added at the same temperature. No hybrid polymer is detected. The MTA data confirm this fact, though traces of PTBA are detected (a certain amount of the homopolymer may be present). The same result (and even more apparent) was obtained when the same process was performed at –65°C. By contrast, the NMR spectrum of the copolymer containing 58% 2-VP and 42% 4-VP (Fig. 2, curve *4*), treated with C_4H_9Li at –65°C and subjected to grafting with TBA, is quite different (Fig. 2, curve *5*). Both the intensities and positions of the characteristic signals change. For example, signals from the $–CH_2–$ (22.7 ppm) and $–CH_3$ (14 ppm) groups are observed (other butyl signals are obscured by signals of the polymer chain atoms). Also, there are signals corresponding to the TBA structures: 80 (–O–C–), 28 ($–CH_3$), and a shoulder at 176 ppm (–C=O). The shoulder at about 52 ppm corresponds to the TBA methylene group bound to the nitrogen atom of the pyridine ring, which confirms grafting of TBA to the pyridine ring. Also, the shape of the lines corresponding to the carbon atoms of the pyridine ring changes (range 170–110 ppm). The signal at 66.8 ppm corresponds to the carbon atoms of the pyridine rings directly bound to the butyl group (C^3 in 2-VP and C^5 in 4-VP fragments). The signal at 60 ppm is due to the same carbon atoms in the pyridine rings transformed into the diene structures. The ratio of the pyridine and diene rings, evaluated from the integral intensities of the C^3 and C^5 signals and the signals of methylene groups of the TBA chains, is approximately 1 : 1.

The above results prove grafting of TBA chains to the N–Li active centers in the 4-VP fragments of the 2-VP–4-VP copolymer. This fact suggests the possibility of controlling within wide limits the content of pendant PTBA chains by varying the content of 4-VP in the copolymer. Furthermore, this result furnishes an opportunity to evaluate the amount of active centers along the backbone molecules of the hybrid polymer and, hence, to determine quantitatively the composition of the whole hybrid polymer. It should be noted also that our results provide a basis for synthesis of a 3D network from the hybrid copolymer by appropriately choosing the concentration of the 2-VP–4-P copolymer in the reaction solution and the size of the pendant TBA chains. For example, with these parameters increased, the reaction of the active centers at the end of the growing PTBA chain with the pyridine ring of the adjacent backbone copolymer molecule becomes possible.



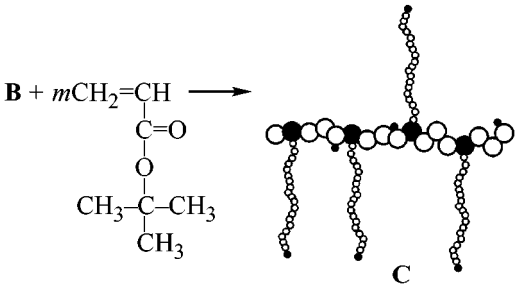
For clearer presentation of the obtained results and further progress of the study, we give the general scheme of formation of hybrid copolymers based on 2-VP, 4-VP, and TBA.

(1) Synthesis of 2-VP and 4-VP copolymer.

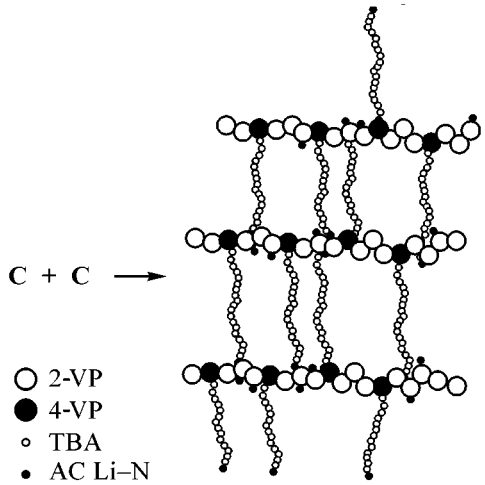


(2) Formation of active centers along the copolymer chain.

(3) Synthesis of the graft copolymer with pendant TBA chains.

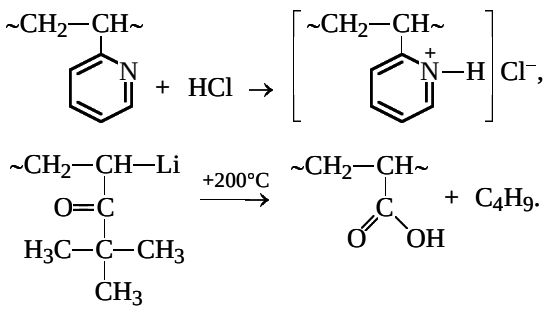


(4) Formation of a 3D structure by grafting of a pendant chain of the hybrid polymer to the backbone copolymer molecule.



This scheme shows that the parameters of the 3D structure can be controlled by the composition and molecular weight of the initial copolymer **A**, concentration of butyllithium, amount of reacted TBA, and concentration of the hybrid polymer **C** in the reaction solution.

The 3D structure of the hybrid polymer can be subsequently converted into a polyelectrolytic pH-sensitive network by transforming the backbone moiety into a salt of the polybase (e.g., by reaction of the polymer with HCl) and of pendant PTBA chains into polyacrylic acid (e.g., by pyrolysis at 200°C) [9]:



CONCLUSION

A study by mass-spetrometric thermal analysis and high-resolution solid-state ^{13}C NMR spectroscopy showed that butyllithium is active in alkylation of pyridine rings of polymers and copolymers of 2- and 4-vinylpyridine. The extent of rearomatization of the alkylated pyridine rings is temperature-dependent in the range from +5 to –65°C. In this temperature range, the N–Li active centers in the 2-vinylpyridine units are weakly active in grafting of *tert*-butyl acrylate units. By contrast, similar centers in the 4-vinylpyridine units are active, which allows preparation of a hybrid copolymer of 2-vinylpyridine, 4-vinylpyridine, and *tert*-butyl acrylate. The revealed trends allowed us to propose a scheme for preparing 3D structures that can be converted into polyelectrolytic networks with controllable structural parameters.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Water-Soluble Chemically Degradable Polymers from Glutaraldehyde and *N*-Vinylpyrrolidone–Allylamine Copolymers

Received November 29, 2000

Abstract—Water-soluble chemically degradable copolymers of *N*-vinylpyrrolidone with allylamine, containing azomethine links between the polymeric chains, were prepared. The composition and molecular-weight characteristics of the polymers were determined.

Polymers based on *N*-vinylpyrrolidone (VP) are widely used in medicine as detoxicants, plasma substitutes, and means for prolonging the effect of various drugs [1]. At the same time, these materials, being carbon-chain polymers, are not biodegradable. The task is to restrict their molecular weight (*MW*) so as to facilitate their elimination from a living body after having fulfilled the biological function. Relatively low-molecular-weight (*MW* 10 000–15 000) polymers can be used only as detoxicants; their molecular weight is too low for use as plasma substitutes or prolongation means, because such polymers will be rapidly eliminated from the living body and will not ensure the required biological effect. At the same time, use of higher-molecular-weight (*MW* 80 000–100 000) polymers, suitable as prolongation means, involves problems associated with their slow elimination and accumulation of high-molecular-weight fractions causing undesirable side biological effects.

Published data show [2] that the maximal molecular weight of poly-VP at which its macromolecules can be filtered through kidneys is 40 000. Distribution of poly-VP in a body and its elimination with urine should be considered as biological fractionation of a heterogeneous mixture of macromolecules of different sizes, some of which (smaller) pass through biological membranes and the others are retained.

It is convenient to use as carriers of biologically active substances (BASs) water-soluble VP polymers with the *MW* lower than the critical value for filtration through kidneys, containing, at the same time, chemically or biologically degradable links between macromolecular chains. In this case the polymer would be retained in a body for a long time, gradually degrading into low-molecular-weight fragments subsequently eliminated by the kidney filtration mechanism [3].

Thus, from the practical viewpoint, it is appropriate to synthesize water-soluble macromolecules of reactive low-molecular-weight VP copolymers undergoing chemical (hydrolysis) or biological degradation in a living body to low-molecular-weight fragments that can be readily eliminated from the living body. Preliminary addition of drugs to such chemically degradable copolymers will ensure their prolonged effect.

This paper reports on synthesis and study of water-soluble VP–allylamine copolymers (VP–Aam) treated with glutaraldehyde to form readily hydrolyzable azomethine links between the polymeric chains. Such polymer systems have not been described previously.

The interest in VP–Aam copolymers (compared, e.g., with VP–vinylamine copolymers) is due to the fact that copolymerization of VP with Aam, similar to other allyl monomers, is accompanied by degradation transfer of a chain to the allyl monomer. Thus, copolymerization of VP with allyl monomers yields low-molecular-weight copolymers without formation of blocks of the reactive units. Copolymers with just these features were required as starting substances for our study.

* (C_{cop}) Copolymer concentration.

It should be noted that radical copolymerization of VP with Aam as a base in solution has been poorly studied [4]. Panarin *et al*. [5] reported copolymerization of VP with allylammonium salts in aqueous solution in the presence of a water-soluble initiator, 2,2'-azo-bis-(2-amidinylpropane) dichloride. They prepared in 98% yield VP–Aam · HX copolymers containing 10.8–27.1 mol % Aam · HX units. At the same time, it seemed appropriate to study single-stage copolymerization of VP with Aam in the form of a base in an organic solvent (acting as transfer agent for the growing polymeric chain) using a readily available initiator, azobis(isobutyronitrile) (AIBN), to evaluate the potentialities and limitations of this route to VP–Aam copolymers, to study the properties of the resulting copolymers, and to bring them into reaction with glutaraldehyde.

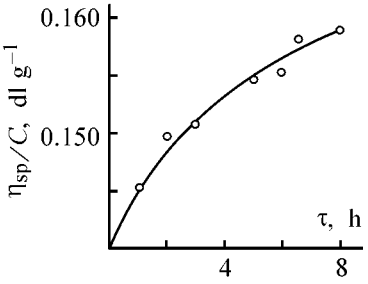

Fig. 1. Variation with time τ of the reduced viscosity η_{sp}/C of aqueous solution of **Ia** in the presence of glutaraldehyde. 45°C; C_{cop} = 5.0 wt %; [GA] : [NH_2] = 0.2 : 1.

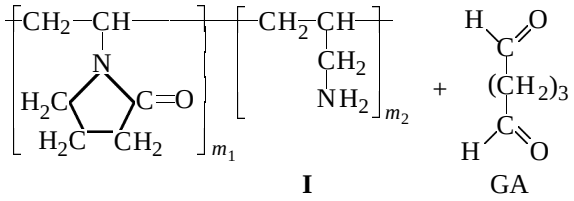
Radical copolymerization of VP with allylamine was performed in isopropanol at 70°C in the presence of 1 wt % AIBN; the total concentration of the monomers in the starting mixture $[M_1 + M_2]$ was 30–50 wt %, $[M_2]$ = 20–30 mol % (Table 1). Isopropanol is a well-known chain-transfer agent, which also facilitated the preparation of low-molecular-weight copolymers. As shown in Table 1, low-molecular-weight ($\overline{M}_v$ = 11000–20000) copolymers **Ia**–**If** are formed under these conditions in 45–50% yield; the content of the allylamine units is from 6.0 to 9.7 mol %.

It is known [6, 7] that radiation-induced copolymerization allows difficultly polymerizable monomers to be involved in the process, because it ensures increased concentration of initiating radicals. Allylamine is among monomers of this kind. Radiation-induced copolymerization of VP with Aam was performed in isopropanol at irradiation dose of 100 kGy. Table 1 shows that initiation of copolymerization by radiation is more efficient than that by a substance. Copolymers **Ig** and **Ih** are similar in composition to, respectively, copolymers **Ia** and **If** (Table 1). However, the yields are different: 92.5 and 89.1% for **Ig** and **Ih** against 44.9 and 49.0% for, respectively, **Ia** and **If**.

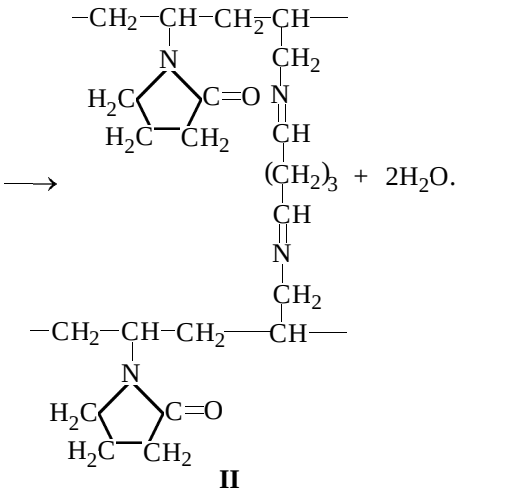
In the preliminary stage of the study, reactions of copolymers **I** with glutaraldehyde were performed in aqueous solution at 45°C in a flask without argon purging (Table 2). As seen from Table 2, gelation is avoided when copolymer **I** is taken in a concentration of 8–12 wt % at a molar ratio of GA to NH_2 groups approximately equal to 0.1 : 1. The main part of experiments were performed in aqueous solution at 45°C in sealed ampules preliminarily purged with argon. The concentration of copolymers **I** was varied from 8.5 to 11.0 wt %, and the molar ratio of GA to NH_2 groups was in the range from 0.10 : 1 to 0.15 : 1. The concentration of copolymers **I** was chosen so as to exclude gelation and keep above unity the product $c[\eta]$ characterizing the degree of solution filling with polymer globules. Under such conditions, polymeric chains can undergo intermolecular cross-linking to

give copolymers **II**. This process manifested itself as an increase in the *MW* of the starting copolymers (Table 3) and in the reduced (Fig. 1) and intrinsic (Table 3) viscosities. The reaction of copolymers **I** with glutaraldehyde to give copolymers **II** can be schematically represented as:



I GA

$m_1 + m_2 = 100$ mol %



II

This process resembles the cross-linking below gel point of linear polystyrene with a bifunctional compound, 9,10-bis(chloromethyl)anthracene, studied in detail by Krakovyak *et al*. [8]. Intrachain cross-links with glutaraldehyde of type **III** are also possible.

$$–CH_2–N=CH–(CH_2)_3–CH=N–CH_2– \quad \textbf{(III)}$$

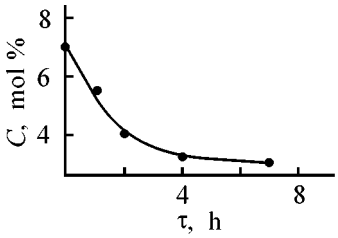


Fig. 2. Variation with time τ of the content C of NH_2 groups in copolymer **Ic** in the course of its reaction with glutaraldehyde in aqueous solution. 45°C; C_{cop} = 10.5 wt %; [GA] : [NH_2] = 0.15 : 1.

Cross-linking is accompanied by a decrease in the molar content of NH_2 groups in the starting copolymer **I** (Fig. 2, Table 3). Copolymer **IIa** was formed at complete conversion of the NH_2 groups. The conversion of the NH_2 groups in the formation of copolymers **IIb**–**IIe** was 47–57%. The resulting cross-linked copolymers **IIb**–**IIe** containing azomethine cross-links between the polymer chains are readily soluble in water, which allowed us to study their molecular characteristics in 0.1 N aqueous solution of sodium acetate. Table 4 lists the intrinsic viscosities [η], diffusion (D_0) and sedimentation (S_0) coefficients, and molecular weights M_{SD} of soluble cross-linked copolymers **IIa**, **IIc**, and **IIe**, determined by combination of the diffusion and sedimentation methods.

Copolymer **IIa** was prepared from linear VP–Aam copolymer with small (4.94 mol %) content of NH_2 groups, which were completely converted in the reaction with glutaraldehyde. The reaction yielded a VP–Aam polymer with M_{SD} = 52 000. In the course of reaction with glutaraldehyde to form polymer **IIa**, the molecular weight of the starting linear VP–Aam copolymer increased by approximately a factor of 3. For copolymer **IIa**, $D_0 = 3.7 \times 10^{-7}$ cm^2 s^{-1} and $S_0 = 1.7 \times 10^{-13}$ Svedberg units (Sv).

Table 3. Reaction of VP–Aam copolymers with glutaraldehyde in aqueous solution at 45°C in a sealed ampule purged with argon

Table 4. Variation of pH of the aqueous solution containing cross-linked copolymer **IIc**

τ, days	pH	Q_{pH}, %	τ, days	pH	Q_{pH}, %
C_{cop} = 0.1 wt %, 25°C			C_{cop} = 0.05 wt %, 37°C		
0	5.50	0	0	5.0	0
3	6.78	38.0	3	7.38	61.6
7	7.25	52.0	7	7.58	66.8
12	7.48	58.9	14	7.65	68.7
26	7.51	59.6	25	7.69	69.7
33	7.58	61.9	32	7.80	72.5

Copolymers **IIc**–**IIe** have close [η] (0.26–0.27) and M_{SD} (84000–103000). The low [η] of copolymers **IIc**–**IIe** at high M_{SD} suggests compaction of macromolecular globules through reaction with glutaraldehyde. The formation of polymers **IIc**–**IIe** is accompanied by growth of the molecular weight by a factor of 5–7 as compared with the starting non-cross-linked copolymer **Ic**. Copolymer **IIe** was prepared at higher content of glutaraldehyde in the starting solution, 0.15 mol %, at C_{cop} = 10.5 wt %. Under these conditions an *MW* of 84000 is reached in 7 h, with the content of residual NH_2 groups decreasing to 3.0 mol %. For copolymer **IIe**, $D_0 = 2.9 \times 10^{-7}$ and $S_0 = 2.15 \times 10^{-13}$. On raising C_{cop} to 11.0 wt % at [GA] : [NH_2] = 0.15 : 1, a cross-linked gel is formed.

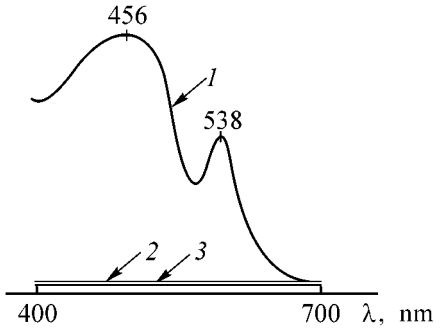

Fig. 3. UV spectra in physiological solution in the range 400–700 nm: (*1*) cross-linked copolymer **IId**, C_{cop} = 0.65 wt %; (*2*) starting linear copolymer **Ic**, C_{cop} = 58.2 wt %; (*3*) glutaraldehyde, [GA] = 6.67 μl ml^{-1} of buffer solution, pH 3.9. (λ) Wavelength.

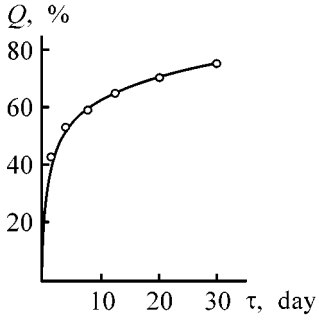

Fig. 4. Kinetics of hydrolysis, judged from variation of the reduced viscosity of cross-linked copolymer **IIe** (M_{SD} = 84000) in physiogical solution. 25°C; C_{cop} = 1.0 wt %. (*Q*) Degree of hydrolysis and (τ) time.

The presence in copolymers **II** of azomethine bonds between the polymer chains cross-linked with glutaraldehyde to the gel point was proved by UV spectroscopy (Fig. 3). The spectrum of **IId** in the range 400–700 nm in aqueous solution contains two absorption bands peaked at 456 and 538 nm, associated with the absorption of the –N=CH bonds. The starting copolymer **Ia** exhibits no absorption in the range 400–700 nm.

It was important to evaluate the hydrolytic stability of cross-linked copolymers **II** in water and in physiological solution at 25 and 37°C. The hydrolysis of copolymers **II** was monitored by measuring the pH of an aqueous solution of **IIc** in the course of hydrolysis and the reduced viscosity of a solution of **IIe** in physiological solution. In both cases we calculated the degree of hydrolysis Q_{pH} (or *Q*) at instant τ. As seen from Table 4, hydrolysis of copolymer **IIc** (M_{SD} = 94000) in aqueous solution, evaluated from pH variation, is fast: Q_{pH} reaches 62.0% in 33 days (25°C, C_{cop} = 0.1 wt %). With temperature raised to 37°C and concentration of the copolymer solution decreased to 0.05 wt %, Q_{pH} increases, reaching 72.5% in 32 days.

Figure 4 shows the kinetics of hydrolysis of high-molecular-weight branched polymer **IIe** in a physiological solution at 25°C, pH 6.8, and C_{cop} = 1 wt %, plotted using data on the reduced viscosity of this copolymer η_{sp}/C. As seen from Fig. 4, the degree of hydrolysis is as high as 75% after 30 days under these conditions. Knowing the *MW* of **IIe** before hydrolysis and the degree of hydrolysis in 30 days, we can calculate the *MW* of **IIe** after hydrolysis for 30 days. We obtained a value of 21000, which is below the critical value for kidney filtration. Thanks to easy hydrolysis, copolymers **IIc**–**IIe** containing reactive NH_2 groups can be used as BAS carriers.

Thus, using two independent procedures, we found that polymers **II** obtained by treatment with glutaraldehyde are readily hydrolyzed in water and in physiological solution at both 37 and 25°C. This means that the azomethine bond is very labile in aqueous solutions, and the chemically degradable VP copolymers obtained can be used as carriers of biologically active substances.

EXPERIMENTAL

N-Vinylpyrrolidone was purified by threefold distillation in a vacuum from KU-2 cation-exchange resin in the presence of hydroquinone. The fraction with bp 75–77°C/667–800 Pa was collected. n_D^{20} = 1.5125, d_4^{20} = 1.0458 g cm^{-3}; MR_D: found 32.00, calculated 31.74 cm^3 mol^{-1}. Allylamine was distilled twice from molecular sieves, bp 58°C. n_D^{20} = 1.4230, d_4^{20} = 0.7627 g cm^{-3}; MR_D: found 19.00, calculated 19.03 cm^3 mol^{-1}. Glutaraldehyde was purchased from Vekton as 50% aqueous solution and purified as follows. First, water was distilled off in a vacuum (22°C, 133 Pa, bath temperature 30°C). The residue was vacuum-distilled. A fraction boiling at 62°C/266 Pa (bath temperature 120°C) was collected and immediately dissolved in water. The concentration of glutaraldehyde was determined by reaction with hydroxylamine hydrochloride, followed by titration of the released HCl with 0.1 N NaOH (bromophenol blue indicator) [9]. The concentration of glutaraldehyde in the resulting aqueous solution was 30 wt %. The purity of glutaraldehyde was judged from the lack of absorption in the UV spectrum of aqueous solution at 235 nm [10]. The initiator, AIBN, was recrystallized three times from chloroform–ethanol (1 : 5) at temperatures ≤ 40°C; mp 103°C.

Copolymerization of VP with allylamine was performed in 2-propanol in the presence of AIBN at 70°C in sealed ampules preliminarily purged with argon. After the copolymerization was complete, the ampules were opened and the copolymers were precipitated by adding the reaction mixture to diethyl ether. The product was collected on a Schott filter and dried in a vacuum to constant weight. The content of primary amino groups in VP–Aam copolymers was determined spectrophotometrically (λ = 424 nm) after complexation with trinitrobenzenesulfonic acid [11]. The molecular weights of copolymers **I** were calculated from their intrinsic visocsities, measured in 0.1 N aqueous solution of sodium acetate. As a first approximation, we used the Mark–Kuhn–Houwink equation known for poly-*N*-vinylpyrrolidone [12]. The radiation-induced copolymerization of VP with allylamine was performed in 2-propanol at a dose of 100 kGy in evacuated ampules on an MRKh-γ-20 installation with a ^{60}Co source.

Reaction of glutaraldehyde with 0.5 g of VP–Aam copolymer was performed in aqueous solution at 45°C in a sealed ampule preliminarily purged with argon. After the reaction was complete, the ampule was opened, and the resulting viscous solution was diluted with 25 ml of distilled water, transferred into a separatory funnel, and shaken with three 20-ml portions of diethyl ether to remove unchanged GA. The aqueous solution was kept under vacuum to remove residual ether and subjected to lyophilic drying. The content of unchanged primary amino groups in the dried product was determined. The intrinsic viscosity of the cross-linked copolymer was measured at 25°C in 0.1 N sodium acetate.

The products of reaction of VP–Aam copolymers with glutaraldehyde were studied by molecular hydrodynamics. The translational friction of macromolecules in the free state (diffusion) and in a centrifugal field (sedimentation, MOM 3180 analytical ultracentrifuge) was studied in 0.1 N aqueous solution of sodium acetate. In both cases the technique of artificial boundary formation was used. The diffusion and sedimentation boundaries were determined after varied periods of time with Lebedev polarization interferometers [13]. The diffusion curves and sedimentograms were processed using standard techniques [14]. The sedimentation experiments were performed at 40 000 rpm. The floatability factor (density increment) $1 - v\rho_0 = 220$ for poly-VP has been determined previously [12]. The molecular weights were calculated from the diffusion (D_0) and sedimentation (S_0) coefficients using the Svedberg formula

$$M_{SD} = \frac{RT}{1 - v\rho_0}\frac{S_0}{D_0},$$

where R is the universal gas constant and T is temperature (K).

The hydrolysis of the cross-linked VP–Aam copolymer was monitored by measuring the variation with time of the pH of the copolymer aqueous solution at 25°C and 37°C and of the reduced viscosity of the copolymer solution in physiological solution at 25°C. In the first case, the degree of hydrolysis Q_{pH} was calculated by the formula

$$Q_{pH} = \frac{pH_\tau - pH_{\tau_0}}{pH_{ip}} \times 100\%,$$

where pH_τ is the pH of a solution of the cross-linked copolymer by instant of time τ, pH_{τ_0} is the initial pH of the solution of the cross-linked copolymer, and pH_{ip} is the pH of the solution of the starting (non-cross-linked) copolymer.

In the second case, the degree of hydrolysis was calculated by the formula

$$Q = \frac{M_{\tau_0} - M_\tau}{M_{\tau_0} - M_{ip}} \approx \frac{(\eta_{sp}/C)_{\tau_0}^{1/\alpha} - (\eta_{sp}/C)_\tau^{1/\alpha}}{(\eta_{sp}/C)_{\tau_0}^{1/\alpha} - [\eta]_{ip}^{1/\alpha}} \times 100\%,$$

where $(\eta_{sp}/C)_{\tau_0}$ is the initial reduced viscosity of the cross-linked copolymer (dl g^{-1}); $(\eta_{sp}/C)_\tau$ is the re-

duced viscosity of the cross-linked copolymer at instant of time τ (dl g^{-1}); $[\eta]_{ip}$ is the intrinsic viscosity of the starting linear non-cross-linked VP–Aam copolymer (dl g^{-1}); α is the empirical constant characteristic of a given polymer in a given solvent and reflecting the shape of polymer macromolecules in solution; to a first approximation, $\alpha = 0.5$; M_{τ_0}, M_τ, and M_{ip} are the corresponding molecular weights.

The UV spectra of the cross-linked and starting copolymers were measured in aqueous solution on a Specord M-40 spectrophotometer in 1-cm cells.

CONCLUSIONS

(1) The reaction of copolymers of *N*-vinylpyrrolidone and allylamine with glutaraldehyde was studied. Water-soluble polymers containing free NH_2 groups and having molecular weights 5–7 times those of the starting copolymers were obtained.

(2) The high-molecular-weight copolymers obtained readily undergo hydrolysis under physiological conditions.

ACKNOWLEDGMENTS

The study was financially supported by the Russian Foundation for Basic Research (project no. 00-15-97318).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Heat Resistance of Polyamidobenzimidazoles

Abstract—Thermal degradation of polymers based on polyamidobenzimidazoles was studied in relation to the monomeric units structure and mole fraction of the initial monomers.

Of particular interest among synthetic macromolecular compounds are polyheteroarylenes whose macromolecule contains amino groups along with thermally stable benzimidazole rings. Such polymers are amorphous; they possess elevated softening points and exhibit high heat resistance depending on the structure of the monomeric units [1]. Mixed polyamidobenzimidazoles (PABIs) based on bis-*o*-phenylenediamines, diphenyl esters of aromatic or aliphatic dicarboxylic acids, and ε-caprolactam, being somewhat less heat-resistant than the corresponding commercial homopolybenzimidazoles, are more soluble in organic solvents. Therefore, their processing into commercial items such as adhesives, films, fibers, lacquers, plastics, and fiber glasses is more convenient [2, 3]. However, wide use of the polymers for preparing heat-resistant film materials is restricted by the lack of data on the mechanisms of thermal degradation and on the qualitative and quantitative composition of the degradation products. Such data are important not only for industrial practice but also for development of approaches to construction of polymers with the preset service properties.

In this work we studied the degradation of PABIs differing in the structure of chemical units of the macromolecular chain. As investigation objects were chosen copolymers prepared from aromatic tetramines, diphenyl esters of aromatic dicarboxylic acids, and ε-caprolactam at different molar ratios of the initial monomers.

EXPERIMENTAL

In this work, we used 3,3',4,4'-tetraaminodiphenyl ether (TADPE) and 3,3',4,4'-tetraaminodiphenylmethane (TADPM), produced by the Novosibirsk Institute of Organic Chemistry, Siberian Division, Russian Academy of Sciences. Diphenyl adipate (DPA) and diphenyl isophthalate (DPI) were prepared by fusion of the corresponding acid dichlorides with phenol [2]; pure-grade ε-caprolactam was additionally purified by vacuum distillation. Thermogravimetric studies were performed with a Q-1000 derivatograph (MOM, Hungary) in platinum crucibles in air or under argon; the sample weight was 100 mg. The IR spectra were taken with a Specord 75-IR spectrometer equipped with an attachment for measuring the spectra in the temperature range 20–250°C. Samples were prepared as pellets with KBr. Thermal degradation products were analyzed with an LKhM-80 gas chromatograph equipped with a thermal conductivity detector and a dynamic pyrolytic cell heated at a rate of 1–10 deg min^{-1}, as in thermogravimetric analysis. The composition of low-molecular-weight degradation products was determined by chromatography; the columns were packed with CaA molecular sieves or Porapak Q sorbent.

A condensation test tube, first empty and then filled with the reactants, was purged with an inert gas by repeated cycles of evacuation and inert gas admission and then placed in a bath heated to 200°C. The temperature was gradually raised over a period of 1–1.5 h. After 20–30 min, the melt solidified and the reaction continued in the solid phase. After 3.5–4 h, when the melt transformed into a solid mass, polycondensation was continued for an additional 1 h at the same temperature in a vacuum (1–2 mm Hg), after which the mixture was slowly cooled to room temperature in an inert gas flow.

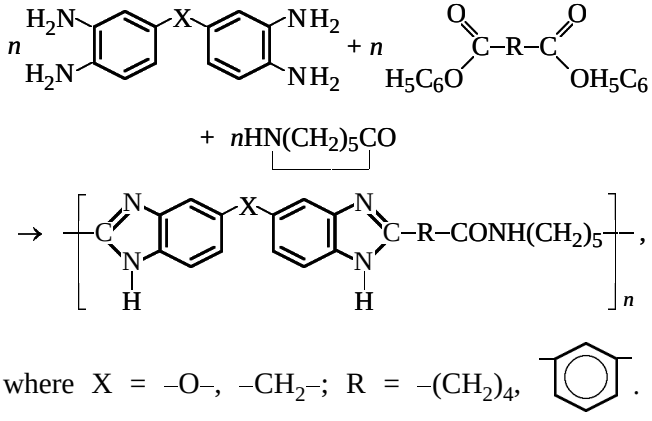
* (η_r) Reduced viscosity of a 0.5% solution of the polymer in HCOOH, 20°C; (T_s) softening point; (CL) caprolactam.

The resulting PABIs are yellow-brown powders. The elemental analyses of the products correspond to the composition of the copolymers. The IR spectra are identical to those of the model compounds and contain absorption bands at 1630–1680 cm^{-1}, characteristic of CO stretching vibrations (amide I band), and at 1515–1570 cm^{-1}, characteristic of NH bending vibrations (amide II band) [4].

Polybenzimidazoles are known [5] to exhibit high heat resistance, but their hardness and insolubility in common organic solvents complicate their processing into finished items by modern industrial methods. Introduction of amide bonds into the macromolecule increases the solubility of PABIs in amides and other available organic solvents, with insignificant decrease in the heat resistance. Polymers prepared by the above scheme have high molecular weight, with the solution viscosity also depending on the molar ratios of the reactants:



where X = –O–, –CH_2–; R = –$(CH_2)_4$, .

All the synthesized polymers are soluble at room temperature in sulfuric and formic acids and, on heating, in acetic acid, DMF, tricresol, and benzyl alcohol. The solubility grows with increasing mole fraction of ε-caprolactam. The copolymers with mole fraction of ε-caprolactam greater than 0.4 are in most cases completely dissolved in tricresol and benzyl alcohol at room temperature. As seen from the table, the synthesized PABIs soften on heating, in contrast to the known polybenzimidazoles [5]; the softening point decreases with increasing mole fraction of ε-caprolactam. According to the results of thermomechanical analysis, the softening point lies within 180–390°C, being lower in polymers with bridging methylene group. Depending on the structure of their monomeric units, polyamidobenzimidazoles exhibit different thermal characteristics; with increasing content of benzimidazole fragments the onset of degradation shifts to higher temperatures. Thermal analysis data show that degradation of PABIs in air in the range 300–600°C occurs in two stages (Figs. 1a, 1b). The first stage, in which the weight loss does not exceed 5%, occurs within 330–400°C. Degradation of PABI in air occurs similarly to degradation in an inert atmosphere. The IR spectra of samples heated to these temperatures do not differ from those of the initial samples, except for a decrease in the intensity of some absorption bands due to cross-linking of the polymer. Presumably, the degradation processes occurring in this stage do not involve the backbone chain, although the polymer becomes insoluble. An appreciable (>5%) weight loss occurs at 380–460°C, which is due to extensive degradation of PABI. With respect to heat resistance,

PABIs prepared from ε-caprolactam, diphenyl esters, and aromatic tetramines can be ranked in the following order (X is the bridging group in the tetramine and R is that in the dicarboxylic acid):

X	R	X	R	X	R	X	R
$-(CH_2)-$	$-(CH_2)_4-$	< $-O-$	$-(CH_2)_4-$	< $-CH_2-$	$-C_6H_4-$	< $-O-$	$-C_6H_4-$.

The relatively low heat resistance of PABI with a bridging methylene chain is probably due to insufficient conjugation with the benzimidazole system and insufficient degree of polymer cyclization. The copolymers with an oxygen bridge are the most heat-resistant. As expected, the polymer containing no bridging groups between aromatic rings is more heat-resistant than the polymers studied in this work, but its solubility drastically decreases [6].

To gain insight into the degradation mechanism, we studied the thermolysis of PABIs by pyrolytic gas chromatography. The gaseous degradation products were assigned to specific macromolecular fragments. Chromatographic curves (Fig. 2) show that the primary gaseous degradation product is hydrogen. The relatively low temperature of hydrogen evolution from the majority of PABIs is mainly due to the lability of the hydrogen atom in the benzimidazole group. Presumably, the polymer is cross-linked in this stage via the nitrogen atom of the benzimidazole ring with evolution of hydrogen and low-molecular-weight side products [7]. This assumption is confirmed by the results of thermal analysis (see above). The evolution of carbon dioxide is due to hydrolysis of amino amide structures with the formation of carboxy groups, followed by their decarboxylation. The increase in the content of carbon oxides suggests decomposition of the linear fragments of the macromolecules and cleavage of bridging bonds with release of volatile degradation products and polycyclization of the polymer. On further heating, minor amounts of CO_2, CH_4, C_2H_4, ammonia, and cyano compounds are detected, suggesting decomposition of aromatic and heterocyclic fragments of the copolymer.

CONCLUSION

The synthesized polyamidobenzimidazoles have high molecular weight, high heat resistance, and good mechanical characteristics and exhibit film-forming properties. These characteristics depend on the structure of the monomeric units and molar ratio of the initial monomers. Being the most heat-resistant, the copolymers derived from 3,3',4,4'-tetraaminodiphenyl ether and diphenyl isophthalate are of practical interest.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Polymer Complexes and Their Flocculation Power

R. K. Zakirov, F. Yu. Akhmadullina, N. N. Valeev, and D. G. Pobedimskii

Kazan State Technological University, Kazan, Tatarstan, Russia

Received April 19, 2000

Abstract—Complexation of various complementary polymers and the flocculating power of the resulting complexes were studied. Regression equations adequately describing the recovery of phenol by polymeric complex reagents are presented.

Polymer complexes are the products of interaction of complementary polymers. They possess specific physical and mechanical properties that strongly differ from those of the initial polymers. The operation stability of polymer complexes determines their wide use as ion exchangers, soil structuring materials, supporting compounds and membranes for medicine purposes, and high-performance flocculants.

In this work, the interaction in binary systems of dissimilar polymers and the flocculating power of the resulting complexes was studied with the aim to develop high-performance macromolecular reagents for pretreatment of wastewater of complex composition with toxic components, produced in base organic synthesis.

In our tests we used a modified ampholyte gelatin—phthaloylgelatin [PG, molecular weight $(60–80) \times 10^4$)], nonionic polyethylene oxide (PEO, 9×10^5), proksanol (PR, 3×10^3), and cation-active polymer VPK-402 (1.1×10^6), which show high-performance in water treatment [1, 2].

Data on complexation and prevailing binding mechanism in the PG–PEO, PG–PR, and PG–VPK systems were obtained by viscometry, conductometric titration of isomolar series, and IR spectroscopy.

The viscosity and conductometric characteristics of individual compounds and their binary systems were measured by common procedures at 25°C using 0.1–1.0% solutions of macromolecular compounds (MMCs). First, we compared the results of the above measurement with the theoretical (additive) dependences that would be observed in the absence of specific interaction in the systems. As a result, certain deviations between the experimental and theoretical data were observed suggesting the formation of associates. The ranges corresponding to maximum extent of complexation between the polymer reagents were determined using the procedure proposed in [3]: the relative viscosities or electrical conductivities corresponding to the additive curve were taken as unity, and then the experimental results were converted into relative quantities ($\eta/\Sigma\eta$ or $\chi/\Sigma\chi$).

For each polymer pair, dependences of the above parameters on the MMC content were recorded (Figs. 1a–1c). The experimental viscosity and electrical conductivity in the binary systems differ from the additive values, which indicates intermolecular

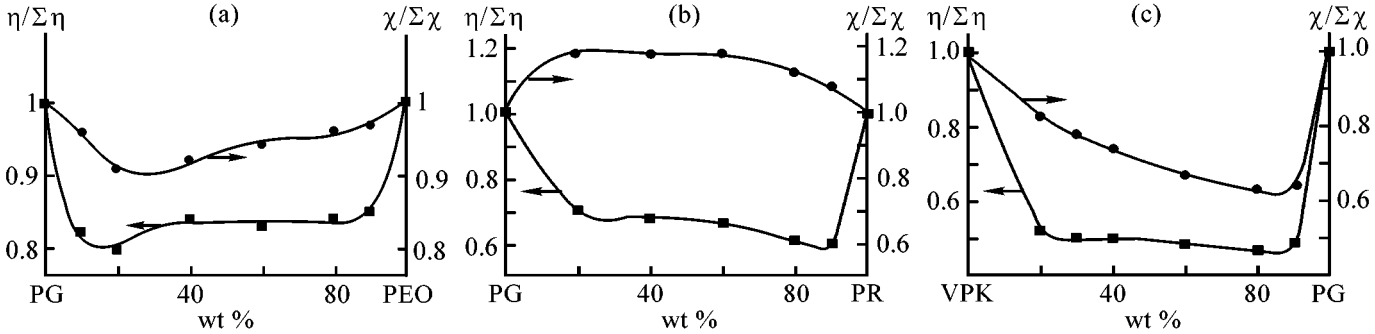

Fig. 1. Reduced electrical conductivity $\chi/\Sigma\chi$ and viscosity $\eta/\Sigma\eta$ in the (a) PG–PEO, (b) PG–PR, and (c) VPK–PG binary systems as influenced by variations in the system composition.

1070-4272/01/7404-0673 $25.00 © 2001 MAIK "Nauka/Interperiodica"

the association with the formation of polymer complexes in these systems.

As seen from Fig. 1a, polymer complexes are formed in the PG–PEO system in a wide concentration range (20–80 wt %). Almost similar dependence is observed for the dependence of the electrical conductivity; a minimum in this parameter is observed in the same concentration region.

Proxanol and PG form polymeric complexes in almost the entire concentration range (Fig. 1b), but the strongest and most stable complexes are formed at PR : PG = 86 : 14. The minimum in the viscosity curve corresponds to $\eta/\Sigma\eta = 0.56$, i.e., a nearly twofold decrease in the solution viscosity (as compared with the theoretical data) is observed, which suggests they formation of stable associates in this system. The significant increase in the electrical conductivity in the system is probably due to an increase in the uncompensated charge of phthaloylgelatin macromolecules in complexation of proksanol with modified gelatin.

As seen from Fig. 1c, in the VPK–PG binary system, the viscosity ($\eta/\Sigma\eta = 0.47$) and the electrical conductivity ($\chi/\Sigma\chi = 0.63$) change most significantly suggesting the strongest, among the systems studied, interaction between the components. Complexation also proceeds in a wide concentration range. The most stable complexes are formed in a narrow PG : VPK range (80–90) : (20–10), which is confirmed by the conductivity data and suggests a compact structure of macromolecular globules of the given polymeric complexes.

An IR study allowed us to analyze the nature of the forces stabilizing the structure of the polymer complexes.

The intermolecular interaction of the polar groups of polyampholyte, polyethylene oxide, and proksanol molecules via hydrogen bonds is a decisive factor in the formation of associates between modified gelatin and nonionic polymers. This is confirmed by the IR spectra of the polymer complexes and starting compounds, which are strongly different in the regions of stretching vibrations of the –NH and –OH bonds. In the 3600–3300 cm^{-1} range, the IR spectrum of PG exhibits a strong band at 3315 cm^{-1} and the stretching vibrations of the terminal hydroxy groups in PEO and PR appear as broad weak bands at 3390 and 3370 cm^{-1}, respectively.

In the case of PG and nonionic VPK complexes, the ν(OH, NH) band is shifted by nearly 30 cm^{-1} to higher frequencies as compared with the spectrum of PG, whereas the vibrations of terminal OH groups in associates with PG are shifted to lower frequencies in comparison with PEO and PR by 28 and 50 cm^{-1}, respectively. This suggests the formation of a new system of hydrogen bonds in the binary systems, which confirms the structure formation via intermolecular hydrogen bonds. It should be noted that these bonds are weaker than the hydrogen bonds in the PG macromolecule and stronger as compared with PEO and PR. Oxygen atoms of the carbonyl and ether groups of polymeric macromolecules are also involved in macromolecule binding, which is confirmed by changes in the shape of the absorption bands of the C=O and C–O–C stretching vibrations in the spectra of polymer complexes.

In the PG–VPK system, another mechanism of macromolecule binding is preferable. Apparently, electrostatic forces play a significant role in the formation of polymer structures in a wide range of component ratios, and the hydrophobic interactions additionally stabilize the resulting complex.

The flocculating power of the copolymers was studied by the known procedure in flow-type aerated apparatus including the units for preliminary clarification and biological purification [1]. The tests were carried out using real industrial wastewaters and slurry suspension under conditions close to those of the industrial process.

The performance of the polymer complexes in the treatment of industrial wastewater was evaluated with respect to phenol (which is the main biological toxin) and calculated as the ratio of the difference between the content of phenols in the wastewater after biological treatment and after preliminary clarification to the content of phenols in the initial wastes (control sample).

To evaluate the mutual influence of various polymers and the effect of the degree of the wastewater contamination on the quality of water purification with respect to the control sample, we performed a mathematical processing of the experimental results. Taking into account the complex and unstable composition of the industrial wastewater, a regression equation in the form of a second-order polynomial was used as a mathematical model:

$$y = b_0 + \sum_{j=1}^{k} b_j x_j + \sum_{j=1}^{k-1} \sum_{l=j+1}^{k} b_{j1} x_j x_1 + \sum_{j=1}^{k} b_{jj} x_j^2,$$

where y is the efficiency of wastewater purification to remove phenol (%), b_j are the coefficients of the regression equation, and x_j are the concentrations of phenol in the initial sample or those of the corresponding flocculants (mg l^{-1}).

Table 1. Coefficients of the regression equation $y = b_0 + b_1c_{PG} + b_2c_{MMC} + b_3x_P + b_{11}c_{PG}^2 + b_{22}c_{MMC}^2 + b_{33}x_P^2 + b_{12}c_{PG}c_{MMC} + b_{13}c_{PG}x_P + b_{23}c_{MMC}x_P$

Flocculating agent	Coefficient										R, %
	b_0	b_1	b_2	b_3	b_{11}	b_{22}	b_{33}	b_{12}	b_{13}	b_{23}	
PG–PEO	13.0	8.78	–0.338	–18.5	–0.312	0.186	2.29	–1.25	0.628	1.68	79.1
PG–PR	7.85	–11.0	5.84	13.7	2.35	0.778	–0.735	–1.08	–0.206	–1.96	58.7
PG–VPK	16.3	4.23	16.6	–2.40	–0.18	–4.30	0.030	–1.00	0.177	0.408	74.7

The results of mathematical processing of the experimental data are listed in Table 1.

Analysis of the resulting dependences and determination coefficients shows fair convergence of the experimental and theoretical values (coefficient of regression R in Table 1).

Since the target function is determined by three variables, the mutual effect of the decisive factors was analyzed using the $y = f(c_i, c_j)$ surfaces at fixed third parameter.

The most complex dependence was plotted for the PG–VPK binary composition (Fig. 2a). These results suggest the decisive role of the polymeric ampholyte; with increasing concentration of this compound in the complex reagent, the efficiency of phenol recovery grows significantly. As for the effect of cation-active VPK, the maximum efficiency with respect to phenol is attained at medium concentrations of the cationic flocculant in the polymeric reagent. Further increase in its concentration impairs the performance of the binary system.

The dependences plotted in Figs. 2b and 2c illustrate mutual effect of a given reagent and the initial concentration of phenol (toxicant) on the quality of purification of wastewater treated with PG–VPK binary system. The resulting dependences have a rather complex saddle shape and confirm the above conclusions on the decisive role of modified gelatin and insignificant effect of VPK (Fig. 2a). With increasing phenol concentration in the wastewater (within the limits of the emergency discharge), the recovery of the toxicant is enhanced, which is obviously due to the increase in the probability of contact between the binary flocculant and phenol molecules.

The binary systems based on PG and nonionic polymers of various molecular weights exhibit an analogous effect of the polyampholyte and phenol concentrations on the quality of the purified water. At the same time, the surfaces obtained for these systems are less complex in shape and smoother.

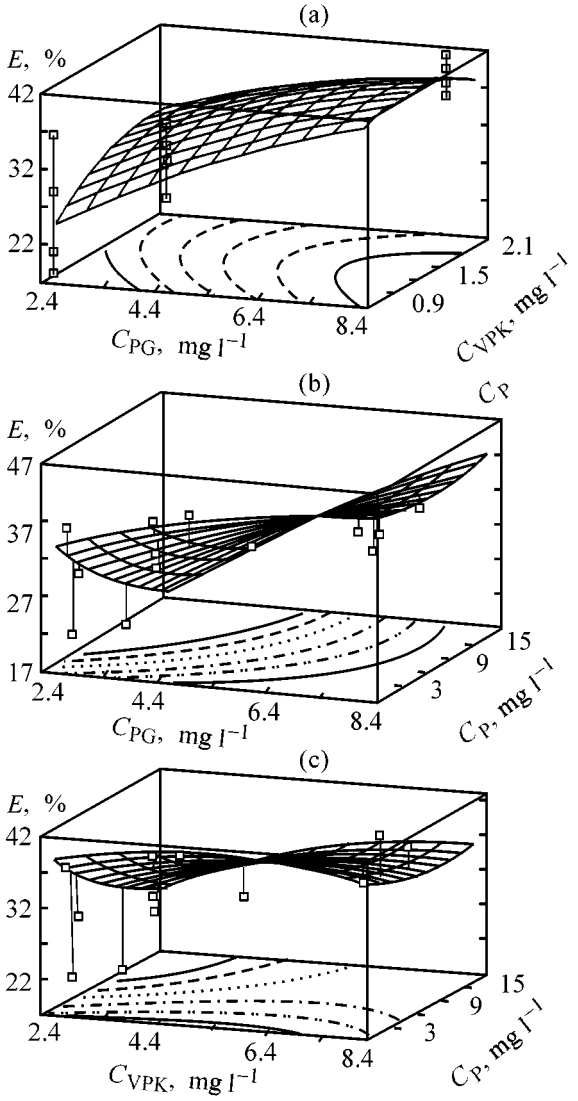

Fig. 2. Mutual effect of (a) modified gelatin and cation-active polymer, (b) modified gelatin and phenol, and (c) cation-active polymer and phenol on the efficiency E of phenol recovery. Concentration of (a) phenol, (b) VPK, and (c) modified gelatin 5 mg l^{-1}.

Table 2. Comparison of experimental and theoretical results

Flocculant	Optimal charge, mg l^{-1}		Optimal ratio			Efficiency, %	
	experiment	calculation	experiment	calculation		experiment	calculation
				model	complexation		
PG–PEO	7–10	7	4 : 1–6 : 1	4 : 1–6 : 1	4 : 1–6 : 1	57–64	60
PG–PR	12–13	10–12	1 : 1–3 : 1	1 : 1–3 : 1	1 : 6	40–55	45–50
PG–VPK	10	8–9	4 : 1–6 : 1	4 : 1–7 : 1	4 : 1–7 : 1	35–38	40

The data presented in Table 2 confirm the feasibility of using the obtained mathematical models to predict the degree of decontamination to remove the most toxic component with polymeric complex flocculants from wastewater formed in base organic synthesis taking into account the initial degree of the wastewater contamination.

As seen, such principal parameters as optimal charges and component ratio in the polymer reagents, ensuring their maximum flocculating power, are consistent with the experiment for the systems studied.

Comparison of the optimal component ratios in the binary reagents, determined experimentally in a study of complexation and theoretically (from the regression analysis), shows that the efficiency of flocculants is the highest at the ratios corresponding to the formation of the most stable polymeric complexes.

The only exception is the PG–PR system. This is probably due to an increase in the uncompensated charge of PG macromolecules in the course of complexation with PR (Fig. 1b), which deteriorates the conditions of phenol recovery. The increase in the content of the polyampholyte improves the efficiency of the complex reagent, which is probably due to the growing concentration of active centers forming hydrogen bonds with proton-donor compounds. The presence of intermolecular hydrogen bonds providing interaction between the binary reagent and phenol with its subsequent recovery from wastewater is confirmed by IR data; it was found that new hydrogen bonds are formed in the complex reagent–phenol system.

As seen from Table 2, the polymeric flocculant based on PG and PEO exhibits the highest efficiency. The use of low-molecular-weight nonionic and cation-active polymers significantly decreases the flocculating power of the complex reagents.

Comparison of the results for the PG–PEO and PG–PR binary systems reveals the contribution from the molecular weight of components of the complex flocculant. As seen, low-molecular-weight PR decreases the flocculating power of the binary reagent by 10–15% on the average [4].

Despite the rather close molecular weights of the complexes of PG with PEO and VPK (similar conditions of complexation, comparable molecular weights of nonionic and cation-active polymers), the PG–VPK system exhibits lower flocculation efficiency. This is probably due to the predominant mechanism of phenol binding with copolymer associates.

With account taken of the composition, structure, and nature of macromolecular compounds forming interpolymer complexes, it is obvious that the binary flocculant based on PG and PEO possesses a greater number of proton-donor and proton-acceptor groups, not involved in the polymer-polymer interaction and forming intermolecular bonds with wastewater components, in particular, phenol. These are carboxy, hydroxy, amido, and other groups of modified gelatin and ether groups of polyethylene oxide. The replacement of a nonionic polymer by a cation-active one makes lower the efficiency of interaction of the resulting copolymer and phenol because of the decrease in the number of the active centers capable of hydrogen bonding.

EXPERIMENTAL

The viscosity of the polymer solutions was measured on a Ubbelohde viscometer with a capillary diameter of 0.73 or 0.86 mm.

To prepare a solution of a macromolecular flocculant, a weighed portion of a polymer was added to a required volume of water and the mixture was agitated with a magnetic stirrer at a rate of no more than 200 rpm. Before measurements, the solutions were filtered through a coarse glass filter.

The conductometric parameters were measured on a P-5021 ac potentiometer, an F582 unit (zero reader),

in a special conductometric cell with a 0.6-mm distance between platinum electrodes (1 cm^2 area).

The mathematical processing of the results was done using a STATGRAPHICS Plus 3.0 software.

CONCLUSIONS

(1) Phthaloylgelatin–polyethylene oxide, phthaloylgelatin–proksanol, and phthaloylgelatin–VPK binary systems are promising for water treatment to decrease the toxicity of wastewater produced in base organic synthesis.

(2) Simulation of the processes of phenol recovery by polymeric complex flocculants allows formulation of recommendations on use of the given flocculants to cope with real emergency discharges of phenol.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Radical Graft Polymerization of Glycidyl Methacrylate and Polycaproamide Fiber

I. V. Lavnikova and V. F. Zheltobryukhov

Volgograd State Technical University, Volgograd, Russia

Received July 13, 2000; in final form, December 2000

Abstract—Graft polymerization of glycidyl methacrylate to polycaproamide fiber, initiated by the highly effective redox system Cu^{2+}–H_2O_2, was studied. The kinetic parameters affecting the yield of grafted polyglycidyl methacrylate and the efficiency of the graft polymerization were determined.

Analysis of the existing procedures for preparing new polymeric fibrous materials and the possibilities of controlling their physicomechanical and chemical properties shows that graft polymerization is a promising procedure for production of manmade (in particular, polycaproamide, PCA) fibers [1–3]. Modification of a PCA macromolecule with glycidyl methacrylate (GMA) containing reactive epoxy groups can be a route to ion-exchange fibers; therefore, development of an efficient process for modification of PCA fiber is of practical interest. The use of GMA in emulsion polymerization of the monomer makes fiber production environmentally appropriate; the process is sufficiently fast and does not involve homopolymer formation, which is typical of the emulsion polymerization [4].

Our goals were to improve the existing procedures [1] for preparing polycaproamide graft copolymers (PGCs) and to find the best conditions for grafting GMA to PCA. The main parameters of graft polymerization of PCA and GMA in the presence of the redox system Cu^{2+}–H_2O_2 are the concentration of the monomer and components of the redox system, and the polymerization temperature and time.

Graft polymerization can be apparently represented by the following scheme. The redox reaction between copper ions and hydrogen peroxide generates $\dot{O}H$ radicals whose reaction with PCA yields long-lived macroradicals initiating graft polymerization [1].

The influence of the GMA concentration on the amount of grafted polyglycidyl methacrylate (PGMA) and on the monomer conversion was studied in the range of GMA concentrations 0.24–16.5 M. Graft polymerization was performed in emulsion, with polyvinyl alcohol (0.1%) as emulsifier:

$$[NH(CH_2)_4CO]_n + \dot{O}H \rightarrow [NH\dot{C}H(CH_2)_4CO]_n,$$

$$[NH\dot{C}H(CH_2)_4CO]_n + m\,CH_2{-}\underset{O}{\overset{}{}}{-}CHCH_2OC(O){-}\underset{CH_3}{C}{=}CH_2 \rightarrow [NHCH(CH_2)_4CO]_n.$$

$$\begin{array}{l} \qquad\qquad\qquad\qquad\qquad\qquad\quad CH_3 \\ \qquad\qquad\qquad\qquad\qquad\qquad\quad | \\ \qquad\qquad\qquad\qquad\qquad\qquad CH_2{-}C]_m \\ \qquad\qquad\qquad\qquad\qquad\qquad\quad | \\ CH_2{-}CHCH_2OC{=}O \\ \diagdown\,O\,\diagup \end{array}$$

We found that graft polymerization is fast in the initial stage (Table 1). Raising the monomer concentration above 2.35 M is not appropriate, because the amount of PGMA increases insignificantly. Based on the data obtained in the [GMA] range from 1.2 to 2.35 M and using the procedure described in [5], we calculated the reaction order with respect to the monomer to be 1.93. This value is somewhat higher than

1070-4272/01/7404-0678 $25.00 © 2001 MAIK "Nauka/Interperiodica"

the values typical of heterogeneous polymerization, which is probably due to the capture of the macroradicals by the polymer phase [4].

At present, PGCs are prepared using redox systems, with initiation based on addition of one of the components to the PCA macromolecule. This method ensures very high efficiency of graft polymerization, because the peroxy compound decomposes either at the fiber itself or in its close vicinity. As a result, an active polymeric center is generated, at which graft polymerization of various monomers subsequently occurs [1]. Experiments at varied H_2O_2 concentration confirmed the trend revealed in studies of graft polymerization [6, 7]: with increasing $[H_2O_2]$, the amount of the graft polymer first increases and then, after reaching a maximum, decreases drastically, which is probably due to participation of H_2O_2 in termination of the growing PGMA chains. The kinetic parameters of graft polymerization with the redox system are listed in Table 2. These data suggest that copper ions catalyze graft polymerization. Without copper, grafting does not occur, and, even at a copper concentration as low as 0.0049 M, the reaction rate is 2.3×10^{-4} mol l^{-1} s^{-1}, and the amount of grafted PGMA, 22 wt %. The reaction rate is higher with the initiating system Cu^{2+}–H_2O_2, compared with the known initiating system Fe^{2+}–H_2O_2 [8]. It should be noted that, with increasing $[Cu^{2+}]$, the initial rate grows by a factor of 2.7, to 6.1×10^{-4} mol l^{-1} s^{-1}. The calculated reaction orders with respect to hydrogen peroxide and copper are somewhat lower than those in heterogeneous polymerization. This is probably due to the fact that the constants of chain transfer to the monomer are low and the escape of radicals from particles is insignificant; however, our results agree with data in [9].

A study of the graft polymerization in relation to temperature showed that at 0–60°C the yield of grafted PGMA is as low as 0.1 wt %, whereas at 70°C it becomes as high as 43 wt %.

The kinetic data in Table 3 show that graft polymerization initially occurs at a high rate in the examined temperature range. For example, the initial polymerization rate is 0.6×10^{-4} at 62°C, and as high as 7.4×10^{-4} mol l^{-1} s^{-1} at 70°C, with simultaneous increase in the yield of PGMA to 43 wt %.

The kinetic curves obtained in studing the temperature dependence of the reaction rate were used to calculate the activation energy of heterophase graft polymerization, found to be equal to 53.33 kJ mol^{-1}, which is typical of radical graft polymerization based on chain transfer from the low-molecular-weight radical

to the polymer [9]. Data in Table 4 show that graft polymerization decelerates with time and fully stops in 80 min.

EXPERIMENTAL

Polycaproamide in the form of staple fiber (1 g) was placed in a flask equipped with a reflux condenser and was activated with the Cu^{2+}–H_2O_2 redox system. For this purpose, PCA was treated with a 0.098–0.198 M aqueous solution of H_2O_2 in the presence of 0–0.018 M Cu^{2+} at 50–100°C for 10–90 min. Copper(II) was taken in the form of sulfate. The bath ratio was 30. Activated PCA was thoroughly washed with water for 60 min to remove excess H_2O_2 and copper salts. The washing completeness was checked by analysis for active oxygen.

Then PCA was treated with a 0.3–16.5 M emulsion of GMA in a flask equipped with a reflux condenser for 10–120 min at 60–80°C. The amount of the grafted polymer was determined gravimetrically and calculated from the content of epoxy groups. The overall activation energy was calculated from the temperature dependence of the rate constant.

CONCLUSIONS

(1) The main features of graft polymerization of glycidyl methacrylate and polycaproamide fiber in the presence of the redox system Cu^{2+}–H_2O_2 were determined.

(2) Under the optimal conditions, the maximal amount of the grafted polyglycidyl methacrylate is 46.5% and no homopolymer is formed.

Received April 12, 2000; in final form, July 2000

Abstract—Properties are studied of drilling solutions modified with carboxymethylated wood prepared by the suspension method under various conditions. Carboxymethylated wood is recommended as a chemical reagent for modification of drilling fluids.

Carboxymethyl cellulose (CMC) was one of the first cellulose-based chemical reagents for modification of drilling fluids. Presently it is a cellulose ether the most widely used for this purpose [1, 2].

Carboxymethyl cellulose sodium salt (NaCMC) (anion-active polymer) is adsorbed on clays. Even at low concentrations of NaCMC (especially with NaCMC having higher molecular weight, and consequently, higher viscosity) filtration can be markedly reduced. Low-viscosity NaCMC is used to reduce filtration of drilling fluids of very high density, and medium-viscosity NaCMC is added to drilling solutions with ordinary concentration of the solid phase.

NaCMC suspensions have the property of shear thinning, they possess high relative viscosity at very low shear rate. Similarly to other polymer suspensions, NaCMC suspensions have relative viscosity decreasing with increasing temperature. The efficiency of NaCMC as an agent reducing the filtration and increasing the viscosity decreases with increasing salt concentration. Some of Ca-containing drilling fluids are thinned out by adding small amount of NaCMC. Carboxymethyl cellulose shows strong effect in neutral and weakly basic solutions (pH 6.0–9.0), but is low-efficient in acidic media. NaCMC precipitates at pH < 6 and coagulates at pH > 9.0 [3].

Addition of NaCMC favors better operation of rock cutting tools, increases boring speed and headway per drill bit, and improves mud pumping. Carboxymethyl cellulose is compatible with most of drilling reagents, providing a synergistic effect. Only chromates, are practically incompatible with NaCMC, being strong oxidants (in the presence of chromates, NaCMC undergoes oxidative degradation, especially at elevated temperatures).

Thermal degradation of carboxymethyl cellulose can be inhibited by adding phenol, aniline, amine hydrochloride, or other compounds. In this case, the clay solution preserves its characteristics up to 180–190°C. However, simultaneous use of several clay suspension inhibitors (to provide synergistic effect) has a number of drawbacks, such as increased consumption of inhibiting reagents (up to 100% relative to the NaCMC weight) and filler, difficulties in transportation (especially in winter time), and high toxicity of phenol-containing inhibitors. The protecting effect of the inhibitors is based on their preferential oxidation, compared with NaCMC [4], as it has been clearly demonstrated for the example of oxidation of phenol fragments of lignin in separation of cellulose from wood by the oxygen–alkaline method, studied with model compounds [5]. It has been shown that it is possible to overcome in part the indicated problems and to improve the inhibiting effect of phenol if NaCMC is synthesized in its presence [6, 7]. Note also that such synthetic reagents as Karbofen (based on phenol) and Karbanil (based on aniline and urea) improve the thermal and salt resistance of drilling fluids.

Among lignin-based chemical reagents used in drilling, mention can be made of Sunil. It is synthesized

by treatment of wood lignin with concentrated nitric acid, followed by partial reduction of the introduced nitro groups to amino groups with sulfite. Sunil provides a considerable decrease in the viscosity and gel strength of drilling fluids. Additionally, Sunil demonstrates such useful properties as bio- and atmosphere resistance.

In our opinion, synthesis of a carboxymethyl derivative of wood without its preliminary decomposition, i.e., containing carbohydrate and aromatic fragments [8–10], will combine in this reagent a set of properties useful in its application as a modifier of drilling fluids [11].

EXPERIMENTAL

Carboxymethylated aspen wood was prepared by successive treatment of sawdust (0.4–0.7-mm fraction) with NaOH and sodium monochloroacetate in 10-l SMKS-10 reactor mixer at a wood-to-NaOH-to-sodium monochloroacetate ratio of 1.0 : 0.6 : 1.5. The moisture content of the reaction mixture was 40%. The yield of the carboxymethylated product was 0.3–3 kg.

Carboxymethylation of wood in organic solvents was carried out as follows. A weighed portion (10 g) of sawdust (0.4–0.75-mm fraction) was placed in a porcelain mortar and vigorously ground with a pestle with 5.83 g of preliminarily crushed NaOH. Then 70 ml of a solvent was added; the mixture was triturated, placed in a reaction flask, and allowed to stand at 80°C for 3 h. Then the reaction mixture was transferred from the flask to a porcelain mortar, 2.4 g of sodium monochloroacetate was added, and the content was thoroughly ground with a pestle to obtain a homogeneous mass. The resulting mass was placed in a reaction flask and allowed to stand at 40°C for 1 h. The resulting product was air-dried and then washed with 96% ethanol. During washing, 90% acetic acid was added to a negative reaction for alkali (with phenolphthalein) and chloride (with silver nitrate).

The solubility of the resulting carboxymethylated products in water, relative viscosity of their alkaline solutions, and content of carboxymethyl groups were determined by the procedures recommended in [12].

The characteristics of drilling fluids [relative viscosity (RV), plastic viscosity (PV), filtration index (FI), yield point (YP), and gel strength (GS)] were determined by the standard procedures used to test drilling fluids [13].

The rheological properties of model drilling fluids were studied with a Haake Viscotester VT550 rotary viscometer. As model drilling fluids served aqueous suspensions containing 8% bentonite clay (< 0.1-mm fraction) and 0.3% of a chemical reagent (carboxymethylated aspen wood prepared in various organic solvents).

Methods are known for carboxymethylation of cellulose in the presence of minor amounts of water in pug mills or reactor mixers [14]. In the present work, we studied for the an example of aspen wood the possibility of carboxymethylation of lignocarbohydrate materials in 10-l SMKS-10 reactor mixer. The conditions of synthesis and characteristics of the products are given in Table 1 (τ_1 and T_1 are the alkaline treatment time and temperature, τ_2 and T_2 are the carboxymethylation time and temperature, CMG is the carboxymethyl group content, S is the solubility in water, and η_{rel} is the relative viscosity of alkaline solutions).

Properties of the products obtained in the reactor mixer are close to those of the products obtained in a laboratory homogenizer [15, 16]. The temperatures of thermal treatment and carboxymethylation were maintained obviously lower than those in [15, 16], assuming that shear stress makes carboxymethylation in a reactor mixer more efficient, which may result in a considerable decrease in the sample viscosity at higher temperatures.

Sample CMD-5 was obtained in aqueous alcohol (isopropanol) solution under the following conditions: liquid-to-solid ratio 13 (weight ratio of isopropanol to water 4.3 : 1); alkaline treatment and carboxymethylation times 6 and 3 h, respectively (the total process

time was 18 h, the carboxymethylation stage being performed twice); and alkaline treatment and carboxymethylation temperatures 50°C. Characteristics of CMD-5: carboxymethyl group content 18.9%, relative viscosity 1.11, and solubility in water 93%.

The carboxymethylation products directly obtained from wood contained carboxymethylated cellulose, hemicelluloses, and lignin, as demonstrated by spectral and chemical analysis. As characteristics of model drilling fluids prepared on the basis of clay (the main structure- and crust-forming component of drilling solutions) we measured the relative viscosity, plastic viscosity, filtration index, clay crust thickness *K*, yield point, gel strengths after 1 and 10 min (GS_1 and GS_{10}, respectively), and pH, i.e., the most significant properties influenced by addition of NaCMC. The results are given in Table 2.

Alkaline solutions of carboxymethylated wood obtained by the suspension method in aqueous alcohol medium show higher relative viscosity (1.11) as compared with samples obtained at low liquid-to-solid ratio in aqueous solutions under conditions of vigorous mechanical agitation.

It should be pointed out that the solubility of carboxymethylated cellulose varies within 86–93%. This value is lower than that of commercial NaCMC (mostly having solubilitions of 98–100%), which does not deteriorate the performance characteristics of drilling fluids modified with CMD.

The suitability criterion of drilling fluids is that the gel strength should be higher than the stress provided by the mass of suspended particles of drill cuttings or a filler (clay). Otherwise these particles start to precipitate when circulation of a drilling fluid in a borehole stops. A general requirement to the structural mechanical properties of a drilling fluid is that its structure should ensure stabilization of a suspension of drill cuttings under non-circulation conditions. To characterize the evolution of the drilling fluid structure strength in the course of time, the gel strength is measured 1 and 10 min after the state of rest is established.

Suspensions modified with CMD are weakly structured as compared with the dispersion medium (16% clay suspension). The disperse phase particles weakly interact each with other, forming no sufficiently stable structures in the state of rest.

GS_1 of drilling fluids modified with various CMDs ranges from 6.80 (CMD-5) to 21.51 dPa (CMD-2), which is considerably lower as compared with that of drilling fluids modified with commercial reagent CMC-Toros, being comparable in this parameter with CMC-600.

For drilling fluids modified with any of CMD samples obtained, GS_{10} increases by about 3–4 dPa, except in the case of CMD-5 (for this sample the rise was about 10 dPa, which is comparable with that for CMC-600). GS_1 and GS_{10} of drilling fluids modified with CMC-Toros are high, indicating that these fluids are highly structured, i.e., have a spatial structure with high mechanical strength. Use of drilling fluids with very strong structure, i.e., with high gel strength, deteriorates the conditions for drilling fluid treatment in chutes to remove drill cuttings, and also results in strongly fluctuating pressure on borehole walls during running and pulling-out of a drill string. The pressure differences caused by motion of a drill string across

a well bore are the higher, the stronger the structure of a drilling fluid in the borehole. During pulling-out of a drill string, the pressure on borehole walls decreases, which may result in distortion of the borehole stability and also in gas (or oil) show or water development. In running of a drill string, the pressure on the walls increases, so that it may reach a value sufficient for formation breakdown and lost return [17].

The most significant rheological characteristics of drilling fluids are the relative viscosity, plastic viscosity, and yield point.

In drilling, it is advisable to use a drilling fluid with as low viscosity as possible, but having a sufficiently high supporting power. A possible exception from this rule are cases of large-size hole boring, when the hole clearance cross-section is so high that, even at the maximal slush pump delivery, it is impossible to provide a return velocity sufficient for cutting transport. A higher viscosity of drilling fluids may improve the cutting transport.

The relative viscosity of CMD-modified drilling fluids ranges from 17.5 to 22.3 s (RV of the initial clay suspension 19 s), i.e., addition of CMD has virtually no effect on this rheological parameter. By contrast, CMC-Toros increases RV to 114.5 s, and CMC-600, to 59.0 s, which impairs well-boring parameters.

The plastic viscosity of the initial 16% clay solution is 6.09 mPa s. For fluids modified with carboxymethylated wood samples CMD_1–CMD-5 this value is 6.02–7.48 mPa s. Addition of CMD-5 increases PV to 10.53 mPa s. The commercial reagents increase PV of the clay suspension by a factor of 2–3 relative to the values obtained for the reagents proposed in this work: PV of model fluid with CMC-600 is 14.60 mPa s, and with CMC-Toros, 19.36 mPa s. Thus, again, the proposed carboxymethylated derivatives of wood are preferable as regards this parameter.

The observed RV and PV of the carboxymethylated reagents proposed may be lower, compared with the known commercial reagents, for two reasons: (1) lower degree of polymerization of the products and (2) lower viscosity caused by the presence of carboxymethylated lignin in the composition of the CMDs. Modified lignins (chlorolignin, Sunil, and Igetan) are widely used, together with NaCMC, as additives to drilling fluids acting as thinners of clay suspensions [3]. The carboxymethylated wood products proposed in this work are multifunctional, containing both the carbohydrate and aromatic fragments.

Addition of CMDs has a stronger effect on the yield point of the initial clay suspensions: depending on a CMD sample, the initial value (17.05 dPa) changes within the range from 8.51 (CMD-5) to 34.45 dPa (CMD-2). As seen, addition of CMD-5 considerably (by a factor of 2) decreases the initial value. The maximal increase in YP is observed with CMD-2. Addition of CMC-600 or CMC-Toros makes YP a factor of 3–4 higher, which is unfavorable in well-boring too, since the yield point characterizes the shearing resistance of the fluid, unlike the gel strength reflecting the strength of the fluid structure in the state of rest. Therefore, the greater the YP, the stronger the resistance of the fluid to a well bore, which is accompanied by such unfavorable effects as gage wear, increasing power consumption, etc.

It is well known that pH considerably affects the properties of drilling fluids. The minimal viscosity of the initial clay suspensions is observed at pH 8.5–9.5. The optimal pH was demonstrated to be 9–11. However, raising the pH of drilling fluids deteriorates the stability of borehole walls built of a clay material as a result of its disintegration, decreases the formation productivity because of the swelling of the clay constituents of the formation material, and leads to rapid corrosion of drill pipes made of light aluminum alloys. The acidic medium accelerates corrosion of steel drill pipes and other steel facilities operating in contact with drilling fluids. The pH of drilling fluids modified with CMD-1–CMD-4 ranges from 7.25 to 7.50, which is somewhat lower than that of drilling fluids with the known commercial reagents. The pH of clay suspension modified with CMD-5 is 8.25, which is comparable with that of drilling fluids modified with commercial reagents.

Thus, addition of carboxymethylated derivatives of wood provides simultaneous decrease in the filtration index, yield point, and gel strength of drilling fluids, having practically no effect on their basic rheological characteristics, such as the relative and plastic viscosities. Commercial reagents CMC-600 and CMC-Toros decrease the filtration index even more efficiently, but, simultaneously, they initiate considerable increase in all or nearly all of the rheological characteristics (relative viscosity, plastic viscosity, yield point) and structural mechanical properties of drilling fluids. Therefore, carboxymethylated wood demonstrates significant advantage over commercial CMC. The reagents proposed in this work constitute a new class of chemical reagents that can be used as modifiers of drilling fluids [11].

The majority of the methods for preparation of CMC are based on treatment of alkaline cellulose in organic

or aqueous-organic solvents. In this work, we synthesized carboxymethylated derivatives of aspen wood in various organic solvents by the method described in [10] and studied the rheological properties of clay suspensions (8% bentonite clay in water) modified with them. The reagent content was 0.3% in all experiments.

The dynamic viscosity was measured at various shear rates with a Haake Viscotester VT550 rotary viscometer. Figure 1 shows the yield point of the clay suspension modified with carboxymethylated aspen wood, prepared in various protic (Fig. 1a) and aprotic solvents (Fig. 1b), as a function of the shear rate. For comparison, data are given for a drilling fluid modified with 0.3% CMC-600. The shape of the curves is similar in all the cases, despite that the properties (solubility in water, content of carboxymethyl groups, and relative viscosity of alkaline solutions) of the carboxymethyl derivatives vary widely, depending on an organic solvent in which they were prepared [18].

The presented results show that all the model drilling fluids demonstrate behavior typical of non-Newtonian fluids. The systems studied are pseudoplastic, since the yield point depends on the shear rate. It follows from a comparative analysis of the curves given in Fig. 1 that the yield point grows more slowly with increasing shear rate for carboxymethylated aspen wood.

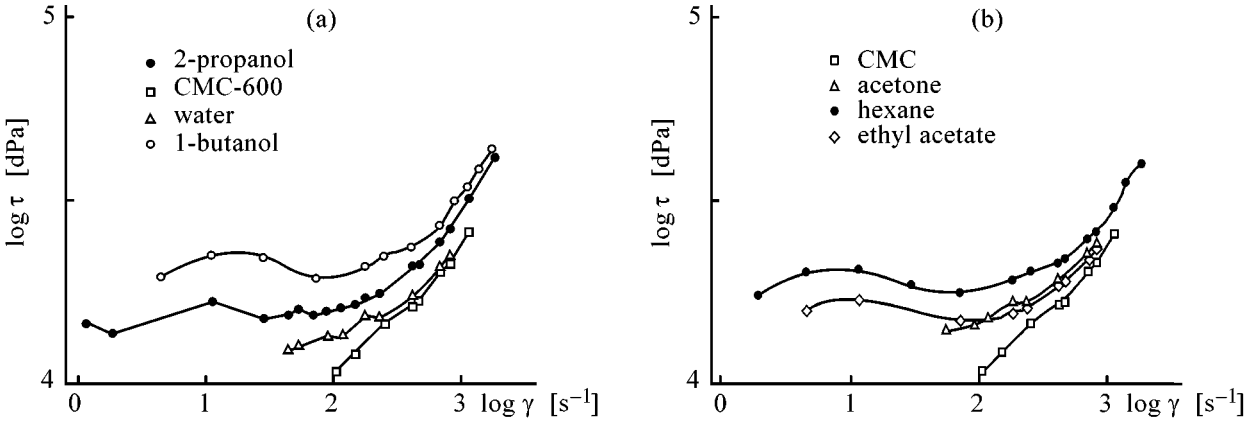

Fig. 1. Yield point τ of bentonite clay suspensions modified with 0.3% carboxymethylated aspen wood, prepared in various (a) protic and (b) aprotic solvents, vs. the shear rate γ.

Table 3 summarizes the rheometric data for clay suspensions modified with carboxymethylated wood prepared in various organic solvents and water.

The list of parameters characterizing the rheological properties of drilling solutions is determined by selection of a theoretical model, i.e., an equation relating the stress τ to the deformation or shear rate γ [18].

It follows from Table 3 that in most cases the rheological properties of the tested modified clay suspensions are described more adequately by the Bingham–Shvedov model.

For carboxymethylated wood samples obtained in chloroform, 1,4-dioxane, methanol, and isopropanol, the yield point is nearly constant over a wide range of shear rates. Chemical reagents based on carboxymethylated aspen wood demonstrate a wider spectrum of rheological parameters as compared with CMC, which allows them to be recommended as modifiers for drilling fluids used in gas and oil-well drilling.

CONCLUSIONS

(1) Carboxymethylated aspen wood reduces the filtration index, gel strength, and yield point of bentonite clay composites without changing their elastic and relative viscosities, which allows use of such composites for preparing drilling fluids.

(2) Rheological properties of clay suspensions modified with carboxymethylated aspen wood, obtained in various organic solvents, can be described more adequately in terms of the Bingham–Shvedov model.

Abstract—Jet fuel containing less than 10 wt % arenes and aromatic petroleum solvents of the Nefras AR-120/200 type was prepared by combination of arene extraction from the hydrorefined kerosene fraction with the acetonitrile–pentane system, followed by concentration of arenes in the course of acetonitrile regeneration from the extract phase, based on the formation of azeotropes of acetonitrile with saturated C_9–C_{10} hydrocarbons.

Environmentally clean jet fuels can be produced by extraction of aromatic hydrocarbons and sulfur-containing compounds with aqueous acetone with addition of pentane [1, 2]. Despite its relatively low selectivity, acetone has significant advantahes as polar extractant: It does not form azeotropic mixtures with feed components and can be readily regenerated by distillation. Addition of water and pentane increases the selectivity; however, in production of environmentally clean jet fuels containing ≤10% aromatic hydrocarbons, their concentration in the extract usually does not exceed 85–90 wt %.

One of the best ways to utilize extracts of middle petroleum fractions is to produce such aromatic petroleum solvents as Nefras AR-120/200 and AR-150/330, analogs of Solvesso and Cyclosol (petroleum naphtha) [3]. These solvents are produced by catalytic reforming of hydrorefined petroleum fractions, followed by extraction of arenes, or by pyrolysis followed by sulfuric acid refining of the pyrocondensate to remove unsaturated hydrocarbons [4–6]. It seems more economically advantageous to produce aromatic petroleum solvents by extraction of hydrorefined middle distillates without using power-consuming catalytic or high-temperature processes. The main problem is how to ensure the required high concentration of arenes in the product: In Nefrases and their analogs the content of arenes is, as a rule, no less than 98 wt % [4, 7]. The requirements to petroleum naphthas are less stringent: 96 wt % according to GOST (State Standard) 10214–78 and 90 wt % according to TU (Technical Specifications) 38001196–79.

Our goal was to produce simultaneously the environmentally clean jet fuel containing ≤10 wt % arenes and aromatic petroleum solvents containing ≥98 wt % arenes from the hydrorefined kerosene fraction by means of the extractive process.

As an extractant we chose the heterogeneous acetonitrile–water–pentane system, successfully used previously for extractive refining of the diesel fraction [8]. Acetonitrile does not form azeotropic mixtures with C_9 arenes but forms them with saturated C_9–C_{10} hydrocarbons, which are components of the kerosene fraction [9]. Saturated hydrocarbons remaining in the extract must mainly include cycloalkanes and C_9–C_{10} alkanes, which are better soluble in acetonitrile than their higher-boiling homologs also present in the kerosene fraction. This fact somewhat complicates the flowsheet of acetonitrile regeneration from the extract phase; on the other hand, it must lead to higher content of arenes in the aromatic concentrate as compared with the extract, since the major fraction of saturated hydrocarbons will be removed as azeotropic mixtures with acetonitrile.

As the feed we used the hydrorefined kerosene fraction (154–220°C) from the Kirishinefteorgsintez Production Association, with the following characteristics: n_D^{20} = 1.4380; ρ_4^{20} = 0.781; content of arenes 14.0 wt %, including 13.2 wt % monocyclic arenes

2	3 : 1	0.7 : 1
3	3 : 1	1.0 : 1

and 0.8 wt % bicyclic arenes. The aromaticity factor determined from the ^{13}C NMR spectrum (Bruker AM-500 spectrometer) according to [10] was 0.09.

The 5-TP extractive refining of the kerosene fraction was performed with countercurrent supply of aqueous acetonitrile containing 5 wt % water and of the feed with addition of pentane. The conditions are listed in Table 1, and the results, in Table 2.

The solvents were regenerated by distillation of the extract and raffinate phases in 20-TP columns. In the course of distillation of the extract phase, the following fractions were obtained: <36°C, azeotrope of pentane with acetonitrile; 36–76°C, azeotropes of acetonitrile with water and saturated hydrocarbons; 76–81°C, mainly acetonitrile with admixture of water. The bottom residue was the aromatic concentrate.

By backwashing of acetonitrile from the 36–76°C fraction with water, we recovered arene-free saturated hydrocarbons distilled-off from the extract phase. These saturated hydrocarbons can be combined with the raffinate.

The characteristics of the raffinates and extracts, and also of aromatic concentrates recovered after distillation of the solvents and removal of the major fraction of saturated hydrocarbons from the extract in the form of azeotropes with acetonitrile and water, are listed in Table 2. The concentration of saturated hydrocarbons decreases from 11.3–15.5 wt % in the extract to 0.5–3.4 wt % in the aromatic concentrate. With increasing acetonitrile : feed ratio, as expected, the degree of arene recovery increases, their

Density ρ_4^{20}	0.876	0.913	0.933

concentration in the raffinate decreases, with, however, simultaneously decreasing content of arenes in the extract and aromatic concentrate (run nos. 1, 2). By contrast, with increasing pentane : feed ratio, the content of arenes in the extract and aromatic concentrate increases, but, at the same time, the degree of arene recovery decreases somewhat (run nos. 2, 3). Raising simultaneously the acetonitrile : feed and pentane : feed ratios allows both the degree of arene recovery and the content of arenes in the aromatic concentrate to be increased (run nos. 1, 3).

After combining the raffinates with the saturated hydrocarbons recovered from the extract phase in the course of acetonitrile regeneration, the yield of the refined jet fuel in run nos. 1–3 increases to 94.63, 93.48, and 93.87 wt %, with the content of arenes decreasing to 9.26, 8.20, and 8.41 wt %.

The bicyclic arenes, whose presence in an environmentally clean jet fuel is particularly undesirable, are recovered to a much greater extent than monocyclic arenes. The content of bicyclic arenes in the raffinate is an order of magnitude lower than the level permitted for Jet A-1 fuel (≤3%) [11].

By distillation on a 20-TP column of the aromatic concentrate obtained under optimal conditions (run no. 3), we isolated three fractions whose characteristics are listed in Table 3. The data in Tables 3 and 4 show that the first fraction corresponds to Nefras AR-120/200. Its density ρ_4^{20} should be no less than 0.865, and the content of compounds undergoing sulfonation, no less than 98 wt %.

The second, with respect to the boiling limits and arene content, fraction corresponds to the solvent Solvesso 150, and the third fraction (bottoms) can be used as a component of Nefras AR-150/330. It is also possible to use as a component of Nefras AR-150/330 the combined second and third fractions.

CONCLUSIONS

(1) Extractive refining of the kerosene fraction with acetonitrile–pentane, combined with azeotropic distillation of acetonitrile with saturated hydrocarbons in the course of regeneration of acetonitrile from the extract, yields under optimal conditions an aromatic concentrate containing up to 99.5 wt % arenes, compared with 83.6 wt % in the extract.

(2) The proposed procedure of extractive refining of the kerosene fraction yields, without using power-consuming catalytic reforming, a jet fuel containing less than 10 wt % arenes and aromatic petroleum solvents of the Nefras AR-120/200 type.

CHEMISTRY OF FOSSIL FUEL

Recovery of Isobutylene from Commercial Butane–Butylene Fractions

K. G. Sharonov, A. M. Rozhnov, S. Ya. Karaseva, Yu. B. Myshentseva, V. I. Barkov, and V. I. Alenin

Samara State Technical University, Samara, Russia

Received February 28, 2000; in final form, September 2000

Abstract—A possibility of recovery of isobutylene with high concentration and purity from abgases of petroleum production and oil refining, e.g., from gases released in pyrolysis or catalytic cracking, by reversible reaction of isobutylene with isobutanol was studied.

In recent years, the production of methyl *tert*-butyl ether (MTBE) and methyl *tert*-amyl ether (MTAE) by alkylation of methanol with isoolefins has increased in many countries. These compounds are used as additives to motor fuel.

The hydrocarbon fractions C_4–C_5 of gases released in pyrolysis and catalytic cracking can be used as low-cost raw materials for production of isoolefins. A review of procedures for recovery of isoolefins from hydrocarbon gases was given in [1]. The procedures are based on the high reactivity of the tertiary carbon atom at the double bond in reactions of electrophilic addition. With many reagents (water, alcohols, and acids), such reactions are reversible, which allows recovery of concentrated isoolefins by subsequent decomposition of these products.

Strong acids, such as sulfuric, hydrochloric, organic sulfonic acids, and Friedel–Crafts catalysts can catalyze this reaction. The common drawback of these acids is their high corrosion activity and the low selectivity of the process. The use of weak acids, e.g., phosphoric, is inefficient owing to the low rate of the process. Of most interest as catalysts are sulfonic cation exchangers, allowing the reaction to be performed with high selectivity at low temperatures (85–90°C).

However, the procedure for hydration recovery of isobutylene via trimethylcarbinol (TMC), in which sulfonic cation exchangers are used as catalysts, has significant drawbacks: (1) the use of aqueous solutions decreases the catalytic activity of sulfonic cation exchanger, and (2) concentrated isobutylene-containing fractions (with isobutylene content of no less than 50 wt %) are used.

These drawbacks are lacking in the case of the reaction of isobutylene with aliphatic alcohols C_4–C_5. The reaction yields *tert*-alkyl ethers, which are subsequently decomposed.

The procedure for synthesizing MTBE and MTAE was thoroughly studied and discussed in [1]. As regards synthesis, and especially decomposition of ethers of higher alcohols, a number of problems still remain unsolved. It is well known [2, 3] that the reactivity of alcohols and the equilibrium degree of their conversion in the reaction with isobutylene decrease with increasing molecular weight of alcohol (Table 1). In addition, butyl alcohols do not undergo intermolecular dehydration on sulfonic cation exchanger (contrary to methanol and ethanol) and have higher boiling point. Therefore, the use of butyl alcohols as chemical extracting agents for recovery of isoolefins is of practical interest.

In this work the possibility of recovery of isobutylene from pyrolysis gases by the reaction with isobutanol was demonstrated by calculations and experiments.

It has been shown in a number of studies concerned with synthesis of MTBE and MTAB [4, 5] that the concentration equilibrium constant K_c does not correspond to the thermodynamic constant K_a owing to deviation of the system alcohol–ether–isobutylene from ideality. At the same time, at the molar ratio alcohol : isobutylene equal to 3 : 1 and higher the concentration equilibrium constant becomes stable. The equilibrium of the reaction

$$CH_3–CH–CH_2OH + CH_2=C(CH_3)_2 \rightleftarrows CH_3–CH–CH_2–O–C(CH_3)_3 \quad (1)$$

was studied in the liquid phase in the range 343–423 K. The experiments were carried out in hermetically sealed glass ampules in the presence of KU-23 sulfonic cation exchanger as catalyst. For the study, we used isobutylene (99.8 wt %), isobutanol (99.8 wt %), and isobutyl *tert*-butyl ether (ITBE) (98.5 wt %).

Isobutyl *tert*-butyl ether was produced by the reaction of isobutylene with isobutanol, with subsequent rectification. The equilibrium for each temperature was reached for both direct and reverse reactions.

The reaction products were analyzed by gas-liquid chromatography on a KhROM-3.1 device equipped with a flame-ionization detector and temperature programming unit on a 6-m-long column packed with 15% PEG-20M on silanized Chromaton AW-HDMS. The results of the experiments are given in Table 2 listing the activity coefficients γ_i of the mixture components and the thermodynamic equilibrium constants K_a. The values of γ_i were calculated by the UNIFAC technique [6], using the quantitative data for molecular fragments given in [7]. The resulting equilibrium constants K_a are described by the equation

$$\log K_a = -4.08 + 1894/T. \quad (2)$$

With the use of K_a values, we calculated the equilibrium composition of the products of reaction (1) by the scheme

$$K_a \rightarrow \text{(composition)} \rightarrow \text{UIFAC} \rightarrow K_\gamma \rightarrow K_c = K_a/K_\gamma. \quad (3)$$

In doing so, the butane-butylene fraction with isobutylene content of 20 mol % was used as isobutylene-containing fraction. The calculations were carried out for the range 343–423 K and *iso*-C_4H_8 : *iso*-C_4H_9OH molar ratios of 1 : 1, 1 : 2, 1 : 5, 1 : 10, and

1 : 20. The value of K_c was determined using approximation procedure by the scheme

$$K_a \rightarrow (\text{composition}, K_\gamma) \rightarrow K_c \rightarrow (\text{composition}, K''_\gamma) \rightarrow K'_c = (\text{composition}, K'''_\gamma) \rightarrow K''_c. \quad (4)$$

The approximation was considered acceptable when the discrepancy in K_c values did not exceed 10 rel. %.

The results of calculations performed by scheme (4), presented in Table 3, suggest that even the first approximation gives K_c constants coinciding with K'_c within 10 abs. %. A plot of the equilibrium conversion of isobutylene against temperature at various alcohol : isobutylene ratios is presented in Fig. 1. The calculations showed that the equilibrium conversion of isobutylene is close to 100% at low temperature andalcohol : isobutylene molar ratio exceeding 5 : 1. The calculations also confirmed that hydrocarbon gases with isobutylene content of approximately 5 wt % are suitable as feed.

The obtained calculated and experimental data were verified on a continuous laboratory setup in a temperature-controlled sectional vertical reactor packed with KU-23 cation exchanger, using butane–butylene fraction from the catalytic cracking installation[1] and isobutanol. The initial isobutanol-containing mixture was fed from the top of the reactor, and the gaseous butane-butylene fraction, from the bottom through a bubbler. The material balance of the synthesis is presented in Table 4. The degree of isobutylene recovery was 90–92%.

[1] "Sintezkauchuk" (Togliatti).

The experimental values of the concentration equilibrium constant K_c for IBTBE synthesis were used to evaluate the equilibrium degree of conversion of ether in its decomposition. The evaluation was carried out for the range 353–403 K and isobutanol : IBTBE molar ratios of 1 : 1, 2 : 1, and 3 : 1. The results of evaluation are represented by lines in Fig. 2. Also

0.3	2.38	88.33	8.86	0.43	85.24	99.17	0.35
0.5	6.60	82.83	8.48	2.09	85.87	96.11	0.49
1.0	2.16	92.70	5.04	0.10	91.60	99.82	1.09
3.0	4.09	89.52	6.20	0.19	89.67	99.65	1.50
5.0	4.96	86.24	8.57	0.23	85.07	99.55	0.60
8.0	6.02	77.76	16.05	0.17	73.27	99.62	0.34
12.0	8.23	68.23	23.39	0.15	61.04	99.61	0.72

given are the experimental IBTBE conversions (*points*) in IBTBE decomposition at 363 K, isobutanol : IBTBE molar ratio in the feed of 1 : 1, 2 : 1, and 3 : 1, and volumetric flow rate of feed equal to 1 h^{-1}. The results of these experiments showed that removal of isobutylene from the reaction zone increases the IBTBE conversion to 91.6%, compared with the equilibrium value of 21%.

The calculations showed that the optimal dilution is the alcohol : ether ratio of 1 : 1. With increasing dilution, the conversion of the ether decreases. Although the ether decomposition is a high-temperature reaction, the temperature should not be raised above 120°C because of the probable polymerization of isobutylene and degradation of sulfonic cation exchanger.

The experiments on IBTBE decomposition were carried out in the liquid phase in a temperature-controlled flow-type reactor packed with KU-23 cation exchanger. A system of traps was mounted at the outlet of the reactor. The first trap served to collect the liquid reaction mass, and the second trap contained a 0.5 N solution of bromine in acetic acid to absorb the released isobutylene. The reaction mass of the first trap was analyzed on a chromatograph without any pretreatment. The material balance was stricken for each run. The maximum error with respect to material balance was 6.54 rel. %.

The experiments were performed at varied temperature, isobutanol : IBTBE molar ratio, and volumetric feed flow rate v. In each run, we determined the conversion and selectivity of ether decomposition. The results of one of ether decomposition runs are presented in Table 5.

This study allows us to propose the following scheme of isobutylene recovery from the butane–butylene fraction of catalytic cracking or pyrolysis gas: etherification of isobutyle with alcohols C_4 → blowing off of unreacted hydrocarbons from the ether fraction → decomposition of ether to isobutylene → successive washing of isobutylene with alcohol C_4 cooled to 263 K and water. Isobutylene produced by this scheme was of no less than 99.9 wt % purity.

CONCLUSIONS

(1) The equilibrium of synthesis and decomposition of isobutyl *tert*-butyl ether in the presence of sulfonic cation exchanger KU-23 was studied. The equilibrium conversion of isobutylene in synthesis is close to 100% at alcohol : isobutylene molar ratios of 5 : 1 and 10 : 1. An experimental verification of the equilibrium data showed that the isobutylene conversion is 90–92%.

(2) The calculations showed that it is appropriate to carry out the decomposition of isobutyl *tert*-butyl ether in a solution of isobutanol at the optimal alcohol : ether molar ratio of 1 : 1. The ether conversion in a flow-type reactor at 363 K reaches 91% and the selectivity is more than 99% at a volumetric flow rate of feed equal to 1 h^{-1}.

(3) A scheme for recovery of isobutylene from dilute gas mixtures was proposed.

Received December 4, 2000

Abstract—The common and specific features of quality standard and substandard bitumens were studied by elemental analysis and by determining the yield and composition of toluene-insoluble substances, the composition and concentration of impurities in standard and substandard bitumens, and the group composition of bitumens before and after aging.

At present, about 2/3 of crude oil in Russia is extracted from West-Siberian fields. At the Kirishi Oil-Refining Plant, vacuum residues from a commercial mixture of West-Siberian crude oils from the Surgut fields are used to produce oxidized bitumens for paving and building. The technical characteristics of these bitumens are determined by their colloid structure, which, to a first approximation, depends on the group composition [1, 2]. The optimal group composition of bitumens produced from vacuum residues of various crude oils (of methane, naphthene, arene base) has not been determined. However, it is commonly accepted that, to attain high technical characteristics, paving bitumens should consist of ~50% mono-, bi-, and polycycloaromatic and paraffin–naphthene compounds, 30–34% resins, and 21–23% asphaltenes. At similar group (and hence chemical) composition, bitumens obtained from the same raw material often exhibit different heat resistances (which is often manifested in a drastic decrease in ductility upon heating). Therefore, bitumens are subdivided with respect to this parameter into quality standard and substandard, despite compliance with the requirements of GOST (State Standard) 7847–93 concerning other technical characteristics (softening point, penetration, flash point, brittle point).

The goal of this study was to reveal, using modern physicochemical methods of analysis, the factors responsible for the difference between the heat-resistant (standard) and non-heat-resistant (substandard) bitumens.

EXPERIMENTAL

Samples of standard and substandard bitumens of BDUS 100/130 and BDUS 70/100 brands (21 samples) were studied by elemental analysis (C, H, N, O, S) and exclusion chromatography.

From each bitumen sample[1] we recovered substances insoluble in toluene and analyzed them by ICP–MS on a VG Plasma Quad Turbo Plus spectrometer (UK). The content of microimpurities in bitumen samples was determined by the same method.

Asphaltenes were recovered from bitumens by exhaustive precipitation with hot pentane in a Soxhlet apparatus. Their elemental analysis was performed with a Carlo Erba analyzer (model 1106, Italy).

HPLC studies were performed on a Gold Systems liquid chromatograph (Beckman, the United States) equipped with a fast-response spectrophotometric detector (model 168) and a 6.2 × 250-mm Zorbax PSM 300 S column for exclusion chromatography (Du Pont, the United States).

Standard samples of BDUS 100/130 bitumens (five samples) have the following parameters: ring-and-ball softening point 43–45°C; penetration (needle 0.1 mm in diameter, 25°C) 103–118; ductility before heating

[1] Produced on a bitumen installation at the Kirishinefteorgsintez Production Association, Joint-Stock Company, in May 2000.

1070-4272/01/7404-0696 $25.00 © 2001 MAIK "Nauka/Interperiodica"

140–150 cm, after heating 112–140 (25°C); brittle point after heating ≤–12°C.

Substandard BDUS 100/130 bitumens (four samples) differed from the standard samples in that their ductility at 25°C was considerably lower (49–74 cm) upon heating, being below the prescribed level of 100 cm.

Standard BDUS 70/100 bitumens (five samples) have the following parameters: ring-and-ball softening point 43–46°C; penetration at 25°C 92–97; ductility before heating 147–150 cm, after heating 113–125 cm at the prescribed level of 100 cm; brittle point after heating ≤–15°C.

Substandard BDUS 70/100 bitumens (seven samples) exhibited the same parameters except that their ductility at 25°C after heating was considerably lower (47–71 cm), being below the prescribed level of 100 cm.

We found no significant differences between the total content of malthenes and asphaltenes in standard and substandard BDUS 100/130 bitumens. The content of malthenes in the studied samples of the standard and substandard bitumens was, respectively, 77.8–79 and 77.9–78.1 wt %.

For standard and substandard samples of BDUS 70/100 bitumens, these differences are also insignificant: The content of malthenes is 77.7–79.4 and 78.7–79.1 wt %, respectively.

The content of toluene-insoluble residue in the substandard samples varies by a factor of 24–25, but in standard samples the variation range is still wider: by a factor of 58. On the whole, no quantitative relationship can be revealed.

The maximal content of toluene-insoluble residue is 0.88% in standard bitumens and 0.73% in substandard bitumens.

The chemical composition of the toluene-insoluble residue was determined by ICP–MS upon dissolution in aqua regia (Table 1). It is seen that the major component of insoluble bitumen residues is iron, apparently present in the form of oxides. Also, the residues contain significant amounts of calcium, magnesium, barium, and aluminum. Zinc, copper, vanadium, manganese, and nickel are present in smaller amounts.

It should be noted that, on the whole, the content of Mg, Al, Ca, Ba, Zn, Cu, and Mn impurities is higher in the residues from standard bitumens (BDUS 70/100 and 100/130), compared with those from the substandard samples. The only exception is iron whose content in residues from substandard bitumens is approximately two times that in standard bitumens of the same brand.

From the whole set of 21 samples, we selected two standard and two substandard samples whose characteristics are listed in Table 2. A comparative study of these samples was performed by HPLC.

Table 2 shows that standard bitumen samples have higher sulfur content than the substandard samples. This phenomenon is due to the fact that the crude oil delivered for processing to the Kirishinefteorgsintez Production Association has significantly varying sulfur content. For example, according to the data of X-ray spectral analysis, the sulfur content in

the crude oil delivered to the oil-refining plant varied from 0.3 to 1.66 wt %, being within 1.2–1.4 wt % in most samples.

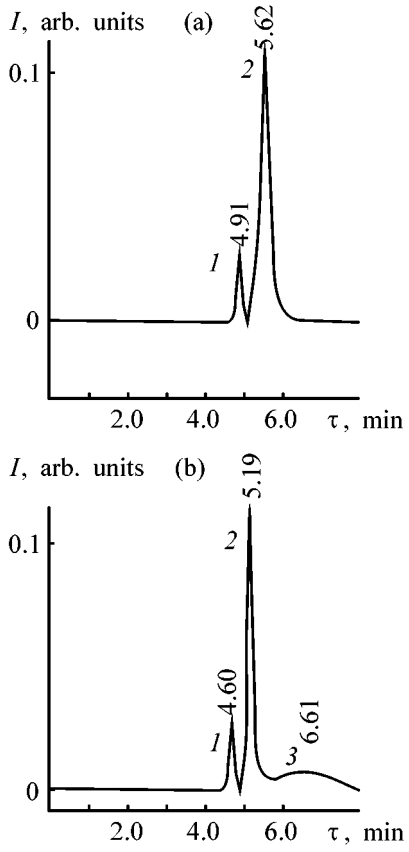

Fig. 1. Chromatograms of standard BDUS 100/130 bitumen. Eluent: (a) THF and (b) THF–CH_3CN (1 : 1). (*I*) Intensity and (τ) retention time. Fraction no.: (*1*) 1, (*2*) 2, and (*3*) 3.

An HPLC analysis of the four selected bitumen samples was performed in a column packed with silanized silica gel based sorbent, with THF (flow rate 1 ml min^{-1}) as eluent. A typical chromatogram is shown in Fig. 1a. It is seen that each bitumen sample is separated in two fractions with similar UV spectra. The area of the first peak with a shorter retention time, corresponding to the fraction that mainly consists of monocyclic aromatic compounds of oils, is higher for standard bitumens than for the substandard samples. The ratio of the areas of the first and second peaks for standard bitumens is 0.13 for BDUS 70/100 and 0.23 for BDUS 100/130, whereas for substandard bitumens this ratio is 0.10 and 0.14, respectively. Thus, standard bitumens are characterized by the higher degree of aromaticity of oils. This may be due to the fact that polycyclic aromatic compounds, resins, and asphaltenes are among the compounds giving in the chromatogram a peak with a long retention time.

The bitumens samples in hand, after aging for 2 h at 160°C and subsequent elution with THF–CH_3CN (1 : 1), also show two peaks in the chromatogram (Fig. 1b). The ratio of the areas of the first and second peaks is different in standard and substandard samples. This ratio changes after heating as compared to the initial samples. Apparently, the fraction with the shorter retention time mainly consists of paranaphthenic (PNCs), monocyclic aromatic (MCACs), bicycloaromatic (BCACs), and toluene (TCs) compounds, and also alcohol–toluene resins (ATRs) in the monomeric and partially associated form. Asphaltenes show a longer retention time. The intensity ratios of these peaks in both initial and aged bitumens suggest

that the structure of bitumens primarily differs on the associative level, with the chemical composition being similar. Samples with more closely packed structural units (a micelle with associated asphaltene molecules in the center, with resins in the shell and MCACs, BCACs, and PNCs in the remote surrounding) exhibit higher ductility, including the ductility after aging. If a sample forms "looser" structures because of the lower aromaticity of asphaltenes, resins, and oils, it will exhibit lower ductility as well.

Table 3 gives experimental data on the content of microimpurities in standard and substandard bitumens, as determined by ICP–MS. Since the total error of the ICP–MS method does not exceed 20%, the difference in the average content of some impurity elements between the bitumen samples can be considered significant (Table 3). As a rule, the content of impurities in standard bitumens is considerably higher than that in substandard samples, except in the case of lead impurity (Table 3). This fact is consistent with the increased content of the same impurities in the residues upon dissolution of standard bitumens in toluene, as compared with the insoluble residues of substandard bitumens (Table 1). The weight content of impurities in standard bitumens is higher than that in substandard bitumens by 80% for Mg, 40% for Ca, 90% for Ba, 270% for Sr, 60% for Al, 40% for B and Zn, and 100% for As.

The most significant difference between the standard and substandard bitumen samples is observed for the Cu content: by a factor of 7.7.

It should be noted that the obtained data on the increased content of impurity elements in standard bitumens as compared with the substandard samples are fully consistent with the results of analysis of toluene-insoluble substances. The insoluble residues of standard bitumens contain increased amounts of alkalineearth metals, aluminum, zinc, copper, and manganese as compared with the toluene-insoluble residues of the substandard samples.

Apparently, the increased content of a number of impurity elements in standard bitumen samples as compared with the substandard samples suggests a stronger catalytic effect of these elements on the oxidation of the initial vacuum residue, resulting in higher quality of the bitumen. Since the oxidation occurs by oxidative dehydrogenation, this assumption also accounts for the increased aromaticity of malthenes and asphaltenes in standard bitumens.

CONCLUSIONS

(1) A study by ICP–MS, HPLC, and elemental analysis showed that samples of standard and substandard paving bitumens have virtually identical qualitative chemical compositions of the base (organic part) but differ in the degree of aromaticity of malthenes and asphaltenes and in the content of ash, sulfur, oxygen, and microelements [alkaline-earth elements (Mg, Ca, Sr, Ba), 3*d* elements (Cu, Co, Zn), and also Al, B, Pb, and Ag].

(2) Aging is accompanied by changes in the group composition of bitumens, primarily on the associative level. The standard and substandard bitumens differ the most significantly in the ratio of monomeric and associated forms of oil, resin, and asphaltene molecules, which is particularly manifested in aging of the bitumens.

BRIEF COMMUNICATIONS

Effect of Chlorine and Nitrosyl Chloride on Nitrogen(II) Oxide Oxidation into Nitrogen(IV) Oxide

A. I. Morozovskii, A. B. Solomonov, and V. I. Skudaev

Perm State Technical University, Perm, Russia

Received July 7, 2000; in final form, November 2000

Abstract—The effect of chlorine and nitrosyl chloride impurities on the regeneration of nitrogen(IV) oxide—oxidizing agent in oxychlorination of hydrocarbons—was studied at two temperatures. An assumption is made that the process occurs by radical-chain mechanism and involves chlorine oxides.

The substitution of oxygen by nitrogen(IV) oxide in oxidative chlorination of a number of organic compounds allows a 2–10-fold acceleration of the process, depending on the chosen technological scheme. To prevent discharge of the forming hydrogen chloride and nitrogen oxides into the atmosphere, nitrogen oxides are used in a closed cycle

$$RH + HCl + NO_2 \rightarrow RCl + H_2O + NO, \quad (1)$$

$$NO + 1/2O_2 \rightarrow NO_2, \quad (2)$$

$$2NO_2 + 4HCl \rightarrow Cl_2 + 2NOCl + 2H_2O. \quad (3)$$

Reaction (2) has been studied in a wide temperature range [1]. In the course of oxychlorination, the reaction may proceed either at room temperature in a separate apparatus, conventionally named the oxidizing vessel, simultaneously with the oxidation of hydrogen chloride [reaction (3)], or directly in the oxychlorination reactor simultaneously with reaction (1) at relatively high temperatures. However, in both cases, it will proceed in the presence of chlorine and nitrosyl chloride—products of hydrogen chloride oxidation by nitrogen(IV) oxide, which may affect the reaction rate. The aim of the present study was to elucidate this influence.

EXPERIMENTAL

The effect of chlorine and nitrosyl chloride was studied by IR spectroscopy on a Specord 75-IR instrument in a 214-ml high-temperature quartz cuvette under atmospheric pressure at 298 and 523 K. The content of chlorine and nitrosyl chloride was up to 25 mol % relative to nitrogen(II) oxide. The reaction conditions were chosen with account of reagent concentrations and temperatures in the oxidizing vessel and oxychlorination reactor. The components of the reaction mixture were introduced into the cuvette with a medical syringe, the cuvette was purged, and the reaction mixture was diluted, with argon. The reaction course judged from the rate of nitrogen(IV) oxide formation measured by recording kinetic curves of NO_2 accumulation at a wave number of 1626 cm^{-1}.

The results of the experiments are presented in Figs. 1a and 1b. At 298 K, the presence of chlorine and nitrosyl chloride has no effect on the rate of nitrogen(II) oxide oxidation into nitrogen(IV) oxide, whereas at 523 K their presence accelerates the process.

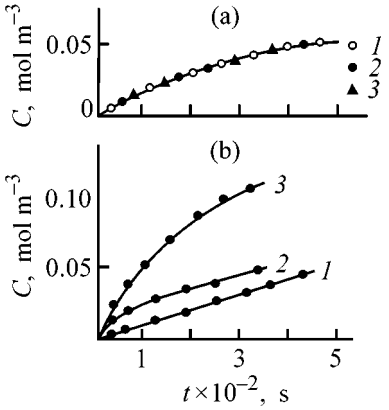

Fig. 1. NO_2 concentration C vs. time t in (a) oxidizing vessel and (b) oxychlorination reactor. Temperature (K): (a) 298 and (b) 523. Initial reagent concentration (mol m^{-3}): NO 0.194 and O_2 0.388. Impurity concentration (mol m^{-3}): (*1*) 0, (*2*) 0.0485 Cl_2 (a) and 0.0291 NOCl (b); (*3*) 0.0485 Cl_2.

1070-4272/01/7404-0700 $25.00 © 2001 MAIK "Nauka/Interperiodica"

The apparent temperature-independence of the reaction rate is accounted for by the low negative activation energy, growing with increasing temperature through a change of the dominant reaction path [1].

Chlorine may affect the rate of NO oxidation into NO_2 through a decrease in the NO concentration caused by the occurrence of a concurrent reaction

$$2NO + Cl_2 \rightarrow 2NOCl. \quad (4)$$

However, the rate of reaction (4) is three orders of magnitude lower than that of reaction (2). The absence of effect of nitrosyl chloride can be attributed to its inertness with respect to nitrogen(II) oxide and oxygen at low temperature.

To account for the acceleration of NO oxidation into NO_2 in the presence of chlorine at high temperature, an assumption should be made that oxygen compounds of chlorine may be formed, exhibiting markedly higher activity in nitrogen(II) oxide oxidation, compared with oxygen. Rather probable is the radical-chain mechanism of the process, according to which a $ClO\dot{O}$ radical is formed upon decomposition of a chlorine molecule

$$\dot{Cl} + O_2 \rightarrow ClO\dot{O}. \quad (5)$$

The reaction of NO with the $ClO\dot{O}$ radical proceeds in two stages [2]

$$NO + ClO\dot{O} \rightarrow NO_2 + Cl\dot{O}, \quad (6)$$

$$NO + Cl\dot{O} \rightarrow NO_2 + \dot{Cl}, \quad (7)$$

with a chain developed after that.

The presence of nitrosyl chloride increases the rate of nitrogen(IV) oxide formation, especially strongly in the first 60–100 s, which can be attributed to thermal decomposition of nitrosyl chloride

$$NOCl \rightarrow NO + \dot{Cl}. \quad (8)$$

This, firstly, makes higher the nitrogen(II) oxide concentration and, secondly, gives rise to a chain process involving oxygen compounds of chlorine, which are, as mentioned above, much more active in nitrogen(II) oxide oxidation as compared with oxygen.

Determination of Carbonyl Compounds by High-Performance Liquid Chromatography

K. A. Dychko, V. V. Khasanov, G. L. Ryzhova, and T. T. Kuryaeva

Tomsk State University, Tomsk, Russia

Received March 10, 2000; in final form November, 2000

Abstract—Carbonyl compounds in the form of 2,4-dinitrophenylhydrazones in alcoholic solutions were analyzed by high-performance liquid chromatography. This simple procedure is characterized by high sensitivity and reproducibility.

Detection of formaldehyde, acetaldehyde, and propionaldehyde in alcoholic solutions by gas chromatography is rather difficult because of the low sensitivity of flame ionization detectors to carbonyl compounds with small number of atoms (especially to formaldehyde) and, in the case of gas-liquid chromatography, because of the poor separation of acetaldehyde and propionaldehyde from the main component (ethanol), which hinders their quantitative determination [1, 2]. In this work we used high-performance liquid chromatography (HPLC) with preliminary preparation of 2,4-dinitrophenylhydrazine (DNPH) derivatives [3]. These derivatives can be easily separated and determined under the conditions of the reversed-phase HPLC.

Carbonyl compounds (aldehydes and ketones) present in the alcoholic solutions determine their quality. These compounds can serve as fragrant additives (aromatic aldehydes and some others) and toxins (formaldehyde, acetaldehyde, glutaraldehyde, etc.). The content of some compounds (e.g., formaldehyde and acetaldehyde) in alcohol liquors is strictly standardized and controlled.

In this work, we studied the behavior of DNPH derivatives under the conditions of the reversed-phase HPLC.

EXPERIMENTAL

The measurements were carried out by reversed-phase HPLC on a Pharmacia-LKB unit equipped with a UV 430 nm detector and a 4×250-mm column packed with LiChrosorb RP-8 (10 μm) silica gel under the isocratic conditions using an acetonitrile–0.1 N acetic acid (2 : 1) eluent with an elution rate of 0.9 ml min^{-1}.

The required derivatives were prepared before placing the sample in the column as follows. A solution of a sample (0.5 ml) containing no more than 1 mg of the carbonyl compound was mixed with a 0.03 M

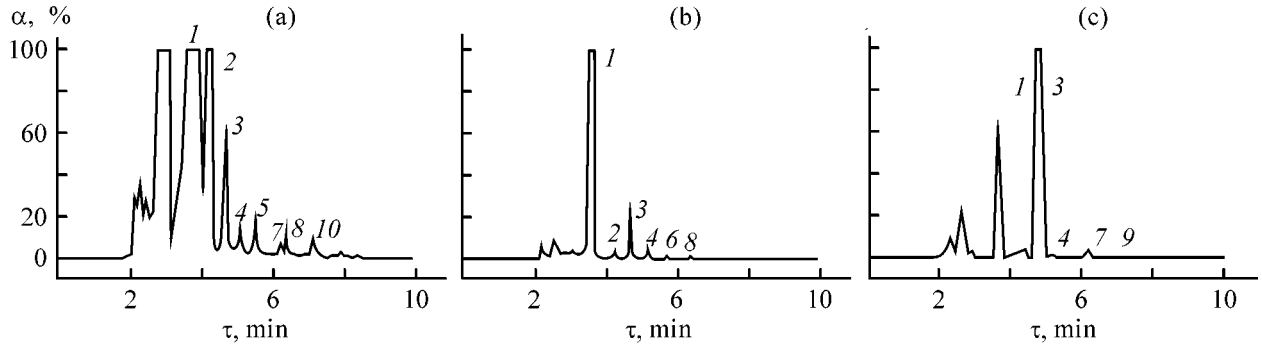

Fig. 1. Chromatograms of samples (a) *III*, (b) *II*, and (c) *IV*. (α) Absorption and (τ) retention time. Content: (*1*) initial DNPH, (*2*) formaldehyde, (*3*) acetaldehyde, (*4*) acetone, (*5*) propionaldehyde, (*6*) isobutyraldehyde, (*7*) butanone, (*8*) benzaldehyde, (*9*) isopentanal, and (*10*) pentanal.

DNPH solution in acetonitrile (0.5 ml), acidified with a drop of concentrated hydrochloric acid, and kept at 50–90°C for 10–15 min. Then the mixture was cooled; if the solution was turbid, it was diluted tenfold with the eluent. In the case of alcoholic liquors, 0.5-ml samples were analyzed without dilution. The reaction conditions ensured quantitative conversion of carbonyl compounds.

The HPLC procedure was performed using 20-μm samples. The retention parameters and the peak areas were determined on a Spectra-Physics SP4290 integrator. The chromatograms are shown in Fig. 1.

As seen, the separation order of the DNPH derivatives of the carbonyl compounds corresponds to the number of carbon atoms in the carbonyls. Moreover, the derivatives with branched carbon chains are eluted before the normal compounds with the same number of carbon atoms. Unchanged DNPH is eluted first and does not hinder detection of the carbonyls in question.

The elution order was determined by comparison with chromatograms of individual carbonyls; the content of carbonyls was found using the gaging dependence for the DNPH–acetaldehyde derivative.

The results of the analysis of alcoholic liquors are listed in the table.

Such compounds as acetaldehyde, propionaldehyde, acetone, and methyl ethyl ketone, difficultly detectable by gas-liquid chromatography, can be determined at concentrations lower than 0.5 mg l^{-1} with increased sample volume. This procedure is fairly promising in analysis of the quality of the alcoholic liquors and in quantitative determination of carbonyl compounds in various objects. However, it should be noted that analysis of herb infusions may be hindered by various extracted compounds. For example, very high content of formaldehyde in sample *III* is probably due to the overlap with a peak of extracted compound. This problem can be solved by using a diode-matrix detector. On the whole, the sensitivity of the developed procedure is higher as compared with that of gas–liquid chromatographic procedure and constitutes at least 0.5 mg l^{-1} with an rms error of no more than 10%.

Initiation of Low-Temperature Polymerization with Hexafluoropropylene Ozonide

D. P. Kiryukhin, I. M. Barkalov, and I. L. Ismoilov

Institute of Problems of Chemical Physics, Russian Academy of Sciences, Chernogolovka, Moscow oblast, Russia

Received December 7, 2000

Abstract—The feasibility of using hexafluoropropylene ozonides for initiating low-temperature polymerization and copolymerization of tetrafluoroethylene, hexafluoropropylene, and some other monomers was demonstrated.

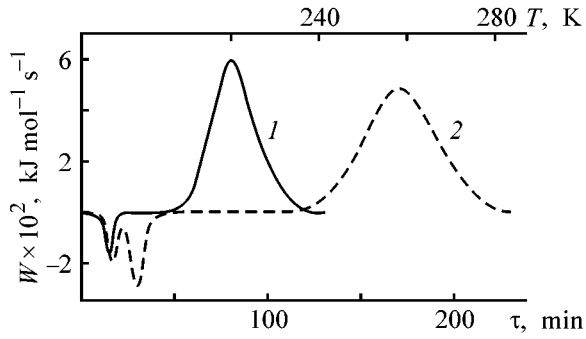
The mechanism of low-temperature ozonolysis of tetrafluoroethylene (TFE) and hexafluoropropylene (HFP) has been studied in detail [1, 2]. It was found that the decomposition products of TFE ozonide effectively initiate the radical polymerization of TFE. In this work, we studied the initiating power of HFP ozonide in low-temperature polymerization of TFE and some other monomers.

EXPERIMENTAL

Studies of the low-temperature ozonolysis, thermal stability of ozonolysis products, and polymerization kinetics were performed by calorimetry, successfully used for this purpose previously [3]. Gaseous TFE and HFP were purified by being passed through a sulfuric acid solution and a column packed with activated carbon, followed by low-temperature fractionation.

Ozone was generated by means of electric discharge; an oxygen flow was passed through a glass ozonizer. To obtain pure ozone, its solution in liquid oxygen was subjected to low-temperature fractionation. Crystalline ozone was additionally purified by sublimation. All experiments were performed in glass calorimetric cells. The IR spectra of polymers prepared as films were taken on an H-800 (Higler) spectrometer.

To evaluate the initiating power of HFP ozonide, we performed the following experiments. First, we prepared HFP ozonide at low temperatures. For this purpose, ozone and HFP in an equimolar ratio were frozen in a calorimetric cell with a vacuum stop-cock at 77 K and then slowly warmed to 220 K (see figure, curve *1*). An endothermic peak of HFP melting was observed at T_m = 117 K. Then, in the range 160–220 K, was observed an exothermic peak due to formation of the ozonide and the corresponding acid fluorides. As shown in [1, 2], HFP molozonide $CF_3–\overset{\diagup O_3 \diagdown}{CF}–CF_2$ is first formed in this temperature interval and then transformed into the ozonide $CF_3–CF\underset{\diagdown O \diagup}{–O–O}–CF_2$ and acid fluorides. After the formation of HFP ozonide, the warming was stopped, the calorimeter with the cell was cooled to 77 K, the cell was connected to a vacuum unit, a certain portion of TFE was condensed, and the cell was again placed in the calorimeter. The calorimetric curve was recorded in the course of slow thawing. The calorimetric curve of thawing of such the system (see figure, curve *2*) shows endothermic peaks associated with dissolution of products of low-tempera-



Calorimetric curves of warming of an HFP (0.0289 g)–O_3 (0.0092 g) mixture: (*1*) initial mixture and (*2*) after warming to 220 K, cooling to 77 K, and addition of 0.096 g of TFE. (W) Heat release, (T) temperature, and (τ) time.

1070-4272/01/7404-0704 $25.00 © 2001 MAIK "Nauka/Interperiodica"

ture HFP ozonolysis and melting of TFE (T_m = 141 K). Further warming in the range 240–290 K is accompanied by vigorous heat evolution related to polymerization of TFE. Note that it is in this range that HFP ozonide decomposes to give a very reactive bipolar ion which can initiate TFE polymerization [1]:

$$F_3C-\overset{\diagup O-O\diagdown}{CF}-O-CF_2 \rightarrow [F_3C-\overset{\diagup O-O^-}{C^+F} + F_2CO]$$
$$\rightarrow F_3-CFO + F_2CO + 1/2O_2.$$

For the initial molar ratio HFP ozonide : TFE = 1 : 50, the conversion of the monomer, determined gravimetrically after the process completion, was 100%. Thus, the decomposition products of HFP ozonide effectively initiate TFE polymerization.

This conclusion is confirmed by the following experiment. If TFE is introduced into the cell after warming the system HFP–ozone to 300 K, when decomposition of the ozonide is already complete and the cell contains only stable decomposition products, no polymer is formed.

It should be noted that low-temperature decomposition of HFP ozonide also initiates copolymerization of TFE with HFP. A mixture of TFE and HFP in a 4 : 1 molar ratio was frozen at 77 K in a cell in which HFP ozonide was prepared. In the course of thawing of this system, we also observed in the range 240–290 K vigorous heat release associated with copolymerization. The yield of the copolymer in such experiments was about 100%. Hence, the resulting TFE–HFP copolymer contains no less than 25% HFP, since it is known [3] that HFP does not undergo homopolymerization under these conditions and can only enter copolymerization. The IR spectra of the resulting copolymer contain absorption bands characteristic of the TFE–HFP copolymer.

With the HFP content in the initial mixture raised further (e.g., to HFP : TFE = 1 : 2), the copolymerization rate decreases and the yield of the polymeric product becomes as low as ~50%.

Note that the products of ozonide decomposition can also initiate polymerization of other monomers, e.g., acrylonitrile and methyl methacrylate. For example, the yield of the polymer in 24 h at 290 K was 65% with acrylonitrile and 30% with methyl methacrylate.

Thus, we have demonstrated the feasibility of using the decomposition products of HFP ozonide for initiating polymerization and copolymerization processes.

Resistance of Rosin-Modified Polyester Resin to Thermal Oxidative Degradation

N. I. Polezhaeva, I. V. Polezhaeva, V. A. Levdanskii, M. Ya. Nikulin, and B. N. Kuznetsov

Institute of Chemistry and Chemical Technology, Siberian Division, Russian Academy of Sciences, Krasnoyarsk, Russia

Received September 7, 2000; in final form, December 2000

Abstract—The resistance of rosin-modified polyester resin to thermal oxidative degradation was studied. This resin can be used as organic binder in low-temperature corrosion-inactive soldering pastes.

Among microelectronic devices under development, a prominent place is occupied by devices produced by hybrid integrated technology. The assembling and mounting of hybrid integrated microcircuits are accelerated and the mounting quality is improved when tin-plating or soldering pastes are used [1, 2].

At present, various resins and polymeric materials are used as organic binders in soldering pastes. A binder imparting to the paste the required viscosity and adhesive power should not evaporate at ambient temperature, but should completely volatilize on heating before the solder starts to melt. Furthermore, it should be inert with respect to the solder in both storage and paste fusion. The most used as the main component of the organic binder are traditional products of wood chemical industry: rosin and products of its processing [3–5]. Studies showed that rosin solutions do not ensure the required process properties of soldering pastes. Rosin has low softening point T_s (60–68°C) and poor heat resistance [6]. Many solutions of polymeric materials are unsuitable for binder preparation because of the high softening point, which results in that the organic matter is not separated from the solder in the course of soldering.

To ensure the required adhesion, heat resistance, and softening point of the organic binder, we prepared a polyester resin modified with rosin. Because the working temperature of fusion of low-temperature soldering pastes is, depending on the solder composition, 200–450°C for template printing and 140–350°C for the dosing unit, the heat resistance of the polymeric product is of crucial importance for development of the organic binder.

In this work, we studied the resistance to thermal oxidative degradation of a rosin-modified polyester resin.

EXPERIMENTAL

The polyester resin was prepared from ethylene glycol (bp 198–200°C, d_4^{20} = 1.115), glycerol (bp 290°C, d_4^{20} = 1.260), maleic anhydride (bp 202°C, d_4^{20} = 0.934), and phthalic anhydride (bp 285°C, d_4^{20} = 1.527). To prevent side reactions, the synthesis was performed under argon. The initial mixture was heated at 195–198°C for 4 h. Then commercial oleoresin pine rosin (OPR) was added, and the addition reaction was performed for 1 h at 198–200°C. The polycondensation equilibrium was shifted by removal of the released water using a Dean–Stark trap. The yield of the polyester was 90% based on the initial charge. The product is a dark yellow transparent solid. The softening point T_s and acid number AN were determined by the procedure given in [7]. The physicochemical characteristics of the samples are as follows: OPR, T_s = 65°C, AN = 165 mg KOH g^{-1}; polyester resin, T_s = 95–100°C, AN = 110 mg KOH g^{-1}.

The parameters of thermal oxidative degradation of the resulting polyester resin were determined by dynamic thermogravimetry [8]. To determine the onset temperature of the resin degradation more accurately by means of thermogravimetric analysis, we recorded along with the TG curves also the DTG and DTA curves [9]. The study was done with an MOM Q-1000 derivatograph (Hungary) in programmed sample heating mode. A 0.1-g sample was heated in a platinum crucible in air at a rate of

1070-4272/01/7404-0706 $25.00 © 2001 MAIK "Nauka/Interperiodica"

5 deg min^{-1}. The instrument sensitivities were as follows: balance, 100 mg; DTA galvanometer, 1/3; and DTG galvanometer, 1/10.

Because the polyester resin contains the solvent, free water, residual alcohol, and unsaponifiable substances boiling in the range 100–250°C, the weight loss starts at relatively low temperatures. Therefore, the heat resistance of the sample was judged from the onset temperature of degradation (T_d^{DTA} is the onset temperature of the exothermic effect in the DTA curve, associated with the onset of oxidation; T_d^{DTG} is the temperature at which the DTG curve starts to deviate from the horizontal), rather than from the temperatures of 5% and 10% weight loss [9]. The activation energy of thermal degradation E_d was estimated by the Freeman–Carrol procedure [8]. Data on the thermal oxidative degradation of the polyester resin are listed in the table.

Data in the table show that, as regards all the criteria: T_s = 95–100°C, T_d^{DTG}, T_d^{DTA}, T_d^{av} (average degradation onset temperature from the DTG and DTA data), the synthesized polyester resin meets all the requirements to organic binders for low-temperature soldering pastes.

In the course of fusion of the soldering paste, a major fraction of the binder evaporates and burns out; the residue should be corrosion-inactive and nonconducting. The polyester resin was tested for corrosion activity on copper plates according to GOST (State Standard) 20.57.406–8 in a humid (93 ± 3% humidity) chamber for 21 days at 40 ± 2°C. An assessment of the results according to GOST 275.97–88 showed that the resin is corrosion-inactive. This fact makes assembling and mounting of hybrid integrated microcircuits less labor-consuming, because the washing stage is eliminated.

The volume resistivity of the polyester resin after partial fusion and storage in a humid chamber was, on the average, 1.7×10^{13} Ω m.

CONCLUSIONS

(1) A new product, rosin-modified polyester resin, was prepared.

Parameters of the heat resistance of samples, as determined by dynamic thermogravimetry

Sample	T_d^{DTG}, °C	T_d^{DTA}, °C	T_d^{av}, °C	E_d, kJ mol^{-1}
OPR	200	160	180	50
Polyester resin	540	460	500	80

* $T_d^{av} = (T_d^{DTG} - T_d^{DTA})/2$.

(2) As shown by dynamic thermogravimetry, the modified polyester resin is resistant to thermal oxidative degradation.

(3) The modified polyester resin can be used as organic binder in low-temperature corrosion-inactive soldering pastes.

OBITUARY

In Commemoration of Professor Gleb Aleksandrovich Mamantov (1931–1995)

G.A. Mamantov, one of the best known specialists in chemistry and electrochemistry of molten salts, honored professor and head of the chemical faculty at the University of Tennessee, Knoxville, USA, would be 70.

G.A. Mamantov was born on April 10, 1931 in a small town of Karsava, situated in the eastern part of Latvia. There lived during the Civil war in Russia his parents, Elena and Aleksandr G.A. Mamantov, general practitioners, both St. Petersburg born. In 1944, the G.A. Mamantov family was taken out of Latvia and they found themselves in a camp for displaced persons at Kleinkotz (West Germany). In 1945–1949, G.A. Mamantov was studying there at a Latvian gymnasium. In 1949, the G.A. Mamantov family moved to the US. In the same year, G.A. Mamantov entered the University of Louisiana, and in 1953 was awarded there the degree of a bachelor of chemistry. At the same university (in 1954) he backed his master's dissertation "Studies in Voltammetry"). In 1957, G.A. Mamantov received his PhD degree in electrochemistry. The title of his PhD dissertation was "Anodic Stripping Voltammetry and Other Studies of Electrode Processes." In final stages of G.A. Mamantov's education, his work was supervised by P. Delahay, the most prominent American electrochemist, author of a number of monographs, two of which have been translated into Russian [Delahay, P., *Novye pribory i metody v elektrokhimii* (New Devices and Methods of Electrochemistry), Moscow: Inostrannaya Literatura, 1957; *Dvoinoi sloi i kinetika electrodnykh protsessov* (Double Layer and Kinetics of Electrode Processes), Moscow: Mir, 1967]. The first of these books had strong impact on the development of voltammetric measurements in the USSR. The second, with a foreword written by Academician A.N. Frumkin, was highly appreciated by him. In 1954–1958, G.A. Mamantov published, together with Delahay, four papers concerned with the theory and practice of voltammetry. In particular, they derived equations for the transient time in the case of linear diffusion and simultaneous migration, and also for the case of spherical diffusion. G.A. Mamantov studied at Delahay's laboratory the reproducibility of the transient time in voltammetric (chronopotentiometric measurements) and reduction of complex ions in aqueous solutions. In 1957–1958, the scientist worked as a researcher chemist at Dupont Corp. (Niagara Falls, NY). In 1958–1960, he served in the US Air Force in California. On having finished his military service, G.A. Mamantov for some time (1960–1961) conducted scientific research together with Prof. J.L. Margrave at the University of Wisconsin. Their publication (1961) was concerned with decomposition of liquid borazine.

G. A. Mamantov (photograph taken in the 1960s).

Beginning in 1961 and till the end of G.A. Mamantov's life, his pedagogical and scientific activities had been associated with the University of Tennessee. In 1971 he became professor, and in 1979, head of the chemical faculty. Simultaneously, he had been a consultant at Oak Ridge National Laboratory since 1962, and held a similar position at Los Alamos National Laboratory since 1986. In 1987, G.A. Mamantov founded a small company Molten Salt Technology and became its president. In the summer of

1070-4272/01/7404-0708 $25.00 © 2001 MAIK "Nauka/Interperiodica"

1991, the scientist delivered lectures at Paris University as an invited professor.

The scientific legacy of G.A. Mamantov is vast and diverse. The list of his works, compiled by the scientist himself shortly before his death, includes 261 items. Let us make an attempt to distinguish the main directions of research. During 1963–1973, more than 30 publications were concerned with the application of modern electrochemical and spectroscopic methods to investigation of fluoride melts which are of interest for the nuclear reactor technology. Particular attention was paid to the behavior of various compounds dissolved in the mixtures $LiF–BeF_2–ThF_4$, $LiF–BeF_2–ZrF_4$, and LiF–NaF–KF. The results obtained in studying fluoride systems were summarized in reviews [1, 2]. In some studies, the behavior of compounds of uranium with various oxidation levels in fluoride melts was analyzed.

G.A. Mamantov and co-workers proposed an original design of a reference electrode for molten fluorides and fluoroborates [3].

About 60 publications (1970–1975) were devoted to investigation of various systems based on chloroaluminate melts by optical and electrochemical methods. In the initial stage of this series of works, the nature of the system $AlCl_3$–NaCl and the behavior of various ions introduced into melt were studied.

Changing the composition of a chloroaluminate melt alters its acid–base properties and affects redox processes involving the dissolved substances and their coordination characteristics. The composition of the species present in a melt was determined by Raman spectroscopy, the equilibria were studied quantitatively by potentiometry. Voltammetric measurements were also widely used to study specific features of electrode reactions. With the chemistry of chloroaluminate solutions and acid–base equilibria in these melts was concerned a summarizing paper by G.A. Mamantov and R. Osteryoung [4]. In 1980, G.A. Mamantov and coworkers were the first to develop and apply an original—spectroelectrochemical—technique for investigation of electrode reactions. Optically transparent electrodes allowed observation of the absorption spectra of substances involved in the electrode process [5, 6]. Particular attention was given by G.A. Mamantov during a succession of years to application of optical methods in studying the behavior of compounds of sulfur in higher oxidation states in chloroaluminate melts and to electrochemical reactions involving these compounds. These investigations were for the most part summarized in [7].

Gleb and Charmaine Mamantov.

In 1980, G.A. Mamantov published an extensive review [8] concerned with the use of molten salts in rechargeable secondary power cells. Together with coworkers, he proposed and comprehensively studied a rather efficient secondary chemical power cell with sodium anode, solid electrolyte composed of β"-alumina, and cathode in the form of a chloroaluminate melt with S(IV) ions [9–11]. Also, quite a number of other cathode formulations were considered. Later, the possibility was demonstrated of using glassy solid electrolyte instead of β"-alumina [12].

A numerous series of works with G.A. Mamantov's participation was devoted to low-temperature spectroscopic and spectroelectrochemical studies of organic compounds [13, 14].

G.A. Mamantov's scientific activities were characterized by an exceedingly close attention to the experimental technique and account of all the factors affecting the interpretation of a result obtained. For example, he was the first to point to the necessity for a repeated study of the electrochemical behavior of a number of rare metals in halide melts when, after the appearance of a number of reports (by Russian scientists, in the first place) in the late 1980s, it became clear that oxygen-containing impurities exert strong influence on the complexation in these media.

By G.A. Mamantov's initiative, and under his and his colleagues' (J. Braunstein, G.P. Smith) editorship, six collections of works *Advances in Molten Salt Chemistry* were published in 1971–1987, together with some other books, the last of which appeared in print in 1994 [15].

The scientific and organizational activities of G.A. Mamantov were distinguished by exceptional intensity. He was a member of the American Chemical Society, Electrochemical Society, Society of Applied Spectroscopy, and other scientific societies, took part in the organization and holding of a great variety of

conferences and symposia. G.A. Mamantov initiated the establishment of M. Bredig's prize awarded for the best works in chemistry of molten salts. G.A. Mamantov was elected a foreign member of the Latvian Academy of Sciences.

The list of G.A. Mamantov's scientific awards is vast. Gleb Aleksandrovich Mamantov had not lived in Russia, but he was brought up in a Russian family, had a perfect command of the Russian, and always showed keen interest in our country. Twice, in 1974 and 1989, the scientist was in the USSR for a long stay, visited scientific centers in Kiev, Moscow, and Leningrad. G.A. Mamantov translated into English B.B. Damaskin's book *Printsipy sovremennykh metodov izucheniya electrokhimicheskikh reaktsii* (Moscow: Mos. Gos. Univ., 1965) (Principles of Modern Techniques for Analysis of Electrochemical Reactions). G.A. Mamantov's elder brother, Il'ya Aleksandrovich, taught Russian philology at the University of Dallas and had repeatedly been to the USSR before 1978.

When the financing of the scientific research and higher school dropped dramatically in the early 1990s, G.A. Mamantov was truly worried about the fate of our scientific schools. He invited to his laboratory several young scientists from Russia, Ukraine, and Latvia for postgraduate education and scientific training. Despite falling severely ill in 1993, G.A. Mamantov was always ready to help in training of young scientists. G.A. Mamantov died on March 12, 1995, at the age of sixty-three at the height of his pedagogical and scientific activities. He was true scientist, excellently educated, talented, and vigorous. And he will be remembered as such by all of those who knew him.

The authors wish to thank Professor Ch. Hussey (University of Mississippi, USA), Dr. G. Stafford (National Institute of Standards and Technology, USA), and I.A. Mamantov's son, Igor Mamantov (Dallas, USA) for help in obtaining the necessary materials.

OBITUARY

Ivan Yakovlevich Tyuryaev (1920–2001)

Ivan Yakovlevich Tyuryaev, a known scientist in the field of industrial catalysis, doctor of technical science, Professor, Honored Scientist and Technologist of Russia, died on March 5, 2001, at the age of 80.

I.Ya. Tyuryaev was born on September 12, 1920. In 1948, he graduated from the Lomonosov Institute of Fine Chemical Technology, Moscow, having returned to the institute in 1946 after being discharged from the army where he went as a volunteer after finishing his first year as a student. He backed his candidate dissertation in 1954, and doctoral dissertation in 1963.

Tyuryaev started his labor activity in 1948, first as a production engineer and then as deputy head of a pilot shop at the Pilot plant (Yaroslavl). From 1952 till 1956, when doing his military service, he was appointed a military representative of the Ministry of Defense. In 1956, by request of the Ministry of Chemical Industry, he was discharged and then worked as a senior researcher at research institutes in Yaroslavl, Leningrad, and Moscow, being also a senior researcher at the Research Institute of Synthetic Alcohols (Moscow). In 1958, he was invited to head the newly organized laboratory of contact-catalytic processes at the Research Institute of Monomers for Synthetic Rubber (Yaroslavl). From 1963 till 1965 he headed the laboratory of catalytic synthesis and was deputy director for science at the Institute of Macromolecular Compounds, Academy of Sciences of the Ukraine (Kiev). From 1965 to 1997, Tyuryaev headed the newly organized laboratory of catalysts and leading researcher at the Prikladnaya Khimiya Russian Scientific Center [former GIPKh (State Institute of Applied Chemistry)].

Tyuryaev's half-century's scientific activities covered the following three main directions of research: petrochemistry, organic synthesis, and catalysis.

Tyuryaev became widely known for his works in the field of petrochemistry (1948–1965, Yaroslavl, Kiev). Tyuryaev developed theoretical foundations of the technology of manufacture of basic monomers (butadiene, isoprene, isobutylene) for synthetic rubbers by dehydration of hydrocarbons. He studied

the chemistry, equilibrium, and rates of the main and all side reactions; dynamics of, and reasons for changes in catalyst activity; chemistry and kinetics of catalyst regeneration.

He developed theoretical basis for calculation of reactors and regenerators with suspended catayst bed and performed mathematical modeling of dehydrogenation reactors of various kinds. The research and development culminated in designing and creating a number of large-tonnage productions of butadiene and isoprene in our country and abroad.

Tyuryaev is the founder of a new scientific direction in monomer synthesis: he (together with coauthors) discovered a new reaction—oxidative dehydrogenation of hydrocarbons to give dienes. He studied the chemistry and kinetics of these reactions and found appropriate catalysts.

Tyuryaev also studied the chemistry and kinetics of the reactions occurring in the three-stage process for isoprene production (propylene $\rightarrow$ 2-methylpentene-1 $\rightarrow$ 2-methylpentene-2 $\rightarrow$ isoprene). He developed a theoretical approach to the choice of a homogeneous catalyst for the last stage.

1070-4272/01/7404-0711 $25.00 © 2001 MAIK "Nauka/Interperiodica"

In the field of industrial organic synthesis (1965–1980, Leningrad), Tyuryaev was in charge of the development of an industrial technology for manufacture of ε-caprolactam via εcaprolactone and studied the chemistry and kinetics of the involved reactions and found appropriate catalysts.

Tyuryaev developed industrial techniques for manufacture of a number of amino acids for agriculture, food industry, health protection service (*L*-lysine, *L*-sodium glutamate, *DL*-tryptophane, *L*-DOFA), from synthesis of starting compounds to separation of racemates and racemation of *D*-isomers. Catalysts for the catalytic stages were found. Extensive research and development work and tests were carried to the stage of industrial production design.

Under Tyuryaev's supervision was developed (1966–1990, Leningrad) a group of catalysts for organic synthesis (production of indole, furan, tetrahydrofuran, ethylenediamine, organofluorine products, etc.) and a set of catalysts for aerospace and defense technology, altogether more than twenty in number. In developing these catalysts, the chemistry and kinetics of the main production stages were studied, comprehensive stand and full-scale studies were carried out, and manufacturing facilities were created. The catalysts developed for the aerospace and defense technologies are unique in their activity and service characteristics and ensure fabrication and reliable operation of the obtained articles and objects.

As a result of his scientific research activities, Tyuryaev published more than two hundred works, including 2 monographs, and received about 50 inventor's certificates.

Together with conducting research studies, Tyuryaev carried out extensive scientific-organizational and pedagogical work. During the period from 1960 to 1990, he was a permanent member of the scientific council of catalysis at the State Committee on Science and Technology; from 1982 till 1990 Tyuryaev was chief chemist for catalysts of the Ministry of Chemical Industry; from 1979 to 1990, he was dean of the base faculty of the Leningrad Technological Institute (LTI) at GIPKh, organized with his direct participation, and a professor of the chair of special catalysts at this faculty; from 1967 till the last days of his life Tyuryaev was a permanent member of a number of qualifying councils awarding the degrees of candidate and doctor of science (GIPKh, VNIINeftekhim, Leningrad Technological Institute); he was one of organizers and a co-chairman of the Leningrad city seminar on catalysis and a member of the Editorial board of *Zhurnal Prikladnoi Khimii*.

Tyuryaev shared his profound knowledge and vast experience with his pupils. Twenty candidate and two doctoral dissertations have been prepared under his supervision.

Tyuryaev was active citizen and a man of principle.

For his services in the development of the domestic chemical science, Tyuryaev was decorated with an Order of Friendship among Nations and a number of medals.

We lost an excellent, nice, and sympathetic person, a truly intelligent man, and a professional of great vigor.

The blessed memory of Ivan Yakovlevich, an outstanding scientist, colleague, and teacher, will be cherished forever in the hearts of those who were lucky to have known him.

BOOK REVIEWS

Reznik, I.D., Ermakov, G.P., and Shneerson, Ya.M., *Nikel'* (Nickel), Moscow: Mashinostroenie, 2000, vol. 1, 384 pp.

The first volume of a three-volume monograph *Nikel'* (Nickel) written by such known specialists as I.D. Reznik, (Gintsvetmet Institute, Moscow), G.P. Ermakov (Severonikel' Combine, Monchegorsk), and Ya.M. Shneerson (Gipronikel' Institute, St. Petersburg) was published in the end of 2000. All the authors have rich experience of work at plants and institutes of the nickel industry. The book comprises 10 chapters, grouped in three parts. The first chapter considers in detail the problems of technical development of nickel plants in the USSR in the postwar years (1945–1991). First batches of nickel metal were obtained in Russia as far back as 1933 at the Ufalei nickel plant (Chelyabinsk oblast); in 1938–1939, Yuzhuralnikel' (Orsk) and Severonikel' combines were put into operation. In 1991, 282 thousand tons of nickel were manufactured in Russia, which constituted 34% of the world's nickel output. In the subsequent years, the manufacture of nickel by the domestic plants decreased, whereas the world's output approached 1 million tons in 2000. The authors discuss separately groups of plants processing oxidized nickel ores (ch. 1) and sulfide copper–nickel ores (ch. 2). The second chapter gives special attention to the Noril'sk mining and smelting combine and the history of its construction. In 1942, the combine produced the first electrolytic nickel. The second chapter also includes information about the Krasnoyarsk plant of nonferrous metals where sludges produced in electrolysis at the Noril'sk mining and smelting combine are processed and platinum-group metals are refined. Both chapters captivate the reader and mention a large number of engineers and researchers who contributed to the creation and development of the domestic nickel industry and to designing and implementing new technological schemes.

Nickel ore processing has its own specificity consisting in the wide variety of ore types, the variability and complexity of their composition, low nickel content, necessity for performing numerous preliminary treatments, and impossibility of ore dressing by the common mechanical methods. The second part of the book describes in ample detail the methods for preparation of ores and concentrates for metallurgical conversion. Such issues are covered as ore blending (ch. 3), sampling (ch. 4), drying (ch. 5), briquetting (ch. 6), agglomeration (ch. 7), and balling (ch. 8). The ninth chapter is concerned with reductive calcination of oxidized nickel ores for subsequent ammonia-carbonate leaching. The third part of the monograph (ch. 10) describes various methods for dressing of oxidized nickel ores. The authors consider the segregation calcination with flotation or magnetic separation of the calcine to be the most efficient method for dressing this kind of ores. The method is in the development stage and has not been used under industrial conditions (segregation calcination could make profitable the processing of lean oxidized ores of the Ural region).

Each part of the book is provided with a list of references to a total of 257 works of domestic and foreign authors. The monograph has clearly technological orientation and analyzes production processes at, in the first place, domestic plants.

The book is of interest for engineers and researchers working in the field of processing of nickel-containing raw materials. The manner of presentation makes the book recommended reading for senior students, masters, and postgraduate students specializing in metallurgy of heavy nonferrous metals.

A. G. Morachevskii, I. N. Beloglazov

Russian Journal of Applied Chemistry, Vol. 74, No. 4, 2001, p. 714. Translated from Zhurnal Prikladnoi Khimii, Vol. 74, No. 4, 2001, p. 692.

BOOK REVIEWS

Gaile, A.A., Somov, V.E., and Varshavskii, O.M., *Aromaticheskie uglevodorody: Vydelenie, primenenie, rynok: Spravochnik* (Aromatic Hydrocarbons: Isolation, Use, and Market: Reference Book), St. Petersburg: Khimizdat, 2000, 544 pp.

The reference-monographic edition systematizes the advances in chemistry and technology of aromatic hydrocarbons with account of numerous publications of, mainly, the last decade. The bibliography of the book, given separately for each chapter, includes about 1900 references.

The first chapter "Isolation and Separation of Arenes" briefly considers, with due regard to the existence of specialized literature, the sources of arenes. The main attention is given to extractive isolation of aromatic hydrocarbons from catalysts for reforming of benzine fractions and pyrocondensates, straight-run medium-distillate petroleum fractions with simultaneous production of ecologically safe jet-engine and diesel fuels. Also considered are methods for isolation and purification of arenes obtained in coal carbonization from "crude benzene" and coal tar and techniques for separation of C_8–C_{10} arenes. Also, this chapter reflects the results obtained by the authors of the book in studies performed at the St. Petersburg State Technological Institute in cooperation with PO Kirishnefteorgsintez.

Chapters 2–4 consider various ways to use benzene and its homologues, naphthalene, and polycycloarenes. Of particular interest are some new promising fields of application of arenes and, in particular, production of phenol by means of vapor-phase oxidation of benzene by nitrogen(I) oxide in the presence of zeolites modified with iron oxide.

The fifth chapter presents technological schemes of industrial processes for production of aromatic hydrocarbons and their most important derivatives—styrene, cumene, phenol, cyclohexane, linear alkylbenzenes, bisphenol A, aniline, caprolactam, phthalic anhydride, terephthalic acid, etc. Performance characteristics of various processes for manufacture of aromatic compounds are compared.

The sixth chapter is concerned with the fields of application of petroleum aromatic solvents and aromatic concentrates—promising products that can be isolated in extraction manufacture of ecologically safe motor fuels, an alternative to hydrocracking, which requires gross investment and involves high energy consumption.

The seventh chapter presents data on the scale of manufacture, consumption structure, and prices of aromatic hydrocarbons and their most important derivatives.

The use of the reference book is facilitated by the provided subject index.

For this reference-monographic edition to be comprehensive, it would be advisable to supplement the book with sections concerning the arene formation processes (catalytic reforming and pyrolysis of oil fractions, coal carbonization), composition of arenes present in oils, and mechanisms of the reactions considered. However, the authors did not aim to cover all arene-related issues in an encyclopedic manner, restricting themselves to provision of references on some of these topics.

The book is well published, contains an ample body of concrete data on industrial processes and advanced investigations in the field of isolation and use of aromatic hydrocarbons. It seems to be a valuable manual both for specialists in petroleum refining and petrochemistry and in organic synthesis and for teachers, postgraduate students, and students of chemical-technological and oil higher school institutions.

INFORMATION

The Second Russian Kargin Symposium "Chemistry and Physics of Polymers at the Beginning of XXI Century"

The Second All-Russia Kargin Symposium "Chemistry and Physics of Polymers at the Beginning of the XXI Century" (Chernogolovka, May 29–31, 2000) was organized by the Russian Academy of Sciences (Department of General and Technical Chemistry and Scientific Council on Macromolecular Compounds) with active participation of the Institute of Problems of Chemical Physics, Institute of Synthetic Polymeric Materials, Institute of Organoelement Compounds, and Moscow State University.

Among the Symposium participants were more than 400 scientists and specialists from 19 Russian towns (Moscow, St. Petersburg, Kazan, Nizhni Novgorod, Chernogolovka, Irkutsk, Ufa, Yekaterinburg, Novosibirsk, Saratov, Samara, Birsk, Barnaul, Tver, Izhevsk, Al'met'evsk, Balakovo, Troitsk), CIS (Azerbaijan, Armenia, Belarus Republic, Uzbek Republic), and also scientists from Egypt, Romania, the United States, France, Switzerland, and Japan. Participants from Russia represented 21 institutions of the Russian Academy of Sciences, 28 universities, and 11 research institutes for various branches of industry.

The symposium program included 19 plenary lectures and 375 posters presented at four poster sessions. By the amount of related contributions, all of them can be arbitrarily subdivided into the following 13 topics.

(1) Polymers and biology. Various aspects of this complex problem were outlined in six plenary lectures. The general strategy of synthesis of biopolymers based on lactic and glycolic acid was analyzed in the lecture given by M. Vert (France). A. Grosberg (US) examined in his lecture the geometry and topology of proteins and also phase transitions in polymers and biopolymers. E. Shakhnovich (US) reviewed recent achievements in computer modeling of the structure/function relationship in proteins. The potentialities of the modern chemistry of medical biopolymers for development of new materials modeling certain functions of organs and tissues of living bodies were discussed in the lecture given by L.I. Valuev (Moscow).

The poster presentations by V.A. Alinovskaya, S.A. Belyaev, S.M. Butrim, and P.M. Bychkovskii (Minsk, Belarus) reported data on immobilization of various drug preparations on monocarboxycellulose. E.A. Baryshnikova and I.I. Vointseva (Moscow) demonstrated the possibility of synthesizing water-soluble *m*-carborane-containing oligo salts for boron-neutron-capture therapy of cancer and biocidic interpolymers based on polyhexamethyleneguanidine and chlorosulfonated polyethylene. T. Budtova (St. Petersburg) reported on a study of polyelectrolyte gels based on cross-linked sodium polyacrylate as models for new drug preparations. Immobilization of lipases into a complex of two oppositely charged polyelectrolytes was reported by I.V. Gorokhova (Moscow). E.N. Danilovtseva (Irkutsk) presented data on synthesis and characteristics of new water-soluble copolymers based on 1-vinyl-4,5,6,7-tetrahydroindole.

It is known that dendrimers bearing amino groups on the surface of their molecules show promise for transport of a genetic material into a cell. M.V. Zhiryakova (Moscow) synthesized for the first time water-soluble positively charged nonstoichiometric polyelectrolyte complexes with polypropylenimine dendrimers. The composition and properties of complexes of polylysine with negatively charged liposomes were reported by O.E. Kuchenkova (Moscow). The contribution by I. Zorin (St. Petersburg) was concerned with synthesis of mesogenic polyamido ethers with amino acid units in the main chain. N.A. Kas'yanenko (St. Petersburg) and O.A. Pyshkina (Moscow) reported the results of a spectroscopic study of interaction of DNA with synthetic polymers and of native DNA and its single-chain analog with distearyldimethylammonium chloride in solution. Synthesis and characterization of collagen–apatite composite for medical use were reported by S.D. Litvinov (Samara). The contribution by A.V. Makeev (St. Petersburg) was devoted to synthesis of polyfunctional polymeric coatings for medical use, based on polyvinyl alcohol and lactic acid.

(2) Synthesis and properties of composites and polymers. The corresponding plenary session included eight lectures covering particular aspects of this complex problem. They were as follows. Rigidity and Plasticity in Solid Polymers (E.F. Oleinik, Moscow); Polymer Chemical Structure, Free Volume, and

1070-4272/01/7404-0715 $25.00 © 2001 MAIK "Nauka/Interperiodica"

Prediction of Membrane Properties (Yu.P. Yampol'skii, Moscow); Liquid-Crystal Elastomers: Features and Mechanisms of Orientation Induced by Mechanical Field (R.V. Tal'roze, Moscow); Ceramic-Reinforced Polymers and Polymer-Modified Ceramics (J.E. Mark, US); New Principles of Development of Photosensitive Multifunctional Materials Based on Chiral Photochromic Copolymers (V.P. Shibaev, Moscow); Langmuir–Blodgett Ferroelectric Polymer Films (L.M. Blinov, Moscow); Block Ionomer Complexes (A.V. Kabanov, US); and Photochemical Effects on Polymer Films and Fibers (A. Mousa, Egypt).

Poster presentations by V.S. Avinkin and M.Yu. Vdovin (Moscow) and by B.N. Anfimov (Moscow) were devoted to the effect of ethylene–vinyl acetate copolymer (EVAC) or paraffins on the mechanical and elastic properties of the LDPE–rubber powder composite and also to the contribution of chemical cross-linking between the components to the properties of polymer composites. O.V. Stoyanov (Kazan) reported the structural mechanical characteristics of mixtures of EVAC and LDPE. The properties of biocompatible implants based on polymers and phosphates modified with polyacrylic acid were reported by E.N. Andreeva (Moscow). Generalized data on the phase composition and structure of fibers of thermotropic liquid-crystal copolyethers were reported by E.A. Antipin (Moscow). The principles of closed-cycle processing of wood by alkylation and etherefication to obtain polymer composites and the molecular topological structure of such composites and various celluloses were reported by N.G. Bazarnova (Barnaul) and Yu.A. Ol'khov (Chernogolovka).

Also, many other aspects related to the topic were considered in poster sessions, including modification of polymers in the solid state under the simultaneous action of pressure and shear stress, studied for the example of mixtures of cellulose and chitosan (T.A. Akopova, Moscow); features of the processes occurring in polyethylene-based metal-containing polymer mixtures and solid-state polymerization of acrylamide (V.A. Zhorin, Moscow); characterization by various methods of the structure and compatibility of such mixtures (N.L. Voropaeva, Tashkent); effect of high pressure on the structure and thermal properties of mixtures of polyethylene terephthalate with liquid-crystal (LC) polymer (H. Al-Itavi, Moscow); and the thermodynamics and structure of polymer mixtures under stress conditions (E.V. Rusinova, Yekaterinburg). The general features and nature of heat-induced relaxation of polymer glasses and a procedure for calculating the quasi-equilibrium stress relaxation curve were considered in the contributions presented by M.S. Arzhakov and G.M. Lukovkin (Moscow). A.P. Safronov (Yekaterinburg) reported a thermodynamic model taking into account the features of dissolution of polymer glasses. The contributions of V.G. Vasil'ev, V.S. Papkov, A.Yu. Rabkin, and M.M. Levitskii (Moscow), V.A. Kovyazin (Moscow), D.D. Korochkin (Moscow), and O.G. Nikol'skii (Moscow) were devoted to various aspects of synthesis and characterization of polyorganosiloxanes.

(3) Theoretical polymer research. In this session two plenary lectures were given: Computer Modeling of Self-Organized Polymers (P.G. Khalatur, Tver) and Multiscaled Modeling of Polymer Properties and Behavior (A. Gusev, Switzerland).

In more than 20 poster presentations, such problems were treated as orientational self-organization in molten rigid-chain polymers (A.E. Arinshtein, Moscow); effect of diblock copolymer on the final stages of phase separation in a polymer mixture (E.N. Govorun, Moscow); computer modeling of systems containing polymer chains and colloid particles (N.V. Davydov) (Moscow); properties of a solution of a flexible-chain polymer under conditions of "contraction" in the field of substrate surface forces (A.I. Dolinnyi, Moscow); adsorption of a polymer chain on a spherical surface (E.I. Zheligovskaya, Moscow); structure of associates of acrylic ester series (A.A. Il'in, Yaroslavl); effect of chemical defects on the structure, dynamics, and macroscopic properties of the *n*-paraffin C_{50} and of ethylene/propylene copolymers (I.A. Karmilov, Moscow); conformation behavior of comb-like macromolecules (A.A. Klochkov, Moscow); evolution of the molecular-mass distribution (MMD) in the interchain exchange reaction in polymer mixtures (Ya.V. Kudryavtsev, Moscow); concentration limits of the phase instability range in polymer–particle systems in the case when the particles are larger than the globules (A.A. Litmanovich, Moscow); phase behavior of a two-dimensional polymer comb in an A–B binary solvent (A.A. Merkur'eva, St. Petersburg); analysis of the spinodal equation for a binary polymer mixture in terms of the contractible lattice model (N.N. Nikitina, Kazan); theory of high-frequency twisting-vibrating relaxation processes in polymer chains (V. Toshchevikov, St. Petersburg); and numerical calculation of the self-diffusion coefficient distribution function (E.B. Shakir'yanov, Birsk).

(4) Polyelectrolytes. A.A. Yaroslavov and V.A. Kabanov (Moscow) reported in their plenary lecture on a study of the interaction of polyelectrolytes with lipid membranes. The session included more than 20 poster

presentations. S.B. Zezin, V.A. Kasaikin, A.A. Zinchenko, S.I. Kargov, A.S. Andreeva, S.A. Andreenko, and I.R. Nasimova (Moscow) reported on a theoretical and experimental study of the structure and conformation behavior of polyelectrolyte–surfactant complexes in weakly polar organic solvents, including the features of phase separation of such complexes, reversible gelation in polyelectrolyte solutions, electrical conductivity of polyelectrolytes, and effect of the polymer matrix structure on the adsorption properties of polyelectrolyte gels. The contributions by A.V. Lezov (St. Petersburg) and E.A. Lysenko (Moscow) were devoted, respectively, to interaction of Cu(II) with azole-containing polyelectrolytes in aqueous solutions and to molecular properties and association of polypeptide–surfactant complexes of block polyelectrolytes in organic solvents of various polarities. T.F. Lelyukh (Novosibirsk) reported on synthesis of cationic polyelectrolyte with tertiary amino groups and their application as flocculants for treatment of wastewater contaminated with mercury. The capability of hydrophobized polyelectrolyte gels to absorb hydrophobic compounds from aqueous solutions was reported by A.V. Tazina (Moscow).

(5) Radical polymerization. The plenary lecture given by K. Matyjaszewski (Poland) was devoted to new promoting systems for "live" radical polymerization of various monomers. Under this topic several poster contributions were also presented. They were devoted to synthesis of alkoxyamines (new class of agents of live radical polymerization) and methods for determining the rate constants of their reversible homolytic decomposition and copolymerization of dimethacrylates with styrene in their presence (G.M. Bakova, M.P. Berezin, and I.S. Kochneva, Chernogolovka). Other contributions discussed specific features of radical polymerization of hydrophobic derivatives of acrylamide (A.I. Barabanova, Moscow) and salts of 2-acrylamido-2-methylpropanesulphonic acid with acrylamide in water and aqueous salt solutions (V.F. Kurenkov, Kazan); mechanism and kinetics of polymerization of tetrafluoroethylene promoted by mechanically activated silica and fluorinated carbonaceous materials (V.P. Mel'nikov, Moscow); radical copolymerization of vinyl acetate with *N*-vinylpyrrolidone and styrene (M.O. Pastukhov, Nizhni Novgorod); possibility of preparing stereoregular polymers by radical polymerization (Yu.I. Puzin, Ufa); and polymerization of acrylonitrile in supercritical carbon dioxide (E.U. Said-Galiev, Moscow). New approaches to chain growth control under conditions of pseudolive radical polymerization were examined in three contributions presented by D.F. Grishin and others (Nizhni Novgorod). The effect of temperature on the kinetics of nitroxylinhibited copolymerization of styrene with butyl acrylate was reported by M.G. Pavlov (Moscow).

R.Z. Azanov (Kazan) reported on a study of cationic polymerization of isobutylene catalyzed by $AlCl_3$ and BF_3. The thermodynamics and features of synthesis of polyurethanes and their reactions with alcohols were discussed in the contributions by T.A. Bykova (Nizhni Novgorod) and E.R. Badamshina and I.V. Doronina (Chernogolovka). Several poster contributions were devoted to such problems as radiation cryopolymerization and copolymerization of HCN and radiationinduced postpolymerization of isoprene and butadiene with sulfur dioxide (D. Kiryukhin and G.A. Kichigina, Chernogolovka); radiation-induced grafting to polyolefins of vinylsilanes that do not enter into homopolymerization (A.M. Mesh, St. Petersburg); and radiation-chemical synthesis of crown-containing gels (S.V. Nesterov, Moscow). The development and practical applications of perfluoroolefin ozonides (new class of promoters for polymerization of fluorinated olefins) and the role of radicals long-lived in solution in polymerization of fluorinated olefins were reported by M.R. Muidinov and S. Allayarov (Chernogolovka).

(6) Nanoparticles in polymers. This session included two plenary lectures: Macromolecular Reactions at Phase Boundary as a Direct Method for Synthesis of Polymeric Nanosystems (V.P. Zubov, Moscow) and Nanosponges and Clusters of These: New Macromolecular Particles and Their Self-Association (V.A. Davankov, Moscow). Of particular interest among the poster contributions were those devoted to self-immobilization of reactive nanoparticles of polyoxometallates in monolayers and Langmuir–Blodgett films of network polymers (V.V. Arslanov, Institute of Physical Chemistry, Moscow); formation mechanism and structure of polymeric nanocomposites with copper and cadmium sulfides (A.V. Volkov, Moscow); structure and properties of cellulose hydrate films containing dispersed silver (N.E. Kotel'nikova, St. Petersburg); polycarbonate-based adamantine nanocomposites (S.V. Krasheninnikov, Moscow); electroluminescence in polymer composites (E.M. Mal'tsev, Moscow); formation of carbonaceous micro- and nanostructures from functionalized polymers (O.V. Nikolaeva, Izhevsk); poly-*p*-xylylene-based metal-containing polymer nanocomposites (S.A. Ozerin, Moscow); formation of nanophases in porous polymer matrices of varied nature, such as polyethylene terephthalate, PVC, and isotactic polypropylene (E.S. Trofimchuk, Moscow).

(7) Dendrimers. A.M. Muzofarov (Moscow) clearly demonstrated in his plenary lecture that, in the recent decade, dendrimers, initially regarded only as exotic illustration to theoretical developments, became one of the most popular objects in the polymer chemistry research. E.V. Agina, E.A. Makeeva, M.V. Zhiryakova, and others (Moscow) considered in their poster presentations synthesis and phase behavior of five generations of LC dendrimers with terminal mesogenic groups (anisic acid derivatives) bound to carbosilane dendritic matrix via an undecyl spacer, and also carbosilane dendrimers with terminal aliphatic groups; synthesis (for the first time) of water-soluble electrically charged nonstoichiometric polyelectrolyte complexes with dendrimer as a lyophilizing polycation; and ionization equilibrium in aqueous Astramol solutions of the first five generations of poly(propylenimine) dendrimers and their interaction with network polyelectrolytes containing peripheral carboxy groups. The properties of the first three generations of dendrimers based on *L*-aspartic and *L*-glutamic acids, containing terminal ester groups and BOC-amino acids as base dendrons were reported by A.Yu. Bilibin, St. Petersburg). S.P. Molchanov (Moscow) discussed a new method for studying individual molecules and small clusters of dendrimers by microscopy. This method was used to study the structure of carbosilane LC dendrimers (S.A. Ponomarenko, Moscow). M.V. Ryabkov reported on a thermodynamic study of a first-generation carbosilane dendrimer with methoxyundecyl terminal groups at 0–340 K. The phase diagram of the system third-generation LC dendrimer–CCl_4 was reported by Yu.V. Panina (Saratov). The effect of methylene and allyl terminal groups on the molecular characteristics of carbosilane dendrimers was studied by G.E. Polushina (St. Petersburg). The translation flexibility of phosphorus-containing dendrimers of fifth and eighth generations in CCl_4 was reported by A.I. Sagidullin (Kazan). A.S. Tereshchenko (Moscow) discussed synthesis of a dendrimer bearing three HO groups at each terminal spacer. New approaches to synthesis of dendrimers without use of protecting groups were presented by G.N. Khimich (St. Petersburg).

(8) Liquid-crystal polymers. The plenary lecture given by R.V. Tal'roze (Moscow) was concerned with LC elastomers prepared through chemical cross-linking or reactions induced by gamma-ray and UV radiation, and also through noncovalent interactions stabilizing both the network structure and LC order under conditions of self-organization of matter. The poster presentations concerned with this topic reported results of a systematic and comparative analysis of the effect of temperature on the structure and mechanical characteristics of highly oriented fibers of LC copolyethers (E.M Antipov, I.A. Volegova, and A.A. Levchenko, Moscow); data on the phase behavior, structure, and magnetic properties of comb-like LC ionomers containing Cu, Ni, Co, Mn, Na, Ca, and Rb cations (E.B. Barmatov and D.A. Pebalk, Moscow); and data on the structure and mechanical properties of H-bonded LC polymer networks (M.A. Koval', Moscow). D.D. Grinshpan (Minsk) reported on formation of LC structures in aqueous solutions of cellulose sulfate sodium salt.

(9) Metal-containing polymers. This class of polymers is of a great scientific and practical interest. In the poster session, reports were presented concerned with synthesis, structure, and properties of metal-containing epoxy polymers (L.M. Amirova, Kazan); metal oxide structures synthesized by thermal treatment of salt forms of carboxyl-containing nitrocellulose with metal ions (I.A. Bashmakov, Minsk); chemical deposition of silica in a polymer matrix (E.A. Burlova, Kazan); properties of metal-coordinated polyurethanes (Davletbaeva, I.M., Kazan); polymers based on unsaturated metal oxacarboxylates and the role of the topography of macromolecular metal complexes in catalysis (G.I. Dzhardimalieva and A.D. Pomogailo, Chernogolovka); molecular properties of metal-containing disubstituted polyacetylene (E.I. Ryumtseva, St. Petersburg); and polyfunctional polymerizable systems based on methacrylates and alkali metal ions (N.A. Gavrilenko, Tomsk).

(10) Synthesis of new polymers. In the plenary lecture A.L. Rusanov (Moscow) discussed new Diels–Alder aromatic adducts based on hexaphenyl-substituted bis-cyclopentadienones and dienophiles. In principle, several poster contributions presented in other sessions can also be regarded as related to this topic. Nevertheless, mention can be made here of reports devoted to synthesis of such polymer materials as polyarylene sulfoxides (new class of sulfur-containing polymers), new fluorine-containing polyether-α-diketones, hydroxyl-containing polyimides (2,4,6-trinitrotoluene derivatives), cyclolinear permethylpolysilanesiloxanes, polyarylenethynylenes with 3-hexyl-multisubstituted oligothiophene blocks, and card polyaryleneetherketones (B.A. Zachernyuk, M.L. Keshtov, L.G. Komarova, D.Yu. Larkin, I.A. Khotina, and V.V. Shaposhnikova, Moscow); new copolymers based on methacrylic acid esters with chromophoric groups capable of heterocyclization; thermostable nonlinearly optically active polyamidoimides, polybenzoxazinones, and their complexes with Cu(I); copolymethacrylates with heteroaromatic nonlinear-

ly optically active chromophoric groups possessing high molecular hyperpolarizability (G.K. Lebedeva, N.L. Loretsyan, N.N. Smirnov, and I.V. Podeshvo, St. Petersburg); and copolymers of butadiene monoxide and propylene oxide (A.V. Nemirovskaya, Kazan).

(11) Conducting polymers. The poster session included reports concerned with electrochemical synthesis of conducting polymers based on metal phthalocyanines (N.P. Alpatova, Moscow); preparation and transport characteristics of microporous polyethylene films with conducting layer (polyaniline and polypyrrole) (G.K. Elyashevich and E.Yu. Rosova, St. Petersburg); electrical and electrochemical properties of composites based on polyaniline and polyacetylene with graphite and zinc (G.I. Kozub, Chernogolovka); synthesis of polyaniline-based interpolymer complexes (N.A. Koryabina, Moscow); and molecular and supramolecular structure of stable electroconducting copolymers of ethylene and acetylene (V.A. Marikhin, St. Petersburg).

(12) Synthesis and properties of polyolefins and aliphatic polyketones. In the poster session, O.N. Babkina and N.M. Brava (Chernogolovka) reported the results obtained in measurements of the electrical conductivity of various metallocene complexes and Al alkyls, boranes, and borates as components of high-performance catalytic systems for polymerization of olefins. These contributions discussed the role of ions in the indicated processes, conditions of synthesis of polyethylene with a broad spectrum of molecular weights and structures. Interesting data on the kinetics of metallocene-catalyzed homo- and copolymerization and molecular structure of polyethylene and copolymers of ethylene with 1-hexene, 1-octene, and 4-methyl-1-pentene were obtained by L.G. Echevskaya (Novosibirsk) and N.I. Ivancheva (St. Petersburg). Ternary copolymerization of propylene with ethylene and diene was considered by A.N. Klyamkina (Moscow). P.M. Nedorezova (Moscow) and N.M. Pakostina (Chernogolovka) discussed synthesis of polypropylene with controllable microstructure and MMD (high-modulus isotactic, syndiotactic, and hemiisotactic polypropylene) and its thermal, mechanical, and optical properties.

A series of poster presentations were devoted to synthesis and characterization of a new generation of functionalized copolymers (so-called aliphatic polyketones) based on olefins and carbon monoxide.

The reports by A.M. Kal'sin (Moscow) was concerned with new ruthenium and palladium complexes as catalysts for copolymerization of ethylene and CO. Other contributions were devoted to studies of the structure and deformation mechanism of new elastomers based on aliphatic polyketones (V.M. Neverov, Moscow); photolysis and photooxidation (S.I. Kuzina, Chernogolovka) and thermodynamics of copolymers of carbon monoxide with ethylene, propylene, and styrene at 0–600 K (A.V. Tsvetkova, Nizhni Novgorod); determination of the surface free energy and acid–base properties (O. Shashkina, Kazan), computer modeling of the crystal structure, phase transitions, and dynamics (N.B. Shenogina, Moscow), and IR spectroscopic study of the phase composition of films of ethylene–CO copolymer (D.M. Shkrabo, Troitsk).

(13) Experimental methods in polymer research. Although mention was already made of the application of particular techniques to studies of various polymer properties, it seems appropriate to say several words about other experimental methods reported by the conference participants. These include scanning electron-probe microscopy for determining the local rigidity of polymer surface (A.M. Alekseev, Moscow). Low-frequency dielectrometry was applied to study films of polyheteroarylenes in methyl methacrylate (L.G. Bradulina, Moscow), epoxyamine polymer mixtures (T.L. Elizarova, Chernogolovka), and segnetoelectric films (N.I. Kuznetsova, Moscow). The phase formation and thermal stability of epoxy polymers and copolymers were studied by the methods of photoactive probe, ESR, solid echo, and local NMR in radiofrequency scattering fields (S.B. Brichkin, B.E. Krisyuk, and N.N. Bolkov, Chernogolovka). M.I. Motornov (Moscow) used PALS (Positron Annihilation Lifetime Spectroscopy) for monitoring volume changes associated with deformations in glassy, partially crystalline, and LC polymers.

Of course, this brief review does not exhaust the diversity of problems discussed at the symposium. Most of the plenary lectures and posters represented scientific research supported financially by the Russian Foundation for Basic Research and other foundations. The 3rd Kargin Symposium is planned to be held in three years as an international conference.

G. P. Belov

Russian Journal of Applied Chemistry, Vol. 74, No. 4, 2001, pp. 720–721. Translated from Zhurnal Prikladnoi Khimii, Vol. 74, No. 4, 2001, pp. 698–699.

========== INFORMATION ==========

1st International Conference on Polymer Modification, Degradation, and Stabilization (MoDeSt 2000)

The 1st International Conference on Polymer Modification, Degradation, and Stabilization was held from September 3 to 7, 2000, in Palermo (Italy). The conference was organized by the Department of Chemical Engineering and Materials (University of Palermo). The conference participants were more than 500 scientists from 27 European Countries (Italy, Switzerland, Sweden, Russia, UK, Hungary, Romania, France, Poland, Netherlands, Germany, Czech Republic, Slovak Republic, Portugal, Belgium, Denmark, Ukraine, Austria, Norway, Spain, Slovenia, Finland, Greece, Belarus Republic, Croatia, Azerbaijan, and Georgia), 3 African countries (Egypt, Algeria, South Africa), 7 Asian countries (Saudi Arabia, Israel, Japan, Malaysia, China, India, Turkey), 5 American countries (US, Canada, Mexico, Venezuela, Brazil), and also from Australia.

The international advisory board of the conference included G. Audisio, C. Bastioli, E. Martuscelli, and C. Neri (Italy), N. Hadjichristidis and C. Papaspyrides (Greece), W. Habicher (Germany), A. Krzan (Slovenia), G. Marosi (Hungary), A. Okuwaki (Japan), A. Queiros (Portugal), F. Shutov (US), L. Utracki (Canada), Jianqi Wang (China), and G. E. Zaikov (Russia). The conference Chairman was Prof. F.P. La Mantia (University of Palermo) and Co-chairman, Prof. G. Camino (University of Torino). Thirteen organizations were sponsors of the conference, among them the University of Palermo, Provincia Regionale di Palermo, and such well-known companies as Alitalia, Banco di Sicilia, CIBA Specialty Chemicals, Rheometric, Belotti Strumenti, and Solvay.

More than 100 oral reports and a plenary lecture entitled Polymer Oxidation and Stabilization—Personal Outlook on the Past and Future (Norman Billingham, University of Brighton, Sussex, UK), were presented. Seven general lectures covered the topical problems of the conference. G. George (Queensland University of Technology, Brisbane, Australia) reported on chemiluminescence mechanisms in heterochain oxidation of polypropylene. Dennis Price (Fire Chemistry Research Group, University of Salford, UK) gave a lecture on polymer pyrolysis studies of relevance to polymer combustion and flame retardance. The effect of processing on melt degradation and stabilization of polymers was discussed in the lecture given by E. Kramer (University of Applied Sciences of Aargau, Windisch, Switzerland). The next general lecture was devoted to photostabilization of polymeric materials by surface modification (C. Decker, Department of Polymer Photochemistry, University of Mulhouse, France). Samuel J. Huang (University of Connecticut, Institute of Material Science, Storrs, Connecticut, US) gave a lecture on biodegradable polymers design, synthesis, and applications. Two last general lectures were devoted to the contribution of organometallic catalysis to reactive processing of thermoplastics (A. Michel, Laboratory of Polymeric Materials and Biomaterials, University of Claude Bernard Lyon I, Villeurbanne, France) and prediction of lifetimes of polymeric materials in environmental conditions from accelerated and ultraaccelerated photooxidation experiments (J. Lemaire, Laboratory of Molecular and Macromolecular Photochemistry, University Blaise Pascal, Aubiere, France).

Further the Conference was held in the form of a number of minisymposia on 9 dedicated topics. The 1st technical session (Oxidation and Stabilization) included 34 oral presentations and 39 posters. In this session the problems of the kinetics and mechanism of oxidation of various polymers in solution, melt, and solid phase were discussed, and also those of polymer stabilization and prediction of lifetimes.

The second session (Thermal Degradation, Combustion, and Fire Retardance) included 35 oral presentations and 35 posters. Of primary concern were the problems of nanocomposites as fireproofing compounds, and also combustion mechanisms of polymeric materials.

In the third session (Processing and Melt Stabilization), 18 oral presentations and 9 posters were given.

The topic of the fourth session was High Energy Radiation in Polymers: New Materials and Technologies. The session included 18 oral presentations and 33 posters. Particular attention was paid to polymer photochemistry and processes occurring upon irradiation of polymers with X-rays, electrons, protons, neutrons, and recoil atoms.

1070-4272/01/7404-0720 $25.00 © 2001 MAIK "Nauka/Interperiodica"

The fifth session (Biodegradation and Biodegradable Polymers) included 6 oral presentations and 20 posters. Of primary concern were the problems of applications of polymers in medicine, particularly in surgery operations.

In the sixth session (Ageing of Polymers and Composites), 12 oral presentations and 15 posters were given, devoted to selective and accelerated ageing of the polymers and composites, and also to prediction of the evolution of the performance characteristics in aging under various conditions of storage and exploitation.

The seventh session (Functionalization and Reactive Processing) included 24 oral presentations and 23 posters. The major attention in this session was paid to reactive processing of polymers, preparation of polymer blends and composites, and solubility (compatibility) of polymers in polymer blends and ways to its improvement.

In the eighth session (Testing and Life Predicition) covered 22 oral presentations and 11 posters were given. In this session, problems of climatic aging of polymers, development of new generations of weatherometers, testing methods for studying polymer aging, and analysis of polymer degradation products were discussed.

Finally, the ninth session (Recycling and Material and Energy Recovery) was devoted to polymer reprocessing and energy recovery from polymer wastes. The session included 25 oral presentations and 34 posters.

A proposal was discussed at the conference to create a permanent MoDeSt forum which would plan and organize future activities encompassing conferences, workshops, seminars, and courses. G. Camino and F. La Mantia became the co-chairmen of the organizing committee of this forum.

It was accepted a good choice to held such interdisciplinary conferences with a broad spectrum of topics. The Conference has demonstrated good potentialities of meetings where lectures are combined with discussions and live contacts of a large number of scientists. The 2nd International Conference on Polymer Modification, Degradation, and Stabilization, MoDeSt-2002, will be held in Budapest (Hungary).

INFORMATION

IV All-Russia Conference with Participation of CIS Countries "Scientific Foundations of Preparation and Technology of Catalysts" III All-Russia Conference with Participation of CIS Countries "Problems of Catalyst Deactivation"

The conferences were organized by the initiative of the Institute of Catalysis, Siberian Division, Russian Academy of Sciences; Institute of Petrochemistry and Catalysis, Academy of Sciences of the Republic of Bashkortostan, Ural Scientific Center of the Russian Academy of Sciences; with the support of the Academy of Sciences of the Republic of Bashkortostan; Government of the Republic of Bashkortostan; Russian Foundation for Basic Research; Ministry of Industry, Science, and Technology of the Russian Federation; Scientific Council of catalysis, Russian Academy of Sciences; and ZAO Kaustic (Sterlitamak).

Among the participants of the conferences were more than 140 scientists and leading specialists from 16 institutes of the Russian Academy of Sciences, 12 universities, 13 applied-research institutes and companies, 15 industrial plants of Russia, and 9 institutes of Ukraine, Belarus, Armenia, and Uzbekistan, who synthesize, study, and use various (heterogeneous and homogeneous) catalysts in large-tonnage industrial processes of hydrogenation, dehydrogenation, isomerization, polymerization, etc. Nineteen plenary talks (including 5 concerned with metal-complex catalysis) were delivered and more than 60 reports (including 15 on metal-complex catalysis) presented at the conferences.

The main scientific directions of the reports presented at IV Conference were the following:

fundamental physicochemical and kinetic aspects of synthesis of heterogeneous catalysts and supports in all stages of their fabrication;

control over catalyst formation to obtain catalysts with prescribed properties;

new methods for catalyst fabrication;

scientific basis for development of technologies, versatile technological lines, and apparatus for the main stages of catalyst and support fabrication; effect of the scaling factor;

present state of the industrial production of catalysts.

The scientific directions of the III Conference were the following:

nature and mechanism of catalyst deactivation;

kinetics and modeling of deactivation processes;

investigation techniques;

ways of extending the service life of catalysts.

Reports on "Metal-Complex Analysis in Organic and Metal-Organic Synthesis" were delivered at a separate section.

Within the first direction, the report by G.R. Kotel'nikov (Yaroslavl) considered the state and problems of production and service life of catalysts for synthesis of styrene, α-methylstyrene, methyl vinylpyridine, and isoprene, and for dehydrogenation of paraffins C_4–C_5 into olefins, and also the provision of rare-earth metals for catalyst production plants. It was pointed out that, because of the lack of the necessary equipment and raw materials of appropriate quality, the possibilities of domestic catalyst production technologies are not always realized. Of much interest was the report by A.A. Galkin (Moscow) on preparation of oxide catalysts and supports in "sub- and above-critical" water.

Five interesting reports were presented by the Institute of Catalysis, Siberian Division, Russian Academy of Sciences (Novosibirsk). The scientific foundations of mechanochemical methods as the ecologically safest technology for fabrication of catalysts, supports for these, and adsorbents were discussed by V.V. Molchanov; the development of a technology of highly dispersed skeleton zirconium phosphates—catalysts for isomerization of paraffins and their selective oxidation into olefins, were analyzed by V.A. Sadykov; methods of preparation and production technology of block catalysts with cellular structure for purification

1070-4272/01/7404-0722 $25.00 © 2001 MAIK "Nauka/Interperiodica"

of exhaust gases of automobiles, selective reduction of nitrogen oxides in fume gases of thermal power plants, and purification of volatile organic substances in oxidation of ammonia in nitric acid production were considered by Z.R. Ismagilov; the development and use of domestic microspherical cracking catalysts were discussed by V.P. Doronin; synthesis, properties, and use of highly dispersed zirconium-containing oxide systems were reported by A.S. Ivanova.

New tendencies in the development of methods for preparation of catalysts for chlororganic synthesis were discussed in the report by I.I. Kurlyandskaya (Moscow). In particular, various techniques for catalyst formation by support impregnation were considered, especially the method making no use of a solvent. E.Z. Golosman (Novosibirsk) analyzed fundamental mechanisms of synthesis and formation of cement-containing catalysts for various processes of organic, inorganic, and ecological catalysis. The industrial production of these catalyst by means of a low-waste technology was commenced at catalyst shops of NIAP and some other domestic plants; the catalysts were introduced into practice of low-temperature conversion of CO, methanization, creation of protective atmospheres, synthesis of a number of organic compounds, and purification of discharge gases at more than 150 plants of Russia, CIS countries, and countries beyond the boundaries of the former Soviet Union.

At the section "Metal-Complex Catalysis in Organic and Metalorganic Synthesis," Y.M. Dzhemilev discussed in detail recent advances of domestic and foreign researchers in the field of application of metal-complex catalysts in promising chemical technologies for production of a wide variety of practically important monomers (α-olefins, isopentanes, vinylarenes, higher mono- and dicarboxylic acids, anhydrides, alcohols, glycols, amines, nitrogen-containing heterocycles, sulfides, sulfoxides, and sulfones).

The reports by V.I. Smetanyuk and E.I. Bagrii (Moscow) considered production techniques and possibilities of metal-complex gel-immobilized catalytic systems for the example of dimerization and oligomerization of ethylene and propylene, and also the biomimetic approach to development of promising catalytic systems for functionalization of saturated hydrocarbons. To a new direction—use of homogeneous catalysts based on palladium complexes for synthesizing a new class of polymers, alternating copolymers of olefins with carbon monoxide—was devoted report by G.P. Belov (Chernogolovka). The results of a quantum-chemical study of the geometric and electronic structure of models of active centers in lanthanide catalysts for diene polymerization were considered by Z.M. Sabirov (Ufa).

Oral reports presented the results obtained in the development of enzyme-modeling catalysts, immobilization of metal-complex catalysts on polymeric supports, and synthesis of catalysts for production of mono- and dicarboxylic acids and alcohols and for selective functionalization of hydrocarbons to give oxygen- and chlorine-containing products.

At the conference on catalyst deactivation, N.M. Ostrovskii and N.A. Pakhomov (Novosibirsk) presented in their reports new models of catalyst deactivation by coke, tested for concrete examples of deactivation of catalysts for cracking and hydrogenation, and also Pt/Al_2O_3 catalysts, in isomerization of paraffins, dehydrogenation of cyclohexane, and dehydrocyclization of paraffins. They also considered problems of reversible and irreversible deactivation of supported bimetallic catalysts for dehydrogenation of lower paraffins. The factors leading to deactivation of V/Ti catalysts for partial oxidation of durene in the temperature range 360–480°C in the course of prolonged operation were discussed in a report by B.I. Kutepov (Ufa).

It was repeatedly emphasized in plenary talks and oral reports that the catalyst deactivation is one of the problems of industrial catalysis. The industry of the developed countries produces annually many hundred thousand tons of catalysts only because of their limited service life, irreversible poisoning, and loss of activity and selectivity; the unstable or periodic (with regular regeneration) work of catalysts leads to markedly higher investment, energy expenditure, and higher-cost products. An important task, whose accomplishment would make faster the solution of the problem as a whole, is to develop methods for fast catalyst testing to prognosticate the rate of their deactivation and their stability under industrial conditions.

The participants of the conference noted that the designs by Russian specialists and the investigations performed retain their high level, but, if the present extent of science is not changed, our scientific achievements will soon become outdated. In the last 10 years the domestic output of catalysts dropped dramatically, constituting at present 10–25% of the level of the early 1990s. The decline in the investment in the catalyst industry has led to physical aging and obsolescence of the equipment used and poorer quality of catalysts. The actively aggressive, to the point of illegal search for consumers, policy of foreign com-

panies at the Russian market leads to purchase of imported catalysts, which have much higher cost, but not higher quality, compared with the domestic catalysts.

Among the recommended measures intended to improve the domestic catalyst industry was mentioned the necessity for address state financing of pilot-evaluation shops for production of catalysts meeting the world's best standards at promising plants, including AO Katalizator (Novosibirsk), catalyst shops at Omsk and Ryazan oil refineries, and some others.

During the conferences, a round-table discussion was held, with the participation of managers of industrial plants and presentation of institutes and production facilities; the state of, prospects for, and problems of the development, manufacture, and consumption of domestic catalysts were discussed. In order to ensure prompt exchange of scientific and technological information and coordination of efforts at the catalyst market, it was proposed that the Institute of Catalysis, Siberian Division, Russian Academy of Sciences, should initiate creation of an association of major manufacturers and consumers of catalysts and set-up a periodic collection of works (journal) devoted to problems of industrial catalysis. The conference participants consider the first experience of holding a joint conference with participation of specialists in homogeneous and heterogeneous catalysis to be a success and recommend the Organizing committee of the future conference to adopt the same way. Full texts of plenary talks are to be published in *Kinetika i Kataliz* journal.

Received December 18, 1998; in final form, December 2000

Abstract—The mechanism of conversion of natural langbeinite with magnesium chloride solutions was studied. The dependence of the degree of conversion on the process time, temperature, $MgCl_2$ concentration in solution, and grain size of natural langbeinite was studied.

The halurgical scheme of processing potassium polymineral ores ensures 18–22% recovery of langbeinite to a solution [1]. Most of it remains in the undissolved halite–langbeinite residue as a waste product. At the same time langbeinite is one of the main minerals of the ore (content up to 20 wt %) and is of special value as potassium–magnesium sulfate mineral. Different ways of langbeinite recovery were suggested. Washing-out of halite with water or salt solutions [2, 3] makes it possible to obtain a langbeinite concentrate used as a fertilizer or processed into schoenite and potassium sulfate. The conversion of langbeinite into schoenite under the action of water is also used [4]. The recovery of langbeinite from the ore increases to 80–85% when it is preliminarily recrystallized into schoenite [5]. However, water is rapidly saturated, which decelerates the process. Moreover, the humidified paste solidifies. The degree of langbeinite conversion does not exceed 80% in 30 days [5]. One more feature of processing of such ores into fertilizers is formation of excess solutions of magnesium chloride, which must be utilized. This is a complicated problem for ore fields that are remote from the magnesium production.

The soluble part of potassium polymineral ores is a five-component system of salts containing a great number of solid phases [6]. Slow reactions occur between these phases depending on the composition of the liquid phase. Langbeinite is known to participate in paragenesis with kainite, as described by the equations

$$K_2SO_4 \cdot 2MgSO_4 + MgCl_2 + 6H_2O \rightleftarrows 2[KCl \cdot MgSO_4 \cdot 3H_2O] + MgSO_4, \quad (1)$$

$$K_2SO_4 \cdot 2MgSO_4 + MgCl_2 + KCl + 9H_2O \rightleftarrows 3[KCl \cdot MgSO_4 \cdot 3H_2O], \quad (2)$$

$$K_2SO_4 \cdot 2MgSO_4 + KCl \cdot MgCl_2 \cdot 6H_2O + 3H_2O \rightleftarrows 3[KCl \cdot MgSO_4 \cdot 3H_2O]. \quad (3)$$

The reactions occur in an $MgCl_2$ solution and in the absence of KCl are accompanied by the formation of $MgSO_4$. The reaction rate is affected by the interface area, the concentrations of $MgCl_2$ and $MgSO_4$ in solution, temperature, and the reactant ratio.

We studied the interaction of natural langbeinite with $MgCl_2$ solutions under laboratory conditions. Natural langbeinite was taken from an operating open pit, crushed to a particle size of <2.5 mm, washed to remove halite impurity with water, treated with acetone to remove intercrystal moisture, dried at 50°C, and sieved. The resulting product contained (wt %) K^+ 18.6, Mg^{2+} 11.64, Ca^{2+} 0.06, Na^+ 0.07, Cl^- 0.05, SO_4^{2-} 69.16, and H_2O 0.42 (or 98.76% langbeinite, less than 0.1% halite, and minor amounts of polyhalite, kieserite, and water). The starting solution to be studied had the following composition (wt %): K^+ 1.38, Mg^{2+} 6.50, Na^+ 0.94, Cl^- 19.39, SO_4^{2-} 3.08, and H_2O 68.71 ($MgCl_2$ 22.4%). This solution was used to prepare 15–36% $MgCl_2$ solutions from $MgCl_2 \cdot 6H_2O$ (analytically pure grade) and distilled water. Pure grade KCl was also used.

A solution of magnesium chloride of a specified concentration was mixed with langbeinite in glass beakers in a weight ratio of 1 : 1. Stoichiometric amounts of KCl [according to reaction (2)] were

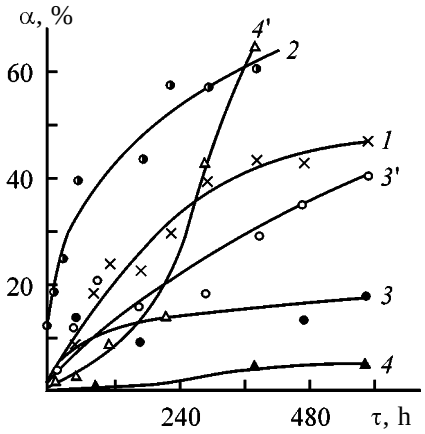

Fig. 1. Degree of langbeinite conversion α into kainite as a function of the process time τ. Temperature (°C): (*1*) 25, (*2*) 50, (*3*, *3*') 75, and (*4*, *4*') 95. (*3*', *4*') Crystalline KCl was added to a system.

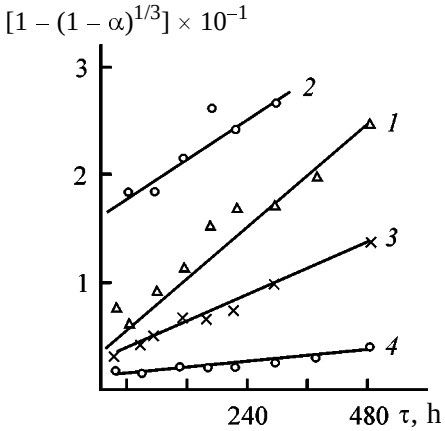

Fig. 2. Graphical confirmation of the fact that the conversion of langbeinite into kainite follows the "compressing sphere" mechanism: (α) conversion and (τ) process time; the same for Fig. 3. Temperature (°C): (*1*) 25, (*2*) 50, (*3*) 75, and (*4*) 95.

added to langbeinite. The components were heated to the required temperature and mixed. The mixture in closed beakers was placed in an air thermostat and kept there at 50 ± 0.5°C for 480 h with intermittent mixing and sampling. The samples were filtered on a Büchner funnel, the filtrate was collected in a preliminarily weighed test tube, the intercrystal solution was removed by washing the solid phase with refined vegetable oil and acetone, and the solid was dried at 50°C. The liquid and solid phases were analyzed for K^+ and Na^+ by flame photometry, for Mg^{2+} and Ca^{2+} by complexometric titration, for Cl^- by mercurimetric titration, and for SO_4^{2-} gravimetrically [7]. The material balance was calculated by solving a system of equations involving the content of ions in the liquid and solid phases; the degree of conversion was determined from the material balance with respect to Cl^- and SO_4^{2-} ions and from the equations of reactions (1) and (2).

The effects of temperature and process time on the degree of langbeinite conversion into kainite were studied. Natural langbeinite with a grain size of 1.0–2.5 mm and a 23.7% solution of $MgCl_2$ were preheated to the reqiured temperature and mixed in a desiccator. The mixture was kept in a desiccator at 25, 50, 75, and 95°C for 480 h with intermittent stirring and sampling.

The data obtained (Fig. 1) show that the degree of langbeinite conversion into kainite at 25°C gradually increases and reaches 47% in 480 h. Under these conditions the rate of conversion remains low. It is known [8] that the degree of kainite formation even from readily soluble carnallite and magnesium sulfate hexahydrate (in the stoichiometric ratio) at 25°C reaches only 35% in 240 h, with the process gradually decelerating. At 50°C the process accelerates, the conversion reaching 61.5% in 312 h. The further temperature rise to 75°C drastically decelerates the process, with the maximal conversion being as low as 18.3% in 480 h.

The addition of crystalline KCl at 75°C facilitates reaction (2). Langbeinite converts into kainite with a higher rate. Heating to 95°C (without adding KCl) favors langbeinite stabilization. Under these conditions the field of kainite crystallization is absent from the stable diagram; the maximal temperature of kainite existence under stable conditions is 83°C [8]. However, kainite can exist as a metastable phase at temperatures up to 105°C [9]. In the presence of a kainite seed the degree of the langbeinite conversion into kainite at 95°C is 5.8% in 480 h. In the presence of KCl this value increases to 65.2%.

The above-given data have shown that the highest degree of langbeinite conversion into kainite is reached at 50°C. The acceleration of the process is affected by the addition of KCl, which salts-out kainite at elevated temperatures [10].

The dissolution of langbeinite in a solution of magnesium chloride is the slowest stage of the process. It follows the "compressing sphere" mechanism. According to the equation describing this mechanism, the plots of $[1 - (1 - \alpha)^{1/3}]$ (where α is the conversion) vs. process time τ are linear (Fig. 2); this fact suggests that the reaction occurs near the surface of spherical langbeinite bodies.

Topochemical reactions involving a solid phase are frequently described by the Erofeev's equation [11]

$$\alpha = 1 - \exp(-K\tau^n), \quad (4)$$

where n is the reaction order.

Transformation of this equation gives

$$n\log\tau = \log(1/K) + \log[-\ln(1 - \alpha)]. \quad (5)$$

The plots of the langbeinite conversion into kainite in the $\log[-\ln(1 - \alpha)]$–$\log\tau$ coordinates are linear (Fig. 3). The rate constant of the reaction can be determined graphically from the condition

$$K = -\ln(1 - \alpha_{\tau=1}). \quad (6)$$

At 25°C K is equal to 0.00602, at 50°C to 0.07079, and at 75°C to 1.46. Substitution of these data in the Arrhenius equation gives the activation energy of 78.9 kJ mol^{-1} for the range 25–50°C. Hence, the conversion of langbeinite into kainite is kinetically controlled [11]. To accelerate the process, it is necessary to heat to at least 50°C and maintain this temperature throughout the process.

The reaction order can be determined from Eq. (5). At 25°C it is 0.83 and at 50°C, 0.47. This means that the reaction is multistage; it is limited by the reaction of crystalline langbeinite yielding intermediate compounds.

The effect of the $MgCl_2$ concentration in solution on the langbeinite conversion into kainite at 50°C was also studied. For these experiments we took the initial langbeinite (grain size 1.0–2.5 mm) after washing. Crystalline KCl was added to the reaction mixture in the stoichiometric ratio to langbeinite corresponding to the equation of reaction (2). Weighed samples of the solution of definite concentration and langbeinite were placed in separate sealed vessels. Samples of liquid and solid phases were taken after 24, 120, and 240 h.

The data obtained (Fig. 4) show that at concentrations of magnesium chloride in the reaction mixture less than 18.0% virtually no conversion occurs. As the $MgCl_2$ concentration increases, the degree of langbeinite conversion also increases. In a 35.9% $MgCl_2$ solution it is 72.9% in 24 h and 84.3% in 120 h.

In the reaction mixture free from KCl the conversion proceeds by Eq. (1); after the process termination the solid phase contained a mixture of kainite, epsomite, and unchanged langbeinite.

In the course of the conversion $MgCl_2$ is incorporated into the solid phase, and its concentration in the liquid decreases. At low initial $MgCl_2$ concentrations a high degree of the conversion cannot be attained. At any concentration of the solution reaction (1) can go to completion only with respect to langbeinite, and $MgCl_2$ should be in excess. To reach a high degree of the langbeinite conversion into kainite, the concentration of $MgCl_2$ in the initial solution should be 24.3–35.9% at the weight ratio of the phases of 1 : 1. Therefore, on completion of the process, the kainite suspension should be separated into the liquid and solid phases. The liquid phase is recycled for concentrating and converting, and the solid phase is processed into a fertilizer.

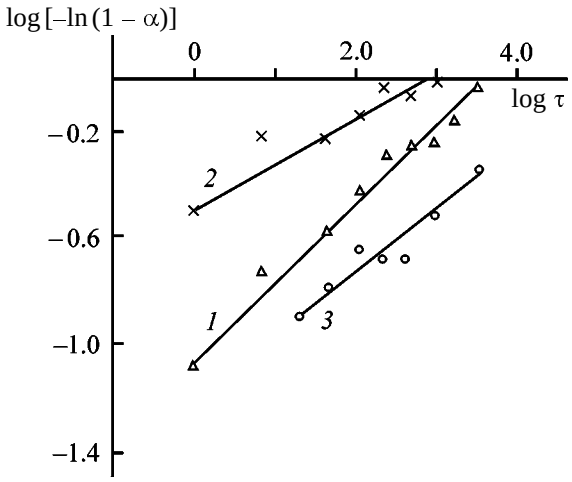

Fig. 3. Graphical determination of the rate constants of reaction (1) by the Erofeev's equation. Temperature (°C): (*1*) 25, (*2*) 50, and (*3*) 75.

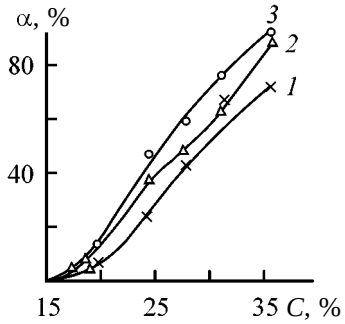

Fig. 4. Degree of langbeinite conversion α as a function of $MgCl_2$ concentration in the liquid phase C. Process time τ (h): (*1*) 24, (*2*) 120, and (*3*) 240.

Magnesium chloride wastes concentrated by evaporation contain carnallite in the solid phase and magnesium chloride in the liquid phase. They can be utilized for langbeinite conversion in the course of processing of polymineral potassium ores. In this case the reaction follows Eqs. (2) and (3), which results in reduced demand for potassium chloride. After the separation of sodium chloride and unchanged $MgCl_2$ solution, the solid phase is a mixture of kainite, sylvite or epsomite, unchanged langbeinite, and impuri-

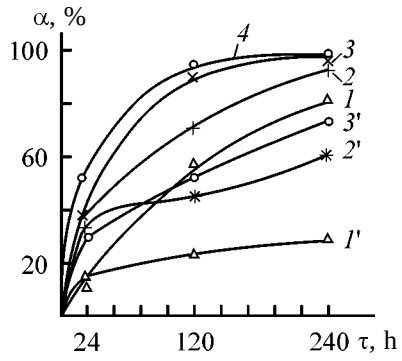

Fig. 5. Degree of langbeinite conversion α as a function of process time τ at various concentrations of $MgCl_2$ *C* and sizes of langbeinite grains *f*. *C* (wt %): (*1*'–*3*') 22.4 and (*1*–*4*) 28.3. *f* (mm): (*1*, *1*') 1.0–2.5, (*2*, *2*') 0.5–1.0, (*3*, *3*') 0.315–0.5, and (*4*) less than 0.315.

ties of anhydrite, kieserite, and polyhalite. After drying it contains (wt %) K_2O 20–25, MgO 10–15, Cl^- up to 20, and NaCl up to 3. When the formation of magnesium chloride waste is undesirable, the solid phase can be processed into chlorine-free potassium fertilizers.

The conversion of langbeinite with an $MgCl_2$ solution is a heterogeneous process influenced by the interface area. Therefore, we studied the dependence of the conversion on the size of langbeinite grains. To do this, we took the initial concentrations of $MgCl_2$ in the liquid phase of 22.4 and 28.3 wt % and langbeinite fractions of 1.0–2.5, 0.5–1.0, 0.315–0.5, and less than 0.315 mm. The temperature was 50°C, and the process time and KCl amount were the same as in the previous experiments.

The results obtained show (Fig. 5) that at the $MgCl_2$ concentration of 22.4 wt % for the 1.0–2.5 mm fraction the conversion degree is 15.1 in 24 h, 22.5 in 120 h, and 29.0% in 240 h. For the 0.5–1.0 mm langbeinite fraction it is 37.0, 43.2, and 58.5%, respectively, and for the 0.315–0.5 mm fraction, 30.8, 52.8, and 72.6%, respectively.

In a more concentrated solution (28.3 wt % $MgCl_2$) the degree of conversion is considerably higher. Its acceptable value is reached for the 0.5–1.0 mm fraction in 240 h (94.5%), for the 0.315–0.5 mm fraction in 120 (91.6%) and 240 h (97.5%), and for the <0.315 mm fraction, in 120 (93.5%) and 240 h (97.3%). Therefore, the size of langbeinite grains less than 0.55 mm and the process time of 120 h can be recommended for practical purposes.

CONCLUSIONS

(1) Natural langbeinite converts into kainite in 24.3–35.9% magnesium chloride solution at 25–75°C. The highest degree of conversion is reached at 50°C and, with KCl added, at 75°C. In the presence of kainite seeds and KCl the conversion is fairly complete also at 95°C.

(2) The degree of conversion increases with increasing $MgCl_2$ concentration in solution within the limits 24.3–35.9% and with decreasing langbeinite grain size. The >90% conversion is reached in 120 h with a grain size less than 0.5 mm.

(3) The data obtained can be used as the basis for the technology of processing polymineral potassium ores without formation of magnesium chloride waste.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Recovery of Transplutonium Elements from Nitric Acid Solutions with Arsenazo Group Reagents

N. P. Molochnikova, B. F. Myasoedov, and O. P. Shvoeva

Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, Moscow, Russia

Received May 30, 2000

Abstract—Sorption recovery of actinides and lanthanides from nitric acid solution with arsenazo group reagents, activated carbon modified with these reagents, and chelating sorbents containing arsenazo functional groups was studied.

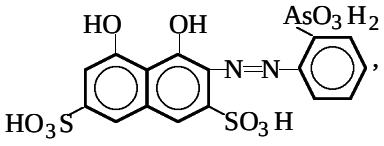
Recovery of transplutonium elements from acidic solutions is an important industrial problem, and search for reagents suitable for sorption and extraction recovery of these elements is urgent. It is known [1, 2] that arsenazo group reagents are widely used in analysis, because they form strong complexes with more then 30 elements including actinides and lanthanides. Reagents based on chromotropic acid, arsenazo I (monoazo derivative) and arsenazo III (bisazo derivative), are used for highly sensitive spectrophotometric determination of certain elements [1, 2] including americium and curium [3, 4]. The use of these reagents for metal extraction is limited because of their low solubility in organic solvents, which increases only in the presence of higher alcohols. Arsenazo III can be used for recovery and separation of actinides and lanthanides [5] including americium(III) and (V) [6] in two-phase, free of organic solvents aqueous systems based on water-soluble polymers. For sorption recovery, we synthesized a series of chelating sorbents containing arsenazo group reagents.[1] It is known [7] that chelating sorbents exhibit enhanced selectivity, which is due to the nature of functional groups reacting with metal ions. These groups are introduced into the polymeric matrix by appropriate chemical reactions or are formed during the synthesis of the polymeric sorbent. The chelating sorbent prepared by azo coupling of diazotized aminopolystyrene with arsenazo I was used for selective concentration of many elements [8–11] and determination of trace elements in uranium ores and concentrates, carbonate and silicate rocks, natural water, and wastewater [2, 7, 12, 13]. Cellulose fibrous sorbent with arsenazo groups is selective toward uranium and lanthanides and was used for selective recovery of these elements form solutions with high concentration of alkali and alkaline-earth metals [14]. A new fibrous chelating sorbent POLIORGS 33A containing amidoxime, hydrazine, oxy, and arsonoazo groups selectively recovers plutonium from acidic saline solutions and allows its separation from the other elements [15, 16].

In this work, we studied the recovery and concentration of transplutonium and rare-earth elements from nitric acid solutions with sorbents containing arsenazo fragments.

EXPERIMENTAL

Nitric acid solutions containing radiochemically pure radionuclides $^{242–244}$Cm, ^{243}Cm, ^{241}Am, ^{239}Pu, and $^{152–154}$Eu were used. Sorption was studied under static conditions by mixing nitric acid solution (V = 2–4 ml) containing a definite amount of radionuclide with the sorbents (m = 5–200 mg) for 0.1–20 h. Sorbents in form of powders were separated by centrifuging after the radionuclide sorption. The degree of radionuclide recovery (%) was estimated from the α- or γ-activity of the initial and resulting solutions (after sorption). The α-activity was determined on a proportional counter with 2π geometry, while the γ-activity was measured on an LP-4900 analyzer.

The following reagents were used: analytically pure grade arsenazo I [2-(2-arsonophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid]



[1] In the Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences.

1070-4272/01/7405-0729$25.00

Table 1. Degree of curium and europium sorption from nitric acid solutions on carbons modified with arsenazo group reagents. V/m = 200, sorption time 2 h

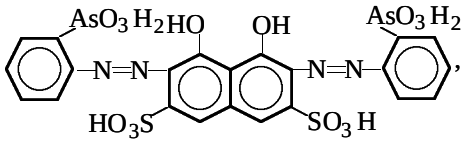
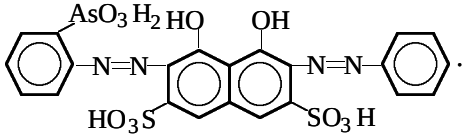
0.1	22	59	33	61	31	24

arsenazo III [2,7-bis-(2-arsonophenyazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid] prepared by the reaction between chromotropic and aminophenylarsonic acid

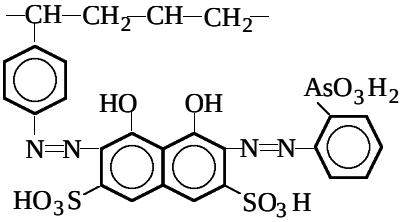


and arsenazobenzene [2-(2-arsonophenylazo)-7-(phenyl-azo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid]

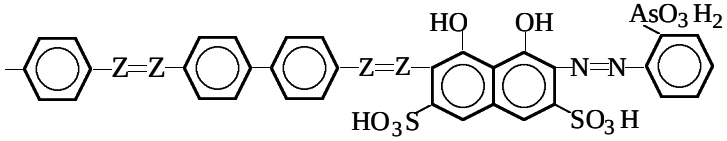


Daukh and Alkaline A activited carbons were used as sorbents. Iron-free carbon was prepared by washing with hydrochloric acid and water. Then it was saturated with reagent solution at agitation for 2 h, washed with water, and dried at 100°C.

The following chelating sorbents (all synthesized in Vernadsky Institute) were used. Polystyreneazoarsenazo was prepared by the reaction of diazotized aminopolystyrene with arsenazo I. It is a dark violet powder insoluble in water and acids. The exchange capacity of this sorbent for KOH is 1.6–2.8 mmol g^{-1}:



Arsenazo I polymers with benzidineazoarsenazo (BAAI and BPVAI):



(Z are various substutuents).

Polyarsenazo-n is filled fibrous chelating sorbent composed of polyacrylonitrile fiber and polystyreneazoarsenazo sorbent containing sulfo, *peri*-dihydroxy-, and *o*-hydroxy-*o*'-arsonoazo groups. The filling degree of the sorbent is 50%. It is a black fibrous material stable in strongly acidic, weakly alkaline, and neutral solutions. Its sorption exchange capacity for NaOH is 2.2 mmol g^{-1}.

We studied sorption of actinides and lanthanides from nitric acid solutions on activated carbons modified with arsenazo group reagents. It is known that a coomon procedure for concentrating and separating elements is sorption on matrices with active surface preliminarily saturated with complexing agents. Modified activated carbons are widely used to concentrate microelements. We modified carbons with arsenazobenzene and arsenazo III, which form the most stable complexes with transplutonium and rare-earth ions. The study of curium and europium recovery as influenced by the arsenazo III content showed that 1.2×10^{-4} M arsenazo III is required to saturate 1 g of carbon. Curium and europium sorption is strongly dependent on the solution acidity and is possible only from weakly acidic medium (<0.1 M HNO_3, Table 1). Car-

Table 2. Degree of metal sorption with chelating sorbents from nitric acid solutions. V/m = 200 (100 for polyarsenazo-n); sorption time 2 h

	Cm	Eu	Cm	Eu	Cm	Am	Pu	Eu	Cm	Am	Pu	Eu
0.1	98	99	97	96	>99	99	99	97	99	99	97	99
1.0	84	74	82	88	94	94	98	87	87	94	94	81
3.0	56	11	27	32	70	72	98	58	61	42	97	51

bons modified with arsenazo III recover metals better than the unmodified carbons. However, quantitative recovery of curium (98%) with unmodified carbons can also be reached at the ratio of the solution volume to sorbent mass equal to 200, when the time of contact of the solution with the sorbent increases to 18 h.

To recover elements from more acidic solutions, we studied their sorption with sorbents containing arsenazo functional groups in relation to the nitric acid concentration. As seen, quantitative recovery of actinides and lanthanides(III) is possible from solutions with nitric acid concentration no more than 1 M (Table 2). Plutonium can be recovered from 3 M HNO_3.

The kinetics of europium sorption from 1 and 3 M HNO_3 with polystyreneazoarsenazo and benzidineazoarsenazo is shown in Fig. 1. At the ratio of the solution volume to the sorbent mass of 200, the equilibrium recovery of europium with polystyreneazoarsenazo at stirring is reached within 1 h, and with benzidineazoarsenazo, within 4–6 h. The study of the degree of europium recovery from 1 M HNO_3 in 2 h as a function of the ratio of the solution volume (V) to the sorbent mass (m) showed that europium is quantitatively sorbed with polystyreneazoarsenazo and benzidineazoarsenazo at V/m 200 and 40, respectively. To recover metals from more concentrated HNO_3 solutions, the polystyreneazoarsenazo mass should be increased (Fig. 2, Table 3): e.g., at V/m 100, 60% europium is recovered even from 5 M HNO_3.

Since polystyreneazoarsenazo and benzidineazoarsenazo are fine powders, they should be separated from the solution by centrifuging, which is inconvenient with radioactive elements.

Fibrous chelating sorbents with high kinetic and selective characteristics are the most promising for recovery of actinides and lanthanides. To increase the efficiency of metal concentration (especially from large volumes), filled fibrous sorbents with higher kinetic characteristics and higher selectivity were used [17]. The study of metal sorption from nitric acid solutions with the filled fibrous chelating sorbent poyarsenazo-n containing polyacrylic fiber as a polymeric matrix and polystyreneazoarsenazo as a filler showed that this material well compares with the above-studied sorbents in sorption properties but has better kinetic characteristics (Fig. 1), since it exhibits

	polystyreneazoarsenazo		polyarsenazo-n	
	200	100	100	50
3	58	72	48	56
4	54	69	42	53
5	46	60	30	53

rapid swelling and larger surface area. Triple-charged metals can be quantitatively recorded with polyarsenazo-n from nitric acid solution with concentration lower than 1 M, and plutonium, from solutions with higher acid concentration. As for polystyreneazoarsenaso, the increase of the polyarsenazo-n mass (Fig. 2, Table 3) increases the degree of metal recovery.

CONCLUSION

Chelating sorbents with arsenazo functional groups can be successfully used for sorption recovery and concentration of actinides and lanthanides from nitric acid solutions. Sorption can be accompanied by both chelation and ion exchange, because, along with chelating groups, these sorbents contain sulfo groups, which can be sites of usual ion exchange. It was shown that chelating sorbents with azo groups (especially those based on fibrous polymers) recover radionuclides from nitric acid solutions better than modified carbons.

SORPTION AND ION-EXCHANGE PROCESSES

Extraction-Chromatographic Separation and Concentration of Phenol and Guaiacol with the Use of Organic Solvent Mixtures as Stationary Phases

Ya. I. Korenman, I. V. Vatutina, and A. T. Alymova

Voronezh State Technological Academy, Voronezh, Russia

Received January 26, 2001

Abstract—Extraction-chromatographic concentration and separation of phenol and guaiacol was studied as influenced by the composition of binary tributyl phosphate–pentyl acetate, tributyl phosphate–dinonyl phthalate, tributyl phosphate–didecyl sebacate, and ternary tributyl phosphate–dicyclohexano-18-crown-6–toluene and tributyl phosphate–dicyclohexano-18-crown-6–chloroform stationary phases.

Extraction chromatography with the use of nonpolar polymeric sorbents as supports and mixtures of organic solvents as stationary phases (SPs) is a promising technique for concentration of microamounts of chemical compounds [1]. For example, phenol can be recovered from aqueous solution with tributyl phosphate (TBP) organic solution applied to the surface of a polymeric sorbent (Polysorb S) [2, 3]. At the same time, extraction-chromatographic concentration of guaiacol exhibiting physicochemical features close to those of phenol but significantly differing from the latter in toxicological characteristics was not studied. In this work we studied extraction-chromatographic concentration of phenol and guaiacol from aqueous solutions with the use of TBP or dicyclohexano-18-crown-6 (DCH18C6) organic solutions as the stationary phases.

The aim of this work was to study the effect of composition of the stationary phase on extraction-chromatographic separation of phenol and guaiacol.

EXPERIMENTAL

Polysorb S was pretreated, impregnated with stationary phase (SP), and packed into a chromatographic column by a common procedure [3]. The choice of the optimal composition of the mixed stationary phase was governed by the data on the selectivity coefficients β and distribution factor D of phenol and guaiacol between immiscible aqueous and organic phases. It was found that TBP–alcohol and TBP–hydrocarbon mixtures commonly used as stationary phases in extraction chromatography are more weakly retained by Polysorb matrice in filtration of aqueous phenol and desorbing solutions than the compounds previously tested for this purpose [4].

Extraction of phenol and guaiacol under static conditions with TBP–pentyl acetate (PA), TBP–didecyl sebacate (DDC), and TBP–dinonyl phthalate (DNP) mixtures is characterized by high values of D and β (Table 1, SP nos. 1–3). In extraction of phenol with DCH18C6 (0.3 mole fraction) solution in chloroform or toluene D = 20–25. Relatively low distribution factors in extraction of phenol and guaiacol with organic solutions of the crown ether can be caused by the lower polarity of the ether oxygen atoms in DCH18C6 as compared to TBP. In extraction of phenol and guaiacol with DCH18C6 solution in toluene their distribution factors are virtually similar (~25). In extraction with DCH18C6 solution in chloroform (SP no. 6) the distribution factor of phenol exceeds that of guaiacol by a factor of 2. The stationary phase no. 6 has the minimum kinematic viscosity η, which facilitates diffusion of the components and increases the separation efficiency. Therefore, in separation of phenol and guaiacol with the use of frontal chromatography stationary phase no. 6 is preferable.

The ternary stationary phases TBP–DCH18C6–toluene (SP no. 4) and TBP–DCH18C6–chloroform (SP no. 5) exhibit larger sorption power as compared to the TBP–DCH18C6 binary stationary phase. We found also that with ternary stationary phase no. 5 the separation coefficient β is maximal (Table 1).

Large distribution factors of phenol and guiacol

between aqueous solution and the binary and ternary stationary phases (nos. 1–5) indicate the high sorption capacity of the columns with respect to the compounds concerned. In experiments on extraction-chromatographic concentration of phenol and guaiacol and determination of the operating parameters, the columns were packed with Polysorb (2.9 g) impregnated with SP (2.9 ml). The bed height of the modified sorbent *h* was 14 cm. More efficient columns used for separate determination of phenol and guiacol contained less viscous stationary phase no. 6, and the bed height was 5 cm.

In our experiments the sorption capacity of the column *E* was conventionally determined from the concentration of the target compound in the initial solution and the solution volume passed by the moment when the component concentration in the eluate became 16% of the initial level [1]. We found that the solution volume passed through the column under these conditions remains constant irrespective of the initial concentration of the compounds being separated [5]. At the same time, the *E* value determined from the eluate volume passed through the column by the moment of breakthrough of the first amounts of the target compound increases with decreasing initial concentration of phenol or guaiacol.

Table 2. Column characteristics*

SP no.	*E*, μg g^{-1}	HETP, cm	*D*'	V_r, ml	V_e, ml

			Guaiacol		
1	302	5.2	110	2.1	8.5
2	293	5.6	109	2.1	8.0
3	276	5.8	103	1.9	8.0
4	190	2.3	56	1.7	6.0
5	155	2.8	48	1.7	7.5
6	20	1.6	11	1.3	3.5

* V_r and V_e are the retention and elution volumes, respectively.

The highest *E* value was observed in filtration of phenol aqueous solution (pH 3) through the column with SP no. 2 (filtration rate 0.4 l h^{-1}). The columns with SP nos. 1 and 2 have a high sorption capacity with respect to guaiacol. Table 2 shows that in passing from the column with SP no. 3 to the column with SP no. 6 containing DCH18C6 instead of TBP the sorption capacity significantly decreases.

In extraction-chromatographic systems the distribution factor *D*' of a component is determined under dynamic conditions as the ratio of the volume of the eluate containing half concentration of the component (relative to the initial solution) to the SP volume [1, 6]. The distribution factors *D*' of phenol and guaiacol determined by this procedure (Table 2) are comparable to those determined under static conditions (Table 1).

As seen from Table 2, increase in the SP viscosity, hindering diffusion of phenol and guaiacol [6, 7], is responsible for decrease in HETP. The HETP is the largest in the case of SP no. 3. The most efficient column with SP no. 6 is characterized by relatively small HETP. It is that column that was used to study the possibility of separate determination of phenol and guaiacol in their mixtures by frontal chromatography (Fig. 1). The differential output curve $\Delta A/\Delta V = f(V)$

has two maxima corresponding to two different retention volumes. The areas under maxima of the differential output curve correspond to the amounts of guaiacol and phenol, respectively [6, 8].

The elution volumes V_e of phenol and guaiacol were determined by their desorption with an aqueous solution containing 0.5 g of NaOH and 5 g of NaCl per 100 g of the solution. As with HETP, V_e decreases with decreasing SP viscosity facilitating diffusion of phenol and guiacol (Table 2).

Table 2 shows that the values of extraction-chromatographic characteristics of guaiacol are lower than those of phenol. We assume that this decrease is caused by introduction of the less hydrophobic OCH_3 group into the phenol molecule, which virtually does not affect the specific interaction with SP but enhances nonspecific interactions with eluent (water) [7]. This assumption is confirmed by the fact that V_r of guaiacol is less than that of phenol, i.e., guaiacol exhibits larger affinity for the aqueous desorbing solution.

In elution of phenol the retention volume V_r can decrease owing to phenol ionization in the alkaline eluent and strong hydration of the resulting ionic species. Table 2 shows that V_r of phenol and guaiacol is close, so that their elution peaks superimpose and separation of the compounds by elution with aqueous alkaline solution becomes impossible.

In analysis of a 1-l sample of solution containing a phenol–guaiacol mixture we found that the column with SP no. 2 has a high sorption capacity for these compounds and provides their 100-fold concentration (V_e < 10 ml). Therefore, it is SP no. 2 that was used for concentrating phenol and guiacol.

We studied also the degree of recovery (*R*, %) of the compounds from aqueous solution (1 l) at a filtration rate of 0.4 l h^{-1} as influenced by the bed height of the modified sorbent. As seen from Fig. 2, the degree of recovery of phenol increases with increasing the sorbent bed height (Fig. 2). The feasibility of selective recovery of phenol from a phenol–guaiacol mixture on the column with h = 3 cm was reported by us previously [9]. Concentration of phenol–guaiacol mixture can be performed on a column with h = 8 cm. In analysis of smaller sample of the phenol–guaiacol mixture (10 ml) on the column with SP no. 5 having a lower sorption capacity but a higher selectivity coefficient, we obtained the similar dependence of the degree of recovery on the sorbent bed height. With this column phenol is selectively recovered within

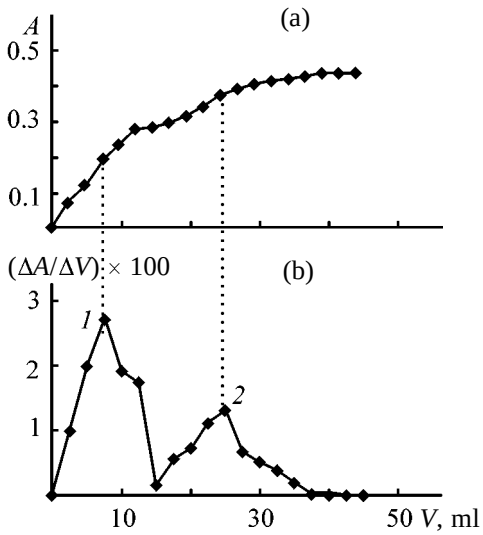

Fig. 1. (a) Integral and (b) differential output curves of (*1*) guaiacol and (*2*) phenol sorption. (*A*) Eluate optical density and (*V*) eluate volume.

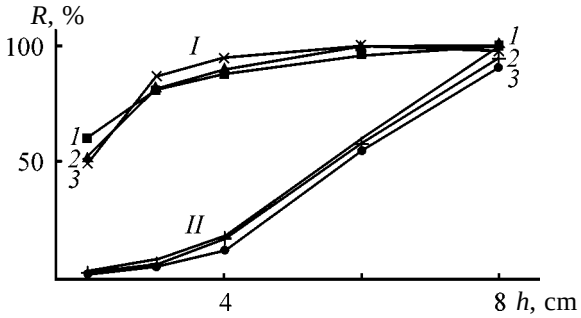

Fig. 2. Degree of recovery *R* of (*I*) phenol and (*II*) guaiacol as a function of the bed height *h* of the modified sorbent. Initial compound content (μg l^{-1}): (*1*) 1.0, (*2*) 2.5, and (*3*) 5.0.

a 2-cm sorbent bed, and guiacol is virtually completely recovered within 6 cm.

In extraction-chromatographic concentration of phenol–guaiacol mixtures on the column with SP no. 2 at a high filtration rate the sorption bands of the compounds are smeared and overlapped [6]. Therefore, the effect of the rate of solution filtration on the degree of recovery was studied on the column with a higher sorbent bed (14 cm). Figure 3 illustrates the recovery of phenol (initial concentration 1.0, 2.5, and 5.0 μg l^{-1}) and guaiacol (initial concentration 1 μg l^{-1}) from aqueous solution (1 l) at variable filtration rate. At a filtration rate within 0.4 – 0.8 l h^{-1} the recovery of phenol is virtually complete (100%). Further increase in the filtration rate causes partial breakthrough and loss of phenol. At the filtration rate of 1.1 l h^{-1} the degree of recovery of phenol does not exceed 60%.

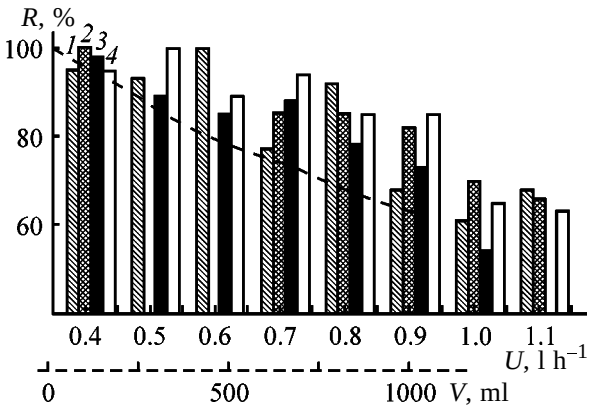

Fig. 3. Degree of recovery *R* of phenol as a function of the (bars) rate of eluate filtration *U* and (dashed line) eluate volume. Content (μg l^{-1}): phenol (*1*) 1.0, (*2*) 2.5, and (*3*) 5.0; guaiacol (*4*) 1.0.

As seen from Fig. 3, the similar relationships occur for guaiacol (Fig. 3).

Figure 3 (dashed line) shows also the degree of recovery of phenol (initial concentration 5 μg l^{-1}) as a function of the solution volume passed through the column (SP no. 2) at a constant filtration rate, approximately equal to 1.1 l min^{-1}. It is seen that at such a rapid filtration phenol can be efficiently recovered only from small volume of solutions. At $V <$ 250 ml phenol is virtually completely recovered from aqueous solution. With increasing solution volume to 500 and 1000 ml recovery of phenol does not exceed 80 and 65%, respectively. Thus, at a filtration rate of 1.1 l h^{-1} recovery of phenol is the most complete at $V <$ 250 ml.

CONCLUSIONS

(1) The optimal compositions of binary stationary phases for separate determination of phenol and guaiacol (dicyclohexano-18-crown-6–chloroform) and concentration of phenol–guaiacol mixtures (tributyl phosphate–dinonyl phthalate) by frontal extraction chromatography were established.

(2) The efficiency of concentration of phenol–guaiacol mixtures was studied as a function of the bed height of the modified sorbent, the filtration rate, and the eluate volume.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Kinetics of Leaching of Nickel Compounds from Spent Electrodes of Nickel–Iron Batteries in Ammonia Solutions

A. I. Demidov and O. A. Krasovitskaya

St. Petersburg State Technical University, St. Petersburg, Russia

Received August 4, 2000

Abstract—The extent of nickel recovery from spent electrodes of nickel–iron batteries in ammonia solutions was studied in relation to time and leaching temperature. The optimal time and the temperature at which the extent of nickel recovery in leaching solutions containing ammonium salts is the highest were determined and the dependence of the process efficiency on the anionic composition of the solution was analyzed. The apparent activation energies of nickel leaching from the active mass preliminarily extracted from lamellas are calculated, and the adequacy to the actual process of the model of leaching controlled by external diffusion is assessed.

The problems of utilization and recycling of raw materials containing non-ferrous metals, including nickel, are presently the matter of strong interest. The priority direction in this field is the development of hydrometallurgical processing techniques characterized by environmental safety and low energy consumption [1–4].

Complexation in ammonia solutions underlies nickel recovery from oxidized ores [5–7]. Previously, it has been shown that this approach is promising for processing of positive electrodes of nickel–iron batteries. Nickel is present in lamellas of spent batteries in the form of hydroxides, mainly $Ni(OH)_2$ dissolving in aqueous ammonia by the overall reaction

$$Ni(OH)_2(s) + 6NH_3(aq) \rightarrow [Ni(NH_3)_6]^{2+}(aq) + 2OH^-(aq). \quad (1)$$

Ammonium salts added to aqueous solutions make higher the dissolution efficiency because of their buffer action preventing accumulation of OH^- ions by reaction (1), which takes the form

$$Ni(OH)_2(s) + 4NH_3(aq) + 2NH_4^+(aq) \rightarrow [Ni(NH_3)_6]^{2+}(aq) + 2H_2O. \quad (2)$$

It was established that the extent of nickel recovery may be as high as 99% in some cases of leaching of lamella fragments in ammonia solutions containing ammonium salts [8]. However, revealing the possibility of such processing on industrial scale requires more detailed studies of the process kinetics.

The rate of leaching (generally dependent on reagent concentration, temperature, rate of stirring, extent to which the surface of the solid phase is developed, etc.) may vary in the course of the process. The heterogeneous process of leaching includes at least three main stages, namely, transport of reagents toward the reaction surface, chemical reactions proper, and removal of dissolved products into the solution bulk. Therefore, one of the basic tasks in studying the kinetics of a complex process consists in finding the apparent activation energy of the process and in determining its limiting stage.

In this study, we analyzed the efficiency of the process in relation to the time and temperature of leaching for several solution compositions. The leaching was performed from a spent active paste, both contained within lamella fragments and preliminarily extracted from it. The leaching solutions were prepared using the following reagents: aqueous ammonia NH_4OH (ultrapure grade) and ammonium salts (chemically pure grade) NH_4Cl, NH_4NO_3, $(NH_4)_2SO_4$, and $(NH_4)_2CO_3$.

The extent of nickel recovery was calculated from the results of spectrophotometric analysis for nickel in the leaching solutions by the technique described in [8]. The leaching process was studied in solutions of the following compositions (M): 2 NH_4OH and 1 NH_4NO_3 (solution A), 2 NH_4OH and 1 NH_4Cl

1070-4272/01/7405-0737$25.00

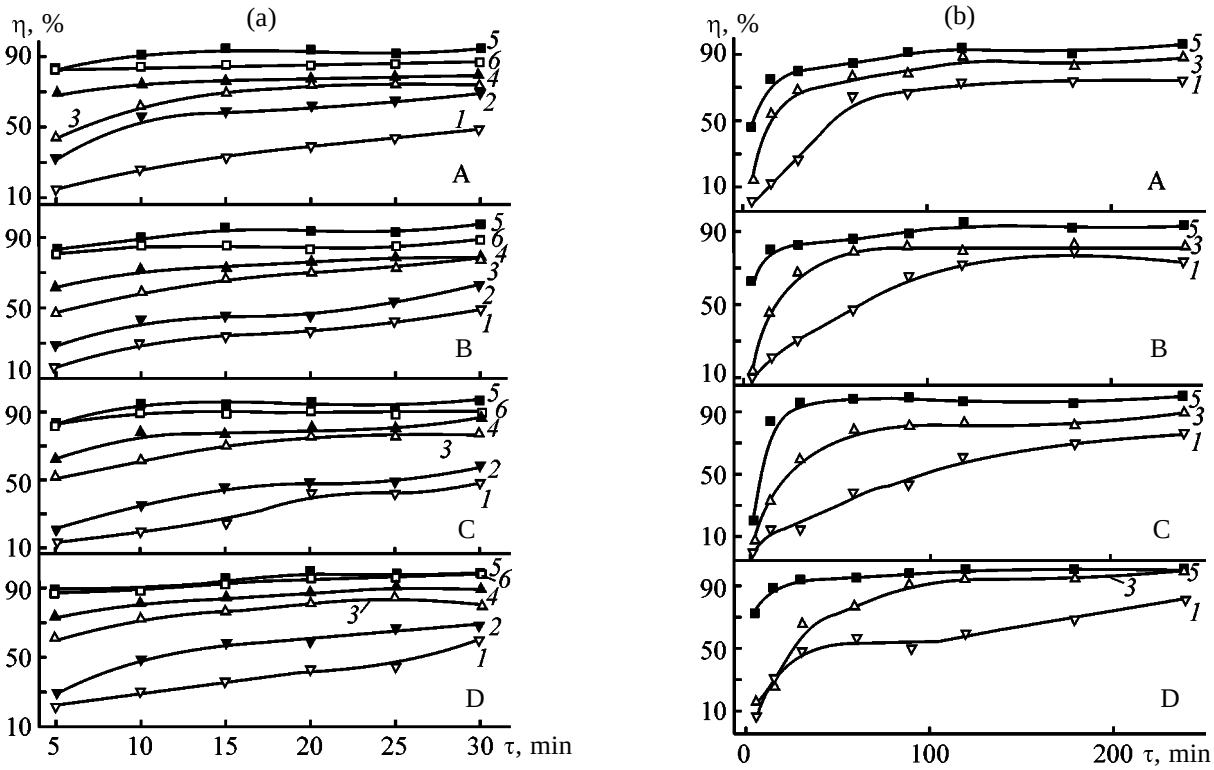

Fig. 1. Kinetics of nickel recovery from (a) active paste and (b) lamella fragments into ammonia solutions A–D at various temperatures. (η) Extent of nickel recovery and (τ) time; the same for Fig. 3. Leaching temperature (°C): (*1*) 30, (*2*) 40, (*3*) 50, (*4*) 60, (*5*) 70, and (*6*) 80.

(solution B), 1.5 NH_4OH and 1 $(NH_4)_2SO_4$ (solution C), and 1.5 NH_4OH and $(NH_4)_2CO_3$ (solution D).

The leaching was done from 1.0-g portions of spent active paste and also from closed lamella fragments containing approximately the same amount of the active paste. A sample was placed in a preliminarily thermostated flask with 50 ml of leaching solution, equipped with a magnetic stirrer. In this stage of the investigation, the rate of agitation was maintained constant. The duration of leaching was varied from 5 to 240 min for lamellas and from 5 to 30 min for the active paste without lamellas.

Figure 1a illustrates the progress in time of isothermal leaching of nickel from the active paste into solutions containing various ammonium salts. Several tentative conclusions follow from the presented plots: (1) the curve shapes are basically the same for all of the studied leaching solution compositions; (2) recovery of nickel is strongly temperature-dependent, especially in the initial stage of the process (first 10 min) and at temperatures lower than 50°C; the maximum extent of recovery is observed at 70°C and then, with temperature raised to 80°C, decreases somewhat; (3) above 50°C the rate of leaching tends to decrease with time, except for the initial stage; (4) at 70–80°C the optimal time of nickel recovery is 10–20 min and 1–2 h for leaching from, respectively, the active paste and lamellas in ammonia solutions, irrespective of their anionic composition.

This suggests that, in its initial stage, the leaching proceeds in a mixed diffusion-kinetic mode and then tends to pass into the predominantly diffusion region [9–11].

The results obtained in leaching of nickel compounds from lamella fragments (Fig. 1b) on the whole agree with the aforesaid, with correction made for the even more pronounced decrease in the leaching rate with time. The shapes of the curves obtained at 30°C differ from those of the curves taken at 50 and 70°C to a greater extent than these latter differ from each other. Comparison of the data in Figs. 1a and 1b shows that direct leaching through the lamella sheath at a given temperature imposes on the process obvious diffusion limitations, which is one more evidence in favor of the above tentative conclusions.

To confirm these conclusions quantitatively, the obtained kinetic dependences were processed to eval-

uate the apparent activation energy of the process. To construct a plot in the Arrhenius coordinates, the rate of leaching was determined from the initial portions of the curves. Figure 2 presents the results of mathematical processing of the kinetic curves obtained in leaching in ammonia solutions of the active paste not enclosed in a lamella. In the same coordinates are shown experimental points describing leaching from lamella fragments under similar conditions. The slope of the straight line presented in the figure was used to determine the activation energy of leaching of the active paste to be, on the average, 30 kJ mol^{-1}, which is a quantitative indication of the occurrence of the process in the transition diffusion-kinetic region [10, 11].

At the same time, the experimental dependence in Fig. 2, well described by a straight line in the Arrhenius coordinates (with correlation coefficients exceeding 0.95) at $1/T > 2.95 \times 10^{-3}$ K^{-1} ($T < 65$°C), shows an obvious tendency toward a decrease in its slope (and, consequently, in the apparent activation energy). These results confirm the assumption that the process tends to pass into the diffusion region with time and with increasing leaching temperature. In addition, the closeness of the experimental points in Fig. 2 indicates that the leaching parameters affect in about the same way the percentage of nickel recovery from the active paste and lamella fragments. It should be noted that no significant differences were revealed between the activation energies obtained for all of the four leaching solutions: 29.9, 32, 33, and 27.4 kJ mol^{-1} for, respectively, solutions A, B, C, and D.

Erofeev and Kolmogorov derived a generalized kinetic equation that can be used to derive, without composing differential equations, formulas of chemical kinetics for homogeneous and heterogeneous reactions. In particular, the equation for topochemical processes has the form

$$E = 1 - \exp(-k\tau^n), \quad (3)$$

where E is the fraction of substance reacted by the instant of time τ, having the meaning of the probability that a molecule has reacted by the time τ.

Bulanov *et al.* [13] used for describing the kinetics of leaching of iron-containing raw materials in obtaining ferrous chloride a similar equation

$$C_i = C_i^0[1 - \exp(\alpha_i\tau)], \quad (4)$$

where $\alpha_i < 0$ is a constant accounting for specific features of the reagent diffusion, C_i^0 is the concentration of ith leached substance in the starting concentrate, and C_i is its concentration in solution.

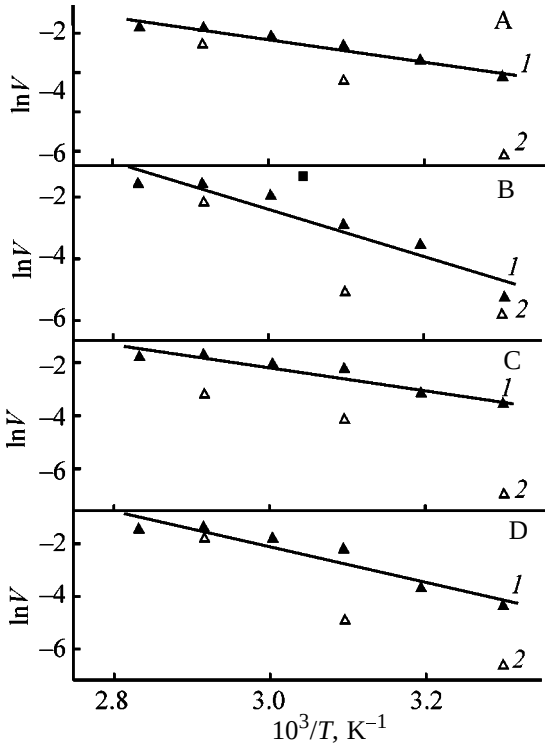

Fig. 2. Dependence of the leaching rate $\ln V$ (for explanation, see text) in ammonia leaching solutions A–D on temperature T. (*1*) Active paste and (*2*) lamella fragments.

The numerical values of the coefficients can be obtained by means of linear regression analysis of experimental data. Such a model of the leaching process requires some assumptions, which idealize somewhat the process in question, but are rather frequently used in modeling. At the same time, the validity of the following assumptions is the criterion for the possibility of regarding the process as an ideal mixing process [13]: (1) all solid particles have spherical shape which is preserved during the chemical reaction; (2) the average granulometric composition of particles is the same throughout the reaction volume; (3) the solid particles and the solution are homogeneously mixed in the reaction volume; (4) the active surface of the particles is proportional to the concentration of the substance being dissolved in the solid phase; (5) the sludge temperature is constant in time and the same throughout the reaction volume; (6) the leaching of the active paste is diffusion-controlled, the substance transfer within pores of a particle toward its boundary (internal diffusion) can be neglected and only external diffusion (substance transfer from the particle surface into the bulk of the liquid) be con-

Results of linear regression analysis of the kinetics of nickel leaching from the active paste and lamella fragments in ammonia solutions at 70°C

Solution	$G = \ln(1 - \eta)$	R
	Active paste	
A	$-1.540 - 7.61 \times 10^{-2}\tau$	0.840
B	$-1.927 - 3.931 \times 10^{-2}\tau$	0.746
C	$-2.119 - 4.945 \times 10^{-2}\tau$	0.764
D	$-1.467 - 1.113 \times 10^{-1}\tau$	0.865
	Lamella fragments	
A	$-1.229 - 8.344 \times 10^{-3}\tau$	0.869
B	$-1.504 - 6.131 \times 10^{-3}\tau$	0.796
C	$-1.888 - 1.307 \times 10^{-2}\tau$	0.704

sidered; (7) the concentration of the leached component at the surface of the solid phase is close to the saturation concentration; (8) surface adsorption can be neglected in considering heterogeneous chemical reactions and the rate at which the adsorption equilibrium is attained greatly exceeds the rate of the chemical reaction; (9) all reactions occur on the surface of the solid phase; (10) ammonia leaching solutions are in excess in the apparatus; (11) the diffusion surface can be taken to be proportional to the nickel hydroxide concentration in the solid phase in considering Ni^{2+} diffusion flows; (12) the leaching process can be considered under conditions excluding hydrolytic decomposition of ammonia solutions.

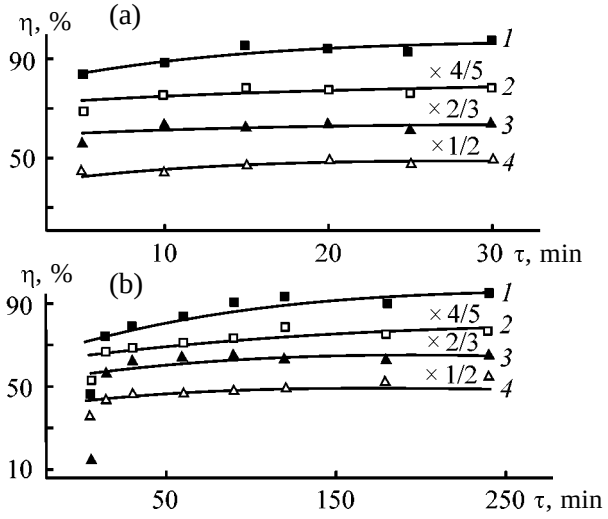

Fig. 3. Comparison of model kinetic curves with experimental data for nickel leaching from (a) active paste and (b) lamella fragments at 70°C. Solution: (*1*) A, (*2*) B, (*3*) C, and (*4*) D.

With account of the fact that the C_i/C_i^0 ratio is in the given case equivalent to the extent of recovery η, an attempt was made to describe the leaching process in terms of the model proposed in [13]. For this purpose, the experimental data were subjected to regression analysis in the coordinates G–τ, where $G = \ln(1 - \eta)$, with the slope of the straight line yielding in this case the coefficient α. The results of the analysis are presented in the table (R is the correlation coefficient).

Thus, the coefficients of the models are significant, since t (Student's test) gives significant correlation coefficients $R \geq 0.67$. Hence, we can obtain theoretical and experimental models describing how nickel passes into solution in the course of time. Model kinetic curves of nickel recovery, plotted using the equations (see table), are in good agreement with the experimental data for the active paste (Fig. 3a). Leaching from lamella fragments is also satisfactorily described by the equations of the model, except in the initial stage when, as shown above, the share of the kinetic component is still relatively high (Fig. 3b).

Analysis of the model suggests that the process of nickel passing into solution can indeed be considered an ideal mixing process with sufficient accuracy. The coincidence of the calculated and experimental data suggests that the process of nickel leaching in ammonia solutions from both the active paste itself and lamellas with active paste is diffusion-controlled.

CONCLUSIONS

(1) A study of the kinetics of nickel leaching from spent electrodes of nickel–iron batteries demonstrated that, in the initial stage (especially at temperatures below 50°C), the process occurs in a mixed diffusion-kinetic mode and then tends to pass into the diffusion region.

(2) The anionic composition of ammonia leaching solutions exerts no fundamental effect on the efficiency of nickel recovery from the active paste and lamella fragments.

(3) The optimal time of leaching at 70–80°C is about 10–20 min for the active paste and 1–2 h for lamella fragments.

(4) The model of outer-diffusion-controlled leaching satisfactorily describes the kinetics of nickel recovery from the active paste and lamella fragments taken from spent positive electrodes of nickel–iron batteries.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Dynamics of Changes in the Anionic Composition of Sodium Chloride Solutions in a Flow-through Electrolyzer

R. G. Romanova, S. I. Agadzhanyan, G. V. Korshin, and V. F. Sopin

Kazan State Technological University, Kazan, Tatarstan, Russia

Received July 7, 2000

Abstract—Products theoretically obtainable by electrochemical treatment of sodium chloride solutions in the dynamic mode are considered. Hydrated chlorine, and hypochlorous and hydrochloric acids are determined quantitatively by iodometric titration, spectrophotometry, and potentiometry. A comparative analysis is made of theoretical and experimental results obtained in determining chlorine-containing ions.

Electrochemically treated solutions of sodium chloride find increasingly wide application in medical practice. At the same time, the mechanism of effective action of these solutions remains unclear because the ionic and gas species in them occur in a labile equilibrium. In this connection, the composition of electrochemically treated sodium chloride solutions in a flow-through electrolyzer with a canvas dam was studied. The obtained experimental data are compared with the results of approximate theoretical calculations.

A wide variety of reactions may occur at electrodes in electrolysis of chloride solutions [1, 2]. Depending on electrochemical treatment (ET) conditions, electrolyzer parameters (type of diaphragm, distribution of current over electrodes, electrode material, stationary or dynamic mode), solution (nature and concentration of electrolytes), and temperature, the resulting solutions may have different chemical compositions. The most probable and practically important are reactions involving chloride ions and products of their oxidation (HClO, ClO^-, Cl_3^-, Cl_2). Reactions leading to deeper oxidation (ClO_2^-, ClO_3^-, ClO_4^-) are kinetically hindered [3], being only possible as a result of redox reactions in the bulk at high content of precursors and elevated temperatures.

Anolyte being of primary practical importance, we restrict consideration to processes occurring in the anode part of the electrolyzer.

At the current densities (1–10 A dm^{-2}) and electrolyte concentrations used, two competitive reactions may proceed at the electrodes:

$$2Cl^- = Cl_2 + 2e, \quad E_0 = 1.359 \text{ V}; \qquad (1)$$

$$2H_2O = 4H^+ + O_2 + 4e, \quad E_0 = 1.229 \text{ V}. \qquad (2)$$

Experiments show that processes (1) and (2) may actually proceed simultaneously; however, with ORTA (ruthenium oxide–titanium) electrodes used, the fraction of current α consumed for process (1) is 98–99% in electrolysis of sodium chloride solutions [4]. At low sodium chloride concentrations, α is much lower, as indicated by the experimental data presented below.

Let us consider processes occurring in the solution bulk. The reaction of molecular chlorine with aqueous solutions proceeds via hydration stage

$$Cl_2(g) = Cl_2(aq), \quad K = 0.104–0.003 \ (25–80°C), \qquad (3)$$

where K is the temperature-dependent equilibrium constant of hydration [5].

Then proceeds disproportionation, with the thermodynamic constant $K = 3.94 \times 10^{-4}$ [5]:

$$Cl_2 + H_2O = H^+ + Cl^- + HOCl. \qquad (4)$$

Also possible is formation of the trichloride ion

$$Cl_2 + Cl^- = Cl_3^-. \qquad (5)$$

The equilibrium constant of reaction (5) is 0.18 at 25°C [1].

In view of the aforesaid, it may be assumed that with the electrolyzer and ET modes used, only molecular chlorine is formed at the electrode from chlorine compounds, and conditions for existence of only hydrated molecular chlorine and hypochlorous and hydrochloric acids are created in the anolyte solution. In addition, thrichloride ions can theoretically exist in the solution; however, under real conditions, the con-

	IM	SP	Cl_2	HClO	fraction of indicated component, %	
			$C \times 10^3$, M		Cl_2(aq)	HClO
1	1.70	1.85	0.31	1.54	16.8	73.2
2	4.00	3.40	0.95	2.09	31.2	68.8
3	5.90	5.79	2.31	3.48	39.9	60.1
4	9.56	8.80	4.17	4.63	47.4	52.6
5	12.80	11.35	5.91	5.45	52.1	47.9

tent of chloride ions is less than 1–2% of the total amount of active chlorine even at the highest current density.

The total amount of oxidants in solution can be determined by iodometric titration. Hydrated molecular chlorine and chlorine-containing ions can be identified spectrophotometrically by their absorption in the UV range [6]. In addition, the content of active chlorine can be found by potentiometric titration of hypochlorous acid. Coincidence of the results obtained by the three methods can validate the assumption made.

Absorption in the UV spectral region is observed for ClO_2^-, ClO^- ions, HClO molecules, and hydrated chlorine [3, 6]. Chlorate and perchlorate ions cannot be identified using UV spectra, having no pronounced absorption bands in this range.

The UV spectra of chemically obtained chlorine water were measured in order to study the direct products of chlorine hydrolysis under conditions when there are no reactions occurring in the case of ET. In doing so, the total content of active chlorine was determined iodometrically. A preset pH value in model solutions was maintained by adding hydrochloric acid or sodium hydroxide. The obtained spectra of chlorine water and sodium chloride after ET were identical at equal pH values (see figure), which indicates that the composition of the solutions is the same as regards the absorbing components. If the formation of the trichloride ion, whose concentration is, as already mentioned, not higher than 1–2%, is disregarded, then measurements at two wavelengths are sufficient for determining separately the concentrations of hydrated chlorine and hypochlorous acid.

Solution of the system of equations describing the absorption of solutions containing hydrated chlorine and hypochlorous acid gives the following expressions, which can be used to determine their concentrations:

$$C(\mathrm{HClO}) = (6.696A_{290} - 2.556A_{320}) \times 10^{-2}, \quad (6)$$

$$C(\mathrm{Cl_2}) = (2.268A_{320} - 1.075A_{290}) \times 10^{-2}, \quad (7)$$

where A_{290} and A_{320} is the absorption by the solutions at, respectively, 290 and 320 nm.

The results obtained in determining spectrometrically various active chlorine species are presented in Tables 1 and 2 for various ET modes in comparison with the data furnished by iodometric titration.

For the cathode fraction the results yielded by the two methods coincide, which is due to the presence in the catholyte of the only active chlorine species, namely, hypochlorite ion penetrating into the catholyte by electromigration. For the anolyte the spectrophotometric method gives somewhat underestimated

11	41.15	75.9	22.3	1.8

values as compared with the iodometric titration data, which is probably due to the departure of the reaction from the 100% efficiency by chlorine. Actually, the efficiency by chlorine may be lower, especially in the initial stages of electrolysis, when the probability of the competing reaction of oxygen evolution grows at high pH values.

Approximate theoretical calculations of the accumulation of various active chlorine species were performed for α of 100, 80, and 60%. It was assumed in the calculations that HClO is not involved in migration processes owing to its being electroneutral, and the contributions of ClO^- and Cl_3^- to migration are negligible because of their low concentration, compared with the concentrations of Na^+, H_3O^+, and Cl^- ions. As a simplifying assumption, it was taken that only Cl^- and Na^+ ions are transferred across the membrane, whereas H^+ and OH^- ions formed at the electrode surface have not enough time to reach the diaphragm. The presented equations are of semiquantitative nature; however, to a first approximation, too, it is possible to obtain the predominant forms of active chlorine accumulation in solution. The calculated data presented in Table 3 indicate that active chlorine is mainly present in solution in the hydrated form and as hypochlorous acid molecules. The share of trichloride ions in the total active chlorine is not more than 2%, and that of hypochlorite ions is negligibly small. HClO predominates in the initial stages of electrolysis, but at current densities exceeding 5 A dm^{-2} the content of hypochlorous acid decreases and most of active chlorine is present in the form of hydrated molecular chlorine.

Hydrolysis of molecular chlorine proceeds, upon shifting the equilibrium, to give hypochlorous and hydrochloric acids. In addition, hydrochloric acid is also formed if the chlorine electrolysis proceeds with less than 100% efficiency. Since the dissociation constants of these two acids are markedly different, hypochlorous acid can be titrated separately and the content of active chlorine can be determined from the results of titration.

The content of HCl and HClO was calculated from the titration curves of sodium chloride solutions electrochemically treated in various modes. The titration curves show two jumps both for chlorine water solutions and for electrochemically treated sodium chloride solutions, with $V_1 = V_2$ for the former and $V_1 > V_2$ for the latter (V_1 and V_2 are the titrant volumes spent for titration to, respectively, the first and second equivalence points). The obtained results are presented in comparison with iodometric titration data in Table 4.

Thus, comparison of the results of spectrophotometric, potentiometric, and iodometric data on active chlorine shows their satisfactory agreement. However, iodometric titration gives 5–20% higher content of active chlorine, compared with the other two methods. The higher concentration of hydrochloric acid, compared with the maximum possible concentration in hydrolysis of hydrated chlorine, indicates that oxidation of water to give oxygen occurs in electrolysis in addition to the oxidation of chloride ions, which is in agreement with practical data [2].

EXPERIMENTAL

Electrochemical treatment was applied to 0.137 M solutions of analytically pure sodium chloride in distilled water. The electrochemical flow-through cell comprised two planar-parallel ORTA electrodes separated by a canvas dam.

Table 4. Results of iodometric and potentiometric (PM) determination of active chlorine in the anode chamber of a flow-through electrolyzer

j, A dm^{-2}	Content of acid $C \times 10^3$, M			Content of active chlorine $C \times 10^3$, M (IM)
	HCl	HClO	active chlorine	
1	1.34	0.89	1.78	1.70
2	2.05	1.79	3.58	3.80
3	3.25	2.90	5.80	5.90
4	4.68	4.29	8.58	9.56
5	5.69	5.14	10.28	12.08

The ET process was performed in a galvanostatic configuration in the dynamic mode, i.e., the liquid flow moved along the electrodes without mixing with subsequent portions of the liquid.

The iodometric determination of active chlorine was done by the procedure described in [7]. The spectrophotometric measurements were performed on an M-40 instrument. Standard solutions of chlorine water were prepared by passing chlorine gas through distilled water. Chlorine was generated by oxidizing hydrochloric acid with potassium permanganate [8]. The potentiometric titration was done with a pH-673M pH meter, using glass and silver chloride electrodes.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Oxidation of Alcohol–Ammonia Mixtures in High-Temperature Fuel Cell with Various Electrodes

N. M. Gamanovich, V. A. Gorbunova, and G. I. Novikov

Belarussian State Technological University, Minsk, Belarus

Received July 26, 2000; in final form, February 2001

Abstract—A high-temperature fuel cell with zirconium oxide electrolyte and various electrode materials, efficiently operating at 1070–1170 K on alcohol–ammonia fuel and air as oxidizing agent, was studied.

The development and practical use of fuel cells (FCs) and, in particular, high-temperature fuel cells (HTFCs) based on a ZrO_2–Y_2O_3 (YSZ) solid electrolyte and operating at 1070–1370 K for direct generation, with high conversion efficiency, of electric power from fuels have been a topical scientific and technological problem for more than a decade [1–3]. Here, mention should be made of the increasing interest (especially in such industrially developed countries as the United States, Japan, Germany, etc.) in use of FCs and HTFCs for obtaining "environmentally clean" electric power [3–6]. For example, a large research center dealing with FC problems has been organized recently in Germany and R&D work in this direction has been commenced, aimed at putting into industrial practice FCs with fuel conversion efficiency of up to 55% [7].

HTFCs based on solid oxide electrolytes and operating on vaporous fuels can be improved by optimizing both the cell design and the composition of the electrolyte and electrode layers and current leads. This could yield in the future an HTFC with power density of 1.5–2.0 W cm^{-2} in dc current generation [8]. A nearly as high power density (0.3–0.8 W cm^{-2} at cell voltage of 1.0–1.2 V) has already been achieved in recent years in HTFCs of planar and tubular design and units on their base with power in the range 1–100 kW, operating on H_2, CH_4, and diesel fuels [5, 8–10].

Recent investigations have been aimed to search for efficient fuels for HTFCs, and one of those found was a fuel based on alcohol–ammonia mixtures. A rather detailed thermodynamic analysis of the electrochemical oxidation of these mixtures in HTFCs was made in [1].

In addition, industrial use of HTFCs requires that noble metals in their electrodes should be replaced by lower-cost materials. By now, a number of materials of different kinds (for cathode and anode) have been developed for HTFCs. These are mainly alkaline-earth- (in position A) and transition-metal-doped (in position B) manganites, chromites, and cobaltites of rare-earth elements of the type ABO_3 [3] and metal–ceramic (cermet) anode materials (of the type of nickel–YSZ composites) [2, 12].

EXPERIMENTAL

The basic element of the employed HTFC is an electrochemical cell based on a solid oxide electrolyte of composition $0.9ZrO_2 + 0.1Y_2O_3$ (YSZ). The electrolyte for these cells was fabricated on a specially designed laboratory installation by hot die slip casting [1, 4]. The cells have tubular shape and the following dimensions (mm): diameter 10.0, working (central) part length 10.0, and wall thickness in the working area 0.35–0.40. The thus obtained electrolyte cells were degreased in C_2H_5OH and the cathode and anode layers were deposited onto them.

Various kinds of electrodes were used in the study: metallic (Pt), metal–ceramic (nickel-based), and ceramic (based on rare-earth manganites). To obtain stable layers close to the YSZ electrolyte in the thermal expansion coefficient, 10–35 wt % YSZ powder was introduced in the electrode paste composed of the above materials. Experiments with Pt electrodes were only carried out to obtain comparative characteristics of HTFCs. The main part of the study was done with lower-cost and more efficient electrodes: anodes based on the Ni–YSZ cermet and ceramic cathodes.

To perform electrochemical oxidation of the alcohol–ammonia mixture, an HTFC with a cermet

1070-4272/01/7405-0746$25.00

anode and a cathode made of an $La_{0.4}Ln_{0.4}Ca_{0.2}Mn_{0.94}Cr_{0.04}Ni_{0.02}O_3$ manganite (where Ln is a mixture of cerium-group rare-earth elements) doped in positions A and B was fabricated. This composition is sufficiently economical (having lower cost as compared with chemically purified compounds of lanthanum or other individual rare earths), being prepared from a mixture obtained industrially as half-product in hydrometallurgical processing of rare-earth-containing ores of the bastnaesite type [13, 14]. It is known that the electrochemical activity of electrodes can be substantially raised by introducing into their composition oxides with mixed-type conduction (oxygen-ion and electronic), such as CeO_2, V_2O_5, PrO_{2-x}, or Bi_2O_3 [1]. Commonly, oxides of this kind are introduced already in the stage of electrode layer formation on the electrolyte [4]. In this study, cathode materials were synthesized from manganites of a mixture of cerium-group rare earths, with increased (due to Pr and Ce ions) oxygen-ion conductivity [13].

Cathode material powders were synthesized by isothermal decomposition (at 1170–1270 K) of a mixture of nitrate salts prepared with the use of an industrial hydrometallurgical half-product: nitrate solution with rare-earth concentration of 300 g l^{-1} (in terms of total rare-earth oxides) and 30 g l^{-1} of free HNO_3 [14]. The specific consumption of the cathode material deposited onto the electrolyte cell was 12.0 mg cm^{-2}, with the material being a composite and containing 10.0 wt % YSZ powder.

The anode (fuel electrode) of the HTFC was made of an Ni–YSZ nickel zirconium cermet obtained by various methods. The specific consumption of the anode material was about 10.0 mg cm^{-2}.

Finely dispersed Raney nickel (70 wt %) and YSZ dross (30 wt %) were mechanically mixed, and the electrode paste was formed on the basis of this mixture (using 10% solution of rosin in C_2H_5OH). The paste was fired-in in a flow of technical-grade helium at 1550 K in the course of 2.5 h. After depositing the anode, the cathode layer was fired-in at 1420–1470 K in air for 2.5 h, which resulted simultaneously in oxidation of the anode layer of nickel to NiO_x oxide.

The cermet working electrode was formed through reduction of the nickel oxide phase in the NiO_x–YSZ layer by high-temperature alcohol–ammonia mixture in the course of operation of the electrochemical HTFC. The process of Ni reduction from NiO_x creates pores, necessary for the operation of HTFC, in the anode material, and the sufficiently uniform distribution of disperse YSZ particles in the anode cermet hinders collective crystallization of nickel particles in sintering, thereby ensuring prolonged electrochemical activity of the fuel electrode [12].

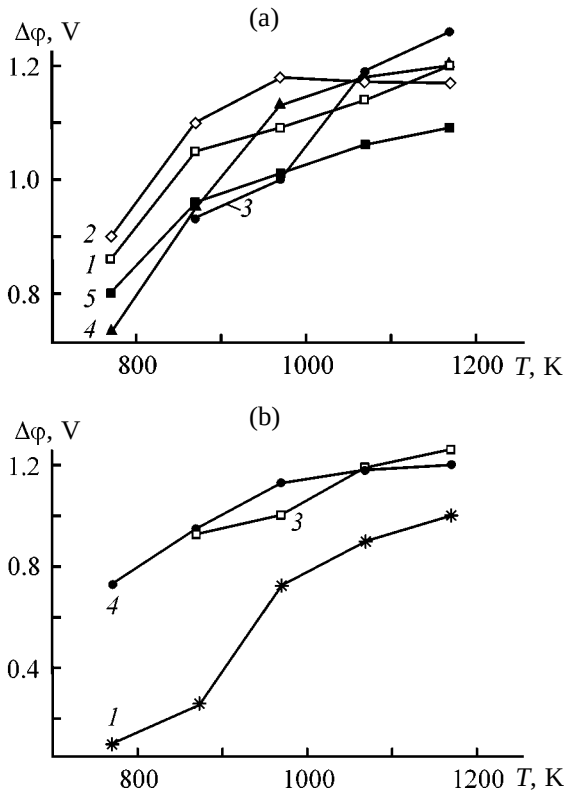

Fig. 1. Potential difference Δφ for an HTFC operating on alcohol–ammonia mixture, alcohol, and ammonia vs. temperature *T*. Digits at curves (a) *1*–*5* and (b) *3*, *4* denote the numbers of HTFC fuels in the table. (b) (*3*, *4*) HTFC with non-platinum electrodes; (*1*) alcohol–ammonia mixture in HTFC with Pt electrodes [11].

As current lead was used platinum wire 0.5 mm thick. As oxidizing agent in the HTFC served atmospheric oxygen supplied into the cathode space (at a pressure of 10^5 Pa).

Figures 1a and 1b show the obtained temperature dependences of the HTFC parameters. Previously [11], the current–voltage characteristics of electrochemical oxidation of an alcohol–ammonia mixture in HTFC on platinum electrodes (Fig. 1b, curve *1*) have been obtained. The maximum potential differences, voltages, and currents in HTFCs with platinum electrodes in oxidation of an alcohol–ammonia mixture are the following: Δφ = 1.0 V, V = 0.9 V, I = 0.85 mA (with an external load resistance R = 1000 Ω).

Preliminarily, electrochemical oxidation of separate components of the mixture, ammonia and ethanol, was performed in an HTFC of this kind. Ammonia and alcohol vapors were obtained by heating a 25% aqueous solution of ammonia and 96% ethanol. After

* Method of fuel preparation: passing NH_3 over the surface of alcohol heated to 300 (fuel no. 3) and 315 K (no. 4); bubbling of NH_3 vapor through alcohol at 293 K (no. 5).

drying (to remove water vapor), the vapors of the alcohol and ammonia were delivered into the anode space of the HTFC. The obtained potential differences, voltages, and currents are presented in the table. It can be seen that the parameters of HTFCs operating on, separately, ammonia and alcohol are rather close.

The alcohol–ammonia mixture used for electrochemical oxidation was prepared by methods providing different concentrations of the components in the working fuel mixture (see table). As oxidizing agent served atmospheric oxygen under ambient pressure. The potential differences, voltages, and currents measured in oxidation of the alcohol–ammonia mixtures are also given in the table. It is noteworthy that the *I* value recorded in a practically important case of HTFC operation in a circuit with an external resistance $R < 1000\ \Omega$ (in a short-circuited mode, in the limiting case) is as high as 0.3 A, which corresponds to a current density $i = 0.1\ \text{A cm}^{-2}$.

As seen from the table and Fig. 1a, the HTFC parameters depend on how an alcohol–ammonia mixture is prepared. The fluctuations of these parameters (potential difference, voltage, and current) are probably due to variations in the alcohol concentration in the mixture.

Analysis of the influence exerted by the HTFC electrode materials on the efficiency of electrochemical oxidation of the alcohol–ammonia mixture (Fig. 1b) suggests that the nickel–cermet anode and manganite cathode have higher activity (yielding $\Delta\varphi = 1.26$ V, $V = 0.97$ V, $I = 1.0$ mA) as compared with HTFCs having platinum electrodes [11]. This may be associated both with an increase in the polarization of the platinum electrode as a result of its surface oxidation to PtO_x and with sintering of platinum grains in the course of HTFC operation, making lower the electrode porosity [1, 3].

CONCLUSIONS

(1) The electrochemical characteristics of a tubular high-temperature fuel cell operating on alcohol–ammonia mixtures with air as oxidizing agent were determined experimentally. It is established that the method by which the alcohol–ammonia mixture is prepared affects the electrochemical parameters of the cell.

(2) The optimal values of the parameters of a high-temperature fuel cell: potential difference $\Delta\varphi = 1.26$ V, voltage $V = 0.97$ V, and current $I = 1.0$ mA (under load $R = 1.0\ \text{k}\Omega$) were obtained for a mixture prepared by passing NH_3 vapor over the surface of ethanol heated to 300 K. The best characteristics of the high-temperature fuel cell operating on this fuel were obtained with an Ni–YSZ cermet anode and a cathode made of a new material, $La_{0.4}Ln_{0.4}Ca_{0.2} \cdot Mn_{0.94}Cr_{0.04}Ni_{0.02}O_3$ (where Ln is a mixture of cerium-group rare earths introduced in the form of an industrial hydrometallurgical half-product), synthesized at 1070–1170 K.

Abstract—The electrocatalytic activity with respect to oxalate ions of spongy osmium immobilized within a carbon-paste electrode was studied. A procedure is proposed for electrocatalytic determination of oxalate ions on a chemically modified electrode based on spongy osmium under conditions of flow-through–injection analysis.

The necessity for analytical monitoring of oxalate ions is due to the biological importance of these compounds. For example, oxalic acid and its salts play an important part in the human body [1–3], quite a number of diseases being associated with disruption of the oxalate exchange. Therefore, it is advisable to use simple, proximate, and accurate analytical techniques in clinical diagnostics.

Analytical laboratories more frequently employ classical methods of analysis, gravimetry and titrimetry, for determining oxalate ions, with potentiometric titration with ion-selective or glass electrodes [4] occasionally used among electrochemical methods. Voltammetric techniques have not found use for this purpose. This is due to the fact that anions, including oxalates, are oxidized or reduced on indicator electrodes with a high overvoltage. However, as reported in [5], the overvoltage effects can be diminished by means of the so-called redox mediators. That is why interest has been aroused recently in electrochemical analytical techniques based on the use of chemically modified electrodes (CMEs) possessing electrocatalytic properties [6–8]. These electrodes are already being used successfully for electrochemical detection of a wide variety of compounds, such as oxygen, hydrogen peroxide, anions, alcohols, aldehydes, carbohydrates, amino acids, etc., including application in flow-through analysis systems [9].

A search for new redox mediators for CME and their use in flow-through–injection analysis (FIA) of biologically important compounds for the purpose of introducing automation and improving the efficiency of determination is a currently pressing problem.

The present study is concerned with the possibility of electrocatalytic determination of oxalic acid and oxalate ions, using carbon-paste electrodes (CPE) modified with spongy osmium under FIA conditions.

Carboxylic acids and their salts are oxidized at graphite electrodes with high overvoltage [10]. When using a CME based on a redox mediator, the overvoltage can be made lower. It was found that CPE modified with spongy osmium exhibits electrocatalytic activity toward oxalic acid. To elucidate the electrocatalysis mechanism, electrooxidation of the modifier and substrate on the CPE and CME was studied.

Oxalic acid is oxidized at CPE at $E > 1.2$ V (Fig. 1, curve *1*). The anodic voltammogram of the supporting electrolyte, recorded with CME in the absence of sub-

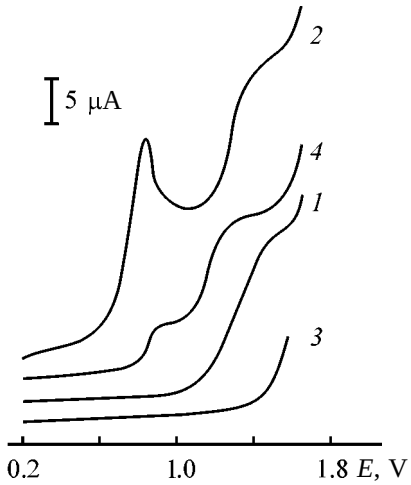

Fig. 1. Voltammograms of oxalic acid oxidation at (*1*) CPE and (*2*) osmium-based CME with borate buffer solution with pH 9.0 as supporting electrolyte. Concentration of oxalic acid 1×10^{-3} M; the same for Fig. 2. (*E*) Potential. Background curve: (*3*) at CPE and (*4*) at CME.

1070-4272/01/7405-0750$25.00

strate in the potential range E = 0.0–1.5 V, shows two waves (Fig. 1, curve *4*). According to published data [4], electron transfer occurs at first-wave potentials ($E \approx 0.8$ V) to give metal oxide, probably OsO_2, oxidizing at second-wave potentials. On adding substrate to the solution, the first electrochemical signal grows in intensity, being now recorded in the form of a peak (Fig. 1, curve *2*). The peak current depends on the substrate concentration. In performing electrolysis in a solution containing oxalate ions, bubbles of a gas, probably CO_2, accumulate on the electrode surface at $E \approx 0.8$ V. No gas evolution at CME in a supporting electrolyte solution was observed in this range of potentials. Similar results were obtained with sodium oxalate as substrate. This circumstance indicates that oxalate ions are oxidized at $E \approx 0.8$ V, i.e., at potentials of modifier oxidation, at CMEs based on spongy osmium. It was found in studying the dependence of the peak current i_p on the potential sweep rate v that the rate coefficient of the electrode process, $\Delta \log i / \Delta \log v$, is 0.27 for CME, which indicates that the process is complicated by a chemical reaction, i.e., electrooxidation of oxalate ions at CME proceeds by the EC mechanism including a preceding electrochemical stage and the subsequent chemical reaction. In the first stage, there occurs electrooxidation of the modifier to form osmium oxides oxidizing the substrate. A similar electrocatalytic behavior of osmium has been also observed in oxidation of other organic molecules [11]. The scheme of the electrode process can be represented as [11]

$$[OsO_x \cdot nH_2O] - e + OH^- \rightleftarrows [OsO_xOH \cdot nH_2O],$$

$$[OsO_xOH \cdot nH_2O] + 1/2C_2O_4^{2-} \rightarrow [OsO_x \cdot nH_2O] + CO_2 + OH^-.$$

Thus, spongy osmium immobilized within CPE exhibits electrocatalytic activity toward oxalic acid and its salts. The catalytic effect consists in that the overvoltage is lowered by 0.5 V. In addition, a significant excess of the anodic current over the modifier oxidation current recorded in the absence of substrate is observed in oxidation of oxalate ions at CME. In the system in question, catalysis occurs with respect to both current and potential.

The influence exerted by the solution pH and nature of supporting electrolyte on the current–voltage characteristics of the first wave of modifier oxidation (anodic current and peak position along the potential axis) was studied with and without the substrate. As seen from Fig. 2a, the peak potential decreases with

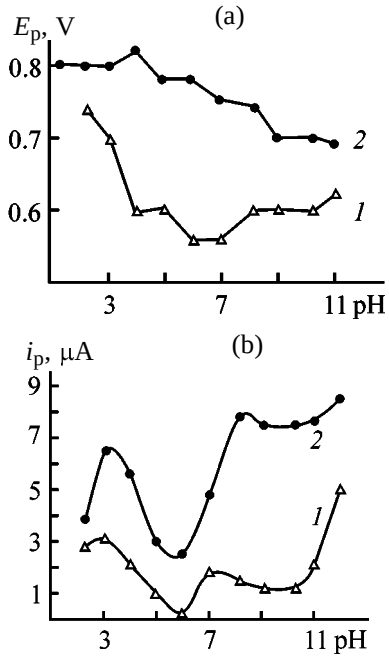

Fig. 2. (a) Peak potential E_p and (b) peak current of modifier oxidation i_p vs. pH value (*1*) without and (*2*) with oxalic acid, with 0.1 M Na_2SO_4 solution as supporting electrolyte and pH adjustment with H_2SO_4 or NaOH.

increasing pH in the range 2–5 and increases at pH from 6 to 12 (Fig. 2a, curve *1*). Presumably, this is due to changes in the position of the acid–base equilibrium between the members of the redox couple. The peak potential of electrocatalytic oxidation of oxalic acid at the modified electrode steadily shifts to less positive potentials (Fig. 2a, curve *2*). This can be attributed to the dependence of mole fractions α of the protonated and deprotonated oxalic acid species on pH [12]: $\alpha_{C_2O_4^{2-}}$ grows with increasing pH, which shifts the potential to less positive values.

The rise in the anodic current in the alkaline medium both with and without substrate (Fig. 2b) is due to the increasing number of catalytically active species on the electrode surface.

The pH value is chosen with the aim of achieving the maximum decrease in the overvoltage of substrate oxidation, on the one hand, and recording the highest catalytic current, on the other. These conditions are met by using high pH values. However, the reproducibility of the catalytic signal is impaired at pH > 11. Therefore, supporting electrolytes with pH ~ 9.0 were used. The following buffer solutions were chosen to maintain stable pH: phosphate, ammonia, and borate. In determining oxalate ions the best metrological characteristics were obtained with borate buffer solution with pH 9.0 as supporting electrolyte.

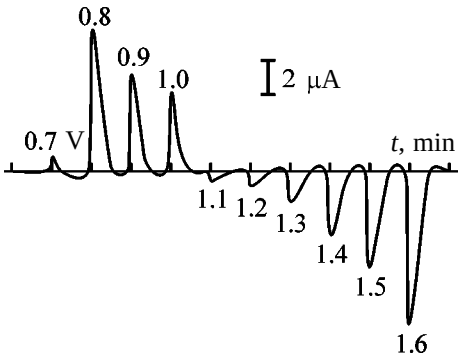

Fig. 3. FIA signal obtained in electrocatalytic oxidation of oxalic acid at an osmium-based CME at different applied potentials E with borate buffer solution with pH 9.0 as supporting electrolyte. (t) Time.

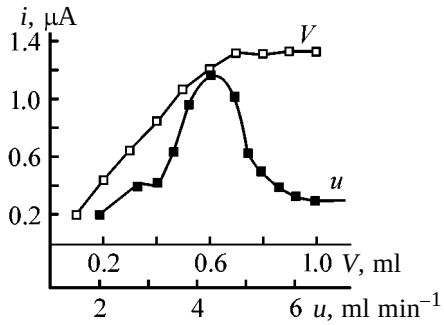

Fig. 4. FIA signal of electrocatalytic oxidation of oxalic acid at osmium-based CME vs. flow rate u and injected sample volume V with borate buffer solution with pH 9.0 as supporting electrolyte. (i) Peak current.

The osmium-based chemically modified electrode can be used for detecting electrochemically oxalate ions in flow-through analysis. In performing FIA, the electrocatalytic signal was recorded in the potentiostatic mode, and, therefore, the dependence of the peak current on the applied potential was studied.

The specific feature of how the FIA signal depends on the discretely applied potential (Fig. 3) is the change in the direction of the recorded peak with the potential shifted to the anodic region, which is due to a change in the charge of the electrophilic species. In order to find out whether this is due to a change in the form of mediator or substrate, a similar dependence was studied on an electrode modified with a complex of cobalt(II) with phthalocyanine. There is published evidence of the use of this redox mediator for amperometric detection of hydroxy acids [13]. In electrooxidation of oxalic acid at such an electrode in the potentiostatic mode, no change in the recording direction was observed with increasing potential. Consequently, the direction of recording of the FIA signal for the osmium-based CME is in all probability affected by a change of the existing modifier species, caused by alteration of the level of its oxidation on applying a more positive potential. Further studies are necessary for this process to be described in more detail.

As shown in Fig. 3, the FIA signal grows at potentials of up to 0.8 V, which confirms the assumption that modifier species formed at first-wave potentials are involved in electrocatalysis. In further studies, the FIA signal was recorded at E = 0.8 V, when the maximum analytical signal is observed.

In studying how the electrocatalytic response of CME in flow-through systems depends on hydrodynamic parameters, it was found that the maximum signal is observed at a flow rate u = 4.3 ml min^{-1} and injected sample volume V = 0.7 ml (Fig. 4).

Thus, the optimal conditions of FIA are as follows: E = 0.80 V, u = 4.3 ml min^{-1}, and V = 0.7 ml. Under these conditions, an FIA capacity of 60 samples per hour can be achieved.

The dependence of the FIA signal intensity on the substrate concentration is linear in the range 0.05–350 μmol, being described by the following equation (i, μA; c, μmol)

$$i = (5.8 \pm 0.7) \times 10^{-2} + (5.6 \pm 0.4) \times 10^{-3} c,\ r = 0.9991.$$

The detection limit calculated using the 3s criterion [14] is 10 nmol.

In evaluating the metrological parameters of the proposed method, it is necessary to consider the precision of analysis. The difficulties encountered in determining oxalate ions with solid electrodes under stationary conditions are due to the formation of carbon dioxide in electrooxidation of these anions. Gas bubbles screen the surface of the indicator electrode. Therefore, to obtain reproducible results, it is necessary to continuously clean the electrode surface. In a flow-through system, all the forming bubbles are carried away by a fluid flow; in addition, the electrode surface itself is renewed in the carrier flow. As a result, the signal reproducibility remains practically unchanged in a prolonged use of an indicator electrode without cleaning in a flow-through cell. The calculated S_r value does not exceed 5% within the working concentration range (Table 1).

The adequacy of the procedure was assessed by comparing the results of a flow-through–injection analysis for oxalic acid of artificial mixtures with data of potentiometric titration with a glass electrode. A statistical analysis of the obtained results by means of

t and *F* tests [14] demonstrated (Table 2) that there is no systematic error in determination of oxalate ions. The chosen methods are equally accurate in the range of concentrations to be determined ($F_{calc} < F_{tab}$), with the discrepancies between means being insignificant ($t_{calc} < t_{tab}$).

It was found that the determination is hindered by compounds exhibiting catalytic activity in the region of potentials under consideration and by those involved in the reaction of heterogeneous catalysis on osmium-based CME.

Thus, osmium-based CME can be used as electrochemical sensor for amperometric detection of oxalate ions in FIA.

The proposed technique can be used for determining oxalate ions in biological fluids, including the case of enzyme analysis.

EXPERIMENTAL

The dc voltammograms were recorded on a PU-1 polarograph with a three-electrode cell. CPE and CME served as indicator electrodes, silver chloride electrode was used as reference, and platinum wire, as anode. The carbon-paste electrode was prepared by mixing activated carbon and paraffin, taken in 6 : 4 ratio. In fabricating CME, a modifier (spongy osmium) was introduced into the carbon paste in amount of 2–5 wt %. After thorough mixing, the mixture of the components was placed in a glass tube 2.6 mm in diameter. The electrode surface was renewed mechanically with the use of abrasives and filter paper.

FIA was made using a setup including a peristaltic pump, injector, flow-through electrochemical cell, and recording device. The solutions used were supplied and discharged through flowing pipes made of silicone tubes with inner diameter of 2.0 mm. The injection was done with a microsyringe through the sealing membrane. A schematic of the flow-through membrane is presented in Fig. 5.

Electrical conductivity was imparted to the solutions with the use of a 0.5 M aqueous solution of Na_2SO_4 with NaOH or H_2SO_4, added to adjust the pH value, and also borate, ammonia, or phosphate buffer solutions. The pH value was monitored using a pH-150 pH meter. Solutions of oxalic acid and sodium oxalate were prepared by dissolving accurately weighed portions of chemically pure geade reagents in distilled water. Solutions with lower concentrations were obtained by successive dilution of the starting solutions.

Table 1. Results of analysis for oxalic acid and sodium oxalate on osmium-based CME (n = 7, P = 0.95)

Substrate	Substrate content, μmol		S_r

1.5 ± 0.3	1.7 ± 0.4	1.8	1.12

CONCLUSIONS

(1) The carbon-paste electrode modified with spongy osmium exhibits electrocatalytic activity toward oxalic acid and its salts. The substrates considered are oxidized at graphite electrodes, including the carbon-paste one, with high overvoltage at E > 1.2 V. For the electrode modified with spongy osmium, the overvoltage decreases by 0.5 V, and the anodic current much exceeds the current of oxidation

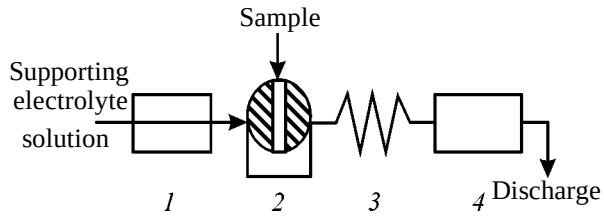

Fig. 5. Schematic of the flow-through–injection system: (*1*) peristaltic pump, (*2*) injector, (*3*) mixer, and (*4*) flow-through electrochemical cell.

of the modifier itself. The electrode process involves electrooxidation of the modifier, probably with the formation of osmium(IV) oxide oxidizing the substrate.

(2) Chemically modified electrode based on spongy osmium can be used for amperometric determination of oxalate ions in flow-through–injection analysis. The optimal conditions of analysis are as follows: E = 0.80 V, u = 4.3 ml min^{-1}, and V = 0.7 ml. The dependence of the analytical signal on the substrate concentration is linear in the range 0.05–350 μmol. The detection limit is 10 nmol. The signal reproducibility S_r = 0.034 (for c = 1 μmol, n = 10). The analysis capacity is 60 samples per hour.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Plating of Iron–Nickel Alloy in the Presence of Triphenylmethane Derivatives and Azo Dyes

A. S. Milushkin

Kaliningrad State University, Kaliningrad, Russia

Received April 27, 2000; in final form, July 2000

Abstract—The inhibiting action of hydrogen absorption in the course of plating of iron–nickel alloy from a sulfate electrolyte in the presence of triphenylmethane derivatives and azo dyes was studied. An electrolyte suitable for plating of iron–nickel alloy on articles susceptible to hydrogen embrittlement was developed.

Iron–nickel alloys as electroplated coatings are used instead of nickel, which is in short supply, to protect articles against corrosion and impart protection-decorative properties [1–8]. With such coatings not only the performance characteristics are improved, but also the productivity of parts is increased along with their reliability and life [7]. The presence of additives complicates composition and requires frequent replacement of electrolyte. Probably, for this reason, plating of the alloy instead of pure nickel is not widely used yet [9].

In this work, the alloy of the composition 80% nickel and 20% iron was used. Triphenylmethane derivatives and azo dyes were additives. Their names and structural formulas are listed in Table 1.

Table 1. Triphenylmethane derivatives and azo dyes

Additive no.	Additive name	Molecular weight
1	Bromocresol green (tetrabromo-*m*-cresolsulfophthalein)	662
2	Eriochrome black	465
3	Methyl red (4'-*N*,*N*-dimethylaminoazobenzene-2-carboxylic acid)	269
4	Eriochrome blue SE (acid chrome dark blue, acid chrome blue T)	520
5	Fuchsin new, rosaniline (3,3'-dimethyl-*p*-triaminotriphenylcarbinol chloride)	365
6	Pararosaniline (tri-*p*-aminotriphenylcarbinol chloride)	323

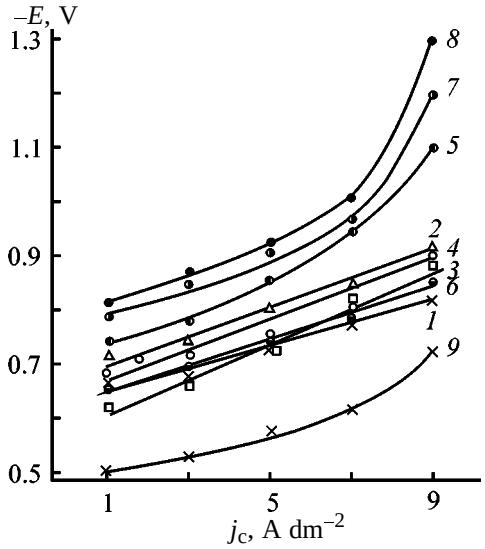

Fig. 1. Cathode potential E vs. current density j_c in the presence of triphenylmethane derivatives and azo dyes (C = 2 mM). The curve numbers are the same as the additive numbers in Table 1; (*9*) no additive; the same for Figs. 2 and 3.

The sulfate–chloride electrolyte in the presence of additives allows preparation of high-quality electroplated coatings with finely crystalline structure, provides good adhesion, and ensures the minimal hydrogen absorption by the steel support. Also, it allows preparation of corrosion-resistant decorative coatings with lustrous surface.

The iron–nickel alloy was plated from an electrolyte containing (g l^{-1}) $NiSO_4 \cdot 7H_2O$ 240, $NiCl_2 \cdot 6H_2O$ 38, $FeSO_4 \cdot 7H_2O$ 80, and H_3BO_3 40 under the following conditions: pH 1.8–2.0, j_c = 1.9–9 A dm^{-2}, 45–55°C, stirring with a magnetic stirrer. The electrolyte was treated for 4 h at the minimal current density. Solutions were prepared from chemically pure grade reagents. The hydrogen absorption was estimated on a U8–A spring wire (100 mm long and 1 mm in diameter) twisted on a K-5 unit. Before plating, the samples were polished with a micrometric abrasive cloth, degreased with lime, and washed with distilled water. This treatment removes the oxide surface layer and eliminates the hydrogen absorption in the course of the preparation of the sample surface.

The hydrogen absorption was performed during the electrolysis time of 12.5, 26, and 52 min and judged from the decrease in the plasticity of the twisted wire samples: $N = (a/a_0) \times 100\%$, where a and a_0 are the number of rotations before failure of the unplated and plated sample, respectively. The cathodic current efficiency (CE) was determined coulometrically.

The $40 \times 40 \times 2$ mm plates were used for studying the physicomechanical properties of the alloy. The iron–nickel alloy was coated to a 20 μm thickness. The silver chloride reference electrode was used. Polarization measurements were recorded on a multigraph. The luster γ was measured on an FB-5 luster meter vs. a uviol glass as reference (luster 65 arb. units). The nonworking side of the plate was protected with a BF-2 glue. The adhesion of the alloy to the support was tested by methods of intersecting scratches or twisting on a K-5 unit. The corrosion resistance of iron–nickel coatings was studied in a chamber filled with a salt fog [10]. The solution containing 30 g l^{-1} NaCl was spread every 15 min for 7 h. The spread time was 3 min. The corrosion protection was calculated by the formula:

$$Z = \frac{K_{corI} - K_{corII}}{K_{corI}} \times 100\%,$$

where K_{corI} and K_{corII} are the corrosion rates (g m^{-2} day^{-1}) for samples coated with the alloy with and without additives, respectively.

In the other conditions, the procedure was similar to that described previously [11].

Plating of iron–nickel alloy is accompanied by strong hydrogen absorption by the steel support, which is reflected as a 15–27% decrease in the plasticity at j_c from 1 to 9 A dm^{-2}. With the electrolysis time decreased to 52 min the further decrease in the plasticity to 65% was observed (Table 2, no inhibitor). The cathodic potential at j_c = 1 A dm^{-2} is –0.48 V, decreasing to a value of –0.72 V as the current is increased to 9 A dm^{-2} (Fig. 1, curve *9*). The deposits are finely crystalline, rough, partially cracked, with satisfactory adhesion to the support. Such deposits do not impede diffusion into the steel support. The surface is dull and semilustrous, with pitting and filament dendrites (Fig. 2, no additive, a luster of 38–20 arb. units). The current efficiency by the alloy is 71–65% (Fig. 3, curve *9*).

Introduction of triphenylmethane derivatives and azo dyes into a sulfate chloride electrolyte decreases considerably the hydrogen absorption by the steel support and enhances the performance characteristics of the iron–nickel alloy. However, the inhibiting and luster-producing action of all the additives is different (Table 2).

The inhibitors on the surface of a cathode metal are adsorbed electrostatically, specifically, and chemically [12]. The bond strength of molecules with a cathode surface is affected by the electron density on the atom

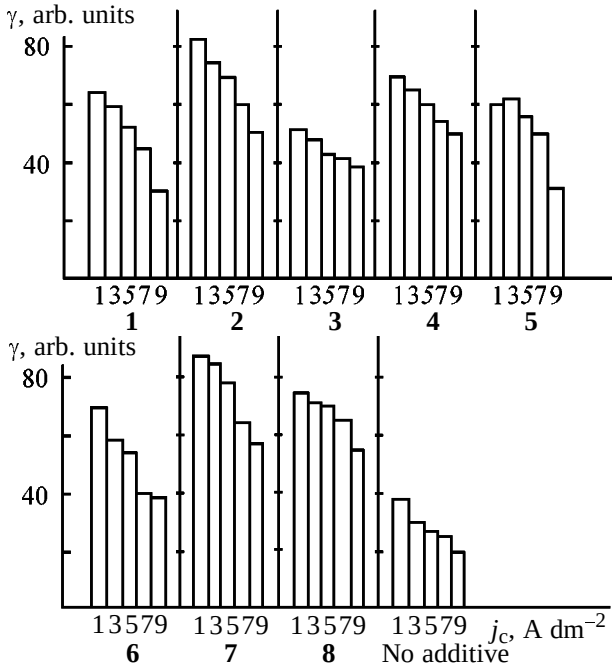

Fig. 2. Luster γ vs. j_c in the presence of additives (C = 2 mM).

acting as adsorption center. With increasing electron density the chemisorption bond between the cathode metal and the inhibitor strengthens [13].

Let us consider the suppression of hydrogen absorption (SHA) in the presence of organic additives (triphenylmethane derivatives and azo dyes) as influenced by their molecular structures.

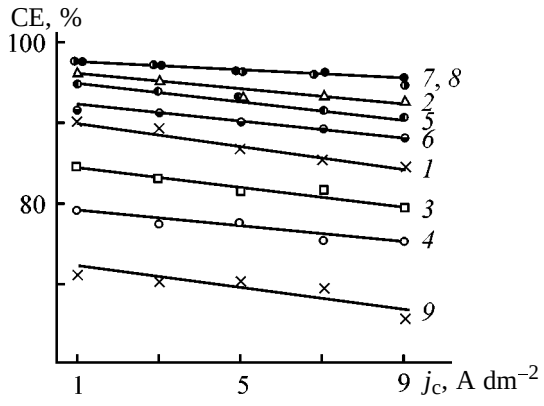

Fig. 3. Current efficiency CE vs. j_c in the presence of additives (C = 2 mM).

The additives of the first group, i.e., azo dyes (Table 1) eriochrome black (**2**), methyl red (**3**), and eriochrome blue SE (**4**) show the inhibiting and luster-producing action. The SHA efficiency of the azo dyes decreases in the following order: **2** > **3** > **4**.

For example, the plasticity of the steel samples in the presence of methyl red is the lowest (76–89% at C = 3 mM) and CE, 79–84% (Table 2, inhibitor **3**). Since the surface of the iron–nickel alloy is charged negatively, not only nitrogen of the NH_2 group but also π-conjugated ensemble of azobenzene carboxylated in *p*-position can be adsorption centers. As a result, the adsorption of this compound increases. The cathodic potential ranges from –0.60 to –0.90 V. The coatings have finely crystalline structure and gray color, are satisfactorily adherent to the support, and crack with increasing current density. The luster is 30–55 arb. units at C = 3 mM. The corrosion damages are of degree IV, and the corrosion protection is 65% (Table 3, **3**). The weak luster-producing action of the additive is due to the presence of electron-donating carboxy group –COOH, which itself actively interacts with the metal, thus competing with the conjugated system and disturbing the equilibrium electron distribution in the chain. As a result, the luster-producing power of this compound decreases [14].

Compared to methyl red, eriochrome blue SE (**4**) is the stronger inhibitor. The plasticity is 79–92% at C = 1 mM (Table 2, **4**). The adsorption of the inhibitor is provided by the N, O, and S atoms, two sulfonate groups as anionic centers, and –N=N– double bonds, possessing a fairly mobile electronic cloud capable of donating π electrons [14]. The high resistance of aromatic azo compounds arises from the conjugation of the –N=N– double bond with the π electrons of the core [15]. An electron-accepting Cl substituent, which serves as acceptor for π electrons of the core, decreases adsorption of the additive. This can explain a decrease by –0.07 to –0.24 V in the cathodic potential compared to that of the initial electrolyte (Fig. 1, curve *4*; Table 2, inhibitor **4**). The coatings are of lower quality; their adhesion to the support is satisfactory but they exfoliate from the edges at higher j_c; the coatings are semilustrous and lustrous. The corrosion damages are of degree IV. The protecting action is 72% (Table 3, additive **4**).

Among compounds of this group, eriochrome black (**2**) is the most efficient inhibitor ensuring the highest plasticity (86–96% at C = 2 mM). CE is 92–96% (Table 2, **2**). The adsorption of the given compound is provided by two electron-donating alcohol groups (–OH), nitrogen group ($–NO_2$), azo group (–N=N–), by the $–SO_3H$ sulfonate group as anionic center, and by two naphthalene cores.

Table 3. Corrosion resistance of iron–nickel alloys as 20-μm-thick coatings plated in the presence of additives (C = 2 mM and j_c = 1 A dm^{-2})

Additive no.	Degree of corrosion damage	K, g m^{-2} day^{-1}	Z, %
1	III	1.51	88
2	II	0.96	92
3	IV	4.20	65
4	IV	3.38	72
5	II	1.04	91
6	III	2.1	82
7	I	0.85	93
8	I	0.71	94
No additive	IV	5.5	55

As a result, the inhibitor is stronger bonded to the cathode surface. The cathodic potential ranges from –0.72 to –0.92 V, which agrees with the coating quality. The deposits are smooth and are characterized by finely crystalline structure, good adhesion to the support, and a luster of 50–83 arb. units. The corrosion rate is 0.96 g m^{-2} day^{-1}. The corrosion damages are of degree II, i.e., the corrosion products are in the form of dots or spots covering 10–15% of the sample surface. The corrosion protection is 92%.

The additives of the second group are triphenylmethane derivatives: bromocresol green (**1**), fuchsin new (**5**), pararosaniline (**6**), a mixture of additives **5** and **2** (**7**), and a mixture of additives **5** and Progress (**8**). The SHA efficiency of triphenylmethane derivatives decreases in the order **8** > **7** > **5** > **1** > **6**.

Introduction of fuchsin new (**5**) into an electrolyte decreases the cathodic potential to the value from –0.65 to –0.85 V. The deposits are dense, gray, and cracked from the ends with increasing j_c. The plasticity of the steel samples is 80–92% and CE, 88–92% at C = 2 mM. The inhibiting action of hydrogen absorption of this additive is due to three benzene rings and three electron-donating NH_2 groups. The luster is 39–70 arb. units and the corrosion damages are of degree III (Tables 2 and 3, additive **6**).

Bromocresol green (**1**) is a stronger inhibitor. The plasticity is 80–94% and CE, 84–90% (Table 2, **1**). The inhibiting action of this additive on hydrogen

absorption can be ascribed to the O and S reaction centers of higher electron density and to electron-donating methyl substituent (CH_3) strengthening this action. The Br electron-accepting substituent reduces the reactivity of the additive. The cathodic potential is from –0.66 to –0.81 V (Fig. 1, curve *1*). The deposits are dense, exfoliating from the support at high current densities, and semilustrous or lustrous (Table 2, **1**). The corrosion damages are of degree III, i.e., the corrosion products occupy 20–40% of the sample surface (Table 3, **1**).

The best inhibitor of hydrogen absorption is fuchsin new (**5**). In the presence of this additive the plasticity N = 90–98% and CE is equal to 93–96% (Table 2, **5**). The strong SHA of this additive is due to the presence of three amino groups NH_2 and two methyl groups CH_3 at three benzene rings [15]. The cathode potential is considerably lower (by –0.28 to –0.48 V) compared to the pure electrolyte (Fig. 1, curve *5*). The quality deposits with good adhesion to the support and semilustrous and lustrous surface were obtained. The presence of the NH_2 groups in the additive, which itself react with the metal, thus competing with the conjugated system and disturbing the equilibrium electron distribution in the chain, reduces the luster-producing power of this compound [14]. The luster was 40–75 arb. units at C = 3 mM. The corrosion damages correspond to degree II. The corrosion protection is 91% (Table 3, **5**).

To enhance the inhibiting and luster-producing power in a sulfate–chloride electrolyte, we studied two mixtures: the strongest inhibitor fuchsin new (**5**) and the most efficient luster-producing agent eriochrome black (**2**). The plasticity of the samples is rather high (85–96%) and CE is 95–98% (Table 2, **7**). The corrosion rate is 0.85 g m^{-2} day^{-1} and the corrosion protection, 93%, i.e., the surface slightly turns dark (Table 3, no. 7).

A mixture of additive **5** and Progress (**8**) is the strongest inhibitor of hydrogen absorption; N = 92–100% and CE is 94–97% (Table 2, **8**). The potential is considerably decreased and ranges from –0.81 to –1.3 V (Fig. 1, curve *8*). The luster is enhanced only slightly (55–75 arb. units). Progress is the efficient antipitting additive ensuring wetting of the cathode surface. Due to its adsorption on the surface, the phase boundary tension weakens, thus facilitating escape of hydrogen bubbles from the surface [16]. The corrosion is the lowest (0.71 g m^{-2} day^{-1}), the corrosion protection amounts to 94%, and the corrosion damage is of degree 1.

CONCLUSIONS

(1) Plating of iron–nickel alloy from a sulfate–chloride electrolyte is accompanied by strong hydrogen absorption by the steel support, which is manifested as a 15–35% drop of the plasticity at j_c = 1–9 A dm^{-2}.

(2) Triphenylmethane and azo dyes are the efficient inhibitors of hydrogen absorption. The strongest inhibiting action was exerted by fuchsin new (N = 90–95%), fuchsin new + eriochrome black (N = 85–96), and by fuchsin new + Progress (N = 92–100%). At the same time, these dyes are efficient corrosion inhibitors (Z 91, 93, and 95%).

(3) Sulfate–chloride electrolyte containing fuchsin new + Progress, fuchsin new + eriochrome black, and fuchsin new can be recommended for industrial plating of iron–nickel alloy on articles susceptible to hydrogen embrittlement. The electrolyte yields quality coatings with lustrous surface and the minimal hydrogen absorption and ensures the high current efficiency and corrosion resistance.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Release Coatings on Apparatus for Fabrication of Electrodes for Chemical Power Sources

M. Yu. Serbinovskii and G. A. Danyushina

South-Russian State Technical University, Novocherkassk, Russia

Received August 9, 2000

Abstract—The influence exerted by the composition and properties of formulations for electrodeposition on the characteristics of release coatings on rollers for rolling of ribbon-type cathodes is described. A composition based on VUPFS-35 resin and magnesium zirconate powder is recommended for use in the formulations.

The well-known problem encountered in manufacture of electrodes for chemical power cells is the high adhesion of the cathode paste to working surfaces and tools of the equipment employed. One of ways to tackle with this problem is to use release coatings of polymeric nature with mineral fillers. The requirements imposed upon coatings of this kind are as follows: chemical inertness and low adhesion to the materials being processed; good cohesion with equipment parts; high hardness, strength, and wear resistance; and, in some cases, dimension precision.

As criteria for assessing the quality of the coatings chosen in the course of the present study served the following parameters: adhesion strength of the active paste–coating system and also wear and roughness of the coating surface. The last two criteria were used in assessing the quality of coatings on roller tools, perforated disks of granulators, and extruder parts. These items are subject to the action of high pressure and abrasive wear, and, at the same time, their dimension precision directly affects the accuracy of fabrication of rolled electrodes or extruded grains. Therefore, the wear resistance and evenness of coating thickness are particularly important for these equipment parts. In this case, the most promising technique for coating deposition is electroplating. This method yields coatings of uniform thickness on articles of complex shape and makes it possible to control the coating structure, producing functional coatings with prescribed properties.

The adhesion strength was evaluated from the rupture stress of two cylindrical samples [GOST (State Standard) 209–75] between whose edges a plate made of copper(II) oxide, manganese(IV) oxide, or carbon was preliminarily squeezed. The sample compression stress was 1.25 MPa for the coal plate and 1.60 MPa for the two others. The wear resistance of coatings was tested on an end friction machine, with plates made of the same CuO, MnO_2, or C serving as counter bodies. The average sliding velocity was 0.048 m s^{-1}, and the load, 0.20 MPa for the carbon plate and 0.25 MPa for two other kinds of materials. The surface roughness was evaluated by parameter R_a (GOST 2789–73).

The service characteristics of electrodeposited organomineral coatings are determined by the formulation composition, deposition conditions, and thermal treatment of the obtained coatings. Commonly, a formulation for electrodeposition contains a water-soluble film-forming agent, neutralizer, and various additives.

A number of film-forming materials are manufactured commercially in the form of insoluble acid pastes. As bases for formulations to be used for electrodeposition of coatings were studied V-KF-093 and V-K-Ch-0207 primers, KCh-0125 varnish, Residrol VA-133, VEP-2100 and UR-1154 enamels, and VUPFS-35 and VUPFS-35A resins. The film-forming materials were converted to the water-soluble state by means of neutralizers: diethylamine, triethylamine, triethanolamine, 2-diethylaminoethanol, and ammonia.

To make the coatings harder and more wear-resistant, oxide powders were introduced into the formulations. Al_2O_3, SiO_2 (Aerosil), MgO, ZrO_2, $MgO \cdot ZrO_2$, and TiO_2, exhibiting high chemical resistance against the materials rolled, were studied. All the oxide powders were of pure grade and had particle size of less than 60 μm; Aerosil of A-175 brand was used [1]. The influence exerted by the type of additive

1070-4272/01/7405-0762$25.00

and its concentration on the properties of the formulations and coatings was analyzed.

In preliminary studies, the best results in rolling of positive electrodes and granulation of the cathode paste were obtained with coatings based on an alkyd–urethane resin VUPFS-35A [2], and, therefore, further studies described below were done with formulations based on this resin. Diethylamine is the most efficient in neutralization of the VUPFS-35A resin. The obtained results indicate that, to obtain high-quality coatings, the formulation pH should be maintained within 8.7–8.9. This can be done with diethylamine.

Studies of the effect of the resin concentration on the coating properties demonstrated that the optimal content of VUPFS-35A is 10–14 wt %. Making the resin concentration higher leads to higher electrical conductivity of the formulation, with the result that the obtained coatings are loose and porous. Lowering the concentrations leads first to a decrease in the strength of the coatings and then disrupts their continuity. The content of the VUPFS-35A resin was taken to be 10 wt %, and further studies were aimed at selecting a mineral additive and determining the optimal composition of the formulation.

To prepare formulations and electrodeposit coatings, the VUPFS-35A resin was neutralized with diethylamine to pH 8.7–8.85, and then the calculated amounts of water and necessary additives were added and the mixture was stirred for 2–3 h. The viscosity, pH, and electrical resistivity of the obtained formulations were monitored. Coatings were deposited onto articles made of carbon construction (45, 40Cr, 40CrNi) and stainless steels (30Cr13, Cr18Ni10Ti, etc.). Prior to depositing the coatings, the surface of the articles to be coated was treated by the known methods [2, 3]. The coatings were deposited on an installation comprising a controlled dc current source and a bath for electrodeposition, equipped with a stirrer. The deposition time was 2 min. The bath voltage in depositing coatings with the use of formulations with Al_2O_3, MgO, and TiO_2 additives was 100 V, and that for SiO_2, ZrO_2, and $MgO \cdot ZrO_2$ additives, 60 V. After depositing the coatings, the samples were thoroughly washed with tap and distilled water and kept at 180 ± 5°C for 40–60 min.

The stability of the electrodeposition process and the quality of the obtained coatings are strongly affected by the pH of the formulation used and its electrical conductivity. As mentioned above, the most effective agent for neutralization of the VUPFS-35A resin is diethylamine. The introduced amount of neutralizer depends on the acid number of the binder. The optimal amount of neutralizer is ca. 0.7 ± 0.1 wt %. Such a content of the neutralizing agent maintains the pH value within the range 8.7–8.9, which favors fabrication of high-quality coatings. The introduction of oxide additives alters the acidity and may impair the coating quality, leading to appearance of beads, craters, and porosity. For this reason the pH of the formulation was adjusted in the appropriate way. Figure 1a shows the dependence of the pH value on the content of additives. Raising the concentration of the chosen additives leads to significant changes in pH only in the case of a formulation with SiO_2. For this composition the pH decreases to below the admissible level, which leads to deposition of poor-quality coatings, and, therefore, an additional, compared with other formulations, pH adjustment is necessary in this case.

The electrical conductivity of a formulation exerts strong influence on the stability of the electrodeposition process and the coating quality. Introduction of Al_2O_3, MgO, TiO_2, and ZrO_2 into formulations does not change their electrical conductivity noticeably (see Fig. 1b). The increase in electrical conductivity on making the content of $MgO \cdot ZrO_2$ or SiO_2 higher than 5 wt % impairs the quality and service characteristics of the obtained coatings. For coatings with $MgO \cdot ZrO_2$, a practically appreciable quality deterioration is observed at additive content exceeding 6.5 wt %. The electrical conductivity of a formulation with $MgO \cdot ZrO_2$ is presumably higher because of the greater charge of colloid particles. Magnesium zirconate does not virtually dissociate in the formulation, and, therefore, the pH value changes only slightly on increasing its content.

With Aerosil, the outward appearance and service characteristics of the coatings are markedly deteriorated already at an SiO_2 content of 5.0–5.5 wt %. This concentration corresponds to an electrical conductivity as high as 120×10^{-3} S m^{-1}, which is the upper limit for obtaining high-quality coatings. The rise in electrical conductivity in formulations with Aerosil is probably due to the high activity of this oxide, which can, under certain conditions, partly dissolve to form H_2SiO_3 and H_4SiO_4 whose dissociation is responsible for the increase in electrical conductivity. The decrease in pH for the formulation with SiO_2 confirms the probability of acid formation (Fig. 1a). The abrupt change in electrical conductivity, observed in this case, and the corresponding deterioration of the coating quality restrict or completely rule out use of SiO_2 in formulations with VUPFS-35A.

Figure 1c shows how the concentration of additives

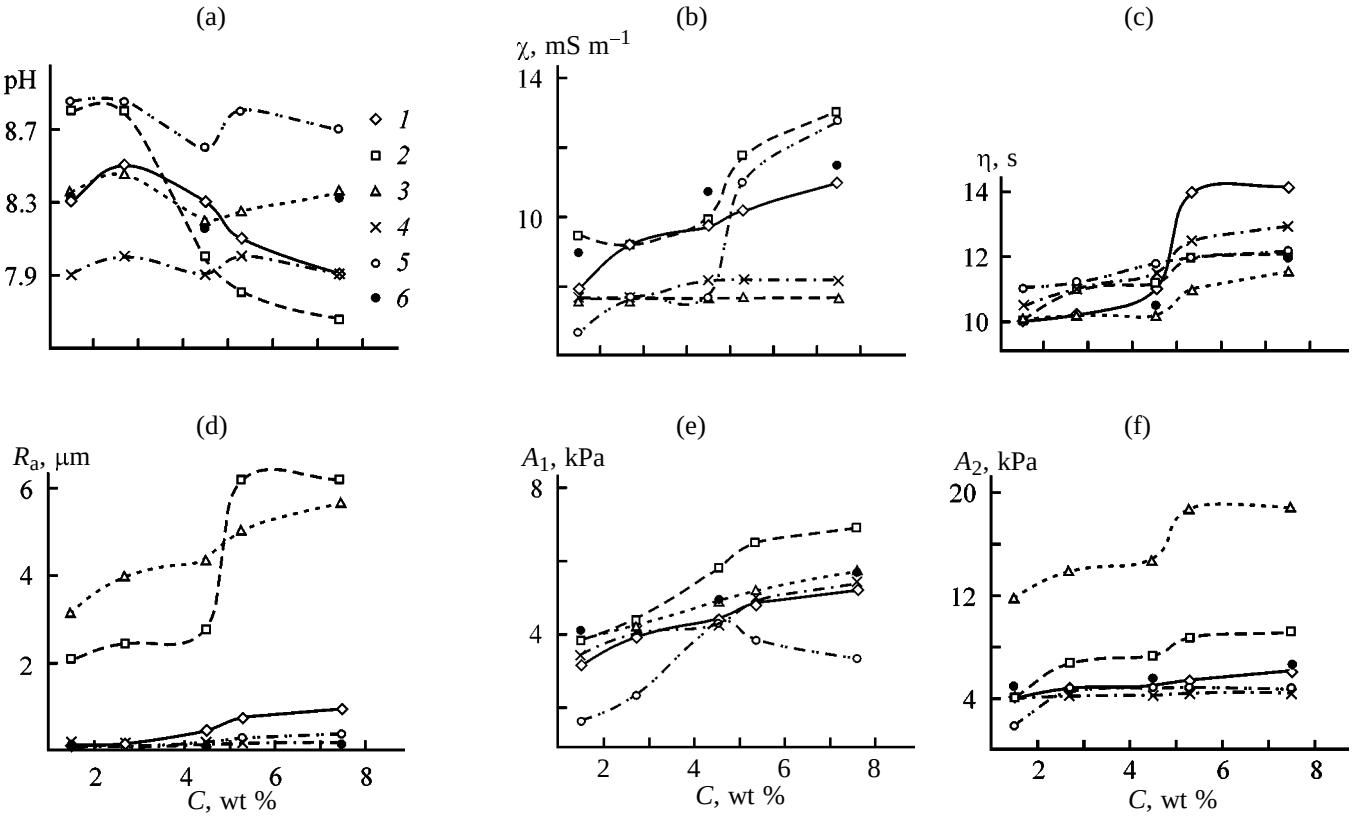

Fig. 1. Effect of additive content C on (a) pH, (b) electrical conductivity χ, (c) viscosity η measured as outflow time from a VZ-4 viscometer, (d) coating surface roughness R_a, and also adhesion of a plate based on (e) PME-100V carbon black, A_1, and (f) MnO_2, A_2, to coatings deposited using VUPFS-35A. Additive: (*1*) Al_2O_3, (*2*) SiO_2, (*3*) MgO, (*4*) ZrO_2, (*5*) $MgO \cdot ZrO_2$, and (*6*) TiO_2.

affects the formulation viscosity, which grows with increasing content of oxides in the suspension. The substantial rise in the viscosity of the formulation with Al_2O_3 in the oxide content range 4–6 wt % is presumably due to formation of larger colloid particles lowering the formulation fluidity. Higher coating quality corresponds to VZ-4 viscosity equal to 10–12.5 s. With increasing viscosity, the adhesion of the cathode paste to the coatings grows. Figure 1d demonstrates the effect of additive content on the surface roughness of the coatings, and Figs. 1e and 1f, the influence exerted by the content of additives on the adhesion of plates based on PME-100V carbon black and MnO_2 to the coatings. The results obtained in testing the wear resistance of the coatings are presented in the table.

The main criteria for suitability of the coatings under study for rolling of plates based on carbon black (technical-grade carbon), manganese dioxide, and copper(II) oxide are the adhesion strength of the system cathode plate–coating and coating wear. However, the surface roughness also affects the characteristics of coatings. For example, the high surface roughness of coatings based on VUPFS-35A resin

Wear of coatings based on VUPFS-35A with oxide additives (5 wt %)

Plate	Wear, μm h^{-1}, of coatings with indicated additives					
	Al_2O_3	SiO_2	MgO	ZrO_2	$MgO \cdot ZrO_2$	TiO_2
PME-100V	0.05	0.03	0.04	0.88	0.04	0.03
MnO_2	0.12	0.06	0.09	1.92	0.09	0.07
CuO	0.10	0.05	0.07	1.61	0.07	0.06

with SiO_2 or MgO additives leads to higher adhesion of the coatings to the active paste of the plate, and, therefore, such coatings are not release coatings for the materials tested. The best combination of processing and service characteristics are observed for coatings based on VUPFS-35A with addition of $MgO \cdot ZrO_2$.

CONCLUSIONS

(1) It is recommended that electrodeposition should be performed using a formulation of the following composition (wt %): VUPFS-35A resin 10, diethylamine 0.7, $MgO \cdot ZrO_2$ 4.5–6.5, surfactant 0.10–0.30, and water the rest.

(2) The optimal properties of the formulation to be used: pH 8.70–8.85, viscosity measured by VZ-4 (GOST 8420–74) 11.0–12.2 s, and electrical conductivity $(66–120) \times 10^{-3}$ S m^{-1}.

(3) The following parameters are recommended for deposition: voltage 60 V, time 2 min, and thermal treatment temperature 180 ± 5°C and time 40–60 min.

(4) The coatings of this kind can be recommended for deposition onto rolls of installations for rolling of carbon, copper oxide, and manganese dioxide electrodes.[1]

CATALYSIS

Catalytic Decomposition of Cumyl Hydroperoxide under the Action of Aspartic Acid Derivatives

B. V. Pekarevskii, V. A. Ivanov, and V. M. Potekhin

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received June 5, 1997; in final form, 2000

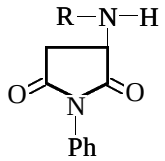
Abstract—The inhibiting activity of aspartic acid derivatives in the stage of degenerate chain branching in decomposition of cumyl hydroperoxide was studied. The kinetic and thermodynamic parameters of the reaction were established.

Petroleum products can be oxidized with atmospheric oxygen during storage and recovery with deterioration of their service characteristics. To stabilize organic materials, antioxidant additives are used. The mechanism of the inhibiting effect of the vast majority of additives (among them Ionol) involves termination of oxidation chains by the reaction with peroxide radicals. However, it is well known [1] that at low extents of oxidation of hydrocarbons hydroperoxides are accumulated in the substrate. These hydroperoxides are capable of spontaneous decomposition with formation of free radicals, which results in additional initiation of oxidation chains (stage of degenerate branching).

At present it is well known that heteroatomic nitrogen-, sulfur-, and phosphorus-containing compounds (esters of xanthic, dithiocarbamic, and dithiophosphoric acids) catalytically decompose hydroperoxides by the molecular mechanism [2], showing no inhibiting activity in the stage of chain propagation reactions, and have a low thermal stability, which restricts their fields of application.

At the same time, sterically hindered phenols used as commercial antioxidants are practically incapable of inhibiting the oxidation in the stage of degenerate chain branching as a result of their partial or complete deactivation with radicals formed by decomposition of the hydroperoxide. In this connection the search for polyfunctional inhibitors capable of termination of the oxidation chains by the reaction with peroxide radicals and decomposition of hydroperoxides with formation of molecular products is an urgent problem.

Previous studies [3] show that derivatives of aspartic acid of the general formula



where R = C_6H_4OH-*o* (HIn_1), $C_6H_4CH_3$-*o* (HIn_2), and C_6H_5 (HIn_3), are highly efficient scavengers of peroxide radicals. Published data on possible participation of hydroxyls and amino groups [4] suggest that these compounds will participate in the stage of degenerate chain branching. In this connection we studied the effect of *N*-phenylarylaminosuccinimides on decomposition of cumyl hydroperoxide.

The kinetics of decomposition of cumyl hydroperoxide (CHP) in the presence of aspartic acid derivatives were studied at 80–110°C in an inert medium at concentrations of acceptors varying in the range 10^{-4}–10^{-3} M. Under experimental conditions the rate of thermal decomposition of CHP is negligible (10^{-7}–10^{-8} mol l^{-1} s^{-1}) [5]. As seen from Fig. 1, the rate of CHP decomposition in the presence of aspartic acid derivatives considerably increases even at moderate temperatures.

Taking into account the difference in concentrations of reactants ([ROOH]/[HIn] > 1000), we can confirm that CHP catalytically decomposes under the action of the test compounds at a high capacity of the inhibitor with respect to hydroperoxide

$$\nu = \frac{[ROOH]_0 - [ROOH]_{res}}{[HIn]_0}, \quad (1)$$

where $[ROOH]_0$ and $[ROOH]_{res}$ are the initial and residual concentrations of hydroperoxide (M), respec-

1070-4272/01/7405-0766$25.00

tively, $[HIn]_0$ is the initial concentration of the inhibitor (M), and ν is the efficiency of the inhibitor with respect to hydroperoxide.

The kinetic curves of CHP decomposition in the presence of HIn_1–HIn_3 have the shape typical for deactivation of the acceptor with hydroperoxide at a high degree of conversion. When $[ROOH]_0 \gg [HIn]_0$, the process can be described by the equation [6]

$$\frac{d[ROOH]}{dt} = k_{cat}([ROOH] - [ROOH]_0) + k_{ir}([ROOH] - [ROOH]_0), \quad (2)$$

where k_{cat} and k_{ir} are the overall rate constants of the catalytic and irreversible stages (s^{-1}).

Integration of Eq. (2) from $[ROOH]_0$ to $[ROOH]_{res}$ gives the relation

$$[ROOH] = ([ROOH]_0 - [ROOH]_{res})\exp[-(k_{cat} + k_{ir})t] + [ROOH]_{res}. \quad (3)$$

Indeed, in the semilogarithmic coordinates the kinetic curves for CHP decomposition in the presence of aspartic acid derivatives are linear, which suggests the first order of the reaction with respect to hydroperoxide (Fig. 1). It was established that the dependence of the rate of CHP decomposition on the acceptor concentration is linear as well (Fig. 2). This suggests that the reaction is first-order with respect to acceptor, and one HIn molecule participates in the event of hydroperoxide decomposition. The rate of CHP decomposition is affected by both the acceptor concentration and the initial concentration of the starting hydroperoxide. When [ROOH] > 0.15 M, the dependence of the decomposition rate on the initial concentration of the hydroperoxide is linear (Fig. 3), which confirms the first order of CHP decomposition with respect to ROOH. In the second portion of the curve, the rate of CHP decomposition is practically independent of the hydroperoxide concentration, and the reaction order approaches zero. This "limiting" dependence of the rate of CHP decomposition on its initial concentration can be the evidence for formation of the acceptor–hydroperoxide complex. In view of these results, the scheme of CHP decomposition in the presence of HIn_1–HIn_3 can be represented as follows:

$$n\text{ROOH} + \text{HIn} \underset{}{\overset{K_m}{\rightleftarrows}} n\text{ROOH}\cdot\text{HIn},$$

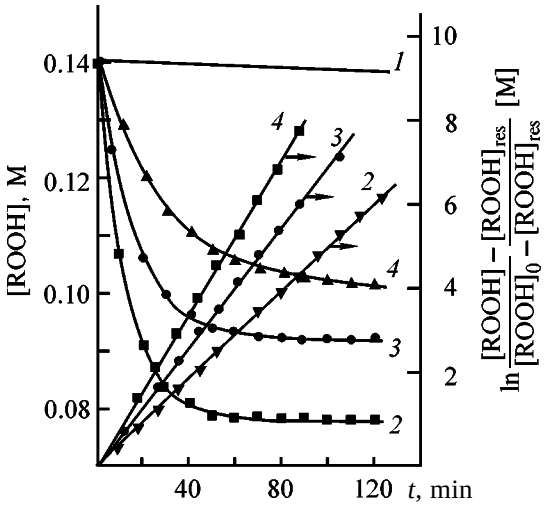


Fig. 1. Kinetic curves of CHP decomposition in the presence of aspartic acid derivatives and their semilogarithmic plots. Temperature 90°C, solvent 1,2-dichlorobenzene, $[HIn]_0 = 5 \times 10^{-4}$ M; the same for Figs. 3 and 4. ([ROOH]) Concentration of hydroperoxide and (*t*) time. Inhibitor: (*1*) none, (*2*) HIn_1, (*3*) HIn_2, and (*4*) HIn_3.

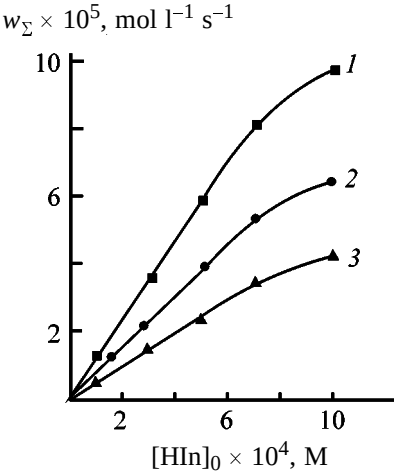

Fig. 2. Initial rate of CHP decomposition w_Σ as a function of the acceptor concentration $[HIn]_0$. $[ROOH]_0$ = 0.14 M, temperature 90°C, solvent 1,2-dichlorobenzene. (*1*) HIn_1, (*2*) HIn_2, and (*3*) HIn_2; the same for Figs. 3 and 4.

$$n\text{ROOH}\cdot\text{HIn} \xrightarrow{k_\Sigma} \begin{cases} \xrightarrow{k_r} \text{Radical products}, \\ \xrightarrow{k_m} \text{Molecular products}, \end{cases}$$

$$n\text{ROOH} + \text{HIn} \xrightarrow{k_{ir}} \text{Reaction products}.$$

Provided that $[ROOH]_0 \gg [HIn]_0$, $n = 1$, and the reaction scheme is adequately described by the

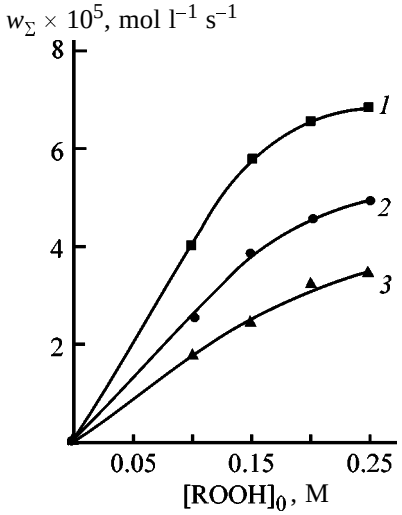

Fig. 3. Initial rate of CHP decomposition w_Σ as a function of the hydroperoxide concentration $[ROOH]_0$.

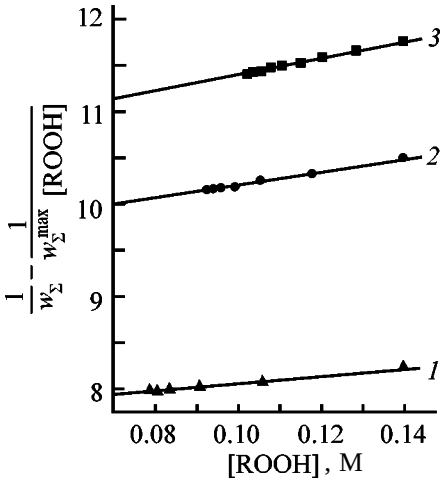

Fig. 4. Dependence of the parameter $(w_\Sigma)^{-1} - (w_\Sigma^{max}[ROOH])^{-1}$ on CHP concentration [ROOH].

Michaelis–Menten equation [7]

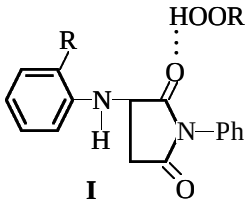
$$w_\Sigma = \frac{k_\Sigma K_m [HIn]_0 [ROOH]}{1 + K_m [ROOH](1 + k_{ir}^{-1}[ROOH])}, \qquad (4)$$

where K_m is the constant of complex formation (l mol^{-1}), k_Σ is the rate constant of hydroperoxide decomposition in the complex (s^{-1}), and k_{ir} is the rate constant of oxidation with hydroperoxide (s^{-1}).

Graphical solution of Eq. (4) (Fig. 4) gave the k_Σ, k_{ir}, and K_m values.

The values of the kinetic and thermodynamic parameters of CHP decomposition in the presence of HIn_1–HIn_3 are listed in Table 1.

With increasing probability of formation of the intermediate HIn·ROOH, the rate of hydroperoxide decomposition increases. The calculated thermodynamic parameters of complex formation (Table 1) suggest energetically favorable formation of the complex HIn·ROOH.

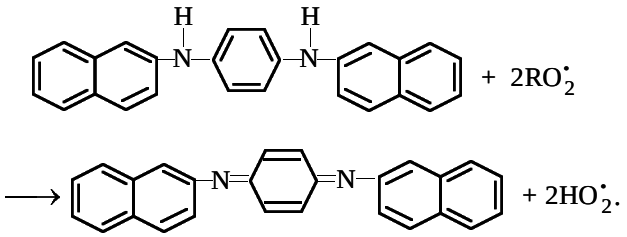


I

In view of published data on the reactivity of aminophenols [8, 9], formation of complex **I** with a hydrogen bond is the most preferable.

The effect of the substituent in the *ortho* position to the nitrogen atom of the amino group is one of the factors governing the kinetic parameters of CHP decomposition in the presence of the compounds in hand. For example, as the electron-donor power increases in passing from HIn_2 to HIn_3, the rate constant of hydroperoxide decomposition grows owing to decreasing activation energy of the process. However, it should be noted that this effect is insignificant.

It is well known that the effect of inhibitor in the stage of degenerate chain branching in the total oxidation process is mainly governed by the pathway by which the hydroperoxide decomposes (molecular or radical). An increase in the inhibition activity of antioxidants is caused by the increase in the fraction of hydroperoxide decomposition catalyzed by these antioxidants with formation of active radicals. To determine the relative contribution of radical decomposition of the hydroperoxide with addition of aspartic acid derivatives, we studied decomposition of CHP under the action of inhibitors in the presence of radical scavenger *N*,*N*'-di-β-naphthyl-*p*-phenylenediamine (DPA), which reacts with free radicals to give colored quinone diimine (QDI) [10]



The rate of DPA consumption was measured from the rate of accumulation of QDI whose concentration was determined spectrophotometrically from absorption in the visible range (λ = 480 nm).

Since aspartic acid derivatives are polyfunctional

HIn_2	0.11 ± 0.01	81.2 ± 0.6	4.3 ± 0.2	8.2 ± 0.1	20.4 ± 0.5
HIn_3	0.08 ± 0.01	86.1 ± 0.6	2.8 ± 0.2	6.0 ± 0.1	21.3 ± 0.5

* k_{in}, w_r, and E_r are the rate constant of initiation and the rate and activation energy of radical decomposition of the intermediate HIn·ROOH, respectively; w_Σ is the total rate of decomposition of the intermediate HIn·ROOH; α is the relative contribution of radical decomposition of the hydroperoxide in the complex.

inhibitors, they can react with radicals formed in decomposition of hydroperoxide after passing of these radicals from the solvent cage to the solvent bulk. However, this reaction is unlikely under the experimental conditions since free radicals react primarily with dissolved DPA, which is a more efficient radical scavenger than HIn. It was found that the rate of CHP decomposition under the action of DPA is 1.2×10^{-6} mol l^{-1} s^{-1} at 90°C, which is substantially lower than the rate of catalytic decomposition of CHP under the action of aspartic acid derivatives. Hence, the effect of DPA on decomposition of hydroperoxide can be neglected. The relative contribution of radical decomposition of CHP is determined as

$$\alpha = w_r/w_\Sigma, \quad (5)$$

The kinetic and energy characteristics of radical decomposition of CHP are listed in Table 2. These data show that aspartic acid derivatives inhibit oxidation of hydrocarbons in the stage of degenerate chain branching, directing hydroperoxide decomposition for the most part to the molecular pathway as compared to thermal decomposition ($\alpha_{therm} \sim 80\%$). In this case, the relative contribution of radical decomposition of CHP in the presence of HIn_1–HIn_3 is practically independent of the nature of the substituent in the *ortho* position to the nitrogen atom of the amino group.

EXPERIMENTAL

Decomposition of CHP was carried out in 1,2-dichlorobenzene in a glass reactor of bubbling type at 85–110°C in high-purity argon. To remove dissolved oxygen, argon was bubbled through the reaction mixture for 30 min before experiments. The temperature was maintained with an accuracy of 0.1°C. The total volume of the samples withdrawn during an experiment did not exceed 10–15% of the volume of the reaction mixture. The discrepancy between the results of parallel runs did not exceed 4–6%. The hydroperoxide content in a sample was determined by iodometric titration in concentrated acetic acid [11]. The discrepancy between the results of parallel runs did not exceed 3%.

The relative contribution of radical decomposition of CHP was determined by the inhibitor technique with the use of spectroscopy. The electronic absorption spectra were recorded on an SF-56 spectrophotometer. The optical density of the samples of the reaction mixture withdrawn from the reactor at certain

intervals was measured at a wavelength of 480 nm at 20°C.

CONCLUSIONS

(1) Aspartic acid derivatives exhibit inhibition activity in the stage of degenerate chain branching caused by their ability for catalytic decomposition of hydroperoxide by the molecular mechanism (relative contribution of molecular decomposition 80–85%). For the compounds studied, the capacity of the antioxidant with respect to hydroperoxide is 58–150, and the overall decomposition constants are in the range 1.8–2.8 s^{-1}.

(2) Based on kinetic and thermodynamic characteristics of decomposition of cumyl hydroperoxide under the action of aspartic acid derivatives, it was proposed that catalytic decomposition of hydroperoxide proceeds with formation of a complex with a hydrogen bond HIn·ROOH.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

A Model of Joint Absorption of Hydrogen Sulfide and Carbon Dioxide in a Moving Drop of Alkaline Solution

S. V. Aniskin, O. I. Protod'yakonova, and S. V. Marasev

St. Petersburg State Technological University of Plant Polymers, St. Petersburg, Russia

Received March 1, 2001

Abstract—A mathematical model of hydrogen sulfide and carbon dioxide absorption by a moving drop of alkaline solution is proposed on the basis of a theoretical analysis of the process. The results obtained in solving numerically the equations of the model are presented and analyzed.

The cost efficiency of jet scrubbers in absorption purification of fume gases formed in recovery units of pulp and paper industry to remove hydrogen sulfide depends on how the problem of reducing the consumption of the alkaline solution absorbing hydrogen sulfide is solved.

As known, the fume gases of recovery units contain, in addition to hydrogen sulfide, also carbon dioxide in amounts much exceeding the content of the former. If the absorption purification of fume gases to remove hydrogen sulfide is performed at comparable rates of hydrogen sulfide and carbon dioxide absorption, this entails an unjustified increase in the absorbent consumption. This poses the problem of reducing the intensity of carbon dioxide absorption, compared with that of hydrogen sulfide. Solving this problem requires a theoretical analysis of the joint absorption of hydrogen sulfide and carbon dioxide in a moving drop of an alkaline solution, which is one of the main components of the gas–fluid jet formed in the absorption apparatus under consideration.

Constructing a model of this process at the level of inclusion of a disperse phase (developing a model of the elementary transfer event) is the aim of the present study. The model is defined under the following assumptions. The drop is spherical. There is no fluid flow inside the drop. The drop moves at a constant velocity. A diffusion boundary layer is formed in the gas phase near the drop surface. Outside this boundary layer, i.e., in the gas flow core, the concentrations of hydrogen sulfide and carbon dioxide are taken to be constant. It is assumed that the main resistance to mass transfer in carbon dioxide absorption by a drop of an alkaline solution rests in the fluid phase. Then the carbon dioxide concentration at the drop surface can be taken to differ only slightly from that in the gas flow core.

The diffusion coefficients of all the chemical components involved in the process in question are the same and constant in time. It is assumed that the heat effect of absorption is negligible, and the temperature of the physical system, constant. The reaction of hydrogen sulfide with the alkaline solution is considered to be instantaneous, which allows use of the Olender condition [1] assuming the existence of a local equilibrium at any point of the drop volume for hydrogen sulfide and products of reaction with OH^- ions. This assumption makes it possible to use in the model equilibrium equations relating the concentrations of chemical components in reactions involving hydrogen sulfide and sodium hydrosulfide.

The reactions of carbon dioxide, involving interactions with water and OH^- ions, are not instantaneous. For the reaction

$$CO_2 + H_2O \rightleftarrows H^+ + HCO_3^- \qquad (1)$$

the expression for the rate constant k_1 has the form [1]

$$\log k_1 = 329.8 - 110.541 \log T - 17\,265.4/T, \qquad (2)$$

where T is temperature (K), and k_1 is the rate constant of the pseudo-first-order reaction (s^{-1}).

In alkaline medium, H^+ ions are neutralized as a result of the following instantaneous chemical reaction:

$$H^+ + OH^- \rightleftarrows H_2O. \qquad (3)$$

The result of two successive reactions (1) and (3)

1070-4272/01/7405-0771$25.00

can be written in the form

$$CO_2 + OH^- \rightleftarrows HCO_3^-. \quad (4)$$

The rate of reaction (4) is governed by the rate of its slower first stage.

Carbon dioxide can also react directly with OH^- ions. This reaction is written in the same way as reaction (4). The reaction is not instantaneous, its rate constant k_2 is expressed as

$$\log k_2 = 13.835 - 2895/T, \quad (5)$$

where k_2 is the rate constant of a second-order reaction ($m^3\ kmol^{-1}\ s^{-1}$).

The overall rate q of the chemical reaction of carbon dioxide with the alkaline solution ($kmol\ m^{-3}\ s^{-1}$) can be expressed in terms of the rate constants k_1 and k_2 as follows:

$$q = k_1[CO_2] + k_2[OH^-][CO_2]. \quad (6)$$

The nature of the dependence of k_1 and k_2 on the ionic strength of the solution was reported in [1].

All other reactions occurring in the alkaline solution in absorption of hydrogen sulfide and carbon dioxide are considered instantaneous. To these belong

$$HCO_3^- + OH^- \rightleftarrows CO_3^{2-} + H_2O, \quad (7)$$

$$H_2S + OH^- \rightleftarrows HS^- + H_2O, \quad (8)$$

$$HS^- + OH^- \rightleftarrows S^{2-} + H_2O. \quad (9)$$

The absorption of hydrogen sulfide by a drop of the alkaline solution can be described using diffusion equations written for each chemical component involved in the process. With account of the assumptions made, these equations are written as follows:

$$\frac{\partial c_1}{\partial t} = D\nabla^2 c_1 - q_1 - q_2, \quad (10)$$

$$\frac{\partial c_2}{\partial t} = D\nabla^2 c_2 + q_1 + q_2 - q_3, \quad (11)$$

$$\frac{\partial c_3}{\partial t} = D\nabla^2 c_3 + q_3, \quad (12)$$

$$\frac{\partial c_4}{\partial t} = D\nabla^2 c_4 - q_1 - q_2 - q_3 - q_4 - q_5, \quad (13)$$

$$\frac{\partial c_5}{\partial t} = D\nabla^2 c_5 - q_4, \quad (14)$$

$$\frac{\partial c_6}{\partial t} = D\nabla^2 c_6 + q_4 - q_5, \quad (15)$$

$$\frac{\partial c_7}{\partial t} = D\nabla^2 c_7 + q_5, \quad (16)$$

where $\nabla^2 = \frac{1}{r^2}\frac{\partial}{\partial r}(r^2\partial/\partial r)$ is a Laplacian; r is the current drop radius; D is the diffusion coefficient of reagents in the fluid phase; c_1, c_2, ..., c_7 are the concentrations of, respectively, CO_2, HCO_3^-, CO_3^{2-}, OH^-, H_2S, HS^-, and S^{2-}; q_1, q_2, ..., q_5 are the rates of chemical reactions (1), (3), (7), (8), and (9).

In order to simplify the written system of equations, let us introduce the following designations:

$$c_1 + c_2 + c_3 = x, \quad (17)$$

$$c_2 + 2c_3 + c_4 + c_6 + 2c_7 = y, \quad (18)$$

$$c_5 + c_6 + c_7 = z. \quad (19)$$

With account of expressions (17)–(19), Eqs. (10)–(16) take the form

$$\frac{\partial x}{\partial t} = D\nabla^2 x, \quad (20)$$

$$\frac{\partial y}{\partial t} = D\nabla^2 y, \quad (21)$$

$$\frac{\partial z}{\partial t} = D\nabla^2 z, \quad (22)$$

The system of Eqs. (17)–(22) contains ten unknowns c_1–c_7, x, y, and z and is nonclosed. It should be supplemented with four closing relations. As three relations of this kind can be used, in accordance with the Olender conditions, equilibrium equations for those chemical components reactions between which are considered to be instantaneous. These relations have the form

$$c_6 = K_1 c_5 c_4, \quad (23)$$

$$c_7 = K_2 c_6 c_4, \quad (24)$$

$$c_3 = K_3 c_2 c_4, \quad (25)$$

where K_1–K_3 are the equilibrium constants (kmol m^{-3}).

The formulas for calculating the equilibrium constants were reported, e.g., in [2]. The fourth closing relation can be derived from Eq. (10) by expanding the terms q_1 and q_2 in accordance with (6). Let us write this relation in the form

$$\frac{\partial c_1}{\partial t} = D\nabla^2 c_1 - k_1 c_1 - k_2 c_1 c_4, \quad (26)$$

The thus obtained system of equations (17)–(26) is closed. The initial conditions for this system can be written as

at $t = 0$ $c_i = c_{0i}$, $i = 1, 2, ..., 7$,

$$x = x_0, \ y = y_0, \ z = z_0. \quad (27)$$

By virtue of the central symmetry of the spherical drop, the following natural boundary conditions can be written

$$\text{at } r = 0 \quad \frac{\partial x}{\partial r} = \frac{\partial y}{\partial r} = \frac{\partial z}{\partial r} = \frac{\partial c_1}{\partial r} = 0. \quad (28)$$

The boundary condition for the variable y has the form

$$\text{at } r = R \quad \partial y/\partial r = 0, \quad (29)$$

where R is the drop radius.

This boundary condition expresses the known fact of zero ion transfer across the phase boundary.

For the variable z, representing the total content of sulfur at each point of the drop, a boundary condition of third kind can be written

$$\text{at } r = R \quad \partial z/\partial R = \beta(A - \mathrm{He}_5 c_5)/D, \quad (30)$$

where β is the mass-transfer coefficient in the gas phase (m s^{-1}), A is the hydrogen sulfide concentration in the gas flow core (kmol m^{-3}), and He_5 is Henry's constant for hydrogen sulfide.

This boundary condition expresses the equality of the hydrogen sulfide flow rate in the gas medium and the flux of the quantity z (the so-called total sulfur) in the fluid medium at the phase boundary.

The flow of hydrogen sulfide transferred in the gas phase toward the drop surface depends on the mass transfer coefficient β which is a function of parameters determining the conditions of gas flow around the drop. The coefficient β can be found using the known Fressling formula [1]:

$$\beta = D(2 + 0.5\mathrm{Re}^{0.33}\mathrm{Sc}^{0.5})/2R, \quad (31)$$

where Re is the Reynolds number and Sc is the Schmidt number.

As known, the main resistance to the transport of carbon dioxide is exerted by the fluid phase, and, consequently, its concentration at the phase boundary can be considered to be equal to the concentration of this component in the gas flow core with sufficient precision. Then the following boundary condition of first kind can be written for Eq. (26):

$$\text{at } r = R, \quad c_1 = c_{R_1}. \quad (32)$$

The c_{R_1} value can be found from the carbon dioxide concentration B in the gas flow core (kmol m^{-2}), using the relation

$$c_{R_1} = B/\mathrm{He}_1, \quad (33)$$

where He_1 is Henry's constant for carbon dioxide. A condition of the third kind for the variable x can be written as follows:

$$\text{at } r = R, \quad \frac{\partial x}{\partial r} = \frac{\partial c_1}{\partial r} = 0. \quad (34)$$

Equation (21) with boundary conditions (28), (29) and initial conditions (27) has a trivial solution

$$y = y_0. \quad (35)$$

Thus, the constructed mathematical model, describing nonstationary diffusion in joint absorption of hydrogen sulfide and carbon dioxide by a moving drop of alkaline solution, includes three parabolic differential equations (20), (22), and (26), involving second-order partial derivatives, with initial and boundary conditions (27), (28), (30), (32), and (34) and seven algebraic equations (17)–(19), (23)–(25), and (35). This system can only be solved numerically. For this purpose, a calculational scheme was developed, having the following specific features. The scheme is marching with respect to time.

An iteration process is performed within each time slice. A finite-difference model is constructed on a four-point T-shaped gage. A grid nonuniform along the spatial coordinate r and uniform in time t was

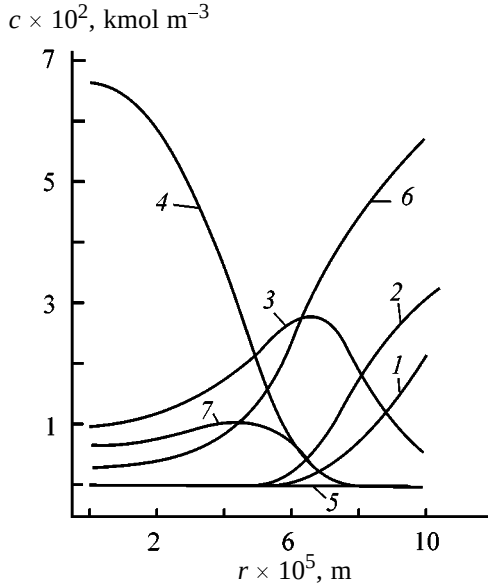

Fig. 1. Distribution of the concentrations c of chemical components involved in hydrogen sulfide and carbon dioxide absorption along the drop radius r. $R = 10^{-4}$ m, $t = 0.8$ s, $E = 520$, $A = 5\times10^{-5}$ kmol m^{-3}, $c_3 = 0$, $c_4 = 0.1$ kmol m^{-3}. c: (*1*) c_1, (*2*) c_2, (*3*) c_3, (*4*) c_4, (*5*) c_5, (*6*) c_6, and (*7*) c_7.

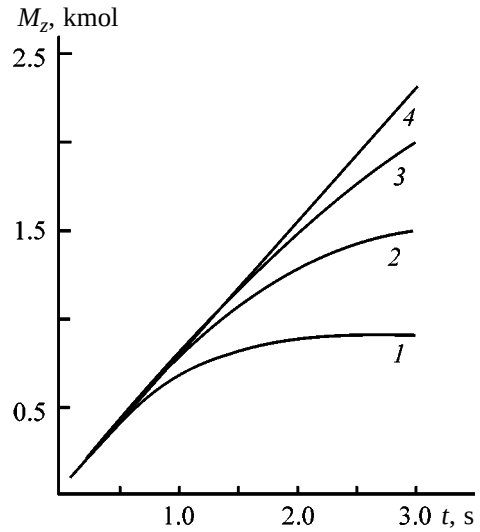

Fig. 2. Amount of hydrogen sulfide, M_z, absorbed by a drop of alkaline solution vs. absorption time t at varied initial concentration of sodium hydroxide in the drop, c_{04}. $R = 10^{-4}$ m, $A = 6\times10^{-6}$ kmol m^{-3}, $c_{03} = 0$, $c_{R_1} = 3\times10^{-3}$ kmol m^{-3}. c_{04} (kmol m^{-3}): (*1*) 5×10^{-2}, (*2*) 0.1, (*3*) 0.2, and (*4*) 0.5.

used. The differential equations were approximated with respect to the parameters x, z, and c_1, using implicit schemes with approximation of first order with respect to time and second order with respect to spatial coordinate. The finite-difference analogs of differential equations are transformed into three-point relations, which, taken together with the initial and boundary conditions also written in the finite-difference form, are solved by the sweep method.

The calculation of the algebraic part of the system consists in solving a fourth-order equation in c_4 and then finding the unknowns c_2, c_3, and c_5–c_7 with the use of the already calculated values of x, z, c_1, and c_4.

To ensure the uniqueness of solution, it is necessary to single out the only positive root of the fourth-order equation in c_4. In finding the numerical solution, the temporal, Δt, and spatial, Δr, steps of the grid are chosen in such a way that, with their values decreasing further, the dependence of the sought-for numerical solution on the grid steps becomes inessential. Thus, the convergence of the scheme chosen for solving the problem in question is established.

Figures 1–4 show the results obtained in solving the equations of the model under the following common initial conditions: $c_{01} = c_{02} = c_{05} = c_{06} = c_{07} = 0$ and constant $D = 10^{-9}$ m s^{-1}, $\beta = 0.1$ m s^{-1}, $He_5 = 0.283$, $He_1 = 1.33$, and $T = 293$ K appearing in the equations of the model as coefficients. The calculations were done at ionic strength $I = 1$ kmol m^{-3}. The values of the other parameters used to obtain the results presented in Figs. 1–4 are given in the figure captions.

Figure 1 shows the curves describing the distribution along the drop radius of the concentrations of the chemical components involved in the absorption of hydrogen sulfide and carbon dioxide. The curves indicate a complex nature of the diffusion processes occurring in the drop of the alkaline solution. The curves were obtained under the condition that $E = 520$, where

$$E = B/A, \tag{36}$$

i.e., under condition that the concentration of carbon dioxide exceeds manyfold that of hydrogen sulfide. It can be seen from Fig. 1 that the sum of the areas under curve nos. *1–3* is approximately equal to that under curve nos. *5–7*. Consequently, the amounts of the absorbed components (hydrogen sulfide and carbon dioxide) can be considered equal. Their concentrations being strongly different, it is apparent that the intensity of hydrogen sulfide absorption much exceeds that for carbon dioxide. Thus, the model is in agreement with the known data [3], which qualitatively confirms its validity.

Figure 2 shows how the amount of hydrogen sul-

fide, M_z (kmol), absorbed by a drop of alkaline solution in the presence of carbon dioxide depends on time. This quantity is given by

$$M_z = 4\pi\int_0^R r^2 z\,dr. \qquad (37)$$

It should be noted that the obtained kinetic curves of absorption of the above two components are similar to the curves characterizing the absorption kinetics of a single component, hydrogen sulfide, by alkaline solution. The initial linear portions of all of the presented kinetic curves correspond to that stage of absorption in which the main resistance to mass transfer is exerted by the gas phase. The rate of this stage is determined by the mass-transfer coefficient β. With the amount of sodium hydroxide in a drop decreasing through absorption of hydrogen sulfide and carbon

dioxide, the resistance to transfer of these components in the fluid phase grows. Correspondingly decreases the absorption rate, which reflects on the shape of the calculated kinetic curves in Fig. 2.

Figure 3 shows the curves characterizing the change with time of the mole fraction N_z of hydrogen sulfide in the total amount of carbon dioxide and hydrogen sulfide absorbed by the drop. The N_z value is given by

$$N_z = \frac{\int_0^R r^2 z\,dr}{\int_0^R r^2(z + x)dr}. \quad (38)$$

From Fig. 2a follows that the largest relative amount of hydrogen sulfide absorbed by the drop in the presence of carbon dioxide in the gas phase is observed at the lowest initial concentration of sodium hydroxide in the drop. Thus, the selectivity of hydrogen sulfide absorption from a gas mixture including also carbon dioxide grows with decreasing absorbent concentration. However, as follows from Fig. 2, this leads to lower total amount of absorbed hydrogen sulfide.

The plots in Fig. 3 demonstrate that the selectivity of hydrogen sulfide absorption varies with time nonsteadily, with the corresponding curves exhibiting a maximum. This is accounted for by the fact that the rate of hydrogen sulfide absorption exceeds that for carbon dioxide in the initial stage of the process. It also follows from Fig. 3b that the absorption time elapsed until the $N_z(t)$ function reaches its maximum is the shorter, the smaller the drop radius.

The plots in Fig. 4 make it possible to evaluate the consumption of sodium hydroxide for hydrogen sulfide absorption, which is important from the technological standpoint. Figure 4 presents the N_m–A dependences in which the quantity N_m defined by

$$N_m = \frac{\int_0^R r^2(c_{04} - c_4)dr}{\int_0^R r^2 z\,dr} \quad (39)$$

expresses the ratio of the amount of sodium hydroxide chemically bound to hydrogen sulfide and carbon dioxide to the amount of hydrogen sulfide absorbed by the drop. It follows from Fig. 4a that the relative consumption N_m of sodium hydroxide decreases with increasing concentration of hydrogen sulfide in the gas phase and grows with increasing carbon dioxide concentration E. This is accounted for by the fact that part of sodium hydroxide is consumed for absorption of carbon dioxide.

Figure 4b demonstrates that the relative consumption of sodium hydroxide, N_m, decreases with increasing absorption time. This result casts doubt on the concept occurring in the scientific literature, namely, that the absorption of hydrogen sulfide by sodium hydroxide in carbon dioxide should be performed at short time of contact between the fluid and gas phases.

From Fig. 4c follows that the presence of sodium carbonate in a sodium hydroxide solution at the initial instant of time (curve *2*) makes lower the relative consumption of sodium hydroxide, N_m, for hydrogen sulfide absorption.

Thus, the presence at the initial instant of time in the alkaline solution of other components (possibly contained in spraying solution circulated in the absorption apparatus) may exert influence on the consumed amount of sodium hydroxide.

CONCLUSIONS

(1) An analysis was made of chemical reactions occurring in absorption of hydrogen sulfide and carbon dioxide in an aqueous solution of sodium hydroxide.

(2) The results of the analysis were used to construct a closed system of differential equations describing the nonstationary diffusion of components involved in these chemical reactions, and the corresponding boundary-value problem was formulated.

(3) Numerical solution of the boundary-value problem yielded relations making it possible to evaluate the selectivity of hydrogen sulfide absorption and the consumption of sodium hydroxide for hydrogen sulfide and carbon dioxide absorption.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Simulation of Extraction from a Capillary-Porous Particle with Bidisperse Structure

R. Sh. Abiev

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received October 30, 2000

Abstract—A mathematical model of extraction from a capillary-porous particle with bidisperse structure is described. Results of numerical simulations are presented together with the criterial equation for calculating the effective diffusion coefficient, obtained on processing these results. A criterion is established for selecting the optimal oscillation frequency. The criterion is tested on a physical model, with the obtained numerical results qualitatively confirmed.

Capillary-porous particles with bidisperse structure, possessing capillaries of two, strongly different sizes, frequently occur in nature and technology. Into this category may be placed tissues of plant or animal origin, and also many kinds of catalysts [1]. Neglecting the polydispersity of capillary sizes in capillary-porous particles makes less accurate the obtained results and gives no way of elucidating some physical mechanisms of substance transfer inside the particles. The bidisperse model of a capillary-porous particle is the analytically simplest variety of the polydisperse model, making it possible to reveal fundamental aspects of mass transfer in real polydisperse particles.

The present study is concerned with the process of extraction from a bidisperse model of a capillary-porous particle.[1] In the simplest case the model of a bidisperse particle can be represented as fine capillaries, which are the main channels for solutions of target components, branching-off from coarse pores (blind or through). As a rule, there is virtually no fluid motion within the capillaries, with substance transfer occurring by the molecular-diffusion mechanism. However, at certain amplitudes, pulsation of the external pressure in coarse pores may give rise to oscillatory motion of fluid because of the compression of gas trapped in capillaries [2, 3]. Thus, coarse pores play the role of transport channels with convective substance transfer, with the resulting manyfold acceleration of solute extraction from the particle as a whole.

In order to simplify the analysis, a planar model [4, 5] of a capillary-porous particle with bidisperse structure was adopted (Fig. 1). The ensemble of fine capillaries was replaced by an anisotropic porous structure with preset porosity ε, a porous block whose pores are filled at the initial instant of time with a concentrated solution of the target component; the anisotropy is manifested in that the diffusion occurs only along the *y*-axis. A transport channel whose side walls border on the porous block passes through the particle. Molecular diffusion of the substance from the porous block into the channel occurs (shown by arrows in Fig. 1) through these boundaries. The diffusion in the channel itself is convective.

The mathematical model of the extraction process in the particle under consideration can be described by the following system of equations [indices: (0) initial state, (1) porous block, and (2) transport channel].

Diffusion equation for the porous block:

$$\partial C_1/\partial t = D(\partial^2 C_1/\partial y^2), \quad (1)$$

where C_1 is the substance concentration in the porous block (kg m^{-3}), t is time (s), and D is the molecular diffusion coefficient (m s^{-1}).

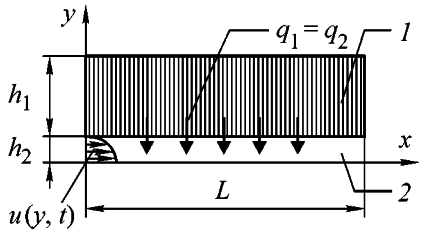

Fig. 1. Planar model of a particle with bidisperse structure and through transport pores: (*1*) porous block and (*2*) transport channel.

[1] The mathematical model was developed with participation of G.M. Ostrovskii (St. Petersburg State Technological Institute).

1070-4272/01/7405-0777$25.00 © 2001 MAIK "Nauka/Interperiodica"

Convective diffusion equation for the transport channel:

$$\partial C_2/\partial t + u\partial C_2/\partial x = D(\partial^2 C_2/\partial x^2 + \partial^2 C_2/\partial y^2), \quad (2)$$

where C_2 is the substance concentration in the transport channel (kg m^{-3}), and u is the longitudinal (along the x-axis) fluid velocity (m s^{-1}).

Initial conditions:

$$C_1(x, y) = C_{10}, \ 0 \le x \le L, \ h_2 < y \le h_1 + h_2; \quad (3)$$

$$C_2(x, y) = C_{20}, \ 0 \le x \le L, \ 0 < y \le h_2, \quad (4)$$

where h_1 and h_2 are the half-widths of the porous block and the transport channel, respectively (m), and L is the particle length (m).

Boundary conditions:

$$C_2(x, h_2) = C_1(x, h_2), \quad (5)$$

$$q_2(x, h_2) = q_1(x, h_2), \quad (6)$$

$$C_2(0, y) = C_2(L, y) = C_{20}, \quad (7)$$

$$q_1(x, h_1 + h_2) = 0, \quad (8)$$

$$q_2(x, 0) = 0, \quad (9)$$

where q_1 and q_2 are the substance fluxes (kg m^{-2} s^{-1}).

With account of the smallness of the actual velocities in the transport channels and the dimensions of these, the fluid flow mode was taken to be laminar, and the velocity profile can be taken, without any significant loss of accuracy, to be parabolic in space and harmonic in time:

$$u(x, t) = u_{\max}[1 - (y/h_2)^2]\sin(\omega t), \quad (10)$$

where ω is the angular velocity of oscillation (rad s^{-1}).

The substance fluxes at the interface between the porous block and the channel (at $y = h_2$) are given, with the diffusion coefficient D assumed to be independent of the substance concentration, by

$$q_1 = -\varepsilon D(\partial C_1/\partial y), \quad (11)$$

$$q_2 = -D(\partial C_2/\partial y). \quad (12)$$

Equation (7) characterizes, in the case of good agitation within the volume of a continuous apparatus, the boundary conditions at the channel ends, which can be taken as conditions of constant concentrations. In the general case, the conditions (7) of the first kind should be replaced by boundary conditions of the third kind, and, with account taken of the variation of the substance concentration in a batch apparatus, by conditions of fifth or sixth kind [6].

Equation (8) corresponds to the absence of a flow through the blind ends of fine capillaries, and Eq. (9), to the symmetry condition along the channel axis.

The coefficient ε in Eq. (11) accounts for the fraction of the surface area across which the substance transfer from the porous block side occurs.

The system of Eqs. (1)–(12) was solved by the grid method, using for approximation of Eq. (2) the modified Pismen–Rackford method of variable directions, accurate to first order, with approximation error [Δt, $(\Delta x)^2$, $(\Delta y)^2$], where Δt is the time step of the grid (s); Δx, Δy are the grid steps along the x- and y-axes, respectively (m), with the grid being absolutely stable in the linear case [7]. Equation (1) was approximated using the absolutely stable Krank–Nicholson method, accurate to second order. The boundary conditions were approximated by expressions accurate to second order.

The fluid volume contained within the transport channel is described by the balance equation expressing the law of mass conservation with respect to the substance being extracted:

$$\partial M_1/\partial t = G_{\text{bc}} - G_0,$$

where $\partial M/\partial t$ is the rate at which the mass of the substance being extracted grows in the transport channel (kg s^{-1}), G_{bc} is the substance flux at the boundary between the porous block and the transport channel (kg s^{-1}), and G_0 is the outward flux from the transport channel (kg s^{-1}):

$$\frac{\partial M_1}{\partial t} = \frac{\partial}{\partial t}\int_0^{h_2}\int_0^{L} C_2 \mathrm{d}x\mathrm{d}y, \quad G_{\text{bc}} = D\int_0^{L} \left.\frac{\partial C_2}{\partial y}\right|_{y=h_2} \mathrm{d}x,$$

$$G_0 = D\int_0^{h_2}\left(\left.\frac{\partial C_2}{\partial x}\right|_{x=0} - \left.\frac{\partial C_2}{\partial x}\right|_{x=L}\right)\mathrm{d}y.$$

The developed software made it possible to observe dynamically the concentration fields at grid nodes and record in a data file instantaneous values of G_{bc}, G_0, and $\partial M/\partial t$ (Fig. 2).

Several numerical experiments were performed. At Peclet numbers

$$\mathrm{Pe}_L = \bar{u}L/D \le 1$$

($\bar{u} = \omega\pi^{-1}\int_0^{\pi/\omega}\int_0^{h_2} u(y, t)\partial y\partial t = 4u_{\max}/3\pi$ is the fluid motion velocity averaged over the half-period and the

transport channel cross-section), the convective transfer in the channel has virtually no effect on the extraction rate. Therefore, the main calculations were done at

$$\mathrm{Pe}_L = \bar{u}L/D > 1. \quad (13)$$

Numerical experiments demonstrated that, all other conditions being the same, there exists the optimal frequency of fluid oscillations in the channel, ω_{opt}, at which the minimum process duration can be achieved.

Analysis of the curves in Fig. 2 shows that two stages exist at any oscillation frequency. The first is the attainment of regularity, with the substance content in the porous block falling fast because of high concentration gradients. In the process, one part of molecules of the substance being extracted goes from the transport channel outwards, and the other is accumulated in the transport channel (for all plots in Fig. 2 this stage is over when curve *2* intersects the abscissa axis and curve *3* has inflection).

The second stage (mode which is "regular" when period-averaged) depends of the oscillation frequency (with all other parameters of the model fixed).

At low frequencies, the role played by convective substance transfer is insignificant; for example, curves *1* and *3* in Fig. 2a are monotonic and the lower portion of curve *2* tends asymptotically to the abscissa axis. At higher frequencies (Fig. 2b), curve *3* exhibits a weakly pronounced maximum nearly coinciding in phase with the minimum in curve *2*; at the same time the intensity of substance transfer is still rather low. This is due to the fact that the molecules of the substance being extracted have to pass a longer way toward the opening of the transport channel virtually by means of diffusion only.

At a nearly optimal frequency (Fig. 2c) all the three curves show clearly pronounced extrema virtually coinciding in phase. The outflow of the substance from the transport channel (curve *2*) is virtually immediately followed by its transfer from the particle outwards, into the fluid surrounding the particle (curve *3*). In addition, transfer from the porous block into the transport channel is enhanced (curve *1* exhibits a pronounced maximum), since the fluid in the transport channel rapidly "releases" the substance outwards, with all the three lines having large amplitudes. This type of substance transfer resembles exchange of potential and kinetic energies in mechanical oscillatory systems and, therefore, quite deserves being termed the "resonance" in mass transfer. It may be stated that the frequency of external action coin-

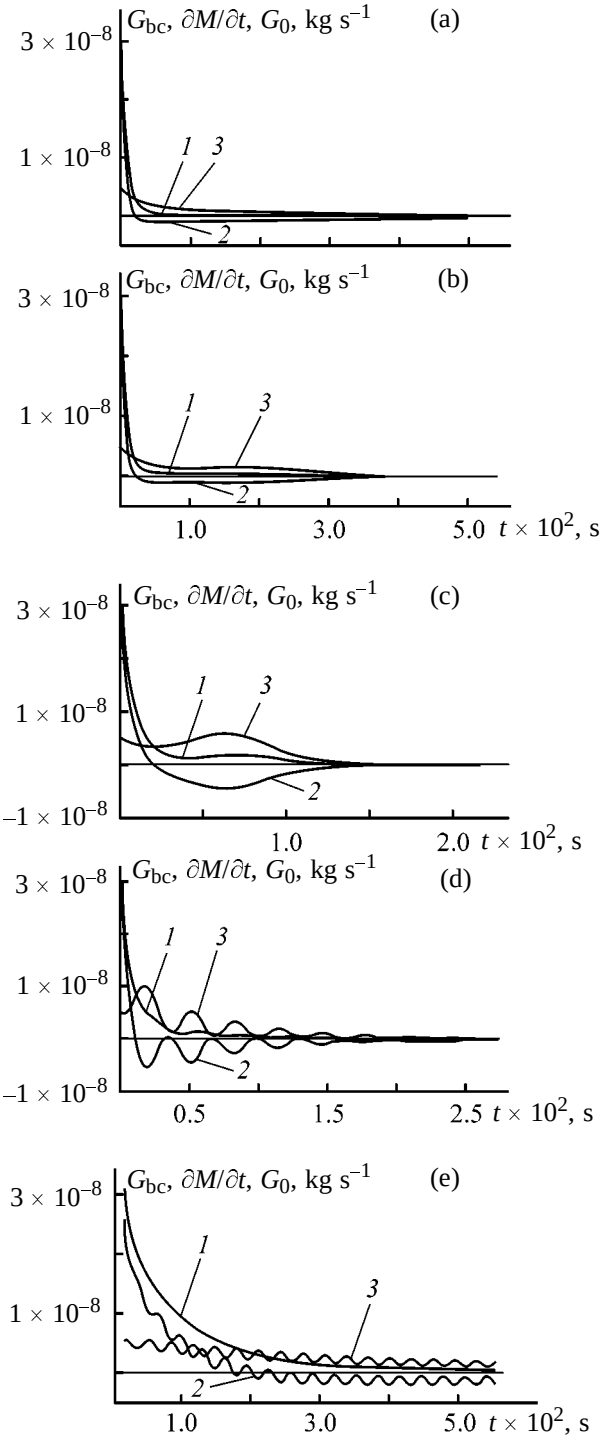

Fig. 2. Variation with time t of the (*1*) substance flux at the block–channel interface, G_{bc}; (*2*) rate of mass gain in the transport channel, $\partial M/\partial t$; and (*3*) substance flux from the transport channel outwards, G_0. Calculated parameters: $h_1 = h_2 = 10^{-6}$ m, $L = 10^{-5}$ m, $D = 0.5 \times 10^{-9}$ m^2 s^{-1}, $\varepsilon = 0.4$, $u_{max} = 5 \times 10^{-3}$ m s^{-1}, $C_{10} = 10$ kg m^3, $C_{20} = 0$. Angular frequency ω (s^{-1}): (a) 1, (b) 10, (c) 100, (d) 1000, and (e) 10000.

cides with the characteristic fundamental frequency of mass transfer inside the capillary-porous particle.

At fluid oscillation frequencies exceeding the optimal frequency severalfold (Fig. 2d), the amplitude of oscillations of curves *2* and *3* decays fast; in addition, curve *2* intersects the abscissa axis at maxima in curve *3*, with the minimum in curve *3* nearly reaching zero. This is accounted for by the fact that the fluid in the transport channel moves, together with the point of maximum concentration, so fast that the substance does not have enough time to be removed from the transport channel outwards. As a result, the maximum concentration in the channel becomes higher than that in the adjacent layers of the porous block, i.e., the transverse concentration gradient is reversed. Thus, the substance in the high-concentration zone starts to penetrate from the transport channel back into the porous block (back transfer), which on the whole hinders the process of substance extraction from the particle [4, 5].

This fact indicates that, in different parts of the transport channel, the G_{bc} flux may change not only its magnitude, but also its sign. This leads to an indisputable conclusion that the rate of molecular diffusion, characterized by the coefficient D, exerts no direct influence on the optimal frequency of oscillations. Indeed, let us assume that, all other parameters being the same, the diffusion coefficient becomes two times greater. Then, the local flux of substance across the boundary between the porous block and the transport channel will increase twofold in accordance with the Fick law. However, further, being saturated fast with the substance being extracted, the fluid in the channel will move to the region in which the porous block is depleted (i.e., the local concentration in the porous block is lower than that in the transport channel), and the local back flux of the substance at the same boundary will also increase twofold. Thus, the faster the fluid in the transport channel is saturated with the substance being extracted, the faster it returns the substance to the depleted porous block. Naturally, these considerations refer to "long" transport channels ($L/h_2 \gg 1$), since the molecular diffusion plays very important role in "short" channels. Numerical experiments demonstrated that at $L \approx h_2$ there is no optimal frequency: The short way to the opening of the transport channel is traveled by molecules fast because of the occurrence of molecular diffusion.

At frequencies exceeding the optimal frequency by an order of magnitude and more (Fig. 2e), the amplitude of oscillations of curves *2* and *3* markedly decreases. Curve *1* becomes monotonic, as in the case of low frequencies (Figs. 2a, 2b), since the concentration field has not enough time to change substantially during a period of oscillation. The dramatic decrease in the total rate of mass transfer can be understood as follows. The fluid flowing into the channel at high velocity has no time to be saturated with the substance and flows back after a short period of time. In doing so it returns the substance that has passed into the fluid in the channel to the depleted layers of the porous block at the ends of the transport channel.

A detailed analysis of the concentration field and fluxes at the channel wall at these frequencies demonstrated the following. The transverse concentration gradient in the channel rapidly approaches zero owing to intense convection; macroscopic volumes of fluid with relatively high concentration at the channel axis rapidly move from its middle part ($x \approx L/2$) into zones with low concentration, where occurs back substance transfer, and the flux signs are reversed, i.e., the substance passes from the fluid in the channel into the porous block.

Thus, too "fast" fluid oscillations within the channel (at, e.g., ultrasonic frequencies) are as inefficient as too "slow" oscillations.

Let us make an attempt to evaluate qualitatively the optimal frequency of fluid oscillations in the channel at fixed other parameters.

In order that the convective transfer of substance from a particle with bidisperse structure occur with the highest intensity it is necessary that, at the highest velocity, the concentration at the right-hand edge of the channel (Fig. 1, at $x = L$) should also be the highest, since the convective flux of the substance $q_{conv} = uC_2$. The velocity reaches its highest value in a time equal to a quarter of the oscillation period; $t_0 = (1/4)2\pi/\omega = \pi/2\omega$. During this time the fluid front must pass a distance on the order of the channel length L, being saturated, on its way, with the substance being extracted. In the model in question, the instantaneous velocity of the fluid front $u_f = (2/3)u_{max}\sin(\omega t)$, and, during a time t_0, it will travel through a distance $x_f = \int_0^{t_0} u_f dt = 2u_{max}/3\omega = u_{av}/\omega$, and just this distance should be on the order of L. Thus, the optimal frequency of fluid oscillations can be found from the condition

$$\mathrm{Sr} = \omega L/u_{av} \sim 1. \qquad (14)$$

The results obtained in calculating the Struchal number Sr at the optimal frequency of fluid oscillations are presented in Table 1.

Engineering calculations require simple relations, e.g., in the form of criteria. An analysis of the mathematical model demonstrated that the determining criteria include the fine-pore porosity ε of the porous block, geometric simplexes $\Gamma_1 = h_1/L$ and $\Gamma_2 = h_2/L$, and the Struchal number Sr, and the dependent criterion is the inverse effective Peclet number: $K_d = 1/\mathrm{Pe}_{eff} = D_{eff}/\bar{u}L$, where $\bar{u} = (4/3\pi)u_{max}$ is the fluid velocity in the transport channel, averaged over the cross-section and the half-period. The effective diffusion coefficient D_{eff} was found from the slope of the kinetic curve [4] in the regular process regime. Processing of results obtained in more than 80 numerical experiments gave the following criterion equation

$$D_{eff}/\bar{u}L = 0.218\mathrm{Sr}^{0.5}\exp(-1.2\mathrm{Sr})\varepsilon^{-0.22}\Gamma_1^{-0.63}\Gamma_2^{0.29}. \quad (15)$$

The exponential factor is introduced into the equation to account for the "resonance" dependence of the effective diffusion coefficient on the Struchal number [Fig. 3 shows the function (15) for fixed ε, Γ_1, Γ_2]. This curve exhibits a maximum at Sr = 0.42, i.e., at Sr on the order of unity.

EXPERIMENTAL

To verify the numerically obtained relations, an experimental setup shown schematically in Fig. 4a was assembled. The oscillatory motion of the fluid through the central channel in the particle was effected by means of a system comprising a compressor *1*, a solenoid-and-pressure-operated valve *2*, and a control unit (pulse generator) *3* with variable repetition frequency and off duty factor of rectangular pulses. The valve *2* was connected by a tube *4* with inner diameter D_t = 15 mm and hose *5* to the model *6* of a capillary-porous particle with bidisperse structure, which, in turn, is connected by means of a tight joint in the form of a plug *7* to a 5-l glass vessel *8*. The amplitude of fluid oscillations was controlled by means of bypass *9* and throttling *10* valves. The U-shaped part of the hose was 5–350 mm long, the length of the pipe connecting the particle model *6* to the plug *7* was 105 mm.

The model of a capillary-porous particle with bidisperse structure is shown schematically in Fig. 4b. In a glass tube *11* is mounted a coaxial polyvinyl chloride plastic tube *12* with through holes *13* of diameter 0.1–0.2 mm, arranged in staggered rows with a step of 2–3 mm. At both ends the tube *11* is sealed with rubber plugs *14*, between which is placed a dense bed *15* of washed river sand (particle size 300–400 μm). After being placed in the model, the sand was impregnated with 10.0 ml of 2 N HCl solution to saturation. It could be seen through the transparent tube *11* that the entire intergrain space of the sand was being homogeneously impregnated with the acid solution, with air removed through holes *13* in the tube *12*. The bed saturation was also judged from the onset of drop fall from the pore space. The volume of the drops was measured with a volumetric cylinder.

Table 1. Struchal number estimated at the optimal frequency of fluid oscillations ($h_1 = h_2$ = 1 μm, L = 10 μm)

$u_{max} \times 10^3$, m s^{-1}	ω_{opt}, rad s^{-1}	Pe_L by formula (13)	Sr by formula (14)
0.5	40	4.24	1.2
1.0	70	8.49	1.05
2.5	150	21.2	0.9
5.0	200	42.4	0.6
7.5	300	63.7	0.9

Thus, a dense grainy bed saturated with liquid was formed in the annular channel between tubes *11* and *12*. The bed was connected to the inner space of tube *12* only through fine holes *13*. This allowed the bed to be regarded as incompressible, and substance transport within this bed, as having purely diffusion nature. The fluid flowing inside the tube *12* provided for the convective transport of the substance.

In this experimental model, the pore space of the bed *15* is analogue of fine capillaries in capillary-porous particles of plant origin, and the tube *12*, analogue of a transport channel.

After switching-on the compressor *1* and control unit *3* and filling the vessel *8* (Fig. 4a) with 1 l of 0.01 N NaOH solution, a stopwatch was set going. The duration τ (s) of the extraction process was judged from the instant of decolorization (neutralization) of the alkali solution to which 1 ml of 1% alcoholic solution of phenolphthalein was preliminarily

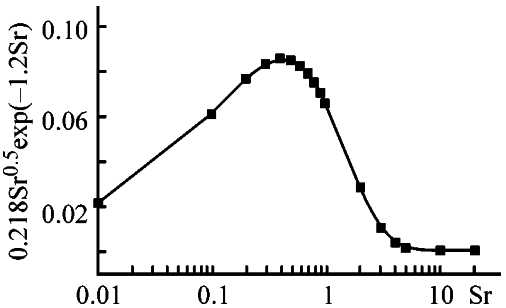

Fig. 3. Typical plot of the quantity $0.218\mathrm{Sr}^{0.5}\exp(-1.2\mathrm{Sr})$ vs. Struchal number.

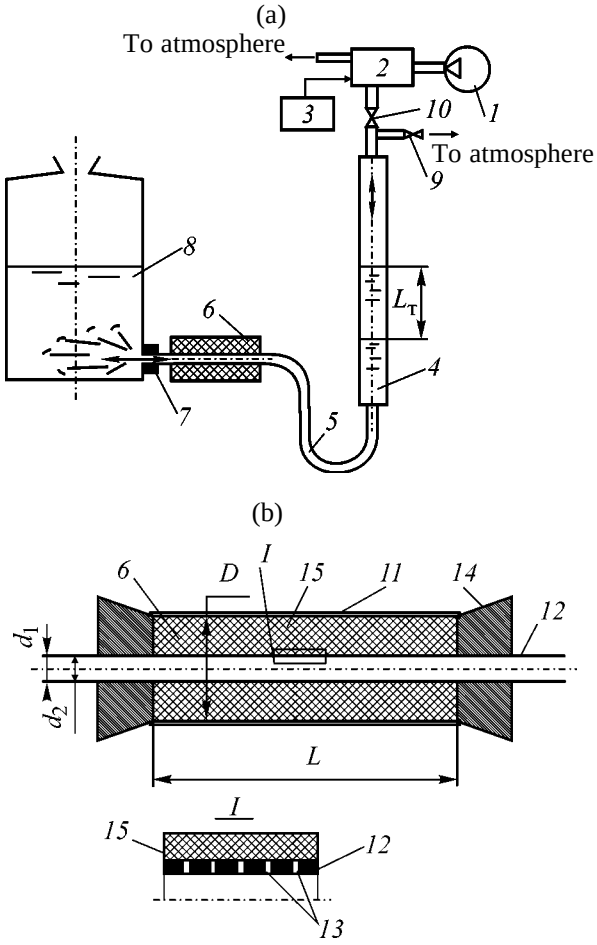

Fig. 4. Setup for modeling extraction from capillary-porous particle with bidisperse structure: (a) overall scheme and (b) cartridge simulating the porous particle. L = 78 mm, D = 23 mm, d_1 = 10 mm, and d_2 = 7.5 mm. (*1*) Compressor, (*2*) solenoid-and-pressure-operated valve, (*3*) control unit (pulse generator), (*4*) glass tube, (*5*) hose, (*6*) particle model, (*7*) plug, (*8*) vessel with bottom neck, (*9, 10*) valves, (*11*) glass tube, (*12*) polyvinyl chloride plastic tube, (*13*) holes, (*14*) rubber plugs, and (*15*) dense bed of sand.

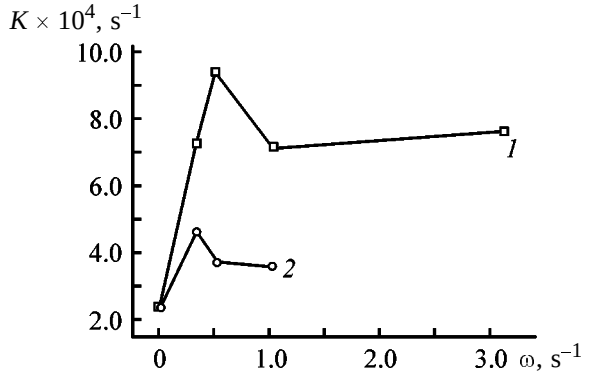

Fig. 5. Extraction index K vs. angular velocity ω of oscillations at different amplitudes A of fluid oscillations in the particle model. A (m): (*1*) 0.60 and (*2*) 0.12.

added. The amount of acid present in the pore space of sand twice exceeded that required by the stoichiometry. In experiments with large oscillation amplitude, the fluid in the vessel was rather well agitated by a pulsing jet; in other cases, the fluid was additionally agitated, in order to equalize concentrations, by slightly rocking the vessel *8*. In an experiment with "immobile" fluid, when no fluid oscillations were generated in tube *2*, the particle model was placed in a volumetric cylinder in which fluid was agitated with a slowly rotating glass rod (with rotation frequency of 1 s^{-1}). These measures were taken to enable the outer-diffusion resistance to substance transfer (outside the particle model) to be considered infinitely small as compared with the inner-diffusion resistance (inside the particle model). Also measured were the pulse duration T_p, interval duration T_i, and the amplitude L_t of fluid motion in the tube *4* (Fig. 4a).

The amplitude of fluid motion in the tube *2* was determined using the formula

$$A = L_t(D_t/d_2)^2, \quad (16)$$

and the average velocity of the fluid in the tube was found as

$$u_{av} = A/T_p. \quad (17)$$

The angular frequency of oscillations were calculated using the relation

$$\omega = 2\pi/(T_p + T_i), \quad (18)$$

and the off-duty factor of pulses was found as the ratio of the pulse duration to the oscillation period:

$$\Psi = T_p/(T_p + T_i). \quad (19)$$

As a similarity criterion, characterizing the simultaneous (homochronous) nature of the diffusion extraction of substance from the intergrain space into the transport channel (tube *12* in Fig. 4b), on the one hand, and the convective transfer of the extracted substance from this channel into the bulk of the fluid in the apparatus, on the other, was taken the Struchal number calculated using the formula

$$Sr = \omega L_{eff}/u_{av}, \quad (20)$$

with the sum of the lengths of tube *12* and hose and tube connections taken as the effective channel length L_{eff} = 0.533 m. As the characteristic of the process intensity was chosen a reciprocal of the extraction process duration: $K = 1/\tau$.

The results of the experiments are presented in Table 2, and dependences of K on ω and Sr in, respectively, Figs. 5 and 6. The run of these dependences

Table 2. Results obtained in modeling the process of extraction from a capillary-porous particle with bidisperse structure

9	9	0.06	0.24	0.349	0.0267	0.50	6.97	1380
6	6	0.035	0.14	0.523	0.0233	0.50	12.0	1260
3	3	0.02	0.08	1.05	0.0267	0.50	20.9	3000

corresponds to the nature of the numerically obtained relations. In particular, the dependence represented by experimental points in Fig. 6 is in qualitative agreement with the approximation yielded by processing the results of numerical simulations and shown in Fig. 3.

CONCLUSIONS

(1) For each fluid oscillation amplitude there exists the optimal oscillation frequency at which the extraction process has the highest intensity.

(2) At a certain Struchal number, approximately equal to unity, the extraction proceeds the most intensely.

(3) In particles with long transport channels practically no effect on the optimal oscillation frequency.

(4) Too high oscillation frequencies, and also too low frequencies (at equal amplitude), do not lead to ($L/h_2 \gg 1$) the molecular diffusion coefficient has any noticeable acceleration of the extraction process as compared with simple infusion, being, therefore, energetically unfavorable.

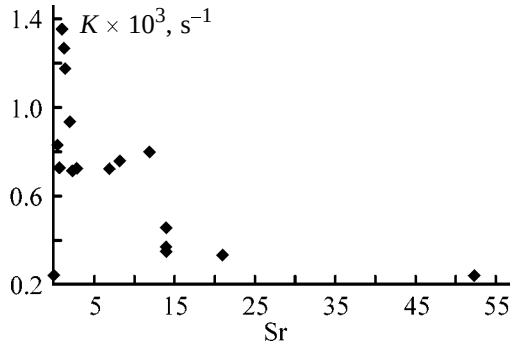

Fig. 6. Extraction index K vs. the Struchal number Sr.

(5) The obtained relations make it possible to provide recommendations for determining the optimal extraction conditions on measuring the pore size in real particles.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Identification of Oil Pollution Sources by a Set of Modern Instrumental Methods

O. Yu. Begak and A. M. Syroezhko

St. Petersburg State Technological Institute, St. Petersburg, Russia
Mendeleev Russian Research Institute of Metrology, St. Petersburg, Russia

Received December 28, 2000

Abstract—Source of contamination of the soil and water with oil can be exactly identified by a set of instrumental methods such as atomic absorption spectrometry, inductively coupled plasma mass spectrometry, atomic emission spectroscopy, X-ray fluorescence analysis, and inductively coupled plasma emission spectrometry.

Sources of pollution of environmental objects (soil, water) can be exactly identified using a set of instrumental methods including FTIR, γ-ray spectrometry, and up-to-date analytical methods for determination of impurities in oil. Identification is carried out by both quantitative analysis for impurities such as S, Na, Ca, Fe, Ni, Cu, V, Mn, Zn, Mg, Al, Ba, and Ti and their relative content.

In the previous work [1] on the basis of analytical data on oils of six oil fields of the Khanty-Mansi autonomous district we recommended to use FTIR and γ-ray spectrometry for preliminary identification of oil pollution sources. Gas chromatography–mass spectrometry and capillary GLC appeared to be low-informative in this respect.

EXPERIMENTAL

For reliable identification of oil pollution sources, in addition to the methods employed in [1] (FTIR, γ-ray spectrometry, gas chromatography–mass spectrometry, and capillary GLC) we used five more up-to-date methods: (1) inductively coupled plasma mass spectrometry (ICP-MS), (2) atomic absorption spectrometry (AAS) in the flame or unflame atomization modes [2], (3) X-ray fluorescence analysis (XFA) [3], atomic emission spectroscopy, and inductively coupled plasma emission spectrometry (ICP-ES) [4].

Metal impurities in samples of oil, oil-polluted soil, and watered oil sample were determined by ICP-MS with a VG inductively coupled plasma mass spectrometer (the United Kingdom). Standards of each of element to be determined were prepared in nitric acid gravimetrically.

Metal impurities were determined by electrothermal atomic absorption spectrometry (ETAAS) with a Perkin–Elmer Model 4100 ZL instrument. Hollow cathode lamps of the same manufacturer were used.

We examined a combined scheme of identification of oil pollution sources by impurities (metal and nonmetal) using two different methods: (1) atomic emission spectroscopy of oil dry ash residue with Ar high-frequency plasma as a light source and an STE-1 crossed dispersion spectrograph and (2) ICP-ES of mineralized acidic solutions of test oil samples on a PS1000 instrument (Leeman Labs Inc., the United States), which allowed determination of a wide variety of impurities in test oils. Also we used a Hitachi 180/80 polarized Zeeman flame atomic absorption spectrophotometer (Hitachi, Japan) with atomization in stoichiometric acetylene–air flame.

XFA examination of oil samples was performed on a Philips PW 1220C automatic scanning spectrometer.

In Fig. 1a are given data on the V, Cu, Ni, and Cr content in the initial oil samples (oil field numbering is as in [1]). Basing on these data, all the oil samples can be arbitrarily subdivided into three groups with high, medium, and low content of the indicated metals. The first group (total content of the four metals above 40 mg kg^{-1}) includes sample nos. 1 (Alekhinskoe oil field), 2 (Lyantorskoe oil field), and

1070-4272/01/7405-0784$25.00

7 (Priobskoe oil field); the second group (10–40 mg kg^{-1}) includes sample nos. 5 (Trekhozernoe oil field), 6 (Prirazlomnoe oil field), and 8 (Petelinskoe oil field); and the third group (<10 mg kg^{-1}) is represented by sample no. 4 (Krasnoleninskoe oil field).

Figure 1b demonstrates the relative metal content in the oil samples. The results obtained by ICP-MS (Figs. 1a, 1b) allow identification of oil from the indicated oil fields. The most difficultly distinguishable are sample nos. 1 and 2 (Alekhinskoe and Lyantorskoe oil fields, respectively). However, in this case also the relative content of impurities differs by more than 10% (effective criterion of the Russian State Ecological Committee). Artificial aging of oil did not change the indicated trends somewhat significantly. Therefore, oil of different oil fields of the West Siberia can be objectively distinguished by the content of the indicated four metals, as determined by ICP-MS.

Also oil samples are unambiguously identified by ETAAS. This method was used for determination of V, Ni, and Cr [5].

The final stage of this study was performing of multi-technique identification of oil pollution sources by impurities. All oil samples were analyzed by atomic emission spectroscopy (vaporization of ash residue in ac arc) for 25 foreign elements (Mn, Cu, Ni, Fe, Zn, Ca, Cr, Mg, Al, Ag, V, Na, B, Ba, Ti, Pb, Co, Be, As, Sb, Cd, Bi, Hg, Se, and S). In none of the samples studied we found As, Sb, Se, Bi, Cd, Hg, Ag, and Be. The content of Co, B, Cr, and Pb was found to be near the detection limits of the indicated analytical techniques. Therefore, it was advisable to develop a multi-technique procedure of oil identification involving determination of 13 foreign elements: S, Na, Ca, Fe, Ni, Cu, Zn, Mg, Al, V, Ba, Mn, and Ti. Combined employment of ICP-ES, AAS, and XFA allows reliable determination of all the indicated 13 foreign elements. In this case Ca, Fe, Ni, Cu, and Zn can be determined by all the three techniques or by any of them separately. Also, if needed, FTIR or γ-ray spectrometry can be attracted.

It should be pointed out that sulfur is best determined by XFA. Na, Al, Mn, and Ti are most reliably determined by ICP-ES; and Mg, Ba, and V, by combination of AAS and ICP-ES.

All the three indicated techniques are applicable to thorough characterization of oil from the Khanty-Mansi autonomous district. The results are summarized in Table 1. They suggest that all the samples studied, including oil-polluted soil and water, are clearly distinct in the absolute and relative content of

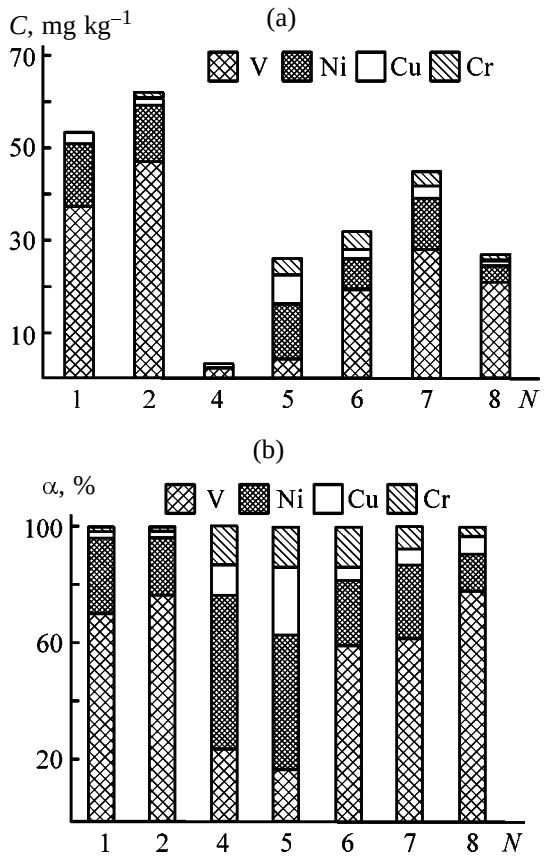

Fig. 1. Identification of oil from various oil fields by (a) the content of metal impurities *C* and (b) their relative content α. (*N*) Sample no.

individual foreign elements and their total content. The concentrations of such foreign elements as Na, Cu, V, Mn, and Ti can differ from sample to sample by a factor of up to several tens. For Ca, Ni, Mg, and Ba this factor is about 10, and for Zn and Al, 5–7.

The total content of 12 foreign elements varies over the range 319–3556 μg cm^{-3}, i.e., by a factor of 11.

The results show a strong variation in the sulfur content from sample to sample. The maximal content (0.95–0.99%) was observed in sample nos. 1 (Alekhinskoe oil field) and 7 (Priobskoe oil field). The minimal content (0.3–0.4%) was found in sample nos. 4 (Krasnoleninskoe oil field) and 5 (Trekhozernoe oil field). The minimal and maximal contents of sulfur in the samples studied differ by a factor of 3.1.

The individuality of the oil samples studied is manifested even more distinctly in comparative analysis of data on the relative content of foreign elements (Table 2). In sample no. 1 the ratio Mg/Ba = 37.5 is maximal among all the samples. Sample no. 2 is characterized by the maximal Mg/Zn ratio (12.5), sam-

* The maximal values are underlined.

ple no. 4, by the maximal Ca/V ratio (12.9), and sample no. 8, by the maximal Ca/Mg ratio (5.7). Sample no. 7 is characterized by the maximal ratio of Cu to the total of foreign elements (Cu/Σ = 0.127). In sample nos. 5 and 7, respectively, the ratios Ca/Ba = 2 and Ca/V = 1.4 are the minimal.

To conclude, the results obtained show that oil from each oil field of the Khanty-Mansi autonomous district has its individual composition of foreign elements and can be identified by a set of up-to-date analytical techniques. One of the possible flowsheets of identification of oil pollution source in the Khanty-Mansi autonomous district is given in the scheme.

CONCLUSIONS

(1) It was demonstrated with an example of oils of the Khanty-Mansi autonomous district that oil pollution sources can be identified by impurity content using such methods as γ-ray spectrometry, atomic absorption analysis, atomic emission analysis, X-ray fluorescence analysis, ICP-MS, and ICP-ES. For primary identification FTIR can be used.

(2) Identification is performed by computer comparison of absorption bands of oil samples in the fingerprint range, and also by the radionuclidic composition of elements of the thorium and uranium

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Solubility of Synthetic Pyrethroids in Organic Solvents

O. I. Mikhailenko, O. A. Kolyadina, and Yu. I. Murinov

Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Received March 30, 2000; in final form, July 2000

Abstract—The solubilities of four synthetic pyrethroids in organic solvents at 0–50°C were determined, and the enthalpies of solution were calculated. The enthalpies of solution of pyrethroids in benzene were measured calorimetrically.

Synthetic pyrethroids show considerable promise as insecticides, being safe for humans, useful fauna, and environment as a whole and meeting in this respect the modern requirements to chemical means for plant protection [1]. The most convenient form of insecticides is their liquid form, in particular, an emulsifiable concentrate [2]. Up to now, pesticide formulations for practical use were selected semiempirically [3]. The emulsifiable concentrate is a multicomponent solution whose properties are determined by a set of physicochemical processes occurring in this system. The scientifically substantiated approach to development of pesticide formulations for practical use requires understanding of these physicochemical processes. In this work we studied the solubility of various pyrethroids in organic solvents.

EXPERIMENTAL

The pyrethroids were prepared in the laboratory of fine organic synthesis. The structure and physicochemical properties of the pyrethroids are listed in Table 1. At various temperatures we determined the solubilities of these pyrethroids in heptane, toluene, tetrachloromethane, and ethanol, and also of Alphametrin and Decametrin in hexane and cyclohexane and of Phenvalerate in chloroform. The solvents were purified by standard procedures [4].

The solubility of synthetic pyrethroids in organic solvents N_s (mole fraction) was determined gravimetrically in the temperature range 0–50°C. Saturated solutions of pyrethroids were prepared by continuous shaking of a solvent with excess pyrethroid in closed temperature-controlled test tubes. The time required to attain the equilibrium varied from 1 to 5 h depending on the solution viscosity and concentration; the process was monitored refractometrically. The temperature was maintained to within ±0.1°C. The relative error of solubility determination was 2–5%.

The enthalpy of solution of pyrethroids in benzene was measured with a Calvet differential microcalorim-

pyrethroids in organic solvents increases in the opposite order: Permetrin < Phenvalerate < Alphametrin < Decametrin. For enantiomerically pure Alphametrin and Decametrin, the solubility, apparently, is largely affected by the crystal lattice strength.

The synthetic pyrethroids are considerably less soluble in saturated hydrocarbons and ethanol, as compared to toluene and chlorinated solvents. As for the solubility of Alphametrin and Decametrin in saturated hydrocarbons, it increases in the order hexane < heptane < cyclohexane. The enthalpies of solution of these pyrethroids in hexane and cyclohexane coincide within experimental error. Hence, the different solubility is due to the entropy factor: More compact cyclohexane molecules, apparently, penetrate more readily into the rigid crystal lattice of Alphametrin and Decametrin and promote their dissolution. The enthalpies of solution in heptane are considerably lower, especially for Alphametrin.

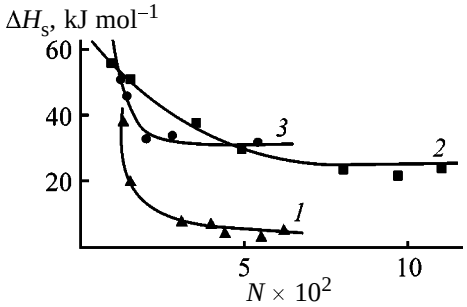

Fig. 1. Enthalpy of solution of pyrethroids in benzene ΔH_s, determined calorimetrically at 30°C, as a function of solute mole fraction *N*. Pyrethroid: (*1*) Phenvalerate, (*2*) Alphametrin, and (*3*) Decametrin.

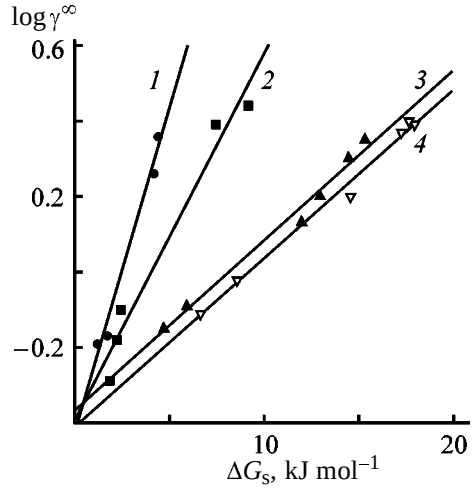

Fig. 2. Correlations between the Gibbs energies of solution of pyrethroids ΔG_s (298 K) and limiting activity coefficients γ^∞ of organic solvents in pyrethroids, calculated from the GLC data (373 K). Pyrethroid: (*1*) Permetrin, (*2*) Phenvalerate, (*3*) Alphametrin, and (*4*) Decametrin.

In dissolution of pyrethroids in CCl_4, the intermolecular interactions with the solvent are largely determined by the dichlorovinyl fragment: The enthalpies of solution of Permetrin and Alphametrin containing this fragment are appreciably lower than those of Phenvalerate and Decametrin.

The concentration dependences of the enthalpies of solution of pyrethroids in benzene, determined calorimetrically, are shown in Fig. 1. At 30°C, in the range of pyrethroid mole fractions 0.03–0.05 and higher, the enthalpies of solution of Phenvalerate, Alphametrin, and Decametrin are 4.3 ± 2.1, 23.8 ± 2.8, and 33.3 ± 2.3 kJ mol^{-1}, respectively. These values are consistent with the values obtained from the temperature dependences of the solubility in another aromatic solvent, toluene: 11.0 ± 0.4, 21.3 ± 0.9, and 30.2 ± 0.8 kJ mol^{-1}, respectively. The lowest enthalpy of solution of Phenvalerate could be expected from the fact that pyrethroid molecules can interact with aromatic hydrocarbons by the π–π mechanism, and Phenvalerate contains three benzene rings in the molecule and exhibits the loosest structure of the crystal lattice. Figure 2 shows that Phenvalerate is characterized by stronger interactions with aromatic hydrocarbons than Alphametrin and Decametrin.

CONCLUSIONS

(1) The solubility of pyrethroids in organic solvents varies in opposite direction with the degree of their self-association.

(2) The calorimetrically measured enthalpies of solution of pyrethroids are comparable with the values calculated from the temperature dependences of the solubility.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Antiradical and Antioxidant Activity of Phenylhydrazones of Aromatic Aldehydes

E. I. Pleskushkina, A. N. Nikolaevskii, and T. A. Filippenko

Donetsk State University, Donetsk, Ukraine

Received April 29, 2000

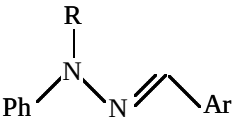
Abstract—With the aim of searching for new antioxidants, including those of the biogenic type, the antioxidant properties of phenylhydrazones of some aromatic aldehydes were studied under conditions of ascorbate-dependent peroxide oxidation of oleic acid residues in Tween-80. Also the reactivity of these hydrazones toward a stable radical, diphenylpicrylhydrazyl, was studied. The correlation between the antioxidant and antiradical activities of phenylhydrazones was examined.

The reactions of free-radical peroxide oxidation of lipids (POL) in biomembranes not only play an important role in the normal cell physiology but also often act as key units of the mechanisms of various pathological states, including the radiation sickness, infection and oncological diseases, etc. [1]. Therefore, search for physiologically active substances exhibiting antioxidant and antiradical properties and favoring normalization of the level of peroxide oxidation of lipids in biomembranes is an urgent problem. It is interesting to study in this respect phenylhydrazones, which exhibit a wide spectrum of physiological activity. It is known that phenylhydrazones (PHs) of some ketones exhibit antitubercular and antiviral activity [2, 3]. Salicylaldehyde benzoylhydrazone inhibits DNA synthesis in cells of radiation-sensitive tissues and is an effective low-toxic radioprotector [4]. It is believed that the pharmacological effect of phenylhydrazone compounds is associated, directly or indirectly, with their effect on the free-radical processes occurring in a living body. Data on the antioxidant activity of phenylhydrazones were obtained only recently [5]. The quantitative evaluation of the antioxidant and antiradical activity of phenylhydrazones will give insight into the mechanisms of their biological effect, on pathways of their transformations in radical processes, and on the structure–antioxidant activity relationships.

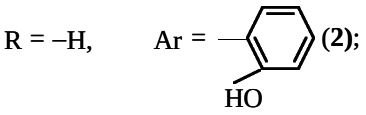
In this work we studied the antiradical and antioxidant activity of phenylhydrazones and the correlation of their reactivity in radical reactions with their composition and molecular structure.

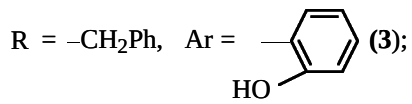
EXPERIMENTAL

The antiradical activity of phenylhydrazones was studied relative to a stable radical, diphenylpicrylhydrazyl (DPPH), as substrate. The reaction was monitored photocolorimetrically with a KFK-3 device. Phenylhydrazones [6] of the formulas



R = –H, Ar = –Ph (**1**);

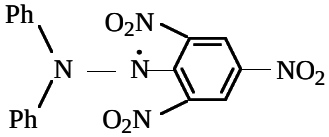




R = –CH_2Ph, Ar = (**3**);

R = –CH_2Ph, Ar = –Ph (**4**)

and DPPH [7]



were prepared and purified by standard procedures. The purity of phenylhydrazones was evaluated by elemental analysis and IR spectroscopy, and that of DPPH, by IR, UV, and ESR spectroscopy. Solutions

1070-4272/01/7405-0792$25.00

of DPPH in hexane ($\varepsilon = 1.4 \times 10^3$ l mol^{-1} mm^{-1}), benzene ($\varepsilon = 1.24 \times 10^3$ l mol^{-1} mm^{-1}), and methanol ($\varepsilon = 1.18 \times 10^3$ l mol^{-1} mm^{-1}) exhibit an absorption maximum in the visible range (520 nm) and are stable in storage. Solutions of phenylhydrazones and DPPH were mixed in an equimolar ratio at 293 K in the range of reactant concentrations 10^{-4}–10^{-5} M, after which variation of the optical density of the DPPH solution was monitored in time and the kinetic curves of DPPH consumption were constructed (DPPH solutions in this concentration range obey the Lambert–Beer law).

The antioxidant activity of phenylhydrazones was studied in oxidation of Tween-80 (polyoxyethylene sorbitan monooleate), which is a model of lipid oxidation. Tween-80 purchased from Laba Chemie Fischamend, Austranal Präparate was used without additional purification. Oxidation of Tween-80 in dilute aqueous solutions was performed for 48–50 h at 313 K in the presence of optimal concentrations of Fe(II) and ascorbic acid. The concentration of malondialdehyde (MDA), which is the peroxidation product, was determined photocolorimetrically from the absorption of a pink complex of MDA with thiobarbituric acid ($\lambda = 540$ nm, $\varepsilon = 1.56 \times 10^4$ l mol^{-1} mm^{-1}) [8]. The performance of phenylhydrazones as antioxidants was evaluated from the decrease in the concentration of malondialdehyde as compared to the control experiment.

Figure 1 shows the kinetic curves of consumption of the DPPH radical in its reaction with phenylhydrazones of salicylaldehyde and benzaldehyde in hexane. Study of the reaction rate as a function of the DPPH and phenylhydrazone concentrations (Fig. 2) showed that the reaction is first-order with respect to both DPPH and phenylhydrazone. Such reaction orders are preserved in hexane for all the compounds studied. Thus, the kinetic equation for the reaction rate can be given as follows:

$$W = k_{app}[\text{DPPH}][\text{PH}].$$

The constants k_{app} calculated by this equation from the initial rates of DPPH consumption are listed in Table 1. It is seen that the rate constants of this reaction depend on the composition and structure of phenylhydrazones. Benzaldehyde benzylphenylhydrazone containing no labile hydrogen atom at nitrogen lacks antioxidant activity. This fact suggests that in the reaction with DPPH the reactive center in the phenylhydrazone molecule is the NH group of the hydrazone moiety. Thus, the reaction pattern can be represented

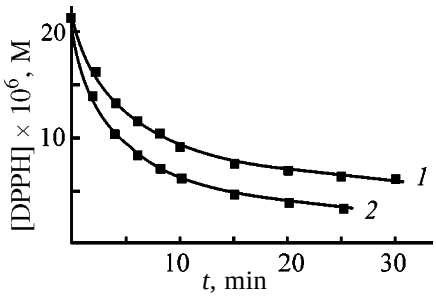


Fig. 1. Kinetic curves of the reactions of DPPH with phenylhydrazones of (*1*) benzaldehyde and (*2*) salicylaldehyde in hexane solution at 293 K. (*t*) Time.

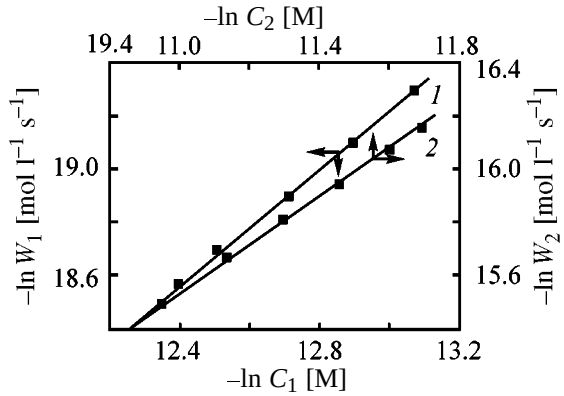

Fig. 2. Rate of reaction of DPPH with benzaldehyde phenylhydrazone as a function of the concentrations of (*1*) phenylhydrazone C_1 and (*2*) DPPH C_2.

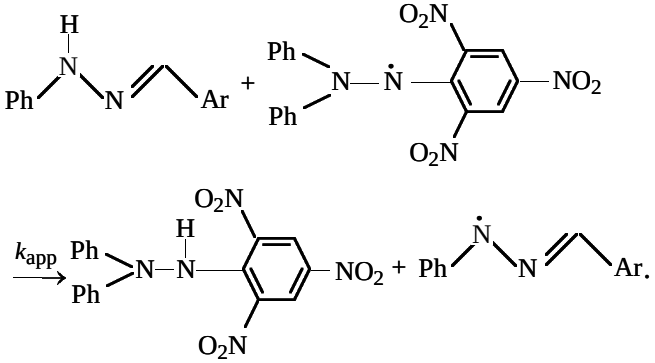
as follows:



The final products of this reaction, along with the reduced form of diphenylpicrylhydrazyl (DPPH–H), are probably recombination products of the phenylhydrazone radicals with DPPH and of two phenylhydrazone radicals.

Comparison of the rate constants for different phenylhydrazones in hexane (Table 1) shows that introduction of the hydroxy group into the aldehyde moiety of the phenylhydrazone (compound **2**) significantly increases k_{app} as compared to **1**. This fact is

Table 1. Kinetic parameters of the reactions of aromatic aldehyde phenylhydrazones with DPPH in various solvents (T = 293 K)

Compd. no.*	k_{app}, l mol^{-1} s^{-1}		
	hexane	benzene	methanol
1	115 ± 5	11 ± 1	6.2 ± 0.6
2	201 ± 7	16 ± 20	155 ± 2
3	0.10 ± 0.01	Weak reaction	3.6 ± 0.5
4	No reaction with DPPH		
5	1.5 ± 0.2	0.27 ± 0.01	4.5 ± 0.6

* Compounds: (**1**) benzaldehyde phenylhydrazone, (**2**) salicylaldehyde phenylhydrazone, (**3**) salicylaldehyde benzylphenylhydrazone, (**4**) benzaldehyde benzylphenylhydrazone, and (**5**) Ionol.

due to additional contribution of the OH group to the reaction with DPPH, which occurs with the homolytic cleavage of the O–H bond. This contribution can be estimated by determining the antiradical activity of the hydrazone containing the hydroxy group in the aldehyde moiety but lacking the labile hydrogen atom at N (compound **3**). Table 1 shows that this activity is low, i.e., the main contribution to the reaction with DPPH (and hence to the antiradical activity) is made by the NH group.

Study of the solvent effect on the reaction kinetics showed that the reaction order is the same in all the tested solvents but the rate constant k_{app} strongly depends on the solvent.

The apparent rate constants of the reaction of DPPH with benzaldehyde phenylhydrazone in various solvents (k_{app}, l mol^{-1} s^{-1}) were measured at various temperatures in the range 293–323 K, and the following relations were obtained:

$$k_{app} = 2.29 \times 10^3 \exp[(-6800 \pm 380)/RT] \quad \text{(hexane)},$$

$$k_{app} = 2.27 \times 10^7 \exp[(-36\,000 \pm 1200)/RT] \quad \text{(benzene)},$$

$$k_{app} = 2.33 \times 10^4 \exp[(-20\,000 \pm 1000)/RT] \quad \text{(methanol)}.$$

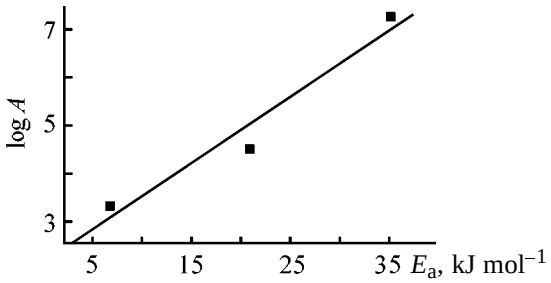


Fig. 3. Correlation between the preexponential term A and activation energy E_a of the reaction of DPPH with benzaldehyde phenylhydrazone in various solvents.

The decrease in the apparent rate constants, increase in the activation energy, and variation of the preexponential term in going from hexane to benzene and methanol show that the reactivity of the hydrazones decreases in going from hexane to benzene and methanol. The logarithm of the preexponential term linearly correlates with the activation energy (Fig. 3), which suggests the presence of a compensating effect. This effect is due to the localized interaction of the reagent with the solvent. For example, in benzene the decrease in the reaction rates is due to the well-known capability of DPPH to form π complexes with aromatic hydrocarbons, in which the radical is considerably less reactive than in the nonsolvated state [9]. In methanol, the reaction center of phenylhydrazone is blocked as a result of hydrogen bonding with the solvent [10]. The decrease in k_{app} and increase in E_a are in this case due to a decrease in the concentration of free, more active phenylhydrazone molecules. A considerably higher rate constant of the reaction with **2** in methanol, as compared to **1**, is due to active participation in the reaction of the hydroxy group in the aldehyde fragment of **2**. Owing to the high dielectric permittivity of methanol, the hydroxy group dissociates in this solvent to a greater extent.

The activity of the examined phenylhydrazones in the reaction with DPPH considerably exceeds that of the commercial inhibitor Ionol.

Our data on the antiradical activity of phenylhydrazones correlate with data on their antioxidant activity in oxidation of ethylbenzene [5]. This fact shows that the antioxidant properties of these compounds are due to their capability for reacting with radicals and confirms the suggested mechanism of the antioxidant action of these compounds in oxidation of hydrocarbons. Study of aromatic aldehyde phenylhydrazones as antioxidants of the ascorbate-dependent peroxide oxidation of oleic acid residues in Tween-80 showed, however, that their activity parameters do not always correlate with the characteristic of the antiradical activity (Table 2). This may be due to specific features of oxidation in this system, and also to possible operation of alternative mechanisms of the antioxidant effect of phenylhydrazones. At present, the mechanism of lipid oxidation in the presence of peroxide oxidation cofactors, Fe(II) and ascorbic acid, is not fully understood. Along with the radical-chain mechanism [1], oxidation by the ionic mechanism [11] is also probable. As seen from Table 2, the antioxidant activity of phenylhydrazones increases in the order **1** < **2** < **4** < **3**. The high antioxidant activity of **3** and **4**, with their low antiradical effect, is due to the possi-

Table 2. Effect of phenylhydrazones of aromatic aldehydes on the rate of accumulation of malondialdehyde (MDA) in oxidation of Tween-80

Compd. no.	MDA concentration $C \times 10^6$, M		Decrease in MDA accumulation rate, %
	control	experiment	
1	1.94	1.46	25
2	2.50	1.47	41
3	2.35	0.67	71
4	1.93	0.65	66

bility of their reaction with hydroperoxides initiating POL and of complexation with iron ions affecting the reaction rate. Also, interaction of oleic acid residues with phenylhydrazones, accompanied by structural changes, can enhance the oxidation resistance of the system.

CONCLUSIONS

(1) The kinetic study of the reactions of aromatic aldehyde phenylhydrazones with a stable radical, diphenylpicrylhydrazyl, in various solvents showed that the parameters of the antiradical activity of phenylhydrazones depend both on the compound structure and on the solvent.

(2) Reactions of diphenylpicrylhydrazyl with phenylhydrazones involve abstraction of hydrogen atom from the NH group of the hydrazone moiety. The contribution of the hydroxy group in the aldehyde moiety to the antiradical activity of phenylhydrazones is significant only in methanol.

(3) The antiradical activity of phenylhydrazones correlates with their antioxidant activity in oxidation of hydrocarbons and does not fully correlate with their antioxidant activity in ascorbate-dependent peroxide oxidation of oleic acid residues in Tween-80 in aqueous solutions. This is due to specific features of oxidation of this system and to possible operation of alternative mechanisms of antioxidant action.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Determination of the Esterification Degree of Polygalacturonic Acid

A. M. Bochek, N. M. Zabivalova, and G. A. Petropavlovskii†

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received January 16, 2001

Abstract—The number of free and esterified carboxy groups of polygalacturonic acid was determined by conductometric titration.

Pectins are abundant in nature. They are present in almost all plants and, in relatively great amounts, in fruits and vegetables [1]. Pectins are also contained in pedicels and plant fibers [2–5]. Pectins are conventionally used in food and pharmaceutical industries and in cosmetics [1, 6, 7].

The number of methoxylated groups of pectin (polygalacturonic acid, PGA) is one of the main parameters determining the properties of its aqueous solutions and gels. The solubility of pectin in water, its gelating power, and sorption properties with respect to heavy metal ions also depend on the number of methoxy groups. The content of methoxy groups in a PGA molecule is characterized by the number of methoxy groups K_{MeO} and the esterification degree (ED, number of esterified carboxy groups per the total number of carboxy groups):

$$ED = (K_e/K_t) \times 100 = [(K_t - K_f)/K_t] \times 100 = [(1 - K_f)/K_t] \times 100, \quad (1)$$

where K_e is the number of esterified carboxy groups; K_f the number of free carboxy groups; and K_t is the total number of carboxy groups, $K_t = K_f + K_e$.

The esterification degree is usually determined by potentiometric titration and by the Ca acetate procedure [1, 8].

When the potentiometric procedure is used, the number of esterified groups is determined by back-titration. It should be noted that determination of both the number of esterified carboxy groups and free carboxy groups contributes to the determination error of ED of pectins. In addition, since polygalacturonic acid is a weak acid, the equivalence point of the titration cannot be precisely determined. We developed a conductometric titration procedure for more accurate determination of the number of free and esterified carboxy groups of pectins.

† Deceased.

EXPERIMENTAL

We studied apple pectin. Its ED was determined by potentiometric titration and conductometric titrations.

When the number of free carboxy groups K_s of PGA was determined by the potentiometric procedure, a weighed portion of the pectin (0.2 g) was placed in a weighing bottle for titration and wetted with ethanol. Distilled water heated at 40°C (20 ml) was added with stirring. The polymer was dissolved with stirring for 2 h. The resulting solution was titrated with 0.1 N NaOH in the presence of phenolphthalein to pail rose color. The pH of the solution was also measured by a laboratory pH meter. The number of free carboxy groups (%) was calculated by the equation

$$K_f = \frac{N_{NaOH} V_{NaOH} \times 0.045}{a} \times 100, \quad (2)$$

where a is the weighed portion of pectin with absorbed water (g); N_{NaOH} and V_{NaOH} the normality and volume (ml) of the alkali solution spent for titration.

The number of esterified carboxy groups (K_e) was determined as follows. 0.1 N NaOH solution (10 ml) was added to a neutralized PGA sample after deter-

1070-4272/01/7405-0796$25.00

mination of the free carboxy groups. The weighing bottle was plugged with a stopper. The content was stirred at room temperature for 2 h to saponify the esterified carboxy groups of the polymer. Then 0.1 N HCl (10 ml) was added. Excess HCl was titrated with 0.1 N NaOH. The number of the esterified carboxy groups was calculated from the volume of 0.1 NaOH solution spent for titration:

$$K_e = \frac{N_{NaOH} V_{NaOH} \times 0.045}{a} \times 100. \quad (3)$$

The total number of the COOH groups (%) is equal to the sum of the free and esterified groups: $K_t = K_f + K_e$.

The number of methoxy groups in PGA can be calculated from the ED by the equation:

$$K_{MeO} = \frac{100ED \times 31}{176 + ED \times 14}, \quad (4)$$

where ED is necessarily expressed in fractions of unity.

The conductometric determination of the number of carboxy groups by was performed similarly.

To determine the total amount of carboxy groups, 0.1 N NaOH (10 ml) was added with the aid of a volumetric pipet to a neutralized sample after determination of the free carboxy groups. The weighing bottle was plugged with a stopper. The content was stirred at room temperature for 2 h to saponify the esterfied carboxy groups of the polymer. The polymer solution was titrated with 0.1 N HCl. The equivalence point was determined form the conductometric titration curves (see Fig. 1a, curve *2*). The total content of the carboxy groups, %, of the polymer was calculated by the equation:

$$K_t = \frac{N_{HCl} V_{HCl} \times 0.045}{a} \times 100, \quad (5)$$

where $V_{HCl} = V_2 - V_1$.

The number of esterified carboxy groups was calculated as $K_e = K_t - K_f$.

As seen from Fig. 1b, neutralization of free COOH groups of pectin is completed at pH 8.5–9.0 (curve *1*). The equivalence point is rather blurred. Usually the titration is performed in the presence of phenolphthalein to appearance of a pail-rose color of the solution [1]. It should be noted that the color of the indicator

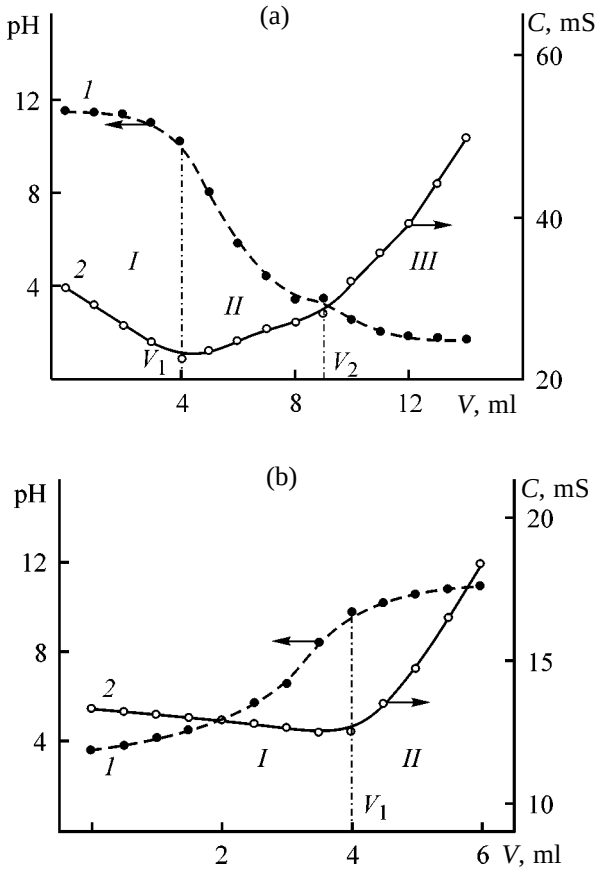

Fig. 1. (*1*) Potentiometric and (*2*) conductometric titration curves constructed for determination of (a) the total number of carboxy groups and (b) the number of free carboxy groups in PGA. (*C*) Electrical conductivity; (*V*) the volume of (a) 0.1 N HCl or (b) 0.1 N NaOH added to the sample.

changes from colorless to rose in a relatively wide pH range (8.2–10.0), which can results in appreciable error. The conductometric procedure is free of this drawback. In this case the electrical conductivity of the solution is measured. The electrical conductivity depends on the mobility, concentration, and nature of the ions present in the solution. The mobility of protons is the highest and it decreases in going to OH^- and then to single-, double-, and higher charged ions. The conductometric titration curve of PGA (Fig. 1b) has a minimum and consists of two sections. Section I is due to conversion of the COOH groups into COONa groups. In the course of this process the proton concentration in the solution decreases and the concentration of Na^+ cations increases owing to dissociation of the COONa groups. Since polygalacturonic acid is a weak acid, its carboxy groups are incompletely dissociated in a solution. Sodium polygalacturate is dissociated completely. The slight decrease in

Esterification degree ED and the concentration of methoxy groups K_{MeO} in PGA, determined by potentiometric and conductometric titration

Method	ED	K_{MeO}
	%	
Potentiometric	72.30 ± 0.35	12.04
Conductometric	67.8 ± 0.15	11.30
Published data	60.0 – 68.0	10.0 – 11.4

the electrical conductivity during titration is caused by the fact that the effect of the introduced Na^+ cations cannot compensate for the decrease in the conductivity due to consumption of H^+ ions, because Na^+ ions are less mobile than protons. As excess NaOH appears after completion of neutralization of the COOH groups the conductivity sharply increases proportionally to the concentration of OH^- and Na^+ ions (section *II*). Thus, conductometric titration allows more reliable and accurate, as compared to the potentiometric titration, determination of the equivalence point of neutralization of the pectin COOH groups with NaOH (Fig. 1b).

The titration curves of PGA saponified with an HCl solution are shown in Fig. 1a. The completion of neutralization of unreacted alkali with hydrochloric acid and the onset of protonation of ionized carboxy groups

$$R–COONa + HCl = R–COOH + NaCl$$

can be determined in the presence of the same indicator from the potentiometric titration curve (curve *1*). The conversion of COONa groups into COOH groups (and appearance of free HCl) is completed at pH 3.2–3.5 and is difficult to detect. Hence in the case of the potentiometric titration the additional manipulation is used: after pectin saponification an HCl solution is added in the amount equivalent to that of NaOH solution used for PGA saponification. The alkali not spent in the saponification is neutralized with the acid. The number of esterified (saponified) carboxy groups in a PGA sample is calculated from the results of titration of the excess acid with an NaOH solution [1].

The above operations are eliminated when the conductometric procedure is used (curve *2*). A saponified pectin sample is titrated with an HCl solution and the total number of carboxy groups in the polymer is determined. Two sharp knees in the titration curves divide it into three sections. Section *I* is assigned to neutralization of the strong base with the strong acid. After the neutralization the concentration of OH^- anions and hence the electrical conductivity decrease. Section *II* is due to conversion of the sodium form of the carboxy groups into the H form. The increase in the electrical conductivity of the solution is typical for titration of a weak acid salt with a strong acid, i.e., is proportional to the proton concentration formed by dissociation of the weak polyacid. Finally section *III* is due to appearance of free HCl. The electrical conductivity increases more sharply owing to an increase in the proton concentration in the solution. Thus, conductometric titration, unlike the potentiometric procedure, allows reliable determination of the onset and the end of protonation of ionized carboxy groups with HCl. Section *II* corresponds to the total amount of PGA carboxy groups. The esterification degree as the arithmetic mean of five measurements performed by the potentometric and conductometric procedures is presented in the table. As seen from the table, the scatter of ED determined by potentiometric titration is higher than that of ED determined by conductometric titration. The average ED of apple pectin determined by conductometric titration agrees well with the published data (ED 0.60 – 0.68). At the same time, ED and K_{MeO} obtained by the potentiometric titration are slightly overestimated [1]. The reasons of the overestimation were discussed above. Thus, conductometric titration allows determination of the esterification degree of polygalacturonic acid with higher accuracy as compared to the potentiometric procedure.

CONCLUSION

Advantages of the conductometric titration over potentiometric titration in determination of the esterification degree were demonstrated.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thermal Chlorination of Methyltrichlorosilane

M. G. Voronkov, V. K. Stankevich, B. F. Kukharev, and K. A. Abzaeva

Irkutsk Institute of Chemistry, Siberian Division, Russian Academy of Sciences, Irkutsk, Russia

Received October 12, 1999; in final form, February 2000

Abstract—The procedure for thermal chlorination of methyltrichlorosilane to chloromethyltrichlorosilane in a circulation flow system was developed. The yield of $ClCH_2SiCl_3$ was studied as influenced by the reaction temperature and the reactant ratio.

Chloromethyltrichlorosilane, $ClCH_2SiCl_3$ (CMTS), is a valuable reagent for preparing carbofunctional organosilicon monomers and polymers (surface-modifying and cross-linking agents, adhesion promoters, immobilized catalysts, etc. [1–6]) and is used in synthesis of sorbents, ion exchangers, and bioprotecting coatings. This compound is also a precursor of widely used biostimulant, 1-(chloromethyl)silatrane (Mival) [7, 8]. Chloromethyltrichlorosilane is usually prepared by free-radical chlorination of methyltrichlorosilane (MTS) with gaseous chlorine:

$$Cl_2 + CH_3SiCl_3 \rightarrow ClCH_2SiCl_3 + HCl.$$

The reaction is performed either in the vapor phase on exposure to UV [9, 10] or visible [11] radiation or in a solution in the dark in the presence of azobis(isobutyronitrile) as the initiator [9, 10]. It should be noted that, since chlorination of mono- and dichloromethyltrichlorosilanes ($ClCH_2SiCl_3$ and $Cl_2CHSiCl_3$) is considerably faster than that of the initial MTS, the monochloro derivative is prepared at its continuous removal form the reaction mixture or at a large excess of MTS. The first procedure is based on photochemical chlorination of $MeSiCl_3$ vapor with gaseous chlorine on exposure to UV [9, 10] or visible light [9].

Large-scale photochemical chlorination of MTS is complicated by the lack of industrial reactors containing parts made form optical quartz and by the need for intermittent removal of the polymeric film absorbing UV–Vis radiation from the surface of the transparent window or from the built-in light sources. It is difficult to construct powerful photochemical reactors since the light intensity decreases proportionally to the square of the distance form the light source. In some cases the photochemical reaction can be accompanied by spontaneous combustion or explosion of a mixture of gaseous reactants [10]. The industrial process of dark chlorination of MTS in the presence of asobis(isobutyronitrile) is performed in a distillation column under inversion conditions (the temperature in the reaction zone and in the still is 64 and 110°C, respectively) [12]. The CMTS yield based on the spent $MeSiCl_3$ is 75%. In this case the steady-state inversion conditions in the upper part of the column and the working temperature in the reaction zone are difficult to maintain, and large amount of the expensive initiator and large excess of $MeSiCl_3$ are required. In addition, $Cl_2CHSiCl_3$ and Cl_3CSiCl_3 are formed in considerable amounts, i.e., the selectivity of the process is low.

Another procedure for preparing CMTS is based on photochemical chlorination of $MeSiCl_3$ with sulfuryl chloride [13, 14]:

$$SO_2Cl_2 + CH_3SiCl_3 \xrightarrow{h\nu} SO_2 + ClCH_2SiCl_3 + HCl.$$

This reaction is catalyzed by yttrium chloride, lanthanum chloride, and manganese chloride [14]. Although this procedure does not require complex equipment, it is more expensive as compared to the chlorination with gaseous chlorine.

We developed a new procedure for preparing CMTS by chlorination of $MeSiCl_3$ with gaseous chlorine at 300–400°C in a circulation system.

This reaction occurs by the radical mechanism similar to that of thermal chlorination of alkanes [15]. The chain propagation involves formation of Cl and CH_2SiCl_3 radicals:

$$Cl_2 \xrightarrow{300\text{–}400^\circ C} 2Cl^{\cdot},$$

$$Cl^{\cdot} + CH_3SiCl_3 \rightarrow CH_2SiCl_3 + HCl,$$

$$Cl_2 + {}^{\cdot}CH_2SiCl_3 \rightarrow ClCH_2SiCl_3 + Cl^{\cdot}.$$

* α is the MTS conversion.
** Yield of CMTS based on reacted and initial (in parentheses) MTS.

It is known that the rate constants and activation energies of radical-chain consecutive chlorination reactions yielding mono-, di-, and trichloro derivatives are almost the same [15]. Hence, for CMTS to be selectively formed, large excess of MTS with respect to chlorine should be used and CMTS being formed should be removed from the reaction mixture.

The chlorination was performed at $MeSiCl_3 : Cl_2$ ~100 : 1 (see table). At 350°C the selectivity of the process (the CMTS yield based on consumed MTS) was higher than 82% and the MTS conversion in 12 h was 51%. With a larger MTS excess, the output of CMTS is lower. At $MeSiCl_3 : Cl_2$ = 25 : 1 49.5% of MTS is converted within 6 h; however the selectivity decreases to 77%. Thus, taking into account the output of the reactor and the process selectivity, the $MeSiCl_3 : Cl_2$ molar ratio can be varied from 25 : 1 to 100 : 1 depending on the technical and economical requirements.

The temperature influence on the MTS chlorination is similar to that of alkane chlorination. With increasing temperature the reaction is accelerated, and its selectivity decreases. In addition, at 500°C the reactor nozzle is strongly clogged with coke.

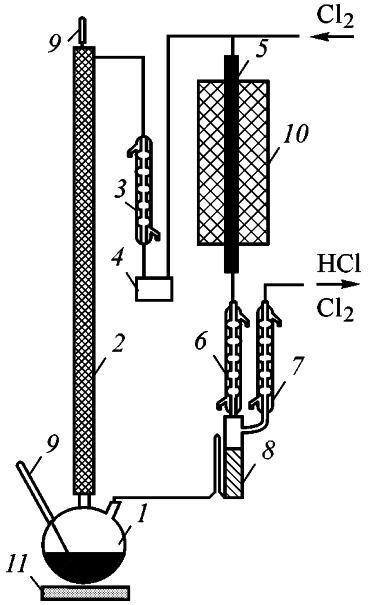
At the same time the process occurs even at 250°C. However, in this case, despite high selectivity (the CMTS yield based on consumed MTS is 86%), a 9% conversion of MTS is reached only in 20 h.

Thus, as seen from the table, the best reaction temperature is 350–400°C.

EXPERIMENTAL

Methyltrichlorosilane was chlorinated on a circulation unit (see figure). The unit consists of a 0.5-l heated flask (*1*), connected through a packed column (*2*) and a condenser with a dosing apparatus and then with an electrically heated flow reactor. The reactor is connected with two condensers (straight-run *6* and reflux *7*). The condensate formed in the first condenser goes in the accumulator with a siphon and then back in the flask. Gaseous HCl and unchanged Cl_2 pass to the absorbers through the reflux condenser. The reactor is a quartz tube 12.5 mm in diameter and 250 mm long, packed with quartz chips.

An MTS vapor formed in the flask passes through the packed column, is condensed in the condenser, and is fed into the dosing apparatus form which it is fed with a controlled rate to the reactor heated to



Scheme of the unit for gas-phase thermal chlorination of methyltrichlorosilane: (*1*) 0.5-l flask, (*2*) packed column, (*3, 6, 7*) condensers, (*4*) dosing pump, (*5*) reactor, (*8*) condensate accumulator, (*9*) thermometer, (*10*) tubular furnace, and (*11*) electric heater.

300–400°C. Chlorine is fed simultaneously form a cylinder. The flow rate of chlorine is measured with a rheometer. The flask temperature in the first and final steps of the process is 65 and 105°C, respectively. The temperature of the column head is about 65°C. The $MeSiCl_3 : Cl_2$ molar ratio at the outlet of the reactor was maintained constant.

An example of the CMTS synthesis is presented below. Methyltrichlorosilane (149.5 g, 1 mol) is placed in the still of the packed column and is heated to boil. When the temperature of the top of the column reaches 65°C, MTS condensate formed in the condenser is fed into the dosing apparatus and then with a 830 g h^{-1} (5.55 mol h^{-1}) flow rate into the reactor heated to 350°C. Simultaneously gaseous chlorine is fed with a 1.18 l h^{-1} (0.0526 mol h^{-1}) flow rate into the reactor. The $MeSiCl_3 : Cl_2$ molar ratio is 105 : 1. The process lasts for 12 h. In this period 14.2 l (0.63 mol) of chlorine is passed through the system. Fractionation of the bottoms on a 20-TP column yields the initial MTS (73.1, 0.49 mol) with bp 65–66°C (720 mm Hg) and CMTS (77.3 g, 0.42 mol) with bp 117–119°C (720 mm Hg), n_D^{20} = 1.4530, d_4^{20} = 1.4420, and a 99.7% purity determined by GLC {published data [14]: bp 118–120°C (760 mm Hg), n_D^{20} = 1.4530}.

Found (%): C 6.56, H 1.03, Cl 77.00, Si 15.07, 6.25, 1.12, 76.91, 15.14.
CH_2Cl_4Si.
Calculated (%): C 6.53, H 1.10, Cl 77.10, Si 15.27.

The CMTS yield based on the initial $MeSiCl_3$ and spent MTS is 82.2 and 42%, respectively. The MTS conversion is 51.1%.

The weight of the remaining bottoms is 10.2 g. As determined by GLC, the bottoms contain 31% $Cl_2CHSiCl_3$ and 69% Cl_3CSiCl_3. $Cl_2CHSiCl_3$ (2.6 g, 0.012 mol) was isolated by fractionation of the bottoms; bp 141–142°C (720 mm Hg), 99.3% purity determined by GLC, n_D^{20} = 1.4715, d_4^{20} = 1.5503 {published data [14]: bp 144°C (760 mm Hg), n_D^{20} = 1.4715}.

Found (%): C 5.40, H 0.41, Cl 81.27, Si 12.32, 5.44, 0.53, 81.21, 13.05.
CH_2Cl_5Si.
Calculated (%): C 5.50, H 0.46, Cl 81.18. Si 12.86.

The purity of the chlorine-containing products was determined by GLC on an LKhM-80 chromatograph equipped with a catharometer. Helium was the carrier gas. A 3000 × 3 mm steel column was packed with 3% OV-17 on Inerton Super (0.160–0.200 mm). The column was heated form 40 to 180°C at a rate of 4 deg min^{-1}.

The ^1H NMR spectra were recorded at 25°C on a Tesla 480 C spectrometer operating at 80 MHz, with TMS as the internal reference. The spectra of $ClCH_2SiCl_3$ and $Cl_2CHSiCl_3$ contain only one singlet at 3.24 and 5.44 ppm, respectively. The chemical shifts agree with the published data [14].

The ^{35}Cl NQR spectrum of $ClCH_2SiCl_3$ recorded on an IS-3 spectrometer contains the following signals, ν^{77}, MHz: 36.77 ($ClCH_2$); 19.555, 19.470 ($SiCl_3$) (cf. [16]).

CONCLUSION

Thermal chlorination of methyltrichlorosilane with elemental chlorine in the gas phase at 300–400°C yields chloromethylchlorosilane in a 63–82% yield based on reacted $MeSiCl_3$.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of the Medium on the (Co)polymerization Kinetics and Properties of *N*-Vinyl-3(5)-methylpyrazole (Co)polymers

N. A. Lavrov

St. Petersburg State Technological Institute, St. Peterburg, Russia

Received December 27, 2000

Abstract—The kinetics of homopolymerization of *N*-vinyl-3(5)-methylpyrazole and its copolymerization with vinyl acetate, 2-hydroxyethyl methacrylate, and acrylic acid, as influenced by the reaction medium, were studied. The properties of the resulting (co)polymers were determined.

(Co)polymers of *N*-vinyl-3(5)-methylpyrazole (VMP) show promise in preparation of coatings, adhesives, films, flocculants, ion-exchange resins, physiologically active substances, etc. [1, 2]. Various procedures were developed for preparing VMP (co)polymers: radical (co)polymerization in the bulk, in an organic solvent, in suspension, in emulsion, or in aqueous-organic media; there are indications that the (co)polymerization can be initiated by ionizing radiation [1, 3–8]. By varying the nature of the comonomer, the composition of the monomeric mixture, and the reaction conditions, it is possible to prepare copolymers with various molecular weights and solubilities, including water-soluble products.

However, published papers, as a rule, are applied and do not involve the kinetic analysis of (co)polymerization; the possibility of controlling the reactivity of the monomers by varying the process conditions and the reaction medium is not examined. Only scarce data are available on the properties of VMP (co)polymers, in particular, of VMP–vinyl acetate (VA) copolymers prepared in the bulk [9]. This paper considers the effect of the medium (comonomer, initiator, solvent) on the kinetic features of the synthesis of VMP (co)polymers and on their properties.

VMP–VA copolymers were prepared by three procedures: in the bulk, in emulsion, and in aqueous-organic solutions. Bulk copolymerization was performed at 70°C with azobis(isobutyronitrile) (AIBN) as initiator (0.1–1.0% relative to the total weight of the monomers); the copolymers were prepared and isolated as described in [10]. Copolymerization in aqueous emulsion was performed at 60°C using the initiating system manganese tris(acetylacetonate)–acetic acid. The initiator concentration was 3.4×10^{-3} M; the emulsifier, sodium laurylsulfonate or Sol'var (VA–vinyl alcohol copolymer with the mole fraction of VA units of 0.12), was added in an amount of 24–29 g l^{-1}; the polymers were prepared and isolated as described in [11]. Copolymerization in a water–dimethyl sulfoxide (DMSO) mixture was performed at 25–45°C with the initiating system ammonium persulfate (AP)–ascorbic acid (AscA); the concentration of the monomers was 1–2 M, and that of the components of the initiating system, 0.02–0.2 M; the copolymers were prepared and isolated as described in [5].

Copolymers of VMP with 2-hydroxyethyl methacrylate (HEMA) and with acrylic acid (AA) were prepared in a water–DMSO mixture at 25–45°C. Copolymerization of the monomers and isolation of the reaction products were performed according to [12, 13]; the component concentrations were similar to those used in copolymerization of VMP with VA. Base hydrolysis of VMP–VA copolymers was performed according to [14].

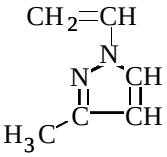
Samples for physicomechanical, thermal, and dielectric tests were prepared and the properties of the (co)polymers wee determined by the procedures in [15]. The thermal analysis was performed according to [16]. The composition of the copolymers was determined from the nitrogen content using a CHN analyzer. The copolymerization constants were calculated taking into account the monomer conversion [17].

A structural feature of the VMP molecule is p–π conjugation between the lone electron pair of the nitrogen atom and the double bond of the vinyl group. As a result, the electron density on the double bond increases. This feature is typical of *N*-vinyl compounds and determines the electron-donor character of VMP.

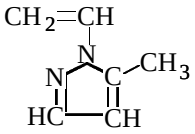
1070-4272/01/7405-0804$25.00

Although the VMP heterocycle contains two nitrogen atoms imparting the acceptor properties to the heterocycle, this fact will not reduce significantly the polarity of the vinyl group. For example, vinylazoles containing two and more nitrogen atoms in the heterocycle are regarded as electron-donor monomers [18]. The donor properties of VMP should be more pronounced than those of *N*-vinylsuccinimide (VSI) whose molecule contains two electron-withdrawing carbonyl groups. The electron-donor character of VMP should facilitate its radical copolymerization with electron-withdrawing monomers.

The existing synthesis procedures allow preparation of VMP as a mixture of two isomers: *N*-vinyl-3-methylpyrazole and *N*-vinyl-5-methylpyrazole:



N-Vinyl-3-methylpyrazole



N-Vinyl-5-methylpyrazole

Irrespective of the catalyst used, the ratio of the 3-methyl and 5-methyl isomers in the monomer is 60 : 40 [4]. The heterocycle of the VMP molecule contains double bonds. Therefore, conjugation in this molecule is stronger than in VSI. It can be expected that the VMP monomer will be more active in copolymerization than VSI. However, the activity of the VMP radical should be relatively low.

Our experimental results are nicely consistent with theoretical analysis of the structural features and reactivity of VMP.

Kinetic study of bulk copolymerization of VMP with VA showed that the reaction rate increases to a definite limit with increasing AIBN concentration. At similar reaction times, the conversion of the monomers increases as the AIBN concentration is increased from 0.1 to 0.5 wt %, but at higher AIBN concentrations the conversion did not increase further. As the relative content of VMP in the initial mixture is increased, the overall copolymerization rate increases (Fig. 1). At the same time, the homopolymerization rate is higher for VA than for VMP. These facts show that the VMP radical is more active than the VA radical. The shape of the dependences shown in Fig. 1 suggests occurrence of the gel effect characteristic of radical (co)polymerization in the bulk and associated with occlusion of the macroradicals in the polymer matrix; as a result, the chain termination rate constant abruptly decreases.

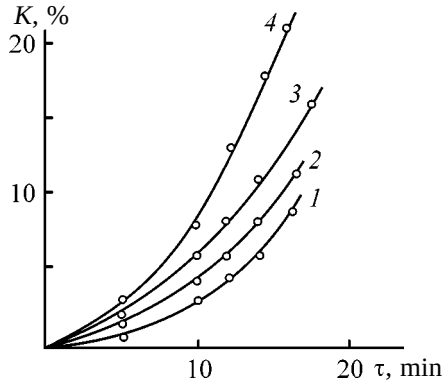


Fig. 1. Conversion of monomers *K* as a function of copolymerization time τ. AIBN content 0.5% relative to the weight of the monomers. VMP mole fraction in the monomer mixture: (*1*) 0.05, (*2*) 0.10, (*3*) 0.15, and (*4*) 0.25.

The copolymers are enriched in VMP units as compared to the initial mixture (Table 1). The VA–VMP copolymerization constants (Table 2) show that VMP is considerably more active. The r_1/r_2 ratio shows that

Table 2. Copolymerization constants of VMP (M_1) with other monomers (M_2)

Comonomer M_2	Copolymerization	T, °C	r_1	r_2	r_1/r_2
VA	Bulk	70	6.90 ± 0.10	0.03 ± 0.01	230
	Emulsion	60	1.58 ± 0.26	0.10 ± 0.02	15.8
	In H_2O–DMSO	25	4.20 ± 0.07	0.01 ± 0.01	420
HEMA	"	25	0.03 ± 0.01	1.94 ± 0.10	0.015
AA	"	25	0.02 ± 0.01	1.54 ± 0.20	0.013

the rate constant of the reaction of VMP macroradical with VMP monomer exceeds by a factor of 230 the rate constant of the reaction of VA macroradical with VA monomer. The calculated relative activities of the monomers toward radicals $1/r$ show that in the course of copolymerization VA reacts faster with VMP radical than with VA radical.

Comparison of the VMP–VA copolymerization constants with the results obtained from studies of the bulk copolymerization of VSI with VA (r_{VSI} = 5.1, r_{VA} = 0.17, r_{VSI}/r_{VA} = 30) [19] shows that the activities of VMP and VA differ to a greater extent than those of VSI and VA, i.e., VMP is a more active monomer than VSI. The same conclusion follows from the Alfrey–Price parameters calculated for VMP. Taking for VA Q = 0.026 and e = –0.22 [20], we obtain for VMP Q = 1.14 and e = –1.47, whereas for VSI Q = 0.13 and e = –0.34 [20].

Preparation of polymers in aqueous media is advantageous from the technological and environmental viewpoints. With high-performance initiating systems, the reaction temperature can be decreased, and the process can be made power-saving. Therefore, we examined the possibility of preparing VMP polymers in aqueous solutions in the presence of emulsifiers, and also in aqueous-organic mixtures.

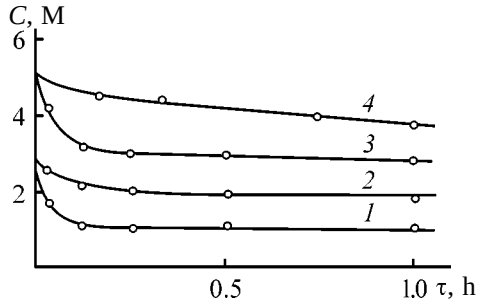

Fig. 2. Concentration C in the reaction mixture: (*1*) VMP, (*2*) VA, and (*3*, *4*) total of monomers, as a function of copolymerization time τ, with (*1*–*3*) Sol'var and (*4*) sodium laurylsulfonate as emulsifiers. Concentrations, M: $Mn(acac)_3$ 3.4×10^{-3} and CH_3COOH 0.84.

Kinetic study of the (co)polymerization of VMP with VA in emulsion in the presence of the initiating system $Mn(acac)_3$–CH_3COOH showed that under these conditions it is possible to prepare both homopolymers of VMP and VA and their copolymers of a wide range of compositions. Homopolymerization of VA is faster (13.8×10^{-3} mol l^{-1} s^{-1}) than that of VMP (8.32×10^{-3} mol l^{-1} s^{-1}), which is due to the higher activity of the VA radical as compared to VMP. VMP monomer is more active than VA monomer; therefore, similar to bulk copolymerization, VMP is consumed in the monomer mixture faster than VA (Fig. 2, curves *1*, *2*). The gel effect characteristic of bulk copolymerization is not manifested in this case. Sol'var as emulsifier is more efficient than sodium laurylsulfonate, as it ensures higher copolymerization rates (Fig. 2, curves *3*, *4*). Emulsion copolymerization does not require elevated temperatures; it can be performed in the range 20–60°C [21].

Similar to bulk copolymerization, the copolymers are enriched in VMP units (Table 1). With increasing conversion of monomers, the differences in compositions are leveled out. The copolymerization constants for the emulsion process differ less significantly than those for the bulk copolymerization (Table 2). This may be due to complexation of VA monomer with $Mn(acac)_3$ [22], affecting the VA reactivity and increasing its relative activity in copolymerization with VMP owing to polarization of the double bond in VA. VMP monomer forms no complexes with $Mn(acac)_3$, as such complexation is characteristic of vinyl esters only [22].

VMP monomer is water-insoluble; therefore, its (co)polymers cannot be prepared in aqueous solutions. We have studied the solubility of VMP and its mixtures with other monomers (VA, HEMA, AA) in aqueous-organic media (water–acetone, water–dimethylformamide, water–DMSO) and examined the possibility of preparing (co)polymers in these media using the redox initiating systems AP–AscA, AP–sodium sulfite, etc. The best results were obtained with the system AP–AscA in a water–DMSO mixture [23].

The reaction can be performed at 25–45°C. Copolymerization of VMP with VA in the presence of the system AP–AscA occurs with an induction period which is longer when the reaction is performed in air. Furthermore, in the presence of atmospheric oxygen the reaction decelerates (Fig. 3a, curves *3*, *5*). Increase in the total concenration of monomers from 1 to 2 M has virtually no effect on the copolymerization rate; the experimental points fall on a common kinetic straight line. Therefore, taking into account the solubility of the monomers in water–DMSO mixtures, it is not appropriate to take the monomers in concentrations higher than 1 M.

Under the chosen conditions, it is possible to prepare both VMP–VA copolymers of a wide composition range and VMP homopolymers. However, the VA homopolymerization under these conditions does not occur even at the concentration of the initiating system increased to 0.2 M. This is probably due to the inhibiting effect of atmospheric oxygen dissolved in water.

The monomer ratio significantly affects the copolymerization rate and the copolymer yield. Similar to the bulk process, VMP monomer is more active: The reaction rate and the copolymer yield increase with increasing contyent of VMP in the monomer mixture (Fig. 3a, curves *2–4*), and the copolymer is enriched in VMP as compared to the initial mixture (Table 1). In the course of the reaction, with increasing conversion the content of VMP in the copolymer decreases, becoming close to the composition of the monomer mixture. The copolymerization constants are as follows: $r_{VMP} = 4.20 \pm 0.07$ and $r_{VA} = 0.01 \pm 0.01$. The activation energy of copolymerization in the range 25–45°C was 41.2 kJ mol^{-1}, which is close to the values obtained for polymerization of the other monomers in the presence of this initiating system [24].

The copolymerization rate and the copolymer yield are affected by the water : DMSO ratio (Fig. 3b). This is probably due to different solubilities of the monomers and copolymer in water and in DMSO and to the heterophase nature of the process, which affects the rates of the elementary reaction events. The effect of the medium on the reaction kinetics was also noted for homopolymerization of VMP in water–acetone mixtures [25].

Copolymerization of VMP with HEMA is sufficiently fast at room temperature; the yield of the copolymer in 1 h exceeds 80% at the monomer ratio varied in a wide range. Similar to copolymerization of VMP with VA, an induction period is observed. In

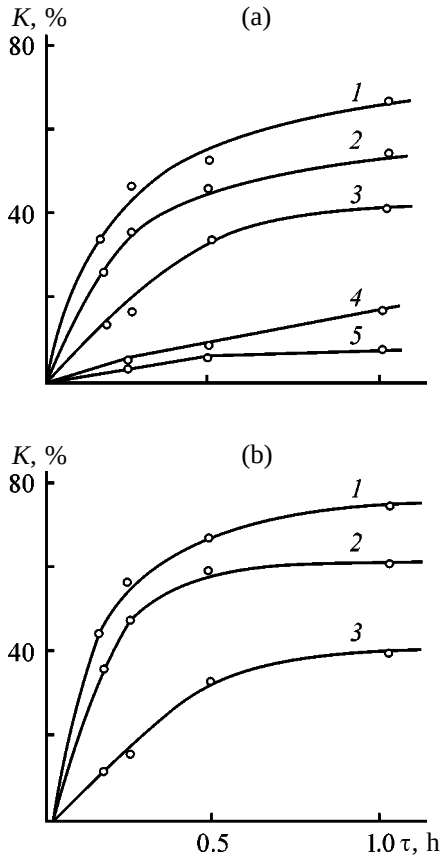

Fig. 3. Conversion of monomers *K* (*1–4*) in argon and (*5*) in air as a function of copolymerization time τ. Concentration, M: monomers 1.0; AP and AscA 0.02 M each. 25°C. copolymerization with *N*-vinyl compounds, HEMA is more reactive [26]. The same trend is observed with VMP: The reaction rate increases from 2.2×10^{-4} to 2.8×10^{-4} mol l^{-1} s^{-1} as the mole fraction of the less active monomer VMP is decreased from 0.75 to 0.25; the copolymer is enriched in HEMA units as compared to the composition of the initial monomer mixture (Table 3).

The copolymerization rate constants were as follows: $r_{VMP} = 0.03 \pm 0.01$ and $r_{HEMA} = 1.94 \pm 0.10$. With conversion, the content of the less active monomer, VMP, in the copolymer increases, approaching its content in the initial monomer mixture (Table 3), which corresponds to the copolymerization constants $r_1 < 1$ and $r_2 > 1$ and is characteristic of copolymerization of *N*-vinyl compounds with acrylates.

Similar trends were also observed in copolymerization of VMP with AA: The copolymers were enriched

in AA units as compared to the initial monomer mixtures (Table 3); the copolymerization constants are listed in Table 2.

The probability of diad formation and the statistical mean length of blocks and chains of VMP–VA copolymers are largely affected by the reaction medium (Table 4).

Since the rate constant of the reaction of VMP macroradical with VMP monomer considerably exceeds the rate constant of the reaction of VA macroradical with VA monomer, the probability of formation of VMP–VMP diads is higher compared to VA–VA diads. For copolymerization in the bulk and in the water–DMSO mixture, this relation is observed at any content of VMP in the monomer mixture. In emulsion copolymerization, this is characteristic of monomer mixtures with the mole fraction of VMP greater than 0.3. In the copolymer prepared in the water–DMSO

mixture, the content of diads with alternating units is higher than in the product of bulk copolymerization but lower than in the product of emulsion copolymerization.

In copolymers of VMP with acrylic monomers, the relation is inverse (Table 5): The probability of formation of VMP–VMP diads is lower compared to HEMA–HEMA or AA–AA diads at a mole fraction of VMP less than 0.9.

By comparing the copolymerization constants (Table 2) and the probabilities of diad formation in copolymer chains (Tables 4, 5), we can compare the relative activities of VMP, VSI, VA, HEMA, and AA in copolymerization. The ratio r_1/r_2 suggests that AA in copolymerization with VMP is more active than HEMA: r_{AA}/r_{VMP} = 77 and r_{HEMA}/r_{VMP} = 64.7. However, it is seen from Table 5 that the probability of formation of HEMA–HEMA diads in copolymerization of VMP with HEMA is higher than that of formation of AA–AA diads in copolymerization of VMP with AA at any monomer ratio. Figure 4 shows that copolymerization of VMP with HEMA is faster than that with AA; therefore, the monomers can be ranked in the following order with respect to activity: VA < VSI < VMP < AA < HEMA.

The VMP homopolymer is a white powder soluble in alcohols and aromatic and chlorinated hydrocarbons but insoluble in water and petroleum ether. VMP–VA and VMP–HEMA copolymers are also isolated as white powders soluble in dimethylformamide and methanol. VMP–AA copolymers are white powders soluble in methanol.

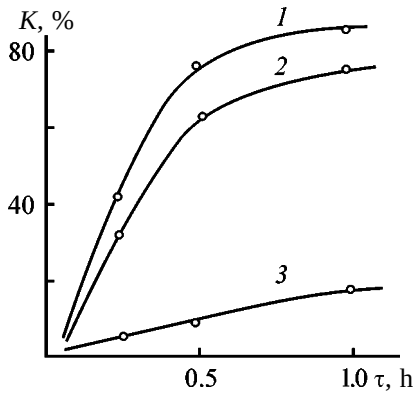

Fig. 4. Monomer conversion K as a function of copolymerization time τ. Concentration, M: monomers 1.0; AP and AscA 0.02 each; VMP mole fraction in the monomer mixture 0.75; volume ratio water : DMSO 7 : 2; 25°C. Comonomer: (*1*) HEMA, (*2*) AA, and (*3*) VA.

Table 6. Properties of VMP homopolymers [27] prepared at 70°C

Copolymerization	AIBN concentration, mol %	$[\eta]$, dl g^{-1}, in benzene at 20°C	T_f, °C
Bulk	0.1	1.15	238–245
In toluene	0.5	0.98	180–200
	1.0	0.89	165–180
	1.5	0.75	150–165
	2.0	0.69	160–170

It is known [6] that homopolymers of VMP with the highest molecular weight (up to 1.3×10^6) are formed by bulk polymerization with AIBN initiator. In organic solvents in the presence of AIBN, poly-*N*-vinyl-3(5)-methylpyrazole (PMVP) of a lower molecular weight is formed: $(0.6–1.0) \times 10^5$ in benzene and $(1.0–3.0) \times 10^4$ in ethyl acetate [7].

As the initiator concentration is decreased, the molecular weight of PMVP decreases, as indicated by decrease in the intrinsic viscosity of polymer solutions $[\eta]$; the flow point T_f also decreases (Table 6).

The properties of VMP–VA copolymers prepared by bulk copolymerization are listed in Table 7. The samples were prepared from the monomer mixtures with the VMP mole fraction varying from 0.05 to 0.75, in the presence of AIBN initiator (0.5% of the total weight of the monomers).

The properties of the copolymers (Table 7) show that, as the content of VMP units increases, the strength, heat resistance, and glass transition point increase. The pyrazole rings of VMP are less polar than the acetate groups of VA; therefore, with increasing content of VMP units the dielectric properties of the copolymers are improved. The thermal properties of the copolymers are as follows: heat conductivity 0.10–0.18 W m^{-1} K^{-1}, temperature conductivity $(4–6) \times 10^{-8}$ m^2 s^{-1}, and specific heat 1.2–3.2 kJ kg^{-1} K^{-1}.

Thermal analysis of the polymers shows that the temperatures of the onset and maximal rate of degradation increase with increasing VMP content. Decomposition of the samples occurs in two stages: At 190–360°C vinyl acetate units degrade, which is followed by degradation of VMP units at 360–500°C (Fig. 5). The homopolymers decompose in one stage.

The preparation conditions affect the intrinsic viscosity of solutions of VMP–VA copolymers (Table 8); the thermal and dielectric properties change insignificantly (within the determination error).

The properties of VMP–HEMA copolymers prepared in the water–DMSO mixture at a VMP mole fraction of 0.50 are as follows: Brinell hardness 116 MPa, Vicat softening point 72°C, temperature of maximal degradation rate 412°C, and water absorption in 2 h 50%.

VMP (co)polymers are highly resistant to hydrolysis. Base hydrolysis of VMP homopolymer at 20–90°C occurs neither under heterogeneous (in aqueous NaOH) nor under homogeneous (in aqueous-methanolic NaOH) conditions. The IR spectrum of the hydrolyzed polymer is identical to that of the initial polymer; the bands at 1530 (stretching vibrations of substituted heteroaromatic five-membered rings) and 780 cm^{-1} (out-of-plane ring vibrations) are preserved.

In VMP–VA copolymers, only VA units are sub-

ject to hydrolysis; VMP–VA copolymers are hydrolyzed faster than VA homopolymers prepared under the similar conditions. This is probably due to the fact that the microstructure of the copolymer macrochains makes the VA units in the copolymer more accessible to the hydrolyzing agent. Separate VA units alternating with VMP blocks are hydrolyzed more readily, and the maximal degree of hydrolysis is close to the content of VA units in the copolymers, so that their conversion is practically 100%.

Thus, hydrolysis of VMP–VA copolymers yields copolymers of VMP with vinyl alcohol. These substances are yellow or yellowish powders. Depending on the composition, the products can be soluble in organic solvents or water. VMP–HEMA copolymers undergo practically no changes at attempted base hydrolysis, because the HEMA units are also highly resistant to hydrolysis up to 80–100°C. The AA units in VMP–AA copolymer in hydrolysis with NaOH solutions transform into sodium acrylate units.

CONCLUSIONS

(1) The reaction medium affects the relative activity of *N*-vinyl-3(5)-methylpyrazole in copolymerization and the alternation of units in the resulting copolymers. The kinetics of (co)polymerization in the bulk, emulsion, and water–dimethyl sulfoxide mixtures were studied, and the copolymerization constants were determined.

(2) *N*-Vinyl-3(5)-methylpyrazole in copolymerization with vinyl acetate is more active, which results in formation of compositionally nonuniform copolymers. Copolymers with a better unit alternation can be obtained by performing the reaction in emulsion in the presence of the initiating system manganese tris(acetylacetonate)–acetic acid.

(3) Copolymers of *N*-vinyl-3(5)-methylpyrazole with vinyl acetate, 2-hydroxyethyl methacrylate, and acrylic acid of a wide composition range can be prepared in a water–dimethyl sulfoxide mixture (volume ratio 7 : 2).

(4) The physicomechanical, thermal, and dielectric properties of *N*-vinyl-3(5)-methylpyrazole were studied. The strength, heat resistance, and glass transition point increase with increasing content of *N*-vinyl-3(5)-methylpyrazole.

(5) The possibility of modification of *N*-vinyl-3(5)-methylpyrazole (co)polymers by base hydrolysis was examined. The *N*-vinyl-3(5)-methylpyrazole units are not hydrolyzed. Depending on the nature of the comonomer, copolymers soluble in water or organic solvents can be thus prepared.

Abstract—The kinetics of copolymerization of acrylamide with magnesium, calcium, and strontium 2-acrylamido-2-methylpropanesulfonates in aqueous solutions in the presence of potassium persulfate–sodium hydrosulfite initiating redox system at pH 9 and 50°C was studied as influenced by the cation nature.

The radical copolymerization in aqueous solutions is the main, but still not clearly studied procedure for preparing copolymers of acrylamide (AA) with salts of 2-acrylamido-2-methylpropanesulfonic acid (H-AMS), which are widely used in various branches of industry thanks to their valuable properties [1, 2]. One of the typical features of copolymerization of the salts of weak [3] and strong [4] unsaturated acids is the dependence of the kinetic parameters of synthesis and characteristics and properties of the resulting polymers on the cation nature [5]. Such dependences were found previously for polymerization of salts of H-AMS with single- [6] and double-charged [7] cations, and in the course of copolymerization of AA with single-charged metal 2-acrylamido-2-methylpropanesulfonates [8]. In this work we studied the kinetics of radical copolymerization of acrylamide with magnesium, calcium, and strontium 2-acrylamido-2-methylpropanesulfonates in water and aqueous salt solutions as influenced by the cation nature.

EXPERIMENTAL

In our work we used acrylamide purchased from Mitsubishi Chem. Ind. Ltd. (Japan) (mp 84.5°C), H-AMS purchased from Lubrizol Corp. (Great Britain) (mp 186°C), distilled water, and other chemically pure grade reagents. Magnesium, calcium, and strontium 2-acrylamido-2-methylpropanesulfonates were prepared by neutralization of H-AMS (upon cooling and mixing) in aqueous solution to pH 9 with suspensions of $Mg(OH)_2$, $Ca(OH)_2$, and $Sr(OH)_2$, respectively, with subsequent filtration of the undissolved residue and were used as aqueous solutions. The procedures of copolymerization, dilatometric measurements, and tests were presented previously in [9]. The shift of the meniscus of the reaction mixture in a dilatometer capillary in the course of reaction was controlled with a KM-8 cathetometer.

After copolymerization the resulting polymers were precipitated from aqueous solutions into acetone, filtered off, washed with acetone, and dried to constant weight in a vacuum at room temperature.

The intrinsic viscosity [η] of copolymer solutions was measured in a 0.5 M NaCl solution at 25°C using a VPZh-3 viscometer (d_c = 0.56 mm).

The content of ionic groups in copolymer was determined from the content of sulfur [10].

Copolymerization of AA (M_1) with H-AMS salts (M_2) was carried out in concentrated aqueous solutions ([M_1 + M_2] = 5–15 wt %) at pH 9 and 50°C with the potassium persulfate (PP)–sodium hydrosulfite (SHS) redox initiating system. Variation in the ionic strengths of solutions μ at changing concentrations of the ionic monomer and low-molecular-weight nonpolymerizing salts does not affect the AA reactivity, because the rate of its polymerization in aqueous solutions is independent of salt addition [11, 12]. Solution pH 9 maintained during copolymerization and utilization of PP initiator provide constant rates of initiation at changing ionic strength μ, because the rate of PP decomposition in alkaline solutions is independent of μ [13]. Moreover, constant pH 9 provides high polymerization efficiency of the PP–SHS system

[14], and hinders hydrolysis of H-AMS salts [15] and imidization of the amide groups possible during polymerization of AA in concentrated aqueous solutions [16].

Copolymerization was carried out under the homogeneous conditions at any conversions, and no spontaneous polymerization was observed in the absence of the PP–SHS initiating system.

The effect of the cation nature on copolymerization of AA and Mg-, Ca-, and Sr-AMS was studied at various concentrations of the initial monomer mixtures $M_1 + M_2$; the initial molar ratio $[M_1] : [M_2]$ was 3 : 7. The kinetic curves of copolymerization were obtained by the dilatometric procedure and are shown in Fig. 1. In all cases the initial sections of the kinetic curves were linear, and, using them, we determined the copolymerization initial rates v_0 at low conversions ($x < 3\%$). The resulting v_0 values are listed in Table 1. As seen from Fig. 1 and Table 1, v_0, conversion, and $[\eta]$ of copolymers increase with increasing concentration of $M_1 + M_2$ in the reaction mixture. The copolymerization rates v_0 and conversion also increase with increasing concentration of low-molecular-weight salts ($MgCl_2$, $CaCl_2$, and $SrCl_2$) at constant $[M_1 + M_2] = 10$ wt % (Table 1). Such a change in v_0 with increasing concentrations of the monomer mixture $M_1 + M_2$ and low-molecular-weight additives is due to the increase in μ, which decreases the electrostatic repulsion between similarly charged sulfonate groups of the ionic monomers and macroradicals and the terminal ionic groups in the events of the chain growth [9].

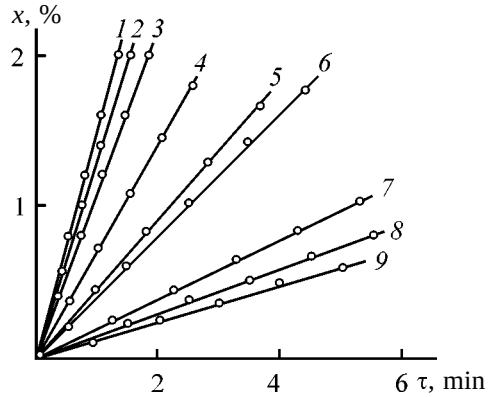

Fig. 1. (*1–3*) Initial sections of the kinetic curves of copolymerization of AA with (*1, 4, 7*) Sr-AMS, (*2, 5, 8*) Ca-AMS, and (*3, 6, 9*) Mg-AMS in aqueous solutions. Initial molar ratio $[M_1] : [M_2] = 3 : 7$; $[PP] = 3.9 \times 10^{-4}$, $[SHS] = 2.6 \times 10^{-4}$ M. (*x*) Conversion and (τ) time. $[M_1 + M_2]$, wt %: (*1–3*) 15, (*4–6*) 10, and (*7–9*) 5.

Table 1 shows that at fixed compositions of the monomer mixture $M_1 + M_2$ v_0 increases in the order $Mg^{2+} < Ca^{2+} < Sr^{2+}$. This dependence is observed in the absence and in the presence of low-molecular-weight salts; v_0 and $[\eta]$ increase in parallel in going from copolymers of AA with Mg-AMS to copolymers with Ca-AMS (Table 1).

The data on copolymerization at various initial molar ratios $[M_1] : [M_2]$ (Figs. 2, 3) confirm the

dependence of v_0 and [η] on the nature of double-charged cation. With Sr-AMS at $[M_1] : [M_2] > 4 : 6$ (Fig. 2) the system was microheterogeneous (the reaction solutions were turbid), and therefore we failed to determine v_0. As seen from Fig. 3, the higher-molecular-weight copolymers of AA with Ca-AMS and Mg-AMS are formed in the monomer mixtures enriched with the ionic monomers.

To explain the observed dependence of the copolymerization parameters on the cation nature in H-AMS salts, we consider the ionization equilibrium of the ionic groups of the monomers and macroradicals in the salt solutions:

$$\underset{\mathbf{I}}{A^-X^+} \rightleftarrows A^- \;\|\; \underset{\mathbf{II}}{X^+} \rightleftarrows A^- + \underset{\mathbf{III}}{X^+}, \qquad (1)$$

where A^- is the anion of the monomer or macroradical; X^+ is the cation; and **I, II**, and **III** are the contact ion pairs, ion pairs separated with a solvent, and free ions, respectively.

The increase in μ and degree of binding of the cations with polyanions shifts the ionization equilibrium (1) to the left, decreasing the intra- and intermolecular interactions in the reaction system. This affects the reactivity of H-AMS salts and their macroradicals and causes instability in the polymerization rate constants and copolymerization constants. As a result, the copolymerization with participation of the ionic monomer could not be described by classical equations with fixed r_1 and r_2.

It is known [17] that with increasing cation radius r (0.72×10^{10}, 1.00×10^{10}, and 1.26×10^{10} m for Mg^{2+}, Ca^{2+}, and Sr^{2+}, respectively [18]) the degree of the cation binding with polysulfonate anions increases in the series $Mg^{2+} < Ca^{2+} < Sr^{2+}$.

As a result, the electrostatic repulsion of similarly charged H-AMS salts with the similar macroradical decreases in the order $Mg^{2+} > Ca^{2+} > Sr^{2+}$, which causes the increase in v_0 and [η] in the reverse order $Mg^{2+} < Ca^{2+} < Sr^{2+}$.

The effect of the monomer molar ratio $[M_1]/[M_2]$ in the initial reaction mixture on the composition of AA copolymers with Mg-AMS and Ca-AMS was studied at $[M_1 + M_2] = 10$ wt %, other conditions being equal (Fig. 4). In these two copolymer systems the rate constants of the monomer addition to the dissimilar macroradical are higher than that to the similar one, i.e., for AA $r_1 = k_{11}/k_{12} < 1$ and for H-AMS salts $r_2 = k_{22}/k_{21} < 1$. The data given in Fig. 4 for $[M_1]/[M_2]$ = const indicate the enrichment of copoly-

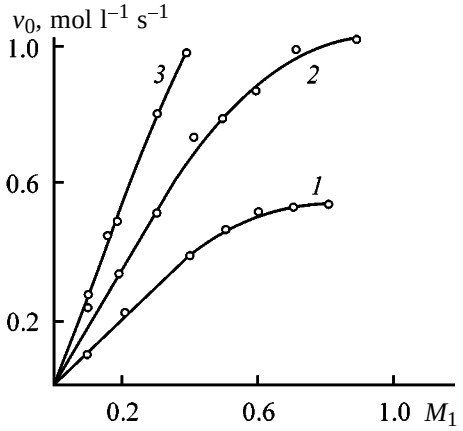

Fig. 2. Initial rate of copolymerization v_0 of AA with (*1*) Mg-AMS, (*2*) Ca-AMS, and (*3*) Sr-AMS as a function of the AA content in the initial monomer mixture M_1 (mole fraction). $[M_1 + M_2] = 10$ wt %, $[PP] = 5.2 \times 10^{-4}$ M and $[SHS] = 3.5 \times 10^{-4}$ M; the same for Fig. 4.

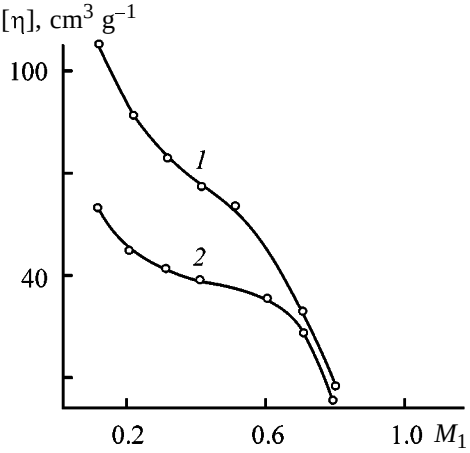

Fig. 3. Intrinsic viscosity of solutions [η] of AA copolymers with (*1*) Ca-AMS and (*2*) Mg-AMS as a function of the AA content in the initial monomer mixture M_1 (mole fraction), $\tau = 2$ h.

Table 2. Composition of AA copolymer with H-AMS salts as influenced by the concentration of the initial monomer mixture (initial molar ratio $[M_1] : [M_2] = 3 : 7$)

Monomer	$[M_1 + M_2]$, M	Contents of indicated units in copolymer	
		AA	H-AMS salt
Mg-AMS	0.57	53.0	47.0
	0.86	47.0	53.0
Ca-AMS	0.56	44.0	56.0
	0.84	43.0	57.0
Sr-AMS	0.51	39.3	60.7
	0.76	37.7	62.3

mers with ionic monomers on passing from Mg- to Ca-AMS (passing from curve *1* to curve *2*).

The data listed in Table 2 illustrate the effect of the cation nature on the composition of AA copolymers with Mg-, Ca-, and Sr-AMS at various concentrations of the monomer mixture $M_1 + M_2$, other conditions being equal. The experimental data at $[M_1 + M_2] =$ const illustrate the increase in the content of the ionic units in the copolymer macromolecule in the series $Mg^{2+} < Ca^{2+} < Sr^{2+}$, which agrees with results given in Fig. 4. Our data (Table 2) also show that the increase in the concentration of the reaction mixture $M_1 + M_2$ causes the enrichment of the copolymers with ionic units. This concentration effect is due to the increase in the ionic strength of the solutions μ. With increasing μ and binding of cations with polysulfonate anions in the order $Mg^{2+} < Ca^{2+} < Sr^{2+}$ the electrostatic repulsion of similarly charged particles becomes weaker, which increases k_{22}. As a result, the copolymers are enriched with ionic units (Fig. 4, Table 2). Similar increase in v_0 with increasing cation radius was found previously in polymerization of Mg-, Ca-, and Ba-AMS [7] and Ca, Sr, and Ba- *p*-styrenesulfonates [19]. This fact suggests that the effect of cations on (co)polymerization is a general feature for salts of strong unsaturated acids.

Thus, the kinetic parameters of copolymerization of AA with H-AMS salts of double charged cations and the properties of the resulting copolymers can be controlled by varying μ and the nature of cations in the ionic monomer.

CONCLUSIONS

(1) The v_0 values increase with increasing concentration of monomers in the $M_1 + M_2$ reaction mixture and with addition of low-molecular-weight salts in the order $Mg^{2+} < Ca^{2+} < Sr^{2+}$.

(2) The intrinsic viscosity of copolymers [η] increases with increasing concentration of the reaction mixture $M_1 + M_2$ in the following order: $Mg^{2+} < Ca^{2+}$.

(3) The content of the ionic groups increases with increasing concentration of the reaction mixture $M_1 + M_2$ and in the order $Mg^{2+} < Ca^{2+} < Sr^{2+}$.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis and Absorption Power of New Polyelectrolyte Tetrazole-Containing Acrylic Hydrogels

A. V. Igrunova, N. V. Sirotinkin, and M. V. Uspenskaya

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received December 21, 2000; in final form, February 2001

Abstract—The kinetic features of formation and equilibrium swelling in water and aqueous solutions of metals were considered for new hydrogels based on acrylic acid and methylenebisacrylamide modified with 2-methyl-5-vinyltetrazole in the polymerization stage. The influence of the concentration of the reactants on the gelation rate and the degree of equilibrium swelling was studied, as well as the influence of 2-methyl-5-vinyltetrazole on the properties of the copolymers prepared. Possible application fields for the new hydrogels were proposed.

Polyacrylate hydrogels find wide application owing to their unique water-absorbing and immobilizing power with respect to various media. These properties are of special value in the context of the present-day problems of biological medicine and ecology [1, 2]. Incorporation into the polymer structure of complexones, in particular, nitrogen-containing heterocyclic moieties, intensifies the absorption of aqueous solutions of electrolytes [3]. High complexing power of the tetrazole ring with respect to heavy and noble metal ions makes these gels suitable for water treatment application. The immunobiological activity of polyvinyltetrazoles and copolymers of vinyltetrazoles with acrylic acid (AA) makes these hydrogels promising for application in living bodies [4, 5].

The aim of this work is to study the kinetic features of gelation and the behavior of the gels in electrolyte solutions, as well as to analyze the mechanism of formation and interaction of the gel prepared with solutions of salts of copper, cobalt, nickel, and other metals.

EXPERIMENTAL

Network copolymers were prepared by radical polymerization of AA partially neutralized with sodium hydroxide (degree of neutralization α = 0.8–0.9), 2-methyl-5-vinyltetrazole (MVT), and methylenebisacrylamide (MBAA) as cross-linking agents in an aqueous solution at 40–60°C. The initiator was the ammonium persulfate–tetramethylethylenediamine (TMED) redox system. The initial concentrations of the reactants in polymerization were as follows: monomer 30, MVT 0–70 wt % of the AA mass, and MBAA 0–0.9 wt % of the monomer mass. Prior to polymerization, 2-methyl-5-vinyltetrazole[1] was purified by vacuum distillation (bp 80°C at 20 mm Hg). The other reactants, as well as their purification and copolymerization procedures, were characterized in [6]. Polymerization was carried out in ampules; the reaction mixture was deoxygenated prior to adding the initiator by passing argon through the solution for 2–3 min. A specific feature of the experiment was freezing of AA in a refrigerator at 3–5°C prior to the reaction.

The kinetic parameter to be measured was the gelation time as estimated from the time of the onset of the fluidity loss by the reaction mixture.

The gel structure was investigated by ^{13}C NMR spectroscopy and differential thermal analysis (DTA). The presence of the tetrazole moiety in the polymer was judged from the peaks in the IR spectrum at ν 1100, 1208, and 1635 cm^{-1} (tetrazole ring vibrations). The resulting copolymers are thermally stable, as evidenced by the thermal oxidation analysis data as processed by the Freeman and Carrol's method (E_a = 420 kJ mol^{-1}).

The copolymers synthesized were kept in distilled water to remove the sol fraction. The equilibrium swelling of the gels and the swelling kinetics were studied by the standard gravimetric method. The degree of equilibrium swelling was calculated by the equation $Q = (m_s - m_d)/m_d$, where m_s, g, is the mass

[1] Synthesized at the St. Petersburg State Technological Institute.

1070-4272/01/7405-0818$25.00

of the swollen sample, and m_d, g, is the mass of the dried sample [6].

The macrokinetics of the three-dimensional copolymerization of AA, MVT, and MBAA have a number of specific features. As seen from Fig. 1, the plot of the gelation time (induction period) vs. the MVT concentration has a maxumim at the MVT concentration of 10–20 wt % with respect to AA. The cross-linking agent, MBAA, exerts the expected effect: the induction period tends to increase, and the gelation rate, to decrease with decreasing MBAA concentration from 0.5 to 0.05 wt %. This is consistent with the mass action law in the gelation macrokinetics. The fact that at the MBAA concentrations over 0.5 wt % the gelation point is observed at a later time is due to the specific features of the gelation mechanism. The gel based on AA and MBAA, most likely, was formed by the colloidal-chemical mechanism, as indirectly noted in a number of works [7]. Dissimilar reactivities of AA and MBAA are responsible for the formation at high MBAA concentrations of blocks from the MBAA units with a low activity of side double bonds and of intramolecular rings, divinyl loops, and network of engagements [7]. Thus, at the MBAA concentration of 0.9 wt % the hydrogel has a heterogeneous structure.

The nonlinear dependence of the induction period on the MVT concentrtation in the reaction mixture can be explained by the difference in the relative copolymerization activity constants: r_{AA} = 0.67 and r_{VT} = 0.29 in the AA–5-vinyltetrazole system [8], $r_{AA} < r_{MBAA}$ [9], as well as by the influence of complexing with TMED [10, 11], formation of an interpolymeric complex in AA and MVT polymerization [12], and formation of ion pairs [8, 12]. It was found [8] that the carboxy groups from AA participate in hydrogen bonding with the proton from the tetrazole ring of unsubstituted 5-vinyltetrazole. As a result, the initial polymerization rate and the degree of conversion of the monomers tend to decrease with increasing content of vinyltetrazole in the monomer mixture. In our case, MVT can also induce polarization of the COO^-H^+ (Na^+) group of AA. A greater reactivity of the AA–MVT–MBAA system compared to the system without MVT is indicated by the calculated activation energies of the reaction, namely, E_{app} of 120 and 140 kJ mol^{-1} in the former and latter cases, respectively [these parameters were calculated form the plots of the gelation time t_g, min, vs. the synthesis temperature T (K)]. This fact can be explained by formation of the redox complex MVT–ammonium persulfate [13] initiating AA copymerization. Formation of a

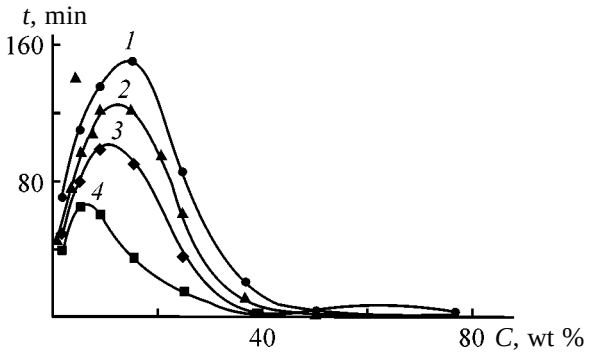

Fig. 1. Gelation time t as a function of the MVT concentration C at different proportions of the cross-linking agent (MBAA). Initiator (ammonium persulfate) concentration 0.4 wt %. MBAA concentration, wt %: (*1*) 0.1, (*2*) 0.2, (*3*) 0.9, and (*4*) 0.5.

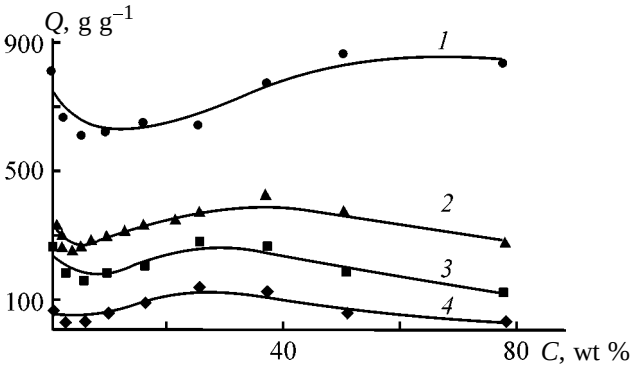

Fig. 2. Equilibrium degree of swelling Q of hydrogels in distilled water as a function of the MVT concentration C in the reaction mixture at different concentrations of MBAA. MBAA concentration, wt %: (*1*) 0.1, (*2*) 0.2, (*3*) 0.5, and (*4*) 0.9.

complex with the charge transfer between the persulfate ions and the "pyridinium type" nitrogen atom of MVT, i.e., of the tetrazole–ammonium persulfate redox system, was observed earlier [12]. Gel formation was observed in the system without ammonium persulfate. In that case, weakly cross-linked networks of predominantly physical nature were formed, as judged from a large amount of the sol fraction. The mechanism of such initiation is, evidently, due to formation of the MVT–TMED complex [10]. A high reactivity of MVT in gelation is supported by the ^{13}C NMR data: the sol fraction contains no MVT. At MVT concentrations over 30%, a strong gel is formed which retains its elasticity and the shape in the equilibrium swollen state. The analysis of the gelation mechanism should, probably, take into account the gel effect, which is indicated by the dependence of the gelation time on the MBAA concentration.

The influence of the MVT concentration on the

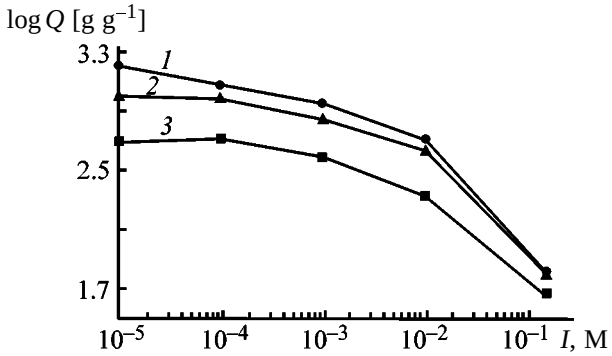

Fig. 3. Equilibrium degree of swelling Q of hydrogels based on AA and MVT as a function of the ionic strength of the external electrolyte I. MVT concentration in the reaction mixture 36 wt %. MBAA concentration, wt %: (*1*) 0.05, (*2*) 0.1, and (*3*) 0.2.

equilibrium degree of swelling of the hydrogel at different proportions of the cross-linking agent MBAA at 20°C is shown in Fig. 2. Based on data in Figs. 1 and 2, it is possible to prepare gels with desired properties within a certain period. This is essential for solving specific technical problems. e.g., fabrication of hollow fibers filled with a water-swelling absorbent. This problem can be solved, e.g., by selecting appropriate concentrations of the reactants.

Figure 2 shows that with decreasing proportion of the cross-linking agent the equilibrium degree of swelling tends to increase. The influence of the MVT concentration is ambiguous. In loosely cross-linked polymers the equilibrium degree of swelling tends to increase with increasing MVT concentraiton (to 80 wt %). With MBAA concentrations over 0.1 wt % the plot of the degree of swelling vs. the MVT concentration passes through a maximum, which shifts to lower MVT concentrations with increasing network density. The decrease in the equilibrium degree of swelling is due to increase in the proportion of the gel fraction.

In electrolyte solutions, the hydrogels of interest behave as three-dimensional membranes. The ion distribution pattern for the hydrogel–solution system varies with the composition of the surrounding solution (e.g., concentration and the nature of salt of polyvalent metal) [14]. Figure 3 presents a typical plot of the equilibrium degree of swelling vs. the ionic strength of the surrounding solution for polyelectrolyte hydrogels differing in the cross-linking density. It is seen that at the salt (sodium chloride) concentrations over 10^{-4} M the degree of swelling tends to decrease. The increased concentration of the ions outside the hydrogel was observed at salt concentrations under 1×10^{-4} M. Budtova *et al*. [2] theoretically interpreted these phenomena in terms of the Donnan theory and the diffusion approach. Those authors treated the gel as an ionic sorbent, and the thermodynamic basis of the phenomenon was considered in [15, 16]. The equilibrium degree of swelling for the gel with the metal salt concentrations of 1×10^{-4} M increases relative to that in distilled water. This can be explained by the structurization of the solution surrounding the gel, owing to participation of the MVT units in the system of intermolecular and ionic bonds [10, 17]. The gels under study collapse with the salt concentration increasing to 1×10^{-1} M.

Equilibrium degree of swelling Q of the hydrogels based on AA and MVT at different concentrations of $NiCl_2$, $CoCl_2$, and $CuCl_2$. MVT concentration 36.6, and MBAA concentration 0.2 wt %

Salt concentration, M	Q, g g^{-1}, in salt solution		
	$NiCl_2$	$CoCl_2$	$CuCl_2$
1×10^{-5}	544	556	546
1×10^{-4}	604	521	466
1×10^{-3}	110	212	238
1×10^{-2}	17	11	26

The table shows how the equilibrium degree of swelling varies with the concentrations of selected salts for hydrogels based on AA and MVT at 16°C.

It is seen that with increasing salt concentration the equilibrium degree of swelling tends to decrease. The hydrogels based on AA and MVT have high degrees of equilibrium swelling in salts compared to those based on AA. This is due to formation of chelate complexes with the Co^{2+}, Ni^{2+}, and Cu^{2+} ions involving both the tetrazole ring [18] and the acrylate groups [19]. It was found that the tetrazole-containing gels decolorize the salt solutions, and the hydrogels based on AA only partly sorb metals ion.

The swelling of the gels based on AA, MBAA, and MVT in salt solutions exhibit the following characteristic features that can be explained basing on the Donnan principle and the diffusion approach. In the initial stage the hydrogel swells faster in a more concentrated solution, and in salt solutions equilibrium is attained faster than in distilled water.

The swelling of the synthesized hydrogels can be described by an S-shaped curve (Fig. 4). It is seen that with increasing MVT proportion in the copolymer the degree of equilibrium swelling in distilled water tends to increase. The swelling rate of the copolymers in the initial stage of the process tends to increase with increasing MVT proportion in the monomer mixture.

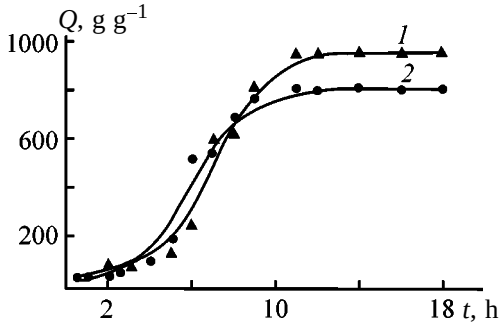

Fig. 4. Degree of swelling Q of hydrogels as a function of the time t at the cross-linking agent (MBAA) concentration of 0.1 wt %. MVT concentration in the reaction mixture, wt %: (*1*) 77 and (*2*) 36.

Our experiments suggest that the synthesis conditions ensuring the maximal absorption capacity of hydrogels based on AA, MVT, and MBAA as cross-linking agent are as follows: ammonium persulfate concentration 0.8 wt %, and synthesis temperature 60°C.

CONCLUSIONS

(1) Tetrazole-containing hydrogels based on acrylic acid, methylenebisacrylamide, and 2-methyl-5-vinyltetrazole were synthesized for the first time by radical copolymerization of monomers in aqueous solution.

(2) The kinetic features of gelation and the properties of the forming products were studied as influnced by the monomer ratio and the initiator concentration. The optimal conditions of preparing hydrogels with the maximal degree of equilibrium swelling and the shortest gelation time were determined.

(3) The equilibrium swelling of the gels in distilled water and solutions of copper, nickel, cobalt, and sodium salts at room temperature was studied. The gels exhibit high water-absorbing power in solutions with the salt concentration under 1×10^{-3} M, namely, up to 600 g g^{-1} for the gels synthesized at the methylenebisacrylamide concentration in the monomer mixture of 0.2 wt %. The high absorbing power of the gels in salt solutions is due to formation of chelate complexes.

(4) High immobilizing power of the gels prepared makes them promising for water treatment and selective binding of metals from salt solutions.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Comparative Analysis of the Methods for Calculating the Viscosity of Binary Nonelectrolyte Mixtures

E. D. Totchasov, M. Yu. Nikiforov, I. A. Luk'yanchikova, and G. A. Al'per

Institute of Solution Chemistry, Russian Academy of Sciences, Ivanovo, Russia

Received April 8, 1999; in final form, June 2000

Abstract—The results of calculating the viscosity of binary nonelectrolyte systems by methods obviating fitting parameters were compared. A method was proposed for calculating the viscosity of *n*-alkanol–*n*-alkane solutions with account of the molecular association by the free-volume theory accurately to within 7.9%.

Studies of the concentration dependence of the viscosity of liquid solutions have recently generated much interest in the context of many practical problems [1–4]. The viscosity as a physicochemical property is very sensitive to intermolecular interactions. For example, experimental data in [5, 6] suggest that in the water–dimethylformamide (DMF) system the maximal deviations from additivity make 2% for density, 9% for heat capacity, and 24% for adiabatic compressiblity against 197% for viscosity. This trend is observed for other nonelectrolyte systems as well. Development of methods for calculating the viscosity of multicomponent liquid systems is in the scope of the theory of solutions [7–9].

By now, the theory of viscosity of liquids has by no means been developed to completion, and the viscosity of solutions can be calculated practically in terms of semi-theoretical concepts like the Eyring theory [10], the free-volume theory [11], or their combination [12]. Also, caclulations can be made by formulas utilizing fitting parameters to be determined using one or several preset experimental points [13–15].

In this work we carry out a comparative analysis of selected methods for calculating the viscosity of binary nonelectrolyte mixtures obviating fitting parameters.

The deviation of the physicochemical properties of mixtures from their additive values is the greatest in the vicinity of the equimolar composition. This makes reasonable analysis of the predictive power of the calculational methods either for the composition corresponding to the maximal deviation from additivity, or for all the systems at the equimolar composition. In this work, we chose the latter option.

In [16], we calculated the viscosity of nonelectrolyte solutions in terms of the Eyring concept of the activation nature of viscous flow. The viscosity of organic liquids and their mixtures is adequately described by the formula

$$\eta = A\exp(\Delta H^{\#}/RT), \quad (1)$$

where $\Delta H^{\#}$ is the activation enthaply of viscous flow.

Following the Eyring's assumption that the activation enthalpy is a fraction of the cohesion energy E_{coh}:

$$\Delta H^{\#} = E_{coh}/n, \quad (2)$$

we obtained eventually for equimolar mixtures [$X_A = X_B = 0.5$ mole fraction (m.f.)] the relation [16]

$$\Delta\ln\eta = -H^E/RT(0.5/n_A + 0.5/n_B) + (\Delta H_A^{vap} - \Delta H_B^{vap})/2RT$$

$$\times [(0.5 + \varphi_A)\times 0.5/n_B + (0.5 + \varphi_B)\times 0.5/n_A], \quad (3)$$

where $\Delta H_A^{vap} = E_{A,coh} + RT$, $\Delta H_B^{vap} = E_{B,coh} + RT$ is the enthalpy of vaporization of the components A and B, respectively; $\Delta\ln\eta = \ln\eta - 0.5\ln\eta_A - 0.5\ln\eta_B$; η is the dynamic viscosity of the equimolar solution; η_A and η_B are the dynamic viscosities of the components A and B, respectively; and φ_A and φ_B are the volume fractions of these components, respectively.

Herefrom, the viscosities of the pure components η_A and η_B are assumed to be known. The ΔH^{vap} values for the pure components were taken from [17], and H^E, from reference books [18, 19]. The experimental values of the viscous flow activation energy for solution $\Delta H^{\#}$ were determined from the dependence $\ln\eta_{exp} = 1/T$, i.e, from the experimental η_{exp}

1070-4272/01/7405-0822$25.00

values for a binary solution taken from the reference book [20].

One of the semi-theoretical methods for describing the viscosity of liquids that obviate fitting parameters is that based on the free-volume theory relating the viscosity η to the so-called reduced volume $\tilde{V}$ [11]:

$$\eta = A\exp[1/(\tilde{V} - 1)], \quad (4)$$

where

$$\tilde{V} = V/V^*, \quad (5)$$

V is the molar volume, and V^* is the volume occupied by the liquid molecule (the occupied volume).

The term "occupied volume" is an ambiguous physical notion that has different definitions [21, 22]. In this work we took advantage of the Flory theory [23] for calculating $\tilde{V}$. This theory relates the reduced volume to the volume expansion coefficient α as

$$\tilde{V}^{1/3} - 1 = \alpha T/3(1 + \alpha T). \quad (6)$$

As the α values are usually known for pure solvents only, formulas (5) and (6) enable calculating $\tilde{V}_A$, $\tilde{V}_B$ and V_A^*, V_B^*. In view of the fact that the occupied volume V^* is physically an additive parameter, for binary mixtures holds

$$V^* = V_A^* X_A + V_B^* X_B. \quad (7)$$

Hence, the reduced volume of the equimolar mixture can be determined by the formula

$$\tilde{V} = V/V^* = V/(0.5V_A^* + 0.5V_B^*). \quad (8)$$

The viscosity of the equimolar mixture can be calculated as

$$\ln\eta = 0.5\ln\eta_A + 0.5\ln\eta_B + (\tilde{V} - 1)^{-1} - 0.5(\tilde{V}_A - 1)^{-1} - 0.5(\tilde{V}_B - 1)^{-1}. \quad (9)$$

Lastly, the Lobe formula [24] enables calculating the kinematic viscosity ν of liquid mixtures by the empirically established relation

$$\nu = \varphi_B\nu_B e^{\alpha_A\varphi_A} + \varphi_A\nu_A e^{\alpha_B\varphi_B}, \quad (10)$$

$$\alpha_B = -1.7\ln(\nu_A/\nu_B),$$

$$\alpha_A = 0.27\ln(\nu_A/\nu_B) + [1.3\ln(\nu_A/\nu_B)]^{0.5}, \quad (11)$$

where the α_B, ν_B, and φ_B parameters characterize the component with a lower viscosity. To change to the dynamic viscosity η, ν is to be multiplied by the density ρ ($\eta = \nu\rho$).

Table 1 presents the results of calculating the dynamic viscosity in terms of various theories for 30 binary systems containing components of different chemical nature (η_1 was calculated in terms of the Eyring theory, η_2, in terms of the free-volume theory, and η_3, in terms of the Lobe theory). Also presented are the rms and the maximal deviations of the calculated values from the experiment, σ_Σ and σ_{max}. The calculations were carried out for the equimolar ratio of the components at 298.15 K. The experimental viscosities of the solutions η_{exp} and pure liquids (Table 2) were taken from [20, 25, 26]. The volume expansion coefficients α of the components required for calculating the reduced volume by formula (6) were taken from the reference book [20]; they are presented in Table 3 along with some other properties of the pure components. The molar volumes of the equimolar mixtures of nonelectrolytes taken from [20, 25, 26] and the V^* and $\tilde{V}$ values calculated by formulas (7) and (8) are presented in Table 4.

All the systems are classified into three groups: both polar components, a polar and a nonpolar component; and both nonpolar components.

Table 1 shows that semi-theoretical methods of calculating the viscosity, afford, on the average, an rms deviation under 10%. For systems polar–nonpolar and polar–polar components, the best results are afforded by the Eyring theory (rms deviation of 4.9 and 5.6%, respectively), and for systems nonpolar–nonpolar components, by the free-volume theory ($\sigma_\Sigma = 4.5\%$).

We separately calculated the viscosities of 15 binary systems *n*-alkanol–*n*-alkane for which the free-volume theory fairly correctly takes into account the molecular association (up to now, this was done only in calculations of thermodynamic properties [27]).

The occupied volume V_{Aass}^* of the associated component, similar to the K and φ_{A1} parameters, becomes in this case a function of the temperature and the composition of the mixture

$$V_{Aass}^* = V_{A1}^* + \Delta V^0 K\varphi_{A1}, \quad (12)$$

where φ_{A1} is the mole fraction of the monomers of A in the mixture as defined by the ratio

$$\varphi_{A1} = [2K\varphi_A + 1 - (4K\varphi_A + 1)^{1/2}]/2K^2\varphi_A, \quad (13)$$

Table 1. Calculated η_1–η_3 and experimental η_{exp} values of the dynamic viscosity of binary nonelectrolyte systems at the equimolar ratio of the components T = 298.15 K)

V^*_{A1} refers to a hypothetical liquid consisting of the monomers; $\Delta V^0 = -5.6$ cm^3 mol^{-1} is the change in the volume in the association reaction [27], and K is the alcohol association constant in the Kraetschmer–Wiebe continuous association model [27].

The V^*_{A1} and K values were taken equal to those in [27]; they are presented, along with some other properties of the pure components, in Table 5. For the occupied volume of the binary equimolar solution we obtain:

$$V^*_{ass} = (V^*_{A1} + \Delta V^0 K\varphi_{A1})\times 0.5 + V^*_B \times 0.5. \quad (14)$$

Consequently, in terms of the association model considered, Eq. (8) for the reduced volume of a binary equimolar mixture takes the form

$$\tilde{V}_{ass} = \frac{V}{V^*_{ass}} = \frac{V}{(V^*_{Al} + \Delta V^0 K\varphi_{Al})\times 0.5 + V^*_B \times 0.5}. \quad (15)$$

Using the calculated $\tilde{V}$ value for solutions, we calculated by formula (9) the dynamic viscosity of the mixtures. The molar volumes V of the equimolar *n*-alkanol–*n*-alkane solutions required for calculating the reduced volumes $\tilde{V}_{ass}$ and $\tilde{V}$ were taken from [20, 28–34]. They are presented in Table 6 along with the V^*_{ass}, V^*, $\tilde{V}_{ass}$, and $\tilde{V}$ parameters.

Table 7 presents the calculated dynamic viscosities for *n*-alkanol–*n*-alkane systems at the equimolar ratio of the components at 298.15 K (η_1 in terms of the Eyring theory, η_2 in terms of the free-volume theory, η_3 in terms of the free-volume theory with account of molecular association, and η_4 by the empirical Lobe method). The experimental viscosities for these solutions and pure liquids (Table 2) were taken from [20, 31, 32, 34–38]. The calculated results (Table 7) show that the empirical Lobe formula is suitable for *n*-alcohol–*n*-alkane mixtures (with the rms deviation of 4.2%). The free-volume theory with the molecular association taken into account affords a closer agreement with the experiment than the classical free-volume theory (rms deviations 7.9 and 10%, respectively). On the whole, there is no interconnection between the nature (polarity) of the mixture components and the accuracy of the calculational method.

As an illustration, we will calculate the dynamic viscosity for the equimolar butanol–hexane mixture by all the calculational methods discussed in this work.

Eyring theory. (1) Using relation (3), we will determine $\Delta \ln \eta$ for the equimolar mixture $\{X_A = X_B =$

Decane	–	196.0	–	156.0

$$\Delta \ln \eta = -0.493.$$

(2) We will calculate the dynamic viscosity of the equimolar mixture (for butanol, $\eta_A = 2.55 \times 10^{-3}$ [31], and for hexane, $\eta_B = 0.286 \times 10^{-3}$ Pa s [31]):

$$\eta = \exp(\Delta \ln \eta + 0.5 \ln \eta_A + 0.5 \ln \eta_B) = 0.522 \times 10^{-3} \text{ Pa s}.$$

Free-volume theory. (1) Using formula (5), we will calculate the reduced volumes of butanol $\tilde{V}$ and hexane $\tilde{V}$ (for butanol at T = 298.15 K V^*_A = 75.7 [27], V_A = 91.98 $cm^3\ mol^{-1}$ [27]; for hexane at T = 298.15 K V^*_B = 99.34 [27], V_B = 131.5 $cm^3\ mol^{-1}$ [27]):

$$\tilde{V}_A = \frac{V_A}{V^*_A} = 1.215,$$

$$\tilde{V}_B = \frac{V_B}{V^*_B} = 1.324.$$

(2) Using formula (7), we will calculate the occupied volume for the equimolar mixture:

$$V^* = 0.5V^*_A + 0.5V^*_B = 87.52 \text{ cm}^3 \text{ mol}^{-1}.$$

(3) Using formula (8), we will determine the reduced volume of the equimolar mixture (for the molar volume of the equimolar mixture butane–hexane V = 111.6 $cm^3\ mol^{-1}$ [31]):

$$\tilde{V} = \frac{V}{V^*} = 1.275.$$

(4) We will determine $\Delta \ln \eta$ of the equimolar mix-

0.868	1.489	1.701	1.693	1.459	1.688

* η_1 by the Eyring theory, η_2 by the free-volume theory without association taken into account, η_3 with association taken into account, and η_4 by the Lobe method.

in the system φ_{Al} (for butanol K = 175 at T = 298.15 K [27], φ_A = 0.412):

$$\varphi_{A1} = [2K\varphi_A + 1 - (4K\varphi_A + 1)^{1/2}]/(2K^2\varphi_A) = 0.00508.$$

(2) Using formula (12), we will calculate the occupied volume for the associated component V^*_{ass} (for butanol V^*_{A1} = 80.89 [27], ΔV^0 = –5.6 cm^3 mol^{-1} [27]):

$$V^*_{Aass} = V^*_{A1} + \Delta V^0 K\varphi_{A1} = 75.91 \text{ cm mol}^{-1}.$$

(3) We will determine the reduced volume of the associated component (butanol) $\tilde{V}_{ass}$ with account of association:

$$\tilde{V}_A = \frac{V_A}{V^*_A} = 1.212.$$

(4) Using formula (14), we will determine the occupied volume for the binary equimolar mixture

$$V^*_{ass} = (V^*_{A1} + \Delta V^0 K\varphi_{A1}) \times 0.5 + V^*_B \times 0.5 = 87.63 \text{ cm}^3 \text{ mol}^{-1}.$$

(5) Using formula (15), we will determine the reduced volume of the equimolar solution with account of association $\tilde{V}_{ass}$:

$$\tilde{V}_{ass} = \frac{V}{V^*_{ass}} = 1.274.$$

(6) We will calculate $\Delta \ln \eta$ for the equimolar system by the relation

$$\Delta \ln \eta = (\tilde{V}_{ass} - 1)^{-1} - 0.5(\tilde{V}_{Aass} - 1)^{-1} - 0.5(\tilde{V}_B - 1)^{-1} = -0.252.$$

(7) We will determine the dynamic viscosity of the equimolar mixture

$$\eta = \exp(\Delta \ln \eta + 0.5 \ln \eta_A + 0.5 \ln \eta_B) = 0.664 \times 10^{-3} \text{ Pa s.}$$

Lobe method. (1) Using formula (10), we will calculate the kinematic viscosity of the equimolar mixture (at T = 298.15 K the kinematic viscosity of butanol $\nu_A = 3.165 \times 10^{-6}$ [31], and that of hexane, $\nu_B = 0.437 \times 10^{-6}$ m^2 s^{-1} [31]):

$$\nu = \varphi_B\nu_B e^{\alpha_A\varphi_A} + \varphi_A\nu_A e^{\alpha_B\varphi_B} = 0.8 \times 10^{-6} \text{ m}^2 \text{ s}^{-1},$$

$$\alpha_B = -1.7 \ln(\nu_A/\nu_B) = -3.366,$$

$$\alpha_A = 0.27 \ln(\nu_A/\nu_B) + [1.3 \ln(\nu_A/\nu_B)]^{0.5} = 2.139.$$

(2) The density of the equimolar mixture butanol–hexane at T = 298.15 K is equal to 0.7178×10^3 kg m^{-3} [31]. Hence, the dynamic viscosuty of this system can be calculated as $\eta = \rho\nu = 0.7178 \times 10^3 \times 0.8 \times 10^{-6} = 0.574 \times 10^{-3}$ Pa s.

Along with the equimolar composition, we also calculated the viscosity throughout the concentration range by all the methods utilized in this work for the butanol–hexane system. The calculated viscosities (Table 8) show that the results of analysis do not markedly change for nonequimolar mixtures either.

CONCLUSIONS

(1) The semi-theoretical methods for calculating the viscosity of the binary mixtures based on the Eyring theory or the free-volume theory afford virtually identical accuracy (rms deviation of 4–9%). The empirical method affords a lower accuracy (8–14%) for all classes of nonelectrolyte systems (classified into polar–polar, polar–nonpolar, and nonpolar–nonpolar component mixtures). The maximal inaccuracy for all the methods can reach 20–26%.

(2) For systems *n*-alkanol–*n*-alkanel set apart for the viscosity calculations as a separate series, because they were extensively studied previously, the best results are afforded, however, by the Lobe method (4.2%). By taking into account the molecular association in terms of the free-volume theory, it is possible to improve the accuracy (from rms deviation of 10 to 7.9%) in predicting the viscosity of the *n*-alkanol–*n*-alkane solutions.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Electrophysical Properties of Coordination Compounds Based on Cobalt(II) and Manganese(II) Chlorides and ε-Caprolactam

Abstract—The metal complex systems based on Co(II) and Mn(II) chlorides and ε-caprolactam were studied. Temperatures of the phase transition, activation energy of the electrical conductivity, and mobility of the charge carriers in the compounds obtained were determined.

In [1–3], we found that a series of coordination compounds of transition metal [Co(II), Mn(II), Cu(II), and V(III)] chlorides cross-link polymers containing electron-donor groups. Up to now, aromatic diisocyanates and related urethane-forming systems were the main objects of the study of interaction with metal complexes.

The initial components forming metal-complex modifying systems can be subdivided in two types. In the first group, 3*d* metal chlorides with variable metal oxidation state [Cu(II), Fe(III), V(III), and Cr(III)] are used as coordinating centers, and *N*,*N*'-diethylhydroxylamine and polyoxyethylene glycol, as ligands. Interaction is accompanied by redox process, and yields polynuclear complexes in which 3*d* metal ions exist in two oxidation states. The resulting reactive system cross-links polyurethane matrix, enhances its physicomechanical properties, and substantially (by a factor of 10^4–10^5) increases the electrical conductivity. It was shown that the cross-linking effect in the urethane-forming system occurs at a low content of metal chloride (0.1–1%).

In the second case, 3*d* metal chlorides in the lower oxidation state [Co(II) and Mn(II)] and monoethanolamine (MEA) were the initial components for obtaining a metal-complex modifier. It was found that the reaction of $CoCl_2$ with MEA is completed by formation of a mixture of mono-, bi-, and polynuclear tetrahedral cobalt complexes in which the metal ions keep their oxidation state and are bound with each other by chloride bridges.

The ability of metal ions to coordinate the urethane amide group and thus to cross-link macromolecules was used in synthesis and studying modifying systems based on Co(II) and Mn(II) chloride complexes with ε-caprolactam.

It was found that on addition of a $CoCl_2$ ($MnCl_2$)–MEA mixture the ε-caprolactam melt becomes turbid, and its viscosity increases. Thermooptical study on a polarization microscope with a thermal stage showed that the resulting turbid melt is a smectic liquid crystal phase, which is readily identified through characteristic "schlieren" textures. These results were confirmed by DSC (Fig. 1).

The intrinsic viscosity was measured for the initial ε-caprolactam and products of the final stage of its reaction with $MnCl_2$–MEA and $CoCl_2$–MeA. For caprolactam, the intrinsic viscosity is close to zero, while for coordinated ε-caprolactam it is 0.027 dl g^{-1}. Such a small increase in the intrinsic viscosity in-

1070-4272/01/7405-0830$25.00

dicates that ε-caprolactam does not polymerize under reaction conditions.

The change of the chemical composition of ε-caprolactam caused by interaction with the metal-complex system was controlled by IR spectra. The most characteristic absorption band for ε-caprolactam caused by stretching vibrations of the amide carbonyl group lies at 1672 cm^{-1}. After interaction with the metal-complex system it shifts to 1678 cm^{-1} and noticeably broadens. Such changes are characteristic for coordinated carbonyl group and suggest that ε-caprolactam forms coordination bonds with metal complexes in the $CoCl_2$–MEA system.

To study features of mesomorphic phase formed, we measured the temperature dependences of electrical conductivity in the systems $CoCl_2$–MEA–ε-caprolactam and $MnCl_2$–MEA–ε-caprolactam. These dependences are shown in Fig. 2 in semilogarithmic coordinates. Three sections of the curves are observed. They can correspond to the crystalline state (C), mesomorphic state of the smectic type (S), and state of isotropic liquid (I).

At phase transitions S → I (at heating) and I → S (at cooling), the electrical conductivity changes by more than an order of magnitude. At C → S phase transition, no jump of the electrical conductivity is observed; however, the break appears in the $\ln\sigma$–$1/T$ curve, caused by the change of the activation energy. The position of this break in the temperature curve approximately corresponds to the C → S phase transition temperature in the DSC curve. Since it is known that the temperature dependence of the electrical conductivity for organic semiconductors is well fitted by the Arrhenius equation, we used the equation

$$\sigma = \sigma_0 \exp[-E_a/kT] \quad (1)$$

to determine the activation energies E_a of the electrical conductivity. The activation energies, phase transition temperatures, and conductivities are listed in the table.

The shape of DSC dependences and the values of E_a obtained in our work are similar to published data for other systems [4–6]. However, we can note certain features characteristic for the systems studied: the activation energies of high-frequency and dc electrical conductivity for the isotropic phase are practically the same; the temperature range of the mesophase existence is fairly broad; the electrical conductivity is several orders of magnitude larger than that described in the literature (up to 10^{-3} Ω^{-1} cm^{-1} in the I phase); the pronounced temperature hysteresis occurs, i.e.

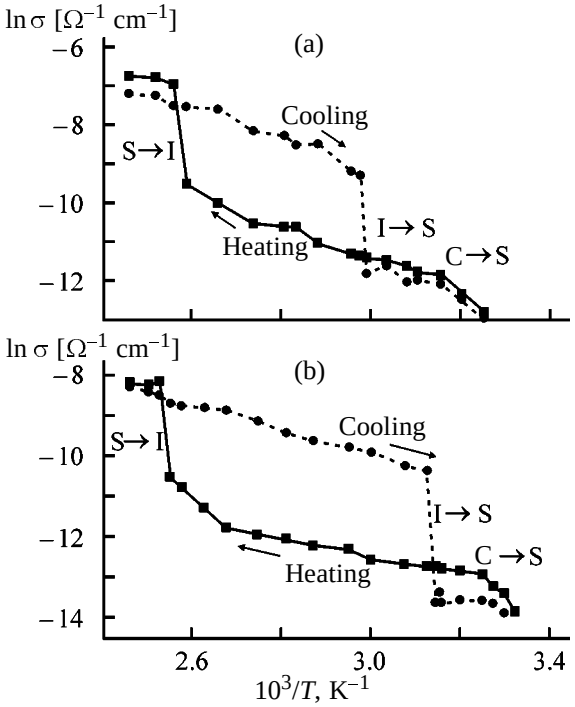

Fig. 2. Temperature dependence of the electrical conductivity σ for the (a) $CoCl_2$–MEA–ε-caprolactam and (b) $MnCl_2$–MEA–ε-caprolactam systems.

at sample cooling the temperature interval of the existence of the mesophase is fairly narrow.

The DSC curves are shown in Fig. 1. For both systems the melting point varies within the range 50–60°C. The DSC curves were measured up to the corresponding S → I transitions. The temperature of the transition into the isotropic liquid was determined from both the corresponding jumps in the curves of temperature dependence of the electrical conductivity and the DSC curves. It is 116–120°C and 115–119°C for the $CoCl_2$–MEA–ε-caprolactam and $MnCl_2$–MEA–ε-caprolactam systems, respectively.

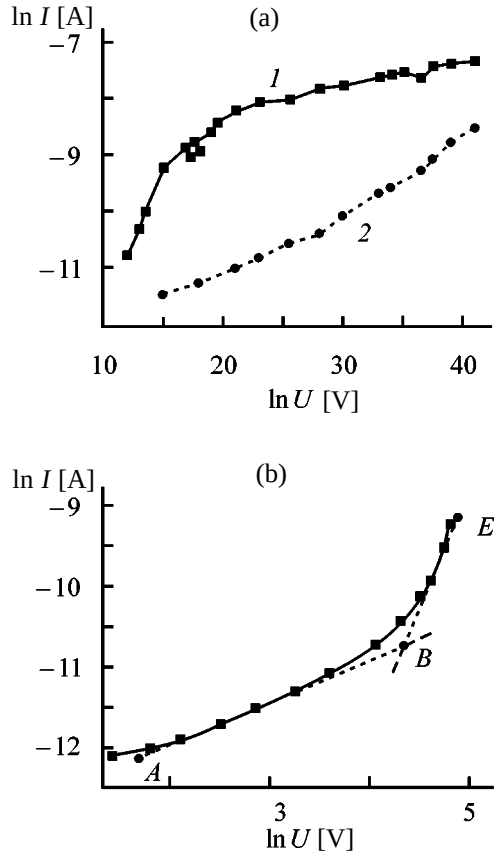

Fig. 3. Volt-ampere characteristics of the (a) $MnCl_2$–MEA–ε-caprolactam and (b) $CoCl_2$–MEA–ε-caprolactam systems. (*I*) Current and (*U*) voltage. Sample: (*1*) initial and (*2*) after electrochemical purification.

The volt–ampere characteristics (VAC) measured for freshly prepared samples are linear at a low field intensity. At fields $E > 4 \times 10^3$ V cm^{-1} they become sublinear up to saturation. Moreover, the current decreases with time. Such a phenomenon is known for liquid crystals and the other systems with the ionic conductance and is due to the electrochemical purification to remove extrinsic ions. After standing for 30 min in the maximal electric field of 2×10^4 V cm^{-1}, the current through the sample decreases and becomes independent of time. Probably, after the electrochemical purification to remove extrinsic ions, the volt–ampere characteristic of samples is mainly caused by the electronic component of the current. The volt–ampere characteristics for $MnCl_2$–MEA–ε-caprolactam and $CoCl_2$–MEA–ε-caprolactam systems are shown in Figs. 3a and 3b, respectively. For the system with $CoCl_2$, both ohmic and nonohmic sections are described by the Child–Langmuir law. Such a behavior of VAC is caused by the following two effects. At a relatively high current density corresponding to the strong electric field, the concentration of current carriers moving in the gap between the electrodes is fairly large, and these carriers form a space charge. The next reason of the VAC nonlinearity is the existence of traps such as impurities, defects of crystal packing, dislocations, and other lattice defects. These defects give rise to additional localized levels in the band gap [7].

At low voltages, injection of current carriers from the electrode is negligible, and the current obeys the Ohm law (section *AB*). In the absence of traps, the current is restricted by the space charge at the voltage corresponding to point *B*. In this point, the concentration of free carriers injected from the electrode begins to prevail over the thermally equilibrium concentration of carriers. After this point, VAC obeys the Child–Langmuir law and follows the *BE* line, and the current I (A cm^{-2}) is determined by the equation

$$I \cong 10^{-13}\frac{\mu\varepsilon U}{d^3}, \qquad (2)$$

where U is applied voltage (V), μ is the carrier mobility (cm^2 V^{-1} s^{-1}), ε is the dielectric constant, and d is the distance between the electrodes (cm).

The current stops to be ohmic beginning from the definite voltage U_{tr} (point *B*) at which the currents start to be limited by the space charge. After determining U_{tr} from the experimental VAC curve for the substance studied ($CoCl_2$–MEA–ε-caprolactam system) and its substitution in Eq. (2), we obtain a formula for determination of the carrier mobility μ:

$$\mu = 10^{13} Id^3/(\varepsilon U^2)$$

All liquid crystal compounds are characterized by anisotropy of dielectric parameters. In this case, the average dielectric constant equal to 41 was used for the $CoCl_2$–MEA–ε-caprolactam system.

After substitution of U_{tr} = 73 V from the VAC curve for the $CoCl_2$–MEA–ε-caprolactam system in Eq. (3), we calculated the mobility of charge carriers: $\mu = 7 \times 10^{-4}$ cm^2 V^{-1} s^{-1}, which corresponds to the electronic mobility characteristic typical of organic semiconductors in the case of hopping (electronic) conductance.

The volt–ampere characteristic for the $MnCl_2$–MEA–ε-caprolactam system after the electrochemical purification is ohmic; transition to the quadratic section at field intensities up to 2×10^4 V cm^{-1} was not observed.

EXPERIMENTAL

The crystal hydrate $MnCl_2 \cdot 4H_2O$ was dried to $MnCl_2 \cdot 3H_2O$ at 106°C, and $CoCl_2 \cdot 6H_2O$ was dried at 60°C in a thermal box. Monoethanolamine was purified by vacuum distillation. Chemically pure grade ε-caprolactam was prepared by recrystallization of commercial grade ε-caprolactam from ethyl acetate. The reaction of $CoCl_2$ and $MnCl_2$ with MEA was performed with vigorous agitation and heat removal. The molar ratios $MnCl_2$: MEA and $CoCl_2$: MEA was 1 : 10 and 1 : 3.6, respectively. The resulting complex was introduced directly into the ε-caprolactam melt at the molar ratio [$MnCl_2$] and [$CoCl_2$] : [ε-caprolactam] = 1 : 9. The reaction mass was agitated at 90°C for 30 min. Catalytic amounts of acetonitrile and 2,4-toluylene diisocyanate were also introduced into the reaction mass.

The IR spectra were registered on a Perkin–Elmer 16PC FT-IR spectrometer with precise fixation of the light radiation (±1%). The thickness of the spectrometric cell was 0.022 cm. Thermograms were obtained on a DSM-2M differential scanning microcalorimeter (rate of heating to 200°C 8 deg min^{-1}). The intrinsic viscosity was determined on a Ubbelohde viscometer at 20°C. Phase transitions were registered with a Polam P-211 polarization microscope equipped with a thermal stage.

The study of electrophysical characteristics was reduced to measurement of the temperature dependences of the dc electrical conductivity within the 290–420 K range by the standard method. Platinum electrodes with optimal size were introduced into the vessel with the sample studied. To avoid field end effects, the fixed distance between the electrodes was substantially smaller than their linear sizes. The temperature was controlled through the change of the voltage on a thermostat heater and monitored with a Chromel–Alumel thermocouple (connected with a V7-21 voltmeter) placed directly in the vessel with the sample. The electrical resistance of the latter was measured with a E6-13A teraohmmeter with an error of 2.5%.

The charge carrier mobility was determined through recording volt–ampere characteristics at 290 K. The sample was installed into a specially fabricated cell of the "sandwich" type: two flat glass plates with the applied transparent conducting layer of SnO_2 were separated by a mica layer with a small window in which the sample was placed. The thickness of the gap between the glass plates was equal to the thickness of the mica layer, which in our case was 4×10^{-5} m. The voltage on the sample (40 V) was fed from a stabilized V5-9 source. The current was recorded on a V7-21 universal voltmeter. The electric field intensity was varied up to 2×10^3 V cm^{-1}.

CONCLUSIONS

(1) Data on electrical conductivity and conductivity activation energy show that the compounds obtained by the reaction between $MnCl_2$ (or $CoCl_2$), monoethanolamine, and ε-caprolactam and existing in the crystalline, liquid-crystalline, and isotropic state are organic semiconductors.

(2) Phase transitions crystal–liquid crystal and liquid crystal–isotropic liquid appear in the temperature dependence of the electrical conductivity as a break or sharp jump (at the liquid crystal–isotropic liquid transition). The pronounced temperature hysteresis in the heating–cooling cycle is observed.

(3) The electrical conductance of freshly prepared samples has a mixed ionic-electronic character. After the electrochemical purification, volt–ampere characteristics of the systems studied are characteristic for organic semiconductors with hopping electronic conductance.

(4) The transition from ohmic to quadratic (the Child–Langmuir dependence) section in the volt–ampere curves of the $CoCl_2$–MEA–ε-caprolactam system is observed. The mobility of charge carriers was calculated from the inflection point.

Received August 15, 2000; in final form, February 2001

Abstract—Epoxidation of 5-vinyl-2-norbornene with *tert*-butyl hydroperoxide in the presence of Mo, V, and Ti compounds was studied. The optimal conditions for synthesis of 2,3-epoxy-5-vinylnorbornane were found.

Recently there has been a great deal of interest in preparation of new polymeric materials for electronics, electrical and medical engineering, etc. Incorporation into polymers of hydrocarbon or functional derivtives of norbornene ensures high thermal and chemical resistance of the resulting materials [1–3]. Among alicyclic epoxy compounds, the demand for 2,3-epoxy-5-vinylnorbornane increases because of its extending application field [3–12].

Development and mastering on the pilot scale in Russia of a process for production of ethylidenenorbornene [13] made 5-vinyl-2-norbornene (VNB) available and created prerequisites for setting up production of 2,3-epoxy-5-vinylnorbornane. The feasibility of selective epoxidation of VNB into mono- and diepoxides was demonstrated in [14–16].

Recent reviews [17–19] reflecting most exhaustively the present state of studies in the filed of epoxidation of unsaturated cyclic hydrocarbons contain practically no data on oxidation of VNB with alkyl hydroperoxides. Among commercially available alkyl hydroperoxides [20], we chose *tert*-butyl hydroperoxide (TBHP), since with this agent the products of hydroperoxide epoxidation of VNB can be separated most readily.

In this work we studied the features of VNB epoxidation with *tert*-butyl hydroperoxide, catalyzed with transition metal compounds.

EXPERIMENTAL

5-Vinyl-2-norbornene was prepared by the Diels–Alder reaction from cyclopentadiene and 1,3-butadiene [21]; the main substance content in the product isolated by sharp fractional distillation in a vacuum was no less than 98.5 wt %. TBHP (99 wt %) was prepared by oxidation of *tert*-butyl sulfate with hydrogen peroxide [22]. As epoxidation catalysts were tested molybdenyl ethanediolate $MoO_2(OC_2H_4OH)_2$, molybdenyl 2,3-butanediolate $MoO_2[OCH(CH_3)CH\cdot(CH_3)OH]_2$, molybdenyl 2-methyl-2,3-butanediolate $MoO_2[OC(CH_3)_2CH(CH_3)OH]_2$, molybdenyl ethylene-1,2-bis(salicylidenimine) MoO_2(salen), molybdenyl resinate $MoO_2(OCOC_{19}H_{29})$, molybdenum boride MoB, vanadium acetylacetonate $V(acac)_3$, vanadyl acetylacetonate $VO(acac)_2$, and tetrabutoxytitanium $Ti(OC_4H_9)_4$, which were prepared by appropriate procedures [20, 23, 24] or taken as commercial chemicals. The solvents (chemically pure grade) were dried before use.

Epoxidation of VNB was performed under nitrogen in a glass or metallic temperature-controlled vessel equipped with a magnetic stirrer. In the course of the experiments, samples of the reaction mixture were taken and analyzed for the content of TBHP (by iodometric titration [25]) and VNB epoxidation products (chromatographically, after treatment of the sample with triphenylphosphine to reduce the unchanged hydroperoxide). An LKhM-80 chromatograph equipped with a thermal conductivity detector and a 3000 × 3-mm column was used; the stationary phase was 5% XE-60 on Chromaton N-AW-DMCS (0.20–0.25 mm). The column temperature was 125°C, and the carrier gas (hydrogen) flow rate, 30 $cm^3\ min^{-1}$. The content of VNB and its monoepoxide was determined using an internal reference (*n*-tridecane).

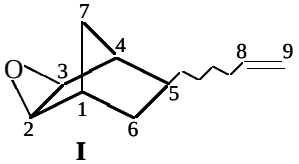
The consumption of the initial reactants, VNB and TBHP, and accumulation of the epoxidation products

1070-4272/01/7405-0834$25.00

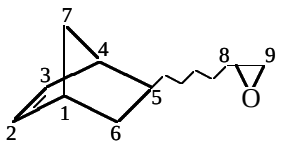
were monitored. As kinetic characteristic was used the initial rate of consumption of TBHP or VNB W_0 or the apparent rate constant k_{app}, calculated graphically from the slopes of the kinetic curves of TBHP consumption in the semilog coordinates. The determination error of these quantities did not exceed 5%.

The ^{1}H NMR spectrum was taken on a Tesla BS-567 spectrometer (100 MHz) from a 20% solution of the sample in CCl_4, with HMDS as internal reference. The IR spectrum was taken on a Shimadzu IR-4354 spectrophotometer in the range 4000 – 400 cm^{-1} from a thin film between NaCl plates. VNB monoepoxide isolated from the reaction mixture by fractional vacuum distillation had the following constants: bp 64.5–65.5°C at 1.13 kPa, d_4^{20} = 1.0224 g cm^{-3}, and n_D^{20} = 1.4875. Published data: bp 53–56°C at 4.5 mm Hg [26], 37°C at 20 mm Hg [4] (the latter value is probably a misprint; 2.0 mm Hg seems to be correct); n_D^{20} = 1.4870 [14].

Catalytic epoxidation of VNB with *tert*-butyl hydroperoxide at 80–100°C and molar ratio VNB : TBHP = 3 : 1 yields exclusively a mixture of isomeric monoepoxides exo-2,3-epoxy-5-vinylnorbornane (**I**) and 5-epoxyethyl-2-norbornene (**II**):



I



II

The chromatogram of the VNB epoxidation product contains two peaks in a 92 : 8 ratio. The structure of the VNB epoxidation product was studied by ^{1}H NMR and IR spectroscopy [27–29]; the spectra were compared with those of the initial VNB [30]. The major signals in the ^{1}H NMR spectrum of the VNB epoxidation product can be assigned to **I**, δ, ppm: 5.75 m (H^8), 5.0 q (H^9), 2.95 q (H^2 and H^3), 2.25 m (H^5), 2.4 m (H^1 and H^4), 1.7 m and 0.75 m ($2H^6$), 1.35 m and 1.1 m ($2H^7$); these parameters are identical to those obtained in [3, 4]. Compound **II** is detected as an impurity; the corresponding signals are weak, δ, ppm: 6.10 m, 5.95 m (H^3 and H^2); 2.8 m (H^8); 2.65 m, 2.15 m ($2H^9$).

IR spectrum, ν, cm^{-1}: 3068 m, 3040 s (ν_{C-H} in epoxy ring), 2966 s, 2864 s, 1636 s ($\nu_{C=C}$, –C=CH_2), 1461 m, 1446 m, 1424 w, 1377 s, 1321 m, 1280 w, 1265 m, 1236 w, 1223 w, 1158 w, 1087 w, 1028 w, 994 s ($\delta_{=C-H}$), 980 s, 910 s ($\delta_{=C-H}$), 866 s, 845 s (ν_{C-O}), 790 w, 764 w, 723 w, 661 w. The spectrum also confirms formation of **I** as the major product [4]. Selective hydroperoxide oxidation of VNB across the norbornene double bond was also noted in [14, 16]. Diepoxide derivatives of VNB are formed only with a large excess of TBHP, or by epoxidation of VNB monoepoxides.

Epoxidation of VNB in the presence of metal complexes can be accompanied by side reactions: radical decomposition of TBHP and reaction of the resulting VNB epoxide with *tert*-butyl alcohol. Experiments showed that the contribution of these reactions is small, and VNB epoxidation occurs selectively with a high conversion of TBHP. Also, epoxidation and subsequent isolation of the products can be accompanied by formation of polymers; this was prevented by adding an inhibitor, 4-*tert*-butylpyrocatechol (5×10^{-3} wt %), to the initial VNB.

We have performed several series of experiments in which we varied the initial concentrations of TBHP and catalyst in the reaction mixture, the molar ratio VNB : TBHP, and the reaction temperature and time. The influence of various factors on epoxidation of VNB is illustrated by Table 1.

The concentration of the catalyst, $MoO_2(OC_2H_4 \cdot OH)_2$, was varied from 1.9×10^{-4} to 23.3×10^{-4} M, which corresponds to the molar ratio Mo : TBHP from 1×10^{-4} : 1 to 12×10^{-4} : 1. We found that, as the catalyst concentration is increased, the TBHP conversion grows and the yield of VNB epoxide (mixture of isomers **I** and **II**) based on reacted TBHP (reaction selectivity) passes through a maximum. At the molar ratio Mo : TBHP = 12×10^{-4} : 1 the reaction selectivity decreases owing to accelerated thermocatalytic decomposition of TBHP. In further experiments on epoxidation of VNB we took the molar ratio Mo : TBHP = 6×10^{-4} : 1 ensuring reproducibly high yield of the target product.

With increasing initial concentration of TBHP in the reaction mixture from 0.97 to 1.95 M at the molar ratio VNB : TBHP = 3 : 1, the TBHP conversion increases, but the yields of VNB epoxide based on reacted TBHP and VNB decrease insignificantly. The best concentration of TBHP is 1.95 M (19.8 wt %); in this case the output of VNB epoxide from the unit of the reactor volume is the highest.

As noted in [20], olefins facilitate heterolytic decomposition of organic hydroperoxides. As the molar ratio VNB : TBHP is increased from 1 : 1 to 3 : 1, the conversion of TBHP increases from 77 to 98% and the yield of VNB epoxide based on reacted TBHP increases from 84.0 to 96.7 mol %. Taking VNB in more than threefold molar excess is not appropriate,

* (*K*) Conversion of TBHP; ** yield of VNB based on reacted TBHP (in numerator) and on reacted VNB (in denominator).

because it will require additional power consumption for recovery of recycled VNB.

With increasing tempertature, the conversion of TBHP increases, but the epoxidation selectivity decreases, especially above 110°C. At 100°C epoxidation is practically complete in 60 min. The residual TBHP concentration is less than 0.4 wt %, which allows safe isolation of VNB epoxide from the reaction mixture.

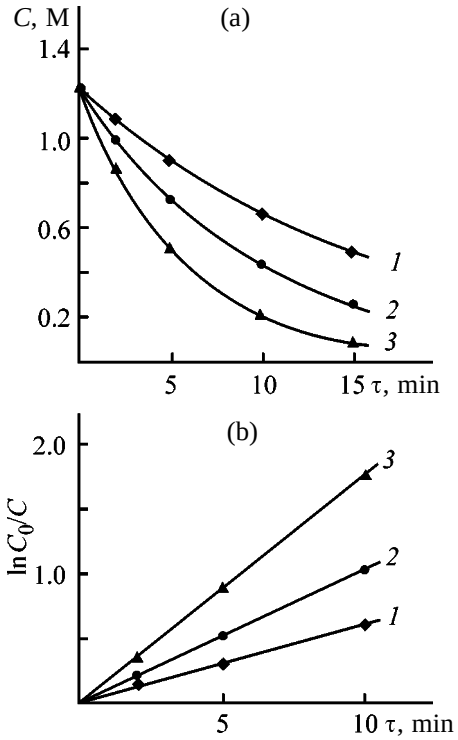

Fig. 1. (a) Variation with time τ of the TBHP concentration *C* in the course of VNB epoxidation and (b) the same curves in the semilog coordinates. Solvent toluene; initial concentration C_0, M: TBHP 1.23, VNB 3.65, and Mo 7.4 × 10^{-4}. Temperature, °C: (*1*) 80, (*2*) 90, and (*3*) 100.

Kinetic study of VNB epoxidation at 80–100°C showed that the hydroperoxide is consumed without noticeable induction period owing to high reactivity of VNB; the reaction rate is described by a first-order equation with respect to TBHP (Fig. 1). Certain deceleration of VNB epoxidation is observed at hydroperoxide conversions exceeding 70%. The temperature dependence of the apparent rate constant k_{app} (s^{-1}) of VNB epoxidation with *tert*-butyl hydroperoxide in toluene, catalyzed with $MoO_2(OC_2H_4OH)_2$, has the form $k_{app} = 5.26 \times 10^5 \exp(-58\,968/RT)$.

It is known [20] that the solvent used in hydroperoxide epoxidation of olefins appreciably affects each elementary stage of oxidation, primarily by affecting the solvation environment of the catalyst and the complexing power of the solvated catalyst toward the components of the reaction mixture. As a result, the epoxidation rate and selectivity are largely solvent-dependent. Studies of the solvent effect (Table 2) showed that the initial rate of TBHP consumption W_0 in the course of VNB epoxidation decreases in the order toluene > chlorobenzene > octane > isobutanol. There is no clear correlation of W_0 with the dielectric permittivity of the solvent. With a mixed solvent alcohol–aromatic hydrocarbon, epoxidation of VNB is accelerated, which is probably due to activation of

the molybdenum catalyst. Under certain conditions alcohol forming a stronger complex with the catalyst weakens the ligand–molybdenum bonds to such an extent that their fast exchange with the olefin becomes possible. The influence of alcohol on epoxidation of olefins was discussed in [31]. To ensure higher selectivity, it is appropriate to perform epoxidation of VNB without a solvent.

As VNB epoxidation catalysts we used the compounds of the most active transition metals [32]: Mo, V, and Ti (Table 3). It is seen from these data that in the presence of molybdenum catalysts, which are readily soluble in the reaction mixture, epoxidation of VNB occurs selectively with a high conversion of TBHP. The catalytic activity of the tested Mo catalysts shows no noticeable dependence on the ligand. The heterogeneous catalyst MoB ensures a higher selectivity of VNB epoxidation, but the reaction rate is lower. Sapunov *et al.* [33] revealed a correlation of the catalytic activity of organometallic epoxidation catalysts with the acceptor power of the metal ion, characterized by the specific charge of the metal ion z/r^2, where *z* is the charge and *r*, the radius of the metal ion [34]. Table 3 shows that the activity of the catalysts decreases in the order Mo > V > Ti, i.e., with decreasing specific charge of the metal ion.

CONCLUSIONS

(1) The optimal conditions were determined for epoxidation of 5-vinylnorbornene with *tert*-butyl hydroperoxide in the presence of a soluble molybdenum catalyst, providing the reaction selectivity of 96–98 mol %: initial concentration of *tert*-butyl hydroperoxide 1.95 M, molar ratios 5-vinyl-2-norbornene : *tert*-butyl hydroperoxide = 3 : 1 and Mo : *tert*-butyl hydroperoxide = 6×10^{-4} : 1, 100°C, and reaction time 60 min.

(2) The apparent activation energy of epoxidation of 5-vinyl-2-norbornene is 59 kJ mol^{-1}.

(3) Analysis by gas–liquid chromatography and ^1H NMR and IR spectroscopy shows that epoxidation of 5-vinyl-2-norbornene yields *exo*-2,3-epoxy-5-vinylnorbornane and a minor amount of isomeric 5-epoxyethyl-2-norbornene.

(4) The activity of catalysts in epoxidation of 5-vinyl-2-norbornene decreases in the order Mo > V > Ti,

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thermal Degradation of Polyvinylpyrrolidone on the Surface of Pyrogenic Silica

V. M. Bogatyrev, N. V. Borisenko, and V. A. Pokrovskii

Institute of Surface Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received November 20, 2000

Abstract—Thermal degradation of polyvinylpyrrolidone was studied by thermogravimetry, IR spectroscopy, and thermal-desorption mass spectrometry.

Due to high complexing and adhesion properties, nontoxicity, and solubility in water and most organic solvents polyvinylpyrrolidone (PVP) is widely used in various branches of industry [1]. Along with common use of PVP in medicine, pharmacology, and textile industry, studies are actively pursued aimed at preparing new materials on its basis. Among them preparation of new copolymers and polymer blends including organic-inorganic hybrid materials and nanocomposites is the most promising. Such polymer–silica composites based on PVP were prepared by adsorption procedure [2, 3] or by grafting to the surface of solid particles with formation of covalent bonds between the polymer and SiO_2 [4, 5]. Previously, the PVP–silica materials were used to prepare selective membranes [6, 7], optical materials [8, 9], and chromatographic supports [10, 11].

In highly filled polymeric systems the fraction of PVP units directly contacting with the silanol surface groups of silica increases. It is known that the degree of filling and the nature of the surface active groups of dispersed filler significantly affect thermal and thermal oxidative degradation of polymeric materials [12]. Since for PVP such data are lacking, the study of thermal transformations of PVP in the adsorption layers of various thickness on the surface of finely dispersed silica is urgent.

EXPERIMENTAL

In our work we used medical-grade PVP (Sintvita, Russia) with an average molecular weight of 10 700 and A-300 Aerosil pyrogenic silica (Khlorvinil, Ukraine) with a specific surface area of 320 $m^2 g^{-1}$.

The samples were prepared as follows. First, a dispersion of silica and a 10% solution of PVP in distilled water were prepared, and the required amount of the PVP solution was added to the silica dispersion. Then the resulting mixture was thoroughly mixed and after 1-h storage deposited on glass plates as thin layers, which were dried at 80°C for 4–5 h. The product was ground in an agate mortar and additionally dried at 80°C for 1 h.

The silica samples with sorbed PVP were analyzed for the carbon content on an AN-7529 express analyzer by combustion in an oxygen flow. The specific surface area was determined by low-temperature desorption of argon according to the standard procedure. The properties of the resulting PVP–silica samples are listed in Table 1.

Thermal analysis was carried out using a Q-1500 D derivatograph. The measurement parameters were as follows: 500, 500, and 250 μV for TG, DTA, and DTG, respectively; sensitivity 200 mg, and heating rate 10 deg min^{-1}. The samples (300.16 ± 0.24 mg) were heated in a ceramic crucible.

The IR spectra were taken from pressed samples (5–6 mg cm^{-2}). The thermal transformations were studied using a heated quartz cell (CaF_2 optics). The

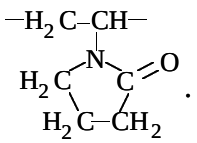
sample was heated in a spectral cell for 15 min in air and then evacuated for 1–1.5 min without cooling. The IR spectra were registered after cooling of the sealed cell to room temperature. Then the temperature of the spectral cell was increased and the measurement cycle was repeated. The IR spectra were registered on a Specord M-80 spectrophotometer.

The mass-spectrometric measurements were carried out on a vacuum thermal-desorption unit with a heated quartz cell. The mass spectra were registered on an MKh 7304 spectrometer equipped with a computer system for registration and treatment of the experimental results. The sample weight was 2.0 ± 0.3 mg.

The average molecular weight of the PVP used indicates that the polymer molecule contains about 96 monomeric units



High solubility of PVP in water allowed preparation of silica dispersions in the PVP solution in a wide concentration range of components. The presence of the silanol groups on the silica surface and the tertiary amine and carbonyl groups in the polymer molecule suggests strong adsorption interaction. However, it was found [13] that in the hybrid PVP–silica material the polymer and SiO_2 are bound only through the hydrogen bonds between the carbonyl and silanol groups.

The IR spectra of the PVP–silica samples studied exhibit the bands of stretching vibrations of the SiO–H groups (3748 cm^{-1}) that do not participate in bonding with carbonyl groups. With increasing polymer concentration the intensity of the absorption band of the C=O group (1664 cm^{-1}) increases, whereas the band at 3748 cm^{-1} decreases and finally completely disappears. With decreasing PVP concentration the fraction of the units in the polymer chain interacting with the silanol groups on the silica surface increases. These results agree with the data on the sorption of PVP on silica [3].

With increasing content of the polymer the specific surface area of the samples decreases because of the increase in the layer thickness of sorbed PVP (Table 1).

The DTG curves of the PVP–silica layers are shown in Fig. 1. The first peak with the maximal weight loss for all the samples occurs at 100–115°C and corresponds to the removal of water physically sorbed on the silica surface [14]. The DTG curves for sample nos. 2–5 exhibit three steps of the weight loss, and only in the case of sample no. 1 thermal oxidative degradation proceeds in two steps. The parameters of the weight loss during thermal degradation are given in Table 2. The weight loss in the 200–1000°C range is taken as 100%. In each sample the temperature boundary between the degradation steps was determined as the point of the minimal rate of the weight loss.

As seen from the above data, despite different width of the temperature range of the first step of oxidative degradation, the temperature maxima of all the samples occur in the narrow range: 315–325°C. Similar pattern is observed for the second step of oxidative thermolysis: T_{max} is 420–425°C, except sample no. 1.

The third stage of degradation is characterized by a lower rate of the weight loss. In this case the DTG curves exhibit a broad peak whose T_{max} increases from 570 to 660°C with increasing content of PVP in the sample.

The TG analysis reveals two stages of thermal oxidative degradation with nearly equal weight losses. The first stage proceeds in two steps, and their parameters change depending on the amount of sorbed PVP. With decreasing content of PVP in the sample the relative contribution of the weight loss in the second step decreases. As seen, in sample no. 1 the first stage of thermolysis proceeds in one step. The second stage

of thermal oxidative degradation occurs in one step, with similar weight loss for all the samples.

For comparison, we performed the TG analysis of the initial PVP under the conditions similar to those used for the PVP–silica samples. The weight composition of the sample was comparable with that of sample no. 5: 100 mg of the polymer was mixed with 200 mg of the inert filler. As seen, the parameters of thermal oxidative degradation of this sample are significantly different. The first peak of the weight loss at T_{max} 105°C belongs to the removal of water, whose presence is manifested by a broad band at 3000–3600 cm^{-1} in the IR spectrum. The most intense weight loss is observed in a narrow temperature range (Table 2). Thermal degradation of the initial PVP powder without filler (137 mg) exhibits nearly similar results. The main weight loss (75%) occurs in the 330–430°C temperature range.

As seen from the data on the weight loss (Table 2), adsorption of PVP on the pyrogenic silica surface induces intense oxidative degradation of the polymer at lower temperatures, but hinders oxidation of the carbonized residue.

Adsorption of the PVP molecules on the silica surface decreases the flexibility of the molecular chains, causing the nonequilibrium strained state of the polymer chain [15]. As a result, the strained sections that appeared in macromolecule more readily undergo thermal oxidation, and thus the volatile products can appear under milder conditions. According to [16], the volatile products of PVP oxidation at 300–400°C are carbon dioxide and pyrrolidone. We assume that the TG peak at T_{max} 320°C belongs specifically to the stage of thermal oxidative degradation of the strained sections of the polymer chain. The relative weight loss in this stage decreases with decreasing weight fraction of silica and thus with decreasing surface area of silica in the sample.

The stage of oxidative degradation at T_{max} 420°C was observed for all the samples containing more than 12% PVP. This stage involves thermal degradation of the polymer chains occurring in the adsorption layer at a larger distance from the silica surface. The relative weight loss in this step increases with increasing content of PVP in the sample.

The IR spectroscopic study of thermal oxidative degradation of the PVP–silica samples in air was performed by heating in steps according to the procedure given above. The IR spectra of sample no. 1 registered in the 20–600°C range are shown in Fig. 2a. As seen, a new absorption band appears at 1600–1800 cm^{-1}.

The dependences of the intensity of the selected absorption bands on the temperatures of thermal degradation are shown in Fig. 2b. Above 200°C a new absorption band appears at 1712 cm^{-1} and reaches the highest intensity at 300°C. At this temperature the majority of the C–H groups is broken down (Fig. 2b, curves *1, 4*) and the sample becomes brown. The IR spectrum of sample no. 5 with the highest content of PVP exhibits an absorption band at 1770 cm^{-1} after heating to 300–350°C (Fig. 2c).

Appearance of new absorption bands in the course of thermal degradation is probably due to the change in the environment of the carbonyl groups of the sorbed polymer, with formation of double bonds. The stretching vibration band of the C=O groups conjugated with these double bonds is observed at 1720 cm^{-1} [17]. With increasing layer thickness of the adsorbed polymer more complex cyclic structures involving carbonyl groups and oxygen atoms in the polymer chain can appear. The frequencies of the C=O groups in such structures are 1740–1800 cm^{-1} [17].

The thermal degradation of the adsorbed polymer in vacuum was monitored by the composition of the

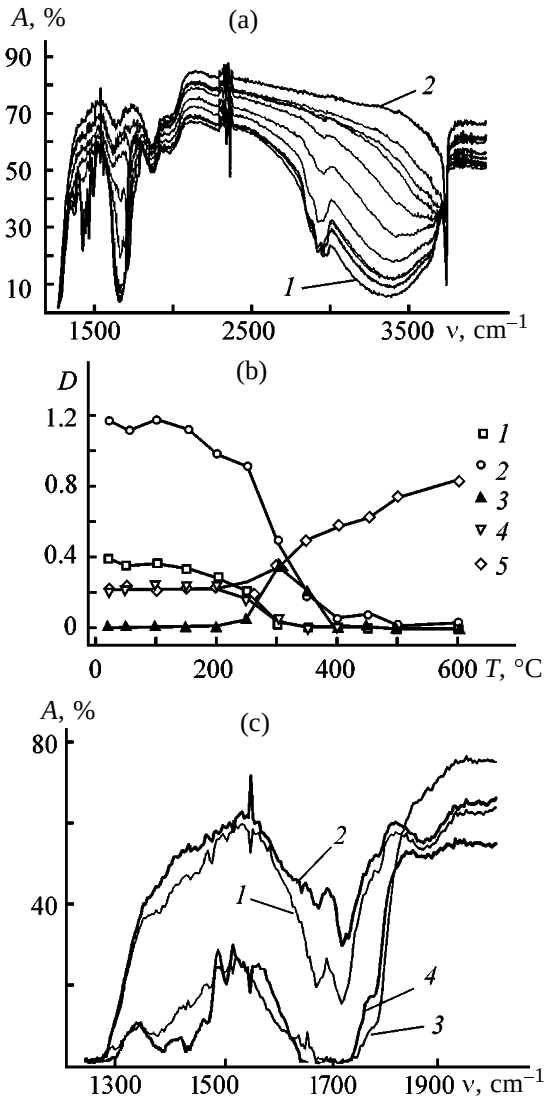

Fig. 2. (a) IR spectra of sample no. 1 (*1*) at room temperature and (*2*) after heating for 15 min to 600°C in air and evacuation for 1 min (intermediate spectra correspond to intermediate heating temperatures); (b) optical density $D = \log I_0/I$ at (*1*) 1428, (*2*) 1660, (*3*) 1712, (*4*) 2924, and (*5*) 3748 cm^{-1} as influenced by the temperature of thermal treatment *T*, and (c) IR spectra of sample nos. (*1*, *2*) 1 and (*3*, *4*) 5 after heating for 15 min in air at 300 and 350°C and evacuation for 1 min. (*A*) Transmission and (ν) wave number.

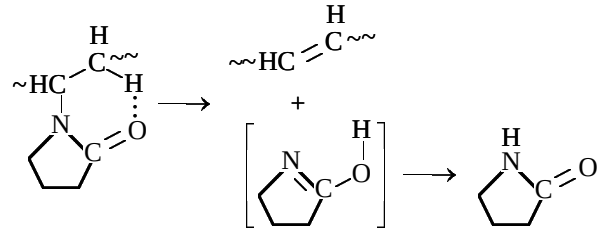
volatile degradation products using mass spectrometry. It was found that the degradation of PVP with liberation of pyrrolidone begins at approximately 100°C in all the samples studied. This low-temperature step in the PVP degradation suggests that similar process occurs in air simultaneously with removal of water from the samples. We failed to separate the contributions of these processes to the weight loss using IR and DTG data.

The degradation of the PVP–silica and initial PVP samples involves different number of stages (Fig. 3). The low- and high-temperature stages proceed at T_{max} 90–105 and 350–390°C, respectively. Additional step is observed for the initial PVP at 280–300°C. To confirm that this intermediate step involves thermal degradation of the initial polymer, we studied the PVP samples with an average molecular weight of 10000. For this purposed we used another PVP sample from Sintvita (Russia), K-15 PVP (Fluka), and PVP after dissolution in water and drying in air at 75°C. In all the cases the intermediate stage of thermal degradation was observed. Simultaneous appearance of various ions in the mass spectra (Fig. 3) indicates degradation of the polymer with formation of volatile products and their further fragmentation in the ionization source of a mass spectrometer.

As seen from the mass spectra registered at T_{max} for low- and high-temperature degradation stages, the difference in the yields of the molecular ions of pyrrolidone (85^+) and vinylpyrrolidone (111^+) is the most significant. These two ions can be used to analyze thermal degradation of PVP, because the relative intensity of the ion 85^+ in the mass spectra of vilylpyrrolidone is lower than 8.1% [18], whereas in the spectrum of pyrrolidone the vinypyrrolidone molecular ion (111^+) is absent.

The mass thermograms for the ions 85^+ and 111^+, taken in the course of degradation of the samples with adsorbed polymer, are shown in Fig. 4. As seen, pyrrolidone is released in two stages, whereas vinylpyrrolidone appears only in one stage; the ratio of the release of pyrrolidone in both stages was determined. For sample nos. 1, 3, 5 the ratio I_{85^+}(2nd stage)/I_{85^+}(1st stage) is 6.56, 2.75, and 1.66, respectively; in the case of the initial PVP it is 1.04.

The degradation of vinyl polymers (polyvinyl alcohol, polyvinyl acetate, polyvinyl chloride) starts with breakdown of the side groups [19] with formation of the corresponding double bonds. Similar scheme of breakdown of the pyrrolidone ring with formation of the intermediate cyclic complex was suggested for PVP in [16].



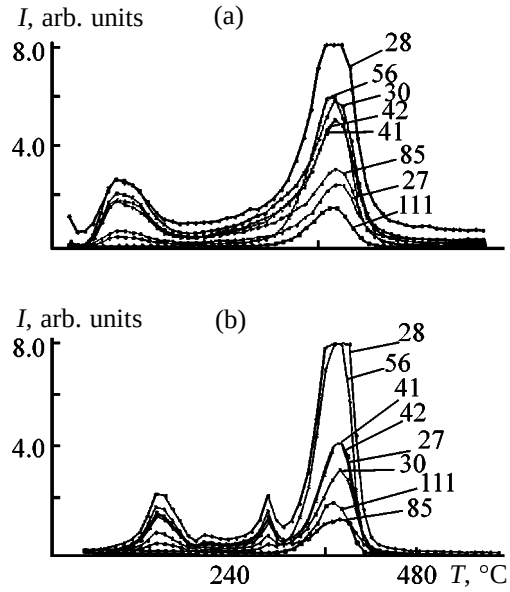


Fig. 3. Mass thermograms of (a) sample no. 5 and (b) initial PVP. (*I*) Relative intensity and (*T*) temperature; the same for Fig. 4. The numbers at the curves are the weights of the positive ions.

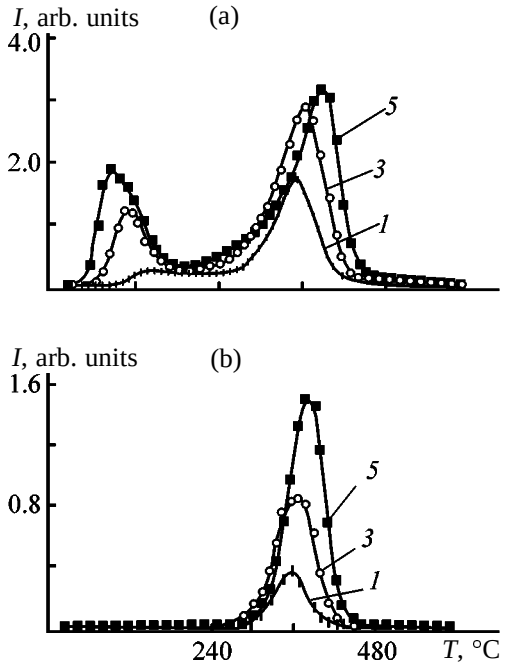

Fig. 4. Mass thermograms for the ions (a) 85^+ (pyrrolidone) and (b) 111^+ (vinylpyrrolidone).

The hydrogen bond between the C=O group in PVP and the silanol group of the SiO_2 surface can block formation of such cyclic complex and thus hinder elimination of pyrrolidone from the polymer chain. This phenomenon is observed in the low-temperature stage of thermolysis. With decreasing amount of adsorbed polymer the fraction of the carbonyl groups bound by hydrogen bonds decreases, which, in turn, decreases pyrrolidone release. Restricted flexibility of the polymer molecules sorbed on the support can also decrease the yield of the intermediate complexes.

Vinylpyrrolidone is released only in the high-temperature stage of PVP degradation. We found certain correlation between the ratio I_{85^+}/I_{111^+} and the content of PVP in the sample. This ratio changes from 4.35 to 2.03 for sample nos. 2 and 5, respectively. In the case of various initial PVP samples I_{85+}/I_{111+} varies within the range 0.53–0.68.

Thermal degradation of the polymer macromolecule is accompanied by breakdown of both side and main chains. This process involves elimination of the monomer units from the ends of the main chain and with increasing number of the breaks in the main chain the polymerization rate increases. Variation of the ratio of the degradation products (ions 85^+ and 111^+) suggests changes in the thermal degradation mechanism.

In all the PVP–silica samples a pronounced dependence is observed between the amount of the adsorbed polymer and degradation with release of pyrrolidone and depolymerization with formation of vinylpyrrolidone. In the samples with a lower content of PVP, i.e., with a higher content of the units of adsorbed macromolecule directly bound to the silica surface, thermal degradation in the high-temperature stage is characterized by a greater contribution of elimination of the pendant rings and smaller contribution of depolymerization. Thermal treatment in a vacuum at 700°C gives a carbonized residue on the silica surface. After vacuum thermolysis in the course of mass spectrometric studies the samples studied became black.

Our experimental results give the following qualitative pattern of PVP degradation. At temperatures of up to 200°C certain fraction of pyrrolidone rings is removed and double bonds in the chains appear. As a result, cross-links in the polymer are formed, which hinder the flexibility of macromolecule. With increasing temperature, separate units of the initial PVP molecules acquire the mobility required to form intramolecular complexes promoting elimination of the pyrrolidone rings (T_{max} 280–300°C). In contrast, in the case of PVP–silica samples the solid matrix significantly affects macromolecules occurring in the adsorption layer, which additionally hinders flexibility of macromolecules and thus elimination of the pen-

dant groups. As a result, the stage with T_{max} 280–300°C in the PVP–silica samples is absent.

Further heating causes the homolytic cleavage of the polymer chains in both initial and adsorbed polymer (T_{max} 360–400°C). In this degradation stage sorbed polymer hinders cleavage of the main chain and thus promotes carbonization of the silica surface.

CONCLUSIONS

Thermal and thermal oxidative degradation of polyvinylpyrrolidone sorbed on the pyrogenic silica surface and of that occurring in the initial state differs in the number of degradation stages and amount of the volatile products appearing in these stages. In both cases adsorption of polyvinylpyrrolidone shifts the processes completing the polymer degradation toward higher temperatures. The increased fraction of the polymer units directly bound with the silanol groups on the silica surface hinders release of pyrrolidone in the low-temperature degradation stage and depolymerization of polyvinylpyrrolidone at high temperatures.

Received November 23, 2000

Abstract—The influence of carborane-containing peroxides on the efficiency of grafting of methylenebutanedioic acid to low-density polyethylene in a single-screw extrusion reactor equipped with a static mixer was studied.

Grafting of monomers containing chemically active functional groups to polyolefin macromolecules is a subject of active study in many research centers [1–6], which is due to growing use of grafted products in preparation of polymeric composites, mostly of polymer blends and alloys. As a rule, grafting is performed in a polyolefin melt; as continuous reactors are used special extruders acting simultaneously as high-performance mixers of the components and providing controllable feeding of the components, removal of by-products, accurate temperature control, control of the velocity of the reaction mixture transport, etc. [1, 6]. The yield of the grafted product and the course of side processes are determined both by the extruder design features and by the reaction mixture composition [1, 5, 6]. In particular, we showed in [5, 6] that the course of grafting of methylenebutanedioic acid (MA) to low-density polyethylene (LDPE), at identical apparatus design and process (thermal) parameters, is largely influenced by the nature and concentration of the peroxide initiator. Use for these purposes of commercial peroxides [dicumyl peroxide (DCP), 2,5-dimethyl-2,5-di-*tert*-butylperoxyhexane, etc.] results in active chemical cross-linking of the macromolecules, occurring simultaneously with grafting of MA. As a result, strongly cross-linked products are formed, which limits their use for fabrication of composites. Furthermore, the product obtained by grafting of MA to LDPE (LDPE-*graft*-MA) with traditional peroxides exhibits a poor resistance to thermal oxidative degradation in air and in aqueous solution [7].

In [8–10] we described the synthesis of unsaturated carborane-containing peroxides. These peroxides can be used for cross-linking of polyethylene [11], initiating high-temperature radical cross-linking reactions. In contrast to cross-linked polyethylene prepared with traditional peroxides, the product obtained with carborane peroxides exhibits enhanced resistance to thermal oxidative degradation [11]. Presumably, the thermostabilizing effect of carborane peroxides is due to grafting of carborane-containing fragments formed by thermolysis of the peroxide to macromolecules and intermolecular cross-linking through boron atoms. The possibility of grafting to polyolefin molecules of functional groups of unsaturated peroxides is indicated, e.g., by Assoun *et al.* [12] who studied grafting of carboxy groups to polypropylene macromolecules in the melt under the action of peroxy acids.

It is interesting to evaluate the effect of carborane-containing peroxides as initiators of grafting of functional monomers to polyethylene macromolecules. Here this problem is studied with grafting of MA to LDPE as example.

EXPERIMENTAL

We used LDPE of 15803–020 brand [GOST (State Standard) 16337–77, Polimir Production Association, Novopolotsk; density 0.92 g cm^{-3}, mp 105°C] and MA purchased from Chemical Division Pfizer, the United States. The following carborane-containing peroxides were chosen (Table 1): peroxy esters **I** and

1070-4272/01/7405-0845$25.00

Table 1. Characteristics of peroxide initiators*

Peroxide	Name	Available oxygen content, %	
		found	calculated
DCP	Dicumyl peroxide	–	5.92
I	3-Methyl-3-(*o*-carboranoylperoxy)-1-butyne	5.66	5.92
II	3-Methyl-3-(*m*-carboranoylperoxy)-1-butyne	5.62	5.92
III	1,7-Bis(*tert*-butylperoxymethylvinylsilyl)-*m*-carborane	6.32	6.95
IV	Bis(3-methyl-3-*tert*-butylperoxy-1-butynyl)-1-*m*-carboranylmethanol	–	6.63

II [8], silylcarborane **III** [9], and mixtures of peroxy alcohols with alkylperoxy groups **IV**–**VII** [10]. For comparison, we also used DCP whose effect on grafting of MA to LDPE, as well as the properties of the resulting products, are relatively well studied [5, 6, 13]. Also we tested mixtures of carborane-containing peroxides with DCP.

Grafting was performed in a single-screw extruder additionally equipped with a static mixing head, under the following conditions: nitrogen atmosphere; screw rotation rate 35 rpm; temperatures, °C: zone I 160 and zones II–IV and mixing head 185. The scheme of the extrusion reactor is similar to that shown in [6] for the Brabender plastograph equipped with a static mixer. The process for preparing the reaction mixture is also described in [6].

As parameter characterizing the progress of grafting, we used the grafting efficiency α: the weight ratio of the grafted acid to its total amount introduced into the polymer [6]. The quantity α was calculated from the content of MA in LDPE before and after extraction with ethanol at 70°C, determined by IR absorption spectroscopy [6, 14].

The viscosity of the polymer melt was evaluated by the melt flow index (MFI), which was determined at 190°C and a load of 10 kg with an IIRT-AM device (Ekodatchik Private Company, Tula, Russia).

The thermal stability of peroxides was evaluated with an MOM derivatograph (Hungary) under argon; the sample weight was 100 mg, and the linear heating rate, 7 deg min^{-1}. The reaction order n of thermal decomposition of peroxides was calculated by the Kissinger method [15]. The apparent activation energy E_a was determined from the exothermic peak in the DTA curve in the temperature range where the linear dependence was preserved (up to 130°C for **I** and **II**, 160°C for **III**, and 155–160°C for **IV**–**VII**) [15]. The thermal analysis of the polymeric samples was performed with a derivatograph in air; the sample weight was 500 mg, and the heating rate, 2.5 deg min^{-1}.

Tables 1 and 2 show that in peroxy esters **I** and **II** the available oxygen content is similar to that in DCP, but the thermal stability of **I** and **II** (T_{od} denotes the temperature of the onset of degradation) is lower: T_{od} = 116–118°C; for *ortho* isomer **I** n = 1.89 and E_a = 153 kJ mol^{-1}; for *meta* isomer **II** n = 1.63 and

Table 2. Characteristics of thermal stability of carborane-containing peroxides

	2	186	485	–	7.0					
V	1	127	192	166	30.5	99	126	168	1.60	153
	2	192	257	–	5.0					
	3	257	463	–	32.0					
VI	1	125	185	170	50.0	–	124	172	1.43	130
	2	185	480	–	14.0					
VII	1	123	194	157	31.0	51	122	163	1.61	153
	2	194	272	–	8.0					
	3	272	470	–	41.0					

E_a = 112 kJ mol^{-1}; at the same time, for DCP T_{od} = 127°C, n = 1.16, and E_a = 154 kJ mol^{-1}. Peroxides **I** and **II** initiate grafting of MA to LDPE under experimental conditions (concentration 0.15 wt %) with an efficiency of 23–25% (with DCP α = 66.7%, Table 3). In diperoxy alcohols **IV**–**VII**, the available oxygen content is somewhat higher than in DCP (Table 1), and their thermal stability is similar to that of DCP (T_{od} = 123–127°C); however, the character of decomposition of **IV**–**VII** is different (n = 1.43–1.61, E_a = 130–153 kJ mol^{-1}). The performance of diperoxy alcohols in grafting MA to LDPE approaches that of DCP. At concentrations of the mixtures **IV** + **V** and **VI** + **VII** of 0.15 wt %, α = 37.5–40.9% (Table 3, entries 6 and 7). At a concentration of the mixture **VI** + **VII** of 0.3 wt %, the grafting efficiency is 83.1%, being similar to the grafting efficiency attained with DCP (84.4%) (Table 3, entries 6 and 7).

An important advantage of carborane-containing peroxides **I**, **II**, and **IV**–**VII** over DCP is suppression, to a large extent, of the concurrent cross-linking of polyethylene macromolecules. The parameter sensitive to cross-linking accompanying MA grafting is MFI

Table 3. Influence of peroxides on the MA grafting efficiency and MFI of the polymer

Entry	Initial composition	MFI, g/10 min	α, %
1	LDPE	16.9	–

Note: Weight ratio of components in peroxide mixtures 1 : 1.

[6]. A significant decrease in MFI on grafting of MA to LDPE is one of the main drawbacks of the process based on using DCP. For example, Table 3 shows that MFI of the initial LDPE is 16.9 g/10 min. Grafting of MA in the presence of 0.15 and 0.3 wt % DCP yields a functionalized product with MFI of 10.2 and 2.8 g/10 min, respectively. Thus, with DCP it is impossible to graft MA to LDPE with a high (>80%) yield and therewith avoid strong cross-linking.

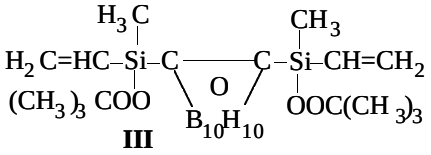
In contrast to the product obtained with DCP, MFI of polyethylene grafted with MA in the presence of peroxy esters **I** and **II** (0.15 wt %) is similar to that of the initial LDPE, which suggests practically no cross-linking. The occurrence of concurrent cross-linking of LDPE macromolecules with diperoxy alcohols **IV** + **V** and **VI** + **VII** depends on the structure of the *tert*-alkyl group at the O–O bond. For example, in the case of diperoxy alcohols **VI** + **VII** with *tert*-pentylperoxy groups (0.15 wt %) the cross-linking of macromolecules is insignificant (MFI 15.9 g/10 min), and with compounds **IV** + **V** containing *tert*-butylperoxy groups MFI of LDPE-*graft*-MA is 12.0 g/10 min (Table 3). It should be noted also that in the case of grafting initiation with peroxides containing *tert*-pentylperoxy groups grafting of MA to LDPE is more efficient (α = 40.9%) as compared to peroxy alcohols with *tert*-butylperoxy groups (α = 37.5%).

As seen from Table 3, addition of carborane-containing peroxide **I** or **II** or of a mixture of diperoxides **IV** + **V** to DCP allows significant reduction of the yield of the cross-linked product with a sufficiently high grafting efficiency. For example, the materials obtained with a mixture of DCP with **I**, **II**, or **IV** + **V** are characterized by MFI = 13.4–15.1 g/10 min and α = 44.5–46.7% (Table 3, entries 11, 13, 15).

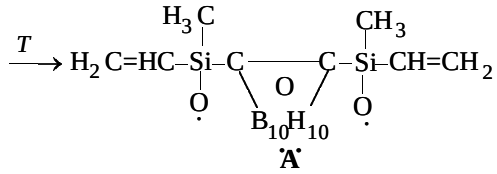
With a concentration of the peroxide mixtures of 0.3 wt %, MFI is lower, 3.7–5.5 g/10 min, at α = 56–74.2%; with straight DCP MFI = 2.8 g/10 min and α = 84.4% (Table 3, entries 3, 12, 14, 16).

Among the tested carborane-containing peroxides, the most thermostable is silylcarborane **III** (T_{od} = 135°C), which can be simultaneously considered as a peroxide monomer owing to the presence of two vinyl groups; however, under the experimental conditions (0.15 and 0.3 wt %) it is the least efficient initiator of MA grafting to LDPE (Table 3, entries 8, 10; α = 18.4 and 29.1%, respectively). This is probably due to partial consumption of radicals generated by decomposition of **III** for initiation of oligomerization of the carborane-containing fragment via double bonds and its grafting to polyethylene macromolecules. This processes can be represented as follows [12, 13].

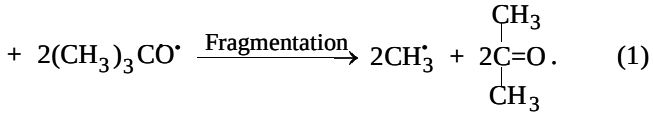
Thermal decomposition of peroxide:



III



A

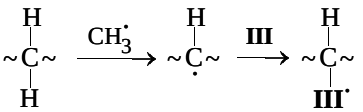


(1)

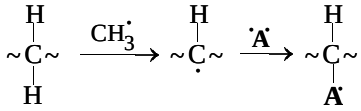
Oligomerization of peroxide:

(2)

Grafting of peroxide to LDPE macromolecules:

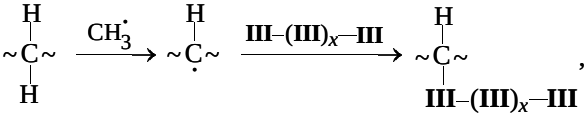


or



(3)

Grafting of oligoperoxide:



(4)

It should be noted that biradical **·A·** owing to steric hindrance is low-mobile and should not exhibit appreciable initiating power as compared to $^{\cdot}OC(CH_3)_3$ and $^{\cdot}CH_3$. Therefore, oligomerization of peroxide **III** by scheme (2) is improbable. Hence, grafting to LDPE of oligomeric fragments of **III** [scheme (4)] is also improbable. The most probable pathway is formation of products with monomolecular grafted fragments of peroxide **III** [scheme (3)].

The noticeably higher MFI (18.5 and 20.3 g/10 min) of the sample obtained with silylcarborane **III**, as compared to the initial LDPE (MFI 16.9 g/10 min) (Table 3, entries 1, 8, 10) indicates that a material with new physical (rheological) characteristics is formed. The higher MFI of LDPE-*graft*-MA obtained in the presence of silylcarborane **III** may be due to

Table 4. DTA data for the polymeric materials prepared

Entry	Initial composition, wt %	T_{od}	T_{10}	T_{50}	T_{ox}
		°C			
1	LDPE	360	390	445	170
2	LDPE/MA + 0.3DCP	360	385	440	160
3	LDPE/MA + 0.3(DCP + **I**)	358	380	445	162
4	LDPE/MA + 0.3(DCP + **II**)	351	380	455	162
5	LDPE/MA + 0.3(DCP + **IV** + **V**)	360	375	450	175
6	LDPE/MA + 0.3(**VI** + **VII**)	362	397	442	180
7	LDPE/MA + 0.3(**III**)	360	388	450	190

Note: (T_{od}, T_{10}, T_{50}, T_{ox}) temperatures of the onset of degradation, 10 and 50% weight loss, and onset of oxidation, respectively.

degradation of the macromolecules, which is hardly probable [9], or to the lubricating effect of grafted (and nongrafted) organosilicon fragments in the polymer melt. It is known [16] that organosilicon compounds are good lubricants. Therefore, the increase in MFI on grafting in the presence of **III** should be mainly due to the lubricating effect of the thermolysis products of **III**.

The use of carborane-containing peroxides (straight or mixed with dicumyl peroxide) noticeably enhances the resistance of LDPE-*graft*-MA to thermal oxidative degradation as compared to the material prepared in the presence of DCP (Table 4). Thermal oxidation of functionalized polyethylene prepared using a mixture of diperoxy alcohols **VI** + **VII** (0.3 wt %, Table 4, entry 6) and a mixture of **IV** + **V** with DCP (0.3 wt %, entry 5) is accompanied by the weight gain in the TG curve, with the onset at 180 and 175°C, which is 15–20°C higher compared to the material prepared with DCP (Table 4, entry 2). The material prepared with peroxide monomer **III** exhibits the highest resistance to thermal oxidative degradation: Its thermal oxidation starts only at 190°C, which is 30°C higher than the onset temperature of oxidation of the functionalized polyethylene formed in the presence of DCP. Presumably, the thermostabilizing effect of carborane-containing peroxides is due to grafting of carborane-containing fragments to polyethylene macromolecules. This effect is especially characteristic of **III**.

CONCLUSIONS

(1) The performance of peroxides containing carborane fragments in initiation of grafting of methylenebutanedioic acid to low-density polyethylene macromolecules depends on the chemical structure of the peroxides.

(2) Initiation of grafting with a mixture of diperoxy alcohols **VI** + **VII** containing alkylperoxy groups ensures formation of the functionalized polymer with the grafting efficiency comparable to that attained with dicumyl peroxide initiator, with the appreciably reduced degree of cross-linking of the macromolecules.

(3) Peroxide silylcarborane monomer **III** used as initiator allows preparation of the material with the melt flow index 10–20% higher than that of the initial LDPE.

(4) Functionalized low-density polyethylene prepared in the presence of carborane-containing peroxides exhibits enhanced resistance to thermal oxidative degradation as compared to the product obtained in the presence of dicumyl peroxide.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Chromatographic Retention Parameters of Certain Benzimidazole Derivatives on Octadecyl Silica Gel

A. I. Zhebentyaev, N. A. Alekseev, and D. A. Rozhdestvenskii

Vitebsk State Medical University, Vitebsk, Belarus

Received October 19, 2000; in final form, February 2001

Abstract—Certain trends in chromatographic retention of benzimidazole derivatives on octadecyl silica gel (mobile phase phosphate buffer–acetonitrile) are considered. Retention parameters of compounds being separated are estimated and interpreted in terms of the reversed-phase HPLC theory.

Benzimidazole (BI) derivatives are widely used in medical practice as spasmolytic (Dibasol), antihypoxanthic (Bemityl) [1], and antisecretory (Omeprazole) drugs. Some of BI derivatives are now studied as potential drugs (Tomerzole, etc.). Therefore, development of universal methods for detection of compounds of this group in medical products and also in biological fluids in studying pharmacokinetics of these drug preparations is an urgent problem. Furthermore, it was demonstrated in [2, 3] that knowledge of the retention parameters in reversed-phase chromatography allows prediction of the lipophilicity of biologically active compounds and, therefore, their behavior in the body, which is particularly important in developing novel drugs by structural modification of known compounds.

In this work we studied the chromatographic characteristics of BI derivatives under conditions of reversed-phase HPLC.

EXPERIMENTAL

In the work we used the following BI derivatives: Bemityl (2-ethylthiobenzimidazole hydrobromide), Dibasol (2-benzylbenzimidazole hydrochloride), Omeprazole (5-methoxy-2-{[(4-methoxy-3,5-dimethyl-2-pyridyl)methyl]sulfonyl}benzimidazole), and Tomerzole (2-ethylthio-5-ethoxybenzimidazole hydrochloride) with 99% content of the main component. As a model compound we used 2-benzyl-5,6-dimethylbenzimidazole hydrochloride (BDB). The samples were 10^{-4} M aqueous solutions of the indicated compounds.

Chromatographic study was carried out with a Milikhrom-4 liquid chromatograph (Nauchpribor Research and Production Association, Russia) (spectrophotometric detector; 64×2 mm steel column packed with Separon-C_{18} sorbent, grain size 5 μm). Mobile phases were prepared by mixing acetonitrile with aqueous KH_2PO_4 of a fixed concentration; pH of the eluent was adjusted with KH_2PO_4, orthophosphoric acid, and KOH. The sample volume was 5 μl. Acetonitrile (Kriokhrom, Russia) of ultrapure grade was distilled with a dephlegmator prior to use. Also double-distilled water and potassium dihydrogen phosphate of chemically pure grade were used. The retention volume of an unsorbable component (sodium nitrite) was 110 μl. The analytical wavelengths were 300 nm for Tomerzole and Bemityl, 274 nm for Dibasol and BDB, and 214 nm for Omeprazole.

For separation of the BI derivatives we used reversed-phase HPLC, since these compounds differ from each other by the structure of alkyl, alkoxy, and other substituents in the BI system. When studying sorption of the tested compounds on a nonpolar sorbent, their tendency to ionization with decreasing pH should be taken into account as well as the contribution of various substituents to the sorption equilibrium constant.

The dependence of the chromatographic retention on the eluent pH is given in Fig. 1. The observed dependence is typical of weak organic bases. The decrease in the retention of the compounds in an acidic medium is primarily due to protonation of the nitrogen atom of the benzimidazole ring and the decrease in the lipophilicity of the molecule. The selectivity coefficient α for the pair Tomerzole/Bemityl is independent of pH of the mobile phase, since these compounds have, evidently, the same pK_{BH^+}. For the pair Tomerzole/Dibasol, on the contrary, the selectivity coefficient depends on the eluent pH (pH_{opt} 4–5),

which can be attributed to the difference in their structure and properties. In the Dibasol molecule there is an electron-donor benzyl radical in the position *2*, causing a higher electron density on the nitrogen atom (according to [4], pK_{BH^+} of Dibasol in water is 4.2).

With increasing the MeCN mole fraction the retention of the organic sorbates decreases under reversed-phased HPLC conditions, which corresponds to the displacement retention models (Figs. 2, 3). The observed deviation from linearity of these dependences is indicative, evidently, of association of molecules of the organic modifier of the mobile phase [5]. The results were treated by linear regression analysis [6, 7] using Eqs. (1) and (2).

$$1/k' = aN + c, \quad (1)$$

$$\log k' = b - p \log C, \quad (2)$$

where k' is the capacity coefficient, N is the mole fraction of MeCN in the mobile phase, C is the MeCN concentration in the eluent (M), and a, c, b, p are the linear regression coefficients.

The results are summarized in Table 1 (equation coefficients are given for the linear section of the dependence).

The coefficient p of Eq. (2) corresponds to the number of moles of MeCN displaced from the sorbent surface in adsorption of 1 mol of the sorbate. Analysis of this parameter allows certain conclusions about the arrangement of the sorbate molecules on octadecyl silica gel. It follows from Table 2 that benzyl radical occupies nearly the same area as the ethylthio group. Introduction of the ethoxy group in the BI ring considerably increases the retention, so that Tomerzole and Bemityl are satisfactorily separated over the MeCN concentration range 20–45 vol %. Introduction of methyl substituents in the Dibasol or BDB molecule does not practically change the sorption site area, which can be attributed to the electron-acceptor effect of the BI system.

Data presented in Fig. 3 are not consistent with those predicted by the theory [8], according to which the dependences described by Eq. (2) must intersect in the same point. This inconsistency can be attributed to the fact that the BI derivatives are polar compounds. Therefore, they tend to ionization, being capable of specifically interacting with the mobile phase and residual silanol groups. As a result, the hydrophobic mechanism of chromatographic separation has certain limitations in the investigated system. The chromatographic data were described by Eq. 3 [8]

$$b = b_0 + b_1 p/p_1, \quad (3)$$

where b_1/p_1 is the ratio of the capability of a compound to be retained to its capacity of competing with

Table 1. Coefficients of Eqs. (1) and (2) for BI derivatives (sorbent Separon C_{18})

Sorbate	Eq. (1)			Eq. (2)		
	a	*c*	r^2	–*p*	*b*	r^2
Bemityl	7.26	–0.53	0.988	2.20	2.04	0.990
Tomerzole	4.63	–0.33	0.982	3.03	3.00	0.991
Dibasol	5.94	–0.38	0.990	2.28	2.19	0.985
BDB	12.23	–0.61	0.991	2.10	1.76	0.990
Omeprazole	9.34	–0.94	0.985	3.48	3.58	0.989

an organic modifier (MeCN) for the site on octadecyl silica gel, and b_0 is the coefficient reflecting the degree of consistency of the retention mechanism to the purely hydrophobic one.

Retention of the tested five BI derivatives is described by the equation $b = -0.70 - 1.23p$ (r^2 0.992), which is in a satisfactory agreement with the results obtained in [8]. The coefficient b_0 is somewhat lower (by the absolute value) that that given in [8] for weakly polar organic sorbates. However, this parameter is close to the value given for 5-fluorouracil derivatives ($b_0 = -0.635$).

The capacity coefficients of BI derivatives with water as a mobile phase (value proportional to the Henry coefficient) were estimated by Eq. (4) [9]

$$\log k' = \log k'_w - SF, \quad (4)$$

where k'_w is the capacity coefficient of a compound with the use of water as a mobile phase, F is the MeCN volume fraction, and S is the empirical constant. The estimated k'_w are well consistent with the coefficients p (Table 1). The results obtained allow comparison of the hydrophobicity of the tested compounds and also estimation of the relative contributions of the substituents to the sorption interaction of the BI derivatives.

To select the optimal chromatographic systems for separation of the BI derivatives, we estimated the separation efficiency and selectivity, and also the effect of the MeCN concentration and eluent pH on these characteristics. It appeared typical that the curves of the dependence of the height of equivalent theoretical plate (HETP) on the MeCN concentration in the mobile phase pass through a minimum. The minimal HETP for Bemityl, Tomerzole, and Dibasol (0.05–0.08 mm) is observed at 25–35 vol % MeCN. Increase and decrease in the MeCN concentration in the mobile phase relative to this value decreased the separation efficiency. For Omeprazole the optimal MeCN concentration in the mobile phase was found to be 25–30%. Decreasing eluent pH from 7.5 to 3.5–4.5 somewhat increases the separation efficiency of the BI derivatives by virtue of a less pronounced erosion of the rear front of the bands. The latter can be attributed to a decreased amount of ionized residual silanol groups on the stationary phase surface [10].

The selectivity coefficient α for the pair Tomerzole/Bemityl decreases from 2.5 (20 vol % MeCN) to 1.5 (40–45 vol % MeCN). At higher MeCN concentration the selectivity coefficient changes only slightly (α = 1.3 at 55 vol % MeCN). This trend can be interpreted in terms of decreasing adsorption of the ethoxy group on octadecyl silica gel with increasing MeCN concentration. The coefficient α for the pair Dibasol/BDB is practically independent of the MeCN concentration in the eluent.

The pharmaco effect of a drug is determined by its concentration in the vicinity of a target cell (receptor) and also by the affinity for the receptor. In its turn, the concentration of a biologically active compound (BAC) at the receptor is determined by such pharmacokinetic characteristics as the bioavailability *f*, comparative distribution volume V_d, and distribution constant [11]. All these parameters are controlled by the ionization constant of a compound and its lipophilicity. As seen from Table 2, Tomerzole is characterized by a higher lipophilicity than Bemityl, which is well consistent with their bioavailability (7 and

Table 2. Coefficients of Eq. (4) for BI derivatives

Sorbate	–*S*	$\log k'_w$	r^2	k'_w
Bemityl	0.03	1.16	0.987	14.45
Tomerzole	0.03	1.74	0.991	54.95
Dibasol	0.03	1.54	0.991	34.67
BDB	0.03	1.11	0.992	12.88
Omeprazole	0.04	1.93	0.995	85.11

20% for Bemityl and Tomerzole, respectively) and V_d (1.3 and 18.3 l kg^{-1}, respectively) [12, 13]. A good correlation (r 0.97) is also observed between k'_w and data of [14], in which the antisecretory activity of BI derivatives (Bemityl, Tomerzole, and Omeprazole) was studied. The pharmaco effect of these compounds on H^+–K^+-ATP-ase was found to be 17.6, 38.0, and 78.1%, respectively. The affinity of a BAC for a receptor is controlled not only by the presence of functional groups, but also by the size of the hydrocarbon fragment of the molecule, i.e., its lipophilicity. Therefore, the chromatographic retention parameters of BI derivatives can be used to predict the dissociation constants of the complex receptor–BAC [15].

CONCLUSIONS

(1) On the basis of experimental chromatographic parameters a comparative analysis is made of the adsorption properties of benzimidazole derivatives on octadecyl silica gel.

(2) The estimated adsorption and chromatographic parameters are in a satisfactory agreement with the pharmacokinetic characteristics of drugs of the benzimidazole group.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Calcium Cation on the Structure of Silica Gel Formed from Decationized Sol

T. F. Kuznetsova

Institute of General and Inorganic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received August 1, 2000; in final form, March 2001

Abstract—Isotherms of sorption of water and tetrachloromethane vapors on a silica gel formed from decationized sol in the presence of calcium chloride are identified on the basis of the IUPAC classification. The manner in which the structure and sorption properties of the samples studied vary with $CaCl_2$ concentration and kind of adsorbate is analyzed.

When the silica gel structure is formed from decationized monodisperse silica sol, the presence of dense SiO_2 particles is ensured till the onset of gelation [1]. In an evolution of this method, silica gel was prepared from a sol with elongate and lamellar shape of particles, acquired under the action of calcium salts [2] or as a result of SiO_2 flocculation with a quaternary ammonium base [3]. Because of their uncommon structure and unique structural properties, laminated silica gels are regarded as potential sensors, membranes, binders, or coatings for obtaining inorganic fibers. However, their microstructure, whose practical importance is determined by their sorption properties and the dependence of these on the kind of adsorbate, by the molecular sieve action, and by the reversibility and kinetics of adsorption has been little studied so far.

The aim of this study was to analyze the effect of calcium chloride on how the silica gel structure is formed from decationized sol, and the primary objective, to establish within the possible limits the relationship between such characteristics as pore size, size distribution and specific surface area of pores, on the one hand, and the sorption properties and dependence of these on the kind of adsorbate, on the other.

A decationized silica sol with pH 3.5 and silicic acid content of 4 wt % was obtained by passing an aqueous solution of sodium metasilicate through a column packed with KU-2 sulfonic acid cation-exchange resin in the hydrogen form. The sol was mixed with aqueous solutions of potassium chloride, with Ca/Si molar ratios in the range 5×10^{-4}–1×10^{-1}. An $NH_3 \cdot H_2O$ solution was added to the mixture to adjust pH 7.5, and a gel was precipitated with hydrochloric acid at constant pH 5.6. After syneresis and aging for 16 h, the gel was thoroughly washed with distilled water, with vigorous stirring to break down clots, till complete absence of chloride ions in washing water, and then dried in air at room temperature and in a drying box at 393 K for 4 h.

The adsorption–desorption isotherms of water and tetrachloromethane vapors were measured gravimetrically at 293 K after preliminary "evacuation" of samples at 413 K for 16 h. The specific surface area A was calculated from the monolayer capacity by the linear BET equation at relative pressures p/p_0 = 0.05–0.25, using landing area of 0.125 nm^2 for water molecule and 0.322 nm^2 for CCl_4 molecule [4]. The limiting sorption pore volume V_p was calculated by the Gurvich method [5] in the form of the amount of vapor sorbed to saturation and expressed in terms of water volumes. The distribution $\Delta V/\Delta r$ of the volumes V of mesopores with respect to their radii r was calculated from desorption curves by the Kelvin equation, and the pore shapes were analyzed on the basis of the form of the vapor adsorption–desorption hysteresis loop [6]. The average pore radius r_p was found for cylindrical and bottle-shaped pores, using the formula

$$r_p = 2V_p/A, \quad (1)$$

and for slotlike pores as a slot halfwidth [6] by the formula

$$r_p = V_p/A. \quad (2)$$

The refractive index n_D of the silica sols was determined using a Zeiss Abbe refractometer at 293 K; the zero-charge point of the silica gels was found by titration [7].

* Apparent values.

The isotherms of sorption of water and tetrachloromethane vapors by the samples under study differ in the type, presence, and shape of capillary-condensation hysteresis (see table, Fig. 1). The isotherms give insight into stages of gradual modification of the structure of silica gel with increasing content of calcium chloride, with micropores transformed into macropores in the process. The isotherms indicate complete pore filling by various adsorbates and satisfactory observance of the Gurvich rule.

The reversible isotherm *1* of H_2O vapor sorption, which is of type I characteristic of microporous adsorbents, takes the form of an irreversible type IV isotherm for mesoporous adsorbents on passing to sample nos. 2–5 (Fig. 1) [6]. The hysteretic curve of H2 shape in isotherm *2*, indicating the presence of bottle-like mesopores, is transformed into H1 hysteresis in isotherm *5*, characteristic of cylindrical pores formed by particle agglomerates or spheres [6]. The shape of the narrow hysteresis in isotherms *3* and *4* of water vapor sorption is difficult to determine.

The reversible type I isotherm of CCl_4 vapor sorption, characterized by the presence of a nearly horizontal plateau, indicates filling of narrow micropores (Fig. 1). Isotherms *2–5* of CCl_4 vapor sorption are irreversible at medium relative pressures $p/p_0 > 0.2$–0.3. The isotherms belong to type IV characteristic of sorption on mesoporous adsorbents, their hysteresis loops of H4 (isotherms *2–4*) and H2 shape (isotherm *5*) confirm the presence in the structure of, respectively, predominantly narrow slotlike or bottle-shaped mesopores.

Isotherm *3* of sorption of water and tetrachloromethane vapors by a silica gel obtained at a molar ratio Ca/Si = 1×10^{-3} is characterized by the strongest absorption in the entire p/p_0 range (Fig. 1), with the sample demonstrating the expected apparent increase in the pore volume and specific surface area, compared with the other samples (see table). Silica gel no. 3 shows approximately the same saturation adsorption for different adsorbates (0.60×10^{-3} $m^3\ kg^{-1}$), but different specific surface areas (718×10^3 and 1600×10^3 $m^2\ kg^{-1}$) found from the monolayer capacities of, respectively, water and CCl_4. The overestimated A values in calculation from the CCl_4 vapor adsorption are due to the predominance of the dispersive interaction: the isotherm of tetrachloromethane sorption is of type I for microporous sample and is more concave with respect to the p/p_0 axis in mesoporous samples. The fact that the Gurvich rule is observed for type I isotherms commonly indicates that the pore size is equal to at least several molecular diameters of the adsorbate to ensure packing of its molecules with a density close to that of the normal liquid [8]. An additional evidence in favor of the overestimated A value in calculation from the CCl_4 adsorption is that $r_p < 0.595$ nm values are obtained, smaller than the kinetic diameter of the CCl_4 molecule (see table). The fact that the adsorption portions of isotherms *2–4* of CCl_4 vapor sorption are of type I indicates the presence of a certain volume of micropores in the structure.

Thus, sample no. 1 is characterized as microporous on the basis of adsorption of both water and tetra-

chloromethane vapors. The pores in this sample are cylindrical, formed by densely packed globules. Numerous fine pores are formed in the silica gel in the presence of calcium cations in amounts not exceeding 1×10^{-3} M Ca^{2+}, which is indicated by the increase in the specific surface area (see table). The narrow hysteresis in isotherms *3* and *4* of H_2O vapor sorption points to filling of these pores via polymolecular adsorption. Judging from the shape of hysteresis in the isotherms of CCl_4 vapor sorption, the pores are determined as very narrow slotlike pores.

The specific features of adsorption and capillary condensation of H_2O and CCl_4 vapors suggest that the pore system is constituted in the obtained samples by (i) spaces between agglomerates of SiO_2 particles elongated under the action of the calcium cation, (ii) spaces between compact three-dimensional agglomerates composed of densely packed interwoven chains, and (iii) intra-agglomerate pores. The loop appears at high relative pressures as a result of condensation of H_2O and CCl_4 vapors within secondary mesopores, i.e., outside the intra-agglomerate pores. It is not improbable that the most open structure is formed by long chain segments and spaces between these at molar ratios Ca/Si $\leq 1 \times 10^{-3}$.

The reason for the above changes in the porous structure of silica gel is that the silica gel inherits the microstructure that existed in the hydrogel after coagulation of the SiO_2 hydrosol in the presence of the calcium cation [9]. Changes in the structural and sorption parameters under the action of different amounts of calcium cations are due to the varied extent of neutralization by this cation of the charge of SiO_2 particles. This charge is a factor determining the aggregative stability of the sol, preventing particle agglomeration via condensation of surface (≡SiOH) and ionized (≡SiO^-) groups to form Si–O–Si bonds. In the beginning of gelation, silica sol particles, dispersed in solution and negatively charged, are held together at points of the weakest electrostatic repul-

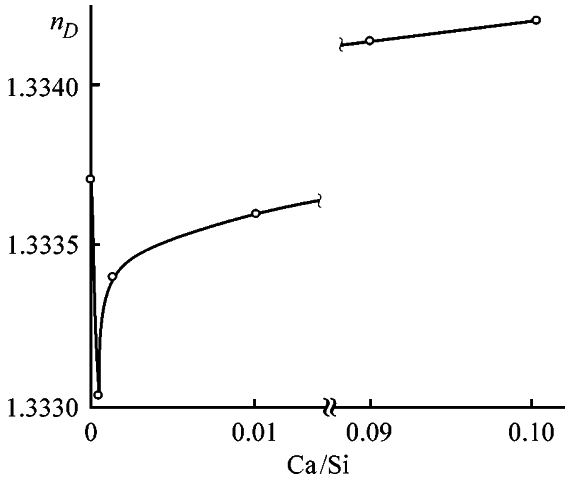

Fig. 2. Effect of the calcium cation on the refractive index n_D of decationized silica gel. (Ca/Si) Molar ratio.

sion under the action of calcium cations. On adding an $NH_3 \cdot H_2O$ solution, there proceeds a special type of chain coagulation of globules, when their mutual repulsion occurs with a force that can overcome interglobule bonds [3]. Agglomerates of SiO_2 particles grow mainly in chains because of the attachment of particles to one another at the ends of the growing chains. Chain-like agglomerates may include regions several particles thick, with arbitrary distribution. Possibly, precipitation of excess SiO_2 on chain agglomerates formed in the presence of calcium cations leads to formation of dense fibers and development of a partially fibrous gel structure [3].

The greater the amount of cations in a gel, to a larger extent is disrupted the binding of the SiO_2 surface to water, and globule cohesion occurs at "hydrophobized" regions [10]. Since the zero-charge point of liquid silica gel nos. 1–5 increases from pH 5.7 for the initial sample to pH 7.0 in a sample containing 1×10^{-1} mol Ca^{2+}, it is also possible that calcium hydroxide nuclei are formed on the SiO_2 surface [11, 12]. Under conditions of strong attraction, rather compact particle agglomerates are formed. In the process, the specific surface area decreases, thin capillaries gradually disappear, being transformed into wider pores responsible for the H1 hysteresis in sample no. 5 for H_2O absorption or H2 hysteresis for absorption of CCl_4 (Fig. 1). This hysteresis can be attributed either to open cylindrical pores with various cavity shapes or to bottle-shaped pores with very wide openings into cavities.

Although the distribution of the volume of bottle-shaped pores with respect to pore size is difficult to interpret, mention can be made, for comparison purposes, of the absence of maxima in curves *2–4* calculated from the desorption of water and tetrachloromethane, in contrast to curve *5* exhibiting maxima corresponding to a predominant mesopore radius of approximately 3.0 nm in the sample (Fig. 1).

Determining the specific surface area by BET gives no way of distinguishing the external surface, formed by globule agglomerates, and the internal surface formed by intra-agglomerate pores. Therefore, the agglomeration and changes in the agglomerate radius with increasing Ca/Si ratio were judged from the variation of the refractive index n_D of the corresponding silica sols in Fig. 2.

The total number N of colloid particles in clusters with nonequilibrium structure formed as a result of a random Brownian motion of colloid particles is related to the cluster radius R, particle radius R_0, and density ρ by Eq. (3) [13]. With increasing size of a cluster composed of N particles, it density decreases following the equation

$$N = \rho(R/R_0)^D, \quad (3)$$

where D is the fractal dimension of the cluster, quantitatively characterizing the space filling by the cluster.

Since, according to Eq. (3), the cluster density increases with decreasing cluster size, the refractive index must also increase. Therefore, the hydrodynamic radius of agglomerates of sol particles, formed on introducing calcium cations in amounts equal to, or less than 1×10^{-3} M Ca^{2+}, must be greater than that in the initial SiO_2 hydrosol and decrease with the amount of Ca^{2+} cations increasing further. The drop in n_D is due to the formation of chain agglomerates of particles on introducing calcium cation, and its subsequent increase, to the decrease in the radii of sol particle agglomerates with increasing Ca/Si ratio, occurring because of their densification.

CONCLUSIONS

(1) The formation of the silica gel structure from a decationized sol in the presence of calcium cations is accompanied by the appearance of mesopores, significant changes in the prehysteresis portion of vapor sorption isotherms, and a decrease in the specific surface area of the xerogel.

(2) Under the action of calcium cations, type I isotherms are transformed into isotherms of type IV. The type of isotherm and the sorption properties of a silica gel depend on the kind of adsorbate and salt concentration.

(3) Chain agglomerates of particles formed at low calcium concentrations are combined with increasing calcium content into dense three-dimensional agglomerates. The specific surface area decreases, without any increase in the limiting adsorption volume of pores in the process.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Single-Component Urethane Sealants

A. D. Elchueva, N. V. Aristova, I. V. Bortnikov, and A. A. Tabachkov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received October 5, 2000; in final form, February 2001

Abstract—Single-component urethane sealing formulations with aldimines as cross-linking agents were developed. The temperature dependence of the curing time of the sealants was examined. The influence of the –CH=N–/–NCO ratio and of fillers (industrial carbon and chalk) on their physicochemical properties was studied.

Polyurethane elastomers are widely used in various branches of industry. With progress of studies in the field of development of single-component formulations, their performance is improved and the application field is expanded. The procedures used in industry for curing of polyurethane sealants have significant drawbacks. All sealants of this type are two-component; they are not quite convenient in service and require performing certain manipulations directly before use. Their curing is effected with diamines and glycols. Curing of a single-component urethane sealant based on an isocyanate-containing prepolymer results in formation of defects (blisters, cavities) due to release of carbon dioxide on contact of isocyanate groups with atmospheric moisture. The goal of this work was to develop single-component urethane formulations with aldimines as cross-linking agents. Aldimines, when reacting with atmospheric moisture, release active curing agents which react with isocyanate groups without releasing CO_2, so that formation of defects in the cured sealant can be avoided.

Urethane elastomers show considerable promise for practice. Polyurethanes are prepared from compounds containing highly reactive isocyanate groups. Their transformations yield polymeric structures with diverse types of chemical bonds and allow preparation, within the same class of polyurethanes, of materials of widely varying properties.

An important factor determining the physicomechanical properties of polyurethanes, especially at elevated temperatures, is the nature of cross-links in the three-dimensional polymer network, depending on the curing agent used.

Studies of the effect of diamines and water as curing agents in single-component systems on the properties of composites based on various diisocyanates showed [1] that strong intermolecular interaction in polymers results in increased modulus of elasticity and tensile strength. The rigid segments in the chain (bulky aromatic diisocyanates and aromatic amines) also enhance the cohesion strength. Flexible groups (e.g., aliphatic amines) contribute to the elastic properties of the elastomers.

Thus, polyurethanes can be considered as block copolymers [2] with flexible polyether or polyester segments and rigid segments formed by urethane or urea fragments. Flexible segments increase the elasticity and relative elongation at break, whereas rigid segments with enhanced intermolecular interactions increase the hardness, tensile strength, melting point, and glass transition point.

The structure of the three-dimensional polyurethane network is determined by the synthesis conditions, in particular, by the preparation procedure (single-stage or two-stage). When the polymer is prepared by a two-stage procedure via a prepolymer, formation of a more regular network can be expected. Elastomers prepared via prepolymer [3] exhibit higher cohesion strength but lower values of the adhesion strength and modulus of elasticity and are less elastic.

In a two-stage procedure for production of polyurethanes the prepolymers are usually highly viscous, and special equipment is required for their mixing and feeding to reaction vessels without air access. The properties of the final product can largely depend on the accuracy of temperature control and on the storage time and stability of the prepolymer.

The advantage of the single-stage preparation of polyurethanes is the stability of the reaction mixture. With aromatic diamines, an additional advantage is

1070-4272/01/7405-0860$25.00

the possibility of dosing these relatively high-melting crystalline substances using standard dosing units. The major problem, however, is to balance the reactivities of the backbone polyol and curing agent to attain the required degree of cross-linking. If both components are diols, it is not difficult, but with amine cross-linking agents it is necessary to add a catalyst accelerating the reaction of the hydroxide with the isocyanate. The advantages of the single-stage procedure are also simpler process and wider range of suitable raw materials.

Analysis of the present state of production of single-component polyurethane elastomers [4] reveals the following trends: improvement of the curing system and development of optimal formulations.

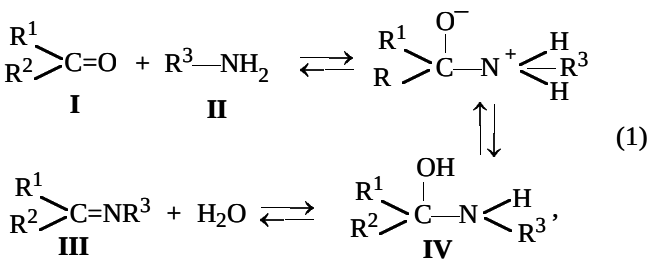
The goal of this study was preparation of single-component urethane formulations with azomethines (Schiff bases) as cross-linking agents. These systems, reacting with atmospheric moisture without release of carbon dioxide, facilitate reaction of the polymer backbone chain with isocyanate groups.

EXPERIMENTAL

In our study we used toluene 2,4-diisocyanate [TDI, TU (Technical Specifications) 6.03331–79), Laprol-5003 polyether (TU 6-05-1513–87), P-803 industrial carbon [GOST (State Standard) 7885–77), and chalk (GOST 842–52). The deformation and strength properties were determined according to GOST 21 751–76, and the Shore hardness, according to GOST 263–75.

Aldimines were prepared by reaction of an aldehyde with a diimine in a 2 : 1 molar ratio (see table).

Schiff bases are prepared [5] by condensation of aldehydes and ketones **I** with various amino compounds **II**, resulting in elimination of water and formation of the corresponding azomethines **III**. The kinetic data suggest a two-stage mechanism [Eq. (1)] of formation (and reverse hydrolysis) of azomethines, involving formation of a tetrahedral intermediate, carbinolamine **IV**, which in some cases can be isolated (e.g., reaction of chloral with hydroxylamine) or detected in solution by ^{1}H NMR spectroscopy:



(1)

Initial substances for synthesis of aldimines

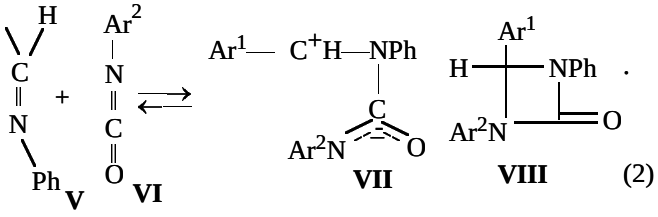
Diamine	Aldehyde	mp, °C
Ethylenediamine	Benzaldehyde	42–44
〃	Nitrobenzaldehyde	145
〃	Furfural	51–52
Hexamethylenediamine	Benzaldehyde	(l)
〃	Nitrobenzaldehyde	86–88
〃	Furfural	43
Phenylenediamine	Benzaldehyde	110–113
〃	Nitrobenzaldehyde	85–90
〃	Furfural	(l)
Diaminodiphenylmethane	Benzaldehyde	121
〃	Nitrobenzaldehyde	172
Diaminodiphenylmethane	Furfural	(l)

where R^1, R^2 = H, Alk, Ar; R^3 = Alk, Ar, OH, OR, NHR, Hal.

Aldehydes and dialkyl ketones smoothly condense with primary amines to give the corresponding Schiff bases, whereas the reactivity of aryl ketones is relatively low, and in this case longer reaction time and Brønsted acid catalysis are required.

Hydrolysis of azomethines to the initial amines and carbonyl compounds is an example of the nucleophilic attack at the C=N bond. This two-stage process involves addition of water molecules to the C=N bond to form a carbinolamine intermediate which subsequently decomposes into the amine and carbonyl compound. The rates of azomethine hydrolysis and formation are pH-dependent.

Cycloaddition of Schiff bases to simple isocyanates **VI** is preceded by reversible formation of zwitter-ionic intermediate **VII** [Eq. (2)] which in some cases can be isolated. The further transformations are determined by the stability of the zwitter-ionic intermediate (i.e., mainly by the steric and electronic effects of substituents in the azomethine molecule) and by the reaction conditions (kinetic or thermodynamic control). On the whole, when the benzylidene moiety of Schiff base **V** contains electron-donor *para* substituents and the reaction is performed at low temperatures (i.e., under conditions of kinetic control), direct ring closure in the zwitter-ion to give [2+2]-cycloadduct **VIII** is favored:



(2)

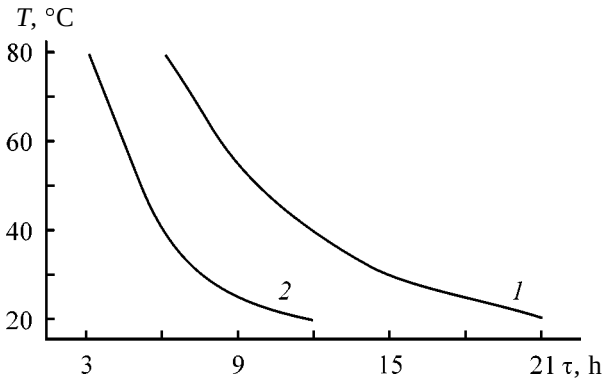


Fig. 1. Correlation between the temperature T and time τ of sealant curing with aldimines based on (*1*) benzaldehyde and (*2*) nitrobenzaldehyde and furfural.

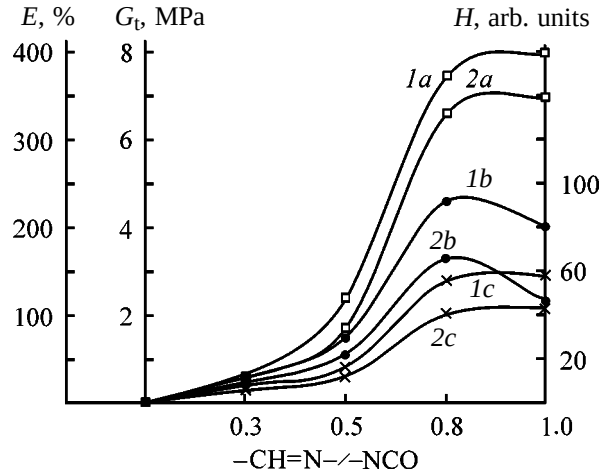

Fig. 2. Influence of the –CH=N–/–NCO ratio on the physicomechanical properties of sealants containing 60 wt parts of industrial carbon, cured with (*1a–1c*) aromatic and (*2a–2c*) aliphatic imines: (*1a*, *2a*) relative elongation E, (*1b*, *2b*) nominal tensile strength G_t, and (*1c*, *2c*) Shore hardness H; the same for Fig. 3.

It was suggested to use Schiff bases for preparing composites from polyisocyanate and aldimine for coatings stable in storage [6, 7]; also, Schiff bases can be used as latent hardeners for low-temperature curing of epoxy oligomers [8].

However, studies by Arbizov and his disciples [9] showed that Schiff bases react with isocyanates only at 100–160°C. Therefore, preparation of cold-curable sealants using the reactions of Schiff base formation is practically impossible. We have studied the hydrolysis of Schiff bases as sealant components.

It is known [10] that aldimines **IX** in the presence of atmospheric moisture are hydrolyzed to the initial compounds: aldehydes and diamines. This reaction, in particular, occurs on a support:

$$R'–CH=N–R''–N=CH–R' + H_2O \rightarrow 2R'–CHO + H_2N–R''–NH_2. \quad (3)$$

The released diamine reacts with the OCN groups of the prepolymer to give a three-dimensionally cross-linked polymer.

Curing of sealants depends on several factors, in particular, on the temperature and structure of substituent R' in the aldehyde molecule (Fig. 1). With increasing temperature, the time of sealant curing decreases. Curing is also accelerated when electron-withdrawing substituents such as NO_2, Br, I, or OCH_3 are introduced into the *para* position of benzaldehyde. These substituents decrease the electron density on the electrophilic center ($–C^+=N–$ carbon atom) and enhance its affinity for water, accelerating the hydrolysis. The amino groups released in the course of hydrolysis react with the isocyanate group even at 0–25°C; as a result, the sealant curing accelerates.

Figure 2 shows the dependences of the physicomechanical properties of sealants on the ratio of the reactive groups –NCO/–CH=N in the oligomeric system. As this ratio is increased, the strength and hardness of the urethane elastomers increase. This is due to the increased degree of cross-linking. The increase in the –NCO/–CH=N ratio to 0.5 has a weak effect on the properties. However, at further increase the strength of the sealants is enhanced, reaching a maximum at the –NCO/–CH=N ratio equal to 0.8–0.85. At the –NCO/–CH=N ratio higher than unity the physicomechanical parameters start to decrease.

The deformation and strength characteristics of sealants are influenced by the structure of the amine moiety in aldimines. For example, the selanats cured with aromatic imines considerably surpass in strength those cured with aliphatic analogs, owing to incorporation of aromatic ring into the polymer structure.

Unfilled sealants are used seldom because of their poor physicomechanical parameters and high cost. To improve the properties and reduce the cost, various fillers are added. In this work we used active (industrial carbon) and neutral (chalk) fillers. Figure 3b shows the dependences of the main physicomechanical parameters of the sealants on the content of industrial carbon and chalk. These data show that, irrespective of the imine type and component ratio, the parameter values as functions of the filler content pass through maxima. The nominal tensile strength and the relative elongation vary in parallel with varying filler content.

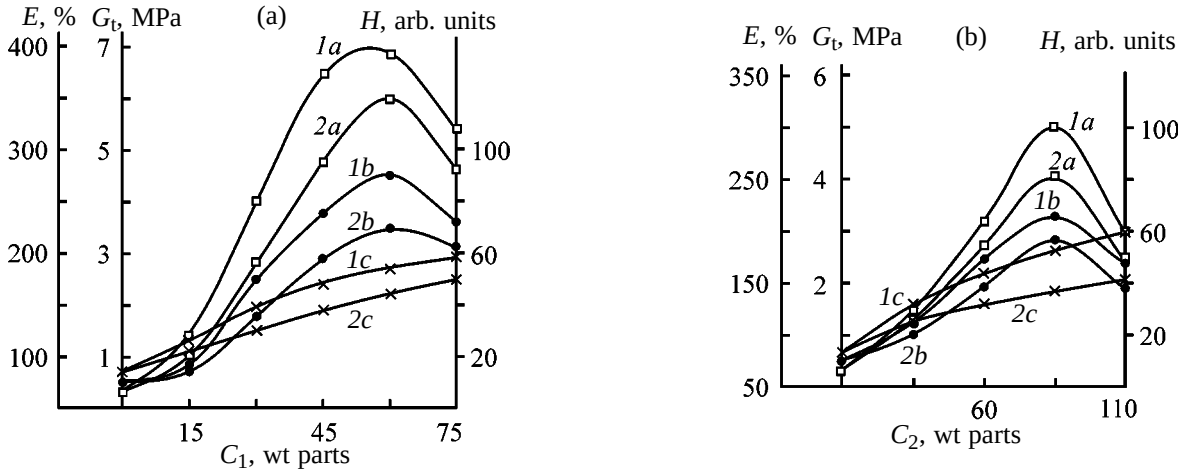

Fig. 3. Influence of the content of (a) P-803 industrial carbon C_1 and (b) chalk C_2 on the properties of sealants cured with (*1a–1c*) aromatic and (*2a–2c*) aliphatic imines.

The hardness of the composites increases monotonically. The physicomechanical properties of polyurethane sealants filled with industrial carbon are considerably better than those of the sealants filled with chalk. However, at high filling (more than 60 wt parts of industrial carbon or more than 90 wt parts of chalk per 100 wt parts of oligomer) the curing becomes complicated because of hindered diffusion. Highly active industrial carbon should be introduced in smaller amounts than chalk; the optimal dosage is 40 wt parts. This filler strongly affects the efficiency of macromolecule binding and formation of the physical network comprising from 60 to 80% of the total content of bonds in the polymer. Replacement of industrial carbon by neutral chalk at the same filler content (60 wt parts per 100 wt parts of prepolymer) decreases the physicomechanical properties of sealants.

CONCLUSIONS

(1) Single-component urethane sealants with aldimines as cross-linking agents were developed.

(2) The effect of temperature on the curing time of sealants was studied. With increasing temperature from 20 to 80°C, the curing time decreases from 12–15 to 2–4 h.

(3) The ratio of the –CH=N– and –NCO groups affects the physicomechanical properties of the sealants, with its optimal value being 0.8–0.85.

(4) The properties of sealants were studied in relation to the filler content. The strength parameters pass through maxima at the following filler content: industrial carbon 60 wt parts and chalk 90 wt parts.

CHEMISTRY OF FOSSIL FUEL

Production of Environmentally Friendly Diesel Fuel and Petroleum Aromatic Solvents by Extraction Combined with Azeotropic Distillation

Received December 26, 2000

Abstract—A method is proposed for production of environmentally friendly diesel fuel, including five-step countercurrent extraction of aromatic hydrocarbons from the hydrofined diesel fraction with dimethylformamide or dimethylacetamide containing 3–5 wt % H_2O and pentane followed by regeneration of the extractants from the extract phase by azeotropic distillation. The process allows production of diesel fuel with the content of aromatic hydrocarbons below 10 wt %. Another product is a petroleum aromatic solvent like Nefras AR-150/330.

In the previous works we demonstrated that environmentally friendly diesel fuel with a content of aromatic hydrocarbons below 15 wt % and sulfur content below 0.003 wt % can be produced by five-step countercurrent extraction of the hydrofined diesel fraction with acetonitrile containing pentane [1–3]. Acetonitrile was selected as a polar solvent, since it does not form azeotropic mixtures with components of the feed and can be readily regenerated by distillation. However, even with additions of water and pentane, increasing the selectivity of separation, the arene concentration in the extract is at a level of 90 wt %.

One of the most promising lines in using extracts of mid oils is production of petroleum aromatic solvents like Nefras AR-120/200 and AR-150/330 [4, 5]. These solvents find use in varnish-and-paint industry and photography, in preparation of cleansing reagents, extraction of precious metals, and flotation of minerals. Petroleum aromatic solvents are produced by catalytic reforming of hydrofined oil fractions followed by extraction of arenes or pyrolysis with sulfuric acid refining of the condensate to remove unsaturated hydrocarbons. Nefras AR-120/200 can be also produced more simply by extraction of arenes from the hydrofined kerosene fraction with acetonitrile containing pentane. In regeneration of acetonitrile, forming azeotropic mixtures with saturated hydrocarbons C_9–C_{10}, from the extract phase, the arene content increases from 85 to 98–99 wt %, which meets the requirements for Nefras AR-120/220 [6]. The hydrofined diesel fraction can be a source of Nefras AR-150/330 without using such power-consuming processes as catalytic reforming or pyrolysis.

The goal of this work is to develop a combined extraction–azeotropic distillation process providing simultaneous production of both environmentally friendly diesel fuel with an arene content below 10 wt % and Nefras AR-150/330 from the diesel fraction.

The criterion for selection of an extractant is that it should not form azeotropic mixtures with arenes C_{10+} and also with saturated hydrocarbons over the range of at least C_{10}–C_{14}. The diesel fraction contains even higher-boiling saturated hydrocarbons C_{15}–C_{20}, but their content in the extract phase is insignificant by virtue of a lower solubility in polar solvents. Thus, the critical temperature of solution of *n*-hexadecane, *n*-decane, and *trans*-decalin in dimethylformamide (DMF) is 112 [7], 84.6, and 64.9°C, respectively [8].

In [9] DMF and also dimethylacetamide (DMAA) and acetonitrile were proposed to be used as azeotropizers for separation of alkylbenzenes C_9–C_{10} from the catalytic reforming fraction containing also about 20 wt % of saturated hydrocarbons C_{10}–C_{11}.

DMF and DMAA can form azeotropic mixtures with higher-boiling saturated hydrocarbons also. In formation of azeotropic mixtures the condition

1070-4272/01/7405-0864$25.00

Table 1. Limiting activity coefficients of hydrocarbons in DMF and DMF to hydrocarbon saturated pressure ratio at 140°C

Hydrocarbon	γ_i^0	bp, °C	P_i^0, kPa [11]	P_{DMF}^0/P_i^0
n-Decane	13.1 [12]	174.1	38.92	1.99

p-Cymene	1.91 [12]	177.2	35.42	2.19
Durene	2.37	196.8	20.26	3.82
DMF	–	153	77.43	–

Table 2. Limiting activity coefficients of hydrocarbons and solvent selectivity

Solvent	*T*, °C	γ_i^0 [14, 15]			γ_h^0/γ_b^0	$1/\gamma_b^0$	γ_{hp}^0/γ_h^0
		hexane	heptane	benzene			
Acetonitrile	25	25.5	41.41	2.7	9.44	0.370	1.62
DMF	25	17.0	22.7	1.4	12.1	0.714	1.34
DMAA	30	9.767	11.60	1.143	8.55	0.875	1.19

$\gamma_i^0 > P_s^0/P_i^0$ should be met, i.e., the limiting activity coefficient of the *i*th component in the solvent *s* is higher than the solvent to component saturated pressure ratio [10]. The experimental γ^0 of *n*-decane, *trans*-decalin, and *p*-cymene at 140°C (temperature close to the expected boiling point of azeotropic mixtures of DMF with the hydrocarbons) is given in Table 1. The limiting activity coefficients of the higher-boiling alkanes were estimated by extrapolation of data for heptane, octane, and decane using the linear relationship $\log\gamma_i^0 = a + bn_C$, where n_C is the number of carbon atoms in the *n*-alkanes. Similarly γ_i^0 of durene was estimated by extrapolation of data on the activity coefficients of toluene and *o*-xylene.

It follows from Table 1 that DMF should form azeotropic mixtures with alkanes C_{10}–C_{13} and branched alkanes C_{14}. At the same time the systems DMF–arenes C_{10+} are zeotropic, except for mixtures with the lowest-boiling alkylbenzenes C_{10} like *p*-cymene, which goes not to the diesel but to the kerosene fraction. The saturated vapor pressure of DMAA, estimated by the Antoine equation [13], at 140°C is 47.6 kPa, which is lower than that of DMF by a factor of 1.6. However, the nonideality of systems DMAA–saturated hydrocarbons is also lower than that of the corresponding systems with DMF by about the same factor. For example, γ^0 of octane at 50°C in DMF and DMAA is 21.2 and 13.0, respectively [14]. Therefore, the probability of formation of azeotropic mixtures of hydrocarbons with DMAA is nearly the same as with DMF. Another requirement to extractants is that they should demonstrate high group selectivity toward components to be separated. This property can be characterized, for example, by the ratio of the limiting activity coefficients of hexane to benzene γ_h^0/γ_b^0. Additionally the effective extractant should be characterized by high solvency $1/\gamma_b^0$ and low molecular-weight selectivity expressed as the ratio of the limiting activity coefficients of homologous hydrocarbons, for example, of heptane and hexane (γ_{hp}^0/γ_h^0). DMF surpasses acetonitrile in all these parameters (Table 2). DMAA, having nearly the same group selectivity toward arenes as acetonitrile, is considerably more efficient by the solvency and molecular-weight selectivity, i.e., by the characteristics which are particularly important in extraction of arenes from relatively high-boiling fractions with a wide boil-off range, with which the diesel fractions are classified.

As a feed we used the hydrofined diesel fraction (Kirishinefteorgsintez Production Association, Limited Liability Company) having the following characteristics: boil-off range (standard distillation) 223–330°C, refractive index n_D^{20} = 1.4684, density ρ_4^{20} = 0.836, and content of aromatic hydrocarbons 24.8 wt %.

Table 3. Parameters of single-stage extraction of aromatic hydrocarbons at 25°C estimated by UNIQUAC method [feed composition (wt %): *n*-dodecane 37.5, *n*-hexadecane 37.5, *n*-hexylbenzene 20.0, and 1-methylnaphthalene 5.0]

Using the UNIQUAC procedure, we estimated parameters of single-step extraction of aromatic hydrocarbons from the model system dodecane–hexadecane–*n*-hexylbenzene–1-methylnaphthalene at 25°C with straight DMF and DMF containing pentane (Table 3).

The theoretical results suggest that (1) at the same concentrations of dodecane and hexadecane in the initial mixture the dodecane content in the extracts is higher than that of hexadecane by a factor of 2–2.3; (2) separation coefficients β, estimated as the ratio of the distribution coefficients of the arenes and alkanes, are higher in the presence of pentane as compared to straight DMF; (3) arene content in the extract is higher in extraction with DMF–pentane also (see experiment nos. 1, 2); (4) to increase the degree of recovery of aromatic hydrocarbons in extraction with DMF–pentane, it is necessary to use an increased DMF to feed ratio (experiment nos. 1, 3); and (5) at weight ratios of DMF to feed and pentane to feed of 5 : 1 and 1 : 1, respectively (experiment no. 4), the same degree of recovery of 1-methylnaphthalene as in experiment no. 1 is realized at higher arene concentration in the extract and β, and also at a lower loss of the raffinate.

The advantages of extraction of arenes with a mixture of the polar (DMF) and nonpolar (pentane) solvents over extraction with straight DMF, which are not clearly distinct in the case of single-step extraction, should be more pronounced in multistep countercurrent extraction. The parameters of five-step countercurrent extractive purification of the diesel fraction are given in Table 4. As a result of higher selectivity and lower solvency of DMF as compared to DMAA, the moisture content in the extractants was 3 and 5 wt %, respectively.

Data on extraction of the arenes are given in Table 5. Pentane and the polar extractant were removed from the raffinate phase by fractional distillation. The yield of the extract and the arene content in it were estimated from the material balance equations. Regeneration of the solvents from the extract phase was performed also by distillation with a 20 TP column. As a result of formation of azeotropic mixtures of DMAA or DMF with saturated hydrocarbons of the extract phase, the arene content in the extract increases from 93–95 wt % in the extract to 98–99 wt % in the concentrate of aromatic hydrocarbons.

Simultaneous increase in the DMAA : feed and pentane : feed ratios (experiment nos. 1, 3) improves all the parameters of the extraction/azeotropic distillation process, including the degree of recovery of arenes, their content in the concentrate of aromatic hydrocarbons, and raffinate quality.

The arene contents in the resulting diesel fuel and concentrate of aromatic hydrocarbons, meeting the requirements for environmentally friendly diesel fuel and Nefras AR-150/330 (≤10 wt % [16] and ≥98 wt %, respectively [17]), are realized in experiment nos. 2 and 4, i.e., under similar conditions for DMAA and DMF. The latter is due to similar values of the selectivity and solvency of DMAA and DMF with a 5 and 3 wt % moisture content, respectively.

Note that, in contrast to DMAA, commercial DMF is available in Russia. DMF finds industrial use

Fraction composition, °C:			
initial boiling point	203	202	220
10%	233	236	236
30%	259	260	263
50%	281	281	283
70%	302	302	304
90%	322	322	331
dry point	352	346	357

for recovery and purification of isoprene by extractive distillation; the same process is used also for recovery of benzene from the benzene fractions of reformer naphtha or pyrolysis condensate. Commercial production of DMAA by condensation of acetic acid with dimethylamine was formerly realized at the Salavat Petroleum Chemical Combine [18], but now it is not manufactured in Russia.

Samples of the feed and concentrate of aromatic hydrocarbons separated in experiment no. 2 were characterized by ^{13}C and ^{1}H NMR spectra on a Bruker AM-500 instrument. The spectra were analyzed by the procedure described in [19]. The results demonstrated that the aromaticity factor characterizing the relative amount of aromatic carbon atoms in a molecular-weight-average molecule increases from 0.111 in the feed to 0.506 in the concentrate, the number of aromatic carbon atoms, from 1.74 to 7.49, and the number of hydrogen atoms bound to aromatic carbon atoms, from 1.03 to 4.3.

Table 6 demonstrates the results of chromatographic distillation, corresponding to the TBP (true boiling point) curve, of samples of the feed, raffinate, and concentrate of aromatic hydrocarbons, obtained in experiment no. 2. TBP curves of the raffinate and feed differ only slightly (raffinate dry point somewhat decreases). The initial boiling and dry points of the concentrate increase as compared to the feed. Nevertheless, practically the whole concentrate can be used as a component of Nefras AR-150/330.The concentrate of aromatic hydrocarbons separated from the diesel fraction can be combined with the component of Nefras 150/330 separated from the jet engine fuel fraction [6].

CONCLUSIONS

(1) In the process including extractive purification of the diesel fraction with dimethylformamide or dimethylacetamide in pentane and regeneration of polar extractants from the extract phase by azeotropic distillation, providing removal of azeotropic mixtures of amides with saturated hydrocarbons C_{10}–C_{14}, the arene content in the concentrate of aromatic hydrocarbons increases to 98–99 wt % against 93–95% in the extract.

(2) The proposed extraction–azeotropic distillation method allows production of environmentally friendly diesel fuel with an arene content below 10 wt %. Another product is a petroleum aromatic solvent like Nefras AR-150/330.

CHEMISTRY OF FOSSIL FUEL

The Use of Pulse Nuclear Magnetic Resonance for Studying the Mechanism of Solvation Separation of Natural Bitumen

V. G. Kozin, A. Yu. Kopylov, and R. S. Kashaev

Kazan State Technological University, Kazan, Tatarstan, Russia

Received April 12, 2000; in final form, November 2000

Abstract—A mechanism of deasphalting and fractionation of Ashal'chinsk natural bitumen with acetone was studied by pulse NMR. The features of distribution of components of the initial material in acetone solutions in deasphalting and also structural variations in the colloidal system resulting in separation of fractions when water is added in portions to the solution were studied. The structural-group composition of the separation products was characterized on the basis of NMR and IR data.

Previously [1, 2] we suggested a procedure of solvation deasphalting and fractionation of natural bitumens (NBs). This separation procedure is of large applied significance and calls for further investigation aimed at studying the mechanism of complicated multistage extraction of components from NB at discrete variation of the solvency of the polar solvent. However, the mechanism of separation of NB, which is a complex colloidal system, by a polar solvent is not adequately studied. The procedures widely used for studying petroleum dispersion systems (PDSs) with preseparation of these systems by distillation, extraction, adsorption, and other methods with subsequent use of chromatography, IR spectroscopy, and polarography allow determination of the elemental, chemical, and structural-group compositions of the separation products [3]. However, all these methods destroy the colloidal system during analysis and do not allow sudying structural variations in PDSs under the action of various factors. These methods should be replaced by noncontact methods which do not destroy the colloidal system and furnish information on the composition and structure of the system components but also on the parameters of molecular motion, structural ordering, and phase transitions of the "living" colloidal system. At present, among these methods, pulse NMR spectroscopy finds expanding application [4, 5].

EXPERIMENTAL

For measurements of NMR relaxation parameters we used an 08RS/BK pulse relaxometer, which is a modification of previously developed pulse relaxometers [6]. The unit is based on the Hahn and Carr–Purcell–Meiboom–Gill methods [5]. We measured the spin–spin relaxation times T_2i (ms) of the components of phases found in NB, its solutions in acetone, and also in the products of deasphalting and fractionation. The number of phases characterized by certain T_2i values and proton population density Pi was determined by expansion of envelope of spin–echo signals to individual components with subsequent separation of linear portions [7, 8]. In studying acetone solutions in NB and solution of the deasphalting product in hydrated acetone, the possibility of finding more than three phases in the system arised owing to using two steps of measurements at various regimes of relaxometer operation. First, the envelope of spin echo was divided in two portions at the fracture point, and then the resulting portions were individually expanded into components whose number did not exceed three. Associated and free acetone molecules and also their associates with the most mobile molecules of oils with long relaxation times (approximately 1000 ms) make the main contribution into the approximately linear portion of the curve at the end of the envelope. The initial portion of the envelope corresponds to less mobile components of the solution.

To study the effect of the solvent amount on restructurization proceeding in deasphalting, we prepared the solution of NBs in acetone in the range of solvent to NB ratio from 0.25 to 1. At the ratio higher than 1 the solution separated in two phases, i.e., deasphalting proceeded; therefore, at the ratio of 3–5 the solutions of asphalt (lower layer) and deasphalting product (upper layer) were studied individually. To study the effect of temperature on the parameters of

1070-4272/01/7405-0870$25.00

molecular motion, the resulting solutions were prepared and analyzed at 20 and 35°C.

To study the mechanism of solvation fractionation, we carried out deasphalting of Ashal'chinsk NB with acetone (ratio of 5) at 20°C. Then, the solution of deasphalting product was fractionated by separation of fractions on adding water in portions in the amounts of 4, 8, 12, and 16 wt %, respectively. The process was carried out similarly at 30 and 40°C. Then, the compositions of the upper (the solution of deasphalting product in wet acetone) and the lower (solutions of asphalt and fractions) phases were studied individually by pulse NMR. The spectrometer was equipped with a temperature-controlled unit for measurement of the spin–spin relaxation time at the same temperature at which the fractionation was carried out.

The initial materials and also asphalt and the fractions produced by the same scheme but at 55°C were also studied by pulse NMR in the temperature range 20–100°C.

To study the structural-group composition of solutions of asphalt and deasphalting product obtained at 20°C and also solutions of asphalt and fractions obtained at 55°C, we registered high-resolution ^{1}H NMR spectra on a Tesla-567A spectrometer operating at 100 MHz. In addition, the fractionation products were studied by IR spectroscopy [3] using a Specord M-85 spectrophotometer.

The spin–spin relaxation time T_2i and proton populations Pi of NB components, products of its separation, and their solutions in acetone were the main characteristics used for studying this colloidal system by pulse NMR.

The temperature dependences of the spin–spin relaxation time of NB components are presented in Fig. 1. It is seen from Fig. 1 that this colloidal system exists in the form of three phases with different molecular mobilities. Curve *1* can be assigned to the most mobile phase whose molecules most likely form the dispersion medium and enter into the composition of the outer solvation shell of a complex structural unit (CSU) being in direct contact with the dispersion medium. Oil molecules and long, fairly mobile aliphatic fragments of resin molecules can be among these components of the system. Curve *2* can be assigned to resin molecules that form the inner solvation shell being in direct contact with the CSE nuclei, asphaltenes. The asphaltene phase is represented by curve *3* characterizing the components of the initial material with the lowest molecular mobility. In this case, asphaltenes as the third phase of the system

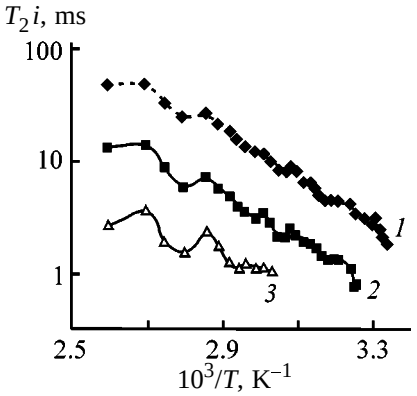

Fig. 1. Relaxation time T_2i of components of Ashal'chinsk NB as a function of temperature T. (*1*) Oils, (*2*) resins, and (*3*) asphaltenes.

begin to be detected by the device only at a temperature above 50°C, since at lower temperatures the structured asphaltene components have too short relaxation time.

As seen from Fig. 1, there are abrupt step variations of the spin–spin relaxation time for the phase corresponding to asphaltenes. These variations characterize the restructurization proceeding in each of the three suggested phases. Thus, each jump in the temperature dependence is apparently caused by variation of the structure of CSU and associates of NB components. Naturally, this restructurization for oils is less pronounced than that for asphaltenes having a stack structure close to the graphite-like structure. Resins have an intermediate structure.

It is of great scientific interest to study by pulse NMR the structural variations occurring in NB in its mixing with acetone. With this purpose we studied the NMR spectra of acetone–NB solutions at 20 and 35°C. In the absence of acetone two phases are revealed by the dependence of T_2i of NB components on the solvent ratio (Fig. 2) at these temperatures, similarly to data in Fig. 1. It should be noted that all the curves corresponding to 35°C lie above the curves characterizing the solution at 20°C, which is due to increase in the molecular mobility with increasing temperature. In addition of acetone to the colloidal system in hand at the acetone : NB ratio of 0.25, these two phases can be observed but the T_21 and T_22 values characterizing their molecular mobilities are significantly higher. In this case a new phase with the relaxation time T_23 appears in the solution; in its formation acetone plays a dominant role. Polar molecules of acetone have formed presumably associates primarily with heteroatomic and aromatic components previously incorporated into the outer solvation shell of CSU. Addition of the next portion of acetone to the

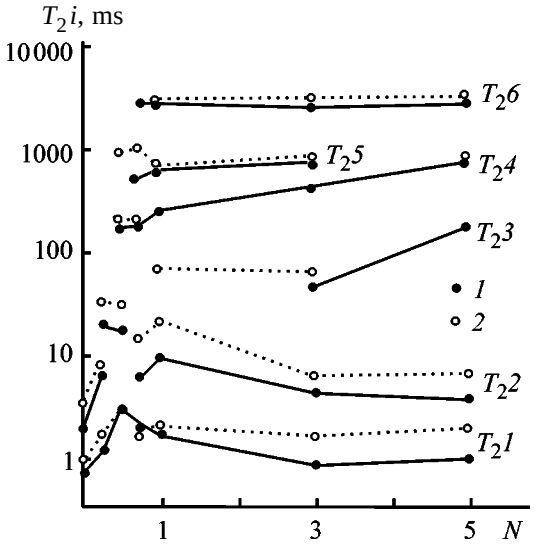

Fig. 2. Relaxation time T_2i of NB components as a function of the degree of dilution of NB with acetone. (*N*) Ratio of acetone to NB. Temperature, °C: (*1*) 20 and (*2*) 35.

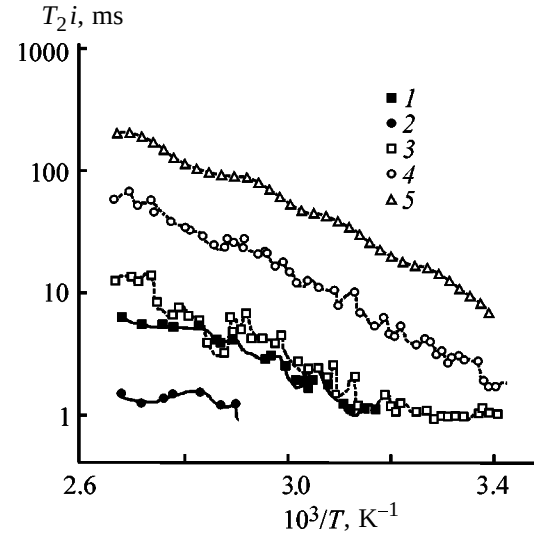

Fig. 3. Temperature dependence of relaxation time T_2i for components of (*1, 2*) asphalt and (*3, 4*) deasphalting product. (*1, 3*) *T1*, (*2, 4*) *T2*, and (*3*) *T3*.

system (the acetone : NB ratio of 0.5) results in an increase in the molecular mobility of the initially coexisting phases *1* and *2*. Phase *3* formed on addition of the first portion of acetone does not change the molecular mobility, and a new phase *4* with a longer relaxation time T_24 appears. It can be assumed that in this case not only the outer solvate layer but also the layer directly adjacent to asphaltenes, CSU nucleus, starts to destroy. This assumption is based on the fact that addition of the next portion of acetone (acetone : NB ratio of 0.75) results in CSU restructurization accompanied by significant decrease in the molecular mobility of asphaltene phase *1* and appearance of new phases *5* and *6* enriched with acetone. From our data in neat acetone, there are two phases with different molecular mobilities, free and associated molecules with relaxation times T_2a = 2800 and T_2b = 1000 ms at 20°C, respectively. Hence, it can be concluded that the relaxation time T_25 is close to the relaxation time of the associated phase and T_26 is close to that of the free phase of neat acetone. Thus, at this ratio of acetone to NB in the system, asphaltenes start to separate as individual microphase, in which the resin and oil molecules in the solvate shell are replaced by acetone molecules.

Further addition of acetone to the system under consideration does not result in formation of new phases, and the initial colloidal system separates in layers forming two coexisting thermodynamically equilibrium colloidal systems: asphalt solution in which asphaltene and heavy resinous components of the initial materials with lower molecular mobility are concentrated and solution of deasphalting product containing molecules of oils and resins and small amount of finely dispersed solvated asphaltenes. When analyzing the dependences of NMR parameters separately for solutions of asphalt and deasphalting product it should be noted that phases *1* and *2* refer to solutions of both asphalt and deasphalting product. The phases having the relaxation times T_23, T_24, and T_26 are present only in the solution of deasphalting product, and the phase with the relaxation time T_25 is distributed between phases *4* and *6* at the ratio of acetone to NB higher than 3. The fact that components of NB dissolved in acetone are separated with respect to their molecular mobility is confirmed by the temperature dependence of the relaxation time of asphalt and deasphalting product components, produced by deasphalting of NB at 55°C and acetone ratio equal to 3 (Fig. 3). In this dependence there are two phases of asphalt whose relaxation times correspond to T_21 and T_22 presented in Fig. 1. These two phases are also present in the deasphalting product; however, their components have considerably higher molecular mobility owing to breakdown of the three-dimensional graphitic structure of asphaltenes which most likely retained only the platelike two-dimensional structure. The most mobile phase in deasphalting product (the upper line in the plot) corresponds to oils.

It is well known that it is the oil fraction of NB, consisting of paraffin naphthene hydrocarbons forming the major fraction of the dispersion medium and the outer solvate shell of CSU, that passes primarily into the deasphalting product. The analysis of the high-resolution NMR spectrum showed that polycondensed aromatic components with short aliphatic

chains also pass predominantly into the deasphalting product solution, while at the same degree of aromaticity and condensation molecules with longer aliphatic substituents remain in the asphalt solution. Association of polar molecules of acetone with polycondensed aromatic components with short aliphatic chains is less hindered sterically and therefore these components predominantly pass into the deasphalting product solution. This suggestion is confirmed in [9], according to which aromatic hydrocarbons with the largest average molecular polarization have the highest solubility in a polar solvent.

The mechanism of solvation fractionation (SF) was studied on the basis of data on distribution of components with various molecular mobilities in solutions of deasphalting product and fractions at portional addition of water. Figure 4 shows the dependence of T_2i on the amount of water added for components of solutions of fractions (lower layer) and deasphalting product (upper layer). It is evident that with increasing amount of water the number of phases in the system increases; however, asphaltene phase *1* is the same in the solutions of all fractions, and its relaxation time T_21 increases with increasing temperature of the process. The presence of asphaltenes in all fractions is confirmed by the data obtained in studying physicochemical characteristics of products of the fractionation carried out at the same solvent ratio but different temperature [2].

Phase *2*, corresponding mainly to the resins incorporated into CSU shells partially retained in deasphalting, is not registered in NMR experiments at 20°C. During SF at 30°C and 40°C this phase is not registered in this colloidal system at water content no more than 8% when the first two fractions are precipitated. Phase *3* with the relaxation time T_23 can be observed only at 20°C at a water content of up to 12%. After isolation of the first three fractions the concentration of acetone molecules (free molecules with the relaxation time T_25 and also self-associated molecules and molecules associated with water and deasphalting product components with the relaxation time T_24) increases to such an extent that the relaxation time of the other components of the system cannot be detected.

Thus, the pulse NMR technique reveals some differences between the mechanisms of deasphalting and fractionation. Thus, in deasphalting an increase in the concentration of acetone is accompanied by appearance of new phases involving deasphaling product and acetone molecules with a higher molecular mobility, whereas in SF with increasing water content the

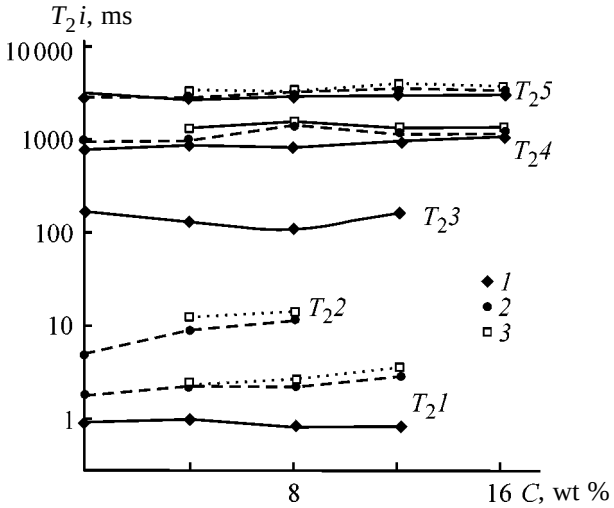

Fig. 4. Relaxation time T_2i of components of solution of fractions and deasphalting product as a function of water content *C*. Temperature, °C: (*1*) 20, (*2*) 30, and (*3*) 40.

number of phases in the system decreases owing to separation of components with the lower molecular mobility. Addition of a new portion of water results in abrupt changes in the structure of the colloidal system, owing to which in precipitation of each fraction the corresponding phase with the relaxation time T_2i is redistributed and disappears. For fraction 2 this is phase *2*; separation of fraction 3 is accompanied by redistribution and disappearance of phase *3*.

Using pulse NMR spectroscopy, we determined the parameters of molecular mobility of the components of fractions obtained at a fractionation temperature of 55°C and the acetone : initial material ratio of 5 after separation of these fractions from acetone and water. With this purpose we studied the temperature dependences of the spin–spin relaxation time of these components, presented in Fig. 5. We determined the physicochemical and structural-group characteristics of the separation products (from the evidence of high-resolution NMR), presented in Table 1.

Analysis of the temperature dependences obtained for the fractions showed that in these fractions, similar to the initial material (Fig. 1), there are three phases corresponding to oils, resins, and asphaltenes. In this case, the relaxation time of the asphaltene phase varies insignificantly for all the fractions, while the relaxation time of the resinous and oil components of the separation products increases with increasing amount of water required for their recovery from the solution of the deasphalting product. Insignificant variations of T_2i values of asphaltenes in the temperature dependence for the fractions may be due to the fact that in the deasphalting product solution to be fractionated

* Molecular weight.

only finely dispersed asphaltenes are retained, having no complicated three-dimensional structure similar to NB and solvated mainly by acetone and water molecules. These associates still remain in the solution with increasing its polarity by adding water, since, as mentioned above, asphaltenes have the highest values of the average molecular polarization in this system and are most strongly retained in a solution of the polar solvent. With increasing water content, coarse less polar components having long aliphatic radicals adjacent to condensed aromatic structures are mainly separated from the deasphalting product. As a result, the most polar, most polarizable, and smallest-size components of the initial material, such as low-molecular-weight heteroatomic and aromatic compounds, are accumulated in the last fraction. This is confirmed by the NMR and IR spectra. In high-resolution NMR spectra of asphalt and all fractions (fractionation temperature 55°C) there are signals with the chemical shifts identified on the basis of published data [10, 11].

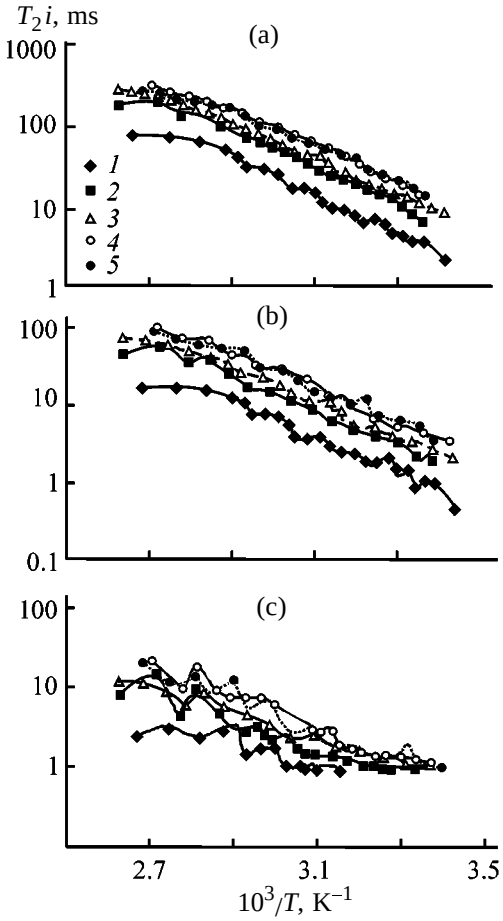

Fig. 5. Relaxation time T_2i of (a) oils, (b) resins, and (c) asphaltenes in fractions 1–5 as a function of temperature T. Fractions: (*1*) 1, (*2*) 2, (*3*) 3, (*4*) 4, and (*5*) 5.

From the ratio of the integral intensities of the signals corresponding to aromatic structures and the total aliphatics in the NMR spectra of separation products and also the ratio of the intensities of the signals of methylene and methyl protons, we obtained the averaged molecular characteristics of the fraction components, such as aromaticity C_{arom} and the length of aliphatic substituents [3, 11] (Table 1, Fig. 6).

Based on the IR data, we determined the parameters described in [12] and characterizing the structure of averaged molecule of separation products: (1) aromaticity C1, (2) degree of branching of aliphatic fragments C2, (3) content of sulfoxide groups in aromatic fragments S1, (4) content of sulfoxide groups in aliphatic fragments S2, and (5) total content of unsubstituted hydrogen atoms in aromatic fragments B1.

Presumably, the increase in the relaxation time of the phases corresponding to resinous and oil components of fractions with increasing water content is due to a decrease in the degree of condensation of molecules in fractions 1–4. The increase in aromaticity of fraction 5 (Fig. 6) is due to accumulation of mono- and bicyclic aromatic compounds.

Variation in the degree of branching of aliphatic fragments C2 in fractions is also characterized by the presence of a maximum. Low degree of branching in asphalt is due to the presence of highly condensed components low-substituted with short aliphatic radicals, which is suggested by the high value of the coefficient B1 and low value of the CH_2/CH_3 ratio. The increase in the coefficient C2 in passing to fractions 1–4 is due to an increase in the solvent polarity, which results in retention of components with a higher polarizability in the solution, namely, of components with shorter carbon chains at the same number of carbon atoms and hence with a greater degree of branching of aliphatic substituents at aromatic rings and a greater number of substituents (Table 2, coefficient B1).

The features of distribution of heteroatomic compounds can be followed for distribution of sulfur-containing compounds among fractions as an example. The character of variation of coefficients S1 and S2 is similar and shows the increase in the amount of sulfoxide groups in passing from asphalt to the last fraction owing to their high polarity and ability to form hydrogen bonds with proton-donor compounds. This results in retention of sulfoxide-containing compounds in aqueous solution of acetone.

An increase in the water content in the deasphalting product solution results in increased role of dipole–dipole interactions and formation of new hydrogen bonds, which facilitates separation of molecules of oil components with the paraffin–naphthene structure, having no tendency to participate in these interactions, from the solution. The presence of more polar water in the solution apparently results in formation of more compact associates with polarizable oil and resinous components with certain molar volume, having short aliphatic substituents at the aromatic ring. In this case, the deasphalting product components having shorter aliphatic fragments and lower degree of condensation as compared to the above components are separated from the solution, which is manifested in longer spin–spin relaxation time of oils and resins in fractions. This assumption is confirmed by data on variation of the molecular weight, aromaticity, and the length of aliphatic chains of fractionation products (Tables 1, 2).

The characteristic feature of the obtained temperature dependences is the presence of an inflection in the curves corresponding to phases of oils and resins (Fig. 5), while for the phase of asphaltenes the jumpwise variations of the molecular mobility, similar to those in the initial material but less pronounced, can be observed (Fig. 2). These jumpwise variations for the asphaltene phase will be studied in the future. The temperature corresponding to the inflection point in the plots for the phases with the lower molecular mobility decreases from 81 to 74°C with increasing water content in the deasphalting product solution, required for separation of the corresponding fraction. The inflection in the curve can originate from the fact that the major part of structural variations in the corresponding phases proceeds up to a certain temperature and further increase in temperature affects insignificantly the molecular mobility of the components.

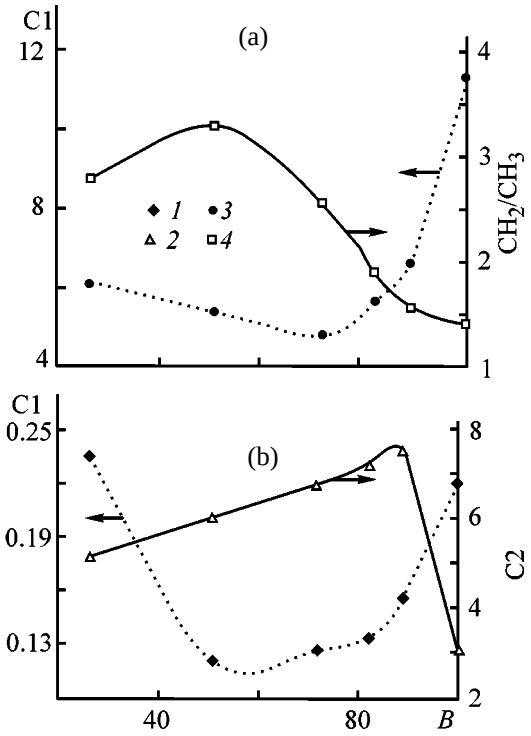

Fig. 6. Structural-group composition of fractions as a function of their yield based on the initial materials: (C1) aromaticity, (C2) degree of branching of aliphatic fragments, (CH_2/CH_3) length of aliphatic chain, and (*B*) total yield of fraction (wt %). Data: (a) NMR and (b) IR spectroscopy.

Table 2. Coefficients characterizing structural-group composition of fractionation products

Fraction	Coefficient

3	0.133	7.230	0.649	0.086	2.579
4	0.155	7.532	0.774	0.122	2.935
5	0.220	3.08	0.688	0.147	3.811

CONCLUSIONS

(1) The mechanism of distribution of components of Ashal'chinsk natural bitumen in its deasphalting and fractionation with acetone was studied by pulse NMR. The restructurization processes occurring in acetone solutions in natural bitumens were studied at various temperatures and solvent ratios and at addition of water in portions.

(2) In the products of deasphalting and fractionation there are three fractions with different molecular mobilities. In deasphalting, the asphaltene phase is concentrated in asphalt. With increasing water amount required for separation of the corresponding fraction the molecular mobility of its oil and resinous components increases.

Abstract—Formation of asphalt–resin oligomers by reaction of petroleum vacuum residues and bitumens with the oligoisoprene fraction from the dimethylformamide distillation bottoms (isoprene production waste) was studied by thermomechanical and thermogravimetric analyses. The number-average molecular weights of the final product and initial components were determined.

Utilization of industrial wastes and by-products, along with solution of environmental problems, will decrease the cost of commercial products and extend the range of raw materials. Among the largest-tonnage wastes of oil-refining and petrochemical industries are pyrolysis tars and bottoms [1], in particular, petroleum asphalts and bitumens. Their condensation with dimethylformamide distillation bottoms (KORD resin, isoprene production waste) containing the oligoisoprene fraction yields asphalt–resin oligomers (ASMOL) [2].

Both ASMOL and formulations thereof are widely used as high-performance corrosion-resistant and waterproofing materials and coatings [3]. In the main service parameters (plasticity, corrosion-resistance power, adhesion) ASMOL surpasses the protective formulations based on petroleum bitumens and high-molecular-weight elastomers [4].

In this work we attempted to reveal factors responsible for the unique properties of this product and, primarily, to find whether ASMOL is merely a mixture of sulfonated products of condensation (or polymerization) of the initial components (bitumen and oligomeric fraction of isoprene) or its formation involves chemical reactions between the components. This is necessary for optimizing the process of ASMOL production and important from the scientific viewpoint, as study of the reactivity of oil cracking residues is one of the major research lines in petrochemistry.

As seen from the table, ASMO contains high-molecular-weight fractions whose molecular weight M exceeds several times that of the initial components, KORD resin and bitumen.

Since ASMOL is produced in the presence of concentrated sulfuric acid, formation of the high-molecular-weight fraction can be associated with condensation of bitumen resins (on heating or acid treatment, neutral resins as components of petroleum bitumens undergo condensation to give asphaltenes, the highest-molecular-weight components of oil [5]). High-molecular-weight compounds can also form by condensation of KORD resin and bitumen, since both the initial and intermediate substances of ASMOL production contain reactive functional groups such as –COOH, –OH, $–HSO_4$, and $–NH_2$. To take into account the contribution of these reactions to the increase in the molecular weight of the final product, we performed separate sulfonation of ASMOL components (bitumen and KORD resin).

As seen from Fig. 1, the thermomechanical curves of ASMOL, KORD resin, bitumen (sulfonated and nonsulfonated), and their mechanical mixtures have a shape characteristic of oligomeric products, with one temperature transition corresponding to the flow point T_f. The resin (low-molecular-weight fraction of isoprene oligomers) and bitumen have the lowest flow points. Introduction into bitumen of 10 wt % resin increases T_f of the mixture, which suggests formation of products with a higher molecular weight. Probably, in the course of ASMOL formation the chemical interaction between the components starts even in the stage of mixing and homogenization. Comparison of the thermomechanical curves of the initial (and separately sulfonated) bitumens and resin shows that sulfonation in both cases increases T_f, with the shift of the total flow branch along the temperature axis for the resin being by a factor of 3 larger than for the bitumen.

no. 1	270	–	–	–
no. 2	350	1250	–	–
no. 3	140	990	–	–

The flow of the sulfonated resin is characterized by slow gworth of the deformation in the course of heating. The polydispersity of the sample (presence of fractions with different *M*) can be indirectly judged from the shape of the initial section of the thermomechanical curve [6] (sharp or gradual inflection), and the shift of the branch characterizing the flow of the sample is primarily determined by its molecular weight. In view of these facts, our results suggest that in the course of joint sulfonation of the resin and bitumen (as it is done in production of ASMOL) the growth of the molecular weight of the final product is mainly due to cationic polymerization of oligoisoprene catalyzed with sulfuric acid, rather than to condensation processes involving bitumen. The resulting sulfooligoisoprene apparently has a wide molecular-weight distribution, as indicated by a slow growth of the deformation in the thermomechanical curve. At the same time, the fact that the flow point of a mechanical mixture of sulfonated initial components differs from that of ASMOL is an indirect evidence of interaction of the bitumen and resin components.

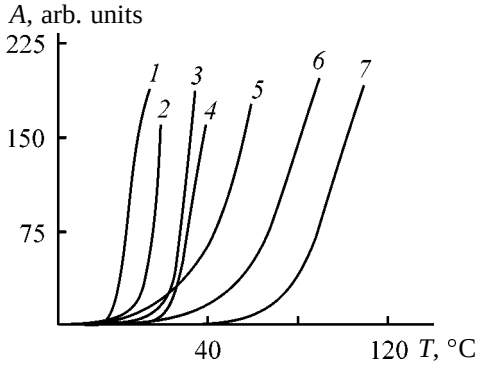

Fig. 1. Thermomechanical curves of (*1*) resin, (*2*) bitumen, (*3*) bitumen–resin mixture, (*4*) sulfonated bitumen, (*5*) sulfonated resin, (*6*) ASMOL, and (*7*) mixture of sulfonated bitumen with sulfonated resin: (*A*) deformation and (*T*) temperature.

This assumption is confirmed by direct determination of the molecular weight of the initial and final products (sulfonated and nonsulfonated). As seen from the table, sulfonation of KORD resin appreciably increases its number-average molecular weight. Sulfonation of oligoisoprenes at double bonds cannot cause such an increase in the molecular weight of the reaction products. Calculations show that addition of two sulfo groups to the initial dimeric isoprene molecule increases its molecular weight by 160 units, whereas actually it increases by 880 units. Such an increase in M_n may be due both to further polymerization of oligoisoprene catalyzed with sulfuric acid and to condensation involving sulfo groups of the oligoisoprene and amino groups of dimethylformamide, always present in a certain amount in the bottoms.

The molecular weights of the bitumen sulfonation products also increase the initial M_n values, but not so significantly. Apparently, with respect to bitumens sulfuric acid mainly acts as a sulfonating agent.

By extraction with heptane (procedure for deasphalting of petroleum bitumens), we separated ASMOL into two fractions: soluble (fraction 1) and insoluble (fraction 2) in toluene and determined their number-average molecular weights in toluene by measuring the thermal effects of condensation; the M_n values obtained are listed in the table. As expected,

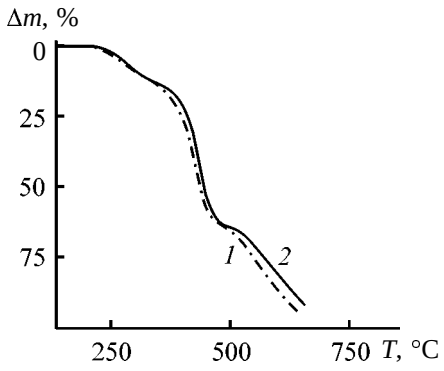

Fig. 2. TG curves of (*1*) commercial and (*2*) laboratory samples of ASMOL in air: (Δ*m*) weight loss and (*T*) temperature; the same for Figs. 4 and 5.

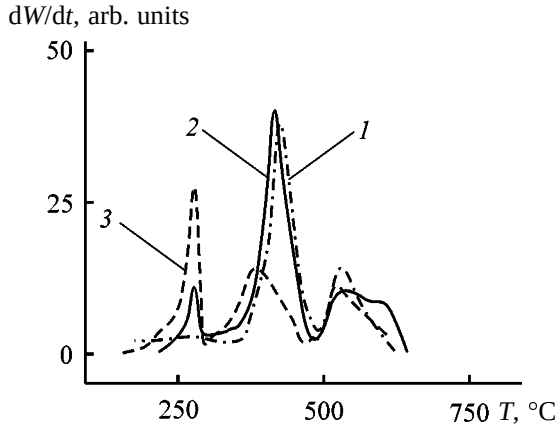

Fig. 3. DTG curves (d*W*/d*t*, rate of weight loss) of (*1*) sulfonated bitumen, (*2*) ASMOL, and (*3*) sulfonated resin in air: (*T*) temperature; the same for Fig. 6.

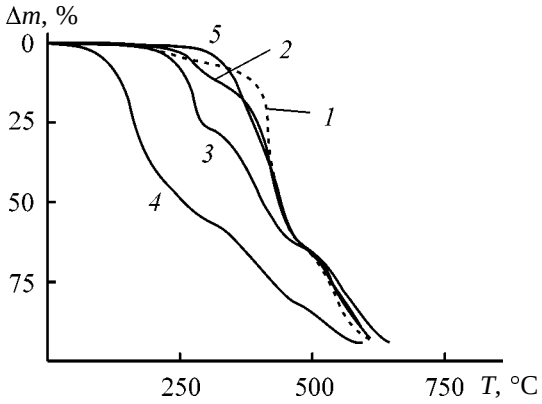

Fig. 4. TG curves of (*1*) sulfonated bitumen, (*2*) ASMOL, (*3*) sulfonated resin, (*4*) resin, and (*5*) bitumen in air.

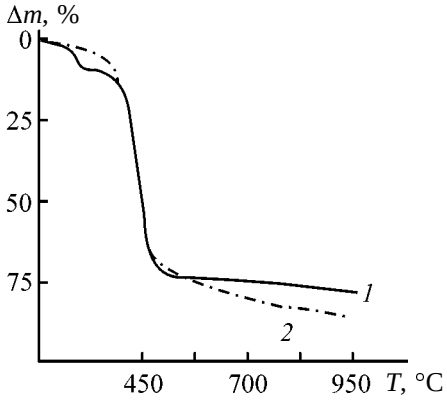

Fig. 5. TG curves of (*1*) ASMOL and (*2*) mixture of sulfonated bitumen and sulfonated resin in argon.

M_n of the heptane-insoluble fraction is considerably higher than that of the heptane-soluble product.

Owing to the presence in ASMOL of components of different molecular weights and different chemical structures, thermal and thermal oxidative degradation of ASMOL is multistage.

According to dynamic TGA data, ASMOL decomposes in air in several stages. In the integral TG curves of laboratory and commercial samples (Fig. 2), we can distinguish three stages, with the corresponding DTG peaks at 280, 420, and 550°C (Fig. 3). To assign these peaks, we performed thermogravimetric analysis of the bitumen and resin (nonsulfonated and separately sulfonated samples) and of two mechanical mixtures prepared, respectively, from the nonsulfonated and sulfonated components. Figures 3 and 4 show that in the TG curves of the sulfonated resin and bitumen a low-temperature decomposition stage appears, and the second decomposition stage shifts toward higher temperatures. Comparison of the TG (Fig. 4) and DTG (Fig. 3) curves of ASMOL and sulfonated initial components suggests that the first decomposition stage and the corresponding DTG peak are due to decomposition of the sulfo groups. Since the weight loss in this stage for the resin is greater than for the bitumen, the extent of sulfonation of the isoprene oligomers is apparently greater as compared to the bitumen. The second degradation stage (about 400°C), apparently, involves decomposition of the bitumen component: The weight loss in this stage is proportional to the bitumen content. Finally, in the range 500–600°C the cross-linked carbon residue is burned out.

Thermogravimetric analysis in an inert atmosphere gave results indirectly suggesting occurrence of condensation of oligoisoprene with bitumene. The TG curves (Figs. 5, 6) show that the course of degradation of ASMOL differs from that of a mechanical mixture of the separately sulfonated bitumen and resin. Whereas with ASMOL there is a sharp step at 280°C, the weight of the mixture sample gradually decreases in

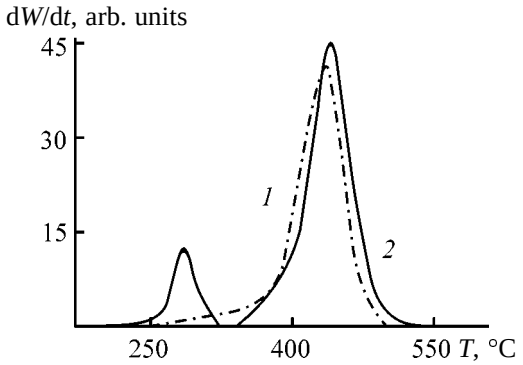

Fig. 6. DTG curves of (*1*) mixture of sulfonated bitumen and sulfonated resin and (*2*) ASMOL in argon.

a wide temperature range. Sharp steps are typical of selective decomposition of specific functional groups and cleavage of specific bonds (with subsequent elimination of low-molecular-weight decomposition products) within relatively high-molecular-weight macromolecules, whereas gradual weight loss, as a rule, suggests gradual evaporation of volatile oligomeric products.

EXPERIMENTAL

Under both industrial and laboratory conditions, ASMOL was prepared in three stages: (1) the initial components (resin and bitumen) were mixed at 90°C; (2) concentrated sulfuric acid was slowly added dropwise, so as to avoid boiling and rise of the reaction temperature (due to exothermic reaction) above 125°C; and (3) the final product was stabilized by heating at 150–160°C for 4 h.

Separate sulfonation of the bitumen and resin and preparation of the mixtures of the initial components (sulfonated and nonsulfonated) were performed similarly.

The flow point was determined on a thermomechanical installation at a load of 3.5 g mm^{-2} and a heating rate of 3 deg min^{-1}.

Dynamic thermogravimetric analysis was performed with an MOM Q-1000 derivatograph in air or argon; the heating rate was 5 deg min^{-1}, and the sample weight, 100 mg.

The number-average molecular weights M_n were determined by measuring the thermal effects of condensation [7]. The device was calibrated using polyethylene glycol samples of various molecular weights as references; the concentrations of solutions of the reference and test samples in benzene was 0.05± 0.01 g ml^{-1}. The measurements were performed at 40±0.01°C. For each sample, five parallel measurements were performed, and the mean M_n value was taken.

CONCLUSION

Our results suggest that formation of asphalt–resin oligomers involves both separate sulfonation and condensation of the initial components and their reaction with each other to give the higher-molecular-weight product. Sulfuric acid plays a dual role: firstly, it catalyzes further polymerization of the initial oligoisoprenes and their condensation with petroleum bitumen components (and also condensation of neutral bitumen resins), and, secondly, it participates in sulfonation of these products.

CHEMISTRY OF FOSSIL FUEL

Estimation of Quality of Petroleum Bitumens by NMR Spectroscopy and X-ray Diffraction

O. Yu. Begak and A. M. Syroezhko

St. Petersburg State Technological Institute, St. Petersburg, Russia
Mendeleev Russian Research Institute of Metrology, St. Petersburg, Russia

Received December 4, 2000

Abstract—Certified and substandard paving bituments of Kirishi Petroleum Processing Plant were studied by ^{1}H and ^{13}C NMR spectroscopy and X-ray diffraction. The differences in the aromaticity degree of asphaltenes and malthenes of these bitumens were revealed. The parameters of layered-block stacks of the asphaltenes were measured.

Previously we studied [1] certified and substandard BDUS 70/100 and BDUS 100/130 bitumens by a number of chemical and physicochemical methods. It was found than these bitumens have close chemical compositions of the organic constituents and different content of ash, sulfur, oxygen, alkaline-earth metals (Mg, Ca, Sr, and Ba), 3*d* metals (Cu, Co, and Zn), aluminum, boron, lead and arsenic. During aging of bitumens, their composition and structure, first of all at the associative level, change.

The aim of this work was to determine quantitative parameters of association of bitumen alsphaltenes and differences in the aromaticity degree of malthenes and asphaltenes of certified and substandard bitumens produced at the Kirishinefteorgsintez Joint-Stock Production Association.

EXPERIMENTAL

We used the certified and substandard bitumens characterized in our previous work [1]. Asphaltenes were recovered from the bitumens by exhaustive precipitation with hot pentane in a Soxhlet apparatus. The NMR spectra of certified and substandard bitumens were recorded in $CDCl_3$ solutions at 22°C on a Bruker AM-500 spectrometer (500 MHz, ^{1}H and 125 MHz, ^{13}C) with a 5-mm proton–carbon detector. The ^{13}C NMR spectra were recorded at inverse strobe proton decoupling. The X-ray diffraction analysis of the asphaltenes was performed on a DRON-2 diffractometer in the range $2\theta = 3°–60°$ (CuK_α radiation). The samples were powdered and placed in a cell 25 mm in diameter and 2 mm thick.

The ^{1}H signal of the residual protons of the $CDCl_3$ solvent appears as a sharp signal with a low integral intensity at 7.25 ppm against a background of the broad and strong signal of the bitumen aromatic protons. In the ^{13}C NMR spectra the solvent is manifested as a triplet at 77 ppm (Figs. 1, 2). As seen from Figs. 1 and 2, the bitumen spectra contain two groups of signals: (1) aromatic signals centered at about 7.5 and 135 ppm in the ^{1}H and ^{13}C spectra, respectively, and (2) aliphatic signals with the strongest peaks at 1.3 and 300 ppm in the ^{1}H and ^{13}C spectra, respectively. The aliphatic region of the carbon spectrum consists of five signals at 32.0, 29.8, 29.5, 22.8, and 14.2 ppm. The H_{ar}/H_{al} and C_{ar}/C_{al} ratios in the tested samples, determined by ^{1}H and ^{13}C NMR spectroscopy, are presented in Table 1.

Table 1. Comparative results of ^{1}H and ^{13}C NMR study of certified and substandard bitumens

Bitumen	H_{ar}/H_{al} (^{1}H NMR)	C_{ar}/C_{al} (^{13}C NMR)
BDUS 100/130: certified, produced 5/15/2000, certificate no. 24	0.066	0.441
substandard bitumen, produced 5/10/2000	0.0616	0.420
BDUS 70/100: certified, produced 5/6/2000, certificate no. 14	0.0595	0.425
substandard bitumen, produced 5/10/2000	0.052	0.365

1070-4272/01/7405-0881$25.00

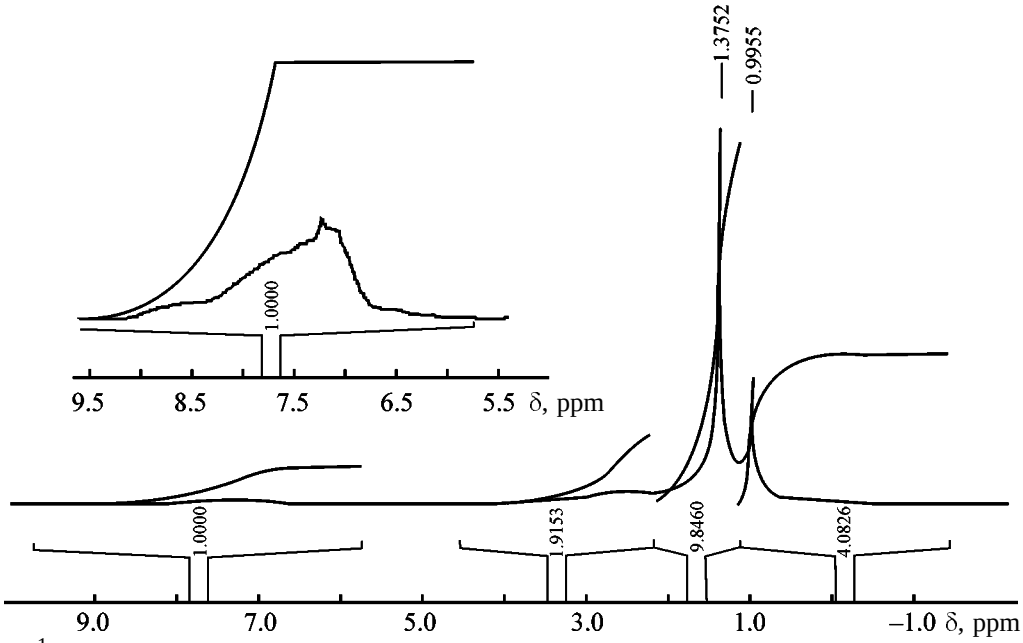

Fig. 1. ^{1}H NMR spectra of certified BDUS 100/130 bitumen. (δ) Chemical shift; the same for Fig. 2.

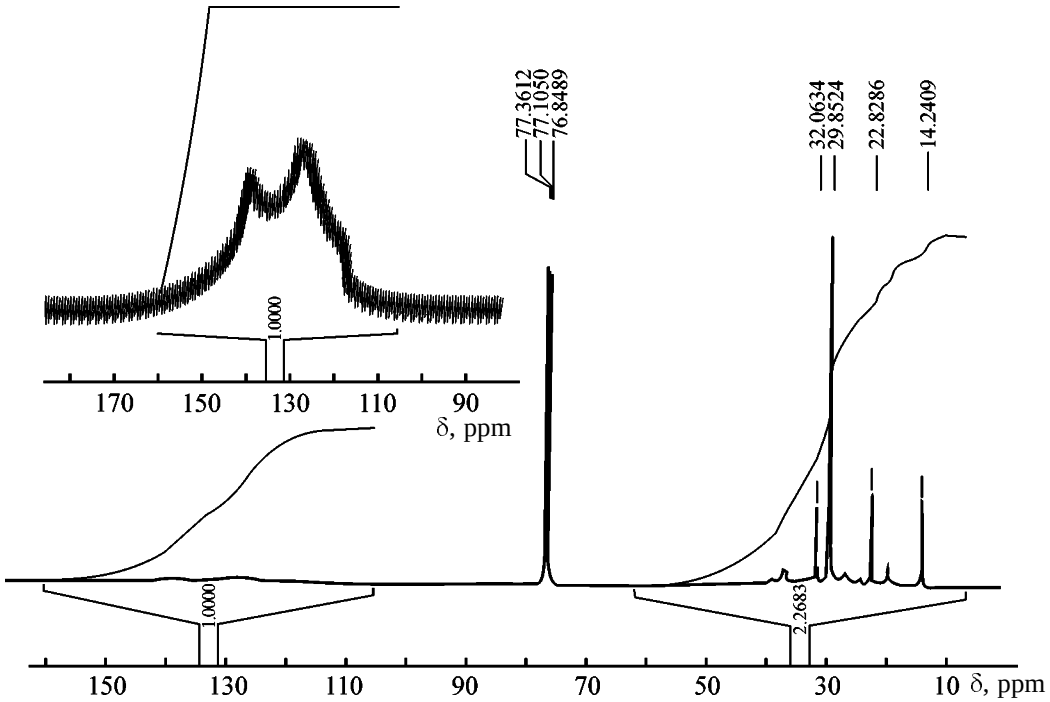

Fig. 2. ^{13}C NMR spectra of certified BDUS 100/130 bitumen.

As seen from Table 1, the H_{ar}/H_{al} and C_{ar}/C_{al} ratios in the both certified bitumens are higher than in the substandard samples (as a whole, these parameters for BDUS 100/130 bitumens are higher than those for BDUS 70/100 bitumens). For example, the H_{ar}/H_{al} ratio in the certified and substandard BDUS 100/130 bitumen is 0.066 and 0.0616, respectively (Table 1).

The H_{ar}/H_{al} ratio in the certified and substandard BDUS 70/100 bitumen is 0.0595 and 0.052, respectively. The C_{ar}/C_{al} ratio in the certified and substandard BDUS 100/130 bitumen is 0.441 and 0.42, respectively (Table 1). In the certified BDUS 70/100 bitumen this ratio is 0.425, whereas in the substandard sample it is 0.365. Thus, the NMR spectroscopic

study, as well as ICP-MS and HPLC [1], reveals differences between BDUS 100/130 and BDUS 70/100 certified and substandard bitumens.

Asphaltene powders recovered from certified and substandard bitumens of the both types were studied by X-ray diffraction at room temperature without using solvent, i.e., under conditions providing maximal degree of association of their molecules in supramolecular structures.

The X-ray pattern of sample no. 1 contains the following reflections. The γ reflection with the maximum at $2\theta_\gamma = 18°$ is due to diffraction on randomly distributed carbon atoms and heteroatoms (the reflection of amorphous carbon). The stack associates are manifested as a weak reflection from the (10) plane at $2\theta_{10} = 42°$ and a reflection form the (002) plane of the stacks with a maximum at $2\theta_{002} = 24°$. In the X-ray patterns of sample nos. 2, 3, and 4 the (002) reflection appears at $2\theta_{002} = 22°$, 21.5, and 22.5°, respectively.

The first step of the treatment of X-ray patterns is subtraction of the background (Fig. 3). To separate the (002) and γ reflections, they were assumed [2] to be symmetrical relative to $\theta = \theta_{002}$ and $\theta = \theta_\gamma$ axis and to be described by the Gaussian distribution function. The interlayer spacings in the stacks $d_m = 0.5\lambda/\sin\theta_{002}$ and the repeated spacings between the saturated molecular fragments $d_\gamma = 0.625\lambda/\sin\theta_\lambda$ (where λ is the wavelength of the radiation used, Å) were calculated from θ_{002} and θ_γ angles after normalization. The average diameter of flat molecular fragments in the stacks $L_a = 0.92/B_{1/2(10)}$ and the average stack thickness $L_c = 0.45/B_{1/2(002)}$ were calculated by the Scherrer equation form the halfwidths of the (10) and (002) reflections $B_{1/2(10)}$ and $B_{1/2(002)}$ measured in the $\sin\theta/\lambda$ units. The average number of layers in a stack was calculated by the equation

$$M = (L_c/d_m) + 1.$$

In addition, the areas of the separated peaks (002) and γ (A_{002} and A_γ, respectively) were measured and the aromaticity factor f_{ar} was calculated as the quotient of division of the area of the (002) reflection by the sum of the areas of (002) and γ reflections:

$$f_{ar} = A_{002}/(A_{002} + A_\gamma).$$

The results of these calculations are presented in Table 2.

The structural parameters of the asphaltene stacks in all samples differ considerably. The most ordered are sample nos. 1 and 2. They have the maximal cohesion which is manifested during the ductility measurement.

It should be noted that the aromaticity degree determined by X-ray diffraction agree well with the results of NMR spectroscopy. The higher the structural ordering of bitumens (the most ordered the

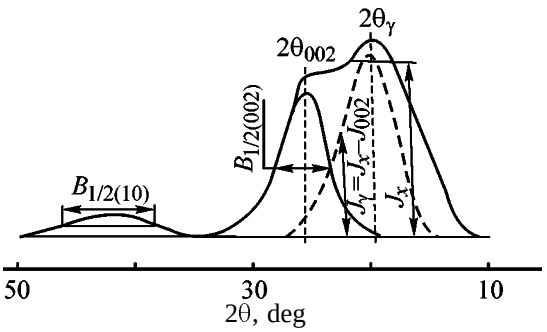

Fig. 3. Scheme for transformation of the normalized X-ray diffraction pattern and measurement of the reflection parameters. (2θ) Bragg angle.

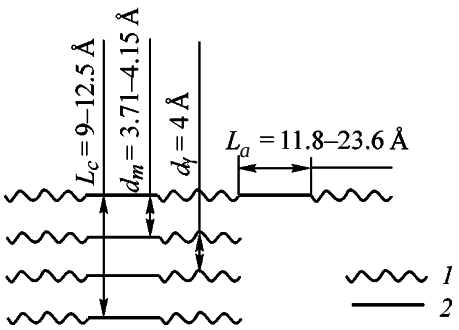

Fig. 4. Schematic structure of asphaltenes in layered-block stacks: (d_m) distance between aromatic layers, (d_γ) intrachain distance ($d_\gamma \sim 4$Å), (L_c) diameter of bunch of condensed layers, and (L_a) the diameter of the condensed aromatic planes. (*1*) Alkyl chains or free naphthene rings and (*2*) section of plates of condensed aromatic rings.

dispersed asphaltene phase), the denser is the packing of malthenes around asphaltene stacks. This affects the service parameters of bitumens (ductility).

Based on the results of the X-ray diffraction study, we suggest that asphaltene molecules are associated in the layered-block stacks (Fig. 4). Thus, X-ray diffraction, along with ICP-MS, HPLC [1], and NMR spectroscopy, can be used to determine meaningful differences between certified and substandard paving bitumens.

CONCLUSION

As compared to substandard bitumens, the layered-block stacks of asphaltene molecules of more structurally ordered (certified) bitumens are denser, and the packing of malthenes around the asphaltene nuclei is more ordered owing to their higher aromaticity. This results in higher thermal stability and, as a consequence, higher ductility of certified paving bitumens.

Abstract—Homogeneous pyrolysis of asphaltenes of G6 coal semicoking tar at 750–900°C was studied.

Optimization of destructive hydrogenation, high-rate pyrolysis, and high-temperature coking requires primarily detailed information on the chemical composition of the organic matter of coals (OMC), fractional, group, and structural-group compositions of the liquid products of "mild" thermal degradation of OMC, and directions and types of high-temperature transformations of "primary" products. Such data can be obtained by studying various coal extracts and separate groups of compounds of semicoking tars under conditions minimizing high-temperature transformations of primary products, which in this case can be considered with confidence as corresponding to native fragments of the coal macromolecule, and also by revealing the features of high-temperature pyrolysis of these products.

In this work we studied the high-temperature pyrolysis of asphaltenes of the semicoking tar of G6 coal (Kuznetsk Coal Fields).

The content of asphaltenes in the coal semicoking tar reaches 30 wt %; therefore, their contribution to formation of high-temperature liquid products and coke structure will be significant.

The combination of elemental, quantitative functional, structural-group, and emission spectrum analyses, cryoscopy, IR, UV, and ^{1}H NMR spectroscopy, and adsorption liquid, capillary gas–liquid, and preparative thin-layer chromatography showed that the asphaltenes of G6 coal semicoking tar are a complex mixture of high-molecular-weight polycyclic compounds of the alicyclic, hydroaromatic, aromatic, and heterocyclic nature, substituted with various functional groups and alkyl chains [1].

Pyrolysis of asphaltenes was performed in a setup consisting of a quartz pyrolyzer (d = 20 mm, l = 500 mm), a three-sectional oven, and systems for feeding the initial substance and condensing and trapping the pyrolysis products [2]. The vapor–emulsion mixture of asphaltenes fed to the pyrolyzer was diluted with argon in a ratio (1 : 25 by volume) close to that of dilution of resin vapor with coke oven gas in the course of high-temperature coking. Also, dilution with argon allowed accurate measurement and fine control of the residence time of the vapor in the pyrolysis zone.

To determine the contribution of asphaltenes to formation of other classes of compounds, we performed the chemical group analysis of the tars [3] followed by study of the qualitative and quantitative composition of separate groups of components by elemental, functional, and structural-group analyses, cryoscopy, capillary gas–liquid chromatography, and IR and UV spectroscopy.

Pyrolysis of coal asphaltenes was performed at 750, 800, and 900°C; the residence time of the vapor in the heated zone was 0.5, 1.5, 3.0, and 6.0 s.

The material balance data for asphaltene pyrolysis and the results of chemical group analysis of the liquid products are listed in Table 1.

It is seen that asphaltenes of G6 coal semicoking tar undergo extensive transformations whose extent is determined by temperature and residence time of the asphaltene vapor in the pyrolyzer.

Within the first 0.5 s at 750, 800, and 900°C the yield of pyrocarbon (a highly condensed product of the carbon black type) was 11.2, 13.4, and 16.5 wt %, the yield of liquid products, 81.3, 70.1, and 61.3 wt %, and the yield of gaseous products, 7.5, 16.5, and 22.2 wt %, respectively. The rate of asphaltene degradation in the next second at 750°C is somewhat lower, as suggested by small changes in the yields of pyro-

"secondary" asphaltenes	49.80	53.20	59.80	72.30	60.10	53.90	64.00	50.30	49.50	52.00	53.50
Gas	7.50	8.90	11.20	19.70	16.50	18.90	23.40	20.45	22.20	26.80	15.00

carbon, tar, and gaseous products (Table 1). However, at 800 and 900°C the decomposition rate in this period is high: The yield of pyrocarbon increases by 15.6 and 31.5 wt %, and that of the tar decreases by 18.0 and 36.1 wt %, respectively. Thus, at higher temperatures the thermal degradation of asphaltenes is intensified.

As the pyrolysis conditions are made more rigorous, the yield of products varies differently. For example, in the period between 1.5 and 3.0 s additional amounts of pyrocarbon are formed (12.7, 21.0, and 22.0 wt % at 750, 800, and 900°C, respectively), and the yield of the tars sharply decreases. In the subsequent 3 s (between 3.0 and 6.0 s) at 750 and 800°C pyrolysis decelerates, which may be due to intermediate formation of thermally stable highly aromatized polycyclic products. The high yield of pyrocarbon suggests predominant occurrence of condensation in the course of asphaltene pyrolysis; it also suggests that asphaltenes are not responsible for formation of liquid products.

The course of asphaltene pyrolysis with several extrema reflects the features of their chemical composition. Subject to degradation is a complex mixture of compounds differing in the thermal stability, with the stability increasing as the degrees of aromaticity and condensation increase. The least stable structures decompose first, after which the degradation rate decreases. Then, as the heat is supplied, other structures of asphaltenes start to degrade. At a sufficiently long reaction time, pyrolysis can occur in steps, as the products of thermochemical transformations of the initial asphaltenes, exhibiting higher aromaticity and higher thermal stability, undergo further degradation but under more rigorous conditions; as a result, a new maximum appears in formation of pyrocarbon and a minimum, in formation of liquid products. It should be noted that in almost all cases the increase in the yield of pyrocarbon is accompanied by a decrease in the yield of the liquid products, with no appreciable changes in the yield of the gaseous products.

The results of chemical group analysis of liquid products show that, as the conditions of asphaltene pyrolysis are made more rigorous, the content of organic bases, hydrocarbons, and neutral oxygen compounds in the tars grows, whereas the content of phenols decreases. The yield of secondary asphaltenes changes significantly; in the first 0.5 s of pyrolysis these compounds rapidly decompose, which is followed by their accumulation as compared to the other groups of compounds. The yield of secondary asphaltenes correlates with formation of pyrocarbon, which is fully consistent with the concept [4, 5] that pyrocarbon is formed via asphaltenes.

The content of organic bases in liquid products at the pyrolysis time of 3.0 s increases from 3.83 wt % at 750°C to 5.62 wt % at 800°C but then decreases to 3.27 wt % at 900°C. The organic bases are formed most actively in the first 0.5 s; their yield at 750, 800, and 900°C is 2.37, 3.20, and 3.00 wt %, respectively.

The influence of pyrolysis time is different at different temperatures. For example, the yield of organic bases in the first 3.0 s is 3.83 and 5.62 wt % at 750 and 800°C, respectively, whereas in the period from 3.0 to 6.0 s their amount increases by 4.0 (750°C) and 0.33 wt % (800°C) (Table 1).

The highest yield of phenols is observed in the first 0.5 s at 800°C. As the pyrolysis conditions are made more rigorous, the yield of phenols decreases, which may be due to prevalence of degradation and condensation of phenols over their formation in thermal degradation of asphaltenes [6–9].

The amount of hydrocarbons in liquid pyrolysis products of asphaltenes increases with time and especially with temperature. For example, as the temperature is increased from 800 to 900°C at a time of 3.0 s, the content of hydrocarbons increases by 6.15 wt %, and as the time is increased from 3.0 to 6.0 s at a temperature of 800°C, their content increases by 2.25 wt %. Similar to organic bases and phenols, accumulation of hydrocarbons is the most significant in the first 0.5 s: 6.37, 9.80, and 12.20 wt % at 750, 800, and 900°C, respectively. The low content of hydrocarbons in liquid pyrolysis products suggests that asphaltenes are not the major source of hydrocarbons in high-temperature tars formed by cracking of vapor–gas products in coke ovens (Table 1).

The content of neutral oxygen compounds considerably exceeds that of phenols (Table 1). For example, at 800°C (6.0 s) the content of phenols is 0.52 wt %, and that of neutral oxygen compounds, 5.15 wt %. Whereas the yield of phenols drastically decreases as the pyrolysis conditions are made more rigorous, the content of neutral oxygen compounds grows. This may be due to features of oxygen incorporation in the initial asphaltene structures, with the thermally stable furan heterocycles prevailing, and to condensation of phenols with formation of furan rings between aromatic rings.

The results of capillary gas–liquid chromatographic analysis of organic bases, phenols, and hydrocarbons isolated from liquid products of asphaltene pyrolysis are listed in Table 2.

It is seen that in the course of pyrolysis the compositions of the considered groups of compounds change significantly. Among organic bases, the content of quinoline, methylquinolines, and quinaldine appreciably increases. For example, at 800°C the yields of quinoline and quinaldine are 0.48 and 0.21 wt % in the first 0.5 s, increasing to 8.52 and 2.68 wt %, respectively, in 3.0 s.

Table 2 shows that under any pyrolysis conditions except 750°C/0.5 s the content of phenol and isomeric cresols among phenols is higher than that of xylenols. This can be readily explained by the higher thermal stability of the former compounds and by hydrodealkylation of the intermediate xylenols and polyalkylphenols. At 750°C and 0.5 s, the phenolic fraction contains 2.29 wt % phenol, 5.84 wt % cresols, and 13.81 wt % xylenols. As the reaction time is increased from 0.5 to 3.0 s, the content of phenol and cresols appreciably grows, with simultaneous decrease in the content of xylenols. Further increase in the pyrolysis time from 3.0 to 6.0 s (at 750°C) favors accumulation in the liquid products of phenol, *m*-cresol, 3,5-xylenol, and also higher-molecular-weight components: naphthols, anthrols, phenanthrols, pyrenols, and chrysenols. The yield of phenol is maximal in 3.0 s at 800°C and in 0.5 s at 900°C.

The phenolic fractions of pyrolysis tars at 800 and 900°C are enriched in phenol, *m*-cresol, and 2,4- and 3,5-xylenols, but the total content of low-boiling products tends to decrease as the pyrolysis conditions are made more rigorous.

Table 2 shows that, as the pyrolysis of asphaltenes is intensified, the hydrocarbon fraction becomes richer in naphthalene, its methyl and dimethyl homologs, and polycyclic aromatics: fluorene, phenanthrene, fluoranthene, pyrene, and chrysene. The content of polycyclic aromatics increases especially significantly at 900°C. As the reaction time is increased from 3.0 to 6.0 s, the developing dealkylation reactions decrease the content of alkylnaphthalenes.

The yield of naphthalene as the major component of high-temperature tars strongly depends on the pyrolysis temperature. For example, at 750, 800, and 900°C the yield of naphthalene in 1.5 s is 8.75, 12.30, and 27.10 wt %, respectively. As the residence time of asphaltene vapor in the heated zone (750°C) is increased from 0.5 to 6.0 s, the content of naphthalene increases from 4.92 to 30.20 wt %. It should be noted that the influence of reaction time on formation of naphthalenes is different depending on temperature. For example, whereas at 750°C the yield of naphthalene is higher at longer reaction times, with increasing time to 6.0 s at 800°C and to 3.0 s at 900°C the yield of naphthalene drastically decreases, with simultaneous increase in the yields of phenanthrene, anthracene, pyrene, chrysene, and other highly condensed aromatic hydrocarbons [10]. For example, at 750, 800, and 900°C the yield of phenanthrene is, respectively, 1.35, 2.20, and 3.10 wt % in 0.5 s and 4.20, 6.70, and 11.60 wt % in 3.0 s. The respective yields of chrysene are 0.19, 0.60, and 1.07 wt % in 0.5 s and 0.94, 1.94, and 1.07 wt % in 3.0 s (Table 2). This fact suggests that, as the temperature and time of pyrolysis are increased, condensations of low-molecular-weight hy-

drocarbons are intensified, yielding polycyclic aromatic hydrocarbons with prevalence of angular structures (phenanthrene, pyrene, chrysene).

The total content of hydrocarbons lower-boiling than chrysene in 0.5 s at 750, 800, and 900°C is 12.78, 19.33, and 30.50 wt %. In the subsequent 2.5 s at these temperatures their content increases, respectively, to 34.64, 44.62, and 48.82 wt %. With the pyrolysis time of asphaltenes increasing further, the content of these hydrocarbons decreases (Table 2).

The high content in tars of naphthalene, phenanthrene, anthracene, pyrene, fluoranthene, and chrysene and the low content of methyl- and dimethylnaphthalenes apparently reflects the structural features of the initial coal asphaltenes.

CONCLUSION

Study of high-temperature pyrolysis of asphaltenes of G6 coal semicoking tar showed that asphaltenes show a strong tendency to condensation with formation of large amounts of pyrocarbon and are not responsible for the yield of liquid products which are enriched in secondary asphaltenes and hydrocarbons.

Synthesis of Garnets by Coprecipitation from Aqueous Solutions

T. N. Bokovikova and M. V. Dvadnenko

Kuban State Technical University, Krasnodar, Russia

Received July 13, 2000; in final form, March 2001

Abstract—Conditions for the coprecipitation of hydroxides of aluminum and rare-earth elements from the $Al(NO_3)_3$–$Ln(NO_3)_3$–NH_4OH–H_2O system (Ln = La, Sm) by $NH_3 \cdot H_2O$ solutions at 25°C were studied. The resulting precipitates were investigated by thermal analysis, IR spectroscopy, and X-ray phase analysis.

A wide application of aluminum garnets of rare-earth elements (REE) to quantum electronics promoted the synthesis and study of garnet-structure compounds. Yttrium aluminum garnet, which is one of the best solid-state laser materials, has been the most studied.

The garnet-structure compounds can be obtained by solid-phase synthesis from a mixture of oxides and also by coprecipitation of hydroxides from salt solutions. One of the shortcomings of the solid-phase synthesis is high temperature (higher than 1600°C). The coprecipitation technique makes it possible to obtain compounds with required structures as well crystallized and finely dispersed products even at 1000–1200°C. The data on this technique are contradictory and few in number [1], thus its application to the synthesis of REE aluminum garnets requires its further more extended study.

The aim of this work was to study the dehydration and interaction of hydroxides of aluminum and lanthanides, coprecipitated from aqueous solutions of their salts by an ammonia aqueous solution, and to demonstrate a possibility of obtaining lanthanum and samarium garnets by calcination of coprecipitated hydroxides at 965–1050°C. The experimental methods in use were differential thermal analysis (DTA), IR spectroscopy, and X-ray analysis.

EXPERIMENTAL

The hydroxides were precipitated from the $Al(NO_3)_3$–$Ln(NO_3)_3$–NH_4OH–H_2O system by a 4% solution of $NH_3 \cdot H_2O$ with permanent stirring of the suspension. The concentrations of aluminum and rare-earth nitrates were kept constant (1.66 and 1.00 N, respectively), and pH was maintained at 9.5–10. The thermal analysis of precipitates was carried out on a D derivatograph at a heating rate of 10 deg min^{-1}. The IR spectra were recorded on a Specord 75-IR spectrometer in the range 400–4000 cm^{-1} at room temperature from Nujol mulls. Phase compositions was analyzed on a DRON-1 diffractometer (FeK_α radiation).

As the $NH_3 \cdot H_2O$ content in the starting mixtures increased, the following reaction stages occurred sequentially: the formation of poorly filterable colloidal precipitates, quantitative precipitation of aluminum and REE hydroxides with an impurity of basic salts, and, finally, the coprecipitation of aluminum and REE hydroxides. The resulting precipitates were washed with distilled water until nitrate ions disappeared and dried at 25°C for 12 h [2].

A number of endo- and exothermic effects were observed upon heating (Fig. 1). The endothermic ef-

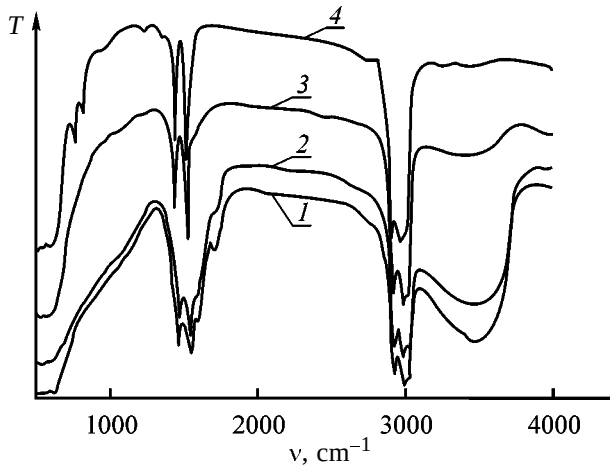

Fig. 2. IR absorption spectra of (*1*) aluminum and REE hydroxides coprecipitated at 25°C and (*2–4*) products of their thermolysis: (*T*) transmission and (ν) wave number. Heating temperature (°C): (*2*) 250, (*3*) 500, and (*4*) 1100.

fects in the range 90–400°C correspond to the removal of adsorbed and structural water, which was proved by the IR spectra.

The IR spectra of coprecipitated hydroxides dried at 25 and 90°C are essentially similar (Fig. 2). Broad bands in the range 3100–3800 cm^{-1} corresponding to the OH stretching vibrations are observed in the both spectra, a wide range of absorption frequencies being typical for bridging OH groups coordinated by metal atoms [3]. Additional bands at 3000–2800 and 1460–1380 cm^{-1} originate from Nujol. A broad strong band caused by the vibrations of –O–M–O– groups in the range 400–850 cm^{-1} is present in the IR spectra of all the precipitates [3]. Thus, all the precipitates have a polymeric structure.

Figure 2 shows that appreciable changes occur in the solid phase in the range 250–1000°C. At 250°C structural water is partially removed (the band of H_2O stretching vibrations decreases) and OH groups are partially lost (a sharp decrease in the intensity of the band in the range 1600 cm^{-1}. Correspondingly, the intensity of the bands of –O–M–O– groups increases, as compared with the IR spectra of the solid phase obtained at 25–90°C. Structural water is almost completely removed at 500°C (Fig. 2), since the bending band at 1630 cm^{-1} practically disappears and the weak band of vibrations of hydroxide groups at 1500 cm^{-1} remains. After heating the precipitates at 1000–1100°C, two bands at 620 and 680 cm^{-1} typical for $Ln_3Al_5O_{12}$ (Ln = La, Sm) garnets are observed in the IR spectrum (Fig. 2), which correspond to the Ln–O stretching vibrations in a tetrahedron [3]. According to X-ray diffraction data, the samples calcined at 950–1050°C have the garnet structure and are free of other phases.

The spectral data agree with the DTA data. For example, the DTA curves contain two exothermic peaks at 1020 and 965°C corresponding to the crystallization and reaction of, respectively, Sm_2O_3 and La_2O_3 with Al_2O_3 [4].

CONCLUSION

Polymeric hydroxo compounds were coprecipitated from solutions of salts of aluminum and rare-earth elements. Their thermal analysis was carried out, and their IR spectra were studied. The calcination at 1050°C of the coprecipitated aluminum and REE hydroxides (5 : 3) results in the crystallization of garnet-structure compounds.

Simulation of Kinetics of Stabilizer Migration from Polyolefins to Air and Water

A. V. Dedov and V. G. Nazarov

Military Academy of Radiation, Chemical, and Biological Defense, Moscow, Russia

Received April 6, 1999; in final form, July 2000

Abstract—The applicability of the model for prediction of the kinetics of stabilizer migration from polyolefins to air and water was analyzed.

Simulation of the kinetics of stabilizer migration from polyolefins is the urgent problem caused by the dependence of polymer properties on THE initial composition [1] and by toxicity of many ingredients [2].

Analysis revealed that the model [1] developed further in [3–6] is advantageous for calculation of the migration kinetics of various low-molecular-weight ingredients [3–6]. The rate of stabilizer migration from polyolefins to air and water is mainly controlled by diffusion of the ingredients in the polymer [4, 7]. The calculation equation in this case has the form

$$\tau_i = a_i l^2/D, \quad (1)$$

where τ_i is the migration time of a given amount of stabilizer, l is the parameter relating the conditions of contact of a material with environment to its thickness t ($l = d/2$ for a two-side contact and $l = d$ for a one-side contact), D is the coefficient of stabilizer diffusion in polymer, and a_i is the coefficient calculated from Eq. (1).

$$\frac{M_i}{M_0} = 1 - \sum \frac{2L^2 \exp(-\beta_n^2 T)}{\beta_n^2(\beta_n^2 + L^2 + L)}, \quad (2)$$

M_τ is the amount of the ingredient migrating from the polymer in time τ, M_0 is the initial content of the ingredient in the polymer, L is dimensionless parameter reflecting the ratio of the fluxes of the ingredients in the bulk of a polymer and from its surface as influenced by the aggregate state of the environment, and β is the positive root of the equation $\beta_n \tan\beta_n = L$; $T = D\tau/l^2$.

The solution of Eq. (2) at an M_τ/M_0 ratio from 0 to 1 is obtained in the form of the dependence $\log L = f(\log T)$. The dependence has three regions, one of which describes the kinetics of ingredient migration from polymers in the diffusion-controlled stage [1]. The region itself is described by the equation $\log T = A_i$. The A_i value is determined by the given ratio M_τ/M_0. The solution of the equation $\log T = A_i$ leads to expression (1) and allows determination of the numerical value of a_i in this equation.

The values of the other variables in Eq. (2), as well as the possible methods of its solution, are presented in [1, 5]. Note that the a_i coefficient, which only implicitly enters Eq. (2), is determined by the M_τ/M_0 ratio specified in solving this equation.

The goal of the work is to analyze the applicability of the model [1] for prediction of the kinetics of stabilizer desorption from polyolefins to air and water.

The model [1] was used for prediction of the migration kinetics of stabilizers based on benzophenone derivatives [4] from isotactic polypropylene to air at 25°C and of various polyethylene stabilizers from polyethylenes of different brands to water at 25°C and within 45–70°C [7]. The D values were taken from tables or derived from their dependences on the molecular weight in the homologous series of the ingredients [8]. The compositions of polymer materials and the migration conditions essentially differed from those accepted in development of model [1] and analyzed in [4–6]. The model was corrected at the expense of the a_i coefficient after comparing the calculated and experimental data for the kinetics of stabilizer migration (table).

The table shows that the correctness of the calculation increases in passing to contact with water instead of air and this increase is even more pronounced at increased water temperature.

1070-4272/01/7405-0892$25.00

The necessity for increasing the migration rate, especially significant in the initial stage, arises from the nonuniform distribution of the ingredient in the bulk of real polymeric materials.

Introduction of stabilizers into polyolefins results in their preferable distribution in the amorphous regions [8]. The stabilizer amounts used in this work are far above their equilibrium solubility in polyolefins [2, 3]. As a result, the stabilizer concentrates on the polymer surface and within its surface layer.

Apparently, owing to accumulation of the stabilizer on the polymer surface, the migration rate in the initial stage is controlled by the flux of the ingredient to environment, which exceeds the mass transfer in its bulk. As the stabilizer is removed from the surface of a polymer and its surface layer, the migration process becomes controlled by flux in the bulk of a polymer. In this stage, the time of which is determined by the phase state and nature of the environment in contact, calculated and experimental data on the migration kinetics are in good agreement (see table).

The proposed mechanism of the ingredient migration is characteristic of contact between polymer and air, when the flux from the surface of a material is limited by the stabilizer volatility. Owing to the low vapor pressure of stabilizers [8], the removal of ingredients from the polymer surface is extended in time compared to the case of contact between polymer and water. At higher water temperatures the model even better predicts real migration process, which is reflected in the value of the correctional coefficient a_i. The necessity for correcting a_i over the entire migration time at 25°C arises from elimination of the another assumption accepted in development of model [1], namely, that ingredients are removed from the polymer surface into the environment immediately. This assumption is fulfilled to a higher degree at higher water temperatures.

The complex mechanism of the stabilizer migration in the case of contact between polymer and air necessitates correction of L used to determine the limiting stage of the process [1, 4–6]. The L values are derived from the equation

$$L = IV/(SD), \quad (3)$$

where V is the stabilizer volatility and S, the equilibrium solubility of the ingredient in the polymer.

At $L > 10$ the limiting stage of the migration of ingredients from a polymer is controlled by their flux in the bulk of a material, and Eq. (1) is used for calculating the process kinetics. At $L < 0.6$ migration is limited by the flux from the polymer surface to the environment in contact, and another equation is used for calculating the kinetics [1]. For $10 > L > 0.6$ no equations exists for calculating the kinetics of the ingredient migration.

Calculated and corrected values of the coefficient a_i

M_τ/M_0	a_i^{cal}	a_i^{cor} for migration at indicated temperature, °C		
		25, air	25, H_2O	45–70, H_2O
0.1	0.004	0.12	0.006	0.005
0.2	0.015	0.15	0.023	0.020
0.3	0.038	0.38	0.055	0.045
0.4	0.063	0.42	0.10	0.070
0.5	0.15	0.63	0.24	0.16
0.6	0.30	0.70	0.45	+
0.7	0.80	+	1.2	+
0.8	0.95	+	1.5	+
0.9	1.2	+	1.8	+

Note: The plus sign denotes cases when the experimental and calculated data coincide and no correction coefficient a_i is required.

The analysis of Eq. (3) shows that the complexity of the determination of the limiting stage of migration is due to the fact that in calculation of L the real distribution of ingredient in the bulk of a polymer is not taken into account under equal other conditions.

CONCLUSIONS

(1) The model considered predicts correctly the migration of ingredients in the case of contact between the polymer and water at temperatures from 45 to 70°C. In the case of contact between polyolefins and air it is reasonable to apply the model to prediction of the migration kinetics in the final stages (at $M_\tau/M_0 > 0.7$).

(2) Under equal other conditions, the accuracy of the model is determined by the stabilizer concentration and by the rate of its transfer from the surface to the environment in contact.

Barbiturates of Aromatic Hydroxy Aldehydes as Components of Inhibiting Systems for Thermal Polymerization of Styrene

A. F. Gogotov, M. V. Parilova, and A. K. Khaliullin

Angarsk Petrochemical Company, Joint-Stock Company, Angarsk, Irkutsk oblast, Russia
Institute of Chemistry, Siberian Division, Russian Academy of Sciences, Irkutsk, Russia

Received January 16, 2001

Abstract—Products of condensation of aromatic hydroxy aldehydes with barbituric acid were tested as coinhibitors in inhibiting systems for thermal polymerization of styrene, based on *p*-quinone dioxime.

Modern production of styrene is impossible without using inhibitors [1]. In practice, the majority of Russian plants use as the main inhibitor in distillation of styrene *p*-quinone dioxime (QDO) which is the most effective [2]. However, QDO is insoluble in hydrocarbons and should therefore be used as a fine suspension. As a result, QDO is often deposited in pipelines and dead zones of the process equipment. Attempts were made to use both a soluble derivative of QDO [3] and cosolvents for QDO (e.g., dimethyl sulfoxide [4]). One of the main ways to improve the inhibition is search for QDO-based systems that would be more effective than straight QDO or development of formulations with a decreased consumption of QDO. For example, an inhibiting system consisting of QDO and *p*-nitrophenol (PNP) is widely used in production [5]. Recently an inhibiting system coinsisting of a *p*-phenylenediamine derivative and eugenol (4-allylguaiacol) was suggested for distillation of ethylene compounds [6]. Experiments showed that an effective alternative to this inhibitor system can be a mixture of QDO with barbiturates of aromatic hydroxy aldehydes: *p*-hydroxybenzaldehyde, vanillin [7], or syringaldehyde. The synthesis procedure and properties of vanillin barbiturate (VB) are described elsewhere [8, 9].

The inhibiting power of the known and newly suggested systems was evaluated by determining the yield of polymerized styrene at heating of the monomer at 120°C for 2–7 h with sampling every hour and distillation of the unchanged monomer on a boiling water bath at a residual pressure of 20 mm Hg.

The table shows that addition of PNP as coinhibitor somewhat decreases formation of the polymer on heating of styrene (run nos. 1, 2, 3–5), with addition of the coinhibitor 2 h after the start of the process being more efficient than its addition simultaneously with the main inhibitor. At a lower amount of the inhibitor the yield of the polymer somewhat increases (run nos. 1–4). The use of eugenol (suggested in [6]) instead of PNP, with the same amount of QDO (run nos. 5, 6) decreases formation of the polymer by an order of magnitude, demonstrating the advantages of methoxylated phenols. Replacement of eugenol, which is in a short supply, by more readily available vanillin (run no. 7) shows that vanillin as coinhibitor is somewhat inferior to eugenol but is considerably more effective than PNP. With vanillin barbiturate, which is prepared by condensation of vanillin with a known methylene-active compound, barbituric acid, at the same amount of the coinhibitor with respect to methoxyphenol (run no. 8), we attained almost the same inhibiting effect as with QDO + eugenol. Experiments with various orders of adding the coinhibitor (run nos. 8–11) showed that addition of VB 2 h after the start of the process is the best. Among derivatives of isomeric vanillins (*o*-, *m*-, and *p*-, run nos. 8, 12, 13), the derivative of the most abundant *p*-vanillin showed the highest performance. Experiments with varied amount of the VB added (run nos. 8, 14, 15) showed that the greatest inhibiting effect is attained at an inhibitor content of 0.017 wt % based on styrene. A blank experiment (run no. 16) showed that, when taken separately (without QDO), VB is not effective as inhibitor. The thio derivative, vanillin thiobarbiturate (VTB, run no. 17), shows poor performance under equal other conditions, which is consistent wiht the known fact that thiobarbituric acid initiates polymerization of styrene [10]. Comparison of the performances of barbiturates of vanillin homologs (nonmethoxylated *p*-hydroxybenzaldehyde, run no. 18; vanillin,

run no. 8; dimethoxy derivative, syringaldehyde, run no. 19) showed that methoxylation of the aromatic ring enhances the inhibiting power of the coinhibitor. The mechanism of interaction of barbiturates of aromatic hydroxybenzaldehydes with QDO responsible for prolongation of the inhibiting power of the main inhibitor apparently coincides with the previously described [11] mechanism of interaction of QDO with sterically hindered phenols.

Thus, we have found a new class of coinhibitors of quinone dioxime effective in inhibition of thermal polymerization of styrene and studied the inhibiting properties of barbiturates of hydroxybenzaldehydes.

Sorption Immobilization of Glucoamylase on Nonionic Sorbent Styrosorb

I. V. Shkutina, O. F. Stoyanova, and V. F. Selemenev

Voronezh State University, Voronezh, Russia

Received January 30, 2001

Abstract—Glucoamylase was immobilized on super-cross-linked nonionic sorbent Styrosorb by the sorption procedure. The features of native and immobilized glucoamylase are compared.

Glucoamylase catalyzes hydrolytic cleavage of starch. This enzymatic reaction is widely used in alcohol industry and in glucose production. Immobilized enzymes are characterized by several advantages as compared to native enzymes: possibility of repeated and continuous use, stability to denaturing agents, and simplicity of preparation of high-purity product [1].

In this work was studied the possibility of sorption immobilization of glucoamylase on super-cross-linked nonionic sorbent Styrosorb used as the efficient sorbent of large biomolecules [2–4].

EXPERIMENTAL

In our experiments we used the enzymic preparation of glucoamylase precipitated with ethanol from an extract of the surface culture *Aspergillus awamori*. Two samples of Styrosorb (Styrosorb-1 with a specific surface area of 440 $m^2 g^{-1}$ and Styrosorb-2 with a specific surface area of 260 $m^2 g^{-1}$) were used as the supports. These sorbents containing no ion-exchange groups were prepared from super-cross-linked polystyrene. Their structure contains certain amount of hydrophobic pockets capable of binding large organic molecules [5]. Glucoamylase was immobilized by sorption from its solution in a 0.1 M acetate buffer under static conditions at 18–20°C for 24 h. The enzyme amount associated with the support was determined as the difference between the protein amount in the solution before and after sorption. The concentration of immobilized protein was expressed as mg of protein per 1 g of the support. The protein concentration in solution was determined by the Lowry method [6], and the glucoamylase activity, by the glucoseoxidase method [7]. The enzyme amount producing 1 μmol of glucose per minute in catalytic hydrolysis of starch at 30°C was accepted as the unit of the enzyme activity.

Glucoamylase molecule consists of the amino acid units which, depending on pH, form various ionic species. Therefore, the hydrogen ion concentration in the enzyme solution can significantly affect the enzyme sorption. We found that the maximal amount of the protein is sorbed at pH 4.7–5.0, i.e., at the isoelectric point of glucoamylase in the solution (Fig. 1).

Figure 2 shows that the curves of glucoamylase sorption on Styrosorb-1 and Styrosorb-2 within the pH range of the maximal sorption rate differ in shape. In passing from Styrosorb-2 to Styrosorb-1 having a larger specific surface area the sorption curve becomes S-shaped, indicating the change in the sorption mechanism. In the first stage of sorption the monomolecular layer of glucoamylase is formed owing to the sorbent–sorbate interactions. Further sorption of enzyme occurs by the mechanism of the sorbate–sorbate interactions. Due to intermolecular association of the enzyme molecules, a polymolecular layers on the sor-

bent surface are formed. Completion of the monolyer formation is manifested as the inflection point in the sorption curve. Thus, the first sorption layer is formed owing to interactions of hydrophobic fragments of glucoamylase molecule with hydrophobic walls of the sorbent pores. It is known [8] that glucoamylase molecule contains numerous amino acid units with alkyl side chains (Ala, Val, Met, Ile) playing the important role in protein stabilization. Styrosorb contains also several amount of unpolymerized carbonyl and chloromethyl groups capable of forming hydrogen bonds between the enzyme and support. After completion of formation of the monomolecular enzyme layer the sorbent modified by enzyme molecules is formed. Further sorption of the enzyme occurs by the mechanism of interaction between hydrophilic and hydrophobic parts of glucoamylase molecules. The shape of the curve of glucoamylase sorption on Styrosorb-2 is typical for the monolayer sorption.

Our assumption about the mechanism of glucoamylase interaction with Styrosorb was confirmed by gravimetric monitoring of water content within the sorbent (Fig. 3). Removal of the water from the sorbent increases the amount of sorption sites. Figure 3 shows that at small degree of the sorbent exhaustion the water content in the sorbent decreases more sharply than in the range of prevalence of the enzyme–enzyme interactions. It is possible that these processes occur by the mechanism of the interfacial lubrication suggested in [2].

In further experiments we studied several features of the biocatalyst prepared by us. It is known that pH of a substrate significantly affects the enzymic activity since variation of the hydrogen ion content changes the conformational state of protein and, therefore, can affect both the local and the general structure of polypeptide chains. To find the optimal conditions for the enzyme functioning, the activity of both the native and immobilized glucoamylase was studied as influenced by pH of a substarte (Fig. 4). These studies showed that the immobilized and native enzymes exhibit the maximal activity within pH ranges 4.7–6.2 and 4.7–5.0, respectively. Thus, immobilized glucoamylase is characterized by the more extended range of high activity.

One of the main consequences of enzyme immobilization is increase in their stability to the denaturing effect of medium and, as a result, manifold increase in performance of enzymic transformation of a substrate. Figure 5 shows the temperature dependence of the enzimic activity of glucoamylase in incubation for 1 h. It was found that the immobilized glucoamylase

exhibits higher thermal stability than its native form. For example, on heating at 70°C for 20 min native glucoamylase is completely inactivated. At the same time, under the similar conditions the immobilized enzymes do not loss enzymic activity for 2 h. The immobilized enzyme acquires more rigid conformation providing higher stability to changes and inactivation.

CONCLUSIONS

(1) Styrosorb with a specific surface area of 440 $m^2 g^{-1}$ exhibits the highest sorption capacity for glucoamylase.

(2) Immoblized glucoamylase, as compared to the native enzyme, is characterized by the more extended pH range of the highest enzymic activity and enhanced thermal stability.

(3) Styrosorb is a suitable support for immobilization of glucoamylase.

BOOK REVIEWS

Denisov, V.M., Belousova, N.V., Moiseev, G.K., Bakhvalov, S.G., Istomin, S.A., and Pastukhov, E.A., *Vismutsoderzhashchie materialy: stroenie i fiziko-khimicheskie svoistva* (Bismuth-Containing Materials: Structure and Physicochemical Properties), Yekaterinburg: Ural'sk. Otd. Ross. Akad. Nauk, 2000

This original monograph analyzing and generalizing experimental data on the structure and properties of metallic and oxide bismuth-containing materials in liquid and crystalline states has been published by the initiative of the Institute of Metallurgy, Ural Division, Russian Academy of Sciences, with participation of a number of leading staff members of the institute. The book gives much attention to the structure and properties of liquid bismuth alloys and also considers bismuth-containing oxide systems.

The monograph comprises an introduction and six chapters. The comprehensive and informative bibliography of the book gives references to 769 works.

The brief introduction (pp. 3–6) substantiates the expediency and utility of generalizing the information about the structure and physicochemical properties of bismuth-containing materials and indicates fields of their application.

The first chapter (pp. 7–78) considers the structure of bismuth-based melts. In fact, investigations of liquid metallic bismuth alloys by means of diffraction experiments are dealt with in the chapter and the results obtained are interpreted. Atomic radial distribution functions, structural factors, and the relationship between the structural features of melts and their physicochemical properties are analyzed.

The second chapter (pp. 79–177) describes the thermodynamic properties of bismuth alloys. The analysis is made rather thoroughly with sufficiently complete coverage of the relevant literature, with emphasis placed on works of Russian authors. Some publications in foreign journals remained unnoticed by the authors, which is not surprising in view of the extent to which libraries are presently provided with foreign publications.

The third chapter (pp. 178–228) discusses the surface and bulk properties of liquid bismuth alloys. Theoretical questions arising in calculating and analytically expressing the surface tension isotherms of binary alloys are considered and ample body of reference data for both metallic and oxide systems is provided. Wetting phenomena are discussed.

The spacious fourth chapter (pp. 251–381) is mainly concerned with the electrical properties (electrical conductivity, charge transport, thermoelectric power, electron work function) of bismuth-containing systems. Also given are data on the speed of sound, viscosity, and diffusion.

The fifth chapter (pp. 381–416) is concerned with oxidation of bismuth-based liquid alloys.

The final, sixth chapter (pp. 417–483) makes a thermodynamic analysis of the bismuth–oxygen system and considers bismuth oxides and their thermochemical characteristics. The systems $SrO–Bi_2O_3$ and $CuO–Bi_2O_3$ are discussed.

In assessing the monograph as a whole, mention should be made of the high value of the work done by the authors in systematization of published data on the physicochemical properties of metallic and oxide bismuth-containing systems. However, no impression is created that the joint consideration of such dissimilar objects as metallic and oxide systems offers some advantages. It seems that, if the monograph were divided, with its total volume preserved, into two parts concerned separately with metallic and oxide systems, the book would be simpler in use and more logically consistent. In the first five chapters, the data on oxide systems "dissolve" in a vaster information concerning metallic systems. And only the sixth chapter, dealing exclusively with oxides and oxide systems, occupies a particular position.

The book is of interest to a wide audience of specialists in inorganic materials science and can serve as reference for masters and post-graduate students specialized in chemical technology and metallurgy.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of Evaporation in the TiO_2–Nb_2O_5 Oxide System by High-Temperature Mass-Spectrometry

G. A. Semenov and S. I. Lopatin

Research Institute of Chemistry, St. Petersburg State University, St. Petersburg, Russia

Received July 5, 2000; in final form, November 2000

Abstract—High-temperature mass-spectrometry was applied to study the vapor phase composition and dynamics of its variation in evaporation of oxide materials of the system TiO_2–Nb_2O_5. The incongruent nature of evaporation processes is established.

Thin films based on titanium and niobium oxides have rather long been used as optical interference coatings [1]. The main technique used to deposit such coatings is vacuum evaporation of an oxide material of appropriate composition with subsequent oxidizing annealing of the obtained film. However, the actual molecular composition of the vapor phase and the dynamics of its variation in the course of evaporation have not been studied until recently. In the only study concerned with this subject [2], an attempt was made to prognosticate theoretically the vapor composition over a hypothetical two-phase mixture of titanium and niobium oxides with account of dissociative evaporation. Having assumed that the oxygen pressure over the system is determined by the dissociation pressure of Nb_2O_5, the authors calculated for T = 2200 K the following partial pressures of the components (mm Hg): $p(O_2) = 3.45 \times 10^{-2}$, $p(NbO_2) = 1.66 \times 10^{-1}$, $p(TiO_2) = 4.8 \times 10^{-3}$. According to their estimate, the NbO and TiO vapor pressure must be no less than three orders of magnitude lower than the vapor pressures of the corresponding dioxides.

The phase diagram of the system TiO_2–Nb_2O_5 has been studied repeatedly [3–6]. Existence of at least two congruently melting compounds with Nb_2O_5 : TiO_2 ratios of 5 : 2 and 1 : 1 has been reliably established. At T > 2100 K all the compositions of the system will be molten. A mass-spectrometric study of the vapor phase composition over titanium and niobium oxides demonstrated that only $NbO_{2.00}$ and $TiO_{0.67}$ (Ti_3O_5) are congruently sublimating [7]. When heated in a vacuum, the compounds Nb_2O_5 and TiO_2 dissociate, even before the onset of evaporation, into NbO_{2+x} and TiO_{2-y} (with $x \approx 0.1$ and $y \approx 0.13$). The presence of NbO_2, NbO, TiO_2, TiO, and oxygen molecules in the vapor phase over individual oxides was established. The relative content of these molecular species varies, depending on temperature and evaporation time, as the condensed phase compositions approach the above-mentioned congruently melting compositions. Solutions with isomorphic substitution are formed in the oxide system NbO_2–TiO_2 [8, 9]. It has also been noted that the formal oxidation state partly increases from +4 to +5 upon calcination of compacted mixtures of dioxides at 1400°C in a neutral atmosphere [10]. All the aforesaid suggests that, because of the thermal dissociation in a vacuum, the evaporation of systems based on TiO_2 and Nb_2O_5 oxides will become incongruent with the composition of the condensed phase approaching NbO_{2+x}–TiO_{2-y}, in which the indices will depend on temperature and oxygen pressure over the system.

The aim of this study was to confirm experimentally the above assumptions by analyzing how the molecular composition of the vapor changes in the course of evaporation of samples with varied initial relative content of titanium and niobium oxides.

EXPERIMENTAL

High-temperature thermodynamic studies were performed using an MS-1301 mass spectrometer [11]. Samples (mixtures of TiO_2 and Nb_2O_5 containing 10, 40, 50, 67, 75, and 90 mol % TiO_2, calcined in air) were evaporated from electron beam–heated twin molybdenum effusion chambers [12]; the chamber temperature was measured with an EOP-66 optical pyrometer. The pyrometer readings were periodically corrected for radiation absorption by the glass win-

dow, using an SI-10-300 temperature lamp. To calibrate the apparatus, the vapor pressure of gold was measured by the method of complete thermal evaporation of a sample [11, 13]. The obtained data were, on the average, different from published data [14] by no more than ±15%, which corresponds to a temperature measurement error of ±8 K at 1580 K. The ions in the mass spectrum were identified by their mass number, isotope composition, and appearance energy (AE) measured by the method of disappearance of the ion current. The energy scale of ionizing electrons was calibrated with $AE(Au^+)$ = 9.226 eV [15]. The partial pressures of vapor components were measured by differential mass spectrometry [11, 13], with the sample and pressure standard placed in separate compartments of the twin effusion chamber. The measured ion currents are related to the partial pressures of a substance under study (i) and the standard (s) by

$$p_i = a\,\frac{p_s I_i T_i \sigma_s \gamma_s}{I_s T_s \sigma_i \gamma_i}, \qquad (1)$$

where p is the partial pressure, I the ion current intensity, T temperature (K), σ the effective cross-section of electron-impact ionization, and γ the sensitivity coefficient of the secondary-electron multiplier.

The factor a (conductivity ratio of effusion apertures) can be determined experimentally by evaporating the standard substance from both compartments of the effusion chamber simultaneously. Implicitly, the factor a also accounts for the possible temperature gradient between separate parts of the effusion unit. The identical conditions of evaporation from both the compartments are achieved by carefully machining the effusion apertures and selecting the diameter and position of the annular cathodes of the evaporator.

As pressure standard [p_s in formula (1)] can, in principle, serve any suitable simple substance or chemical compound with vapor pressure measured with sufficient accuracy. In this case, the relative ionization cross-sections $\sigma_{i,s}$ are found from the atomic element ionization cross-sections [16], with the use of the additivity rule [11, 13] in calculating the molecule ionization cross-sections. The error appearing in this case may be substantial. The accuracy of pressure measurements can be markedly improved if the vapor pressures of the pure components of the system are used as standards. In this case, the coefficients σ and γ in formula (1) are cancelled and there is no need to make corrections to the ion current intensities $I_{i,s}$ for the mass spectrum coefficients and the isotope composition of ions. As standards were chosen congruently sublimating oxides, NbO_2 and Ti_3O_5. In preliminary experiments, the NbO_2 vapor pressure was again measured by the method of complete isothermal evaporation over a sample of composition $NbO_{2.008}$. The obtained results virtually coincided with the data of Matsiu and Naito [7] for the composition $NbO_{2.011}$. Further, the standard NbO_2 vapor pressures p_s (mm Hg) were calculated using the equation

$$\log p = -28\,640/T + 11.15 \quad (2012\text{–}2155\ \text{K}). \qquad (2)$$

The sample fraction evaporated in the form of NbO was calculated from the ratio $I(NbO_2^+)/I(NbO^+)$ in mass spectra obtained at electron energy E = (AE + 3) eV on the assumption of a negligible fragmentation of molecular ions in this operation mode of the ion source. Table 1 presents a mass spectrum of a vapor over NbO_2 at 2200 K and two electron energies.

Previously, some fundamentally important recent observations have been discussed [12, 13], concerning the ionization cross-sections of MO_2 and MO molecules for which the postulate of additivity of the cross-sections of the constituent atoms is seemingly not observed. Experimental data, although being rather diverse, indicate that the ionization cross-section ratio

$\sigma(MO_2)/\sigma(MO) \approx 0.35$–$0.45$ for Ti, V, Th, and U oxides. The same result was obtained in an earlier study [17]: the $\sigma(NbO_2)/\sigma(NbO)$ ratio was found to be close to 0.5 at 11 eV. If this concept is adopted, the partial pressure of NbO in a saturated pressure over NbO_2 must be not higher than 5–6% of the NbO_2 pressure. Similar reasoning was done when analyzing the results obtained in studying the evaporation of Ti_3O_5. Table 1 presents a typical mass spectrum of the vapor over Ti_3O_5 at 2200 K and ion appearance energy of 25 eV and (AE + 3) eV.

AE measurements show that TiO_2^+ ions have molecular, TiO^+ partially "fragmentary," and Ti^+ completely fragmentary origin. At electron energy (AE + 3) eV, only molecular ions are recorded; however, the ratio of their intensities apparently does not correspond to the ratio of partial pressures (the intensity of the TiO_2^+ current is strongly underestimated, probably because of the different slopes of the ionization efficiency curves for the TiO^+ and TiO_2^+ ions. If the difference in the mass spectra obtained at 25 and (AE + 3) eV were accounted for solely by fragmentation under electron impact, then, the content of TiO_2^+ ions in the mass spectrum should have been higher in the second case in the absence of fragmentation than that at 25 eV, which is not the case. As a result, it was accepted, as before [12], in calculating the partial pressures of TiO_2 and TiO that the content of ions-fragments at 25 eV does not exceed 5% of the content of molecular ions, and no correction for fragmentation was introduced. The method of complete isothermal evaporation of samples was applied to measure the effective Ti_3O_5 vapor pressure and the result was compared with similar data of Wahlbeck and Gilles [18], obtained by the effusion Knudsen method (in both studies the pressure was calculated without taking into account the real vapor composition for M = 223.7, i.e., for the molecular weight of Ti_3O_5). Taking $T_m(Ti_3O_5)$ = 2050 K and enthalpy of melting $\Delta_m H^0(Ti_3O_5)$ = 1669 kJ mol^{-1}, the straight line describing the dependence $\log p_{eff}(Ti_3O_5) = f(1/T)$ was extrapolated to the temperature range analyzed in the present study (Fig. 1). It can be seen that the obtained data lie somewhat higher than this extrapolated line, at good reproducibility. The reliability of the measurements performed was confirmed by satisfactory results of a calibration against the international standard–gold, as discussed above. Therefore, a decision was made to use these data in calculating the TiO_2 and TiO vapor pressures over Ti_3O_5 standard. The ionization cross-section ratio $\sigma(TiO_2)/\sigma(TiO)$ = 0.5 and temperature dependences of the TiO^+ and TiO_2^+ ion currents [12] were used to find the equilibrium TiO and TiO_2 vapor pressures (mm Hg, 2500–2300 K):

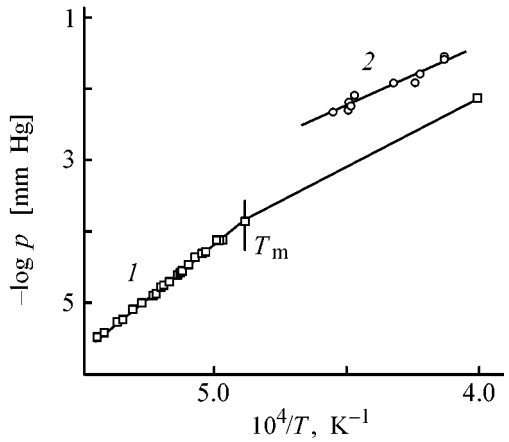

Fig. 1. Ti_3O_5 vapor pressure p_{eff} vs. temperature T. Data: (*1*) [18] and (*2*) present study.

$$\log p(TiO) = -25\,450/T + 9.008, \quad (3)$$

$$\log p(TiO_2) = -25\,120/T + 8.681. \quad (4)$$

The evaporation of all compositions of the system under consideration was studied in the isothermal mode at a temperature close to 2200 K. Figure 2 presents a typical time dependence of the main ion currents in the mass spectrum of vapor over a composition containing 50 mol % TiO_2 (standard Ti_3O_5).

The mass spectrum shows the same ions as the mass spectra of vapors over individual oxides—components of the system; NbO_2^+ and TiO_2^+ ions are molecular, the NbO^+ and TiO^+ ion currents contain 5–6% fragmentary ions. A thorough search for more complex ions, which could be formed in the intermolecular interaction (e.g., of the $TiNbO_3^+$ type), has been unsuccessful: their detection limit can be estimated at less than 0.01% of the NbO_2^+ intensity. It can be clearly seen that the evaporation process has incongruent nature: (a) a more volatile oxide NbO_2 is evaporated and (b) the TiO_2^+/TiO^+ ion current ratio, i.e. the ratio of partial pressures of TiO_2 and TiO, varies continuously.

At the chosen temperature of 2200 ± 30 K, no azeotrope formation was observed for any compositions, including those TiO_2-rich. The TiO_2^+/TiO^+ ratio at the end of an experiment virtually coincides with that for the Ti_3O_5 standard (as seen from Fig. 2). The incongruent nature of evaporation gives rise to well-defined difficulties in calculating the partial pressures of vapor components, since the condensed phase

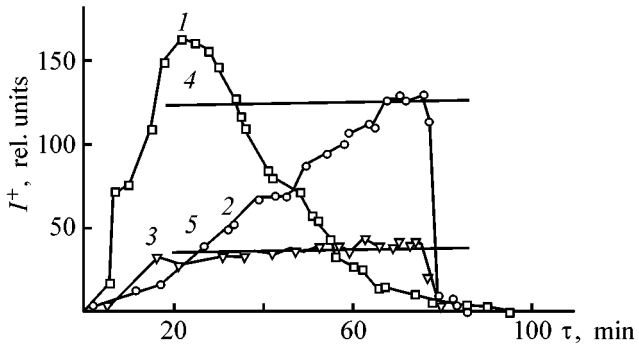

Fig. 2. Ion current intensities I^+ vs. time τ for a sample containing 50 mol % TiO_2. (*1*) NbO_2^+, (*2*) TiO^+, (*3*) TiO_2^+, (*4*) TiO^+ (standard), and (*5*) TiO_2^+ (standard).

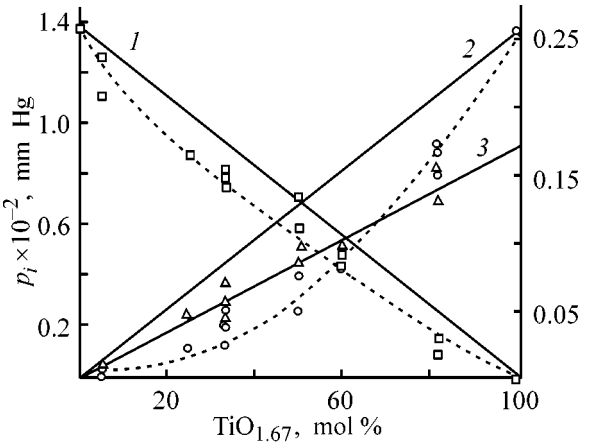

Fig. 3. Diagram partial pressure p_i–condensed phase composition. (*1*) NbO_2, (*2*) TiO, and (*3*) TiO_2.

composition is not invariable, with the loss of oxygen occurring to a substantial extent even before the onset of oxide evaporation in the range of temperature rise to the working temperature of 2200 K. The effusion chamber temperature was rapidly raised from approximately 1700 K (temperature of preliminary keeping at which no evaporation is observed) to the working temperature in order to preclude any substantial distillation of the system by the beginning of measurements; the Ti : Nb ratio in the melt at this instant of time was taken to be equal to that in the sample of the initial composition. However, dissociation of oxides with oxygen loss did occur and the true index by oxygen could not be established. Nevertheless, an attempt was made to characterize quantitatively the evaporation processes in the oxide system under study by constructing a partial pressure–condensed phase composition diagram, with the following conditions introduced.

(1) As a result of thermal dissociation in a vacuum and loss of oxygen with preserved Nb : Ti ratio, all the compositions of the starting system TiO_2–Nb_2O_5 can be interpreted within the new system $TiO_{1.67}(Ti_3O_5)$–NbO_2, in which the pure components are dissociation products—congruently sublimable niobium and titanium oxides. Then, to the starting samples correspond compositions with 5.6, 25.0, 33.3, 50.0, 60.0, and 82 mol % Ti_3O_5 in the new system. The experimental points in the diagram (Fig. 3) reflect the partial pressures of NbO_2, TiO, and TiO_2 over the above compositions. Since the temperature was somewhat different (within 30 K) from 2200 K in some experiments, the experimental partial pressures were recalculated to 2200 K using the equations describing the temperature dependence of the vapor pressure for pure oxides [Eqs. (2)–(4)].

(2) Since the samples were evaporated from effusion chambers in which the thermodynamic equilibrium vapor–condensed phase was maintained during the experiment, it was considered possible to plot in the diagram (Fig. 3) straight lines representing the dependence of the partial pressures on the composition of the condensed phase in accordance with the Raoult law and to analyze the position of the experimental points relative to these straight lines (lines *1*–*3*). Despite the assumptions made, the diagram yields quantitative information about the order of magnitude and relative values of the partial pressures of the vapor components over the system under study. It can be seen that the NbO_2 vapor pressure is only slightly underestimated, and the TiO_2 vapor pressures coincide, to within data scatter, with the values corresponding to evaporation by the Raoult law, which points to a weak interaction of niobium and titanium oxides in the melt. By contrast, the TiO vapor pressure (measured in the initial stage of an experiment, when the O_2 vapor pressure over the system being evaporated is higher than that over TiO_{2-y}, at least for NbO_2-rich compositions) is strongly underestimated and increases only after a pronounced evaporation of NbO_2 (Fig. 2). The dashed lines and in Fig. 3 represent the real averaged positions of points for the partial pressures of NbO_2 and TiO. The experimentally measured NbO_2 and TiO_2 pressures over system are much lower (5–8-fold) than the estimates by Yudin *et al*. [2], whereas the pressures of NbO, and especially TiO, exceed the estimated values by more than an order of magnitude.

Several samples of the system were studied on a UELI–MASS laboratory mass-spectrometric installation with an electron-beam evaporator [20], operating in a mode reproducing the technological condi-

Table 2. Mass spectrum of vapor over a composition 50 mol %TiO_2–50 mol %Nb_2O_3

Ion	Intensity, rel. units		Ion	Intensity, rel. units		Ion	Intensity, rel. units	
	a*	b*		a*	b*		a*	b*

* Evaporation: (a) fron Knudsen chamber and (b) by electron beam.

tions of film deposition by evaporation. Table 2 presents a mass spectrum of vapor over a sample containing 50 mol % TiO_2, with the mass spectrum obtained in evaporation of a sample of the same composition from a Knudsen effusion chamber given for comparison. The spectra are normalized to the highest ion current of NbO_2^+. Differences in the vapor composition are well seen: in the case of electron-beam evaporation the vapor phase is strongly enriched in TiO_2. Probably, in evaporation from the crater surface, the degree of dissociation of the oxides is lower than in the case of evaporation from the effusion chamber because of the greater sample mass, convection agitation of the melt, and arrival of fresh portions of the material from the boundary between the crater and the unmelted bulk of the sample. Nevertheless, even under conditions of intensive evaporation of the material by the electron beam, the more volatile oxide NbO_2 continues to evaporate. Thus, the results obtained in direct mass-spectrometric studies of the real molecular composition of the vapor over the TiO_2–Nb_2O_5 system demonstrate that the incongruent nature of evaporation must lead to a nonuniformity of the TiO_2/Nb_2O_5 ratio across the layer thickness, smoothed out only in the course of thermal annealing of the film.

CONCLUSIONS

(1) The assumption of the vapor phase composition and incongruent nature of vacuum evaporation of oxides of the system TiO_2–Nb_2O_5 was confirmed experimentally.

(2) The partial vapor pressures of titanium and niobium oxides were measured and vapor pressure–condensed phase composition diagrams at 2200 K were constructed.

(3) The vapor composition is qualitatively the same in thermal and electron-beam evaporation of the system under study, with the TiO_2 content somewhat higher in the latter case.

Received July 10, 2000

Abstract—The results obtained in a study of the stability of potassium fluoride peroxosolvates $KF \cdot nH_2O_2$ (n = 1, 2), including that in prolonged storage, are presented. The kinetics of $KF \cdot nH_2O_2$ decomposition in solid state and in aqueous solutions was analyzed. The obtained results characterize potassium fluoride peroxosolvates as the most stable solid carriers of hydrogen peroxide, promising for practical use.

It was shown in [1, 2] that the peroxosolvates $KF \cdot nH_2O_2$ (n = 1, 2) show a wide spectrum of antimicrobial activity. These compounds have been used to create disinfectants possessing a number of essential advantages over other presently used disinfectants, especially those containing chlorine. The developed preparations are ecologically safe in manufacture and use, corrosion-inactive, nontoxic, have no odor, and cause no allergic reactions.

Among important operation characteristics of any disinfectant are such parameters as stability in storage in solid state and in aqueous solutions.

The present communication summarizes results of investigations of the stability of potassium fluoride peroxosolvates. The kinetics of $KF \cdot nH_2O_2$ decomposition in solid state and in aqueous solutions was studied and the stability of the solvates in prolonged storage was determined.

Potassium fluoride peroxosolvates were synthesized as described in [3]. Samples of composition $KF \cdot H_2O_2$ and $KF \cdot 2H_2O_2$ were used, and also an equimolar mixture of these, with bulk chemical composition $KF \cdot 1.5H_2O_2$.

The content of hydrogen peroxide in the samples, found by permanganatometric titration, corresponded to that calculated for $KF \cdot H_2O_2$ and $KF \cdot 2H_2O_2$. The content of H_2O_2 in equimolar mixtures of these solvates was in the range from 40 to 44 wt % (41.6 wt % calculated for $KF \cdot 1.5H_2O_2$).

The stability of solid samples and aqueous solutions of the solvates in prolonged storage was studied at 20 ± 4°C in closed glass and polymer vessels. The degree of decomposition of hydrogen peroxide was judged from changes in its content with time. The stability was calculated in the form of a coefficient β equal to percentage of decomposition in unit time. In comparing the stabilities of different objects under study, the β values were taken for equal exposures.

The kinetics of decomposition of solid $KF \cdot H_2O_2$ samples was studied under isothermal conditions in the temperature range 90–125°C. A device for decomposition comprised a gas burette and a thermostated 15-cm^3 glass vessel, in which a 0.15–0.25-g portion of a sample was placed. The liberated water was absorbed by a layer of anhydrone in the upper part of the vessel. The volume of evolved oxygen was measured using a gas burette with an accuracy of 0.05 cm^3. The degree of decomposition was determined as the volume ratio of oxygen evolved by instant of time τ to oxygen contained in the weighed portion of a sample.

Solutions prepared in studying the kinetics of solvate decomposition in aqueous solutions contained approximately 7 wt % H_2O_2. The solutions were placed in a device comprising a vessel (Pyrex glass) equipped with a reflux condenser, control thermometer, and aperture for agitation and sampling in order to make analysis for the content of hydrogen peroxide. The solution volume was 40 ml. The device was placed in a furnace thermostated to within ±0.5°C. The study

Table 1. Stability of $KF \cdot 1.5H_2O_2$ solvate at different temperatures

T, °C	β, % day^{-1}	Annual loss of H_2O_2, %
–18	0.0039	1.4
20	0.0052	1.9
37	0.0217	7.8

was performed in the temperature range 75–95°C. Prior to the beginning of the main set of experiments, the assembled device was filled with a solvate solution and kept at 75°C for 6–7 h. Reproducible kinetic data were obtained after performing several preliminary passivating operations of this kind. Special experiments demonstrated that the water loss associated with incomplete condensation was less than 1% in the temperature range 75–90°C and as high as 3% at 95°C.

Mono- and diperoxosolvates are rather stable in solid state. The results obtained in studying the decomposition kinetics were used to find, by extrapolating the degrees of decomposition to low temperatures, that $KF \cdot H_2O_2$ loses 4×10^{-2}% H_2O_2 per year at 25°C [4]. Under real conditions, $KF \cdot H_2O_2$ obtained under laboratory conditions from high-grade components and stored in a polymer vessel at 20 ± 2°C for five years retains the initial content of H_2O_2. However, the stability of peroxosolvates strongly depends on the presence of microimpurities of foreign substances brought into the solvate together with the starting reagents and also impurities present on the reaction vessel surface or washed out of it. Therefore, the averaged results obtained for many syntheses give real data characterizing the stability of the solvates. At a storage time of 6 months the β values are as follows

Solvate	β, % day^{-1}	Annual loss of H_2O_2, %
$KF \cdot H_2O_2$	0.0031	1.10
$KF \cdot 1.5H_2O_2$	0.0066	2.40
$KF \cdot 2H_2O_2$	0.0057	2.05

The dependence of the stability of peroxosolvates on their storage temperature is demonstrated for the example of $KF \cdot 1.5H_2O_2$ (Table 1). It can be seen that the annual loss of H_2O_2 is 1.4% at –18°C and as high as 7.8% at 37°C. Thus, even in the case when the solvate is stored at 37°C, the annual loss of H_2O_2 does not exceed 10%.

The kinetics of thermal decomposition of potassium fluoride peroxosolvates was studied for the example of $KF \cdot H_2O_2$. The $KF \cdot H_2O_2$ decomposition curves processed using the Kolmogorov–Erofeev equation

$$[-\log(1 - \eta)]^{1/3} = k(\tau - \tau_0)$$

give two rectilinear portions with deceleration in the second stage. The duration of the initial portion with high rates grows with increasing temperature from $\eta = 0.01$ at 90°C to $\eta = 0.12$ at 125°C. The decomposition rate constants take the following values

T, °C	90.0	95.2	100.2	105.2
$k_1 \times 10^3$, min^{-1}	0.33	0.39	0.46	0.67
$k_2 \times 10^3$, min^{-1}	0.21	0.26	0.37	0.42
T, °C	110.2	115.2	120.2	125.2
$k_1 \times 10^3$, min^{-1}	0.78	1.20	1.40	2.07
$k_2 \times 10^3$, min^{-1}	0.50	0.76	0.80	1.05

Comparison of the kinetic parameters of $KF \cdot H_2O_2$ and other investigated peroxosolvates of salts of inorganic acids (Table 2) shows that potassium fluoride peroxosolvates exhibits the highest thermal stability.

The main reason for the high stability of solid $KF \cdot H_2O_2$ and $KF \cdot 2H_2O_2$ is that no compounds forming strongly alkaline or acid solutions are present among the products of solvate interaction with moisture.

All the known peroxosolvates are hygroscopic. Moisture absorption by peroxosolvates or their insufficient dehydration results in that a solution whose nature depends on the nature of a salt being solvated is formed on the surface of, or within crystallites consti-

tuting the film or the local zone. For example, sodium carbonate peroxosolvate forms a solution with high pH value, which favors catalytic decomposition of coordinated hydrogen peroxide. The stability of $Na_2CO_3 \cdot 1.5H_2O_2$ is much lower than that of $KF \cdot H_2O_2$. For example, in the initial stage, k_1 for $Na_2CO_3 \cdot 1.5H_2O_2$ is 6.8 times k_1 for $KF \cdot H_2O_2$; and in the second stage, k_2 is 12 times higher.

In the case of phosphate peroxosolvates, the stability of the peroxosolvates is affected in opposite directions by the following two factors: a certain stabilizing effect of phosphate ions on hydrogen peroxide and the alkaline medium of the solution. The predominant influence is exerted in this case by the alkalinity of the solution formed in hydrolysis, with the result that the stability of phosphate peroxosolvates is also lower than that of $KF \cdot H_2O_2$.

Neutrality or weak alkalinity of the products formed in reaction of KF with water is the key factor determining the stability of $KF \cdot nH_2O_2$ both in solid state and in aqueous solutions.

The stabilities of aqueous solutions of some peroxosolvates and hydrogen peroxide at exposure of 40 h are compared in Table 3.

It can be seen that the stability of potassium fluoride peroxosolvate in an aqueous solution is two orders of magnitude higher than that of the industrial hydrogen peroxide and nearly five orders of magnitude higher than that of sodium carbonate peroxosolvate.

$KF \cdot H_2O_2$ solutions are also stable at elevated temperatures. For example, when heated at a rate of about 10 deg min^{-1}, solutions virtually retain the initial content of hydrogen peroxide on reaching a prescribed temperature in the range from 30 to 100°C at intervals of 10°C.

Kinetic curves describing the decomposition of aqueous solutions of $KF \cdot H_2O_2$, measured at 20°C within the time range extending to 960 h and processed using the equation $\log C_0/C = k(\tau - \tau_0)$, exhibit two linear portions with acceleration in the later stage. The time τ of changeover is 380 h (see the figure, curve *1*). In the initial stage, $k_1 = 2.5 \times 10^{-6}$ min^{-1}, and in the second, $k_2 = 9.3 \times 10^{-6}$ min^{-1}. The average degree of $KF \cdot H_2O_2$ decomposition during a storage time of 960 h (40 days) is 0.0017 % h^{-1}, or 1.2 % $month^{-1}$. Thus, potassium fluoride monoperoxosolvate solutions can be stored at room temperature and used during no less than 1 month without virtually any loss of H_2O_2.

It seemed important to characterize quantitatively the stability of $KF \cdot H_2O_2$ solutions at as high temperatures as possible, enabling their use for disinfecting. It is known for the example of hydrogen peroxide and other disinfectants that elevating the temperature by 30°C (from 20 to 50°C) raises tenfold the extinction rate of microorganisms.

Table 3. Stability of aqueous solutions of selected peroxosolvates 20°C, 10 wt %, τ = 40 h

Solvate	Average decomposition coefficient, % h^{-1} (in glass)
$KF \cdot H_2O_2$	0.00008 ± 0.00001
$Na_2CO_3 \cdot 1.5H_2O_2$	2.4170 ± 0.011
$(NH_2)_2CO \cdot H_2O_2$	0.0278 ± 0.0002
H_2O_2	0.0048 ± 0.0004

The kinetics of decomposition of aqueous solutions of $KF \cdot H_2O_2$ was studied at the highest possible temperatures (75–95°C) at intervals of 5°C. The typical dependence of $\log C_0/C$ on τ is presented in the figure (curves *2–6*). Table 4 lists the average decomposition rate constants calculated on the basis of 5–7 parallel runs.

As in the case of 20°C, the curves obtained in the range 75–95°C show a bend. The shape of curves with a bend is characteristic of the thermal decomposition of all the presently studied solid peroxides: $Na_2CO_3 \cdot 1.5H_2O_2$, $K_2CO_3 \cdot 3H_2O_2$, $NH_4F \cdot H_2O_2$, $KF \cdot H_2O_2$, $BaF_2 \cdot 2H_2O_2$, $Na_2HPO_4 \cdot 2H_2O_2$, and $Na_4P_2O_7 \cdot 3H_2O_2$ [5]. However, only in a single case $Na_2CO_3 \cdot 1.5H_2O_2$ the process is accelerated in the

	E_1 = 72.8 kJ mol^{-1}		E_2 = 60.4 kJ mol^{-1}	

second range. In all other cases, the second stage proceeds with deceleration.

The decelerated decomposition of solid peroxosolvates can be attributed to disrupted contact between the solvate and the catalytically acting surface of the reaction vessel as a result of formation of a solid shell composed of reaction products. Explaining the acceleration of $Na_2CO_3 \cdot 1.5H_2O_2$ decomposition in the later stage without additional studies is difficult.

The similarity of $KF \cdot H_2O_2$ decomposition processes in solid state and in aqueous solution consists, in addition to double-stage nature, also in that the temperature dependence of the rate is stronger in the initial stage, compared with the second one. For example, E_1 = 69.9 and E_2 = 52.7 kJ mol^{-1} for $KF \cdot H_2O_2$, and E_1 = 72.8 and E_2 = 60.4 kJ mol^{-1} for solution. However, decomposition proceeds in the second stage with deceleration for the solid solvate, and is accelerated in aqueous solution.

The acceleration of $KF \cdot H_2O_2$ decomposition in solution at a certain τ value is possibly related to the involvement of an additional homogeneous decomposition of H_2O_2 in the solution bulk, catalyzed by products coming into the solution from the decomposing glass surface, in the process of heterogeneous catalytic decomposition of H_2O_2.

The extent of the catalytic influence exerted by the glass surface on H_2O_2 decomposition in aqueous solutions of $KF \cdot H_2O_2$ is seen from a comparison of the rates of the process in a glass device and in the same device, but with the surface insulated by a thin polymer pocket inserted into the device. The solution was isolated from the glass surface completely, but part of hydrogen peroxide could be decomposed catalytically on the uninsulated members of the device. With account of the low concentration of the solutions under study, this part seems to be insignificant.

At 85°C, decomposition of $KF \cdot H_2O_2$ solutions in a polymer vessel proceeds in the entire time range without acceleration (see the figure, curve *7*). The rate constant $k = 1.0 \times 10^{-4}$ min^{-1} is more than an order of magnitude lower than $k_2 = 11.4 \times 10^{-4}$ min^{-1} for the same temperature and 6 times lower than $k_1 = 6.1 \times 10^{-4}$ min^{-1}. On adding catalysts to the solution, the rate markedly increases immediately after their introduction, and no characteristic process acceleration is observed, either (curves *8–10*). $k = 2.8 \times 10^{-4}$ min^{-1} for ground glass (1 g) and 5.1×10^{-4} min^{-1} for Fe_2O_3, in the presence of MnO_2 the decomposition process is complete in 10–15 min.

The obtained data are in agreement with the assumption that a homogeneous bulk reaction catalyzed by glass disintegration products is additionally included in the heterogeneous process of hydrogen peroxide decomposition catalyzed by the reaction vessel surface. In the given case, this process is manifested most clearly, since fluoride ions are hydrolyzed in water to give HF and HF_2^-. Both of these species exert destructive influence on the glass.

This assumption is supported by the enhanced stability of aqueous solutions of peroxosolvates in glass at lower content of KF. For example, in the case of storage for 120 h at 20°C, β = 0.0012 % h^{-1} for

$KF \cdot H_2O_2$ (63.1% KF), 0.0009 % h^{-1} for $KF \cdot 1.5H_2O_2$ (58.4% KF), and 0.0007 % h^{-1} for $KF \cdot 2H_2O_2$ (46.1% KF).

CONCLUSION

The results obtained in studying the kinetics of decomposition and the stability in prolonged storage of $KF \cdot nH_2O_2$ solvates in solid state and in aqueous solutions demonstrate that potassium fluoride peroxosolvates belong to the most stable solid carriers of hydrogen peroxide. A strong influence of the material of which the vessels used in experiment are made on the stability of $KF \cdot nH_2O_2$ in aqueous solutions is established.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of Lower Oxides of Transition Metals from Chloride Melts

V. V. Lesnyak, D. A. Stratiichuk, N. S. Slobodyanik, and V. S. Sudavtsova

Shevchenko National University, Kiev, Ukraine

Received November 13, 2000; in final form, March 8, 2001

Abstract—Synthesis of transition metal oxides MO_2 (M^{IV} = Mo, W, or Nb) and V_6O_{13} in alkali chloride melts and their crystallographic characteristics are described. The advantages of the proposed technology are demonstrated. The thermodynamic parameters of the proposed reactions are calculated.

Basic and applied studies aimed to develop new energy-saving methods for obtaining oxide materials allow synthesis of materials for electronics, catalysis, automatics, and radio engineering in considerably shorter time at a fundamentally new level. Dioxides of polyvalent metals, e.g., molybdenum and tungsten dioxides, which have found wide application as multifunctional heterogeneous catalysts for oxidation of NO and CO and for selective oxidation of *n*-butane and other hydrocarbons [1, 2], are widely used in solving both industrial and ecological problems. Some metal oxides, e.g., niobium and vanadium oxides, are semiconductors.

Since the known methods for synthesizing polycrystalline compounds involve gross consumption of energy and employ high-cost equipment [3], we developed in this study a method for synthesizing oxides of transition metals (Mo, W, Nb, and V) from fluxes—alkali chloride melts. The method makes it possible to perform the reaction at comparatively low temperature in a short time without use of expensive equipment.

EXPERIMENTAL

The experiment was carried out using mixtures of higher *d*-element oxides and finely dispersed powders of the respective metals, in amounts corresponding to the stoichiometry of the following reactions.

$$2MoO_3 + Mo \rightarrow 3MoO_2, \quad (1)$$

$$2WO_3 + W \rightarrow 3WO_2, \quad (2)$$

$$2Nb_2O_5 + Nb \rightarrow 5NbO_2, \quad (3)$$

$$13V_2O_5 + 4V \rightarrow 5V_6O_{13}. \quad (4)$$

As the reaction medium served a flux of a eutectic composition of the system LiCl–KCl (40 mol % KCl), chosen because of its being readily available and having a low melting point. The eutectic composition of the LiCl–KCl system (T_{mel} = 352°C) is inferior in temperature characteristics solely to the composition LiCl–RbCl (44.5 mol % RbCl; T_{mel} = 312°C).

Thoroughly ground metal oxides, powdered metals, and the eutectic mixture LiCl–KCl (Table 1) were used to prepare formulations in the initial stage of the experiment. Then, the formulations were placed in porcelain crucibles and heated to 400°C. The system was kept under these conditions for 30–40 min until residual oxygen was removed and two separate fractions were obtained: lower layer containing a mixture of oxide and a metal and upper layer composed of the eutectic melt LiCl–KCl and occupying 20–30% of the working volume of the crucible. Then, the temperature was raised to 750–780°C at a rate of 30–40 deg h^{-1}. After being kept at 780°C for 30–40 min, the system was cooled at a rate of 30–40 deg h^{-1}. The melt cooled to approximately 400°C was decanted, with the obtained solid residue washed with hot distilled water and dried at 120°C.

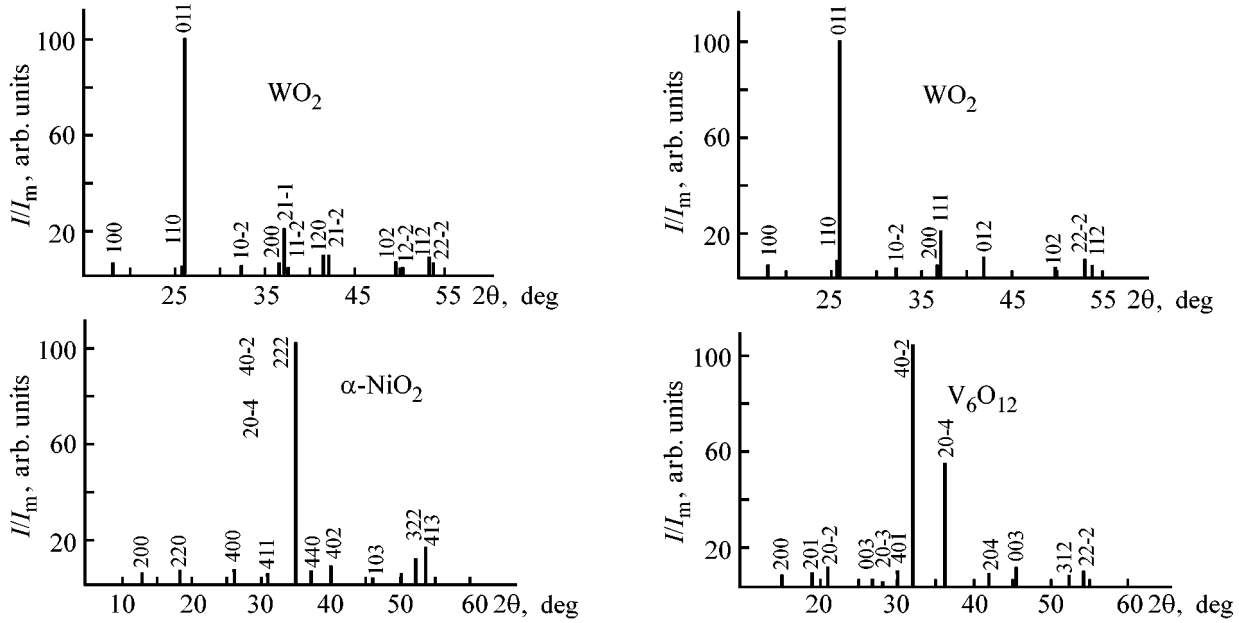

Fig. 1. X-ray powder diffraction patterns of the prepared oxides. (I/I_m) Relative intensity and (2θ) Bragg angle.

The reactions proceeding in these systems yielded finely dispersed brown powders of molybdenum and tungsten dioxides ($\rho_{X\text{-}ray}$ = 6.47 and ρ_{exp} = 5.44 g cm^{-3}). Vanadium and niobium form dark blue oxides ($\rho_{X\text{-}ray}$ = 3.91 and ρ_{exp} = 5.98 g cm^{-3}). It should be noted that, in synthesizing tungsten dioxide WO_2, a 10–15%-excess of metallic tungsten and a temperature not higher than 650°C are the optimal phase formation conditions. This can be attributed to high oxidizability of tungsten and formation of bronzes of variable composition.

Analysis of spent fluxes revealed that the *d*-element compounds are not dissolved in salt melts even in trace amounts, which, in fact, indicates that the process cannot occur via the solvent–solute stage. Most likely, the scheme of the given reaction is as follows: (1) thermal dissociation of an oxide with the formation of MO_x^+ cations, (2) formation of a transition complex with the melted flux, (3) its transfer to the metal surface, and (4) interaction of the complex with the metal to give a lower oxide. This reaction scheme formally occurs in many heterogeneous processes in temperature-reducing fluxes. In addition, the chloride melts strongly activate the metal surface, with oxide films removed and the number of defects increased. It should be noted that, in the case when a direct reaction metal–oxide or oxide–oxide (sintering) is used, the process rate is limited in early stages by the rate of reagent transfer to the reaction region, and later, by reagent diffusion through a layer of the formed products [4].

The phase composition of the reaction products was studied by X-ray phase analysis (XPA). The obtained results are shown in Fig. 1 and listed in Table 2. According to the ASTM Powder Diffraction Data File, the obtained oxides are the monoclinic V_6O_{13}, WO_2, MoO_2 and rhombic α-NbO_2 (Table 2). The amount of metal in the samples, *M* (wt %), was determined by X-ray fluorescence analysis on a Philips-1500 apparatus (Table 3).

Table 4. $-\Delta G^0$ values for reactions (1)–(4)

Reaction	$-\Delta G^0$ (kJ mol^{-1}) at indicated temperature, K						
	298	400	600	800	1000	1200	1400
(1)	129.0	142.4	151.6	161.3	168.4	–	–
(2)	38.3	42.5	32.9	28.4	23.2	–	–
(3)	168.0	168.5	165.5	154.0	147.0	–	–
(4)	449.5	449.5	450.0	462.5	463.0	432.0	421.8

To predict the course of the reactions studied, we calculated the standard change in the Gibbs energy of the reactions, ΔG^0, at 298–1000 K from the data reported in [5]. The obtained results are presented in Table 4 and Fig. 2.

To predict the possibility of reactions of metals belonging to subgroups V-B and VI-B with their higher oxides in an oxygen-free atmosphere at 298–1000 K, the change in the Gibbs energy of the reactions

$$2CrO_3 + Cr \rightarrow 3CrO_2, \quad (5)$$

$$2V_2O_5 + V \rightarrow 2.5V_2O_4 \quad (6)$$

was calculated on the basis of the standard thermodynamic functions of the starting and final substances [5]. For reaction (1), the dependence of ΔG^0 on temperature is a nearly linear within 298–1000 K, which indicates that the reaction rate grows with increasing temperature.

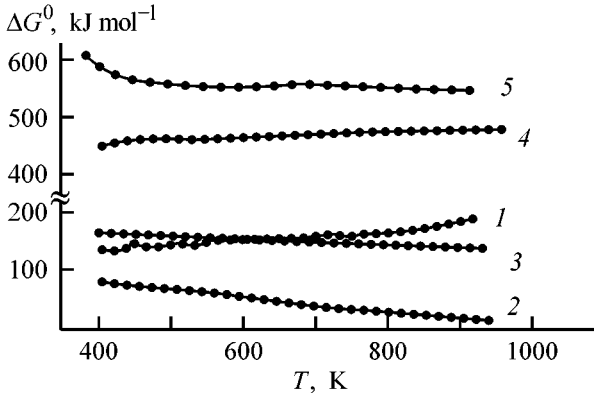

Fig. 2. ΔG^0 vs. temperature T for reactions (1)–(5). (*1*) MoO_2, (*2*) WO_2, (*3*) NbO_2, (*4*) V_6O_{13}, and (*5*) CrO_2.

The experimentally selected conditions of molybdenum dioxide synthesis in chloride melts are the optimal and agree well with the thermodynamic data. The dependence $\Delta G^0 = f(T)$ for reaction (1) is nearly linear within 298–1000 K. The conditions of MoO_2 synthesis in the range 823–1053 K correspond to the maximum absolute value of ΔG^0. This means that such a temperature interval is necessary for reaction (1) to occur, in which the diffusion coefficients of the reagents are high enough and the reagent surfaces are sufficiently active. In this case, the rate of the presented reaction will be high [6].

Reaction (2) is characterized by low Gibbs energy and, according to the ΔG^0 values, its optimal temperature is 600 K. The temperature of interaction in chloride melts approaches 923 K, which is due to the necessity for a higher rate of back diffusion of components. According to the thermodynamic data, reaction (3) must occur at 800 K, which is in agreement with the experimental results. To compare the ΔG^0 values for reactions (4) and (6), we performed a thermodynamic calculation of the interaction for 1 mol of vanadium(V) oxide. ΔG^0 is –135.6 and –89.9 kJ mol^{-1} for, respectively, reactions (4) and (6). Thus, it is evident that reaction (4) is more probable from the standpoint of thermodynamics and will occur in the first place.

A calculation of ΔG^0 for reaction (5) showed that the tendency toward interaction decreases with increasing temperature (Fig. 2). At the same time, ΔG^0 of this process is rather high (in absolute value). The fact that chromium dioxide cannot be obtained is mainly related to the very high thermodynamic stability of chromium(III) oxide Cr_2O_3 in comparison with other oxides.

CONCLUSIONS

(1) Based on the thermodynamic calculations and experimental results, the optimal conditions were determined for the interaction of higher oxides of *d*-metals (V, Nb, Mo, and W) with the respective metals in alkali chloride melts.

(2) A method for industrial manufacture of lower oxides of *d*-metals was developed.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of Crystallization in the System $TiO_2(Al_2O_3)$–H_2SO_4–$(NH_4)_2SO_4$–H_2O in Obtaining Titanium–Aluminum Tanning Agent

M. V. Maslova, D. L. Motov, and L. G. Gerasimova

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Russia

Received December 7, 2000

Abstract—The conditions under which a titanium–aluminum tanning agent is obtained from sulfuric acid solutions were studied. The composition was established and the properties were studied of the forming phases.

Recently, the manufacture and use of multicomponent tanning agents making it possible to do without toxic chromium(III) compounds at tanneries have been studied intensively[1–4]. A combination of positive properties inherent in the components of such a tanning agent enables its use in tanning of supple and stiff leather.

The technology for manufacture of tanning agents of this kind is based on the so-called salting-out of a crystalline salt from a mono- or polycomponent sulfate solution. Mainly technological aspects of synthesis of tanning materials have been described in the literature [5, 6].

The aim of the present study was to analyze the influence exerted by the salting-out conditions in the system $TiO_2(Al_2O_3)$–H_2SO_4–$(NH_4)_2SO_4$–H_2O on the composition and properties of the forming solid phases. Data of this kind are necessary for substantiating a new technology for manufacture of a complex titanium–aluminum tanning agent possessing versatile properties [7].

EXPERIMENTAL

The salting-out was done from a sulfate titanium–aluminum solution containing (g l^{-1}): TiO_2 92.6, Al_2O_3 25.9, and H_2SO_4 175, prepared by dissolving oxotitanium monohydrate in water with subsequent addition of a necessary amount of aluminum sulfate.

The crystallization was performed by introducing crystalline ammonium sulfate and concentrated sulfuric acid into this solution, with their excess (free) concentration in the reaction mass varied between 50 and 500 g l^{-1}.

The experimental procedure was as follows. A titanium–aluminum solution with prescribed concentration of free sulfuric acid was introduced into a suspension of ammonium sulfate [1000–1200 g l^{-1} $(NH_4)_2SO_4$] in the course of 1 h at a temperature not exceeding 25°C. The mixture was kept with stirring for 2 h and then allowed to stand without stirring for 1 h for crystals to be formed. The precipitate was separated from the liquid phase, washed with an ammonium sulfate solution [450 g l^{-1} $(NH_4)_2SO_4$] with s : l = 1 : 0.5, dried in air, and analyzed for the content of salt components. The phase composition of the precipitates was determined by the crystal-optical method. In doing so, the basicity of a salt (ratio of titanium and aluminum ions bound to OH^- groups to the total amount of titanium and aluminum ions in the tanning agent, expressed in percent), characterizing the quality of a tanning agent, was calculated.

The choice of the end points with respect to salt mass components is due to technological features of the process. At a content of free sulfuric acid exceeding 500 g l^{-1}, $Al_2(SO_4)_3 \cdot 18H_2O$ precipitates, in agreement with the solubility data for the system H_2SO_4–$Al_2(SO_4)_3$–H_2O at 25°C [8]. It is known that ammonium sulfate is a weaker salting-out agent than H_2SO_4, and making its concentration higher than 500 g l^{-1} is unpractical, since it will exert no essential influence of the degree of salting-out of the tanning salt.

In the concentration range studied there occurs crystallization of the monohydrate salt $(NH_4)_2TiO(SO_4)_2 \cdot H_2O$ [titanium(IV) ammonium sulfate, TAS], $NH_4Al(SO_4)_2$

1070-4272/01/7406-0916 $25.00 © 2001 MAIK "Nauka/Interperiodica"

(ammonium aluminum alum, AAA), titanium–aluminum salt, and, at some points of the system, anhydrous TAS as impurity phase. The degree of salting-out and the dispersity of the titanium salt depend on the concentration in solution of free sulfuric acid and ammonium sulfate. At H_2SO_{4exc} content of up to 100 g l^{-1} the degree of TAS precipitation does not exceed 40% over the entire range of $(NH_4)_2SO_{4exc}$ concentrations. The crystallizing titanium salt is finely disperse, with particle size of 1–2 μm.

With increasing concentration of salting-out agents, the extent of TAS precipitation grows, and, at a total concentration of free H_2SO_4 and $(NH_4)_2SO_4$ exceeding 550 g l^{-1}, more than 95% of the titanium salt is precipitated at 1 : (0.8–1) mass ratio of free H_2SO_4 to $(NH_4)_2SO_4$. In this case, TAS crystals grow in size to 7–9 μm.

Substantially raising the ammonium sulfate concentration at low content of H_2SO_{4exc} leads to a minor change in the solubility of the double salt. Raising the content of ammonium sulfate at high free sulfuric acid concentrations causes a more dramatic decrease in the solubility of TAS and the corresponding increase in the degree of its precipitation.

At H_2SO_{4exc} concentration exceeding 400 g l^{-1}, an anhydrous product impairing the quality of the tanning agent is formed together with TAS monohydrate. Under these conditions, a finely crystalline salt with particle size of 2–5 μm is formed, with a large amount of the mother liquor in inclusions.

The degree of AAA precipitation under the chosen conditions depends only slightly on the concentration of salting-out agents and constitutes 94–98%. The alum is in the form of coarse crystals 15–30 μm in size.

A comparison of the obtained data with those for the quaternary system TiO_2–H_2SO_4–$(NH_4)_2SO_4$–H_2O [9] demonstrated that, at low concentrations of salting-out agents, aluminum(III) has little effect on the TAS solubility, whereas at a total concentration of free H_2SO_4 and $(NH_4)_2SO_4$ exceeding 300 g l^{-1} the solubility of the titanium salt increases in the presence of aluminum(III).

The obtained experimental data were used to construct composition–property diagrams in the Cartesian coordinate system in relation to the content of free sulfuric acid and ammonium sulfate not bound to titanium(IV) in the form of a salt. For convenience of technological use of the diagrams, the concentrations of salting-out components are given in grams per liter. The presented curves are horizontal projections of the basicity and solubility surfaces.

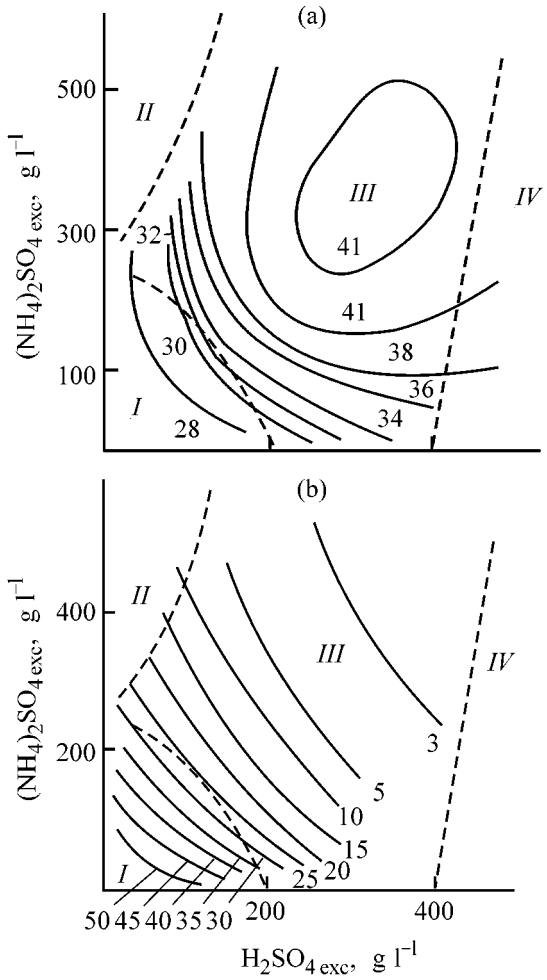

Fig. 1. (a) Basicity of titanium–aluminum product obtained along the section of the system $TiO_2(Al_2O_3)$–H_2SO_4–$(NH_4)_2SO_4$–H_2O (TiO_2 92.3, Al_2O_3 26.5 g l^{-1}) and (b) TiO_2 content of the mother liquor after salting-out of the titanium–aluminum product. [$(NH_4)_2SO_{4exc}$, H_2SO_{4exc}] Content. Isolines: (a) basicity (%) and (b) TiO_2 concentration (g l^{-1}).

Figure 1a shows the surface formed by basicity isolines. With this method of presentation, the surface is stretched in the direction toward the ordinate axis. This means that the H_2SO_{4exc} concentration affects the basicity of the tanning agent to a greater extent than that of $(NH_4)_2SO_{4exc}$. Low basicity (28%) corresponds to a tanning agent obtained at a total concentration of salting-out agents of 100–200 g l^{-1}. In such a product, the mass ratio TiO_2 : Al_2O_3 = (0.8–1) : 1. Low content of Ti(IV) in the tanning agent gives no way of using it in the main process and it can only serve as a pre- or post-tanning agent.

With the concentration of salting-out agents increasing to their total content of 400 g l^{-1}, the basicity of

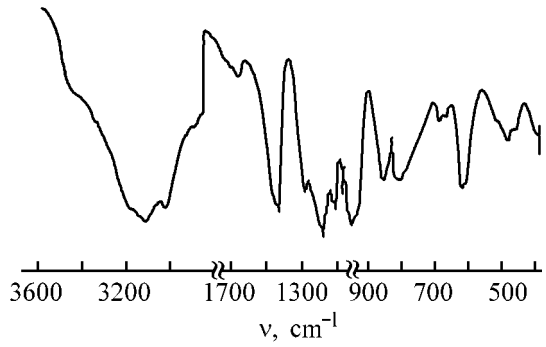

Fig. 2. IR spectrum of the titanium–aluminum product. (ν) Wave number.

the tanning agent grows from 30 to 38%, with the change in basicity to a greater extent depending on the H_2SO_{4exc} concentration. The tanning salts contain 9–14 TiO_2 and 7–4.5% Al_2O_3 and can be used as tanning agents for supple leather.

Products with basicity of 40–41% were obtained at H_2SO_{4exc} and $(NH_4)_2SO_{4exc}$ concentrations of 200–400 and 160–500 g l^{-1}, respectively. Tests with the Ti–Al tanning agent demonstrated that the highest temperature of leather cooking is achieved with tanning agents having a basicity of about 41%. Salts with the required basicity were obtained at a total concentration of H_2SO_{4exc} and $(NH_4)_2SO_{4exc}$ of 540–860 g l^{-1} and mass ration H_2SO_{4exc} : $(NH_4)_2SO_{4exc}$ = 1 : (0.8–1).

One of characteristics of the crystallization process is the degree of precipitation of tanning components, which should be no less than 90%. To determine the optimal range of the salting-out agent concentration for obtaining a high-quality tanning agent, lines of TiO_2 content (g l^{-1}) in the mother liquor after salting-out, which are horizontal projections of the conventional solubility surface in the three-dimensional coordinate system, were plotted (Fig. 1b).

The surface is gently inclined toward the increasing content of the salting-out agents. At a content of free sulfuric acid higher than 300 g l^{-1}, the residual content of TAS in the mother liquor does not exceed 5 g l^{-1} in terms of TiO_2.

By superimposing the projections of the surfaces of basicity and TiO_2 content in the mother liquor, the region in which high-quality product is obtained was determined, limited to concentrations of 250–300 g l^{-1} for free sulfuric acid and 280–400 g l^{-1} for free ammonium sulfate at a total content of salting-out agents of 550–700 g l^{-1} and H_2SO_{4exc} : $(NH_4)_2SO_{4exc}$ = 1 : (1–0.8).

Four characteristic zones can be distinguished in the diagrams, differing in the concentration of salting-out agents, dispersity of the forming solid phase, and, correspondingly, its basicity. In zone *I*, a finely disperse salt is formed in salting-out from solutions, the tanning agent has low basicity, and up to 40 g l^{-1} of TiO_2 remains in the mother liquor. The unsatisfactory technological characteristics indicate that high-quality products cannot be obtained in this region.

In zone *II*, where the content of free ammonium sulfate much exceeds that of free sulfuric acid, the degree of salting-out and the basicity of the tanning agent approach the required values with increasing total content of salting-out components, but the product is finely disperse, which affects adversely the technological regime of the process.

In zone *III*, a product is formed with varied basicity depending on the concentration of salting-out agents, with an increase in the content of free sulfuric acid affecting the basicity and degree of TAS salting-out to a greater extent than that in the content of free ammonium sulfate.

In zone *IV*, where the content of free sulfuric acid in solution exceeds 400 g l^{-1}, anhydrous TAS crystallizes in the solid phase together with TAS monohydrate. The higher the content of H_2SO_{4exc}, the greater amount of anhydrous TAS, inapplicable as tanning agent, is formed.

The composition and properties of titanium–aluminum phases obtained in studying the system $TiO_2(Al_2O_3)$–H_2SO_4–$(NH_4)_2SO_4$–H_2O were investigated by means of X-ray phase analysis (XPA) and IR spectroscopy. For this purpose, precipitates were washed with alcohol to remove the mother liquor and dried in air for 2 h. It was found that, at high $(NH_4)_2SO_{4exc}$ concentrations and low acidity, crystalline ammonium sulfate is present in the product together with TAS and AAA.

According to XPA, the precipitates contain, together with TAS and AAA, a phase characterized as individual (see the table). Significant changes in the X-ray diffraction patterns of the synthesized titanium–aluminum phase, compared with TAS and AAA, may point to a distortion of the crystal lattice of TAS through incorporation of aluminum. According to crystal-optical data, the content of this phase fluctuates between 5 and 15% over the volume.

IR spectra of the precipitate are complex (Fig. 2). They reflect the presence of H_2O, and SO_4^{2-}, NH_4^+, O–M–O, and M–OH groups.

Crystal water manifests itself at 3700–3200 (symmetric stretching vibrations of O–H) and 1630–1600 cm^{-1} (deformation vibrations of H–O–H). The absorption band at 1440 cm^{-1} is associated with δ-NH [10].

It is known that the sulfate group gives rise to a great number of absorption bands in an IR spectrum at 500–700 and 1000–1250 cm^{-1}, corresponding to stretching, deformation, and other vibrations of this group [10].

The spectra of the precipitate indicate that its structure is characterized by two types of symmetry of SO_4^{2-} groups. Noteworthy is the strong splitting of the ν_3 and ν_4 bands of SO_4^{2-}, which is due to the presence of bi- and polydentate groups. Compared with those in the spectrum of TAS [11], these bands are narrower and have lower intensity, which can be attributed to a change in the bond strength under the influence of the aluminum ion. The presence of ν_1 and ν_2 bands of medium intensity confirms the symmetry lowering to C_{2v} and the presence of a bidentate complex. The absorption band at 800 cm^{-1} is associated with stretching vibrations of bound Al–OH [12].

The IR spectral data confirmed that the precipitates under study are composed of a mixture of compounds, including TAS, AAA, and a titanium–aluminum phase in which titanium(IV) is bound to aluminum(III) via an OH^- group.

CONCLUSIONS

(1) The results obtained in studying the system $TiO_2(Al_2O_3)$–H_2SO_4–$(NH_4)_2SO_4$–H_2O were used to construct composition–property diagrams. The employed presentation technique can be conveniently used for technological purposes.

(2) In studying the salting-out process along a section of the system $TiO_2(Al_2O_3)$–H_2SO_4–$(NH_4)_2SO_4$–H_2O, the solution concentration range was established, in which the degrees of titanium(IV) and aluminum(II) precipitation are, respectively, 94–96 and 97–98%.

(3) A region with the optimal concentrations of free ammonium sulfate (280–400 g l^{-1}) and sulfuric acid (250–300 g l^{-1}) was chosen in the system under study, in which the technological process yields a tanning agent of required quality.

(4) Salting-out from sulfuric acid titanium–aluminum solutions yields, in addition to $(NH_4)_2TiO(SO_4)_2 \times H_2O$ and ammonium aluminum alum, a complex titanium–aluminum compound whose existence is confirmed by IR spectral and XPA data.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Geometric Photoisomerization of Chiral Platinum(II) Sulfoxide Compounds

V. N. Spevak, D. A. de Vekki, and N. K. Skvortsov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received January 17, 2001

Abstract—Photochemical behavior of platinum(II) sulfoxide-containing complexes in methyl chloride was studied by polarimetry and ^{1}H NMR spectroscopy.

Effective catalysts for hydrosilylation of unsaturated compounds [1, 2] and antitumor preparations [3] were found among platinum(II) aminosulfoxide compounds [Pt(RR'SOAmCl_2] (Am is amine; R and R' are Alk or Ar). Their catalytic properties and biological activity depend on the arrangement of ligands in the inner coordination spheres of Pt(II) square-planar complexes. For example, diamino derivatives are biologicaly active if they have *cis*-arrangement of neutral ligands, whereas in the case of [Pt(RR'SO)AmCl_2] the *trans*-isomer is the most active [3].

cis-Aminosulfoxide complexes appeared to be more active in catalytic hydrosilylation, and diamino coordination compounds were completely catalytically inactive in this reaction.

In this work, we made an attempt to study photoinduced isomerization of the complex [Pt(RR'SOAmCl_2]. The photoinduced effect is known [4–8] to change in some cases the geometry of certain coordination compounds, which may be useful for photoactivated catalytic hydrosilylation.

As subjects for this study we chose geometrical isomers of (–)[Pt(Me-*p*-TolSO)(Py)Cl_2], investigated earlier [9, 10] by X-ray diffraction analysis, ^{1}H and ^{13}C NMR and IR spectroscopy, and the method of optical rotation dispersion (ORD), enabled by the presence of a chiral sulfoxide. Along with NMR spectroscopy, the ORD method provides valuable information, for example, in analyzing the ligand exchange in platinum(II) coordination compounds [2, 11–13] or for determining kinetic and thermodynamic parameters of changes in the inner coordination sphere of complexes in solution [11].

Chiral sulfoxides in the complex compounds under consideration are coordinated via a sulfur atom {specific rotation of (–)*trans*-[Pt(Me-*p*-TolSO)(Py)Cl_2] measured in methyl chloride is –22° in contrast to –117° for the *cis*-isomer}, which makes it possible to readily monitor any processes involving a sulfoxide ligand in both the resulting geometrical isomers by means of polarimetry. In this case, the isolation of a free sulfoxide [specific rotation (+)Me-*p*-TolSO is +142°] results in a sharp change in the observed angle of rotation for the reaction mixture, to the point of a full inversion of the sign of rotation.

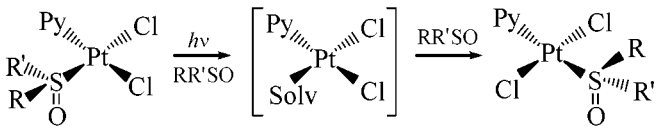
monstrated that platinum(II) *trans*-pyridinesulfoxide complexes are inert when irradiated with near UV light, whereas *cis*-compounds rather easily transform to *trans*-products (Figure, curve *1*). Prolonged photolysis of a solution of (–)*cis*-dichloropyridine-(methyl-*para*-tolylsulfoxide)platinum(II) in methylene chloride gives solely the chiral complex (–)*trans*-[Pt(Me-*p*-TolSO)(Py)Cl_2]. When the solvent is gradually removed, 100% conversion into the desired product is reached in 1.5 h.

Reverse slow dark isomerization of the *trans*-compound occurs in a toluene solution at higher temperature (boiling water bath, yield of the *cis*-complex in several days 15%). Thus, the quantitative photoisomerization is attributable in this case to the absence of a fast spontaneous interconversion of such compounds in uncoordinated solvents, in contrast to solutions in dimethyl sulfoxide [14], where isomerization is catalyzed by sulfoxide:

$$\textit{cis}\text{-[Pt(Me-}p\text{-TolSO)PyCl}_2\text{]} \underset{\Delta}{\overset{h\nu}{\rightleftarrows}} \textit{cis}\text{-[Pt(Me-}p\text{-TolSO)PyCl}_2\text{].}$$

Additional monitoring by the intensity of the ^{1}H NMR signal of the methyl group in *cis*- ($CDCl_3$; δ, ppm: 3.59 t, $J_{Pt–H}$ 23 Hz) and *trans*-complexes ($CDCl_3$; δ, ppm: 3.47 t, $J_{Pt–H}$ 20 Hz) demonstrated that, along with both the geometrical isomers, up to 1% uncoordinated (+)methyl-*para*-tolylsulfoxide ($CDCl_3$; δ, ppm: 2.70 s) is present in the reaction solution; the signal from this compound disappears upon complete conversion of the starting compound. The photolysis of such *cis*-complexes seems to give rise to dissociation of sulfoxide, leading to a coordinatively unsaturated intermediate, stabilized via formation of a thermodynamically unstable chiral *trans*-product, which is not photoactivated:



The photolysis of bissulfoxide complexes is known [8] to result also in *cis*- → *trans*-isomerizations; however, attempts to isolate the *trans*-product in pure state were unsuccessful. A study of the photochemical behavior of (–)*cis*-dichlorobis(methyl*para*-tolylsulfoxide)platinum(II) in methylene chloride {the specific rotation of (–)*cis*-[Pt(Me-*p*-TolSO)$_2Cl_2$] measured in acetone is –220°C [12]} demonstrated that side processes occur along with photoisomerization (figure, curve *2*). These are fast reverse dark isomerization (curve *3*), and, on prolonged photolysis (60 min and more), formation of colloidal platinum, which is not characteristic of pyridine-sulfoxide compounds.

This phenomenon can be explained on the basis of X-ray data [9, 10, 12]. For example, the length of the Pt–S bond is 2.214 Å in (–)*cis*-[Pt(Me-*p*-TolSO)-(Py)Cl_2] and 2.249 Å in (–)*cis*-[Pt(Me-*p*-TolSO)$_2Cl_2$] (length of the Pt–N bond in the pyridine-sulfoxide complex is 2.032 Å), which makes the isomerization and destruction of the metal complex easier and, therefore, is responsible for the high mobility of sulfoxide in platinum(II) bissulfoxide complexes.

The aforementioned researches show that platinum(II) pyridine-coordination compounds, catalyzing hydrosilylation, can be further photoactivated with the homogeneous metal-complex center preserved.

It is necessary to note in conclusion that the photolysis of optically active geometrical isomers of (–)[Pt(Me-*p*-TolSO)(Py)Cl_2] does not result in loss of chirality of both the complexes themselves and the coordinated sulfoxide, as opposed to the data of [15], indicating that free (+)Me-*p*-TolSO undergoes photoracemization. However, this process requires high-energy irradiation for several hours, whereas in our case the reaction occurs under mild conditions in the course of 1.5–2 h.

The whole set of the obtained data allows photoirradiation to be recommended as a method for synthesizing thermodynamically unstable Pt(II) sulfoxide *trans*-compounds, which at the same time do not isomerize spontaneously.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded in $CDCl_3$ on a Bruker AC-200 instrument with spectrum accumulation, operating at 200 MHz.

Optical rotation dispersion was measured on a Perkin Elmer 241MC polarimeter in methyl chloride in temperature-controlled quartz cells of length 10 cm in the range 450–610 nm. The concentration of the complex was varied in the range 1×10^{-4}–1×10^{-5} M.

The IR spectra were taken on a Perkin Elmer Spektrum-1000 spectrometer (4000–400 cm^{-1}) in chloroform, l = 0.135 mm, 1% solution; the FIR spectrum was recorded on a Hitachi FIS-3 spectrometer (400–100 cm^{-1}) in KBr pellets.

Photolysis of metal complexes was carried out in a polarimeter cell in methylene chloride solution under the action of broadband UV light (DRL-400 lamp, quartz or pyrex filter) passing through a water layer of 40 mm thickness.

Methylene chloride of "Merk" production was used in the experiments. (–)*cis*-Dichlorobis(methyl-*para*-tolylsulfoxide)platinum(II), potassium (–)trichloro-(methyl-*para*-tolylsulfoxide)platinite(II), and (+)methyl-*para*-tolylsulfoxide were obtained as described in, respectively, [12], [16], and [17].

(–)*cis*-Dichloropyridine(methyl-*para*-tolylsulfoxide)platinum(II). Potassium (–)trichloropyridineplatinite(II) (79.6 mg, i.e., 0.190 mmol) was dissolved in 4 ml of water in a beaker. Then 29.3 mg (0.190 mmol) of (+)methyl-*para*-tolylsulfoxide was added slowly with stirring. The reaction mixture was kept at room temperature for 1 day, then the resulting white flocculent precipitate was filtered off and dried in a thermostat at 50°C to give 85.6 mg (0.171 mmol, yield 90.4%) of (–)*cis*-[Pt(Me-*p*-TolSO)$PyCl_2$]. $[\alpha]_{589}$ = –117°C (5 g in 100 ml of CH_2Cl_2). ^{1}H NMR spectrum (δ, ppm): 2.46 s (3H, Ph–CH_3); 3.59 t ($J_{Pt–H}$ 23 Hz, 3H, S–CH_3); 7.30 t ($J_{Pt–H}$ 6 Hz, 2H, Py); 7.37 d ($J_{H–H}$ 8 Hz, 2H, Ph); 7.82 t ($J_{Pt–H}$ 15 Hz, 1H, Py); 7.96 d ($J_{H–H}$ 8 Hz, 2H, Ph); 8.61 t ($J_{Pt–H}$ 41 Hz, 1H, Py); 8.64 t ($J_{Pt–H}$ 40 Hz, 1H, Py). IR spectrum (cm^{-1}): ν(Py) 1612; δ (CH, Me) 1454; ν(S=O) 1150, 1116; δ(CH, Py) 1075, 1059; τ(Me) 970; δ(CH, Ph) 810. FIR spectrum (cm^{-1}): γ(CSO) 391; ν(Pt–Cl) 339, 324, 318; ν(Pt–Py) 277.

(–)*trans*-Dichloropyridine(methyl-*para*-tolylsulfoxide)platinum(II). Potassium (–)trichloro(methyl-*para*-tolylsulfoxide)platinite(II) (81.3 mg, i.e., 0.164 mmol) was dissolved in 3 ml of water in a beaker. Then 1 ml of 0.163 M aqueous solution of pyridine was added slowly with stirring at 15°C, which immediately resulted in the formation of a finely dispersed precipitate. The reaction mixture was stirred for 20 min more, then the precipitate was filtered off and dried in a thermostat at 50°C to give 72.7 mg (0.145 mmol, yield 88.6%) of the light yellow precipitate of (–)*trans*-[Pt(Me-*p*-TolSO)$PyCl_2$]. $[\alpha]_{589}$ = –22°C (5 g in 100 mls CH_2Cl_2). ^{1}H NMR spectrum (δ, ppm): 2.48 s (3H, Ph–CH_3), 3.47 t ($J_{Pt–H}$ 20 Hz, 3H, S–CH_3), 7.40 d ($J_{H–H}$ 8 Hz, 2H, Ph), 7.43 t ($J_{Pt–H}$ 18 Hz, 2H, Py), 7.88 t ($J_{Pt–H}$ 16 Hz, 1H, Py); 7.97 d ($J_{H–H}$ 8 Hz, 2H, Ph); 8.78 t ($J_{Pt–H}$ 33 Hz, 1H, Py), 8.81 t ($J_{Pt–H}$ 32 Hz, 1H, Py). IR spectrum (cm^{-1}): ν(Py) 1612; δ(CH, Me) 1455; ν(S=O) 1145, δ(CH, Py) 1077; τ(Me) 969; δ(CH, Ph) 813. FIR spectrum (cm^{-1}): ν(Pt–Cl) 353.

CONCLUSION

Irradiation of a solution of (–)*cis*-[Pt(Me-*p*-TolSO)$PyCl_2$] with broadband light results in the isomerization of the complex into the *trans*-complex, which is photochemically inert. Platinum(II) *cis*-bissulfoxide coordination compounds are more sensitive to irradiation, decomposing to colloidal platinum. Coordinated chiral sulfoxides in the systems under study are not racemated under the action of light. Thermal activation of (–)*trans*-[Pt(Me-*p*-TolSO)$PyCl_2$] leads to its conversion to the *cis*-form.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Solubility of Carbon in Sulfide Melts of the System Fe–Ni–S

L. B. Tsymbulov and L. Sh. Tsemekhman

Institut Gipronikel' OAO, St. Petersburg, Russia

Received February 20, 2001

Abstract—The solubility of carbon in iron-nickel sulfide melts at 1673 K was studied in the entire range of compositions of the Fe–FeS–Ni_3S_2–Ni tetragon. The boundaries of the stratification area were determined in this system upon its being saturated with carbon. Lines of carbon isosolubility are plotted in the tetragon field outside the stratification area.

To reduce oxides of non-ferrous metals, various carbon-containing materials are added to blends when nickel and cooper-nickel raw materials are smelted to produce a matte (an alloy of iron, copper, nickel and cobalt sulfides), with slag depleted of these non-ferrous metals. These manufacturing processes were described in detail in [1–7].

Carbon dissolves in the sulfide phase formed upon smelting. Its concentration is determined not only by the amount of a reducing agent added to a blend, but also by the content of sulfur in the matte, relative content of metal components in it, and temperature.

The available published data on the solubility of carbon in matte melts are extremely scarce and mainly concern the Fe–S system [8, 9].

The scantiness of the published data is related, on the one hand, to the absence, until recently, of reliable procedures for determining the carbon content in sulfide products with sufficiently high content of sulfur, and, on the other, to the conventional opinion that admixtures (of which the main are oxygen and carbon) insignificantly affect both the distribution of metals in a matte–slag system and the physicochemical processes occurring in further processing of the matte. However, a trend has appeared recently toward smelting to obtain mattes with greater metal content, which is known to make lower the loss of non-ferrous metals with slag [10].

It is natural to assume that the carbon content in such mattes will be higher, and, therefore, its effect will be stronger. Furthermore, data on carbon solubility can be also useful for gaining deeper insight into the structure of sulfide melts.

The initial object of our research was the system Fe–S–C [11]. It is known from the literature that it is characterized by separation into the sulfide and metallic phases [8, 9]. We confirmed this once more, our data on the carbon solubility in both phases being in good agreement with the data of [8]. This fact proved the correctness of the selected experimental technique, which was as follows.[1]

A 30-g portion of powdered iron, nickel, and sulfides of these metals was placed in a graphite crucible, and 5 g of graphite powder was poured above. The crucible with the blend was placed in an alundum reactor mounted in a furnace with a graphite heater. The reactor was heated to 1673 K in an argon atmosphere, and the melt was kept at this temperature for a specified time (this time was 5 h for stratifying compositions and 2 h for homogeneous melts). On completion of experiment, the crucible was taken out of the furnace and cooled in an argon flow. The thus cooled sample was analyzed for the content of iron, nickel, sulfur, and carbon.

The content of metals and sulfur in the sulfide phase was determined by chemical methods, that of sulfur and carbon in the metallic phase—on a CS-444 analyzer ("LECO" production), and that of carbon in the sulfide phase—on an analyzer of the same make but upgraded for determining the carbon content at high sulfur content. The inaccuracy of carbon determination in the sulfide phase was as follows (wt %): ±0.014 for concentrations 0.05–0.10, ±0.018 for 0.10–0.20, ±0.025 for 0.20–0.50, ±0.09 for 0.50–1.00,

[1] The experimental technique is described in more detail in [11].

and ±0.11 for 1.0–3.0. The inaccuracy of carbon determination in the metallic phase was ±0.015% for concentrations of 1.0–5.0 wt %.

The following stage of our work was to study the carbon solubility in the system Fe–Ni. The solubility of carbon in this system, both in the solid and in the molten states, has been repeatedly studied. Among the publications dedicated to the carbon solubility in Fe–Ni at temperatures close to our experimental temperature of 1673 K, [12–15] are noteworthy.

Figure 1 presents the results of various authors together with the data of the present work, which are in good agreement with [14]. The smaller solubility of carbon, reported in other publications, seems to result from a lower (by 50 K) temperature of the experiment.

Therefore, our data on the carbon solubility may well be considered reliable. Furthermore, they additionally confirm the reliability of the chosen experimental technique.

It is evident from Fig. 1 that all the authors have found that carbon is the least soluble in melts containing about 80 wt % nickel.

This phenomenon, which is abnormal at first sight, is also observed in studying the solubility of other components in Fe–Ni melts. For example, H.A. Wriedt and J. Chipman observed a minimum in the oxygen solubility at nickel content of about 90 wt % [13]. They attributed this minimum to an increase in the oxygen potential of the slag, enriched with nickel oxide when the nickel content in the alloy in contact with the slag is greater than 90 wt %, i.e., these authors were not inclined to see any anomalies in Fe–Ni alloys.

However, the reasoning on this problem in [15] seems to be the most convincing. The authors of this work studied the carbon solubility in Fe–Ni melts (Fig. 1) and came to a conclusion that the minimum in the solubility at nickel content of about 80 wt % is attributable to the existence of short-range order in the melts of $FeNi_3$ composition.

We started studying the carbon solubility in sulfide melts of the system Fe–Ni–S from the stratification area by adding various amounts of nickel to melts of the system Fe–FeS.

As a result, we determined the boundaries of the stratification area, shown in the Fe–FeS–Ni_3S_2–Ni diagram (Fig. 2). Compositions of the stratified phases are given in the table.

As already noted, melts of the system Fe–S separate into sulfide and metallic phases on addition of carbon. It is necessary to note that the separation takes place if the initial content of sulfide sulfur is in the range from 1.94 to 28.7 wt %.

The stratification results from positive deviations from ideality in the Fe–S system [16, 17]. The deviations increase upon addition of carbon, which points to mutual repulsion of carbon and sulfur atoms in the melt [18].

The following takes place upon addition of nickel to the system Fe–S. The increase in the nickel content in the metallic phase lowers the solubility of carbon in it and increases the solubility of sulfur. The content of sulfur in the sulfide phase is lowered correspondingly, i.e., it becomes more metallized, and, therefore, the solubility of carbon in it increases. Gradually, with increasing amount of added nickel, the metallized phase becomes more and more sul-

fidized, and the sulfide phase—more metallized. The contents of sulfur in these phases approach each other, and the melt becomes homogeneous at nickel concentrations greater than 25%.

To confirm the boundary of the stratification area at nickel content of about 25%, we replicated experiments nos. 9 and 11 with fast quenching of a melt. In these experiments, a melt was poured out onto a copper disk rotated at a speed of 25 000 rpm, which ensured a quenching rate of approximately 1000 deg s^{-1}. The quenched samples were studied by scanning electron microscopy and X-ray fluorescence microanalysis (Fig. 3).

The morphology of microstructures (Fig. 3) indicates beyond any doubt that the melt with the composition of experiment no. 11 is homogeneous (Fig. 3a), and the melt with the composition of experiment no. 9 consists of two phases arranged in layers on pouring the melt onto the disk. The boundary between the layers is well pronounced (Fig. 3b).

After determining the boundaries of the stratification area, we studied the solubility of carbon throughout the remaining range of compositions of the system Fe–FeS–Ni_3S_2–Ni. Using the obtained data, we plotted isosolubility lines of carbon (Fig. 2) on the phase diagram. The arrangement of these lines points to a rather complicated nature of the variation of the carbon concentration in this metal–sulfide system.

The minimum carbon solubility in metallic melts, at nickel concentration of about 80%, also takes place in strongly metallized mattes containing up to 15% sulfur (Fig. 2). It is necessary to note that the minimum is somewhat shifted to greater Ni : Fe ratios with increasing content of sulfur. This fact agrees well with the data of Vaisburd [16] on the system Fe–Ni–S. Examining the activity of components in melts of

Note: Iron content was determined as difference.

the system Fe–Ni–S, Vaisburd concluded that, in the melt, the bonds of nickel with sulfur are stronger than those of iron. It follows from his theory of microheterogeneous structure of sulfide melts that nickel in a melt is predominantly surrounded by sulfur, and iron is concentrated in more metallized areas. Therefore, if sulfur is added to a metal alloy with Ni : Fe ratio of 80 : 20, this ratio will be less than 80 : 20 in metallized microareas of the sulfide melt (where, most likely, the main body of carbon dissolves). Such a ratio of metal contents will also take place in melts lying to the right of the line connecting the 80 : 20 Ni–Fe alloy with the vertex corresponding to pure sulfur (Fig. 2).

The next feature of the solubility of carbon in metal-sulfide melts of the system Fe–FeS–Ni_3S_2–Ni is

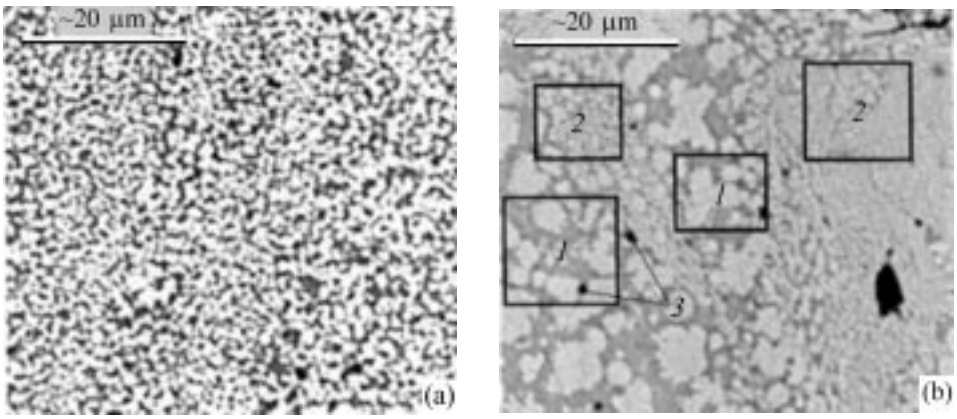

Fig. 3. Microstructures of (a) homogeneous sulfide melt saturated with carbon and (b) melt separated into sulfide and metallic phases. Quenching on a fast-rotating copper disk. (*1*) Sulfide phase, (*2*) metallic phase, and (*3*) carbon precipitated upon crystallization.

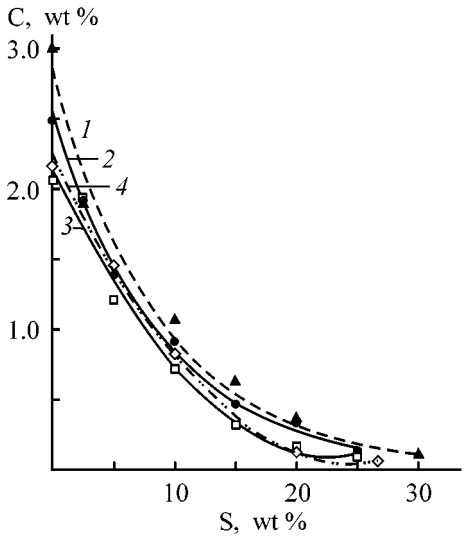

Fig. 4. Solubility of carbon C vs. the content of sulfur in a melt, S, at 1673 K. Fe : Ni ratio: (*1*) 50 : 50, (*2*) 40 : 60, (*3*) 10 : 90, and (*4*) 0 : 100.

its nonlinear change upon addition of sulfur to the metallic melt (Fig. 4). It is evident from the plots that the solubility of carbon sharply decreases upon addition of minor amounts of sulfur, with its decrease becoming insignificant further.

The irregular change in the solubility of carbon is attributable to the change in the nature of bonds in the melt from metallic to ionic-covalent on addition of sulfur to the metallic melt [19, 20].

The authors of [20] came to a conclusion that sulfur atoms form multicenter ionic-covalent bonds with metals. Therefore, addition of even minor amounts of sulfur results in a rather sharp decrease in the number of metal–metal bonds, which seems to be responsible for the dependences given in Fig. 4.

We point out that the initial decrease in the solubility is sharper for melts with large content of iron. This is attributable to the difference in electronic configuration between iron and nickel atoms. Iron has two electrons less than nickel on its *d*-level, and, therefore, it involves a greater number of centers participating in the formation of multicentered metal–sulfur bonds [20].

It is also necessary to pay attention to a number of carbon solubility maxima at high concentrations of sulfur and Fe : Ni = 70 : 30 (Fig. 2).

The increase in the carbon concentration with growing content of iron in a melt (at constant content of sulfur) in the region of compositions to the right from the maxima is quite natural, since the metal–metal groups are also enriched in iron dissolving a greater amount of carbon than nickel does.

At the same time, with the content of iron in a melt increasing at constant content of sulfur, the number of multicentered ion-covalent bonds between metal and sulfur grows, because iron forms a greater number of such bonds, compared with nickel. Certainly, this should result in decreasing solubility of carbon.

The presence of two opposite tendencies seems to be the reason for the occurrence of maxima in the isosolubility lines.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Modeling of Thermodynamic Properties of Liquid Alloys in the System Magnesium–Tin

A. G. Morachavskii and K. B. Erofeev

St. Petersburg State Technical University, St. Petersburg, Russia

Received April 3, 2001

Abstract—The results obtained in studying experimentally the thermodynamic properties of liquid alloys in the system magnesium–tin are analyzed. The concentration dependences of the excess molar Gibbs energy and the enthalpy of mixing of the magnesium–tin system in the liquid state are described in terms of the ideal and regular solution models, using modified software.

The phase diagram of the system magnesium–tin is characterized by the formation of only a single congruently melting compound Mg_2Sn (mp 1043.7 K) forming eutectic mixtures both with magnesium (mp 834.4 K, $x_{Sn} = 0.107$, x_{Sn} is the mole fraction of tin in the alloy) and tin (mp 505.0 K, $x_{Sn} = 0.904$) [1, 2].

The thermodynamic properties of liquid alloys of the system Mg–Sn have been repeatedly studied by various methods [3–13]. These include measuring the saturated vapor pressure under isopiestic conditions [3, 6] and the emf in concentration cells with liquid electrolyte [4, 7, 10–13], the emf method with CaF_2 solid electrolyte [9], quantitative thermography [8], high-temperature calorimetry of mixing [10], and calculations based on the phase diagram [5]. The isotherms of component activity in the system show significant negative deviations from the ideal behavior, the enthalpy of mixing is negative, with its minimum value close to a composition corresponding to Mg_2Sn. The agreement between the data obtained in different studies can be assessed by considering a number of examples. According to the first systematic study of thermodynamic properties of the Mg–Sn liquid alloys (773–1123 K, $0.10 \le x_{Mg} \le 0.90$, x_{Mg} is the mole fraction of magnesium in the alloy), the maximum enthalpy of mixing, as obtained by the emf method, is –14.06 kJ mol^{-1} over the given temperature range [4]. In the same range of compositions, calorimetric measurements [11] yield the following ΔH values (kJ mol^{-1}): –14.8 (1073 K), –14.3 (1133 K), and –13.4 (1213 K), in sufficiently good agreement with the results of [4]. According to the data of [7], the minimum value of ΔH in the temperature range 973–1173 K is –14.31 kJ mol^{-1}.

Mozer *et al.* [13] pointed to a good agreement between the partial molar Gibbs energies of magnesium, ΔG_{Mg}, obtained in [4, 6, 7, 9–13] at comparable temperatures. Only the activity coefficients of magnesium and tin obtained in [8] are markedly different from the results of other researchers. All these circumstances make the system Mg–Sn a convenient object for verifying the reliability of various models or polynomial expressions for describing the dependence of the thermodynamic functions on concentration.

The interaction in liquid alloys of the system Mg–Sn was analyzed in detail in terms of the associated solution models in [14–25]. The model of the ideal associated solution requires taking into account both the compound Mg_2Sn and the product of its partial dissociation, MgSn. With the model of the regular associated solution, it suffices to take into account only the compound Mg_2Sn.

Eckert *et al.* [17] proposed a somewhat different approach to determining the composition of associates in liquid alloys of magnesium with tin. Based on the similarity of properties of the systems Mg–Sn and Ca–Sn, the authors postulated for liquid magnesium–tin alloys the existence of three associates (Mg_2Sn, MgSn, and $MgSn_3$), for which the following constants: 306.4, 41.3, and 84.7, respectively, were found at 1073 K. In this approach, too, Mg_2Sn remains the dominating associate. Only the compound Mg_2Sn is revealed in the curve describing the dependence of the structural factor on composition for magnesium–tin liquid alloys [14].

Note: [11], [12], and [18] are references from which experimental data were taken. IAS and RAS stand for the results of approximation in terms of ideal and regular associated solution models, respectively.

The dissociation of the complex via the pathway $Mg_2Sn \rightleftarrows 2Mg + Sn$ at 1073 K was described in terms of the regular associated solution model in [18]. The K_{dis} value is 0.0854, and the characteristic parameters of the model, ω_{12}, ω_{13}, and ω_{23}, are equal to (kJ mol^{-1}): –35.33, –53.44, and –63.61, respectively. The enthalpy of complex formation is –22.76 kJ mol^{-1}.

Sommer [19, 20] described, using the equations of the regular associated solution model, the excess heat capacity and the enthalpy of mixing of the magnesium–tin liquid alloys as functions of temperature. As follows from the ΔH^0 and ΔS^0 values reported by the author for the associate Mg_2Sn at 1073 K, the equilibrium constant of compound formation from pure components is 329.8. It should be noted that in [19, 20] the energies of interaction of pure components with the associate were assumed to be zero.

In [21], the possibility of extrapolating the thermodynamic data on liquid alloys to lower temperature was discussed and a new model of chemical interaction between the components was proposed. According to the data obtained by the authors, the degree of association near the composition Mg_2Sn is higher than that reported in earlier studies. In [26], the dependences of the enthalpy of mixing on temperature and composition were described in terms of algebraic polynomials.

Analysis of the literature suggests that, despite the fact that the polynomial dependences based on associated solution models describe experimental data satisfactorily in all the works cited, the sets of constants playing the role of fitting parameters are different. To determine the parameters of the associate models used to describe the concentration dependence of the thermodynamic functions of liquid metal systems with strong interaction between the components, thermodynamic properties of a model system, magnesium–tin, at 1073 K are described here, using the most reliable experimental data. For this purpose we

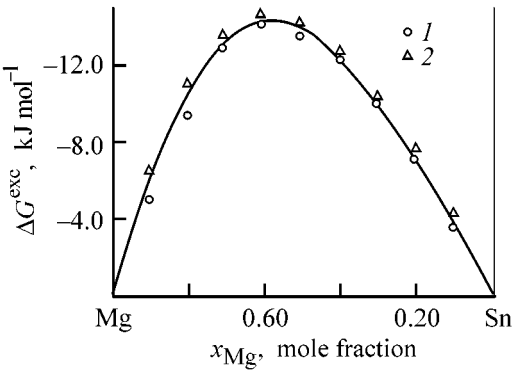

Fig. 1. Integral molar excess Gibbs energy ΔG^{exc} vs. composition x_{Mg} for the magnesium–tin system at 1073 K. Reference: (*1*) [12] and (*2*) [18].

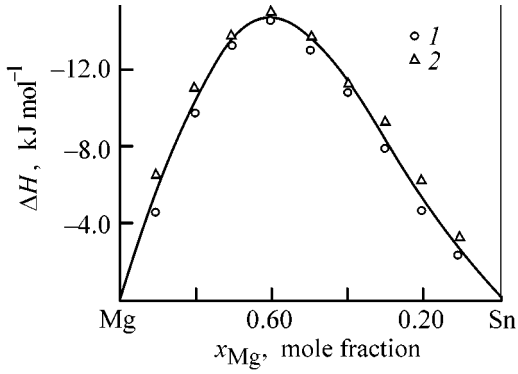

Fig. 2. Integral molar enthalpy of mixing ΔH, vs. composition x_{Mg} for the system magnesium–tin at 1073 K. Reference: (*1*) [11] and (*2*) [18].

used modified software whose main parameters were described previously in [27]. The calculations were done using the ΔG^{exc} value obtained by the emf method in [12], ΔH obtained calorimetrically in [11], and ΔG^{exc} and ΔH taken in modeling the Mg–Sn system in [18]. The input data and the results of approximation are given in the table. The maximum in the concentration dependences of ΔG^{exc} and ΔH at 1073 K (Figs. 1, 2) is shifted somewhat from the composition Mg_2Sn (x_{Mg} = 0.667) toward the tin-richer region (x_{Mg} of about 0.60).

In applying the model of an ideal associated solution in this study, the formation of the Mg_2Sn and MgSn groups in liquid alloys was taken into account. To compare the calculation results for the dependences $\Delta G^{exc} = f(x_{Mg})$ and $\Delta H = f(x_{Mg})$, we used the formation constants of both the associates. In the case of the model of a regular associated solution, the formation of only a single compound, Mg_2Sn, was taken into account. The following values of the formation constants at 1073 K were obtained by processing the above data in terms of both the models:

Input data	Ideal solution model		Regular solution model
	K_{Mg_2Sn}	K_{MgSn}	K_{Mg_2Sn}
ΔG^{exc} [12]	261.0	65.3	237.0
ΔG^{exc} [18]	252.8	53.9	249.7
ΔH [11]	263.0	55.2	239.0
ΔH [18]	254.0	55.6	250.3

The associate formation constants determined with different input data agree sufficiently well with one another and with the results of other authors [11, 12, 14, 22]. This confirms the applicability of the associated solution models for describing the concentration dependence of thermodynamic functions in the Mg–Sn system, the objectivity of the assessment of the complexation processes in it, and the reliability of the employed software.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Comparative Analysis of Open Evaporation and Pervaporation in the Ternary System Water–Ethanol–Isopropanol

A. M. Toikka, E. L. Aksenova, and Yu. P. Kuznetsov

St. Petersburg State University, St. Petersburg, Russia
Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received April 24, 2000; in final form, February 2001

Abstract—A comparative analysis is made of pervaporation and equilibrium open evaporation. The possibilities are considered of using data on the liquid–vapor equilibrium for analyzing the pervaporation process. Some specific features of the structure of diagrams for pervaporation and open evaporation of a ternary system are discussed for the example of the water–ethanol–isopropanol system.

The interest in membrane separation processes is largely associated with technological issues. In particular, the efficiency of pervaporation–evaporation through a membrane, compared with distillation, initiated quite a number of studies aimed to search for highly selective high-throughput membranes. Theoretical investigations in this field include analysis of the mechanisms of the process and its modeling [1–6]. At the same time, such traditional problem of thermodynamics as the topology of diagrams has been little studied. The present communication discusses some aspects of the thermodynamic approach and makes a comparative analysis of pervaporation and distillation in a ternary system.

Let us compare of the equilibrium open evaporation and the evaporation through a membrane. As in the case of equilibrium evaporation, the pervaporation process is described by balance equations of the type

$$\frac{\mathrm{d}x_i^{(1)}}{\mathrm{d}\ln m^{(1)}} = x_i^{(2)} - x_i^{(1)} \quad (i = 1, 2, ..., n), \qquad (1)$$

where $x_i^{(1)}$ and $x_i^{(2)}$ are the concentrations (mole or weight fraction) of i-th substance in the feed liquid mixture and in the permeate (vapor); $m^{(1)}$ is the amount of liquid phase (moles or kg); and n is the number of substances.

Equations (1) allow calculation of the permeate composition or verification of the relation between the solution and permeate compositions and the amount of evaporated solution.

The use of Eqs. (1) is limited to the following: in most of experiments the solution composition is maintained constant by means of the flow of the feed mixture, and the system as a whole is in a steady state. At constant composition, it is convenient to determine the separation or enrichment factor and the flux at a given solution concentration. At the same time, in solving practical problems, e.g., substance purification by pervaporation, information is necessary on composition changes in the retentate (liquid outflowing from the membrane unit). A typical process of this kind is the dehydration of organic solvents [2], which, in contrast to conventional rectification, enables separation of azeotropic mixtures. According to [7], at manufacture rates not exceeding 5000 $\mathrm{l\,h^{-1}}$, pervaporation is undoubtedly preferable in economical regard, too. In laboratory practice, changes in composition are possible when installations are used operating in a nonstationary mode, in the absence of feed flow. To a shift of composition corresponds a trajectory in an $(n - 1)$-dimensional concentration space described by equations of the type

$$\left(\frac{\mathrm{d}x_i}{\mathrm{d}x_n}\right)^{(1)} = \frac{x_i^{(2)} - x_i^{(1)}}{x_n^{(2)} - x_n^{(1)}} \quad (i = 1, 2, ..., n - 1). \qquad (2)$$

It should be noted that relations (1) and (2) are merely mass balance equations and, strictly speaking, are not thermodynamic.

Even though the theory of pervaporation relies upon notions closely related to the theory of liquid–

1070-4272/01/7406-0933 $25.00 © 2001 MAIK "Nauka/Interperiodica"

vapor equilibrium (e.g., that of the separation factor α analogous to the relative volatility), the thermodynamics of pervaporation cannot be constructed on the basis of the equilibrium theory. For example, the pervaporation diagrams may have points corresponding to the condition $x_i^{(1)} = x_i^{(2)}$, or $\alpha = 1$ ("permazeotropic point"), but this circumstance is not related to pressure or temperature extremum conditions, as in the case of equilibrium phases. At the same time, data on the liquid–vapor equilibrium are necessary for determining the thermodynamic characteristics of the feed mixture and permeate, in particular, the chemical potentials.

Commonly, it is mentioned that the chemical potential gradients $\nabla\mu_i$ are the driving force of the transfer across a membrane [1–4]. This corresponds to the notions of flows and forces in nonequilibrium thermodynamics (diffusion vectors J_i and gradients of chemical potentials). However, the theory of pervaporation is based, as also the majority of diffusion studies, not on the phenomenological Onsager equations, but on Fick laws relating the mass flux to concentration gradients ∇c_i, rather than to $\nabla\mu_i$. This leads to analysis of problems concerning the dependence of the diffusion coefficients on composition along the membrane profile. In the case of pervaporation, this dependence can be calculated, e.g., in terms of the known Rautenbach–Albrecht model [8].

When written correctly, the phenomenological equations of thermodynamics must include as forces $\nabla\mu_i$, rather than ∇c_i. Then the relation between the fluxes and forces is represented as the dependence of the component transfer rates on the gradients of chemical potentials and pressure:

$$J_i = J(\nabla\mu_1, \nabla\mu_2, ..., \nabla P).$$

The corresponding phenomenological equations make it possible to obtain the relations for fluxes across the membrane in terms of linear nonequilibrium thermodynamics, with the ratios of the transfer rates of different components directly characterizing the selectivity. At the same time, it should be noted that these quantities—fluxes and selectivity, are the parameters commonly determined in experiment. Therefore, an alternative (recursion) form of the equations, defining the thermodynamic forces as functions of fluxes, can also be effective in describing the pervaporation. In both cases, data on the liquid–vapor equilibrium can be used for verification and correlation.

Data on the liquid–vapor equilibrium allow calculation of the component activities a_i (and also μ_i) in the feed mixture. However, determining the a_i values in the permeate requires refining of the very notion "permeate." Since separation occurs in the case of pervaporation only within the membrane (dissolution–diffusion) and on its surfaces (sorption–desorption), the aggregative state of substances cannot be unambiguously determined even in the final stage (desorption). However, it is for this stage (for already separated substances) that the activities should be determined in calculating the driving force. It is noteworthy that vaporization is in fact only permeate sampling.

If the following conditions are met in the final stage: (a) the aggregative state corresponds to a liquid, (b) the entire amount of liquid is vaporized, and (c) the interaction with the membrane surface has no effect on the activity coefficients, then the activities can be calculated from data on the liquid–vapor equilibrium. On the assumption of vapor ideality and possibility of neglecting the effect of pressure P on μ_i in the liquid, the a_i and μ_i values are calculated by

$$a_i = \frac{Px_i^{(2)}}{P_i^0}, \quad \mu_i^{(1)} = \mu_i^0(T, P) + RT\ln a_i, \qquad (3)$$

where $x_i^{(2)}$ and P are determined from data on the equilibrium with the solution whose composition $x_i^{(1)}$ is the same as that of the permeate, P_i^0 is the vapor pressure of i-th pure component at a given temperature T, and $\mu_i^0(T, P)$ is the standard chemical potential.

If, however, the separated substance is in the vapor state at the membrane surface, then the μ_i^0 values in the permeate are to be found using the formula

$$\mu_i^{(2)} = \mu_i^0(T) + RT\ln p_i, \qquad (4)$$

where $p_i = Px_i^{(2)}$ is the partial pressure of i-th component.

In this case, the driving force of the transmembrane transfer of a component is determined not only by the composition of the solution and permeate, but also by pressure, with its value not corresponding to the condensation pressure, as in the case of formula (3). The P value may correspond to the permeate pressure, as indicated indirectly by data on the pressure dependence of selectivity [4]. At the same time, such an interpretation of formula (4) seems to be ambiguous if, as already mentioned, the created rarefaction serves for permeate sampling—this must have no effect on its composition A similar situation occurs in equilibrium evaporation: the rate of the process

has no effect on the vapor composition. The evaporation rate may exceed by hundreds of times the rate of diffusion of the forming vapor through the gas layer adjacent to the surface [9]. Therefore, diffusion is the rate-determining stage of the process. In the case of vapor removal (rarefaction, flux), the evaporation rate grows, but this does not affect the composition.

Relations (1) and (2) can serve as a basis for a thermodynamic-topological analysis of the pervaporation diagrams, as also equations describing the open evaporation curves can be used for analyzing the liquid–vapor equilibrium diagrams. Let us consider the results obtained in an experimental study of pervaporation in the water–ethanol–isopropanol ternary system at 303.15 K. The method used for experimental study of pervaporation in ternary and binary systems was described in [10]. It is noteworthy that the type of membrane was chosen so that the experimental conditions should be reproducible, which is, in the first place, determined by the insignificant change in the properties of the membrane in the course of experiments. The selectivity was unimportant for the present investigation; in studying the entire range of compositions in the concentration triangle, one could expect occurrence of not only a quantitative, but also a fundamental change in how the enrichment factor depends on concentration. The composite membrane made of SILAR-M polymer (polyacrylatesiloxane on polysulfoneamide/phenylone substrate), used in the study, shows organophilic behavior in ethanol–water solutions up to ethanol concentration of 0.65 (mol fraction). With increasing content of ethanol, the membrane mainly passes water, i.e., exhibits organophobic properties (Table 1). It should also be noted that no direct experimental study of pervaporation in the ethanol–isopropanol system was performed in the present investigation because of the high hygroscopicity of ethanol, requiring special experimental conditions. In data processing and discussion, "ternary" data were extrapolated to zero water concentration; the obtained results were used as "binary" data in analyzing the pervaporation diagrams.

Table 2 lists the differences (gradients) of the chemical potentials of the components, calculated using formula (3) for 36 compositions of ternary feed solutions and permeate and also the fluxes J across the membrane.

Despite the quite natural correlation between the differences of the component concentrations in the permeate and feed mixture, on the one hand, and differences of the chemical potential, $\nabla\mu_i$ (having the same sign in most cases), the quantities $\nabla\mu_i$ cannot be substituted in the linear relations (phenomenological equations of nonequilibrium thermodynamics) as thermodynamic forces related to substance fluxes. This would lead to a fundamentally erroneous result: the direction of the flow across the membrane would correspond to permeate transfer into the feed solution.

Table 1. Experimental data on pervaporation in the ethanol–water and isopropanol–water systems (Feed solution temperature 303.15 K, permeate pressure 15 mm Hg)

Ethanol, mol %		Isopropanol, mol %	
feed mixture	permeate	feed mixture	permeate
2.0	14.2	10.0	30.8
7.0	31.5	20.0	39.5
10.0	33.0	30.0	43.2
20.0	47.0	40.0	47.9
25.0	49.3	50.0	58.4
30.0	52.4	60.0	62.0
40.0	57.6	70.0	65.2
50.0	61.4	80.0	72.7
60.0	67.0	90.0	87.1
70.0	70.1		
80.0	80.0		
89.4	87.8		

If, however, the thermodynamic forces are defined on the basis of the component activities in the permeate, with account of the pressure at the back side of the membrane (0–20 mm Hg), then, by virtue of the low P values, $\mu_i^p \to -\infty$. In this case the corresponding differences of the chemical potentials are approximately the same. This gives no way of evaluating even the relative fluxes of different substances across the membrane. At the same time, data on $\nabla\mu_i$ (Table 2) enable characterization of the departure of the system from the equilibrium liquid–vapor state ($\nabla\mu_i = 0$). The J values (Table 2) indicate that the fluxes grow somewhat with increasing total content of alcohols in water.

The positions of the points representing the compositions of the starting solutions and the corresponding permeate compositions are shown in the concentration triangle in Fig. 1. The arrow-heads of the lines connecting these compositions are directed toward the points representing the feed solution compositions. Also presented are some solution–permeate tie lines for binary systems. The arrangement of the tie lines (feed mixture–permeate) corresponds to the direction

* Flux not determined for a given composition.

of run of the curves for pervaporation in the ternary system, describing the shift of the solution composition in the course of pervaporation. The direction of the process is shown schematically in Fig. 2.

One of characteristic features of the structure of the pervaporation diagram is the presence of a triple point at which the permeate and the feed mixture have the same composition. This is indicated by the arrangement and direction of the solution–permeate tie lines. Such a phenomenon has been observed previously in experimental studies of pervaporation in binary systems [11] in which this point was named permazeotropic (by analogy with azeotrope). An analysis of the literature demonstrated that a diagram with a triple permazeotropic point was obtained for the first time in the present study.

The curves in question are similar to those of open evaporation, with the direction of the process indicated by the arrangement of liquid–vapor nodes. Since no direct experimental data on the liquid–vapor equilibrium can be found in the literature for the given system at 303.15 K, the equilibrium was calculated

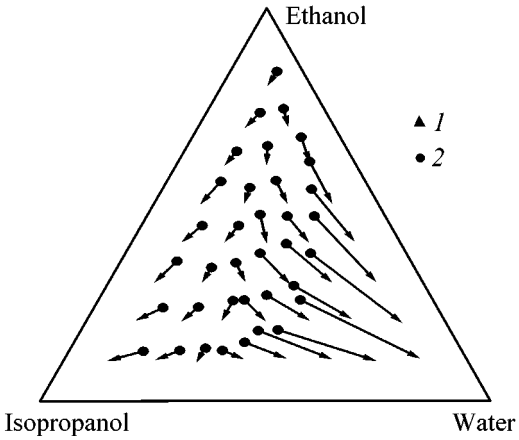

Fig. 4. Liquid–vapor nodes in the ternary system water–ethanol–isopropanol at 303.15 K (calculation by the NRTL equation). Points: (*1*) liquid compositions (lying at nodes of the coordinate grid of the composition triangle), (*2*) vapor compositions.

in the present study by means of the NRTL equation which, as a rule, adequately describes systems of this kind. The equilibrium in the system ethanol–isopropanol was calculated on the assumption that the given binary system exhibits ideal behavior. The isotherms-isobars of the solution, nodes, and a schematic diagram of open evaporation are presented in Figs. 3–5. At 303.15 K the ternary system has only a single (binary) azeotropic point (water–isopropanol); according to a reference book [12], there is no azeotrope in the water–ethanol system at the given temperature. The arrangement of liquid–vapor nodes is strongly different from the corresponding tie lines in the case of the pervaporation diagram.

Comparison of the diagrams in Figs. 2 and 5 shows that they belong to fundamentally different topological types. The pervaporation diagram includes two double and one triple singular points. The diagram of open evaporation includes only one double singular point and belongs to class 3.1.0, type 2 by Serafimov's classification.

To conclude, it should be noted that the behavior of the pervaporation curves in the vicinity of singular points requires additional theoretical analysis, which may be complicated (compared with the case of equilibrium open evaporation) by the lack of equilibrium between the solution and permeate. Correspondingly, the existence is possible of topological types of diagrams thermodynamically forbidden in the case of a liquid–vapor equilibrium. These problems invite separate investigation with the use of methods of nonequilibrium thermodynamics.

CONCLUSION

Experimental data are presented on the process of pervaporation in the ternary system water–ethanol–isopropanol at 303.15 K. The possibilities are considered of using data on the liquid–vapor equilibrium in studying the pervaporation. Comparative analysis of the diagrams of open evaporation and pervaporation shows the existence of a triple permazeotropic point.

Institute for Problems of Chemical Physics, Russian Academy of Sciences, Chernogolovka, Moscow oblast, Russia

Received July 5, 1999; in final form, May 2000

Abstract—A thermodynamic analysis of the burning temperatures and products formed in combustion of formulations containing zinc or lead was made in relation to the elemental composition and total enthalpy of formation of the starting mixture in order to develop programs searching in the existing database for such formulations whose combustion will produce a prescribed fraction of a metal in gaseous state.

A study of the thermodynamics of combustion of metal-containing solid rocket propellants and blasting powders demonstrated that, under certain conditions, the combustion products contain much more than trace amounts of gaseous metals even in the case of aluminum—an element with high affinity for oxygen. When the energetics of blasting powders and rocket propellants is discussed, presence of gaseous metals in products of their combustion is highly undesirable, but this phenomenon may prove rather useful in a totally different field—in developing special fast-burning formulations aimed to deposit metal coatings or create surface layers doped with specially selected metals. This way to create a gas flow of metal could find application for resolving a number of technological problems, similarly to the known technique in which the reaction of acetylene combustion in oxygen is the source of energy and the concurrent gas flow, and a wire or plate, the source of metal [1].

In developing metal-containing combustible formulations—sources of a high-temperature flow of metal vapor, it is necessary to achieve a combustion temperature sufficient for the metal to be in the gas phase and the equilibria

$$M_xO_y + CO \rightleftarrows M + CO_2, \quad \text{(a)}$$

$$M_xO_y + H_2 \rightleftarrows M + H_2O \quad \text{(b)}$$

to be shifted to the right. In addition, the share of oxygen (or, more precisely, the ratio of the amount of oxygen to the total amount of carbon and hydrogen) in a formulation should not be too high in order that the equilibrium of the reaction $CO_2 + H_2O \rightleftarrows H_2 + CO + O_2$ and, consequently, that of reactions (a) and (b) be strongly shifted to the right. At the same time, the share of oxygen should be sufficient for achieving a combustion heat that is necessary for combustion products to be heated to temperatures ensuring a high fraction of evaporated metal. Therefore, it is apparent that it is immeasurably easier to solve the given problem for metals with high volatility and low chemical activity, e.g., cadmium, compared with more active and higher-boiling metals, e.g., aluminum and chromium. To achieve a relatively high share of gaseous aluminum, it is necessary to use rather specific components, as discussed below, whereas the share of gaseous cadmium (relative to its total content) in combustion products of even the simplest combustible mixture containing 23% cadmium oxide + 8% polyethylene + ammonium nitrate is close to 100%, despite that metal oxide, rather than free metal, is contained in the formulation. In the combustion of a mixture of the above composition (here, a mixture of ammonium nitrate and saturated hydrocarbons is meant) with zinc or lead, the temperature sufficient for lead evaporation is not reached and lead is liberated in liquid state. The combustion temperature reached in the case of zinc is sufficient for its complete evaporation, but insufficient for shifting the equilibria $Zn + CO_2 \rightleftarrows ZnO + CO$, $Zn + H_2O \rightleftarrows ZnO + H_2$, and even $Zn + CO \rightleftarrows ZnO + C$ to the left because of the higher activity of zinc, with mainly zinc oxide formed as a result.

The present study was devoted to a detailed analysis of formulations with zinc and lead, i.e., metals whose physical and chemical properties conform to

1070-4272/01/7406-0939 $25.00 © 2001 MAIK "Nauka/Interperiodica"

the greatest extent to the purposes of development of combustible formulations—sources of a high-temperature flow of metal vapor.

EXPERIMENTAL

As model compositions were considered metal (20 wt %) + C + H + N + O system with widely varied overall enthalpy of formation and relative contents of C, H, N, and O in the organic part of formulations. To determine the chemical composition of a formulation, the following parameters were introduced: $R_1 = (O - C)/(C + 0.5H)$ and $R_2 = 2C/(2C + 0.5H)$, where O, C, and H are the atomic compositions in a formulation, and N_p is the mass fraction of nitrogen.

The R_2 value determines the share of carbon in the sum of carbon and hydrogen (g-equiv). Of interest in the context of the formulated problem are only those formulations in which the content of oxygen is not lower than that necessary to oxidize the entire amount of carbon to CO and not higher than that necessary for complete oxidation of carbon and hydrogen to CO_2 and water (making R_1 higher than unity does not lead to any increase in the combustion heat of the components C, H, N, and O, with the probability of oxidation of free metal by excess oxygen increasing dramatically). In this connection, compositions with R_1 equal to 0, 0.2, 0.4, 0.6, and 0.8 were studied, with the lowest value corresponding to an amount of oxygen strictly equivalent to that of carbon, and the highest is somewhat lower than the amount of oxygen necessary for complete oxidation of carbon and hydrogen. The R_2 values were 0, 0.5, 0.67, 0.8, 0.89, 0.95, and 1.0 (which approximately corresponds to C : H atomic ratios of 0 : 1, 1 : 4, 1 : 2, 1 : 1, 2 : 1, 4 : 1, 1 : 0). The N_p value was in the range from 0 to 0.4 with a step of 0.1 (i.e., from 0 to 40 wt % in a composition). At known metal content, these three quantities (R_1, R_2, and N_p) uniquely determine the elemental composition of a formulation.

Calculation requires setting additionally the enthalpy of formulation formation, ΔH_f^0. This parameter was varied between –750 and +750 kcal kg^{-1} with a step of 250 kcal kg^{-1}. Thus, the chosen interval covers virtually any conceivable formulations with preset limitations on the R_1 value. All thermodynamic studies for calculating the temperatures T_c (K) in the combustion chamber and T_a (K) at the nozzle exit and the product composition were done on Pentium-133 PC with standard software Astra-4 [2] at preset pressures in the chamber and at the nozzle exit of, respectively, 1 MPa (10 atm) and 0.1 MPa (atmospheric). The process of combustion product expansion through the nozzle was considered to be isoentropic.

For each of the metals under study, a thermodynamic calculation of an array of more than 1200 compositions (7 ΔH_f^0 values, 7 R_2 values, 5 R_1 values, and 5 N_p values) gave the temperatures and shares of gaseous metal in the chamber and at the nozzle exit. The difference of temperatures and product concentrations in the chamber and at the nozzle exit depends on the nozzle shape, being the largest for the so-called Laval nozzle in which the maximum fraction of the energy of the chemical reaction is converted into mechanical work. With account of a practical application of the present study (possibility of surface coating with metal present in gaseous state in combustion products of a combustible formulation and condensed from the gas phase directly on a surface being treated), a case is deliberately considered, which is the least favorable as regards the content of gaseous metal at the nozzle exit, namely, the expansion of combustion products in the Laval nozzle, i.e., isoentropic expansion. Mainly the dependence of the fraction of gaseous metal at the nozzle exit, rather than in the combustion chamber, is analyzed.

It should be noted that in the case of zinc the main metal-containing combustion products are condensed zinc oxide and gaseous zinc and other gaseous compounds, e.g., ZnH. Gaseous zinc oxides are present in trace amounts, and condensed (liquid) zinc, only at a very low temperature at the nozzle exit. In the case of lead, a condensed metal is present, together with gaseous Pb and Pb_2 (the fraction of Pb_2 does not exceed 1% of Pb), condensed and gaseous PbO, and gaseous Pb_2O_2, PbO_2, and PbH (the fraction of the last three is very low).

Thus, a practical task is to be set, concerning the development of compositions with a combustion temperature sufficiently high for a free metal to be present in the gas phase having such a composition that the overwhelming fraction of the metal be ejected in the form of a gas (Zn, Pb_x), producing the minimum amount of condensed compounds. The obtained data were analyzed as a dependence of T_c, T_a, and [Me(g)] on ΔH_f^0, R_1, R_2, and N_p, characterizing a combustible formulation. $[Me(g)]_c$ and $[Me(g)]_a$ are the atomic fractions of gaseous free metal in the combustion products, related to, respectively, the total initial amount of metal in the combustion chamber and at the nozzle exit.

The main relationships were analyzed for the example of zinc-containing formulations. Naturally,

an increase in ΔH_f^0 (Figs. 1a and 1b) or decrease in N_p leads to higher T_c and T_a. In this case, the $\partial T_c/\partial \Delta H_f^0$ value is negative because of the progressively deep extent of H_2O and CO_2 dissociation with increasing T_c and T_a. An increase in the oxygen balance R_1 within the interval studied leads to higher combustion heat and, consequently, higher T_c and T_a (Fig. 2). The $\partial T_c/\partial R_1$ value is also negative for the same reason as $\partial T_c/\partial H_f^0$. Variation of R_2 affects the T_c value to a much lesser extent (Fig. 3). It should be noted that raising R_2 from 0 to 1 (transition from a composition with predominance of hydrogen to that with prevalence of carbon) at small R_1 (0.2) leads to a pronounced rise in T_c (by approximately 700 K), whereas at $R_1 = 1$ an increase in R_2 has virtually no effect on T_c. This is a consequence of the physical meaning of R_1—at low R_1 only a minor part of hydrogen is oxidized and, with both R_2 and R_1 approaching zero, the amount of oxygen in a formulation tends to zero, i.e., there is no energy release via oxidation and energy can be only liberated owing to the contribution from ΔH_f^0 in the case of its being positive.

In developing applied software for performing a search for formulations ensuring a share of gaseous zinc at the nozzle exit that would not be lower than a prescribed value, it is necessary to obtain empirical relations between the share of gaseous zinc $[Zn(g)]_a$ and the parameters characterizing the starting combustible mixture. Studying the dependence of $[Zn(g)]_a$ on T_c (Fig. 4a) proved useful for this purpose. It can be seen that the curve describing the dependence $[Zn(g)]_a = f(T_c)$ shows a steep rise in $[Zn(g)]_a$ from 0 to 1 in a rather narrow temperature range (1500–1900 K), with the curves with a certain R_1 value appearing separately. At higher R_1 values, the prescribed $[Zn(g)]_a$ values are achieved at higher temperatures. This a consequence of the fact that a decrease in the share of reducing gases (CO, H_2) in the combustion products shifts to the right the equilibrium of the reactions $Zn + CO_2 \rightleftarrows ZnO + CO$ and $Zn + H_2O \rightleftarrows ZnO + H_2$. At the same time, The difference in R_2 and N_p values between the compositions affects the dependence $[Zn(g)]_a = f(T_c)$ only slightly (R_2, N_p directly affect T_c, similarly to ΔH_f^0 and R_1), and an approximate empirical formula can be found for the dependence of the minimum admissible T_c for reaching the prescribed $[Zn(g)]_a$ value:

$$T_c = A + BR_1. \quad (1)$$

Thus, an estimate was made that $A = 1827$ and $B = 302$ for $[Zn(g)]_a = 0.8$ and $A = 1725$ and $B = 322$

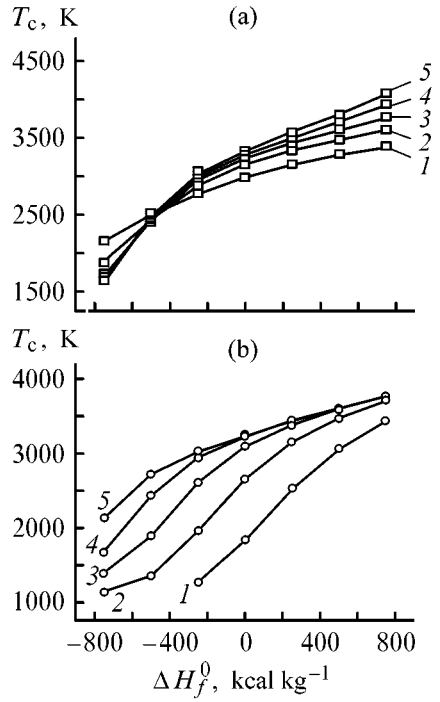

Fig. 1. Temperature T_c in the combustion chamber vs. enthalpy of formation of the formulation, ΔH_f^0. Composition with 20% zinc, $N_p = 20\%$, $R_1 = 0.6$ (a), $R_2 = 0.8$ (b). (a) R_2: (*1*) 0, (*2*) 0.5, (*3*) 0.8, (*4*) 0.95, and (*5*) 1.0. (b) R_1: (*1*) 0, (*2*) 0.2, (*3*) 0.4, (*4*) 0.6, and (*5*) 0.8.

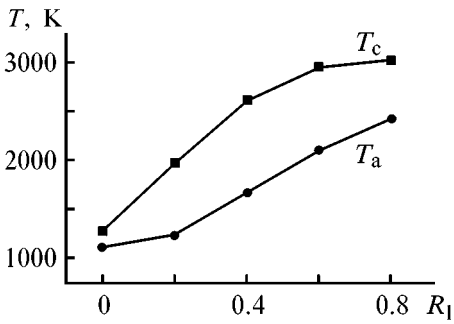

Fig. 2. T_c and T_a vs. R_1 for formulations with 20% zinc. $R_2 = 0.8$, $N_p = 20\%$, $\Delta H_f^0 = -250$ kcal kg^{-1}.

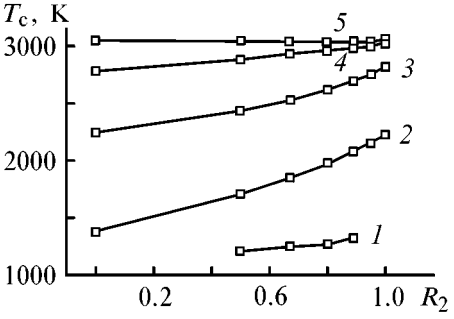

Fig. 3. T_c vs. R_2 for formulations with 20% zinc. $\Delta H_f^0 = -250$ kcal kg^{-1}, $N_p = 20\%$. R_1: (*1*) 0, (*2*) 0.2, (*3*) 0.4, (*4*) 0.6, and (*5*) 0.8.

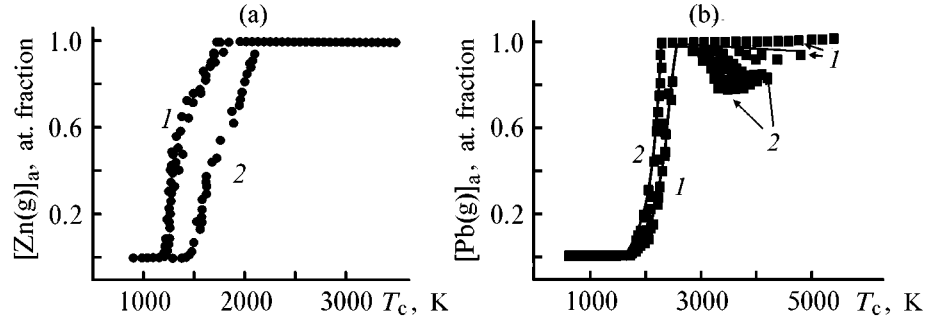

Fig. 4. (a) $[Zn(g)]_a$ and (b) $[Pb(g)]_a$ vs. temperature T for formulations with 20% (a) zinc and (b) lead. R_2 = 0.5–1.0, N_p = 0–40%, ΔH_f^0 = –750 … +750 kcal kg^{-1}. R_1: (*1*) 0 and (*2*) 0.6.

for $[Zn(g)]_a$ = 0.7. As for the T_c value as a function of chemical composition and enthalpy of formation of the starting formulation, it was possible to relate it, with much poorer accuracy, by an empirical formula to R_1, R_2, ΔH_f^0, and N_p. For this purpose, it was necessary to make the interval under study somewhat narrower: only formulations with T_c in the range from 1000 to 3000 K were considered, with the formulations with zero R_1 and R_2 values excluded. However, even after imposing this restriction the array remained rather huge, including more than 350 out of the 1200 calculated compositions. The following empirical formula relating the system parameters was chosen:

$$\Delta H_f^0 = p_0 + p_1 N_p + p_2 N_p^2 + p_3 R_1 + p_4 R_1^2 + p_5 R_2 + p_6 R_2^2 + p_7 T_c + p_8 T_c^2, \quad (2)$$

where ΔH_f^0 is the enthalpy of formation of the overall formulation (kcal kg^{-1}) and N_p is the mass fraction of nitrogen in the formulation.

Parameters of the empirical equation (2) for formulations containing zinc and lead and the average error of ΔH_f^0 calculation by Eq. (2)

Parameter	Parameter value	
	Zn	Pb
T_c, K	1500–2400	1500–3000
p_0	–1120	–511
p_1	1003	1060
p_2	471.6	270.4
p_3	–1595	–1829
p_4	720	934
p_5	–413	–513
p_6	185.2	208
p_7	0.717	0.219
p_8	-6.84×10^{-5}	3.75×10^{-5}
Average error in V, ΔH_f^0, kcal kg^{-1}	60	50

At the above limitations ($1000 < T_c < 3000$ K, $0.2 < R_1 < 0.8$, $0.5 < R_2 < 1$), the parameters of Eq. (2) are presented in the table, with the mean deviation for ΔH_f^0 constituting about 60 kcal kg^{-1}, which is equivalent to an error in T_c of ~130 K in the T_c range 1500–2400 K.

A similar calculation performed for T_a, i.e.,

$$\Delta H_f^0 = P_0 + P_1 N_p + P_2 N_p^2 + P_3 R_1 + P_4 R_1^2 + P_5 R_2 + P_6 R_2^2 + P_7 T_a + P_8 T_a^2, \quad (3)$$

gives the following parameters of Eq. (3): P_0 = –1877, P_1 = 925, P_2 = 829, P_3 = –1652, P_4 = 635, P_5 = –565, P_6 = 260, P_7 = 2.11, and P_8 = –0.0005 with virtually the same deviation.

The obtained parameters of Eq. (2) and the fact that, in a search for compositions with prescribed $[Zn(g)]_a$, T_c can be replaced by the expression $A + BR_1$ {A and B are functions of the sought-for quantity $[Zn(g)]_a$} were used to develop a program executing a computer search for suitable compositions on the basis of the available components. On setting by the user of a required $[Zn(g)]_a$ value, e.g., 0.8, it only remains to bring into operation the system of cyclic pairwise sorting of components present in the database and solve an equation with a single unknown x—the content of the first component, with all the parameters of Eqs. (1) and (2) either already known (p_0–p_8, A, B) or being functions of x and characteristics (chemical composition, ΔH_f^0) of a considered pair of components. If the obtained analytical solution x lies in the interval 0–80% and R_1 is less than unity, then the solution has physical meaning and is acceptable. In this case, the solution is delivered to the output and the program proceeds to considering a next pair of components. The program covers compositions containing not only a free metal, but also its oxide

(provided that the total content of metal is 20%); a correction for the known ΔH_f^0 of the oxide and additional amount of oxygen contained in the oxide is made for this purpose.

The program allows for introduction into a formulation of a preset number of components necessary for ensuring various operation properties, with the search for a formulation composition remaining virtually unchanged. The program can be modified to enable a search for a composition with contents of three components varied. In this case, if a solution exists, it may be multiple since there is a single equation for two unknowns, but in some cases this may be useful for preliminary analysis. In addition, various restrictions can be introduced into the program. It is to be specified that the use of the described application software should only be a first step for preliminary search, and it is necessary to further finally refine the composition of the formulation by means of a standard program for thermodynamic calculations and to test real formulations.

As an example, a search for compositions with $[Zn(g)]_a$ of 80% was performed among formulations containing 20% free zinc. The numerous output formulations included the following formulations containing (%): (a) 14.5–17 polyethylene + ammonium salt of dinitramide (ADNA, a new oxidant for solid propellants [3], (b) 7–19 acetylene + ammonium nitrate (AN), (c) 17.5 carbon + ADNA, (d) 30 trinitrocellulose (TNC) + 50 mononitrocellulose (MNC), (e) 30 TNC + 11 water + 39 dinitrocellulose (DNC), (f) 30 TNC + 47 NA + 3 polyethylene, (g) 48 TNC + 32 trinitrotoluene (TNT), and (h) 67 DNC + 13 TNT.

A calculation by the standard technique gives the following content of components in the compositions studied (%): (a) 14 polyethylene, (b) 5 or 12 acetylene at acetylene content between 5 and 12%, $[Zn(g)]_a$ exceeds 80%}, (c) 17 carbon, (d) 31.5 TNC + 48.5 MNC, (e) 14.5 water + 35.5 DNC + 30 TNC, (f) 7 polyethylene + 43 AN + 30 TNC, (g) 50 TNC + 30 TNT, and (h) 69 DNC + 11 TNT, i.e., the developed algorithm of the program gives quite satisfactory results as a basis for tentative choice of the most acceptable target compositions.

A search gave no compositions containing 25% ZnO (amount corresponding to 20% Zn) and ammonium nitrate for any of the combustibles present in the database. Indeed, in a formulation with free zinc and ammonium nitrate, only introduction of such a high-enthalpy combustible as acetylene allows creation of the desired formulation; at the same time, on lowering the initial enthalpy of formation of a formulation (by approximately 250 kcal kg^{-1}) by replacing zinc with its oxide, even use of acetylene as combustible has no positive effect. The engineering problem of practical use of a gaseous product as a component of formulation is not considered in the present study; it should only be mentioned that this is quite technically possible. A special-purpose calculation confirmed that the maximum achievable $[Zn(g)]_a$ value in the formulation containing 25% ZnO + AN + acetylene is at the level of 0.55–0.60 at acetylene content of 8–9%. However, if such widely used compounds as nitrocellulose or trinitrotoluene are allowed as combustibles in the case of AN, then the program gives a wide variety of compositions, e.g., 25% MNC + 15% AN + 35% TNC, or 25% MNC + 3% water + 47% TNC, or 21% TNT + 54% TNC, even though nitro compounds, rather than AN, form the basis of such formulations, with AN only diluting somewhat the main formulation.

A study of a similar system with lead demonstrated the only basic difference between the systems with zinc and lead. In a system with zinc, with the combustion temperature increasing at any of the studied R_1 and R_2 values, the $[Zn(g)]_a$ value reaches unity an then remains virtually unchanged (Fig. 4a). At the same time, when a $[Pb(g)]_a$ value of ~1 is reached in a system with lead, further increase in T_c (at $R_1 \geq 0.2$) leads to a decrease in $[Pb(g)]_a$ because of the growing share of gaseous PbO at the output. In this case, the higher R_1, the more pronounced this effect (Fig. 4b). S-shaped portions of the curve describing the dependence $[Me(g)]_a = f(T_c)$ are qualitatively the same for both the metals, with the quantitative difference consisting only in the T_c of the onset and completion of a rise in $[Me(g)]_a$—in the case of zinc, T_c is approximately 250°C lower. It should be noted that this value (250°C) is much smaller than the difference between the boiling points of the two metals (1186 and 2025 K). This is due to the fact that, as a result of the higher (compared with lead) affinity of zinc to oxygen, compositions with zinc require higher overheating to achieve the equal shares of gaseous metal at the output. The parameters of Eq. (2) were found for $1500 < T_c < 3000$ K, $0.2 < R_1 < 0.8$, and $0.5 < R_2 < 1$ (see the table).

The same method as in the case of zinc-containing compositions gave the following results: the $[Pb(g)]_a$ value is as high as 0.8 at $T_c = 2417 - 247R_1$ and 0.7 at $T_c = 2330 - 165R_1$. It is noteworthy that, in zinc-containing compositions, the coefficient B at R_1 [Eq. (1)] is positive, whereas in the case of lead it is negative. The positive sign of the coefficient B in the case of zinc is readily accounted for by the fact

that, in contrast to a temperature rise, an increase in R_1 shifts to the right the equilibria of the reactions $2CO + O_2 \rightleftarrows 2CO_2$, $2H_2 + O_2 \rightleftarrows 2H_2O$, $Zn(g) + CO_2 \rightleftarrows ZnO(cond) + CO$, and $Zn(g) + H_2O \rightleftarrows ZnO(cond) + H_2$, and, therefore, at higher R_1 in zinc-containing compositions it is necessary to raise the temperature to preserve the high share of zinc vapor. In the case of lead, however, gaseous PbO is formed, by contrast, just at elevated temperatures and higher R_1 values, i.e., the equilibria of the reactions $Pb(g) + CO_2 \rightleftarrows PbO(g) + CO$ and $Pb(g) + H_2O \rightleftarrows PbO(g) + H_2$ are shifted to the right with increasing temperature or R_1. At 1700–2400 K {S-shaped portion of the curve describing the dependence $[Pb(g)]_a = f(T_c)$}, virtually no oxide is formed yet and nearly the entire amount of lead is present in free state in equilibrium between the liquid and gas phases.

Replacing in the above-described program searching for compositions with 20% zinc the parameters of Eqs. (1) and (2) for the respective parameters obtained for compositions with lead allows a search for suitable compositions in the same way as it was described for the case of zinc.

A similar analysis can be performed for many other metals: theoretically, a formulation can always be obtained with extremely high ΔH_f^0 value to raise the combustion temperature at low R_1. For example, even if a combustible formulation with elemental composition $C_xH_{2x}N_xO_{2x}$ or $C_xH_{2x}N_xO_{3x}$ with extremely high (ΔH_f^0 = +3000 kcal kg^{-1}, which is absolutely unrealistic) enthalpy of formation could be created in a mixture with aluminum, this would give a content of gaseous metal not exceeding 30%. However, if high-enthalpy compositions with extremely low, or even zero content of oxygen are used, e.g., dicyanoacetylene {N≡C–C≡C–C≡N, $\Delta H_{f(l)}^0$ = +119.6 kcal mol^{-1} = 1574 kcal kg^{-1} [4]}, for which the nozzle exit temperature of about 3000 K is achieved, the share of gaseous aluminum may exceed 60–70%.

In addition to the considered zinc and lead, the described scheme can well be used for bismuth. This was done in the same volume as in the case of zinc and lead to give the results close to those for lead. There is no need to consider these results in more detail since, in our opinion, the case of bismuth is of no practical value. Solving the problem for copper is a somewhat more complicated task since, because of the lower volatility of copper, higher combustion temperatures are necessary to make higher the yield of gaseous metal. A composition containing 10% metallic copper mixed with TNC gives in combustion under the above-described conditions 67% of the metal in the form of gas. Introduction of MNC, DNC, octogen, or even acetylene into the composition fails to raise the output of gaseous metal. However, use of a more powerful oxidant—ADNA, with acetylene as combustible, raises to 95% the content of gaseous copper. If liquid acetylene-containing compounds with empirical formula C_nH_n with $\Delta H_f^0 \approx +1000$ kcal kg^{-1} (quite a number of such compounds are known) are used as a combustible in combination with ADNA, then yields of gaseous copper of up to 76% are achieved. As for compositions with iron, nickel, and especially chromium, i.e., metals less volatile than copper and having higher oxygen affinity, the problem of creating such formulations is rather difficult to solve.

CONCLUSIONS

(1) Combustible formulations can be composed on the basis of readily available components, ensuring nearly 100% content of gaseous cadmium, zinc, lead, or bismuth in combustion products.

(2) An analysis of how the yield of gaseous metal (Zn, Pb, Bi) in isoentropic burning of a combustible formulation depends on its elemental composition and enthalpy of formation gave: (a) empirical equations relating the chemical composition of a starting combustible formulation, its enthalpy of formation, temperatures in the chamber and the nozzle exit, and the yield of gaseous metal; and (b) programs for finding satisfactory combustible formulations, with their components chosen from the available component database.

(3) A thermodynamic calculation established that a combustible formulation containing 10% copper and trinitrocellulose can be created, whose combustion gives about 67% of the metal in the gaseous form.

Received April 11, 2000

Abstract—Extractive recovery with *n*-octanol of tantalum(V) and niobium(V) from hydrofluoric acid solutions containing large amounts of titanium (up to 2–3 M) was studied. The conditions were found for separation of tantalum(V) and niobium(V) from titanium(IV), allowing recovery of 95.7 and 84.1% of tantalum and niobium fluoride complexes, respectively, in one extraction cycle, with 2.6% recovery of titanium.

Extractive recovery of tantalum(V) and niobium(V) is performed under industrial conditions with methyl isobutyl ketone and, more seldom, with tributyl phosphate [1]. These extractants have several substantial drawbacks: methyl isobutyl ketone is dangerously explosive and is highly soluble in the aqueous phase; tributyl phosphate is toxic and is readily converted to other phosphorus-containing compounds contaminating the final product. Alcohols are characterized by extraction features close to those of methyl isobutyl ketone. Extraction of tantalum(V) and niobium(V) with alcohols has been studied insufficiently [1]. Several reports concerning extraction processing of relatively pure niobium-tantalum raw material with the use of octanol as extractant have been published recently [2–4]. No data on extractive recovery of tantalum(V) and niobium(V) from solutions containing large amounts of foreign metals are known.

In this work, tantalum(V) and niobium(V) were extracted with *n*-octyl alcohol (OCL). This extractant is free of the above-noted drawbacks of methyl isobutyl ketone and tributyl phosphate and is commercially produced in Russia. Tantalum(V) and niobium(V) were recovered from titanium fluoride solutions in hydrofluoric acid containing no other mineral acids. These solutions are formed in processing loparite with hydrofluoric acid [5, 6]. They contain small amounts of tantalum(V) and niobium(V), ~0.0045 and ~0.11 M, respectively, and a large amount of titanium (up to 2–3 M). It has been reported previously [7-11] that the effect of fluorotitanic acid on the extraction of tantalum(V) fluoride is close to that of sulfuric acid.

The aim of this work was to study the possibility of preparing pure compounds of tantalum(V) and niobium(V) by their extraction from solutions containing large amounts of titanium(IV) without introduction of additional mineral acids hindering HF recovery from spent process solutions [5, 6]. Extraction of tantalum(V) and niobium(V) from hydrofluoric-sulfuric acid solutions was reported in [2–4].

Procedures for preparing solutions, performing experiments, analysing target metals, and safely handling chemically aggressive hydrofluoric acid solutions have been reported in detail previously [1]. Characteristics of octyl alcohol used in our experiments were as follows: main substance content about 98% (content of 3-octanol as an impurity was less then 0.5%), solubility in water 0.05 wt %, density 0.824 g cm^{-3}, mp 15–16°C, bp 195°C, and flash point 81°C. The extraction was performed in the course of 5 min. Preliminary experiments showed that the extraction equilibrium is attained at a contact time of no more than 3 min.

The data on the effect exerted by the solution composition and ratio of the organic and aqueous phases $V_o : V_a$ on the distribution of the main components are listed in the table, where HF_{free} is the HF concentration calculated as the difference between the total HF concentration and the HF amount in the main complexes $HTa(Nb)F_6$, H_2TiOF_4, and H_2SiF_6 formed in the systems [1, 11–13].

Since the degree of tantalum(V) recovery exceeds 90% throughout its concentration range, the main goal was to search for conditions for extraction

of niobium(V), with minimum amount of titanium(IV) passing into the organic phase. This is particularly important because of a high molar ratio of titanium(IV) and niobium(V) in the aqueous phase (up to 40 : 1).

At low HF_{free} content (run nos. 1–4), the extraction of niobium(V) and especially titanium(IV) is most strongly influenced by the concentration of titanium(IV), occurring in the form of fluorotitanic acid, as a source of protons. With the titanium(IV) content increasing from 1.88 to 3.12 M, the extraction of niobium(V) (depending on the ratio $V_o : V_a$) grows from 36.5–49.3 to 50.7–71.3%, and that of titanium(IV), from 0.23–0.46 to 12.8–23.8%. Introduction into the system of additional HF (run nos. 5–10) improves the recovery of niobium(V) to the acceptable level of about 80%. Such conditions also ensure lower recovery of titanium(IV). Variation of the HF concentration affects the niobium(V) distribution to a greater extent than does the variation of the $V_o : V_a$ ratio. Under the optimal conditions (run no. 11), exhaustive extraction of tantalum(V) and niobium(V) is readily reached in continuous countercurrent extraction at relatively low recovery of titanium(IV) (about 3%).

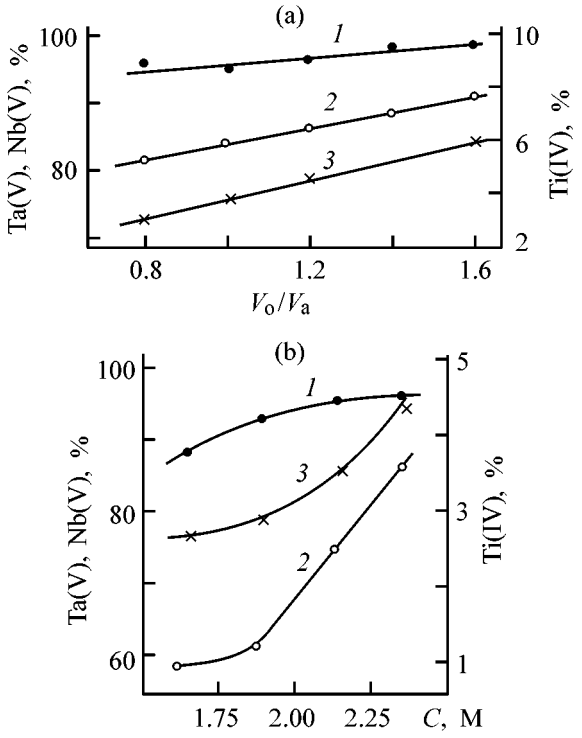

Fig. 1. Effect of (a) volume ratio of the organic and aqueous phases (V_o/V_a) and (b) titanium(IV) concentration C on distribution of (*1*) tantalum(V), (*2*) niobium(V), and (*3*) titanium(IV). *Ordinate*: recovery of indicated elements.

Figure 1a shows the effect of variation of the $V_o : V_a$ ratio on the distribution of the main metals. The extraction was performed from aqueous solutions of the following composition (M): Ta(V) 0.0047, Nb(V) 0.11, Ti(IV) 2.34, Si(IV) 0.14, and HF_{free} 8. With decreasing $V_o : V_a$, the recovery of Ta(V), Nb(V), and Ti(IV) decreases. The recovery of these metals varies in direct proportion to $V_o : V_a$. The slopes of the straight lines increase in the order tantalum(V) < niobium(V) < titanium(IV), which correlates with the order of increasing extractability of fluoride complexes of the elements in question: tantalum(V) > niobium(V) > titanium(IV) [1].

Figure 1 shows that, with the $V_o : V_a$ ratio decreasing by a factor of two, the amount of titanium passing into the organic phase decreases to the same extent, and only a minor amount of niobium(V) passes into the organic phase. However, owing to the high titanium(IV) concentration in the initial solution, the molar ratio Ti(IV) : Nb(V) in the organic phase in exhaustive recovery of niobium(V) by means of continuous countercurrent extraction is considerable: about 0.67 : 1

even at $V_o : V_a = 0.8$. This ratio is lower than that in the initial solution (21 : 1) by a factor of approximately 30, but, nevertheless, this indicates that the organic phase should be washed effectively to remove titanium(IV) impurities.

The trends in extraction of metals (Fig. 1a) suggest that the $V_o : V_a$ ratio can be decreased further, which must make lower the coextraction of titanium(IV) with niobium(V) and tantalum(V).

The distribution of the target metals is shown in Fig. 1b as influenced by the titanium concentration. In these experiments, the composition of the initial solution was the same as in Fig. 1a. It should be noted that lowering the titanium(IV) concentration to less than 2.3 M results in a sharp decrease in extraction of both titanium(IV) (positive effect) and niobium(V). At titanium(IV) concentrations lower than 1.6 M, the distribution of titanium(IV) and niobium(V) fluoride complexes weakly depends on the titanium(IV) amount because the extraction of the metals is apparently controlled by the HF content under these conditions.

In our extraction system, both niobium(V) and titanium(IV) are extracted in the form of fluorometallic acids by the hydrate-solvate mechanism [1, 14]. If no additional mineral acids are introduced into the system, then fluorotitanic acid, predominantly H_2TiOF_4, becomes the main source of protons. Therefore, with decreasing titanium(IV) content in the system, the recovery of niobium(V) and tantalum(V) diminishes. It is evident that the above-noted critical titanium(IV) concentration, equal to 2.3 M, is virtually the concentration of dibasic H_2TiOF_4 acid present in this solution, which is equivalent, in terms of proton content in the system, to 2.3 M H_2SO_4 (approximately 230 g l^{-1}). According to the data reported in [1] for approximately the same concentration, the dependence of niobium(V) recovery with oxygen-containing organic extractants on the H_2SO_4 concentration, as a rule, starts to change. This fact shows that both titanium(IV) and H_2SO_4 affect the distribution of niobium(V) fluoride complexes by the identical mechanisms.

Our experimental results show also that, with increasing HF concentration facilitating the formation of the readily extractable complex $HNbF_6$ [1, 14], the recovery of niobium(V) grows. The dependence of the extraction of titanium(IV) on the HF content, or, more precisely, on the ratio HF : Ti(IV), is more complicated. Titanium(IV) forms fluorotitanic complexes of various compositions exhibiting different extractability. According to the data reported in [1, 14], the recovery of titanium(IV) increases in the order $H_2TiOF_4 < H_2TiF_6 < HTiF_5$. It was noted above that the complex H_2TiOF_4 is predominantly formed in the system under consideration. Therefore, the fraction of titanium passing into the organic phase is relatively low and its variations are mainly caused by variations in the contributions of H_2TiF_6 and $HTiF_5$ complexes to the total content of the fluorotitanic acids in the aqueous phase. Therefore, with increasing HF concentration, first the recovery of titanium can be expected to grow owing to the formation of a readily extractable monobasic acid $HTiF_5$ and then to decrease through an increase in the concentration of the less extractable acid H_2TiF_6. This complicated extraction system deserves separate study.

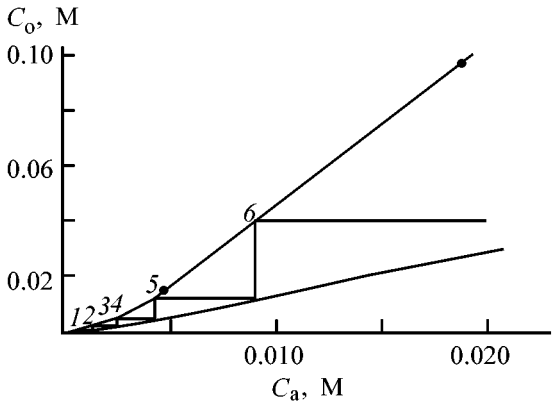

Fig. 2. Extraction isotherm of niobium(V) at HF_{free} concentration of 8.2 M and $V_o/V_a = 1 : 1$. (C_o, C_a) niobium(V) concentration in the organic and aqueous phases, respectively. (*1*–*6*) For comments, see text.

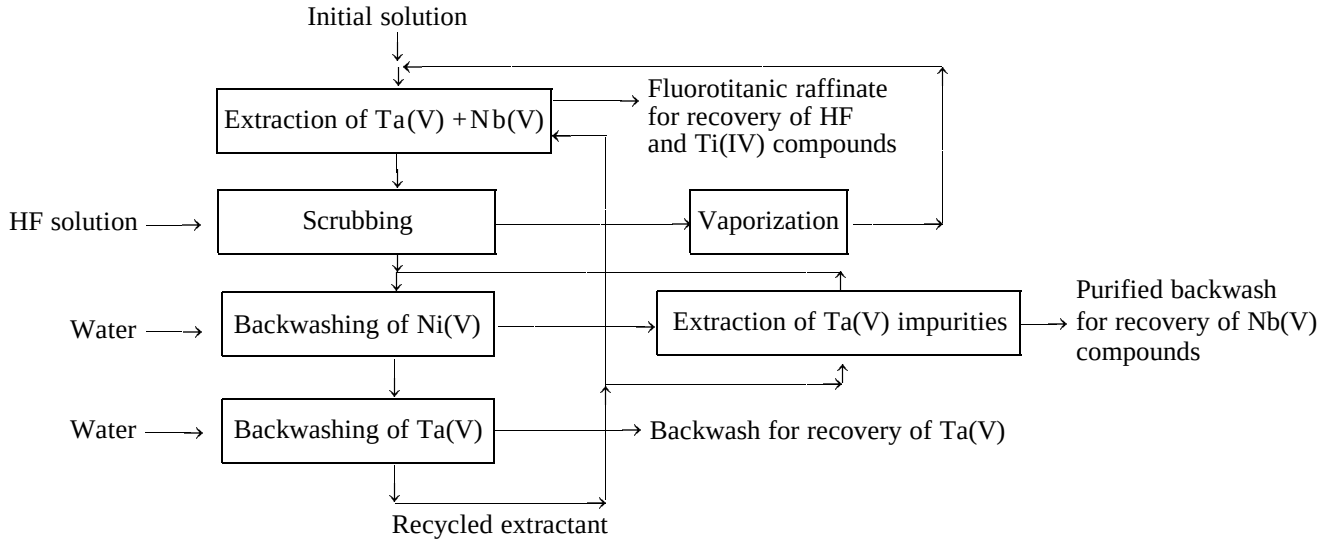
Figure 2 shows an extraction isotherm of niobium(V) obtained by the "exhaustion" technique. According to this technique, the metals were successively extracted four times from aqueous solution with the initial composition close to that given in Fig. 2. In the first extraction, the recovery was 95.7% for tantalum(V), 84.1% for niobium(V), and 2.6% for titanium(IV). In each subsequent extraction with OCL, the recovery of niobium falls owing to a decrease in the titanium(IV) and HF_{free} concentrations. This is one of the main drawbacks of the exhaustion technique.

The plot in Fig. 2 shows that, for the working line corresponding to $V_a : V_w = 1 : 0.7$ (slope of the working line) and a residual niobium(V) concentration of 0.00058 M [99.5% recovery of niobium(V)], six successive equilibrium stages are necessary for continuous countercurrent extraction. Since the recovery of niobium(V) is deteriorated in the course of the "exhaustion" extraction, the actual number of the extraction stages should be lower. A calculation by the well-known Kremers equation [15] showed that

General flowsheet for preparation of pure niobium(V) and tantalum(V) compounds by extraction from hydrofluoric acid solutions with OCL.



at a constant degree of niobium(V) recovery equal to 84% (in the first extraction stage) the niobium(V) recovery by 99.9% is reached with only four stages of continuous countercurrent extraction.

We also performed preliminary studies of scrubbing of the organic phase containing tantalum(V) and niobium(V) to remove titanium(IV) impurities. It was found that, with 25 M HF ($V_a : V_o$ = 0.088 : 1), 72% of titanium and approximately 10% of niobium(V) and tantalum(V) pass from the organic phase in a single scrubbing into the hydrofluoric acid solution containing 0.0046 M Ta(V), 0.095 M Nb(V) and 0.062 M Ti(IV). With increasing volume of the scrubbing solution ($V_a : V_o$ = 0.17 : 1), the amount of titanium(IV) passing into the aqueous phase slightly increases (to 77%). However, under these conditions, the amount of titanium(IV) and niobium(V) passing into the scrubbing solution grows, too.

Further processing of washed extract can be done by successive backwashing of niobium(V) and tantalum(V) with water, similarly to processing of the loparite solutions with methyl isobutyl ketone as extractant with basicity close to that of OCL [1, 2].

In this paper, we present a general flowsheet for treatment of solutions formed in hydrofluoric acid processing of loparite [5, 6]. This flowsheet is based both on our experimental results and on published data [1, 2–4, 14]. Processing of dilute niobium–tantalum solutions containing up to 2–3 M titanium by this technique allows preparation of pure niobium(V) and tantalum(V) compounds.

CONCLUSIONS

(1) The influence exerted by the composition of aqueous solutions and ratio of the organic and aqueous phases $V_o : V_a$ on the distribution of tantalum(V) and titanium(IV) in their extraction from hydrofluoric acid aqueous solutions containing large amounts of titanium(IV) with *n*-octanol was studied.

(2) Within the concentration range studied the recovery of tantalum exceeds 90%, the recovery of niobium(V) is high, at a concentration of HF_{free} and titanium(IV) of no less than 8 and 2.3 M, respectively.

(3) Conditions for separation of tantalum(V) and niobium(V) from titanium(IV) were found at which no more than 3% of titanium(IV) passes into the organic phase.

(4) Continuous countercurrent extraction of tantalum(V) and niobium(V) allows complete recovery of these metals in 4–6 extraction stages.

(5) General flowsheet for preparation of pure niobium(V) and tantalum(V) compounds by extraction from fluorotitanic solutions with OCL was developed.

SORPTION AND ION-EXCHANGE PROCESSES

Vanadium(V) Sorption by Organosilicon Polymers

Abstract—Features of vanadium(V) sorption by cross-linked organosilicon polymers—polyorganylsilsesquioxanes containing acetamide, phthalamide, malondiamide, and thiourea dioxide functional substituents, were studied.

Polymers studied in this work contain carbofunctional substituents with nitrogen, oxygen, and sulfur atoms and can exhibit complex-forming and ion-exchange properties with respect to many elements. The cross-linked organosilicon polymers poly[*N*-(3-silsesquioxanylpropyl)acetamide] (PSMA-3) and poly[bis-*N*,*N*'-(3-silsesquioxanylpropyl)phthalamide] (PSF-3) are efficient sorbents of rare-earth elements [1]. In [2], sorption of gold, silver, and platinum by poly[bis-*N*,*N*'-(3-silsesquioxanylpropyl)thiourea dioxide] (PSOT-3) was studied. It is known that vanadium(V) is also recovered with sorbents containing oxygen and nitrogen atoms in the functional groups [3–5]. Therefore, a study of the sorption power of PSOT-3, PSF-3, PSMA-3, and poly[bis-*N*,*N*'-(3-silsesquioxanylpropyl)-malonamide] (PSMD-3) with respect to vanadium(V) ions is of interest:

$[O_{1.5}Si(CH_2)_3NH–C(SO_2)–NH–(CH_2)_3SiO_{1.5}]_n$,
PSOT-3

$\{[O_{1.5}Si(CH_2)_3NHC(O)]_2C_6H_4\}_n$,
PSF-3

$[O_{1.5}Si(CH_2)_3NHC(O)CH_3]_n$,
PSMA-3

$[O_{1.5}Si(CH_2)_3NH–CO–CH_2–NH–CO(CH_2)_3–SiO_{1.5}]_n$.
PSMD-3

EXPERIMENTAL

The static sorption of V(V) by the above polymers was studied. A sorbent sample was vigorously agitated with V(V) solution for the optimal time. Then the sorbent was separated from the liquid phase by filtration. The residual amount of V(V) in the solution was monitored spectrophotometrically [6] and by the atomic-absorption method. Chemically pure reagents were used. A stock V(V) solution (1 g l^{-1}) was prepared from NH_4VO_3. Less concentrated solutions were prepared by dilution of the stock solution.

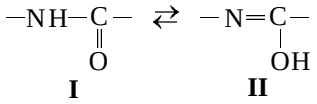
The most important factors affecting the sorption are the V(V) concentration and pH. At V(V) concentration less than 1×10^{-4} g-ion l^{-1}, the following monomeric species exist in equilibrum in the solution:

$$VO_2^+ \overset{+OH^-}{\rightleftarrows} HVO_3 \overset{-H^+}{\rightleftarrows} VO_3^- \overset{+OH^-}{\rightleftarrows} HVO_4^{2-} \overset{-H^+}{\rightleftarrows} VO_4^{3-}.$$

VO_2^+, VO_3^-, HVO_4^{2-}, and VO_4^{3-} species prevail at pH 0–3, 3.5–8, 8.0–12.0, and 12–14, respectively. At vanadium concentrations higher than 1×10^{-4} and pH 0–3, VO_2^+ species remain prevalent. With decreasing acidity (pH > 3), these species react with OH^- ions to form vanadium polyions. For instance, at pH 5.0–8.0 the $V_3O_9^{3-}$ and $V_4O_{12}^{4-}$ ions and at pH 10–12, the $H_2V_2O_7^{2-}$ ions exist in the solution. Condensation of these ions yields more complex polyions [7, 8]. Our experimental data confirm the above pattern. As seen from the figure, the V(V) sorption starts at pH 1, reaches a maximum at pH 3, and then decreases with pH growing further.

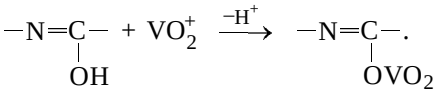
The polymers PSF-3, PSMA-3, and PSMD-3 have similar structures as polymeric derivatives of carboxylic acid amides. It is known that the amide group **I** exhibits prototropy and can react in the tautomeric isoamide form **II**:

1070-4272/01/7406-0950 $25.00 © 2001 MAIK "Nauka/Interperiodica"

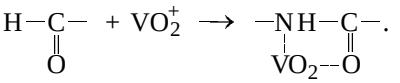


I **II**

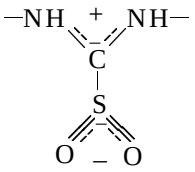
Thus, V(V) can be sorbed by the ion-exchange mechanism in accordance with the scheme



However, the VO_2^+ reaction by the donor–acceptor mechanism with the formation of chelate complexes is also possible:



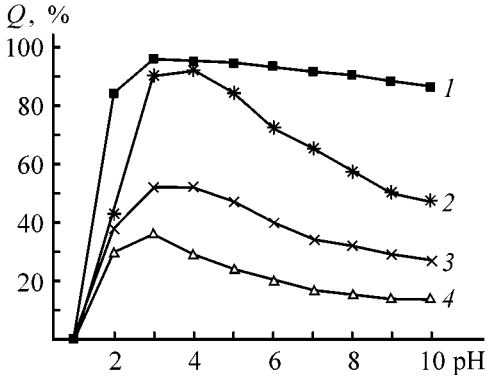
A specific feature of PSOT-3 is that it efficiently recovers V(V) within the pH range 2–9. This is probably due to reaction of V(V) with thiourea dioxide group of the polymer, having the zwitterionic structure.



As a result, PSOT-3 is able to bind both cationic VO_2^+ and anionic VO_3^- vanadium species.

A study of the degree of recovery as a function of the phase contact time showed that the sorption equilibrium in V(V) solutions is reached in 60 min, and the main part of the metal is recovered in 10–20 min with all the sorbents (Table 1).

The effect of the ionic strength μ of solution was studied for the example of NaCl. It was found that with the ionic strength increasing to 0.25 (C_{NaCl} > 15 g l^{-1}) the V(V) recovery decreases, and, within the $0.25 < \mu < 1$ range, the metal sorption is sharply suppressed. The PSMA-3 polymer does not recover V(V) from solutions with μ exceeding 0.25. Probably, this is due to competitive interaction of VO_2^+ species with chloride ions to form negatively charged complexes. To determine the sorption capacity, the V(V) recovery from solutions was studied as a function of metal concentration, the sorption isotherms were obtained, and then the static sorption capacities SSC (mg g^{-1}) and distribution coefficients D (cm^3 g^{-1}) were calculated (Table 2). The sorption capacities of PSOT-3 and PSMD-3 and the distribution coefficients show that these sorbents can be used for recovery and concentration of V(V) trace amounts from solutions of both artificial and natural origin.



Degree of V(V) recovery Q vs. pH. Sorbent: (*1*) PSOT-3, (*2*) PSMD-3, (*3*) PSF-3, and (*4*) PSMA-3.

To determine the possibility of vanadium recovery from multicomponent solutions, the V(V) sorption in the presence of Co(II), Cd(II), Cu(II), Ni(II), Zn(II), Mo(VI), and U(VI) was studied (Table 3). It was found that 100-fold excess of Co(II), Cd(II), Cu(II), Ni(II), and Zn(II) does not hinder vanadium(V) sorption by PSOT-3 and PSMD-3, and their 10-fold excess, V(V) sorption by PSF-3. Mo(VI) and U(VI) do not hinder V(V) sorption by PSOT-3 at V : M ratio of 1 : 1.

0.5	0.5 ± 0.1	0.14
0.9	0.8 ± 0.2	0.13
2.0	1.9 ± 0.3	0.13

* Solution composition, mg l^{-1}: Cu(II), Cd(II), Zn(II), Co(II), and Ni(II) 15; Mo(VI) and U(VI) 1; NaCl 15.

For repeated use of the above sorbents, we studied the V(V) desorption from the surface of PSOT-3, PSMD-3, PSMA-3, and PSF-3 sorbents. The choice of desorbing agents was governed by their complexing properties with respect to V(V). It follows from Table 4 that V(V) desorption is virtually completely effected by hydrochloric acid, ammonium hydroxide, and sodium carbonate. They do not produce any substantial changes in the sorbent structures. The polymers preserve their sorption properties and can be used repeatedly.

Using the above data, we performed recovery and concentration of V(V) from model solutions with PSOT-3 and found that vanadium is recovered from solutions completely (Table 5).

A statistical treatment of sorption data demonstrated their good reproducibility. For instance, at a V(V) concentration of 0.05–30.0 mg l^{-1} the relative standard deviation S_r was 0.13–0.15.

CONCLUSION

Organosilicon polymers poly[bis-*N*,*N*'-(3-silsesquioxanylpropyl)thiourea dioxide] and poly[bis-*N*,*N*'-(3-silsesquioxanylpropyl)malonamide] are rather efficient sorbents of V(V) and can be recommended for concentration, separation, and determination of this element in multicomponent solutions.

SORPTION AND ION-EXCHANGE PROCESSES

Precipitation Recovery of Rhenium(VII) from Aqueous Solutions with Coagulating Cationic Polyelectrolyte

D. G. Petrov, I. D. Troshkina, A. M. Chekmarev, and A. B. Maiboroda

Mendeleev Russian University of Chemical Engineering, Moscow, Russia

Received January 31, 2001

Abstract—Rhenium(VII) recovery from dilute aqueous solutions by coprecipitation with VA-212 cationic polyelectrolyte in the presence of nitrate ions was studied.

In industry, rhenium (one of the least abundant chemical elements) is recovered from dilute but, as a rule, highly saline solutions [1, 2]. Sorption methods are the most frequently used in this case, but their use is restricted by low sorbent exchange capacity and slow metal sorption at its low concentrations.

The aim of this work was to study the use of water-soluble polyelectrolytes (PEs) for rhenium(VII) recovery from dilute mineralized solutions.

EXPERIMENTAL

A commercial cationic polyelectrolyte VA-212, polybisdimethylaminoisopropyl methacrylate alkylated with benzyl chloride and containing 3.4 mg-equiv g^{-1} of tertiary ammonium groups, was used.

Preliminarily, we studied the aggregation stability of VA-212 in solutions of various salts. It was found that this polyelectrolyte starts to coagulate in the presence of low-molecular-weight electrolytes (LME) when the LME concentration exceeds a certain limit C_t (coagulation threshold) depending on the LME nature. The concentration C_t was determined by the method based on variation of the optical properties of the disperse system during coagulation. Raising the LME concentration in the PE–LME system decreases the thermodynamic stability of the polyelectrolyte solution, and, on attaining C_t, spontaneous aggregation of polyelectrolyte macromolecules (coagulation) starts. The growth of aggregates increases the turbidity of the system because of the increasing light scattering and absorption [3]. The C_t value was experimentally determined from a jump discontinuity in the curve of the solution optical density vs. LME concentration.

The rhenium(VII) recovery was performed by PE precipitation from nitrate-containing solutions. A 2% solution of PE in distilled water was introduced into a solution containing sodium nitrate and ammonium perrhenate with agitation. The change in the rhenium(VII) concentration was monitored with the use of ^{188}Re tracer ($T_{1/2}$ = 16.7 h) [4]. The concentrations of the polyelectrolyte, nitrate ion, and rhenium were varied within 1.0–2.0 g dm^{-3}, 0.1–0.5 g-equiv dm^{-3}, and 0.5–10 mg dm^{-3}, respectively. The solution with the PE precipitate was agitated for 20 min and then filtered. After precipitate separation, the Re(VII) concentration was determined from the residual radioactivity of the solution. To determine the time in which thermodynamic equilibrium is attained between the precipitated PE and solution, a solution with the PE precipitate was stored with stirring for a week, and then the Re(VII) content was determined by the kinetic method with sulfonitrazo R [5]. The Re(VII) concentration in this solution was the same (within the analysis error) as in the solution contacting with PE for 20 min. Thus, we showed that this time is enough for equilibrium in the PE precipitate–solution system to be attained.

We studied the influence exerted by the nature of cations and anions of low-molecular-weight electrolyte on the coagulation threshold. Below are presented the threshold concentrations of sodium, potassium, ammonium, calcium, and nitric acid, causing precipitation of VA-212 polyelectrolyte at its concentration of 1 g dm^{-3}:

Nitrate of	Na^+	K^+	NH_4^+	Ca^{2+}	H^+
$C_t \times 10^2$, M	4.82	4.89	4.84	4.79	4.77

As seen, the coagulation threshold is practically independent of the nature of the low-molecular-weight

Table 1. Threshold of VA-212 polyelectrolyte coagulation for various salting-out agents

Agent	C_t (g-equiv dm^{-3}) at indicated PE concentration, g dm^{-3}					
	0.01	0.05	0.10	0.50	1.00	5.00
$HClO_4$	2.09×10^{-4}	1.98×10^{-4}	1.82×10^{-4}	1.77×10^{-4}	1.75×10^{-4}	1.76×10^{-4}
HI	9.81×10^{-4}	9.77×10^{-4}	9.78×10^{-4}	9.77×10^{-4}	9.76×10^{-4}	9.77×10^{-4}
HBr	4.05×10^{-2}	3.42×10^{-2}	3.35×10^{-2}	3.33×10^{-2}	3.31×10^{-2}	3.31×10^{-2}
NH_4NO_3	5.03×10^{-2}	4.91×10^{-2}	4.84×10^{-2}	4.82×10^{-2}	4.84×10^{-2}	4.84×10^{-2}
NaCl	1.94×10^{-1}	1.92×10^{-1}	1.90×10^{-1}	1.91×10^{-1}	1.91×10^{-1}	1.90×10^{-1}
$(NH_4)_2SO_4$	1.17	1.15	1.15	1.15	1.14	1.15
$NaNO_2$	3.21	3.07	3.06	3.06	3.07	3.06

electrolyte. Therefore, in further studies C_t was regarded as the limiting concentration of the anion causing coagulation.

In Table 1, the C_t values are listed for various LMEs as a function of the polyelectrolyte concentration. As seen, the coagulation threshold depends on the anion nature and remains constant for the given anion at polyelectrolyte concentration of 0.1 g dm^{-3}.

The distribution of ions in an electric double layer around the polyelectrolyte molecule depends on their polarizability. More polarizable ions can make closer approach to the macromolecular counterion. As a result, the charge of the macromolecule is shielded more effectively, and the coagulation threshold efficiency is lowered [6]. The molar refraction R_0 is the physical constant characterizing the polarizability of a molecule or an ion. It is a function of the refractive index and substance density and, to a first approximation, is proportional to polarizability. The coagulation thresholds found for VA-212 (at polyelectrolyte concentration of 1.0 g dm^{-3}) were compared with the ionic refractions of anions as saltingout agents [7]. Table 2 shows a linear $\log C_t$–R_0 dependence. The efficiency of oxygen-containing anions as precipitants of cationic polyelectrolytes substantially depends on the strength of the conjugated acids [6]. For the oxygen-containing anions studied (Table 2), it was found that $\log C_t$ is a linear function of pK_a, where K_a is the acid dissociation constant.

To predict the aggregative stability of polyelectrolytes in multicomponent solutions (containing several LME anions), we determined the coagulation thresholds in the VA-212–NO_3^-–SO_4^{2-} and VA-212–NO_3^-–Cl^- systems at varied ratio of anions. The choice of these anions was due to their high abundance in rhenium-containing process solutions (mine water, wastewater, and solutions of underground leaching). Table 3 and Figs. 1a and 1b show that sulfate and nitrate ions affect the VA-212 coagulation additively, and synergism of the anions is observed for the VA-212–NO_3^-–Cl^- system.

We also studied the effect of PE and nitrate ion concentrations on Re(VII) distribution between the precipitate and solution at coagulation of VA-212 (Table 4). The polyelectrolyte is precipitated in the form of nitrate. The precipitate captures trace amounts of ReO_4^- ions. The equation of the reversible exchange of the perrhenate ions between the solution and the precipitated (as nitrate) polyelectrolyte is as follows:

$$\underset{\text{Solution}}{ReO_4^-} + \underset{\text{Precipitate}}{[R_4N]NO_3} \rightleftarrows \underset{\text{Precipitate}}{[R_4N]ReO_4} + \underset{\text{Solution}}{NO_3^-}, \quad (1)$$

where R is the hydrocarbon skeleton of PE.

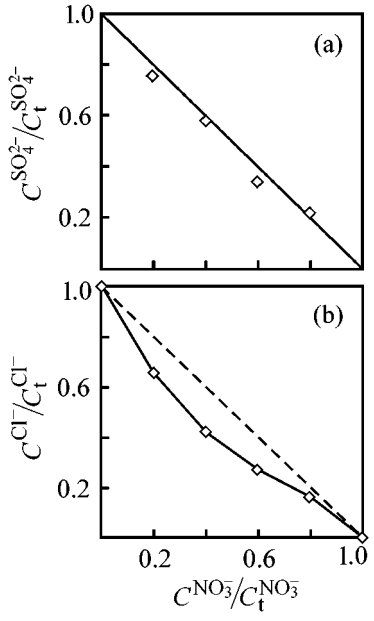

Fig. 1. Correlations of (a) $C^{SO_4^{2-}}/C_t^{SO_4^{2-}}$ and (b) $C^{Cl^-}/C_t^{Cl^-}$ with $C^{NO_3^-}/C_t^{NO_3^-}$.

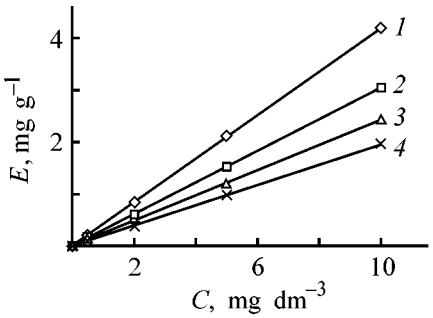

Fig. 2. VA-212 capacity E for rhenium(VII) vs. the Re(VII) concentration in the solution C. [PE] = 2 g dm^{-3}. Concentration of nitrate ions (M): (*1*) 0.1, (*2*) 0.2, (*3*) 0.3, and (*4*) 0.5.

The concentration equilibrium constant for reaction (1) can be presented as follows:

$$K = \frac{[ReO_4^-]_{PE}[NO_3^-]_f}{[ReO_4^-]_f[NO_3^-]_{PE}}, \quad (2)$$

where $[ReO_4^-]_f$ and $[NO_3^-]_f$ are the concentrations of the perrhenate and nitrate ions in the solution after separation of the PE precipitate (M) and $[ReO_4^-]_{PE}$, and $[NO_3^-]_{PE}$ are the concentrations of the perrhenate and nitrate ions in the phase of the PE precipitate (mol g^{-1}).

Assuming that the coagulated polyelectrolyte captures anions from the solution in amounts corresponding to the number of PE quatertiary ammonium groups (C_q = 3.4 mg-equiv g^{-1}), we can transform Eq. (2) into

$$K = \frac{[ReO_4^-]_i - [ReO_4^-]_f}{[ReO_4^-]_c} \cdot \frac{[NO_3^-]_i - C_q[PE]}{C_q[PE]}, \quad (3)$$

where $[ReO_4]_i$ and $[NO_3^-]_i$ are the concentrations of the perrhenate and nitrate ion in the solution before introduction of PE (M), and [PE] is the concentration of PE introduced into the solution (g dm^{-3}).

The degree of Re(VII) recovery and ion-exchange constants are listed in Table 4 in relation to the concentrations of PE and nitrate ions. The K values calculated by Eq. (3) are of the same order of magnitude. A small decrease in K with increasing NO_3^- concentration and decreasing PE concentration is probably due to a change in the activity coefficients of ions involved in the ion-exchange reaction both in

solution and in the PE precipitate phase. The average concentration constant of ion exchange $K = 40.3 \pm 7.3$ shows that the recovery of ReO_4^- by coagulation of VA-212 cationic polyelectrolyte under the action of nitrate ions is highly selective.

We obtained isotherms of Re(VII) sorption by the precipitated PE. Figure 2 shows the dependences of PE exchange capacity with respect to rhenium E on the Re(VII) concentration at different concentrations of NO_3^- ions. They are linear within the range of Re(VII) concentrations studied (0.5–10 mg dm^{-3}). The obtained exchange capacities show that rhenium is concentrated by a factor of 200–400 in recovery of perrhenate ions with VA-212 polyelectrolyte, depending on the nitrate ion concentration.

CONCLUSION

The possibility of selective concentration of Re(VII) from nitrate-containing solutions with VA-212 water-soluble cationic polyelectrolyte was demonstrated.

SORPTION AND ION-EXCHANGE PROCESSES

Combined Activation of Anthracite

V. V. Strelko, N. V. Gerasimenko, and N. T. Kartel'

Institute of Sorption and Endoecological Problems, Ukrainian National Academy of Sciences, Kiev, Ukraine

Received September 12, 2000; in final form, March 2001

Abstract—The effect of anthracite pretreatment on the production of activated carbons and increase in the specific porosity of the resulting adsorbent was studied.

Production of new types of activated carbons is an urgent problem owing to the growing demand for carbon adsorbents for water treatment, purification of drinking water, recovery of solvents, and decontamination of gases released by chemical, metallurgical, and fuel-producing plants. Among starting materials used for production of activated carbons, anthracite shows much promise owing to the inexhaustible resources, low cost, high carbon content, and low content.

However, it should be noted that anthracite has low reactivity, which is due to the high degree of metamorphism of this type of coal (fairly well arranged supramolecular structure with the short- and, partially, long-range order of the carbon lattice). This is the reason why all attempts to develop fairly efficiently its porous structure and to produce adsorbents with high specific characteristics of porosity by direct activation have, as a rule, failed.

A number of treatments preceding steam-gas activation of anthracite have been proposed for the development of porosity of the final product. For example, Bessant and Walker [1] and Walker and Almargo [2] proposed a two-stage process including prepyrolysis of anthracite in an N_2 flow at 850–950°C and then activation proper with carbon dioxide. This procedure yields samples with fairly high specific surface area, reaching 1800 $m^2 g^{-1}$.

It is believed that the porosity of activated carbons is governed to a large extent by their pretreatment preceding the activation. For example, Parra and coworkers [3, 4] showed that preoxidation of carbons with atmospheric oxygen is one of the most important pathways for producing high-quality sorption materials. In this oxidation, a transport porous structure is formed, which facilitates the activation [5, 6].

A procedure including treatment of anthracite with chemical activators is also known [7]. For example, anthracite was activated with steam at 850–900°C up to combustion loss of 10–20%, and an intermediate product with a specific surface area of 770 $m^2 g^{-1}$ was obtained. Then, carbon was impregnated with aqueous solution of NaOH, Na_2CO_3, or Na_2SO_4, dried, and calcined at 850–910°C. The residue was washed with water and dilute sulfuric acid. The remaining carbon was additionally activated with steam at 750°C, and mesoporous activated carbon with specific pore surface area of 900 $m^2 g^{-1}$ was obtained.

Based on the above procedures of anthracite activation, it was appropriate to carry out a pretreatment of the initial raw material, including combination of the above procedures.

The aim of this work was to study the effect of anthracite pretreatment on its activation with steam, with the aim to raise the reactivity of highly metamorphozed material with respect to oxidizing gases in gasification.

As a starting material we used anthracite of brand A.[1] The chemical composition of the main components of the initial raw material was as follows: A^c = 4–5%, V^{dat} = 6–7%, and C^{daf} = 95%. The particle size of anthracite was 0.25–1.0 mm; the initial volume of sorption pores with respect to benzene, less than 0.01 $cm^3 g^{-1}$; and the bulk density, 0.9 g cm^{-3}.

The pretreatment included a series of operations. Initially, the starting material was activated with steam at 900°C up to combustion loss of 30%. Then, the samples were oxidized with moistened air at 270–

300°C until a static exchange capacity (SEC) of 0.5–1.0 mg-equiv g^{-1} was reached. It was assumed that this oxidation of anthracite surface must facilitate the subsequent pretreatment process involving incorporation of "wedging" ions into the anthracite structure by the ion exchange [8]. Oxidized anthracite was impregnated with a solution of chemical activator (sodium nitrate) and dried at 120–130°C for 2–3 h. The anthracite samples impregnated with a solution of alkali metal compound were repeatedly activated with steam at 900°C up to combustion loss of 80%. The steam flow rate was 0.1 l h^{-1}, which provided a 8–9-fold excess with respect to the reaction stoichiometry.

To confirm the effect of anthracite pretreatment on the activation process, we directly activated in parallel the initial (untreated) sample at the same temperature and the same steam flow rate.

At all stages of the study we carried out porometric monitoring of the samples by measuring the volume of sorption pores with respect to benzene W_s [9]. At the oxidation stage, we also determined the static exchange capacity SEC from the sorption of 0.1 N NaOH. At the preliminary and final stages of activation, we determined the weight and volume yields of the sample (R_m and R_v), bulk density Δ, and the combustion loss ω. The errors did not exceed 2 rel. %.

The specific surface area was measured with a Quantochrome Autosorb Automated Gas Adsorption System (United Kingdom).

The activation of anthracite by the above procedure produced microporous carbons. This is suggested by the isotherm of nitrogen adsorption on activated carbons subjected to thermochemical treatment. This isotherm has a shape typical of microporous adsorbents (Fig. 1). The calculated specific surface area reaches 820 $m^2 g^{-1}$.

A kinetic study of the combustion loss for the anthracite samples showed that the pretreatment considerably accelerates gasification of the samples (see table). It is seen from the data listed in the table that

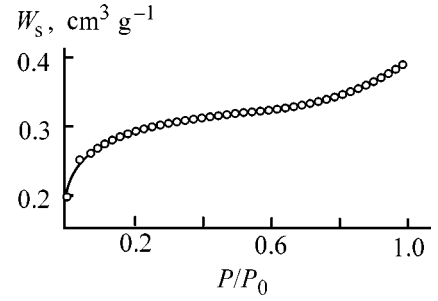

Fig. 1. Isotherm of nitrogen adsorption on activated carbon produced from anthracite subjected to thermochemical treatment. (W_s) Pore volume, and (P/P_0) relative pressure.

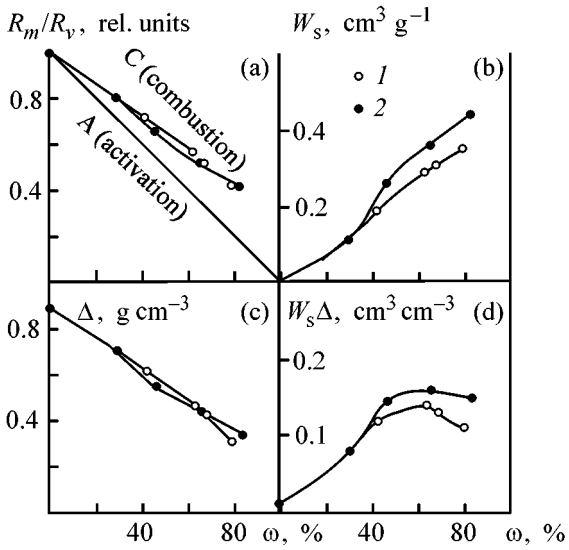

Fig. 2. Parameters of activated carbons produced from anthracite by (*1*) the standard scheme and (*2*) the modified scheme vs. combustion loss ω. (R_m/R_v) Activation index, (W_s) volume of sorption pores with respect to benzene, (Δ) bulk density, and ($W_s\Delta$) bulk porosity.

the maximum of combustion loss is reached in 6.5 h with direct activation and in 3 h with the thermochemical pretreatment, which is important from the standpoint of processing, since it allows the maximum pore formation to be achieved in a shorter time interval.

Figure 2 shows how the parameters of carbon sorbents produced by activation of the initial anthracite

Combustion loss for samples obtained at various activations of the initial anthracite

Activation	τ, h	ω, %	Activation	τ, h	ω, %
Direct	0	0	With thermochemical treatment	0	0
	2	29.7		2	29.7
	3	41.7		2.25	46
	5	62.7		2.5	60.7
	6	67.5		3	82.4
	6.5	79.4			

with pretreatment and by direct activation depend on the combustion loss. The dependence of the activation index R_m/R_v on the combustion loss (Fig. 2a) shows that thermochemical treatment of anthracite samples does not complicate the activation process. The gasification process is the same as that in direct activation. In both cases, the process occurs smoothly and is practically optimal, with strong prevalence of pore formation (line A) over combustion (line C).

Of some interest are data presented in Fig. 2b, in which the dependence of the sorption pore volume with respect to benzene W_s on combustion loss is shown. The curves coincide up to a combustion loss of 29.7%, since for both samples the initial process is direct activation. Then, one of the samples is subjected to thermochemical treatment, and the activation is continued. This action affects the subsequent second stage of activation, so that higher values of W_s at the same combustion loss are attained (curve *2*). At maximum combustion loss equal to 80% in direct activation, the largest attainable sorption pore volume with respect to benzene is 0.35 $cm^3\ g^{-1}$; in this case, the bulk density reaches 0.32 $g\ cm^{-3}$. In activation of anthracite samples subjected to thermochemical pretreatment, the largest attainable value of W_s is 0.44 $cm^3\ g^{-1}$ at the same bulk density.

The dependence of the bulk density Δ on the combustion loss is linear in both cases (Fig. 2c), and the lines practically coincide. Taking into account that the dependences of the activation index on the combustion loss completely coincide for both samples, we can conclude that this coincidence is not occasional.

The dependences of the bulk porosity $W_s\Delta$ on the combustion loss (Fig. 2d) are somewhat different for the samples subjected to direct activation with thermochemical pretreatment. Such a modified sample has a great resource of capacity to form the "sorption potential." In other words, it is likely that pretreatment of anthracite affects not only the activation rate but also the development of porous structure, presumably owing to an increase in the number of meso- and micropores.

CONCLUSIONS

(1) Combined anthracite activation by thermochemical treatment somewhat improves the porous structure of the matrix.

(2) The main advantage of the improved procedure of anthracite activation is the intensification of the final stage; in this case, the activation rate considerably increases (by a factor of 2).

(3) Our study reveals new potentialities for production of carbon adsorbents even from such highly metamorphozed material as anthracite.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrocrystallization of Molybdenum Carbide in Oxide Melts and the Influence of Electrolysis Parameters on Grain Size and Quality of Deposits

V. V. Malyshev, Kh. B. Kushkhov, and V. I. Shapoval

Received October 16, 2000

Abstract—The influence of current density and temperature on crystal grain size in electroplating of molybdenum carbide from tungstate–molybdate–carbonate melts was studied. The initial stages of molybdenum carbide electrocrystallization from tungstate–molybdate–carbonate melts at 750–900° on different substrates were studied by the method of galvanostatic switch-on curves and *in situ* microstructural analysis.

Electrodeposition of molybdenum carbide coatings from tungstate–molybdate–carbonate melts [1, 2] is a more advanced method than plating from halide–oxide electrolytes [3, 4]. Pure oxide melts allow use of a wider variety of substrates than halide–oxide melts do (in this case, steels of various brands can be used in addition to graphite, copper, nickel, molybdenum, and tungsten). They do not require any protective atmosphere, open up possibilities of using open electrolytic baths, and give much thicker coatings (up to 200 μm).

It has been established [5] that in a wide range of cathode current densities the phase overvoltage depends on current density logarithmically, similarly to the Tafel dependence:

$$\eta = a + b\log i. \qquad (1)$$

Analysis of the data reported in [6–13] shows that the values of the coefficients a and b vary widely between different electrode–deposited metal–electrolyte systems: a = 40–230 mV and b = 10–85 mV. The coefficient a decreases with increasing temperature or concentration of the deposited metal in the melt. These dependences are accounted for by the fact that the interaction between the metal and the substrate becomes stronger at higher temperatures.

In the case when dilute solutions of a salt of the metal being deposited are subjected to electrolysis in a melt, the growth rate of a crystal nucleus is determined by diffusion of discharging ions to its surface. The number of crystals being formed was determined by the authors of [5] by calculating in a quasi-stationary approximation the rate of substance transfer to the growing nucleus with the use of the equation of transient diffusion toward a continuously expanding semi-sphere:

$$Z = \frac{2.3 \times 10^{12} K_3^{1/2} T^{3/2} i^{3/2}}{z^{5/2} V^{1/2} D^{3/2} C_0^{3/2} C_c^{1/2} \eta^3} = K \frac{T^{3/2} i^{3/2}}{\eta^3}, \qquad (2)$$

where $K_3 = W^* \eta^2 / KT$ is a parameter independent of the overvoltage (W is the work of nucleus formation), T the melt temperature, i the cathode current density, z the ion charge of the metal being plated, V the molar volume of the metal being deposited, D the diffusion coefficient of an ion being discharged, C_0 the concentration of discharging ions in the melt volume, C_c the cathode capacitance, and η the maximum overvoltage.

As seen from Eq. (2), the number of crystals is affected by the crystallization overvoltage, temperature, and cathode current density. Analysis of experimental studies [6–13] shows that in the galvanostatic mode the number of forming nuclei as a function of the cathode current density can be found using the empirical equation

$$Z = K i^{\nu}, \qquad (3)$$

where ν is within 1–1.25.

1070-4272/01/7406-0961 $25.00 © 2001 MAIK "Nauka/Interperiodica"

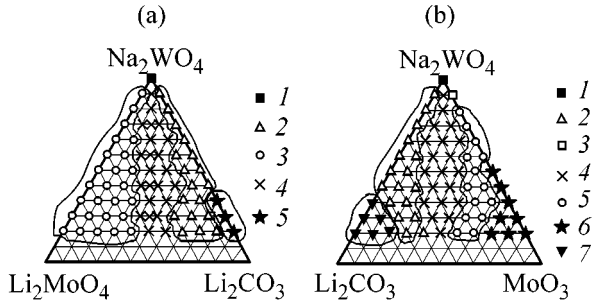

Fig. 1. Composition diagrams of the cathodic products of the systems (a) Na_2WO_4–Li_2MoO_4–Li_2CO_3 and (b) Na_2WO_4–MoO_3–$LiCO_3$. *T* 1173 K; cathode–C, Ni, and Cu; anode–graphite; i_c = (5.0–7.5) × 10^{-2} A cm^{-2}. (b) (*1*) No deposit, (*2*) C powder, (*3*) Mo coating, (*4*) Mo_2C coating, (*5*) Mo_2O coating, (*6*) Na_2MoO_3 bronzes, and (*7*) WC powder.

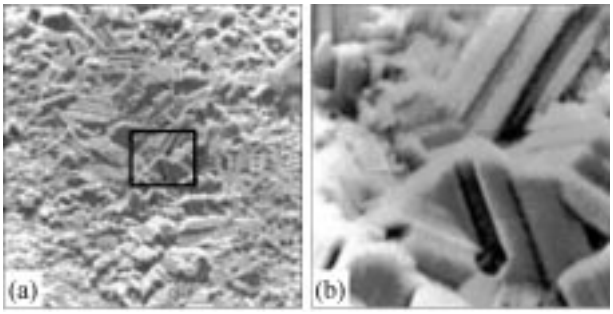

Fig. 2. (a) SEM microgram of the surface of molybdenum carbide coating electrodeposited from the melt Na_2WO_4–5 mol % Li_2MoO_4–5 mol % Li_2CO_3 and (b) its enlarged fragment. *T* = 1173 K, i_c = 0.075 A cm^{-2}. Magnification 3410.

This is in good agreement with the theoretical Eq. (2). The decrease in the amount of forming nuclei leads to increasing crystal size [5]:

$$L = Z^{-1/2}. \quad (4)$$

Thus, the amount of the nuclei grows with increasing cathode current density. All the coefficients of Eq. (2), combined into the constant *K*, are temperature-dependent. However, the effect of temperature on the coefficients of ion diffusion in the melt is the strongest, and the number of the nuclei decreases with increasing temperature. The amount of deposited nuclei is larger and the crystal sizes are smaller at lower temperatures and higher cathode current densities.

EXPERIMENTAL

It was reported in [1, 2] that plated coatings of molybdenum carbide can be, in principle, electrodeposited from oxide melts. The results obtained in studying the cathodic products of tungstate–molybdate–carbonate melts are represented in more detail in composition diagrams of the cathodic products (Figs. 1a and 1b). Molybdenum carbide coatings are deposited from the Na_2WO_4–Li_2MoO_4–Li_2CO_3 electrolyte when the concentrations of lithium molybdate and lithium carbonate are equal (to within 2.5 mol %) and do not exceed 20–25 mol %. The deposit contains carbon, molybdenum, and carbide at lower lithium molybdate concentrations, and molybdenum oxides at higher concentrations. At lower concentrations of lithium carbonate, the deposit mainly contains molybdenum, with free carbon predominantly deposited at higher concentrations. A more accessible industrial reagent—source of molybdenum, is its oxide. With molybdenum oxide used as a source of molybdenum, an approximately two times higher amount of lithium carbonate is needed as compared with the case of lithium molybdate.

Continuous molybdenum carbide coatings were obtained at 1073–1223 K and current densities of up to 0.5 A cm^{-2}. At temperatures below 1073 K and current densities exceeding 0.5 A cm^{-2}, a finely dispersed molybdenum carbide powder was obtained with specific surface area of up to 30 $m^2 g^{-1}$. Uniform and absolutely non-porous coatings with good adherence were deposited from the Na_2WO_4–5 mol % MoO_3–10 mol % Li_2CO_3 electrolyte at current densities ranging from 0.01 to 0.10 A cm^{-2} at 1173 K. In the current density range under study, the deposition rate is 5–25 μm h^{-1}, the current efficiency by molybdenum carbide in the form of a coating reaches 80%, and the coating are as thick as 100 μm. The effect of temperature and cathode current density on the crystal grain size in electroplating of molybdenum carbide was studied in the melt Na_2WO_4–5 mol % Li_2MoO_4–5 mol % Li_2CO_3 at 800–950°C and cathode current densities of 0.02–0.15 A cm^{-2}. The amount of electricity remained constant in all the runs (0.075 A h). After being washed with distilled water under identical conditions, the deposits were studied on a Stereoscan S-4 scanning electron microscope. The grain size was determined as the arithmetic mean of 50–100 grains. The outward appearance of a coating is presented in Fig. 2.

With the temperature raised from 800 to 950°C, the average grain size grows from 11.3 to 17.8 μm at the same cathode current density (0.075 A cm^{-2}).

The influence of temperature and cathode current density is demonstrated in Fig. 3. The average grain size increases from 13.5 μm at a current density of 0.15 A cm^{-2} to 19.6 μm at 0.02 A cm^{-2}).

It has been shown that epitaxial deposition of molybdenum carbide onto a substrate occurs in electrodeposition of the carbide from tungstate–carbonate melts [14]. The grain size can be reduced by applying a current pulse at the beginning of electrolysis or by using the reverse electrolysis mode. The pulsed current was produced by a special generator of rectangular pulses. The dc current density at the cathode was 7.5×10^{-2} A cm^{-2} in all the runs.

Application of a cathodic pulse at the beginning of electrolysis makes the deposit grains finer. For example, when a pulse with amplitude of 30 A cm^{-2} and 40–50-ms duration is applied, the grain size changes from 10–14 to 3–5 μm. Presumably, a slight, from 1860 to 1990 kgs mm^{-2}, increase in microhardness can be attributed to the finer grain structure of the deposit. An X-ray study showed that the initial pulses with amplitude of up to 30 A cm^{-2} have no effect on the deposit orientation. Irrespective of an initial pulse, the molybdenum carbide deposit has a (110) structure. In this case, only the layer defectiveness grows on applying pulses of this amplitude because of the formation of new metal nuclei on each grain of the deposit. When the pulse amplitude exceeds 50 A cm^{-2}, the deposits become spongy and weakly adherent to the surface. Presumably, this means that the near-cathode layer of the electrolyte is virtually completely depleted of bimolybdate and carbonate ions. In this case, the deposit properties can be explained by secondary reduction of $Mo_2O_7^{2-}$ and CO_3^{2-} ions by sodium atoms deposited on the cathode by the primary reaction and diffusing away from it.

Use of the reverse electrolysis mode yielded coatings with less coarsely crystalline structure and thickness increased up to 200 μm. The optimal parameters are as follows: $\tau_c/\tau_a = 20-40$, the anodic period duration 0.5–2.0 s, and the anode current density 0.15–0.50 A cm^{-2}. The main features of metal electrocrystallization from molten salts, including nucleation at the cathode, kinetics of electrode processes, microdistribution of the current, and structure of cathodic deposits, were established in [5, 10, 11]. The electrocrystallization in electrochemical synthesis has been studied to a considerably lesser extent. The electrocrystallization of tungsten oxide and molybdenum oxide bronzes was studied in [15, 16]. Published data on the electrocrystallization of molybdenum carbide are virtually lacking. This problem was investigated

by means of electrochemical methods for studying phase formation, combined with a simultaneous microstructural analysis of the substrate surface and electrolysis products being formed.

The employed experimental setup included an electric-resistance crucible furnace with a platinum heater, a complex for measuring galvanostatic switch-on potential–time curves, and a microstructure analyzer based on an MBS-9 microscope. The measurements were performed in a three-electrode cell. A platinum crucible served as the anode and melt reservoir. As the working electrode was used platinum, molybdenum, or glassy carbon microelectrode 0.5–1.0 mm in diameter sealed in quartz glass. A platinum–oxygen electrode Pt, $O_2 | Na_2WO_4$–0.2 WO_3 in air served as reference. The reversibility of such an electrode in oxide melts was demonstrated in [17–19].

The shape of the upper part of the oscillogram describing the variation of the platinum electrode potential on switching-on dc current indicates (by the presence of a characteristic peak) that crystallization overvoltage exists at the onset of molybdenum carbide formation. A quantitative estimate of the phase overvoltage yields a value of 8–40 mV for silver electrodes at 1023–1123 K.

Microstructural analysis of the dynamics of growth of the new phase shows that a great number of crystallization centers are formed at the beginning of the process. Then, separate crystals grow and merge into a continuous layer with the formation of a plane crystallization front. Slight depolarization is observed in the switch-on curve. To ascertain its origin, we studied the electrocrystallization of individual components of the compound being synthesized.

Comparison of the molybdenum phase formation from a Na_2WO_4–K_2WO_4(1 : 1)–Li_2MoO_4(5 mol %) melt and of molybdenum carbide from a similar melt with addition of lithium carbide shows similarity of their *E*–*t* curves. A slight depolarization preceding the main process can be attributed to the formation of platinum and molybdenum intermetallides [20, 21]. This result is indirectly confirmed by the change in the substrate color, observed visually at the beginning of polarization. The nucleation of molybdenum crystals occurs similarly to electrocrystallization of metals from molten salts. The crystallization centers appear solely at the beginning of the process, which corresponds to the peak in the switch-on curve, and then grow [5]. The phase overvoltages and the intervals of time in which the maximum nucleation overvoltage is reached under the identical plating conditions are well comparable for molybdenum and its carbide. However, the duration of the metastable state (i.e., the width of the overvoltage peak) is two times longer in the case of carbide formation, compared with that when the metal phase is formed.

No pure carbon is deposited from the tungstate–molybdate melt at 900°C owing to the formation of carbides. Carbon powders badly adherent to the electrode surface can be obtained on lowering the temperature to 750°C. No overvoltage peaks were observed in the *E*–*t* curve upon carbon deposition. This experimental fact suggests that there is no crystallization overvoltage in carbon deposition.

Thus, to a first approximation, the electrocrystallization of molybdenum carbide resembles crystallization of both molybdenum and carbon. On the one hand, similarly to electrodeposition of elementary carbon, nucleation of a great number of crystallization centers of molybdenum carbide occurs virtually over the entire substrate surface. On the other hand, formation of the Mo_2C phase requires a certain supersaturation, which corresponds to the phase overvoltage in electrocrystallization of pure molybdenum.

We studied the influence of the current density and temperature on the initial stages of electrocrystallization of molybdenum carbide. For example, changing the current density from 5×10^{-3} to 0.10 A cm^{-2} alters not only the phase composition of the obtained product, but also the nature of electrocrystallization in the initial stage. With the current density raised further, formation of lithium oxide also occurs along with the growth of Mo_2C layers. When the Li_2O solubility in the near-electrode region reaches the limiting value, the surface of the carbide deposit is passivated via blocking by lithium oxide. This affects the stability of the plane crystallization front and results in the deposition of a carbide powder, especially at lower temperatures. The performed study demonstrated that the temperature of electrodeposition is the most important parameter determining whether or not molybdenum carbide crystallizes as a continuous deposit.

Interesting results were obtained in studying the nucleation of the molybdenum carbide phase on glassy carbon. In equilibrium conditions, the following redox processes occur at the glassy carbon|melt interface:

$$C + CO_3^{2-} = 2CO + O^{2-}, \quad (5)$$

$$C + CO_2 = 2CO. \quad (6)$$

Gaseous carbon oxides are well sorbed by the substrate. The shape of the switch-on curves shows that electrochemical synthesis is unstable immediately after the dc current is switched on. It is interesting to note that synthesis of molybdenum carbide occurs on the surface of CO and CO_2 bubbles sorbed by the electrode and acting as a source of carbon.

In conclusion, we present some considerations concerning the mechanisms of electrochemical synthesis of molybdenum carbide. In the bulk of the Na_2WO_4–K_2WO_4 melts containing Li_2CO_3 and Li_2MoO_4, there occur the following equilibria [1, 2]:

$$CO_3^{2-} + xLi^+ = (Li_x^+CO_3^{2-})^{x-2} = Li_xO^{x-2} + CO_2, \quad (7)$$

$$MoO_4^{2-} + xLi^+ = (Li_x^+MoO_4^{2-})^{x-2}. \quad (8)$$

On switching on the electrode current, carbon dioxide and molybdate ion discharge simultaneously with the deposition of carbon and molybdenum atoms.

$$2CO_2 + 4e = C + 2CO_3^{2-}, \quad (9)$$

$$(Li_x^+MoO_4^{2-})^{x-2} + 6e = Mo + x/2Li_2O + (4 - x/2)O^{2-}. \quad (10)$$

Then, carbon and molybdenum atoms interact at the electrode to form Mo_2C.

CONCLUSION

A study of the influence exerted by the current density and temperature on the crystal grain size in electrodeposition of molybdenum carbide from tungstate–molybdate–carbonate melts revealed the existence of a crystallization overvoltage in nucleation of molybdenum carbide.

CATALYSIS

Synthesis of Catalyst for Hydrorefining with Domestic Raw Materials

Abstract—Basic requirements to the physicochemical and texture properties of supports for hydrorefining catalysts are formulated. Methods have been developed for synthesizing supports and hydrorefining catalysts with the use of kaolin, bentonite, and regenerated zeolites.

Aluminocobalt- or aluminonickel–molybdenum catalysts are widely used in the world practice as hydrorefining catalysts [1, 2]. These catalysts are synthesized by coprecipitation of the components or impregnation of a pretreated support with solutions of salts of the active components. However, in virtually all technologies of oil refining and gas processing, the main kinds of the employed catalysts are imported. The possibility of large-tonnage manufacture of these catalysts is limited in the first place by the lack of domestic aluminum hydroxide or oxide, whose content in finished catalysts may be as high as 85%. In this connection, the aim of the present study was to analyze the possibility of preparing nickel–molybdenum catalysts for hydrodesulfirization of natural gas and hydrorefining of various fuel fractions on a support produced with the use of domestic raw materials: Angren kaolin, Keles bentonite, and spent zeolite—a waste formed in natural gas purification to remove hydrogen sulfide.

EXPERIMENTAL

The supports were produced as follows: a thoroughly ground raw material was used to prepare a homogeneous paste formed into cylinders 5 mm in diameter and 5–7 mm long. The obtained granules were successively dried and calcined at 550–600°C. Catalyst samples were obtained by successive impregnation of the supports with solutions of nickel nitrate and ammonium paramolybdate $(NH_4)_6Mo_7O_{24}$. The catalyst activity was tested on flow-through laboratory and pilot installations, with, respectively, 2.0 and 50.0 cm^3 of catalyst charged. Diffuse reflection (DR) spectra were measured on a HITACHI-330 instrument with a DR attachment.

It should be noted that, in replacing aluminum oxide or hydroxide, the raw material used must possess the necessary set of physicomechanical properties: hydrophilicity and properties ensuring production of a homogeneous and well-formable paste. Moreover, the granules of the obtained support must have, upon calcination, the required strength and low wearability. In addition, for catalyst preparation by impregnation, these granules must also have a total porosity enabling introduction of the necessary amount of impregnating solutions. No less important are the acid–base properties of the surface structures of a support. The obtained supports must not have too high acidity. Otherwise, cracking of the hydrocarbon raw material will proceed concurrently with the hydrogenolysis of sulfur-containing compounds, making lower the production output and leading to catalyst caking. The performed analysis allowed formulation of the basic requirements to how new supports for hydrorefining catalysts are to be chosen. The hydromechanical characteristics of the synthesized catalyst samples are presented in Table 1.

As indicated by the obtained data, supports prepared from pure kaolin and bentonite have the highest mechanical strength, but relatively low specific surface area and water absorption capacity. The highest values of these latter were obtained for a sample of regenerated zeolite and its mixture with aluminum hydroxide. At the same time, the introduction of aluminum hydroxide into the bentonite and kaolin supports in a 1 : 1 ratio led to an increase in the specific surface area from 39.5 and 46.2 to 65.6 and 100.4 $m^2 g^{-1}$ and in water absorption capacity from 21.4 and 23.1 to 63.6 and 63.0%, respectively.

It can be seen from the presented results that physicomechanical characteristics of support samples N-4,

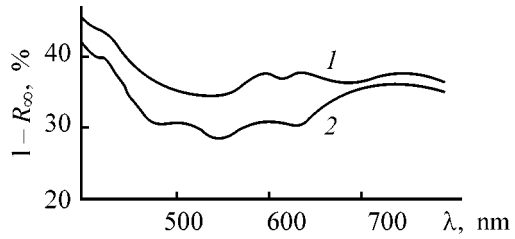
Table 2. Activity of nickel–molybdenum catalyst samples in AMC hydrogenolysis (G 5000 h^{-1})

Support	AMC conversion (%) at indicated temperature, °C					
	200	225	250	300	350	380
N-4	45.7	80.5	97.8	98.4	99.5	99.8
N-6	–	58.9	67.1	98.3	98.3	99.3
N-7	33.6	74.4	87.5	97.6	99.8	99.8
N-8	–	63.7	70.2	98.3	99.6	99.8
KND-46	80.5	90.9	96.0	99.3	99.4	99.5
Rhone-Poulenc	88.6	96.5	96.5	99.5	99.6	99.8
ACM catalyst	26.3	78.0	88.0	98.9	99.3	99.6

N-6, N-7, and N-8 satisfy requirements to catalyst supports. Therefore, the obtained supports were used to prepare by impregnation nickel–molybdenum catalysts containing (%): 14 active components, 10.5 MoO_3, and 3.5 NiO. For comparison, catalysts were also synthesized on imported supports KND-46 (Japan) and Rhone-Poulenc (France). The activities of the synthesized catalysts were tested on a flow-through laboratory installation in a model reaction of amylmercaptan (AMC) hydrogenolysis. The obtained results are presented in Table 2.

As seen from the data in Table 2, at temperatures higher than 300°C all the synthesized catalysts differ in activity only slightly and compare well with the catalysts obtained on imported supports and with the aluminocobalt–molybdenum catalyst AKM (Russia). Differences in activity start to appear at process temperatures lower than 300°C. In this case, the highest activity is observed for catalyst samples synthesized on Rhone-Poulenc and KND-46 supports. The lowest activity is exhibited by catalyst samples prepared using regenerated zeolite RK-38 (N-6) or its mixture with kaolin (N-7) or bentonite (N-8). Comparison of the data in Tables 1 and 2 shows that the zeolite much exceeds in specific surface area the Rhone-Poulenc (210 m^2 g^{-1}) and KND-46 (195 m^2 g^{-1}) supports. Therefore, this parameter cannot account for the observed low activity of the catalyst on the zeolite support. In this connection, an assumption was made that this fact may be related to formation of active centers in catalysts based on γ-Al_2O_3 and highly crystalline Al–Si zeolite.

It is known that a number of nickel-aluminum structures are not revealed by X-ray analysis owing to the low temperature of their calcination (450–550°C) and the nonstoichiometric NiO/Al_2O_3 ratio. Spinel



Spectra of diffuse reflection, $1 - R_\infty$, from nickel–molybdenum catalysts on different supports. (λ) Wavelength. (*1*) Al_2O_3 and (*2*) RK-38 zeolite.

structures formed through incorporation of nickel ions into tetrahedral voids in γ-Al_2O_3 are commonly identified using DR spectra [3–5]. The DR spectra of the catalyst samples, measured in this connection in the range 400–750 nm, are presented in the figure. It can be seen that the spectra of the synthesized samples contain the following sets of bands (nm): zeolite catalyst, 430, 490, and 720; catalysts with Rhone-Poulenc and KND-46 supports, 430, 550, 600, 635, and 730. Both sets of bands have been identified in the literature. The bands at 550, 600, and 635 nm are the most characteristic of a nickel-aluminum spinel, and those at 430, 490, and 720 nm, of nickel molybdate.

Table 3. Activity of a sample from the pilot batch of the ANM-2/1-1 catalyst (G 7500 h^{-1})

T, °C	AMC conversion (%) on indicated catalyst		
	ANM-2/1-1	AKM	TK-550
250	58.3	57.0	59.1

300	65.0	67.0	70.0
325	67.3	68.8	71.2
350	69.6	72.0	80.0
375	80.5	81.3	88.7
400	89.3	90.0	92.5

Thus, the use of supports with varied chemical nature leads to different surface and bulk structures of nickel and molybdenum compounds. On the zeolite and a mixture of the zeolite with kaolin predominates reaction between the active components to give $NiMoO_4$. On aluminum oxide or hydroxide supports, nickel-aluminum spinel is present together with $NiMoO_4$. This circumstance can presumably account for the different activities of the catalysts synthesized at low temperature.

Previously [4, 5], it has been shown that the reduction of the Ni–Al system strongly depends on the calcination temperature of a catalyst.

Samples calcined at 450–500°C show maximum hydrogen absorption at 400–500°C, which virtually coincides with the catalyst testing temperature and indicates nickel reduction under these conditions.

In addition, it should be kept in mind that the small sizes of micropores and their openings can make the sufficiently large surface area of the catalyst prepared with the use of the zeolite, found from low-temperature nitrogen adsorption, inaccessible to organosulfur compounds whose molecules are larger than the pore openings in the CaA zeolite.

The obtained data served as a basis for selecting a catalyst sample on a support composed of aluminum hydroxide and kaolin in a 1 : 1 ratio (N-4) for further tests. A technology was developed for preparing nickel–molybdenum catalyst ANM-2/1-1 on the given support, and its pilot batch was manufactured. The results obtained in testing the activity of this catalyst in a model reaction of AMC hydrogenolysis and in gas-condensate purification are presented in Tables 3 and 4. It can be seen that the activity of a sample from the pilot batch of the synthesized catalyst in hydrodesulfurization of natural gas and hydrorefining of highsulfur gas condensate compares well with the activities of the known commercial catalysts TK-550 (Holdor Topsoe) and AKM (Russia).

Thus, the performed investigations allowed formulation of the basic requirements to the physicochemical and texture properties of supports for hy-

drorefining catalysts. Methods were developed for synthesizing hydrorefining catalyst supports with the use of domestic raw materials: Keles bentonite, Angren kaolin, and regenerated zeolites.

CONCLUSIONS

(1) The specific surface area and total porosity (water absorption capacity) should be not lower than 50 $m^2 g^{-1}$ and 50%, respectively; and the mechanical strength, not lower than 4.0 kg/granule.

(2) The aluminonickel–molybdenum catalyst ANM-2/1-1 on a support composed of Angrene kaolin and aluminum hydroxide in a 1 : 1 ratio compares well in activity in hydrorefining of natural gas and high-sulfur gas condensate with the known commercial catalysts.

Abstract—The method of small-angle X-ray scattering was applied to study the Na_2O–B_2O_3 glass-forming system at Na_2O concentrations of up to 33 mol % at 400–1000°C. The temperature-concentration intervals close to binodal curves (at liquidus temperatures corresponding to stable formation of first crystals of the solid phase on cooling the system) were analyzed in most detail.

Previously, the method of small-angle X-ray scattering (SAXS) has been applied to study the structure of melts and glasses in a number of borate systems [1–5], in the concentration range with relatively low content of alkali metal oxide (Na_2O), Li_2O, K_2O) [1–4], and, additionally, in regions with higher content of Na_2O and K_2O (up to 33 and 20 mol %, respectively) [5]. In all cases, the plotted temperature dependences of the SAXS intensity [$I_{SAXS} = f(T)$] exhibited bends in close vicinity of the liquidus temperature (near the binodal curve corresponding to a stable phase equilibrium between the melt and the solid phase). In [1, 2], an assumption was made that the existence of such bends is associated with the transition of the liquid phase from the stable into a metastable, supercooled state.

Simultaneously, in crossing a binodal curve, it is impossible to detect precipitation of a new phase in crystalline form by direct experimental methods [by measuring the specific heat C_p, density ρ, or volume V of the system (Fig. 1)]. In other words, it is impossible to reveal any anomalous behavior of the first and second derivatives of the Gibbs potential of the liquid phase. From the thermodynamic standpoint, this result is quite expected, since, when the fluid transforms into a metastable state without precipitation of a new phase and, thus, with the homogeneous state of the system preserved, the thermodynamic potentials must exhibit a continuous dependence on the state parameters, determined by the partial equation of phase in terms of van der Waals–Storonkin [6]. Appearance of discontinuities in any-order derivatives of the Gibbs potential G would be inexplicable in the case under consideration.

The aim of the present study was to provide a possible explanation for the obtained experimental fact, based on the assumption that an infinitesimal amount of a "new" phase that differs to an infinitely small extent from the "old" phase is formed on crossing the binodal curve (passing from the stable liquid phase to

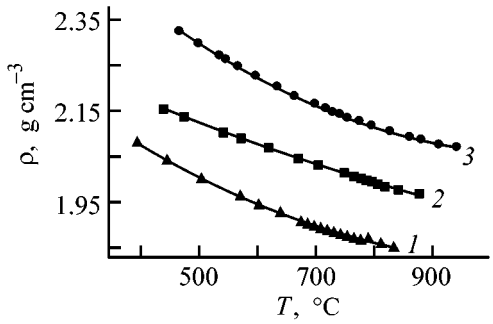

Fig. 1. Liquid phase density ρ vs. temperature T in the Na_2O–B_2O_3 system at constant composition. Na_2O content (mol %): (*1*) 12.5, (*2*) 20.0, and (*3*) 33.0.

a metastable one), i.e., nuclei (microdrops) of a new liquid phase, from which crystals of the solid phase are further formed, appear in the matrix of the old liquid phase. To accomplish this task, the Na_2O–B_2O_3 glass-forming system was studied most thoroughly in the composition range up to 23 mol % Na_2O in the temperature interval 400–1000°C, with primary attention given to the temperature–concentration ranges in close vicinity to the binodal curves (at liquidus temperatures corresponding to stable formation of first crystals of the solid phase upon cooling). As a result, the anomalous behavior of some third mixed derivatives of the Gibbs potential of the liquid phase, the most pronouncedly manifested in the temperature and concentration dependences of the derivatives of the isothermal compressibility β_T with respect to temperature T and concentration X at, respectively, constant concentration and temperature, was confirmed experimentally.

The experimental procedure was described in detail in [1–5]. Typical experimental temperature dependences of the SAXS intensity I_{SAXS} at constant melt composition X in the Na_2O–B_2O_3 system are presented in Fig. 2 together with the liquidus temperatures (binodal temperatures) for the melt composition studied, found from the data of [7]. It can be seen from Fig. 2 that the temperatures of discontinuities of II kind (bends) in the I_{SAXS}–T curves coincide within the experimental error (±5 deg) with the liquidus temperature. This phenomenon is observed for all melt compositions except $0.2Na_2O \cdot 0.8B_2O_3$ corresponding to the stoichiometry of the compound $Na_2O \cdot 4B_2O_3$ crystallizing to give a solid phase in this composition range [7]. It is for this composition that virtually no bend is observed (Fig. 2).

Typical temperature dependences of the isothermal compressibility of the liquid phase, $\beta_T(T)_X$, in the system Na_2O–B_2O_3 are presented in Fig. 3. Naturally, in this case, too, discontinuities of II kind are observed in the functions $\beta_T(T)_X$, coinciding with high precision with the liquidus temperature for all compositions except $0.2Na_2O \cdot 0.8B_2O_3$.

To evaluate the relative discontinuity in the derivative in passing through the liquidus temperature, the function $I_{SAXS}(T)$ was approximated mathematically and the obtained approximation was used to calculate the functions $\beta_T(T)_X$ and $(d\beta_T/dT)_X$. A typical result of approximation for the composition $0.33Na_2O \cdot 0.67B_2O_3$ is presented in Fig. 4. It can be seen that the function $\beta_T(T)_X$ is virtually linear before and after the liquidus temperature, and the function $(d\beta_T/dT)_X$ shows a discontinuity which is relatively significant

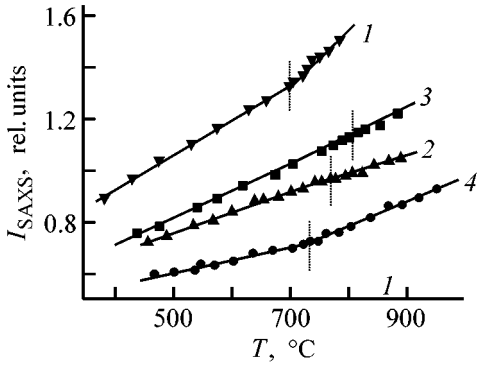

Fig. 2. Intensity of small-angle X-ray scattering by the liquid phase, I_{SAXS}, vs. temperature T in the Na_2O–B_2O_3 system at constant composition. Na_2O content (mol %): (*1*) 10.0, (*2*) 15.0, (*3*) 20.0, and (*4*) 33.0; the same for Fig. 3. *Dotted lines* show the liquidus temperatures according to [5, 7]; the same for Figs. 3 and 4.

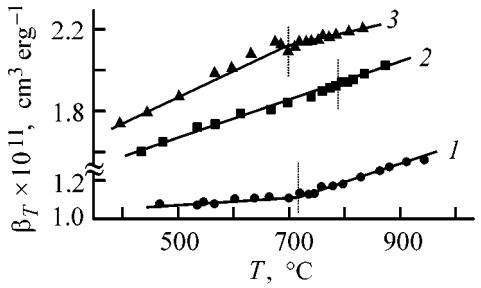

Fig. 3. Isothermal compressibility of the liquid phase, β_T, vs. temperature T in the Na_2O–B_2O_3 system at constant composition.

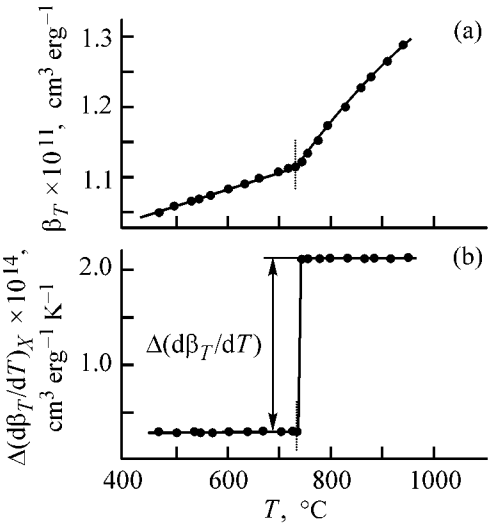

Fig. 4. Approximation of (a) isothermal compressibility β_T and (b) its temperature derivative $(d\beta_T/dT)_X$ for the liquid phase in the system Na_2O–B_2O_3 for the composition $0.33Na_2O \cdot 0.67B_2O_3$. ($T$) Temperature.

and constitutes hundreds of relative percent [in terms of the $(d\beta_T/dT)_X$ function value]. A similar pattern is observed for other compositions studied in the Na_2O–B_2O_3 system, with the discontinuity in the $(d\beta_T/dT)_X$ function also varying between tens and hundreds of relative percent.

An exception is the composition $0.2Na_2O \cdot 0.8B_2O_3$ corresponding to the composition $Na_2O \cdot 4B_2O_3$ which should have crystallized in the solid phase. For this composition, $(d\beta_T/dT)_X \approx$ const and there is no discontinuity in the corresponding derivative.

A similar pattern is observed in considering isothermal concentration dependences of the functions $I_{SAXS}(T)$. In [5], this kind of behavior was observed in a number of other systems, in particular, silicate and borate, containing potassium and lithium oxides. It follows from elementary considerations that a similar pattern must be observed in the behavior of other temperature- or concentration-related baric or volume functions—coefficients of volume and linear thermal expansion, compressibility factors, etc.

It can be seen from experimental data that, in crossing a binodal curve, part of third mixed Gibbs derivatives, e.g., $(d\beta_T/dT)_T$ and $(d\beta_T/dT)_X$, suffers a discontinuity, with the lower-order derivatives, e.g., $\beta_T(X)_T$, $\beta_T(T)_X$, $\rho(X)_T$, $\rho(T)_X$, ... (ρ is density), exhibiting no discontinuities of this kind. Indeed, we are dealing with specific features of just third mixed derivatives, since, e.g.,

$$(d\beta_T/dT)_X = (\partial V/\partial T)(\partial^2 G/\partial P^2)/V^2 - (1/V)(\partial^3 G/\partial P^2 \partial T) \quad (1)$$

and it apparently follows that $(\partial^3 G/\partial P^2 \partial T) = \pm\infty$ from the fact that the derivative $(d\beta_T/dT)_X = \pm\infty$ and, according to the experimental data, $(\partial V/\partial T) \neq \pm\infty$ and $(\partial^2 G/\partial P^2)/V^2 \neq \pm\infty$.

Let us consider crossing a binodal (curve or liquidus surface) as a result of some infinitesimal perturbation—change in temperature, dT, at constant composition $\mathbf{X}$ and pressure P, or upon a change in the concentration of one of the components in the system, dX_i, at constant T, P, and concentrations of all other components $X_{j\neq i,n}$ (the number of components in the system has no effect on the following reasoning). In the case of such a perturbation in the old liquid phase, the following phase processes may, in principle, occur.

(1) Let us assume that a finite mass is formed of a phase differing from the old phase to a finite extent. Such a situation occurs, e.g., when the binodal curve is crossed at the melting point of a component or congruently melting compound, or at the extremum of the melting point of the solid solution. From the system of differential equations describing the process of phase formation, e.g., crystallization, follows, in the case of the only variable intensive parameter of the heterogeneous complex, e.g., temperature ($n \geq 2$) [8, 9], that

$$(\mathbf{X}^{(s)} - \mathbf{X}^{(l)})\hat{G}^{(l)} d\mathbf{X}^{(l)} = (Q^{(ls)}/T)\,dT, \quad (2)$$

$$d\mathbf{X}^{(l)} = (\mathbf{X}^{(s)} - \mathbf{X}^{(l)})\,dm^{(s)}, \quad (3)$$

where $\mathbf{X}^{(s)}$, $\mathbf{X}^{(l)}$, and $d\mathbf{X}^{(l)}$ are vectors representing, respectively, the compositions of the solid phase and the melt and the shift in melt composition upon formation (e.g., crystallization) of $dm^{(s)}$ moles of the new phase s (e.g., solid) from 1 mol of the melt; $\hat{G}^{(l)}$ is the operator corresponding to the matrix of second derivatives of the Gibbs potential of the melt with elements $G_{ij}^{(l)} = (\partial^2 G/\partial X_i \partial X_j)^{(l)}_{TPX_{k\neq j,n}}$—the differential molar heat effect of crystallization.

The vectors $\mathbf{X}^{(j)}$ originate in the Cartesian space of independent variables—mole fractions of the components, $X_i^{(j)}$ [8, 9]. From the system of Eqs. (2) and (3) follows that

$$(\mathbf{X}^{(s)} - \mathbf{X}^{(l)})\hat{G}^{(l)}(\mathbf{X}^{(s)} - \mathbf{X}^{(l)})T/Q^{(ls)} = dT/dm^{(s)}. \quad (4)$$

Since in the case in question the node vectors are zero and the phase effect of crystallization is nonzero, the corresponding derivative of temperature with respect to the mass of the crystallizing phase is zero and the derivative of the mass of the crystallizing phase with respect to temperature is infinite. Indeed, to an infinitesimal change in temperature must correspond a finite change in mass:

$$\mathbf{X}^{(s)} - \mathbf{X}^{(l)} = 0, \quad Q^{(ls)} \neq 0, \quad dm^{(s)}/dT = \pm\infty. \quad (5)$$

This kind of consideration disagrees with the experiment, since, according to the thermodynamic theory of first-order phase transitions [6], the Gibbs potential G of a heterogeneous system suffers in this case a discontinuity of second kind, and the first, second, and other derivatives of the Gibbs potential (V, S, β_T, ...) suffer a discontinuity of the first kind, which is not observed in the experiment under consideration. The discontinuity is determined by the difference of these derivatives in the liquid (l) and solid (s) states.

(2) Let us assume that no new phase is formed, i.e., the state of the metastable liquid is in this case in no way distinguishable from the state of the stable liquid.

This variant of preservation of the homogeneous state of the system is also impossible since in this case the thermodynamic potentials of the system and any of their derivatives must exhibit a continuous dependence on the state parameters, determined by the partial equation of phase.

(3) Let us assume that a finite amount of a phase differing from the old phase to an infinitely small extent. Such a situation occurs, e.g., when critical phases are formed from a homogeneous melt. It is noteworthy that the solid and liquid phases cannot, in principle, form a critical phase [6] since they are described by fundamentally different equations of phase. This means that in this case two or more new liquid phases must form from a homogeneous melt.

In this case, the node vectors in Eq. (4) are again zero, with, however, the phase effect being zero, too (by definition of the critical phase); the operator $\hat{G}^{(l)}$ corresponds to a matrix with zero determinant; the corresponding indeterminate form in Eq. (4) is evaluated as zero [6], the derivative of the mass of the crystallizing phase with respect to temperature is infinite, and to an infinitesimal change in temperature must correspond a finite change in mass:

$$\mathbf{X}^{(s)} - \mathbf{X}^{(l)} = 0, \quad Q^{(ls)} = 0, \quad dm^{(s)}/dT = \pm\infty. \quad (6)$$

Let us demonstrate that this variant is also impossible in principle. Let (h), (s), and (l) be the indices of a heterogeneous complex of new (e.g., solid) and old (e.g., liquid) phases; Par is some arbitrary intensive state parameter: T, P, X_i, ... (we take derivatives with respect to only one parameter, a similar situation will be in considering mixed derivatives); $m^{(s)}$ is the mass of the new phase appearing at the points where the binodal curve is crossed; ΔG is the difference of the molar Gibbs potentials of phases l and s; $G^{(l)}$ and $G^{(s)}$ are the molar Gibbs potentials of the respective phases; and the index α characterizes the corresponding parameter fixing in differentiation. Then

$$G^{(h)} = G^{(l)} + m^{(s)}\Delta G, \quad (7)$$

$$(\partial G^{(h)}/\partial \mathrm{Par})_\alpha = (\partial G^{(l)}/\partial \mathrm{Par})_\alpha + (\partial \Delta G/\partial \mathrm{Par})_\alpha m^{(s)} + \Delta G(\partial m^{(s)}/\partial \mathrm{Par})_\alpha, \quad (8)$$

$$(\partial^2 G^{(h)}/\partial \mathrm{Par}^2)_\alpha = (\partial^2 G^{(l)}/\partial \mathrm{Par}^2)_\alpha + (\partial^2 m^{(s)}/\partial \mathrm{Par}^2)_\alpha \Delta G + (\partial^2 \Delta G/\partial \mathrm{Par}^2)_\alpha m^{(s)} + 2(\partial \Delta G/\partial \mathrm{Par})_\alpha (\partial m^{(s)}/\partial \mathrm{Par})_\alpha, \quad (9)$$

where $(d\mathrm{Par})_\alpha$ is a first-order infinitesimal, $(\partial G^{(l)}/\partial \mathrm{Par})_\alpha$ is finite, and $(\partial^2 G^{(l)}/\partial \mathrm{Par}^2)_\alpha$ is infinite physically, all these parameters being taken for a homogeneous (stable or metastable) phase α; $m^{(s)}$ is finite at the given perturbation according to the starting assumption 3; ΔG is infinitesimal according to phase equilibrium conditions; $(\partial \Delta G/\partial \mathrm{Par})_\alpha$ and $(\partial^2 \Delta G/\partial \mathrm{Par}^2)_\alpha$ are infinitesimal according to the critical phase properties; $(\partial m^{(s)}/\partial \mathrm{Par})_\alpha = \pm\infty$ also in accordance with assumption 3 and Eq. (6); the corresponding indeterminate form $\Delta G(\partial m^{(s)}/\partial \mathrm{Par})_\alpha$ is evaluated as finite and, consequently, $(\partial G^{(h)}/\partial \mathrm{Par})_\alpha$ is also finite, in agreement with the experiment.

Let us now consider the behavior of $(\partial^2 G^{(h)}/\partial \mathrm{Par}^2)_\alpha$. All the terms in Eq. (9) are finite with the exception of the product $\Delta G(\partial^2 m^{(s)}/\partial \mathrm{Par}^2)_\alpha$, an indeterminate form evaluated as $\pm\infty$. Therefore, $(\partial^2 G^{(h)}/\partial \mathrm{Par}^2)_\alpha = \pm\infty$, which contradicts the experiment.

(4) Let us assume that an infinitesimal amount is formed of a phase differing to a finite extent from the old phase. Such a situation occurs when the binodal curve is crossed at a "nonsingular" point of a multicomponent system, with the new phase formed but formation of infinitesimal amounts of the solid phase always corresponding to an infinitesimal change in temperature. In this case, the node vectors in Eq. (4) are nonzero, the phase effect of crystallization is other than zero, the derivative of the mass of the crystallizing phase with respect to temperature is finite, and to an infinitesimal change in temperature must correspond an infinitesimal change in mass:

$$\mathbf{X}^{(s)} - \mathbf{X}^{(l)} \neq 0, \quad Q^{(ls)} \neq 0, \quad dm^{(s)}/dT \text{ is finite.} \quad (10)$$

This case is similar to the already considered case 3, i.e., $(\partial G^{(h)}/\partial \mathrm{Par})_\alpha$ is finite and $(\partial^2 G^{(h)}/\partial \mathrm{Par}^2)_\alpha = \pm\infty$, which again contradicts the experiment.

(5) Let us, finally, consider the case not analyzed previously [6], namely, the formation of an infinitesimal amount of a new phase differing from the old phase to an infinitely small extent. This case is close to variant 3; however, by virtue of the fact that the node vectors are zero the corresponding indefinite form in Eq. (4) is evaluated as finite and the derivative of the mass of the forming phase with respect to temperature is also finite:

$$\mathbf{X}^{(s)} - \mathbf{X}^{(l)} = 0, \quad Q^{(ls)} = 0, \quad dm^{(s)}/dT \text{ is finite.} \quad (11)$$

In this case, both the derivatives $(\partial G^{(h)}/\partial \mathrm{Par})_\alpha$ and $(\partial^2 G^{(h)}/\partial \mathrm{Par}^2)_\alpha$ are finite, in agreement with the experiment.

Let us again use relation (7), differentiating it once more:

$$(\partial^3 G^{(h)}/\partial \mathrm{Par}^3)_\alpha = (\partial^3 G^{(l)}/\partial \mathrm{Par}^3)_\alpha + 3(\partial^2 m^{(s)}/\partial \mathrm{Par}^2)_\alpha(\partial \Delta G/\partial \mathrm{Par})_\alpha + 3(\partial^2 \Delta G/\partial \mathrm{Par}^2)_\alpha(\partial m^{(s)}/\partial \mathrm{Par})_\alpha + (\partial^3 G/\partial \mathrm{Par}^3)_\alpha m^{(s)} + (\partial^3 m^{(s)}/\partial \mathrm{Par}^3)\Delta G, \quad (12)$$

where $(\partial^3 G^{(h)}/\partial \mathrm{Par}^3)_\alpha$ is finite and $(\partial^n G^{(h)}/\partial \mathrm{Par}^n)_\alpha$ ($n = 1, 2$) are infinitesimal physically.

In their turn, $(\partial^2 m^{(s)}/\partial \mathrm{Par}^2)_\alpha$ and $(\partial^3 m^{(s)}/\partial \mathrm{Par}^3)_\alpha$ are equal to $\pm\infty$. This means that $(\partial^3 G^{(h)}/\partial \mathrm{Par}^3)_\alpha = \pm\infty$ and the third derivative of the Gibbs potential suffers a discontinuity of I kind, in good agreement with the experiment.

Of the variants considered, assumption 5 is the only one that does not contradict the experiment. Naturally, this assumption is a sufficient, but in no way necessary condition.

Thus, in crossing the binodal curve, an infinitesimal amount (micronuclei) of a new liquid phase originally differing to an infinitely small extent from the old phase is formed in the matrix of the old liquid phase. From these nuclei, the solid phase is further formed. Let us make several additional remarks.

(1) The given crystallization mechanism (always going via preliminary segregation) has not been, to our knowledge, proposed so far. The liquid phase seemingly "prepares" to form from itself a solid phase. It is noteworthy that in this case there is virtually no interface between the old liquid phase-matrix and the new liquid phase differing to an infinitely small extent from the old one. Therefore, no essentially positive surface energy appears in the system, i.e., the nuclei are not limited in their growth by the surface tension.

(2) This mechanism describes the onset of crystallization in systems tending to form metastable states (supercooled, oversaturated, etc.). If a system does not tend to form metastable states (to be supercooled or oversaturated), then the "distance" between the binodal and spinodal curves in a variable parameter (temperature or, e.g., concentration) is relatively small and the effect under consideration may be not actually observed in the experiment.

(3) Let us elucidate the wording "infinitesimal amount of new phase." This means the amounts conforming to the concept of phase as such ($>10^{10-12}$ particles per mole of old phase). The seeming contradiction is eliminated if we assume in our reasoning that the mass of the formed phase $m^{(s)}$ and the perturbation d Par are mathematically quantities of the same order of smallness (simply infinitesimals).

(4) Let us now elucidate the wording "phase differing to infinitely small extent from old phase." The difference may be associated with dissimilarity in properties (as a result of, e.g., the appearance of long- or medium-range order) or, simultaneously, with that in composition. We assume that in the given case we have an infinitesimally small difference in composition. This is indicated by the absence of any effects for the composition corresponding to the stoichiometry of the equilibrium solid phase ($Na_2O \cdot 4B_2O_3$ in the case in question). Indeed, if a new liquid phase emerges, shifting its composition toward that of the solid phase, then such a shift will be always observed except in the case when the compositions of the liquid and solid phases coincide. However, this explanation cannot be exhaustive since the compound $Na_2O \cdot 2B_2O_3$ (also melting congruently) does show the corresponding effect.

(5) If we adopt the mentioned postulate, then, under the conditions in question, the third derivatives of the Gibbs potential of a heterogeneous system with respect to extensive state parameters (S, V, ...) must pass through zero, or second derivatives of the intensive parameters (T, P, X, ...) with respect to extensive parameters (S, V, m_i) must pass through zero, or second derivatives of the extensive parameters with respect to intensive parameters must be infinite or suffer a discontinuity of I kind, and its own state parameter fixing in differentiation should be performed for each derivative.

(6) Other mixed second or third derivatives can be considered in a similar way. Noteworthy are some fundamental functions which (in terms of the proposed mechanism) must suffer a discontinuity of I kind in crossing the binodal curve: first derivatives of the isothermal compressibility, thermal expansion coefficients, and compressibility factors, etc. with respect to temperature and concentration; first derivatives of the isobaric or isochoric specific heat with respect to temperature and concentration; second derivatives of the chemical potentials of the components with respect to temperature and second mixed derivatives of the same parameter with respect to temperature–concentration or concentration–concentration, etc.

(7) In a real experiment, the discontinuities in derivatives of this kind may be unobservable because of the relatively poor precision of the experiments performed: the accuracy of determining the third derivatives of the Gibbs potential is incomparably poorer than that with which the second, and the more so the first, derivatives are found, and the jumps of I(II) kind themselves may be relatively weak, especially in sys-

tems that do not tend to form metastable states (see remark 2). In particular, even data on G_p are determined in a thermodynamic calorimetric experiment indirectly, by measuring the corresponding heats (temperatures). In this regard, the experiment on determining the isothermal compressibility holds a distinctive position, since this parameter is measured in experiment virtually directly with rather high accuracy, which gives reason to believe that jumps in derivatives of just this function will be revealed in the simplest way.

CONCLUSION

A plausible and consistent explanation for the experimental fact that the derivatives of the isothermal compressibility of the liquid phase with respect to concentration and temperature suffer discontinuities of I kind in crossing the binodal curve is the assumption that nuclei of a new liquid phase (microdrops) are formed in this case in the matrix of the old liquid phase, with crystals of the solid phase further formed from these nuclei.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Flow-Through Conductometric Analysis for Microconcentrations of Ammonia in Natural Water with Chromatomembrane Separation into Deionized Water

L. N. Moskvin, G. L. Grigor'ev, and A. G. Papsueva

Received October 19, 2000

Abstract—A new scheme is considered of flow-through conductometric analysis for ammonium ions in natural water, based on chromatomembrane separation of ammonia into deionized water. The proposed scheme is compared in efficiency with that based on dialytic separation of ammonia.

Determining the content of ammonia is an important task in monitoring the quality of natural water, since these ions belong to biogens promoting development of phytoplankton. At concentrations in water exceeding 0.2 mg l^{-1}, ammonia is toxic for quite a number of aquatic organisms [1]. Presently, the following maximum permissible concentrations of ammonium nitrogen in water are established (mg l^{-1}): 0.4 for fishing reservoirs and 2.0 for those with water used for technological and drinking purposes. Thus, on-line monitoring of the quality of natural water regarding the ammonia content requires procedures for determining ammonia in the concentration range 0.2–(3–5) mg l^{-1}.

Ammonia is most frequently determined in aqueous solutions photometrically, using the Nessler reagent and the Berthelot reaction. Both variants of the photometric method for ammonia determination are well known and are used both in classical and in flow-through schemes of analysis: flow-injection (FIA) and continuous flow-through analysis (CFTA). The possibilities of different variants of flow-through analysis for ammonia were compared in [2, 3]. Photometric methods generally enable ammonia determination in the required range of concentrations, but have a common shortcoming associated with the use highly toxic reagents.

This shortcoming can be eliminated in the case of the Berthelot reaction by replacing the toxic phenol with sodium salicylate [4]. However, the most efficient solution for overcoming this disadvantage of the photometric techniques was the idea to include into the scheme of flow-injection determination of ammonia a stage of its preliminary dialytic separation [5, 6]. According to this scheme, an alkali solution is introduced into water being analyzed. The ammonia formed in the process diffuses through pores of the hydrophobic membrane of the dialyzer into a flow of deionized water circulating in a closed circuit including a flow-through conductometric detector. The advantage of this scheme of analysis consists, in addition to ruling out use of highly toxic components, in a high selectivity and possibility of achieving low ammonia detection limits because of the high sensitivity of the conductometric sensor in deionized water. With a specially developed flow-through conductometric cell and slit dialyzer (slit depth 100 μm) and a 50-μm-thick poly(ethylene terephthalate) membrane, the calibration plot is linear within the range 0.03–0.5 mg l^{-1}) NH_3 [6].

Apparently, the range of determinable concentrations and the possibility of adjusting its limits are governed in the given scheme of analysis in the first place by the efficiency of operation of the membrane mass-exchange device—narrow-slit dialyzer. The flow of a substance being isolated is limited in the course of dialysis by the diffusion coefficient and membrane thickness. Correspondingly, all other conditions being the same, the range of determinable concentrations can be only changed by varying the thickness of the membranes used. In gas-diffusion processes, the diffusion coefficient is not, as a rule, the rate-determining factor in the case of sufficiently thin membranes (less than 100 μm thick). However, this gives rise to a technical problem associated with the easy de-

1070-4272/01/7406-0976 $25.00 © 2001 MAIK "Nauka/Interperiodica"

formability of such membranes. For reproducible operation of dialyzes with thin gas-diffusion membranes, the pressures in the feed and receiving chambers of the dialyzer should be maintained strictly equal. This is difficult to achieve in the FIA scheme with mixed flows of aqueous media, created by peristaltic pumps, switched at the inlet of the feed chamber.

In order to extend the limits of the range of determinable concentrations and possibilities of control over these limits, and to simplify the conditions under which reproducible results can be obtained, it is proposed to use the chromatomembrane way to perform mass-exchange processes in the liquid–gas system [7] as an alternative to the dialytic separation of ammonia with its subsequent conductometric determination in the FIA and CFTA schemes.

The aim of the present study was to develop a scheme and procedure for flow-through conductometric determination of ammonia ions in natural water, based on chromatomembrane separation of ammonia into deionized water, and to compare the efficiency of the developed scheme with that of the known scheme of analysis with dialytic separation of ammonia under the same conditions of conductometric measurements.

EXPERIMENTAL

To perform chromatomembrane separation of ammonia, a special cell was designed with two identical mass-exchange chambers having separate inlets and outlets for the aqueous solution and gas phase. The mass-exchange chambers are filled with biporous polytetrafluoroethylene with micro- and macropores 05–1.0 μm and 1–2 mm in size, respectively. The inlet and outlet collectors are separated from the biporous mass-exchange layers in the chambers and from each other by a microporous (0.2 mm) polytetrafluoroethylene membrane (Fig. 1). The geometric dimensions of the mass-exchange chambers in the chromatomembrane cell (CMC)—length, width, and height along the liquid flow direction—are 2, 1, and 1 cm, respectively. At the chosen chamber dimensions and porous structure of mass-exchange layers, the flows of the aqueous phase in both CMC chambers can be varied independently within the limits from 0 to 15 ml min^{-1}, and the carrier gas flow rate, from 0 to 20 ml min^{-1}.

The comparison dialyzer has the form of a mass-exchange cell with two chambers separated by a polytetrafluoroethylene membrane identical to those used in the CMC. To reduce the probability of membrane deformation in the case of the possible pressure surges in the dialyzer chambers, the chambers are designed as labyrinths. The depth of channels forming the labyrinths is 0.5 mm, i.e., corresponds to the minimum radius of macropores in the mass-exchange layer of the CMC.

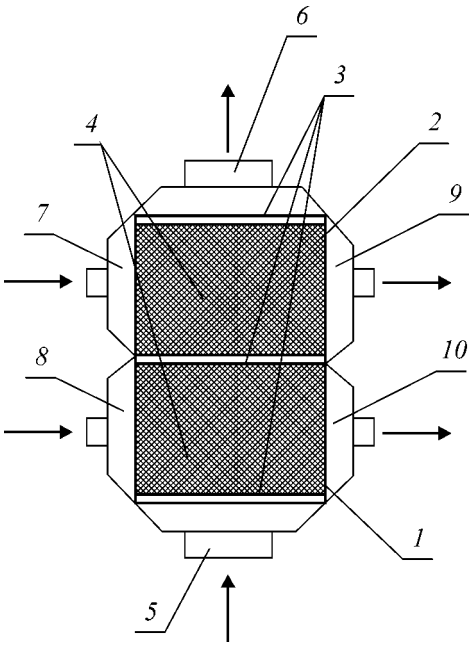

Fig. 1. Schematic of a two-chamber chromatomembrane cell. (*1*) Feed chamber; (*2*) receiving chamber; (*3*) membranes; (*4*) mass-exchange layer; (*5*, *6*) inlet and outlet gas phase collectors, respectively; and (*7–10*) inlet and outlet collectors of the receiving and feed chambers, respectively, in order of enumeration.

The area of the membrane separating the feed and receiving solutions in the dialyzer is 10 times the area of the interface between the mass-exchange chambers in the CMC, or 20 cm^2.

The hydraulic scheme of FIA for ammonium ions in natural water (Fig. 2) was assembled on the basis of standard units of a PIA-ION[1] commercial flow-through analyzer. The scheme variants A and B differ solely in the type of a mass-exchange device (CMC and dialyzer, respectively). The analyzer allows work in two modes: FIA and CFTA. The electrical conductivity of the receiving solution was measured on the standard flowthrough conductometric detector of a TsVET-3006 ion chromatograph.

Irrespective of the analysis mode, the receiving chambers of the mass-exchange devices were included into the closed circuit with deionized water. To maintain constant the composition of deionized water at

the inlet of the mass-exchange device, a column with mixed ion-exchange stock of KU-2×8 cation-exchange resin and AB-17×6 anion exchange resin. In the CFTA mode, either analyzed or deionized water was alternately fed, using a switching cock, at a rate of 4 ml min^{-1} into the feed chambers of the mass-exchange cells. In calibrating the analyzer, standard solutions of ammonium ions of known concentration were fed instead of water to be analyzed. The standard solutions of ammonia ions were prepared by diluting the starting solution obtained by dissolving a precisely weighed portion of ammonium chloride (chemically pure) predried at 110°C for 12 h [8].

Before being fed into the mass-exchange cells, the flows of water to be analyzed or a standard solution were mixed with a solution of Trilon B (0.1%) in 0.3 M NaOH (flow rate 2 ml min^{-1}). Addition of Trilon B to the alkali is necessary to prevent precipitation in the form of hydroxides of metals contained in natural water. Gaseous ammonia formed in mixing of flows of a sample (standard solution), and the adjusting solution came, driven by the concentration gradient (scheme B) or carrier gas flow (scheme A), into the receiving chamber of the mass-exchange cell, included into a closed circuit with a flow-through conductometric detector. Water was circulated through the closed circuit mainly through stainless steel pipes. The length of sections formed by silicone hoses in the peristaltic pump and connections between metallic pipes was made as short as possible to reduce the diffusion supply of atmospheric carbon dioxide into the deionized water. CO_2 was removed from air used for mass-transfer of ammonia from the feed into the receiving chamber in the CMC by passing air through a flow of alkaline solution in the feed chamber.

To compare the response times of the chromatomembrane and dialytic schemes of ammonia separation, the background value of the analytical signal was recorded in the switching cock position corresponding to delivery of a sample of deionized water into the feed chambers of the CMC and dialyzer through the input line. After a stationary value of the analytical signal was reached, the cock was switched into the position for feeding-in a sample in the form of a standard solution with ammonium ion concentration of 0.54 mg l^{-1}.

Figure 3 presents kinetic curves demonstrating how the signal from the conductometric detector reaches its stationary value for schemes A and B after such flow switching. The analytical signal *A* was measured

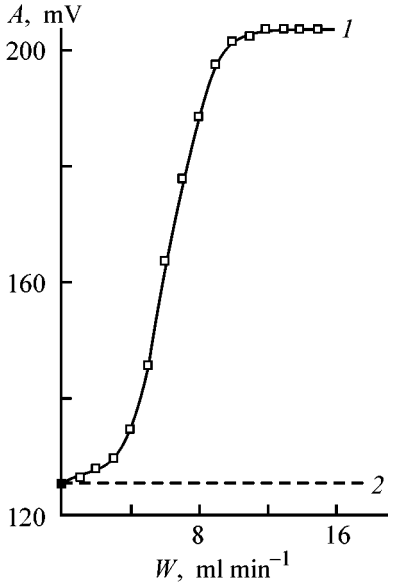

Fig. 4. Detector signal *A* vs. carrier gas flow rate *W*. Ammonia concentration in the feed solution 0.54 mg l^{-1}; flow rates of the feed and receiving solutions 6 and 1.5 ml min^{-1}, respectively. (*1*) Solution of ammonia ions and (*2*) deionized water.

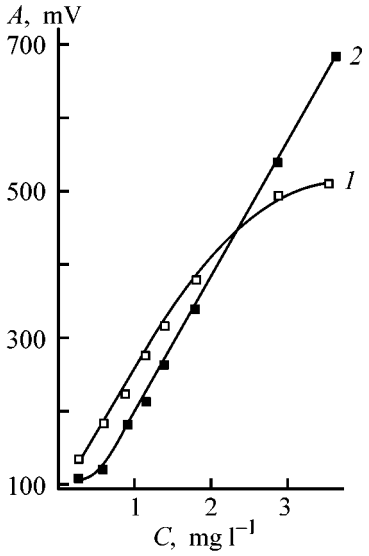

Fig. 5. Detector signal *A* vs. ammonium ion concentration *C* in the aqueous solution in chromatomembrane separation of ammonia into deionized water. Flow rates of carrier gas and feed solution 12 and 6 ml min^{-1}, respectively. Flow rate of receiving solution (ml min^{-1}): (*1*) 1.5 and (*2*) 5.

in millivolts on the scale of the conductometric detector of an ion chromatograph. In view of the relative nature of the measurements, no calibration against standard solutions in electrical conductivity units was done. It can be seen that the analytical signal is formed in a scheme with chromatomembrane separation and substance transfer from a sample into the receiving chamber induced by the carrier gas flow, much (3 times) faster than in the case of dialytic separation with diffusion mass transfer of ammonia from the feed into the receiving solution, despite the fact that in the former case the interface area in the mass-exchange chambers is 10 times that in the latter.

A similar pattern of slowed-down operation of the dialytic scheme is also observed in the following FIA stage—washing of the sample passage line in the hydraulic system with deionized water to bring the detector signal to the background value. With scheme A, the duration of this stage is virtually independent of the concentration of the substance to be determined over the entire concentration range studied (0.15–3.5 mg l^{-1}), being equal to approximately 1.2 min. For scheme B, this time is 3 min at a NH_4^+ concentration in a sample of 0.54 mg l^{-1} and grows with increasing concentration of the component to be determined.

The decrease in the response time of the analytical signal on passing from the dialytic scheme to a chromatomembrane one depends on the flow rate of the carrier gas (Fig. 4). All other conditions being the same, the detector signal grows with increasing carrier gas flow rate, to reach a maximum at 12–15 ml min^{-1}, which corresponds to a linear velocity in pores of about 1 cm s^{-1}. The contribution from the purely diffusion component to the overall mass transfer can be evaluated by comparing the detector signals in those cases when a solution of ammonium ions (Fig. 4, curve *1*) and pure deionized water (Fig. 4, straight line *2*) are used as feed solutions. The fact that the initial portions of the curves virtually merge indicates that, at a carrier gas flow rate $W \to 0$, this contribution is no more than several percent. It is the exceedingly low contribution of the purely diffusion component to the overall mass transfer that accounts for the fast response of the analytical system with chromatomembrane separation of ammonia. Hence follows one important practical consequence: in view of its fast response, the chromatomembrane method of sample processing can be effectively used not only in FIA, but also in CFTA. This is indicated by the shape of the analytical signals (Fig. 3) corresponding to the response to a change in the ammonium ion concentration in a solution being analyzed in the continuous mode. An important factor in this case is the high stability of the background signal, ensured by the invariable quality of deionized water in the closed circuit with an ion-exchange column.

The implementation in the chromatomembrane process of an advantage of the membrane methods of separation—the possibility of varying the flow rates of the feed and receiving solutions, makes it possible to solve one more practically important problem: enable control over the range of determinable concentrations within the same scheme of analysis. It can be seen from Fig. 5 that the calibration plot is linear at a receiving solution flow rate of 1.5 ml min^{-1} and ammonium ion content in the range from 0.15 to 1.4 mg l^{-1}. However, since ammonia concentrations on the order of 2 mg l^{-1} are of interest in monitoring the quality of some kinds of water, e.g., water for technological and drinking purposes, a necessity arises for expanding the range of determinable concentrations.

The investigations performed with the use of the chromatomembrane method of ammonia separation in its flow-injection conductometric determination demonstrated that, all other conditions being the same, raising the flow rate of the receiving solution makes the upper limit of determinable ammonia concentrations higher. For example, at a flow rate of the receiving solution of 1.5 ml min^{-1}, the calibration plot is linear up to ammonia concentrations of 3.5 mg l^{-1}, with the slope of the curve independent of the flow rate.

The obtained data suggest that the scheme of conductometric determination of ammonium ions in natural water, based on chromatomembrane separation of ammonia into deionized water, is preferable to the dialytic scheme. The proposed scheme of analysis can be used for any kind of natural water on making an appropriate choice of the range of determinable concentrations by fixing the corresponding flow rate of the receiving solution.

CONCLUSIONS

(1) A new scheme and a procedure for flow-injection and continuous flow-through analyses for ammonium ions in natural water is proposed, based on chromatomembrane separation of ammonia. The method makes it possible to determine ammonium ions in water at concentrations in the range from 0.15 to 1.4–3.5 mg l^{-1}, depending on the flow rates of a sample, absorbing solution, and gas inducing the mass transfer of ammonia.

(2) The efficiency of the developed scheme is compared with that of the analytical scheme with dialytic separation of ammonia under identical conditions of conductometric measurements. It is shown that the chromatomembrane scheme ensures faster response of the analytical signal and, correspondingly, the possibility of on-line continuous flow-through analysis.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Calculation of Capillary Disintegration of Fluid Jet into Drops in Terms of Linear Theory

Yu. G. Chesnokov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received May 23, 2000; in final form, February 2001

Abstract—A formula is derived for calculating the wave number at which the highest rate of perturbation build-up is observed in relation to the Reynolds number. The diameter of drops appearing in spontaneous disintegration of a fluid jet into drops and the time elapsed from the appearance of a perturbation till the fluid jet disintegration into drops are plotted as functions of the Reynolds number.

A fluid jet outflowing from a nozzle into a gaseous medium may spontaneously disintegrate into drops. This phenomenon occurs as a result of instability of the fluid flow in the jet against minor perturbations. The reason for flow instability is the action of surface tension forces at the jet surface. When there occurs a local decrease in the jet radius, the capillary forces cause a local increase in pressure. Contrariwise, in the case of a local increase in the jet radius, the pressure decreases. As a result, the fluid flows from regions with higher pressure to those with lower pressure, and the perturbation is enhanced. The phenomenon of capillary disintegration of a fluid jet into drops finds numerous applications in chemical engineering and other fields of technology [1]. For this reason capillary waves on the fluid jet surface have long been studied both experimentally and theoretically. A review of the literature on this issue was given in [1, 2].

As long ago as in Rayleigh's works it was shown that, in the presence of a sinusoidal perturbation, the flow is unstable when the perturbation wavelength exceeds the perimeter of a circle delimiting the jet cross-section. Rayleigh used linearized equations of hydrodynamics and boundary conditions at the jet surface, assuming that the amplitudes of perturbations of fluid velocity and pressure and jet radius are small. He obtained an algebraic equation relating the perturbation wavelength and the rate of perturbation amplitude build-up. The Rayleigh theory is applicable, generally speaking, only to description of the initial stage of perturbation development. In the course of time, the perturbation amplitude grows and the linearized equations, only valid for small-amplitude perturbations, become inapplicable. That is why further development of the theory has been aimed at describing the nonlinear interaction of perturbations.

The nonlinear stage of perturbation evolution has been described using different approaches. In [3–7], a solution to the problem of nonlinear development of capillary waves on the surface of a jet of ideal fluid was constructed in the form of expansions in terms of a small parameter—perturbation amplitude. In [8–12], the process of fluid jet disintegration into drops was subjected to direct numerical modeling, involving a huge expenditure of computing time. Therefore, it is difficult to use such calculations for a systematic study of the influence exerted by various factors on the capillary disintegration of a jet.

As shown by the experimental data obtained in [13, 14], the linear theory well describes the experimentally measured rate of perturbation build-up. This theory can be used to calculate the interval of time between the onset of a perturbation and the jet disintegration into drops. In the case when perturbations arise spontaneously, perturbations with different wavelengths are possible. Since a perturbation with a certain wavelength has the highest build-up rate, the fluid jet may disintegrate into drops through build-up of perturbations with just this wavelength. The wavelength of the perturbation with the highest build-up rate can be calculated using a relation obtained by Rayleigh. However, calculations of this kind are rather labor-consuming, since they require multiple solution of a transcendent equation involving Bessel functions.

1070-4272/01/7406-0981 $25.00 © 2001 MAIK "Nauka/Interperiodica"

The aim of this study was to construct simple calculational expressions for determining the wavelength of the perturbation having the highest build-up rate and to find the build-up rate of this perturbation.

Let as consider the development with time of a small perturbation on the surface of a cylindrical jet of a Newtonian viscous fluid outflowing into a gaseous medium. It is assumed that fluid flow is laminar. If the fluid velocity in the jet is high enough, the gravity force will have no significant influence on the fluid motion in the jet. Also, at not-too-high fluid velocities the interaction of the fluid with the ambient can be disregarded. Both these conditions are considered to be fulfilled. As far back as in Rayleigh's works it was established that the fluid flow in a jet may be unstable only with respect to perturbations possessing axial symmetry. Therefore, the fluid motion in the jet is assumed to be axially symmetric.

When writing down equations describing the fluid flow and boundary conditions for these equations, we use dimensionless variables. Let us introduce the following designations: a, the jet radius which can be used as the characteristic linear scale of the problem; ρ, the fluid density; and σ, the surface tension at the fluid–ambient interface. As is known, in the case of a jet of ideal fluid, the interval of time between the instant of perturbation appearance and that of jet disintegration into drops is proportional to a quantity having dimensionality of time, $t_0 = (\rho a^3/\sigma)^{1/2}$. We use this quantity as the characteristic time scale for the problem under consideration. Then, $u_0 = a/t_0 = (\sigma/\rho a)^{1/2}$ can be used as velocity scale. As pressure scale we introduce $p_0 = \sigma/a$.

Let us introduce into consideration a cylindrical system of coordinates (r, ϑ, z) whose z-axis coincides with the jet axis. We denote time by t; the axial and radial components of the fluid flow velocity by, respectively, u and ν; and the fluid pressure by p. All these quantities are assumed to be dimensionless. The equations describing the fluid flow in a jet are the continuity equation and the axial and radial components of the Navier–Stokes equation. In dimensionless form, these equations are as follows:

$$\nu_r + \nu/r + u_z = 0,$$

$$u_t + \nu u_r + u u_z = -p_z + \frac{1}{\mathrm{Re}}\left[\frac{1}{r}(r u_r)_r + u_{zz}\right],$$

$$\nu_t + \nu\nu_r + u\nu_z = -p_r + \frac{1}{\mathrm{Re}}\left[\frac{1}{r}(r\nu_r)_r - \frac{\nu}{r^2} + \nu_{zz}\right].$$

The Reynolds number Re, appearing in these equations, is defined by

$$\mathrm{Re} = (\rho a \sigma)^{1/2}/\mu,$$

where μ is the fluid viscosity.

In writing the equations, the subscripts of the variables denote differentiation with respect to the corresponding variable, i.e., $\nu_r = \partial\nu/\partial r$ etc.

We now consider the boundary conditions at the fluid surface. Let the equation of the free surface have the form

$$r = \eta(z, t).$$

Then we have kinematic boundary condition

$$r = \eta: \quad \eta_t + u\eta_z = \nu$$

and two dynamic boundary conditions

$$r = \eta: \quad 2\nu_r\eta_z + (u_r + \nu_z)(1 - \eta_z^2) - 2u_z\eta_z = 0,$$

$$p - \frac{1}{\mathrm{Re}}\left[2\nu_r - (u_r + \nu_z)\eta_z\right] = p_a + \frac{1}{\eta(1 + \eta_z^2)^{1/2}} - \frac{\eta_{zz}}{(1 + \eta_z^2)^{3/2}},$$

where p_a is the ambient pressure.

In a coordinate system moving together with the fluid, the formulated problem has the following solution

$$\eta = 1, \quad u = \nu = 0, \quad p = p_a.$$

This solution describes the unperturbed motion of the fluid jet in a coordinate system moving together with the fluid.

Let us assume that at the initial instant of time there exists a sinusoidal perturbation of the jet surface

$$t = 0: \quad \eta = 1 + \varepsilon\cos(kz),$$

where ε is the initial amplitude of the perturbation, and k is the wave number.

The equations of hydromechanics and the boundary conditions, written in the dimensionless form, contain a single dimensionless parameter—Reynolds number. Therefore, the process of fluid jet disintegration into drops will be entirely defined by setting three quantities: Reynolds number Re, initial perturbation amplitude ε, and wave number k. The development of

this perturbation with time can be described as follows. The quantities η, u, v, and p can be sought for as power series in small parameter ε:

$$\eta = 1 + \varepsilon\delta\eta + ..., \quad p = p_a + \varepsilon\delta p + ...,$$
$$u = \varepsilon\delta u + ..., \quad v = \varepsilon\delta v...$$

Substituting these expansions into the equations of hydromechanics and the boundary conditions and neglecting terms quadratic in ε, we obtain linearized equations and boundary conditions for determining $\delta\eta$, δu, δv, and δp. These equations allow a solution of the following type

$$\delta\eta = \eta_0 e^{\omega t}\cos(kz), \quad \delta p = q(r)e^{\omega t}\cos(kz),$$
$$\delta u = f(r)e^{\omega t}\cos(kz), \quad \delta v = g(r)e^{\omega t}\sin(kz).$$

The quantity ω in these formulas should be found by solving the problem. It depends on the wave number k and Reynolds number Re and determines the rate of perturbation amplitude build-up. Rayleigh obtained a relation between the wave number k and ω, which can be written as [15]:

$$F(k)\omega^2 + \frac{k^2}{\mathrm{Re}}[4F(k) - 1]\omega = \frac{k^2}{2}(1 - k^2) + \frac{4k^4}{\mathrm{Re}^2}[F(k_1) - F(k)], \quad (1)$$

$$k_1^2 = k^2 + \omega\mathrm{Re}, \quad F(x) = \frac{xI_0(x)}{2I_1(x)},$$

where $I_0(x)$ and $I_1(x)$ are, respectively, modified zero- and first-order Bessel functions.

At prescribed values of the Reynolds number Re and wave number k, Eq. (1) can be solved for ω. At $k < 1$, Eq. (1) has two real roots, one of which is positive. Therefore, the perturbation amplitude will increase in this case in the course of time, which will lead to jet disintegration into drops. Equation (1) was used to plot the dependences $\omega = f(k)$ at varied Re, shown in Fig. 1. It can be seen that at a certain wave number k, depending on Re, we have a maximum value of ω. Let us denote these values by, respectively, k_m and ω_m. In order to have a possibility to find fast k_m for a given Re, we construct an approximate formula for calculating this value. As shown by calculations, in the case of the ideal fluid ($\mathrm{Re} \to \infty$), $k_m = 0.697019$ and $\omega_m = 0.343339$. As seen from Fig. 1, k_m falls with decreasing Re. Figure 2 shows the dependence of $\ln k_m$ on $\ln \mathrm{Re}$. This dependence was determined by solving numerically Eq. (1) at varied Re and k. It can be seen that, at small Re, the k_m value is also small. Therefore, an approximate

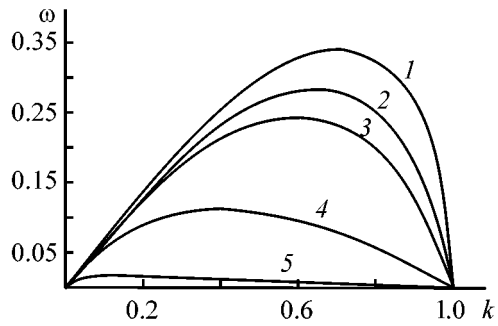

Fig. 1. Effect of wave number k on the rate ω of perturbation amplitude build-up. Reynolds number: *(1)* ∞, *(2)* 10, *(3)* 5, *(4)* 1, and *(5)* 0.1.

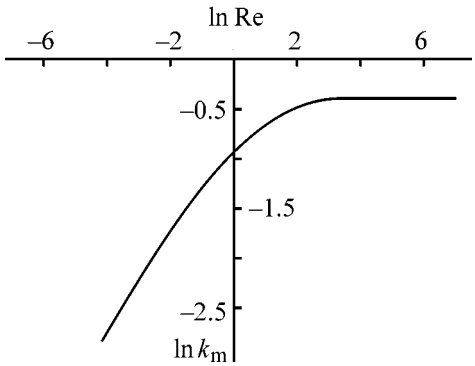

Fig. 2. Effect of Reynolds number on the wave number k_m at which the rate of perturbation build-up is at a maximum.

formula can be obtained at small Re by expanding the Bessel functions appearing in the left- and right-hand sides of Eq. (1) in power series in small parameter k. As a result, we have for long-wavelength perturbations, instead of (1), the following approximate equation

$$\left(\frac{2}{k} + \frac{k}{4}\right)\omega^2 + \frac{6k}{\mathrm{Re}}\omega = k(1 - k^2). \quad (2)$$

It is necessary to find such a wave number value k_m at which the function $\omega(k)$ has a maximum. At the extremum point the derivative $d\omega/dk$ vanishes. Differentiating Eq. (2) with respect to k and assuming that $d\omega/dk = 0$ in the obtained relation, we have

$$\left(\frac{1}{4} - \frac{2}{k^2}\right)\omega^2 + \frac{6\omega}{\mathrm{Re}} = 1 - 3k^2. \quad (3)$$

From Eqs. (2) and (3) follows that at small Re the k_m and ω_m values are related by

$$\omega_m = k_m^2/\sqrt{2}. \quad (4)$$

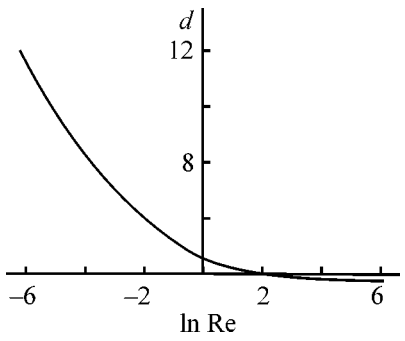

Fig. 3. Dimensionless diameter d of drops into which the jet disintegrates in spontaneous disintegration vs. the Reynolds number Re.

Substituting (4) into Eq. (2), we obtain

$$\frac{k_m^4}{8} + \frac{6k_m^2}{\sqrt{2\mathrm{Re}}} = 1 - 2k_m^2.$$

Since k_m is small at small Re, the first term in the left-hand side of this formula can be dropped. Therefore, the approximate formula for calculating k_m, valid at $\mathrm{Re} \to 0$, will have the form

$$k_m = \frac{1}{\sqrt{\dfrac{6}{\mathrm{Re}\sqrt{2}} + 2}}. \quad (5)$$

Let us modify formula (5) in such a way that at $\mathrm{Re} \to 0$ its asymptotic form should coincide with (5), and at $\mathrm{Re} \to \infty$ it give a correct limiting value of 0.697. Such a procedure for constructing approximate formulas was named by Polyanin and Dil'man [16–18] the method of asymptotic interpolation. As a result, we have

$$k_m = \frac{1}{\sqrt{\dfrac{6}{\mathrm{Re}\sqrt{2}} + \dfrac{2 + \mathrm{Re}}{1 + 0.697^2\mathrm{Re}}}} = \frac{1}{\sqrt{\dfrac{4.24264}{\mathrm{Re}} + \dfrac{2 + \mathrm{Re}}{1 + 0.48584\mathrm{Re}}}}. \quad (6)$$

The obtained formula is applicable over the entire range of Re variation. Comparison with results of numerical calculations by Eq. (1) shows that the maximum relative error of calculation by Eq. (6) does not exceed 0.25%.

In a similar way can be obtained a formula for calculating ω_m as a function of Re. At small Reynolds numbers, formula (4) is valid. Using relations (4) and (5), we obtain a formula valid at small Re ($\mathrm{Re} \to 0$)

$$\omega_m = \frac{1}{6/\mathrm{Re} + 2\sqrt{2}}. \quad (7)$$

Let us modify this relation so that it would give the correct limiting value of 0.343 at $\mathrm{Re} \to \infty$. As a result, we have

$$\omega_m = \frac{1}{\sqrt{\dfrac{6}{\mathrm{Re}} + \dfrac{2\sqrt{2} + \mathrm{Re}}{1 + 0.343\mathrm{Re}}}}. \quad (8)$$

Having formulas (6) and (8) for k_m and ω_m, we can calculate in relation to the Reynolds number the diameter of drops formed in spontaneous disintegration of a fluid jet into drops and also the interval of time between the instant at which a perturbation appears and that when the fluid jet disintegrates into drops. Since the amplitude of the perturbation with wave number k_m increases at the fastest rate, it can be considered that the jet will disintegrate into drops because of the increasing amplitude of the perturbation with this wave number. The wavelength λ of a perturbation is related to its wave number k by

$$\lambda = 2\pi/k.$$

Therefore, in dimensionless variables, the diameter of drops formed in jet disintegration can be found using the formula

$$d = (12\pi/k_m)^{1/3}.$$

The dependence of the drop diameter on the Reynolds number is shown in Fig. 3. It should be noted that, in fluid jet disintegration into drops, comparatively small drops, the so-called drops-satellites, can be formed in addition to the comparatively large drops of the predominant size. The formation of drops-satellites cannot be described in terms of the linear theory. This phenomenon appears as a result of a nonlinear interaction of capillary waves on the fluid jet surface [6, 11]. Whether or not the drops-satellites appear depends on the Reynolds number and the initial perturbation amplitude. Even if the drops-satellites do appear, their volume is comparatively small. Therefore, in this case, too, the diameter of drops with the predominant diameter can be approximately determined from Fig. 3 or using the above formulas.

The interval of time t_1 between the instant of perturbation appearance and that of jet disintegration into drops can be found as follows. At $k < 1$, Eq. (1) has

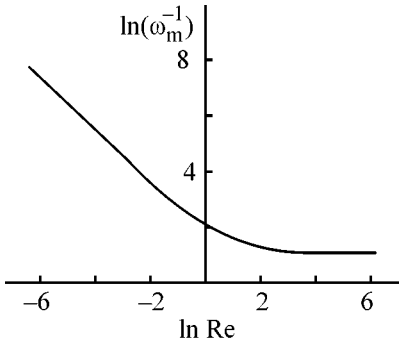

Fig. 4. ω_m^{-1} vs. Reynolds number Re.

two real roots, one positive and the other negative. Therefore, the expression for the amplitude of jet radius perturbation will contain terms exponentially increasing and exponentially decreasing with time. The exponentially decreasing term can be neglected and the t_1 value found from the condition

$$\varepsilon e^{\omega_m t_1} = 1, \text{ i.g., } t_1 = -(\ln \varepsilon)/\omega_m. \quad (9)$$

This condition means that, at the instant of disintegration, the amplitude of jet radius perturbation becomes equal to unperturbed radius, so that the jet radius becomes zero in the narrowest cross-section of the jet. Naturally, the perturbation amplitude cannot be considered small as compared with radius at the point of jet disintegration. Therefore, the linear theory, generally speaking, breaks down. Nevertheless, the available experimental data [13, 14] indicate that calculation of t_1 in terms of the linear theory is in satisfactory agreement with experiment. In dimensionless variables, the fluid velocity in the jet is unity and the length of the nondisintegrated part of the jet can be calculated using formula (9). The effect of the Reynolds number on the interval of time elapsed till jet disintegration into drops and on the length of the nodisintegrated part of the jet is illustrated in Fig. 4.

CONCLUSION

The obtained approximate formulas for calculating the wavelength of a perturbation whose amplitude increases at the highest rate and the ω_m value governing the build-up rate of the perturbation with this wavelength are applicable at any Reynolds numbers, being in good agreement with the results of an exact solution of the problem. These formulas can be applied to find the diameter of drops formed in spontaneous jet disintegration and the length of the nondisintegrated part of the jet.

Abstract—A mathematical description is presented of the duration of separate stages and the whole cycle of adsorption dearomatization of liquid paraffins from the 200–320°C fraction in a fixed bed of an aluminosilicate adsorbent.

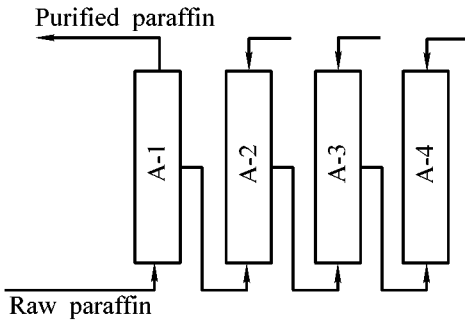
Of particular importance in optimal design, calculations of the economical efficiency, and control over sorption processes is a mathematical description of the duration of a cycle and separate stages of adsorber operation [1, 2]. The present study describes mathematically the duration of separate stages and the whole cycle of adsorption dearomatization of liquid paraffins of the 200–320°C fraction in a fixed bed of an aluminosilicate adsorbent.

In sorption processes, the possibility of prognostication of how the product composition changes with time is rather important. It is known that under transient conditions the process is more intensive. Therefore, it is more economically efficient to withdraw a product from a column before equilibrium is attained. Moreover, it is also known that the extent of departure from equilibrium determines the cycle duration of a diffusion process [1, 2].

To ensure the continuity of the adsorption dearomatization of liquid paraffins as regards the raw material and finished product flows, four adsorbers are present in the installation, with one stage of the process performed in each of these during a certain time interval [2]. The technological scheme of the process is shown in the figure. At the considered instant of time, adsorber A-1 is in the adsorption stage; A-2, in the stage of discharge of the raw material and desorption of aromatic hydrocarbons; A-3, in the stage of purging and adsorbent dehydration; and A-4, in the stage of cooling (see the figure). The operation schedule of the adsorbers is given in Table 1.

The process of adsorption dearomatization of liquid paraffins comprises the following stages: (1) adsorption of aromatic hydrocarbons from the raw material in the liquid phase by the adsorbent, with pure paraffins obtained; (2) removal of raw material residues from the adsorber volume and desorption of aromatic hydrocarbons from adsorbent pores with the use of isopropanol; (3) adsorber purging with a mixture of overheated steam and purge gas to remove the alcohol, dehydration of the adsorbent bed; and (4) cooling of the adsorbent bed to the adsorption temperature with a circulating purge gas.

In performing practical calculations for optimal design of the adsorption dearomatization of liquid paraffins, it is necessary to determine correctly the duration of each stage and the cycle as a whole [3, 4]. The previously developed mathematical model of the adsorption dearomatization of liquid paraffins in a fixed bed [5] makes it possible to determine the duration of the adsorption cycle. The mathematical model has the form of a system of second-order partial differential equations. The system was solved with the use of the Laplace–Karson transforms. On performing some mathematical operations with this system, the following system of equations was derived [6, 7]:



Technological diagram of adsorbers.

$$a_* = 2K_a D_a \frac{1}{r_*}\tau_a, \quad (1)$$

$$a = D_a 4\pi r_0^2 N' K_a \tau_a, \quad (2)$$

$$C_c = 2K_c D_c \frac{1}{r}\tau_a - a, \quad (3)$$

$$K_c = \frac{C}{R}, \quad (4)$$

$$K_a = \frac{a}{r_0}, \quad (5)$$

$$C_c = \frac{a}{[b(a_\infty - a)]}, \quad (6)$$

$$C = 0.9[-C_S(S_1) + \frac{16}{3}C_S(S_2) - \frac{16}{5}C_S(S_3)], \quad (7)$$

$$C_S = f(D_{eff}), \quad (8)$$

$$S_1 = \frac{1}{(2.89r_a)}, \; S_2 = \frac{3}{(2.89r_a)}, \; S_3 = \frac{5}{(2.89r_a)}, \quad (9)$$

where a_* is the concentration of the substance being adsorbed in microporous formations, C the adsorbate concentration, D_a the diffusion coefficient of the substance being adsorbed in the microporous formations, τ_a the adsorption time, r_* the running radius of microporous formations, r_0 the radius of the macroporous formations, D_c the diffusion coefficient of the substance being adsorbed in transport pores, R the adsorbent grain radius, r the running adsorbent grain radius, N' the number of microporous formations per unit volume, b constant in the Langmuir equation, D_{eff} the effective diffusion coefficient, K_a and K_c coefficients, and a_∞ the limiting adsorbate concentration.

The adsorption time is found with the use of Eqs. (1)–(9) by the random search method [7] on the basis of the criterion

$$F = (\tau_a^{calc} - \tau_a^{exp}) \le \varepsilon, \quad (10)$$

where τ_a^{calc} and τ_a^{exp} are, respectively, the calculated and experimental adsorption times; and ε is a certain prescribed error, $\varepsilon = 0.01$.

It should be noted that the time of desorption of aromatic hydrocarbons from the aluminosilicate adsorbent can also be calculated using the system of equations (1)–(9) with account of the changing signs of some terms of the equations.

To determine the time of drying of the aluminosilicate adsorbent, let us write the equation for the rate of drying [3] as follows

$$\nu = -\frac{M}{S}\frac{dx}{d\tau_{dr}}, \quad (11)$$

where ν is the rate of drying, M the amount of adsorbent in terms of dry residue, x the moisture content of the adsorbent, S the area of drying, and τ_{dr} the time of drying. Integrating Eq. (11) between the limits from x_1 to x_2, we obtain an expression for the quantity τ_{dr}:

$$\tau_{dr} = \frac{M}{S}\int_{x_2}^{x_1}\frac{dx}{\nu}. \quad (12)$$

It is known that the dependence of the adsorbate drying rate on x is linear. Then, Eq. (12) can be written in the form

$$\tau_{dr} = \frac{M}{S}\frac{x_1 - x_2}{\nu_n}, \; \nu_n = a_1 x + a_2, \quad (13)$$

where a_1 is the slope of the straight line, and a_2 is a constant.

Taking into account the drying rate ν in Eq. (12), we obtain

$$\tau_{dr} = \frac{M}{S}\int_{x_2}^{x_1}\frac{dx}{a_1 x + a_2} = \frac{M}{a_1 S}\ln\frac{a_1 x_1 + a_2}{a_1 x_2 + a_2}, \quad (14)$$

where $a_1 x_1 + a_2 = \nu_1$, $a_1 x_2 + a_2 = \nu_2$, and $a_1 = (\nu_1 - \nu_2)/(x_1 - x_2)$.

Then we have

$$\tau_{dr} = \frac{M}{a_1 S}\ln\frac{\nu_1}{\nu_2}. \quad (15)$$

It is known that an infinitely small quantity of heat dQ released by a solid during an infinitely short pe-

riod of time $d\tau_0$ is proportional to the temperature difference between the solid and the ambient:

$$dQ = -K(t_2 - t_1)d\tau_0, \quad (16)$$

where t_1 is the temperature of the ambient, t_2 the temperature of the solid (adsorbent), K a constant, and τ_0 the duration of the adsorbent cooling stage.

The amount of heat released by the adsorbent in cooling is given by the equation

$$Q = cm(t_2 - t_1),$$

where m is the mass, and c the specific heat of the adsorbent.

The quantity c will be considered constant:

$$dQ = cmdt.$$

With account of this relation, formula (16) takes the form

$$cmdt = -K(t_2 - t_1)d\tau_0. \quad (17)$$

Hence

$$d\tau_0 = -\frac{cm}{K(t_2 - t_1)}dt. \quad (18)$$

Integrating Eq. (9), we obtain

$$d\tau_0 + C = -\frac{cm}{K}\ln(t_2 - t_1). \quad (19)$$

If $\tau = 0$, then $t_3 = t_2$ and we have

$$C = -\frac{cm}{K}\ln(t_3 - t_1). \quad (20)$$

Subtracting Eq. (20) from (19), we obtain

$$\tau_0 = cm\frac{1}{K}\ln\frac{t_2 - t_1}{t_3 - t_1}. \quad (21)$$

The optimal values of τ_a, τ_d, τ_{dr}, and τ_0 were calculated by the method of dynamic programming on the basis of Eqs. (7), (15), and (21) with the use of the data from Tables 2–5.

The following optimal values of the process parameters were obtained (h): $\tau_a = \tau_d = 6.34$, $\tau_{dr} = 6.29$, and $\tau_0 = 6.32$. The complete cycle duration is 25.29 h. It should be noted that prior to optimization the duration of the adsorption cycle was 28 h. The possible improvement of the adsorption technology is largely associated with the creation of more perfect schedules of adsorption apparatus operation. Here, the following tendencies can be distinguished: making shorter the total duration of the adsorption cycle and raising the intensity of operation of an adsorption installation, and, consequently, reducing the capital outlays.

Thus, Eqs. (7), (9), (15), and (21), describing the duration of separate stages, can serve as a basis for developing the algorithm and system of optimal control over the sorption process.

CONCLUSIONS

(1) A mathematical description of the duration of separate stages of liquid-phase adsorption in a fixed bed was developed.

(2) The optimal duration of separate stages of the adsorption dearomatization of liquid paraffins was determined, making the total duration of the process shorter and the process intensity higher.

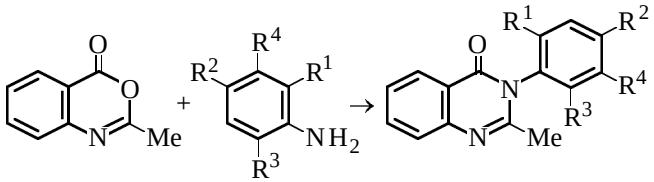
Abstract—Alkenylphenyl-substituted quinazolinones were prepared by reactions of 2-methyl-4*H*-3,1-benzoxazin-4-one with *o*- and *p*-alkenylanilines.

The interest in quinazoline derivatives is largely due to their high biological activity; intensive studies have been performed in this field recently [1–10]. A traditional line of synthetic studies is preparation of numerous derivatives of N^3-substituted quinazolinones. The spectrum of biological effect of these derivatives is wide; their preparations are used in neurology, microbiology, endocrinology, cardiology, and gerontology. Synthetic routes to quinazolin-4-ones are mostly based on the use of anthranilic acid and 3,1-benzoxazin-4-one derivatives [1–5].

Previously synthesized [11] alkenyl- and cycloalkenylanilines were used for preparing 3-alkenylphenylated heterocycles of the quinazoline series with the aim of subsequent functionalization at the alkenyl moiety.

For example, fusion of benzoxazine **I** with amines **II**–**XVII** at 140°C gives quinazolines **XVIII**–**XXXIII** (the analytical data are given in Table 1) in good yields (Table 2).

Condensation of benzoxazine **I** with *p*- or *m*-alkenylanilines yields a single reaction product (Table 2):



I **II**–**XVII** **XVIII**–**XXXIII**

R^1 = $CH_2(CH_3)CH{=}CHCH_3$, R^2 = R^3 = R^4 = H (**II**), (**XVIII**)*; R^2 = R^4 = H, R^3 = CH_3 (**VII**), (**XXIII**)*; R^2 = R^3 = CH_3, R^4 = H (**XV**), (**XXXI**)*; R^2 = $CH_2(CH_3)CH{=}CHCH_3$, R^1 = R^3 = R^4 = H (**III**), (**XIX**); R^1 = R^4 = H, R^3 = CH_3 (**VIII**), (**XXIV**), R^3 = R^1 = H, R^4 = CH_3 (**XIV**), (**XXX**); R^3 = $CH_2(CH_3)CH{=}CHCH_3$, R^2 = R^1 = H, R^4 = CH_3 (**XIII**), (**XXIX**); R^1 = 2-cyclopenten-1-yl, R^2 = R^3 = R^4 = H (**IV**), (**XX**)*; R^2 = R^4 = H, R^3 = CH_3 (**IX**), (**XXV**)*; R^2 = R^3 = CH_3, R^4 = H (**XVI**), (**XXXII**)*; R^1 = 2-cyclohexen-1-yl, R^2 = R^3 = R^4 = H (**V**), (**XXI**)*; R^2 = R^4 = H, R^3 = CH_3 (**X**), (**XXVI**)*; R^1 = 1-cyclopenten-1-yl, R^2 = R^4 = H, R^3 = CH_3 (**XI**), (**XXVII**); R^2 = R^3 = CH_3, R^4 = H (**XVII**), (**XXXIII**)*; R^1 = 1-cyclohexen-1-yl, R^2 = R^3 = R^4 = H (**VI**), (**XXII**); R^2 = R^4 = H, R^3 = CH_3 (**XII**), (**XXVIII**) (the compounds in which some of the signals in the ^{13}C NMR spectra are doubled are marked with an asterisk).

At the same time, a similar reaction with *o*-alkenylanilines yields two isomers. We believe that this is due to the sterically hindered state of the alkenyl unit. This can be clearly seen from the ^{13}C NMR spectra in which some carbon atoms in compounds **XVIII**, **XX**, **XXI**, **XXIII**, **XXV**, **XXVI**, and **XXXI**–**XXXIII** give double signals. When a substituent with the vinyl double bond is present in the *o*-position, doubling of signals is observed only in 1-cyclopent-1-enyl-containing quinazoline **XVII**.

The mass spectra of **XVIII** and **XIX** contain strong molecular peaks $[M]^+$, which are base peaks or are close to base peaks in intensity, in contrast to the previously studied structurally related quinazoline alkaloids [12–14]. The loss of the hydrogen atom ($[M - H]^+$ ions) or methyl radical ($[M - CH_3]^+$ ions)

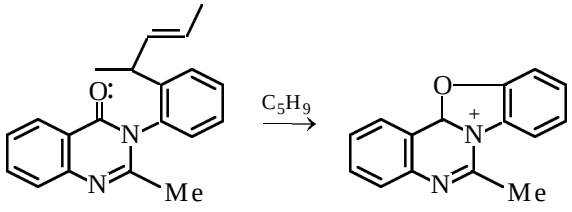
was observed in all cases. The first process is characteristic of all aromatic compounds [15]. We also detected numerous double-charged ions, characteristic of binuclear aromatic compounds. The methyl radical is probably lost from the 3-aryl substituent to a greater extent than from the 2-methylquinazoline core [16]. In the mass spectrum of compound **XVIII** containing an *o*-pentenyl group in the *N*-aryl substituent, we observed strong fragment peaks $[M - 29]^+$, $[M - 41]^+$, $[M - 43]^+$, $[M - 55]^+$, $[M - 56]^+$, $[M - 57]^+$, and $[M - 69]^+$, which may be due to the following ions: $[M - H - CO]^+$, $[M - CH_3CN]^+$, $[M - CH_3CO]^+$, $[M - H - CO - C_2H_2]^+$, $[M - CH_3 - CH_3CN]^+$, $[M - H - CH_3CN - CH_3]^+$, and $[M - C_5H_9]^+$. The loss of HCN, CH_3CN, and CO molecules is characteristic of quinazoline alkaloids [12, 13], and the loss of C_2H_2 and H, of aromatic compounds [15].

The ions $[M - C_5H_9]^+$ deserve special consideration. Their formation seems to be improbable as involving disadvantageous cleavage of the bond at the phenyl ring. Previously, Ramana and Kantharaj [17] stuidied the mass spectra of 2-substituted 3-(2-methylphenyl)-4(3*H*)-quinazolinones and their analogs. A strong intermolecular interaction of the C=O and C=S groups with the *o*-substituent in the 3-phenyl ring resulted in the formation of stable cyclic fragment ions formed through the loss of both the *o*-substituent and the $OH^{\cdot}$ or $SH^{\cdot}$ radical. Also observed were the ions $[M - ArO]^+$ and $[M - ArS]^+$ forming through migration of the aryl substituent from the nitrogen atom to

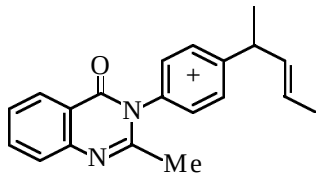
the oxygen or sulfur atom. Our results are fairly consistent with the data in [17]. For example, in the mass spectra of structural isomers **XVIII** and **XIX** with the *o*- and *p*-positions of the alkenyl substituent, the relative intensities (%) of certain fragment peaks differed significantly: $[M - C_5H_9]^+$, m/z = 235, 100 (**XVIII**), 9.5 (**XIX**); and $[M - CH_3]^+$, m/z = 289, 57 (**XVIII**), 100 (**XIX**). The major fragmentation pathway of **XVIII** is the loss of the pentenyl radical due to anchimeric assistance of the C=O group [18], with *ortho* cyclization to form ion **A**.



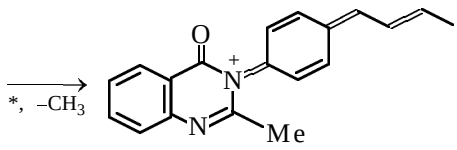
A

$[M]^+$ = 304 (69.6) 235 (100)

The major fragmentation pathway of **XIX** is the loss of the methyl group. The high stability of ion B is due to the conjugated system of double bonds and the formation of the quinoid structure [15].



$[M]^+$ = 304 (93.9)



289 (100)

EXPERIMENTAL

The ^1H and ^{13}C NMR spectra were taken on a Bruker AM-300 spectrometer (working frequencies 300.13 and 75.47 MHz, respectively); internal reference TMS. The IR spectra were recorded with a Specord M-80 spectrophotometer. The product purity was checked with a Chrom 5 chromatograph (Chromaton N-AW, 5% SE-30, 1200 × 3-mm column, carrier gas He, heating rate 12 deg min^{-1}) and by TLC on Silufol UV-254 plates (eluent hexane–ethyl acetate, 6 : 1). The mass spectra were taken on an MKh-1320 spectrometer (70 eV).

Quinazolin-4-ones were prepared by fusion of 3.1 mmol of appropriate amine with 3.1 mmol of 2-methyl-4H-3,1-benzoxazin-4-one at 140°C for 5 h. If required, the product was passed through a column packed with alumina (eluent pentane).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Color Characteristics of Aqueous Solutions of Synthetic Food Dyes

A. V. Gerasimov

Russian Research Institute of Food Aromatizers, Acids, and Dyes, St. Petersburg, Russia

Received October 20, 2000; in final form, March 2001

Abstract—The color characteristics of aqueous solutions of synthetic food dyes Azo Rubine, tartrazine, Indigo Carmine, Ponceau 4R, Sunset Yellow, and Brilliant Blue were studied. A formula is proposed for determining the hue of dye solutions.

The color of solutions of both individual and mixed dyes is determined by sensor methods. Usually the solution color is visually compared with that of solutions of references dyes or with a special color scale on paper or on plastic cards [1]. Despite the apparent roughness, this method is widely used up to now, because it does not require any special analytical equipment. In our previous studies we developed a procedure for determining the color characteristics of colored compounds, based on scanning and subsequent computer processing of the image. This method was successfully used for interpreting the results of separation of food dyes, in a thin sorbent layer [2, 3].

In this work we studied the color parameters of synthetic food dyes using the previously developed procedure.

EXPERIMENTAL

We chose six synthetic food dyes: Azo Rubine (**I**), Brilliant Blue (**II**), Sunset Yellow (**III**), Indigo Carmine (**IV**), Ponceau 4R (**V**), and tartrazine (**VI**), produced by Warner Jenkinson and Flevo Chemie (the Netherlands). These dyes are widely used as components of foodstuffs and belong to different classes of substances (azo, indigoid, and triphenylmethane dyes). The characteristics of the dyes are listed in Table 1.

Aqueous solutions of dyes were placed in cells for a photoelectric colorimeter and then scanned on a Mustek Scan Express 6000P scanner (True Color mode, 24 bit/pixel or 16.7×10^6 colors, optical resolution 100 dpi). Since the scanner detects reflected light and solutions of food dyes are transparent liquids, we placed a white paper sheet behind the cell. The color characteristics were determined with the Adobe Photoshop 5.0 package by the procedure described in [3], in the color modes CMYK [cyan (blue)–magenta (red)–yellow–black] and HBS (hue–saturation–brightness).

Typical color spectra of 100 g t^{-1} aqueous solutions of dyes, obtained in the CMYK mode, are shown in Fig. 1. The CMYK mode allows operation with three main colors: red, yellow, and blue. The dye solutions exhibit pronounced peaks in each of the color bands in accordance with the dye color. Sunset Yellow (imparts orange color to solutions) absorbs in both yellow and red ranges, and dyes of the red group (Azo Rubine and Ponceau 4R) exhibit absorption in the yellow range, more pronounced with Ponceau 4R.

Table 1. Characteristics of synthetic food dyes

Dye	EC index	INCI(CTFA) nomenclature	Color index
I	E 122	C.I.14720 Acid Red 14	14720
II	E 133	C.I.42090	42090
III	E 110	Sunset Yellow	15985
IV	E 132	C.I.73015 Acid Blue 74	13015
V	E 124	C.I.16255	16255
VI	E 102	C.I.191140 Acid Yellow 23	19140

Color spectra of aqueous solutions (100 g t^{-1}) of synthetic food dyes: (*a*) tartrazine, (*b*) Azo Rubine, (*c*) Indigo Carmine, (*d*) Sunset Yellow, (*e*) Ponceau 4R, and (*f*) Brilliant Blue. (*I*) Color intensity: (C) cyan (blue), (M) magenta (red), (Y) yellow, and (K) black; the same for Figs. 2 and 4. The *dotted line* shows the background absorption (water).

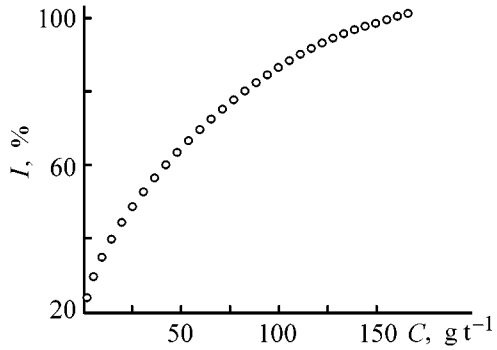

Fig. 3. Solution color intensity *I* in the red range vs. dye content *C*, by the example of calibration solutions of Azo Rubine.

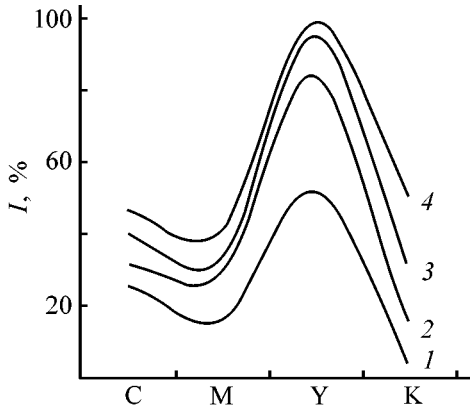

Fig. 2. Tartrazine color intensity as influenced by layer thickness, mm: (*1*) 1, (*2*) 3, (*3*) 5, and (*4*) 10.

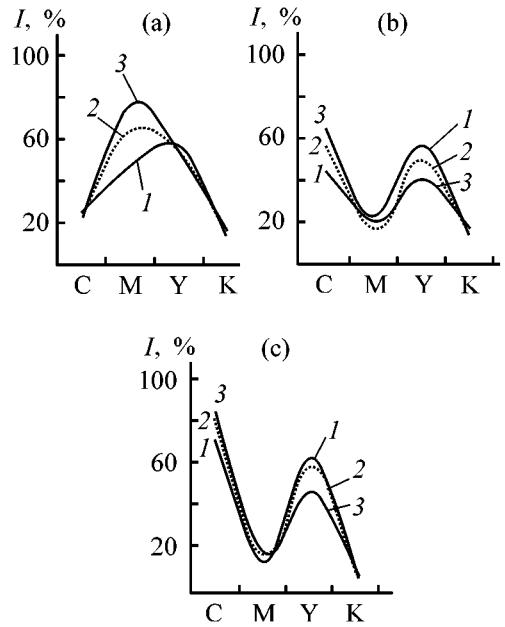

Fig. 4. Color spectra of binary solutions of synthetic food dyes. Dye mixture: (a) Azo Rubine + tartrazine, (b) Indigo Carmine + tartrazine, and (c) Brilliant Blue + tartrazine. Mixture composition (g t^{-1}): (*1*) 25 : 75, (*2*) 50 : 50, and (*3*) 75 : 25.

The influence of layer thickness on absorption is demonstrated for the example of tartrazine solutions. Figure 2 shows that, with increasing layer thickness, the color intensity grows in all ranges. Since it is appropriate to use lower color intensities for analytical purposes, we employed 1-mm cells for determining the color characterstics of dye solutions. Furthermore, capillary forces prevent outflow of solution from such thin cells, which facilitates scanning with a common flatbed scanner.

It was interesting to find how the color intensity depends on the dye content in solution. This was done for Azo Rubine as an example. We found that the concentration dependence of the solution color intensity is nonlinear (Fig. 3). It is known that the linear Bouguer–Lambert–Beer law is valid for the transmission mode only. In the reflection mode, used in scanning, the concentration dependence of the color intensity is described by nonlinear equations based on the Kubelka–Munk theory [4, 5].

In the food industry, preference is usually given to mixed dyes. The possibility of combining dyes, makes feasible any hue. As a rule, only two components are combined, since taking more components would complicate the process and lead to higher the product cost. We studied the color characteristics of some binary solutions of synthetic food dyes. With the relative content of the components varied, the color maximum shifts from one color range into another, as illustrated in Fig. 4.

As already noted, the color intensity evaluated in the CMYK mode nonlinearly depends on the concentration, which complicates analysis of dye mixtures in the CMYK mode. To characterize solutions, we chose hue as a parameter (H function in the HSB mode). This parameter (for more detail, see [3]) denotes the angle on the color circle (Fig. 5); it is independent of the dye concentration in solution. We found that the solution hue varies by approximately linear law, depending on the concentration ratio of the dissolved dyes. Examples of such dependences are given in Figs. 6a and 6b. The dependences (for calculation scheme, see Fig. 6c) are described by the formula

$$H_x = H_1 + \frac{H_2 - H_1}{100}\omega_2, \quad (1)$$

where H_x is the hue of a binary solution, H_1 and H_2 are the hues of the solutions of the individual dyes, and ω_2 is the relative content (rel.%) of component 2:

$$\omega_2 = \frac{C_2}{(C_1 + C_2)} \times 100, \quad (2)$$

provided that H_2 is located to the left (clockwise) relative to H_1, and H_1 takes the values

$$H_1 = \begin{cases} H_1 \text{ at } |H_1 - H_2| < 180, \\ (360 - H_1) \text{ at } |H_1 - H_2| \geq 180. \end{cases} \quad (3)$$

The second alternative in conditions (2) reflects the situation when, as the concentration of one of the components is varied, the hue passes through the point 0, 360 on the color circle (see, e.g., Fig. 6b).

The proposed procedure for calculating the hue of binary solutions was tested with mixed dyes (Table 2). The method gives fairly good results (the correlation factor of the calculated and true hue values is r = 0.974). At the same time, in some cases, the calculated and true hue values differ by more than 50°. Our further studies showed that the difference between the true and calculated hue values depends on the differ-

	2	**II**	25	189			

ence between the hues of the individual substances (correlation factor $r = 0.81$):

$$\Delta_i = 0.304[(H_1 - H_2)_i] - 5.107. \quad (4)$$

It was noted that this parameter also depends on the dye nature. The difference between the calculated and true hue values was the largest with solutions containing Brilliant Blue (Table 2).

Table 3. Formulation of dye mixtures with preset hue ($H = 142°$)

A	Component	Dye	H_i, deg	C_i, g t^{-1}	H_s, deg
1	1	**VI**	59	36.15	165
	2	**II**	189	63.85	
2	1	**VI**	59	38.97	150
	2	**IV**	195	61.03	
3	1	**III**	25	28.66	168
	2	**II**	189	71.34	
4	1	**III**	25	31.18	158
	2	**IV**	195	68.82	

Note: (A) Alternative, (H_i) dye hue, (C_i) dye content in solution, (H_s) hue of mixed dye solution.

Nevertheless, mathematical prediction of the hue value of binary solutions of food dyes can be used in formulating dye mixtures, since the difference of ±10°–15° affects the hue only slightly and is not always detectable visually (especially in the finished product). Thus, calculation by formula (1) can be used for rough estimation of the hue value of a mixed dye solution.

A better approach is, apparently, to find the relative content of components of a mixed dye, required to obtain the desired hue (or hue range) of the solution. In this case, using practically any graphics editor, it is possible to obtain the desired hue on the computer monitor and evaluate it visually, to determine the color characteristics of the chosen hue, and then to estimate the formula of the mixed dye. However, in this case it is desirable to choose dyes with the following characteristics: (1) their hues must be as close as possible to the desired hue, (2) the condition $H_1 < H < H_2$ must be met (H is the desired hue, and H_1 and H_2 are the hues of the individual

dyes), and (3) the colors of the dyes must be as close as possible to the main colors, i.e., to colors that cannot be obtained by mixing other colors: red, yellow, and blue.

With these conditions met, the binary dye mixture can be preliminarily formulated by Eq. (1) (with the exception of mixtures including Brilliant Blue).

Let us consider as an example the formulation of a green mixed dye. For convenience, we fixed the total dye concentration at 100 g t^{-1}. The results are listed in Table 3. We selected two yellow (tartrazine and Sunset Yellow) and two blue (Indigo Carmine and Brilliant Blue) dyes.

Table 3 shows that the experimental hue values of the binary solution are close to the prescribed values. The best results are obtained with the mixtures containing tartrazine. This fact agrees with the recommendations in [5], as the tartrazine hue (H = 59) is closer to the hue of the resulting solution (142) than the hue of Sunset Yellow (H = 25). Thus, it is possible to formulate binary dye mixtures on the basis of the prescribed hue of the finished solution, which can be useful in food industry.

CONCLUSIONS

(1) The correlation between the hues of binary dye solutions and their components was revealed and described mathematically.

(2) For binary solutions, the hue is a function of the relative content of dyes in solution.

(3) A method is proposed for formulating dye mixtures to obtain a prescribed hue.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Biocidal and Anticorrosive Effect of 2-Aminothiazole Derivatives Used as Additives to Jet Fuels

K. A. Karpov, A. V. Nazarenko, B. V. Pekarevskii, and V. M. Potekhin

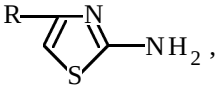
St. Petersburg State Technological Institute, St. Petersburg, Russia

Received April 16, 2001

Abstract—The effect of 2-aminothiazole derivatives on the biological resistance and corrosion activity of jet fuels was studied under conditions of water condensation.

2-Aminothiazole derivatives are widely used in pharmacology [1]. Aminothiazoles exhibit antimicrobial [1–3] and antioxidant [4] activity. Some disubstituted aminothiazole derivatives are used as antioxidant additives to hydrocarbon fuels, mineral and synthetic lubricating oils, solid paraffins, polyolefins, and animal and vegetable fats [5]. *sym*-Triazine derivatives containing substituents with 2-aminothiazole fragments are effective anticorrosive, antiwear, and antiscuff additives to lubricating oils [6].

With the aim to look for high-performance additives of polyfunctional effect among 2-aminothiazole derivatives, we studied the compounds of the general formula



where R = H (**I**), Me (**II**), Ph (**III**), and 1-naphthyl (**IV**).

In this work, we studied the biocidal and anticorrosive properties of 2-aminothiazole derivatives **I**–**IV** when used as additives to jet fuels.

Biocidal additives to fuels are used to suppress the biological damage by microorganisms, impairing the service properties of fuels [7–9]. The effect of these additives is based on inhibiting the activity of microorganisms contaminating the fuel and living in hydrocarbon medium. Biocidal additives are active in concentrations that do not exceed the level prescribed for additives serving for other purposes. In any processes of fuel purification, the danger of fuel deterioration by microorganisms is decreased. However, these measures can only diminish, but not prevent the possibility of fuel contamination [7]; it can be fully precluded only by using special additives.

EXPERIMENTAL

Compounds **I**–**IV** were prepared by the Hansch procedure, namely, by reactions of thiourea with α,β-dichlorodiethyl ether (**I**) [10], with iodine and acetone (**II**) [11, 12], with iodine and acetophenone (**III**) [10, 11], and with iodine and 1'-acetonaphthone (**IV**). The purity and structures of **I**–**IV** were proved by TLC and by IR and NMR spectroscopy. The relevant physicochemical data are listed in Table 1.

The biological resistance of jet fuels RT anbd TS-1 [GOST (State Standard) 10227–86, intended for use in different climatic zones] protected with biocidal additives was determined according to GOST 9.023–74 within the framework of a common system of measures for corrosion and aging protection. The procedure involves incubation of fuels with additives in contact with an aqueous-mineral medium containing test microorganisms which actively grow in the fuel with no additive. Incubation was performed for 15

days under conditions optimal for the microbial growth. The extent of fuel protection with a biocidal additive was evaluated by comparing the samples with unprotected fuel (control). The results of the tests are listed in Table 2.

Our results show that 2-aminothiazole derivatives **I**–**IV** are fairly effective biocidal additives. In this connection, it is of interest to compare the microbial resistance of jet fuels containing additives **I**–**IV** and commercial additive Ionol (2,6-di-*tert*-butyl-4-methylphenol). As seen from Table 2, this additive shows no biocidal properties, and the microbial impact tests give results identical with those for the control sample.

To obtain quantitative characteristics of the biocidal effect of **I**–**IV**, we evaluated the sensitivity of test microorganisms to 2-aminothiazole derivatives by the method of duffusion into agar [13]. For the tests we used the standard culture media: Czapek agar and meat–peptone agar.

Table 3 shows how 2-aminothiazole derivatives affect the microbial growth. With respect to the efficiency of the bactericidal effect the compounds can be ranked in the order **II** > **I** > **III**.

According to our results, the structure of the 4-substituent in 2-aminothiazole derivatives affects the activity toward test microorganisms. Compound **II**, containing the methyl substituent, is characterized by the largest diameters of growth delay spots. Aromatic substituents drastically decrease the biocidal effect of the additives. Compound **IV** showed no biocidal properties under the experimental conditions.

The biological activity of 2-aminothiazole derivatives **I**–**IV** correlates with the electron-donor and electron-acceptor power of substituents. According to [14], compounds containing heteroatoms and multiple bonds can enter into donor–acceptor interactions with biopolymers, disturbing the normal vital activity of a microorganism. In our case, compound **II** containing

Table 4. Corrosion resistance of St.3 steel in hydrated RT jet fuel in the presence of 2-aminothiazole derivatives **I**–**IV** (98°C, additive concentration 5×10^{-4} M)

Additive	K, g m^{-2}	γ
–	1.71	–
I	1.32	0.30
II	1.24	0.38
III	0.78	1.19
IV	0.57	2.00
Ionol	1.36	0.26

an electron-donor methyl substituent exhibits the strongest biocidal effect, whereas compounds **III** and **IV**, containing aromatic substituents lowering the electron density in the thiazole ring, show a weak biological activity.

It is believed that antioxidants mainly behave as biocides [15]. However, as shown in Table 3, commercial oxidation inhibitor Ionol shows no biocidal effect at all.

As biocidal additives are used ammonia and amine derivatives, potassium permanganate, copper sulfate, zinc chloride, and a number of organic compounds [16]. However, many of them stimulate corrosion [17]. The corrosion activity of hydrocarbon media toward metal surfaces is, in particular, due to acids [18] formed by oxidation. 2-Aminothiazole derivatives, inhibiting oxidation of hydrocarbons [5], decrease the probability of corrosion. To evaluate unambiguously the anticorrosive effect of **I**–**IV**, we determined the corrosive activity of RT fuel in the presence of test compounds according to GOST 18597–73. It was evaluated by the weight loss of a metallic plate (St.3 steel) immersed in a fuel for 4 h under conditions of fuel saturation with water and its condensation on the plate. The corrosion activity of fuels under conditions of water condensation, K (g m^{-2}), was calculated by the formula

$$K = \frac{(m - m_1) - h}{S}, \quad (1)$$

where m is the plate weight before the test (g), m_1 is the plate weight after the test (g), h is the etching constant (g), S is the area of the top and side surfaces of the plate (m^2; the bottom surface is in contact with the vessel bottom and does not participate in corrosion).

The corrosion inhibition factor γ was calculated by the formula

$$\gamma = \frac{K - K'}{K'}, \quad (2)$$

where K' is the corrosion activity of the fuel containing an additive (g m^{-2}).

The corrosion activities and corrosion inhibition factors are listed in Table 4.

Thus, 2-aminothiazole derivatives show high anticorrosive power and surpass commercial inhibitor Ionol in performance. Along with the already noted inhibition of acid formation in fuel, the mechanism of the anticorrosive effect of 2-aminothiazole derivatives may also involve formation of a monomolecular layer of compounds (as a rule, coordination compounds) on the metal surface, insulating it from the hydrocarbon medium [19].

CONCLUSIONS

(1) 2-Aminothiazole derivatives exhibit biocidal properties and can be used as additives to RT and TS-1 jet fuels.

(2) The biocidal properties of **I**–**IV** depend on the nature of a 4-substituent.

(3) Aminothiazoles **I**–**IV** exhibit anticorrosive activity in RT fuel under conditions of water condensation.

Abstract—Two procedures for synthesis of water-soluble poly-*N*-methacryloyloxyethyl-*N*,*N*,*N*-trimethylammonium methyl sulfate are compared. Synthesis occurred by the radical mechanism with the Co(III)–glycine system and with acid catalytic initiation. The effect of the initiator nature and the reaction conditions on the course of polymerization was studied.

This work is devoted to synthesis of poly-*N*-methacryloyloxyethyl-*N*,*N*,*N*-trimethylammonium methyl sulfate, widely used for solving environmental problems. Previously, two fundamentally different procedures for radical polymerization, resulting in the formation of water-soluble polymers with molecular weights of $(10–30) \times 10^6$, were developed. One of these is based on the use of the redox system Co(III)–glycine as initiator [1], and the other is based on generation of polymerization centers by catalytic decomposition of monomer molecules [2].

In this report, we compare these processes with the aim to elucidate the features of the reactions allowing production of polymers with ultra-high molecular weights and to establish factors governing the structure and characteristics of the resulting polymers. The developed procedures of synthesis have been patented [3, 4] and served as the basis for production of ultra-high-molecular-weight flocculant Akromidan LK used for purification of drinking water and wastewaters.

EXPERIMENTAL

Poly-*N*-methacryloyloxyethyl-*N*,*N*,*N*-trimethylammonium methyl sulfate was synthesized as follows. In polymerization by the redox system Co(III)–glycine, solutions of the initiator and monomer were prepared separately. To obtain a solution of the initiator, a calculated amount of $Co_2(SO_4)_3 \cdot 18H_2O$ was added to an aqueous solution with a given concentration of glycine, cooled to 0°C; then argon was bubbled-through to remove dissolved oxygen. The solution with the required monomer concentration and acidity was bubbled with argon, cooled to 0°C, and added to the reaction mixture. The reaction was carried out in an inert medium. After the process was complete, the polymer was dissolved in distilled water and purified by dialysis to remove the residual monomer and low-molecular-weight impurities with the use of a cellulose membrane. The conversion was determined from the concentration of the resulting polymer solution by weighing the dry residue.

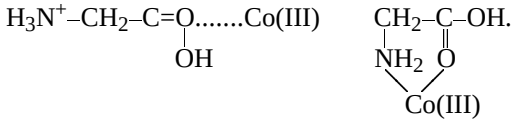
In polymerization by the acid-catalytic procedure, the working solution with required pH and monomer concentration was blown-through with argon and placed in a thermostat with a given temperature. The reaction was carried out in an argon medium. After the reaction was complete, the polymer was dissolved and the conversion determined as described above.

The intrinsic viscosity of the resulting polymers was measured in a 1 M aqueous solution of $NaNO_3$ in an Ostwald viscometer at 20°C. The molecular weight of polymers M was determined by the light-scattering technique (M_w) on a Fica-50 photodiffusimeter [5] and by the sedimentation-diffusion technique (M_{sd}) [6]. In the light-scattering technique,

1070-4272/01/7406-1002 $25.00 © 2001 MAIK "Nauka/Interperiodica"

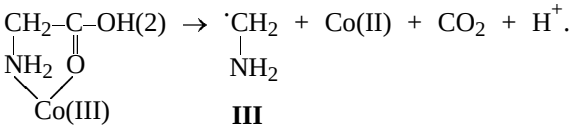
the wavelength of the incident vertically polarized light was 546 nm. The increment of the refractive index d*n*/d*c* was determined on an IRF-23 refractometer to be 0.154. The experimental data were processed by the Zimm double extrapolation technique.

The initiation methods have the following features. It was shown by NMR that, in initiation of polymerization with the redox system Co(III)–glycine [1], the reaction proceeds to form intermediate complex **I** and chelate **II**:



I **II**

Chelate **II**, in turn, decomposes to form free radical **III**:



III

The $^{\cdot}CH_2$–NH_2 radical initiates polymerization. The equilibrium constant of formation of the linear complex is $\beta_1 = 0.91 \pm 0.16$, and that of the chelate, $\beta_2 = 0.31 \pm 0.07$ M. Cobalt(III) is a strong oxidizing agent [7], but the chelate is fairly stable in dilute aqueous solutions and at a Co(III) concentration of 0.3–0.6 mg-equiv l^{-1} provides active development of polymerization in the course of 7–10 h at 20–40°C.

The initiation by the acid-catalytic procedure occurs via decomposition of monomer molecules under the action of protons [2]. The reaction proceeds by the radical mechanism. The initiation rate $V_{OR\cdot}$ is expressed by the equation

$$V_{OR\cdot} = K_{pr}\, x K_{OR\cdot}\, x\,[M]\, x\,[H^+],$$

where K_{pr} is the protonation constant of the monomer, $K_{OR\cdot}$ is the decomposition constant of the protonated species with formation of free radicals, and [M] and $[H^+]$ are the concentrations of monomer and protons in the reaction mixture, respectively.

The optimum conditions of synthesis of macromolecular polymers by this procedure are at concentrations of radicals in the range $(0.7–0.8) \times 10^{-8}$ M [2].

Studies showed that, to synthesire high-molecular-weight polymers, a monomer concentration of no less than 50–70% and stable concentration of the radicals on the order of 10^{-8} M are required in both cases [1, 2]. The use of kinetic methods for monitoring the polymerization course is hindered under these conditions; therefore, as the main parameters of monitoring we selected the yield of the polymer, its molecular weight, and the average number of macromolecules formed [8], which gives insight into the overall course of the reaction.

Table 1. Yield and molecular weight of polymer *M* at various initiator concentrations for the system Co(III)–glycine*

* [M] = 50 wt %, pH 2.5, T = 30°C.

A study of polymerization of methacryloyloxyethyl-*N*,*N*,*N*-trimethylammonium methyl sulfate with the use of the redox system Co(III)–glycine showed that the key factor of its development is generation of free radicals via decomposition of chelate **II**. We found that the optimum concentrations of reagents are in the following ranges: Co(III), 0.3–0.6 mg-equiv l^{-1} and glycine, 3.0–6.0 mM. Taking into account the high redox potential of Co(III), we selected the upper temperature limit of 40°C to provide stable operation of the initiator.

The dependences of the yield of poly-*N*-methacryloyloxyethyl-*N*,*N*,*N*-trimethylammonium methyl sulfate and its molecular weight on the initiator concentration in the case of the system Co(III)–glycine are presented in Table 1. With the concentrations of Co(III) and glycine growing by a factor of 2, the polymerization rate increases abruptly. For example, in the first case, the yield of the polymer is 12.5% and 48%, and in the second case, 69.0% and 90.2% in 2 and 5 h, respectively. In this case, an increase in the concentration of Co(III) and glycine results in a decrease in the molecular weight of the polymer, since free radical **III** is not only the polymerization initiator but also a chain-terminating agent.

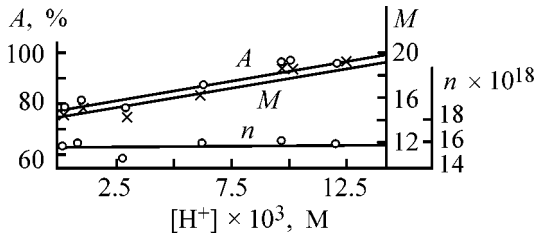

Fig. 1. Effect of the concentration of hydrogen ions $[H^+]$ on the yield of polymer *A*, molecular weight *M*, and the average number of marcomolecules *n* in 1 l of the reaction solution. Initiation with the system Co(III)–glycine. Reaction conditions: [M] = 50 wt %, [Co(III)] = 0.6 mg-equiv l^{-1}, [gl] = 6.0 mM, *T* = 40°C, and reaction time 4 h.

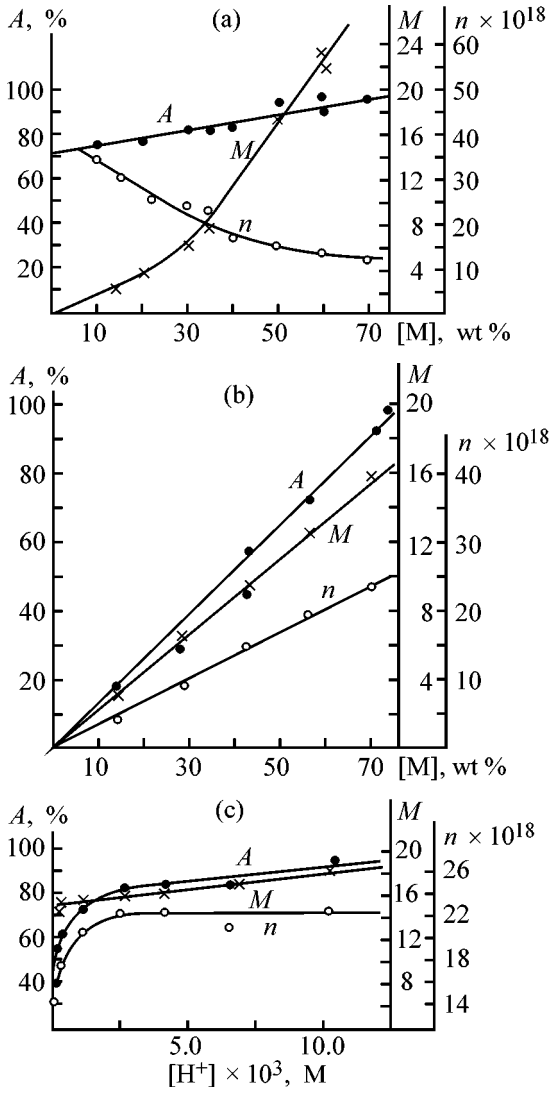

Fig. 2. Effect of concentration of (a, b) monomer [M] and (c) hydrogen ions $[H^+]$ on the yield of polymer *A*, molecular weight *M*, and the average number of macromolecules *n*. (a) Initiation by the system Co(III)–glycine, [Co(III)] = 0.6 mg-equiv l^{-1}, [gl] = 6.0 mM, pH 2.5, *T* = 40°C, and reaction time 4 h; (b) acid-catalytic procedure, *T* = 60°C, reaction time 6 h. (b) [M] = 70 wt % and (c) pH 2.0.

Varying the concentration of hydrogen ions also affects the polymerization process. According to data presented in Fig. 1, the molecular weight and the yield of the polymer grow steadily with increasing concentration of hydrogen ions throughout the studied range of pH at a constant number of formed macromolecules.

The dependences of the polymer yield and its molecular weight on the monomer concentration are presented in Fig. 2a. With increasing concentration of the monomer, the yield of the polymer grows steadily and reaches 88–95%. At the same time, the rate of increase in the molecular weight of the polymer in the range of monomer concentration above 30% grows by a factor of 2, which is apparently caused by changes in the nature of termination of the growing chains. It is seen from Fig. 2a that the number of chains in the second period considerably decreases. It should be noted that gelation begins even at a monomer concentration of approximately 2%.

Three factors affect acid-catalyzed polymerization: monomer concentration, pH of the reaction solution, and temperature [2]. The corresponding dependences are presented in Figs. 2b and 2c and in Table 2.

It is seen from Fig. 2b that the yield of the polymer, its molecular weight, and the number of the resulting macromolecules increase in direct proportion to the monomer concentration and, with this concentration increasing from 10 to 70%, the yield of the polymer grows from 14 to 93%, *M* increases from 2.4×10^6 to 16×10^6, and the average number of macromolecules *n* in 1 l of the reaction solution increases from 3.5×10^{18} to 24×10^{18}.

It is evident that the initiation by the acid-catalytic procedure proceeds differently: The number of the resulting polymer chains increases progressively, and, hence, the way in which the growing chains are terminated does not change. In this process the monomer is the polymerization initiator; therefore, its initiating power grows in proportion to the increasing concentration of the monomer.

Figure 2c shows the effect of proton concentration on the yield of the resulting polymer, its molecular weight, and the number of polymer chains. The study was carried out in a wide range of proton concentration, 10^{-5}–10^{-2} M. It was found that the polymerization begins at $[H^+] = 10^{-4}$ M; however, the yield reaches only 40%. The optimum conditions of synthesis of high-molecular-weight polymers are in the range $[H^+] = 2.5 \times 10^{-3}$–$1 \times 10^{-2}$ M. At a monomer concentration of 70% the concentration of hydrogen ions

of 2.5×10^{-3} M is sufficiently high for the process of polymer formation to become stable. In this case, the yield of the polymer reaches 83.0–94.2%, M = $(16.3–18.2) \times 10^6$, and the average number of macromolecules n in 1 l of the solution is 22.4×10^{18}.

The yield and molecular weight of the polymer are presented in Table 2 as functions of the temperature and time.

It is evident that the yield of the polymer grows with increasing reaction time. The optimum temperature of synthesis is in the range 60–70°C; in this case, the yield of the polymer reaches 95–98% and the molecular weight decreases insignificantly. However, the reaction at lower temperatures is of interest since it yields a polymer with increased molecular weight. At 50°C and the reaction times of 6 and 20 h we obtained polymers with M = $(18.9–19.2) \times 10^6$, and, at 20°C and 0°C, polymers with M = $(30–35) \times 10^6$.

The molecular weights of poly-*N*-methacryloyloxyethyl-*N*,*N*,*N*-trimethylammonium methyl sulfate were determined by two absolute methods: light scattering (M_w) [5] and sedimentation-diffusion analysis (M_{sd}) [6]. The results of determination by both methods are in good agreement within the experimental error (10–15%). The results obtained show that the samples studied have relatively narrow molecular-weight distribution (MWD), M_w/M_n = 1.5.

Figure 3 shows the dependence $\log[\eta] = f(\log M_w)$ in a wide range of molecular weights (5×10^4–3×10^7) for samples synthesized with the redox system Co(III)–glycine [9, 10]. For samples obtained by the acid-catalytic procedure (Table 3) the intrinsic viscosity [η] and molecular weight M fit in nearly the same dependence, which suggests structural and conformational homology of the macromolecules formed with the system Co(III)–glycine and by the acid-catalytic initiation procedure.

CONCLUSIONS

(1) Two procedures with different ways of initiation were developed for production of ultra-high-molecular-weight water-soluble poly-*N*-methacryloyloxyethyl-*N*,*N*,*N*-trimethylammonium methyl sulfate with molecular weight of $(10–30) \times 10^6$. The first is based on generation of free radicals by decomposition of a complex of Co(III) with glycine, and the second, on generation of polymerization centers in the reaction of the monomer with protons.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Polymerization of Vinyl Chloride in the Presence of Alcohols

A. G. Kronman, G. L. Groshev, L. V. Leshina, E. F. Sitnikova, and T. V. Sulina

Research Center, Kaprolaktam Joint-Stock Company, Dzerzhinsk, Nizhni Novgorod oblast, Russia

Abstract—Precipitation polymerization of vinyl chloride in solution in the presence of alcohols was studied. The reaction mechanism was suggested, and the product composition was estimated by IR spectroscopy and selective extraction.

In polymer chemistry, major attention is given to synthesis of modifiers, in particular, telomers, which can be used as plasticizers. Synthesis of vinyl chloride (VC) telomers using such telogens as polychloroalkanes (carbon tetrachloride, chloroform, tetrachloropropane), bromo and iodo derivatives (methyl bromide, bromoform), and esters was described in ample detail in monograph [1]. Initiating systems include iron trichloride, pentacarbonyliron, benzoin, acetonitrile, and dimethylformamide. The telomerization temperature was varied from 90 to 140°C, depending on the nature of a telogen and initiator.

Also, in the case of chloroalkanes (trichloroethane, 1,1,1,3-tetrachloropropane), telomerization of vinyl chloride with cleavage of the C–Cl bond cannot be effected with initiation by azo compounds and peroxides [2].

The use of such monomers as vinyl and vinylidene chloride, characterized by high rate constants of propagation of the intermediate radicals in homopolymerization, is favorable for formation of telomers containing more than three units [1]. However, the molecular weight M of these products is very low (200–1000). It is known [3, 4] that, to prepare low-molecular-weight vinyl chloride polymers, mono- and dihydric alcohols are added to a polymerization formulation, with the process performed in the presence of traditional initiators (peroxides, percarbonates). Therefore, we made an attempt to prepare low-molecular-weight polyvinyl chloride (PVC) in alcohols by precipitation polymerization in solution. The results are reported in this paper.

EXPERIMENTAL

Synthesis of low-molecular-weight PVC in the presence of alcohols was performed in a 3-l steel vessel with a stirrer at 70°C for 36 h. The reaction medium was monohydric isopropyl alcohol (IPA) or polyethylene glycol PEG-400. The vinyl chlolride : alcohol ratio was 1 : 1. The polymerization was initiated with azobis(isobutyronitrile) (AIBN). After polymerization was complete, the product was thoroughly washed with water to remove isopropyl alcohol; the completeness of IPA removal was checked by a procedure based on the reaction of alcohol with *p*-dimethylaminobenzaldehyde in sulfuric acid. Removal of PEG-400 was monitored by means of the Nessler reagent. The polymer was dried at 40–45°C and analyzed to determine the Fickentscher constant K_f and the chlorine content. The molecular weight M of the polymers was calculated by the formula $[\eta] = KM^{\alpha}$, where $[\eta]$ is the intrinsic viscosity, and K and α are the empirical constants equal, respectively, to 2.04×10^{-3} and 0.56 (solvent cyclohexanone). Also, we measured the IR spectra in the range 3800–400 cm^{-1} (Specord M-80 spectrophotometer). Films for IR spectroscopy were prepared from THF solutions on a KBr support.

To compare the properties of the polymers prepared in the presence of alcohols, we synthesized under the same conditions a PVC sample by suspension polymerization.

The table shows that the polymers prepared by precipitation polymerization of vinyl chloride in solution in the presence of alcohols have intermediate molecular weights between the telomers and common PVC. The strong difference between the molecular weights of the polymers prepared in run nos. 1 and 2 and that of the control sample (run no. 3) is due to the high efficiency of termination reactions; in PEG-400 this effect is stronger, which is confirmed by the considerably lower yield (50%, compared with 90%).

1070-4272/01/7406-1007 $25.00 © 2001 MAIK "Nauka/Interperiodica"

Synthesis of PVC in the presence of alcohols

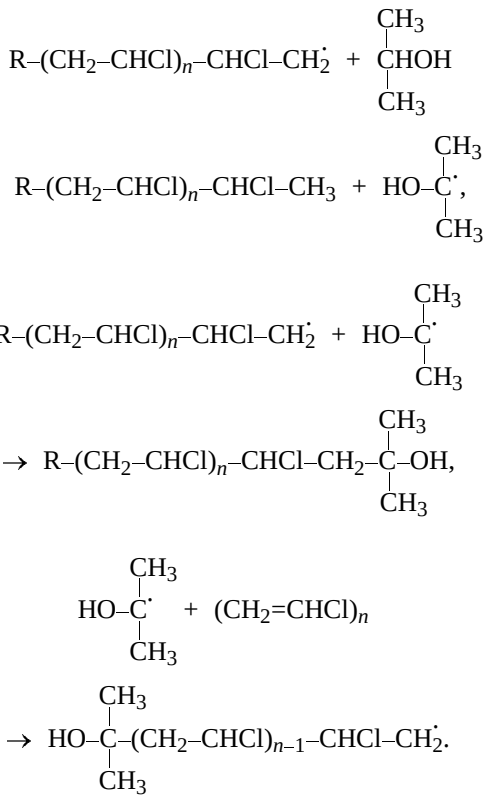
Run no.	Medium	Yield, %	Product composition, wt %			K_f	$[\eta]$, dl g^{-1}	M
			Cl	VC	PEG-400			
1	IPA	90	55.4	96.7	–	28.9	0.197	3500
2	PEG-400	50	49.9	87.8*	12.2	24.1	0.162	2500
3	Water	94	56.6	99.6	–	52.2	0.644	29 000

* Data for the fraction after separation of PVC homopolymer.

The lower content of chlorine in product no. 1, compared with the control PVC sample, is due to the considerably higher relative content of terminal groups (fragments of the initiator and IPA as chain-transfer agent). Analysis of product no. 2 shows that occurrence of chain transfer under conditions of vinyl chloride polymerization results in formation of a chemical bond between PVC and PEG-400, since the reaction product is preliminarily thoroughly washed to remove PEG-400 (checked with the Nessler reagent). However, in this case it was of interest to study the product composition in more detail.

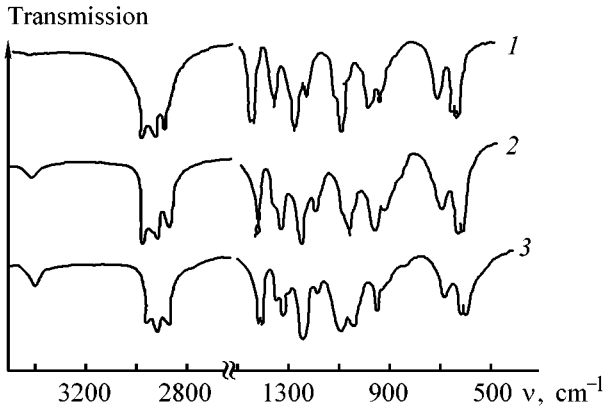
The chain transfer in polymerization of vinyl chloride in the presence of PEG must inevitably result in the formation of a mixture of the homopolymer and a block copolymer of PVC with PEG-400. Since PVC is insoluble in trichloroethylene, we attempted to extract the reaction product with this solvent (4 h at 50°C). Analysis of the insoluble fraction for chlorine showed that this is a homopolymer; its content in the reaction product was about 60%. The block copolymer of PVC with PEG-400 was isolated by precipitation with heptane of the fraction soluble in trichloroethylene.

The figure shows the IR spectra of suspension PVC (control sample) and the polymers prepared in the presence of IPA and PEG-400. Comparison of the spectra of sample nos. 1 and 2 with that of the control sample shows that an additional band appears at 3420 cm^{-1}, belonging to stretching vibrations of the OH groups. Their presence in the polymer is confirmed by the preservation of this band in the reprecipitated product. Thus, polymerization of vinyl chloride in IPA can be represented by the following scheme:



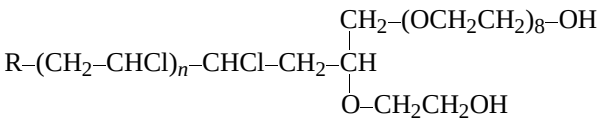
Apparently, in this case the polymerization product will be a mixture of polymers both with and without the hydroxy group; therefore, the intensity of the band at 3420 cm^{-1} is relatively low.

The IR spectrum of PVC prepared in the polyethylene glycol medium contains a strong absorption band of OH stretching vibrations at 3420 cm^{-1} and a new band at 1104 cm^{-1}, belonging to vibrations of the ether



IR spectra of PVC samples prepared (*1*) by suspension polymerization, (*2*) in the presence of IPA, and (*3*) in the presence of PEG-400. (ν) Wave number.

bond C–O–C. Also, the bands at 2910 and 1350 cm^{-1}, belonging, respectively, to the stretching and bending vibrations of methylene groups, become stronger. The structure of the block copolymer formed in the process can be represented as follows:



The suggested structure of the polymers prepared in the presence of IPA and PEG-400 can be confirmed by the fact that alcohols are among telogens reacting in radical polymerization with cleavage of the C–H bond. Since the C–H and O–H bond energies are 85.5 and 110 kcal mol^{-1}, respectively [5], it can be stated that the hydroxy groups will occur in the main polymer chain in both cases.

CONCLUSIONS

(1) Based on the results of precipitation polymerization of vinyl chloride in alcoholic solutions (isopropyl alcohol and polyethylene glycol PEG-400), the mechanism was suggested in which the alcohols act as effective chain-terminating agents with respect to polyvinyl chloride.

(2) According to the IR spectra, the polymer prepared in the presence of isopropyl alcohol contains, in contrast to traditional polyvinyl chloride, hydroxy groups, and the polymer prepared with PEG-400 contains hydroxy, methylene, and ether groups.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Process for Preparation and Modification of Formulations for Medicine, Based on Blends of Ultra-High-Molecular-Weight Polyethylene and Polysiloxane

O. O. Nikolaev, V. P. Britov, and V. V. Bogdanov

Received December 21, 2000

Abstract—A process is proposed for preparing formulations based on ultra-high-molecular-weight polyethylene and polysiloxane, yielding materials with the required adhesion between the phases. Procedures are developed for physicochemical modification of the compositions with the aim to prepare items for medical purposes with various properties on working surfaces.

The range of polymeric materials used in such a specific field of medicine as endoprosthetics is very limited. Among such materials are ultra-high-molecular-weight polyethylene (UHMWPE) and polysiloxanes (PSNs).

Thanks to a combination of biological inertness, high levels of strength, wear, and creep resistance, and low friction coefficient [1], UHMWPE is widely used in endoprosthetics, in particular, in fabrication of inserts for coxa prostheses. However, a significant disadvantage of UHMWPE from the standpoint of functional performance of prostheses is the lack of elasticity. The natural human joints could be imitated more adequately by inserts with the required combination of rigidity and elasticity in different sections of the item in the direction perpendicular to the load. Thus, items with property gradients are required. Such prostheses of a new generation can be fabricated only from composites; however, among potentially suitable polymers, only PSNs, along with UHMWPE, are permitted for use in endoprosthetics.

A number of properties of polysiloxanes are quite opposite to those of UHMWPE. Along with such positive characteristics as elasticity in a wide temperature range, high resistance to heat, thermal oxidative degradation, and hydrolysis, biological inertness, low adhesion to living tissues, and high gas permeability, they have such drawbacks as poor strength and low hardness [2].

Formulations based on UHMWPE and PSNs could eliminate the drawbacks inherent in both polymers and form be a new class of medical materials exhibiting, along with bioinertness, a set of controllable physicomechanical and service characteristics. By varying the component ratio, preparation conditions, and modification procedure, one could produce materials with a property gradient and to control within wide limits their elasticity and strength. This, in turn, would allow development of prostheses imitating human organs more closely than the existing polymeric items.

The chemical composition and structure of UHMWPE and PSNs rule out the possibility of their reaction to form a chemical compound; the most suitable procedure for preparing formulations from them is, apparently, mechanical blending. However, traditional blending procedures are unsuitable for this polymeric system, because the viscosity of PSNs is considerably lower than that of UHMWPE. Thus, new procedures for preparing formulations are to be developed.

The working surfaces of items used in endoprosthesis, as a rule, play different roles and should have different and in some cases quite opposite properties: hardness and density close to that of soft human tissues; rigidity in combination with wear resistance and elasticity. Such a combination of properties can be ensured by physicochemical modification of separate phases of a UHMWPE–PSN blend, which opens broader possibilities than modification of a homogeneous material. In this case it is necessary to develop procedures for modification of both the formulations and the surfaces of items fabricated from these materi-

1070-4272/01/7406-1010 $25.00 © 2001 MAIK "Nauka/Interperiodica"

als. Such materials, owing to their unique properties, can be used in various fields of engineering.

The goal of this work was to develop composite materials based on UHMWPE–PSN blends and items from them for medical purposes. The study involved (1) development of a process for preparing UHMWPE–PSN formulations, (2) comprehensive study of the physicochemical, rheological, and service properties of the formulations, and (3) development of procedures for physicochemical modification of the formulations and finished items.

In our study we used siloxane rubbers SKTV-Shch1 (Russia) and LSR 2050 (Bayer, Germany) and UHMWPE produced in Gur'ev (Kazakhstan) and by Hostalen Gur (Germany).

The formulations were prepared by a common mechanical blending procedure (rollers, rubber mixer). Since specific features of the initial components do not allow high-quality blending by a common procedure, we developed a new procedure involving additional heat treatment of PSN.

Although the chemical composition and structure of the components do not suggest the possibility of chemical reactions between them, we analyzed both the separate components and the composition by IR spectroscopy, taking into account the intended use of the materials in endoprosthetics.

Thermal analysis under dynamic conditions was performed on an MOM derivatograph (Hungary). Vulcanization measurements were done according to GOST (State Standard) 12535–84 (ISO 3417–77).

The structure of uncured formulations was studied with an optical microscope (×150 magnification), and that of the cured (vulcanized) formulations, with REM-100 [×(1000–10000) magnification] and BS-500 [with a microtome, ×(4000–16000) magnification] scanning electron microscopes.

The physicomechanical properties (density, hardness, elasticity, strength) were determined by standard procedures. The durability tests were performed as recommended by Zhurkov and Tomashevskii [3].

The radiation treatment was performed by irradiation with fast electrons generated with an ILU-6 pulse electron accelerator (Institute of Nuclear Physics, Siberian Division, Russian Academy of Sciences). This installation generated an electron beam with energy of up to 2.2 MeV, pulse frequency of up to 50 Hz, and beam power of up to 25 kW. In irradiation runs, the electron beam parameters were as follows: electron energy 1.0–2.0 MeV, pulse frequency 50 Hz, and dose rate 0.2–0.6 Gy min^{-1}. The absorbed dose was varied from 0.2 to 0.6 MGy.

Traditional blending procedures do not ensure high interphase adhesion in UHMWPE–PSN formulations. Therefore, the physicomechanical parameters of the material are poor. We suggested that the problem can be solved by modifying the process characteristics of the formulations in the stage of blending. In this case, it would be possible to use the existing blending procedure without developing special equipment. Therefore, we analyzed possible ways to ensure strong adhesion of the couple.

In the existing theories, the adhesion strength is considered a function of many variables; as applied to the polymer system in hand, only the temperature, molecular weight (viscosity), pressure, and time can affect the adhesion in the course of formulation preparation.

The adhesion strength, as a rule, increases with increasing blending temperature. However, UHMWPE does not pass to the viscous-flow state with increasing temperature, and the effect of temperature on the viscosity of PSN, is very weak. To blend the components more efficiently, high shear stresses are required, which can be provided by increasing viscosity; however, with PSN, this cannot be attained by decreasing temperature. The viscosity can be increased by partial scorching of PSN; in this case, the role of temperature will be decisive.

The necessity for increasing the shear stress in the course of component blending also follows from the results of an optical study of UHMWPE and its blends with PSN. Despite the fact that UHMWPE particles have a relatively developed surface, cavities are formed preventing flowing-in of PSN.

Based on these views, a procedure was developed for preparing UHMWPE–PSN formulations [4], consisting in the following. The PSN phase is subjected to partial scorching (the conversion should not exceed 25–50%), which increases the viscosity by a factor of 2–10. At the same time, it is necessary to choose the scorching conditions so as to ensure development of the required shear stress at any component ratio; the scorching temperature (range 120–150°C) is chosen according to the scheme shown in Fig. 1. The figure contains two curves. Curve *1* shows the viscosity of the blend η_b as a function of the UHMWPE content: $\eta_b = F(x)$; curve *2* shows the viscosity as a function of the scorching temperature T_{sc} and time τ_{sc}. If the degree of filling is known, we find the corresponding point *1* in the curve $\eta_b = F(x)$. Then we find the

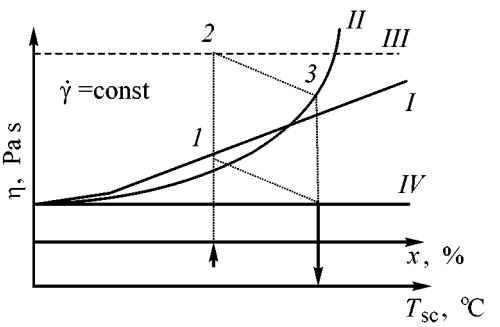

Fig. 1. Scheme for choosing the scorching conditions: (η) viscosity, (*x*) degree of filling, and (T_{sc}) scorching temperature. (*I*) $\eta_b = F(x)$, (*II*) $\eta = F(\eta_0, T_{sc}, \tau_{sc})$, (*III*) $\eta = \tau_{req}/\dot{\gamma}$, and (*IV*) η_0. (*1–3*) For explanation, see text.

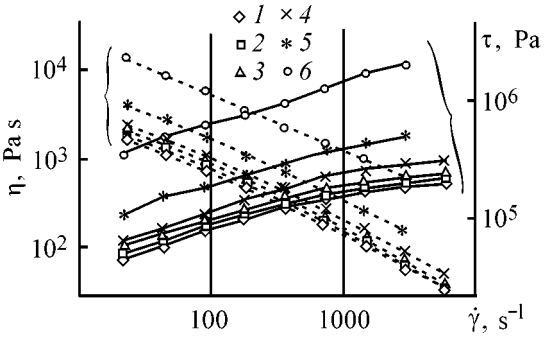

Fig. 2. Viscosity η and shear stress τ of formulations with SKTV and UHMWPE (Gur'ev) vs. shear rate $\dot{\gamma}$. UHMWPE content (wt %): (*1*) 0, (*2*) 20, (*3*) 40, (*4*) 60, (*5*) 70, and (*6*) 100.

extent η_0 to which the viscosity of the initial system should be increased (segment 1–2). In the curve $T = f(\eta_0, T_{sc}, \tau_{sc})$ we find point *3* corresponding to this additional viscosity and then determine the scorching temperature.

Of no less importance than determination of the scorching time is the choice of conditions for preparing a formulation. Traditional views on the shear strain are unsuitable as criteria of efficiency of the external action on the system, since they do not take into account the shear stress, which is one of the major factors in obtaining a couple with strong adhesion. We have chosen a criterion which is, in the physical sense, the strain energy density and is a product of the shear stress and shear strain $\tau\gamma$ ($\gamma = \dot{\gamma}t$, where $\dot{\gamma}$ is the shear rate and *t* is the action time). This criterion takes into account the main parameters required to obtain a high-quality blend and is a function of the processing conditions. Knowing the required strain energy density (depending on the UHMWPE content, it varies from 950 to 600 000 mJ m^{-3}), it is possible to determine the process parameters for any type of the mixer.

Comparison of the traditional blending procedure with that developed by us shows that the strength of the formulation can be increased by 10 to 100%, depending on the UHMWPE content.

To evaluate the applicability of the formulations in medical items, we should analyze the components and consider the possibility of chemical transformations in the system. The IR data confirmed the absence of chemical interactions between UHMWPE and PSN in the stage of formulation preparation by our procedure (the spectrum of the unvulcanized stock is the superposition of the spectra of the components); the vulcanization procedure used is traditional for medical items.

Thus, we can tentatively conclude that the composites developed are suitable for medicine and, in particular, for endoprosthetics.

A study by electron and optical microscopy showed that the formulations have a macroheterogeneous structure consisting of the PSN matrix, UHMWPE phase, and developed interphase layer. The size of the polyethylene particles is about $(5–7) \times 10^{-2}$ (Hostalen Gur) and $(1–2) \times 10^{-2}$ mm (Gur'ev), being essentially the same as in the starting polyethylene. However, the interphase layer on the polyethylene surface is fairly developed. This fact shows that the shear stresses arising in the course of blending by the developed procedure are sufficient for "unrolling" of PSN molecules on the UHMWPE surface and, at the same time, do not exceed the level at which the polyethylene grains are broken down.

Rheological tests were performed with formulations based on two UHMWPE brands: from Gur'ev (Kazakhstan) and Germany. The plots of the viscosity and shear stress vs. shear rate for the Gur'ev sample are shown in Fig. 2.

Irrespective of the UHMWPE type, the rheological behavior of the formulations with the polyethylene content from 0 to 60% is described by the equation

$$\eta / \eta_m = 1 + (A/B)x,$$

where η_m and η are the viscosities of the matrix (polysiloxane phase) and blends, respectively (Pa s); *A* and *B* are coefficients; and *x* is the weight fraction of polyethylene.

The equation is similar in form to the Einstein and Gut equations for solid particles in a viscous medium (with particle size small as compared with the vessel

size and large as compared with the size of liquid molecules). However, the A/B ratio is in the range 0.6–0.7, i.e., is a factor of 2–3 lower than in these equations. This may be due to a certain plasticity of polyethylene particles at the vulcanization temperature.

The strength, relative elongation at break, and hardness of the formulations, depend, as expected, on the type and content of UHMWPE. For UHMWPE samples with more developed surface, these characteristics are approximately additive.

Analysis of the physicomechanical properties of the formulations shows that, by varying the component ratio, it is possible to attain the required combination of hardness, strength, and elasticity. However, in medical practice, items with so-called property gradient are required; for example, the working surfaces playing different roles must have different characteristics (in particular, hardness). The developed polymeric formulations open up new possibilities for creating such materials. These materials are, as shown above, heterogeneous systems; therefore, both UHMWPE and PSN can be, in principle, subject to modification. The possibilities of modifying UHMWPE by procedures acceptable for medical formulations are very limited, whereas modification of PSN allows variation of its properties in a wide range. Therefore, we initially examined the possibility of modifying PSN.

We suggested that materials with controllable properties can be produced by combining thermochemical and radiation vulcanization of PSN. A detailed study of thermochemical vulcanization and radiation crosslinking showed that the scorching temperature should be in the range 125–145°C, and the dose of electron irradiation should not exceed 0.4 MGy. Combination of the two types of vulcanization allows the strength of PSN samples to be raised to 14.0 MPa, and relative elongation, to 100%; the hardness of the item surfaces being treated and the treatment depth can be varied in a wide range.

Based on the results of this study, a procedure [5] was developed for preparing PSN items with gradient of properties on different surfaces. The procedure involves preliminary scorching of a PSN item at a temperature depending on the required hardness of the "soft" surface of the item ($T \approx H_{B,\,soft} + 125$), after which the other surface is subjected to radiation vulcanization in the dose range 0.1–0.6 MGy to attain the required hardness ($\alpha \approx 0.88H_{B,\,hard}$, where α is the radiation dose). Thus, it is possible to obtain items in which one side is similar in hardness to human tissues and the other has increased hardness and wear resistance.

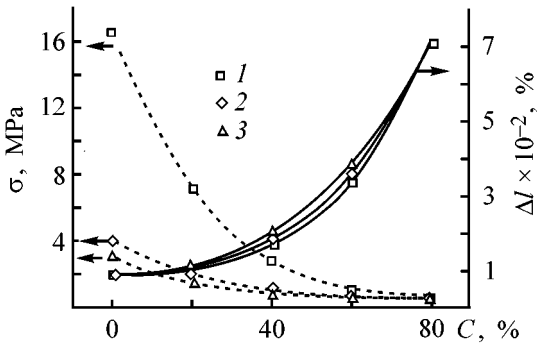

Fig. 3. Strength σ and relative elongation at break Δl of vulcanized UHMWPE (Gur'ev)–PSN formulations vs. UHMWPE content C. Irradiation dose, MGy: (*1*) 0, (*2*) 0.2, and (*3*) 0.4.

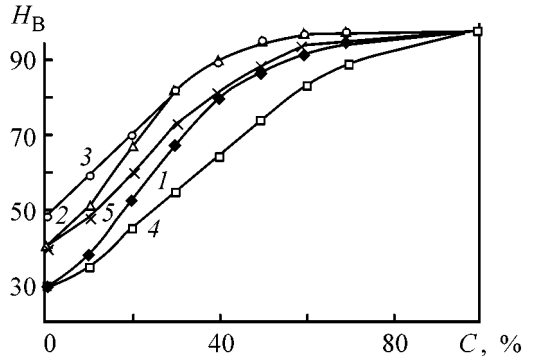

Fig. 4. Shore hardness H_B of SKTV–UHMWPE formulations irradiated with fast electrons as a function of the UHMWPE content C. UHMWPE sample: (*1–3*) Gur'ev and (*4, 5*) Hostalen Gur. Irradiation dose, MGy: (*1, 4*) 0, (*2, 5*) 0.2, and (*3*) 0.4.

This procedure can also be applied to UHMWPE–PSN formulations. Experimental studies showed an increase in the sample hardness by up to 30% (Figs. 3 and 4), with a slight increase in strength and drastic decrease (by up to 80%) in the relative elongation at break. The degree of variation of the physicomechanical properties strongly depends on the component ratio. This is due to the fact that the radiation resistance of UHMWPE is considerably higher than that of PSN. As a result, the physicomechanical properties of polyethylene vary to a lesser extent than those of PSN. For example, the hardness as a function of the radiation dose varies the more strongly, the higher the content of PSN in a formulation.

The procedure for preparing and modifying the formulations was used as the basis for developing new materials and items based on UHMWPE, PSN, and their blends, including those with the property gradient. An extreme case of items with property gradient are multilayer composites. The developed UHMWPE–

Materials and items based on UHMWPE, PSN, and their composites

Note: (H_B) Hardness, (σ) strength, (Δl) relative elongation (elasticity), τ_d durability (resistance to cracking), (ρ) density, and (Δ) all parameters are controllable; ( ) PSN, ( ) UHMWPE, and ( ) UHMWPE + PSN.

PSN formulation allows, owing to its structure and properties of the components, fabrication of multilayer items. In such items, PSN can be covulcanized with the elastomer phase of the formulation, and UHMWPE can be sintered in the plastic phase. Experiments showed that the strength of both types of couples is determined by the intrinsic strength of the layers.

Possible variants of such items are shown in the table: (1) UHMWPE item in which one or both surfaces were subjected to radiation treatment; the surface hardness and wear resistance of the items depend on the absorbed dose; (2) semifinished or finished PSN item; thermochemical vulcanization of PSN in the range 140–150°C allows fabrication of materials

with controllable elasticity and hardness and with increased durability (lower probability of cracking); (3) semifinished of finished item with controllable hardness and density; (4) semifinished or finished PSN item whose hardness and elasticity can be varied in wider limits than those of variant 3 and differing from item 1 by the presence of elastic properties; (5) semifinished or finished item with a combination of strength and elasticity controllable by varying the component ratio (prepared using the developed blending procedure); (6–8) semifinished or finished item with a combination of strength and elasticity and with controllable hardness, elasticity, and durability; (9) elastic material on a rigid support; rigid material on an elastic support; (10) the same as 9, but with controllable elasticity of the PSN support; (11) the same as 9, but with controllable surface hardness of the rigid support and controllable density, elasticity, and hardness of the elastic support; (12) the same as 9, but with combination of variants 10 and 11; (13–16) similar to 9–12, but in another range of properties of the elastic support; (17–20) similar to 9–12, but in another range of properties of the elastic and rigid supports; (21) elastic material with two-sided hard coating; (22) similar to 21, but with controllable elasticity; (23) similar to 21, but with controllable coating hardness; (24) similar to 21, but with combination of variants 22 and 23; (25–28) similar to 21–24, but with another range of properties of the elastic component; (29) hard material with two-sided elastic coating; (30–32) similar to 29, with controllable properties of elastic coatings; (33–36) similar to 29–32, but with another range of properties of the rigid component; (37–40) similar to 21–24, but with another range of coating properties; combines hardness and elasticity; (41–44), similar to 29–32, but with another range of coating properties; combines hardness and elasticity; (45) material with properties smoothly varying from rigid, hard to soft, elastic; (46–48) similar to 45, but with component properties varying in a wider range; (49–52) similar to 21–24, but with properties of one of the coatings varying in a wider range, from hard, rigid to elastic; (53–56) similar to 29–32, but with properties of one of the coatings varying in a wider range, from hard, rigid to elastic.

CONCLUSIONS

(1) Preliminary heat treatment of polysiloxane yields partially cross-linked three-dimensional network modified with the low-molecular-weight component; subsequent mixing with ultra-high-molecular-weight polyethylene at a prescribed strain energy density ensures formation of a material with the required adhesion between the phases.

(2) In the range of ultra-high-molecular-weight polyethylene concentrations from 0 to 60 wt %, the formulation has a macroheterogeneous structure consisting of the polysiloxane matrix and a phase of ultra-high-molecular-weight polyethylene with the same particle size as in the initial polyethylene and developed interphase layer; the rheological behavior of the formulation is described by the Gut law. In the range of ultra-high-molecular-weight polyethylene concentrations from 60 to 70 wt %, phase inversion occurs in the course of blending, and the flow mode changes from shear to boundary slipping. At higher content of polyethylene, the continuity of the formulation is broken.

(3) Combination of the thermochemical scorching of polysiloxane with the subsequent radiation treatment of the surfaces allows preparation of items with different properties on the working surfaces.

(4) Owing to their structure, formulations of ultra-high-molecular-weight polyethylene with polysiloxane allow covulcanization with polysiloxane and sintering with ultra-high-molecular-weight polyethylene, with the adhesion equal to the cohesion of the components. This allows fabrication of binary, two-component ternary, three-component ternary, and multicomponent composites.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Reactivity of Polysaccharide Aldehydes toward *N*-Nucleophiles

O. B. Suvorova, A. A. Iozep, and B. V. Passet

St. Petersburg State Academy of Pharmaceutical Chemistry, St. Peterbsurg, Russia

Received October 16, 2000; in final form, March 2001

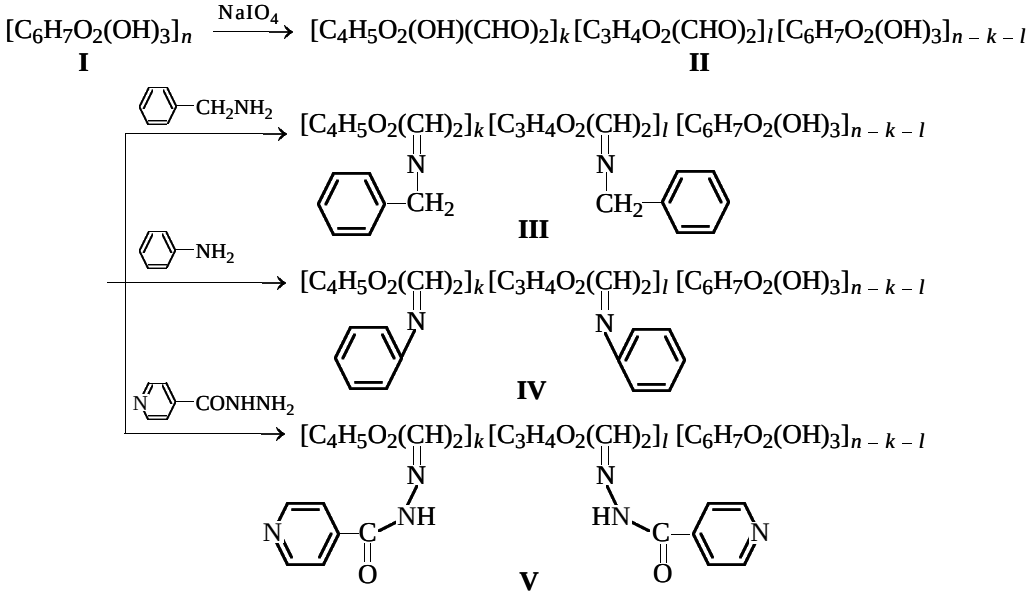
Abstract—The conversion of aldehyde groups in polysaccharide aldehydes to azomethine groups in reactions with amines and hydrazine derivatives was studied in relation to the structure of polysaccharide aldehyde and reaction conditions.

Chemically modified polysaccharides are used in medicine, biotechnology, and food and cosmetic industry, in particular, to develop new and improve the existing drugs. One of methods for activation of neutral polysaccharides is periodate oxidation allowing introduction of a required amount of aldehyde groups into the polymer. Polysaccharide aldehydes react with amine and hydrazine derivatives to give azomethines and hydrazones. This reaction occurs under mild conditions and is used for fixation of antibiotics, enzymes and other protein compounds, and biologically active hydrazides on polysaccharide matrix with the aim to develop new and improve the existing drugs.

Published data refer mainly to reactions of *N*-nucleophiles with polyaldehydes derived from cellulose and dextran. Furthermore, there is no common approach to choosing conditions for modification of polysaccharide aldehydes with biologically active substances. Therefore, the goal of this study was to determine the optimal conditions for reaction of polysaccharide aldehydes with amines and hydrazides for the example of dextran polyaldehyde (DPA) and to compare the reactivities of polyaldehydes with different structures toward aniline, benzylamine, and isonicotinic acid hydrazide, taken as model compounds.

In this study we used extracellular microbial polysaccharides: aubasidan (branched β-1,3-β-1,6-α-1,4-glucan produced by yeastlike fungus *Aureobasidium pullulans*), rhodexman (β-1,3-β-1,4-mannan, produced by *Rhodotorula rubra*), rhonasan (sulfated rhodexman), and also dextran commercially produced in Russia.

The chemical modification of the polysaccharides was performed by the scheme



1070-4272/01/7406-1016 $25.00 © 2001 MAIK "Nauka/Interperiodica"

Polysaccharides **I** were activated by periodate oxidation [1] in an acetate buffer solution (pH 4.1). The consumption of sodium metaperiodate was monitored spectrophotometrically at 222.5 nm [1]; the amount of released formic acid was determined by volumetric titration. Water-soluble polyaldehydes **II** derived from dextran (DPA), rhodexman, and rhonasan were isolated from the reaction mixture by dialysis (to remove low-molecular-weight substances), followed by concentration in a vacuum at 60°C and precipitation with ethanol. Water-insoluble aubasidan polyaldehyde (APA) was filtered off, washed successively with distilled water, alcohol, and ether, and dried under reduced pressure (20–25 mm Hg) at 60°C.

Reactions of polyaldehydes with *N*-nucleophiles were performed in water at 20–60°C in the course of 15–180 min at pH 2–12; the molar ratio of *N*-nucleophile to aldehyde groups of the polysaccharide was (1–5) : 1. The reaction with isonicotinic acid hydrazide (INAH), which is soluble in weakly acidic solutions, was performed in a buffer solution at pH 5. After the reaction was completie, the products were filtered off, washed with alcohol and acetone, and dried under reduced pressure (20–25 mm Hg) at 60°C. In the case of rhonasan, the reaction products were precipitated with alcohol and reprecipitated from aqueous alkali to remove ionically bound *N*-nucleophiles. The product purity was checked by thin-layer chromatography.

The products are amorphous colorless (**V**), light beige (**III**), or yellow (**IV**) powders, insoluble in water (except azomethines and acylhydrazones derived from rhonasan), alcohol, ether, and most of other organic solvents.

The products were characterized by IR and UV spectroscopy, elemental analysis, and conductometric titration after hydrolysis of the azomethine bond with 0.1 N HCl.

The IR spectra of the derivatives of the polysaccharide aldehydes with aniline and benzylamine contain absorption bands at 690 and 730 cm^{-1}, characteristic of monosubstituted benzene, at 1500 and 1580–1600 cm^{-1} ($\nu_{C=C(arom)}$), and at 1640–1660 cm^{-1} ($\nu_{C=N}$). The IR spectra of acylhydrazones contain absorption bands in the range 1650–1670 cm^{-1} characteristic of the stretching vibrations of the C=N and C=O (amide **I**) bonds, and also the bands at 1510 and 1400 cm^{-1}, absent in the spectra of the polyaldehyde and characteristic of INAH.

The UV spectra of the products formed in reactions of rhonasan polyaldehyde with *N*-nucleophiles exhibit absorption peaks absent in the spectrum of the initial polyaldehyde and characteristic of the initial *N*-nucleophiles: 275 (**III**), 238 and 276 (**IV**), and 262 nm (**V**). UV spectra of the other reaction products were not taken because of their poor solubility in water and organic solvents.

* Reaction time 2.5 h.

The derivatives of polyaldehydes with *N*-nucleophiles were characterized by the degree of substitution C_s (number of low-molecular-weight fragments per monosaccharide unit), which was calculated from the data of elemental analysis, conductometric titration, and UV spectroscopy. The reactions of polyaldehydes with *N*-nucleophiles were characterized by the degree of conversion of aldehyde groups $C_{ca} = [C_s/C_{sa}] \times 100\%$, where C_{sa} is the number of aldehyde groups in the initial polymer per monomeric unit.

To determine the conditions for introducing into the polyaldehyde molecule the required amount of *N*-nucleophile, we studied the influence of temperature, reaction time, reactant ratio, and pH on the degree of conversion of the aldehyde groups in dextran polyaldehyde.

Table 1 shows that the major fraction of aldehyde groups in DPA react with benzylamine even at room

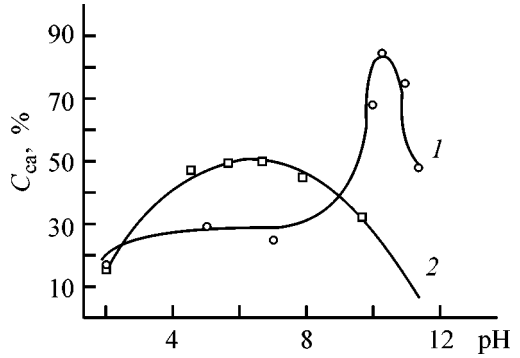

Fig. 1. Degree of conversion of DPA aldehyde groups, C_{ca}, in reactions with (*1*) benzylamine and (*2*) aniline vs. pH (20°C, 1 h, 2 mol of amine per mole of aldehyde groups).

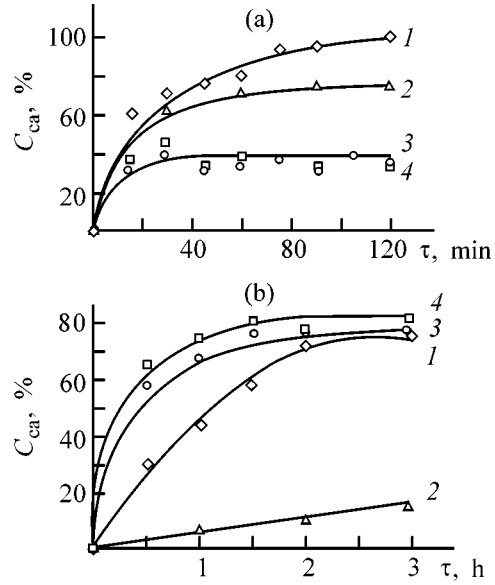

Fig. 2. Dynamics of azomethine formation in reactions of (a) benzylamine and (b) aniline with the polyaldehydes derived from (*1*) dextran, (*2*) aubasidan, (*3*) rhodexman, and (*4*) rhonasan. (C_{ca}) Degree of conversion of aldehyde groups and (τ) time. 20°C; molar ratio of amine to aldehyde groups: (a) 2 and (b) 3; pH: (a) 10 and (b) 6.0.

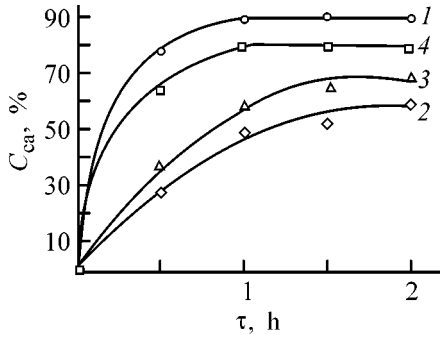

Fig. 3. Dynamics of the reaction of isonicotinic acid hydrazide with the polyaldehydes derived from (*1*) dextran, (*2*) aubasidan, (*3*) rhodexman, and (*4*) rhonasan. 20°C, 5 mol of INAH per mole of aldehyde groups, pH 5. (τ) Time.

temperature in 2 h. When the reaction temperature is raised to 60°C, the degree of substitution does not increase appreciably; the conversion of the aldehyde groups in the polysaccharide does not exceed 80%. With aniline, as expected, DPA reacts more slowly; the amount of azomethine fragments incorporated into the polymer grows with temperature, but C_{ca} remains less than 80%. With increasing molar ratio of aniline to aldehyde groups, the degree of substitution increases considerably; at a fivefold molar excess of the amine the result is similar to that attained by heating to 60°C. In view of this fact, and taking into account that many biologically active amines (enzymes, antibiotics) are labile, subsequent syntheses of azomethines were performed at room temperature.

In the reaction of DPA with benzylamine, the degree of conversion of the aldehyde groups varies with the reactant ratio in a more complex fashion: At a larger excess of the amine, C_{ca} slightly decreases rather than increases. This may be due to higher pH of the reaction medium, provided by excess amine.

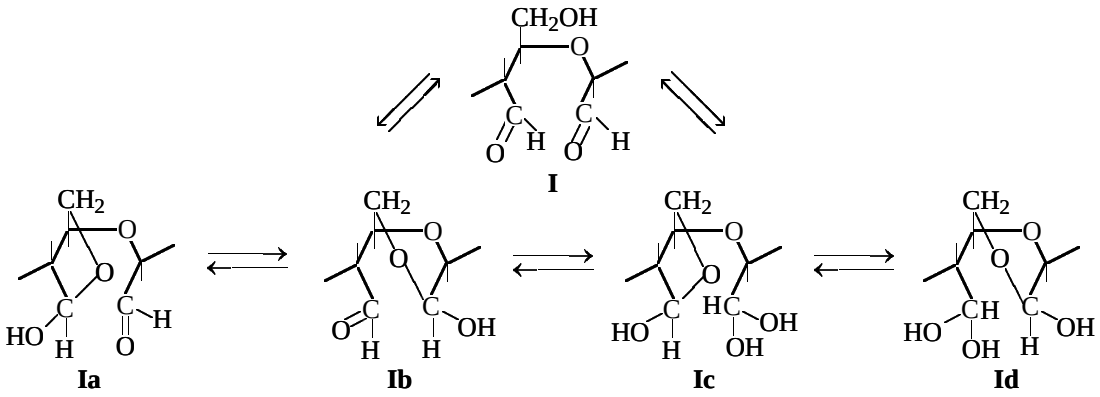
In the reaction with INAH, the amount of the nucleophile also affects the completeness of transformation of the aldehyde DPA groups into hydrazones more strongly than the temperature does. The C_{ca} values at 20 and 60°C are practically equal, whereas at the equimolar ratio of the reactants the conversion of the DPA aldehyde groups is about 55%, and at a 4–5-fold excess, about 90%. Therefore, subsequent syntheses were performed at room temperature with a fivefold excess of the nucleophile. Under these conditions the reaction is fast, being virtually complete in 2 h.

As expected, the greatest effect on the conversion of the aldehyde groups is exerted by pH of the medium; this reaction is catalyzed by both acids and bases, but the highest degree of substitution with benzylamine is attained at pH 10, and with aniline, in the range pH 4–7 (Fig. 1).

Having determined the temperatures of the reactions of DPA with *N*-nucleophiles, molar ratios of reactants, and pH values ensuring the highest degrees of substitution, we studied the dependence of the reactivity of DPA and other polysaccharide aldehydes under these conditions on the reaction time. The results are presented in Figs. 2 and 3.

We found that under these conditions the aldehyde groups of DPA react with benzylamine to practically 100% in 2 h. Aubasidan polyaldehyde is also highly reactive toward benzylamine. The maximal degree of

substitution of its aldehyde groups (C_{ca} = 70%) is attained still faster, in 1 h; however, in further reaction it remains virtually unchanged. The smallest amount of the azomethine groups is formed in reactions of benzylamine with rhodexman and rhonasan polyaldehydes. In these polymers, the maximal C_{ca} values (less than 40%) are attained in 20–30 min and then do not increase further.



Such a variation of the reactivity of polyaldehydes is probably associated with the presence in them of various amounts of 2,3-oxidized fragments able to form three types of structures: dialdehyde (**I**) and its hemiacetal (**Ia**, **Ib**) and hemiacetal–hydrate (**Ic**, **Id**) forms existing in equilibrium [2]. In alkaline solutions, the equilibrium is shifted toward formation of structures **Ic** and **Id**; the reactivity of the aldehyde groups thus decreases, and, to ensure more complete reaction, it becomes necessary to take the nucleophile in a larger excess than in the case of DPA and APA (Table 2).

In dextran and aubasidan polyaldehydes, 2,4-oxidized fragments prevail. Such fragments can exist in form **I** only; therefore, high degrees of substitution are attained.

In contrast to benzylamine, aniline is poorly soluble in water; hence, the conversion of the aldehyde groups is largely influenced in this case by the solubility of the polysaccharide aldehydes in water. Indeed, the highest degrees of substitution are attained in reactions of aniline with the polyaldehydes derived from rhodexman and rhonasan, readily soluble in water. The poorly soluble DPA reacts more slowly, and approximately the same C_s values are attained in a longer time. With insoluble aubasidan polyaldehyde, only 16% of the aldehyde groups are converted, probably because the APA reaction centers are inaccessible to the amine.

To make higher the conversion of the aldehyde groups of rhodexman and aubasidan polyaldehydes in reactions with benzylamine and aniline, we varied the reaction time, temperature, and reactant ratio. In each particular case the goal is reached in a different way (Table 2). With rhodexman, raising the amount of benzylamine by a factor of 1.5 increased C_{ca} from 34 to 77% (by a factor of 2.5), in reactions of APA with a tenfold excess of aniline C_{ca} increased to only 37%. At the same time, with temperature raised to 60°C, more than 90% of APA aldehyde groups reacted with the amine.

In reactions with INAH, all the polysaccharide aldehydes show high reactivity. However, as in the reactions with amines, the reactivity depends on the

Table 2. Influence exerted by conditions of reactions between polyaldehydes and amines (2 h) on the conversion of the aldehyde groups into azomethine groups

* Reaction time 24 h.

structural and conformational features of the polyaldehyde molecules (Fig. 3).

In the reactions with INAH, the highest C_{ca} values of the polyaldehydes derived from aubasidan, rhodexman, rhonasan, and dextran (60, 70, 80, and 90%, respectively) vary practically in the same order as in the reactions with aniline, which may be due to different primary and secondary structures of the polysaccharides. For example, rhonasan polyaldehyde is more reactive than rhodexman polyaldehyde, probably because introduction of sulfate groups into the rhodexman polyaldehyde molecule somewhat unrolls it, facilitating the access of the nucleophile to the aldehyde groups [3].

CONCLUSIONS

(1) Aubasidan, rhodexman, and rhonasan polyaldehydes react, similarly to dextran polyaldehyde, with *N*-nucleophiles and can be used for developing new and improving the known biologically active substances.

(2) When choosing conditions for chemical modification of polyaldehydes, account should be taken of their structure, solubility, and other factors. In reactions with *N*-nucleophiles, the polyaldehydes derived from aubasidan, rhodexman, and rhonasan are, in some cases, more active, and in other cases, less active than dextran polyaldehyde.

(3) Water-soluble polymeric azomethines can be prepared by reactions of amines with polyaldehydes derived from sulfated polysaccharides.

Received February 8, 2001

Abstract—The influence of ferrocene and iron acetylacetonate additives on the chemical, magnetic, and electrophysical properties of thermolyzed and nonthermolyzed polyacetylenes prepared by phase-transfer dehydrochlorination of polyvinyl chloride was studied.

Properties of polymers containing conjugated double bonds appreciably change upon introduction of iron compounds. For example, partial oxidation of polyacetylene doped with trivalent iron compounds (chloride, perchlorate, phosphate, acetate, etc.) raises the conductivity from 10^{-8} to 10^{2} Ω^{-1} cm^{-1} and improves the polymer stability [1, 2].

Iron compounds can be incorporated in the polymeric chain, e.g., during synthesis of polyferrocenevinylenes. Pendant ferrocene groups have virtually no effect on the polyvinylene conductivity. The electrical conductivity $\sigma_{50°}$ of this polymer is 2.85×10^{-10} Ω^{-1} cm^{-1} [3]. When the polyvinylene chains are cross-linked with ferrocene groups, the conductivity at 50°C decreases to 9.2×10^{-13} Ω^{-1} cm^{-1} [3]. The electrical conductivity of polyferrocenevinylenes calcined at 300°C is $(1.0–1.15) \times 10^{-9}$ Ω^{-1} cm^{-1}.

Ferrocene-containing polymers are highly paramagnetic compounds: their specific static magnetic susceptibility is $(400–500) \times 10^{-6}$ g^{-1} at magnetic field intensity of 3.0–3.5 kOe, whereas polyvinylenes containing no ferrocene groups have negative susceptibility not exceeding $-(0.5–1.5) \times 10^{-6}$ g^{-1} in the same magnetic field [4].

In this work, we studied the influence of biscyclopentadienyliron (ferrocene) and iron acetylacetonate [Fe(acac)$_3$] on chemical, magnetic, and semiconducting properties of polyacetylenes whose thermolysis products contain ferromagnetic compounds [5].

Polyacetylenes were prepared by phase-transfer dehydrochlorination of polyvinyl chloride and had different supramolecular structures. Another aim of this work was to find a new dopant raising sharply the electrical conductivity of polymers.

EXPERIMENTAL

Amorphous and polycrystalline polyacetylene samples were prepared by dehydrochlorination of polyvinyl chloride with an aqueous potassium hydroxide solution; those with mixed structure, by dehydrochlorination with granulated potassium oxide in the presence of phase-transfer catalysts [6]. Purified polymers were dried at 100°C in a vacuum. The size of perfect polyacetylene crystals in the polycrystalline sample is larger than the known values and reaches 1.0×10^{3} μm. Traces of an amorphous phase are present in the sample. The sample with mixed structure is amorphous polyacetylene containing 20% crystalline phase.

Commercial dicyclopentadienyliron $Fe(C_5H_5)_2$ (ferrocene) and iron acetylacetonate $Fe(C_5H_7O_2)_3$ [Fe(acac)$_3$] of chemically pure grade were used. The melting points of these compounds are 173 and 184°C, respectively, which agrees with published data [7]. Since the iron complexes are readily soluble in various solvents and have low sublimation temperatures (~100°C), their excess can be readily removed during washing and drying of polyacetylene.

The iron complexes were introduced into the polymer by two procedures. The first is treatment of polyacetylene with a 1.5% Fe(acac)$_3$ solution in absolute ethanol, with subsequent washing of the product with ethanol until the solution becomes colorless. The sec-

ond is synthesis of polyacetylene in the presence of the iron compounds in amounts of 40 wt % with respect to polyvinyl chloride.

The samples were heated at a 1.5 deg min^{-1} rate in a quartz tube in a vacuum (residual pressure about 10^{-3} mm Hg) and then kept at required temperature for 2 h. The loading and unloading of the samples were performed in an argon atmosphere. The iron content in the polymer was determined by chemical analysis.

Atmospheric oxygen dried over P_2O_5 was used as the oxidizing agent. The thermal stability was studied on an MOM derivatograph. The heating rate was 0.08 deg min^{-1}. The weighed portion of the sample was 0.1×10^{-3} kg.

The structure of polyacetylenes prepared without iron additives was studied by optical and electronic microscopy.

The resistivity was measured in a cell with stainless steel electrodes by the four-probe method using an E 7-8 ac bridge operating at 1 kHz. The design of the measuring cell allowed preparation of polymer pellets 50–300 μm thick.

The magnetic susceptibility of polyacetylene powders was measured by Faraday's procedure [8] in magnetic field with intensity ranging from 2 to 15 kOe and at temperature from 20 to 100°C.

Incorporation of iron compounds into the polymer is determined by its structure. The iron content in polyacetylene treated with an alcoholic solution of $Fe(acac)_3$ and a ferrocene solution is 1–2 and 0.03–0.20 wt %, respectively. The iron content in the polymer prepared by phase-transfer dehydrochlorination of polyvinyl chloride in the presence of $Fe(acac)_3$ and ferrocene is 5–9 and 0.03–0.035%, respectively. As indicated by IR spectroscopy, the resulting polymer is not a mechanical mixture and its structure differs from that of pure polyacetylene. The IR spectrum of polyacetylene containing and not containing $Fe(acac)_3$ is shown in Fig. 1 as an example. The spectrum of the polymer prepared in the presence of $Fe(acac)_3$ contains no bands of acetylacetonate group coordinated to the metal ($\nu_{C=O}$ 1570 cm^{-1} and $\nu_{C=C}$ 1530 cm^{-1} [9]), typical for $Fe(acac)_3$ (curves *1, 3*). The spectrum of a mechanical mixture of the polymer with $Fe(acac)_3$ in amounts similar to that in the iron-doped polymer contains these bands (curve *2*). The out-of-plane bending vibrations of the *trans*-=C–H fragments of the polyacetylene chain (curve *4*) are manifested as a weak band at 1000–1015 cm^{-1} in the spectrum of the sample containing $Fe(acac)_3$ additive (curve *3*).

Similarly, the ferrocene bands (1002 and 1107 cm^{-1} [10]) are absent in the IR spectrum of polyacetylene doped with ferrocene. This indicates the absence of a free cyclopentadienyl ring in the sample. Hence, the organoiron compounds react with polyvinyl chloride during polymer synthesis.

Semiconducting and magnetic properties of polyacetylene due to the presence of delocalized π electrons in the macromoleclues change considerably upon introduction of the iron compounds into the polymer.

Polyacetylene is a weakly magnetic material, since its magnetic susceptibility χ, characterizing magnetization of a substance in a magnetic field, does not exceed 10^{-6} g^{-1}. Both amorphous and crystalline samples are diamagnetic: $\chi < 0$. The amorphous polymer containing 20% crystalline modification is paramagnetic, since its $\chi > 0$. The dependence of the static

magnetic susceptibility of the amorphous sample on the magnetic field intensity differs from that of the crystalline sample. With increasing magnetic field intensity, the susceptibility of crystalline polyacetylene grows and that of amorphous and amorphous-crystalline structure decreases (Fig. 2). In a weak field (2–8 kOe) the diamagnetism of the crystalline sample is higher than that of the amorphous sample: the curves for the dependence of χ of the crystalline polyacetylene on the magnetic field intensity H lie below those of the amorphous samples (Fig. 2, curves *1* and *2*).

As determined by chemical and X-ray fluorescence analysis, the transition metal content in thermolyzed polymers does not exceed 10^{-3} wt %. Even traces of ferromagnetic impurities can change the actual magnetic susceptibility. However, the influence of the structure of the polymer and products of its thermolysis on the magnetic properties of the polymer can be determined by comparing changes in χ of the solid samples at two or more magnetic field intensities H. The influence of the structure was revealed by studying the magnetic properties of structurally different polyacetylenes treated with an alcoholic solution of $Fe(acac)_3$. As seen from Fig. 2, diamagnetic polyacetylene is converted into the paramagnetic state (χ becomes positive) upon treatment with diamagnetic [11] $Fe(acac)_3$. The magnetic susceptibility of the polymer does not correlate with the iron content, but depends on the polymer structure. The magnetic susceptibility of the polymer with mixed structure, containing 1.12% Fe, exceeds by and order of magnitude that of amorphous and crystalline samples containing 2.03 and 0.98% Fe, respectively.

The electrical conductivity of polyacetylene is low (10^{-9}-10^{-11} Ω^{-1} cm^{-1}). Introduction of ferrocene or $Fe(acac)_3$ during polymer synthesis or by treating polymer isolated from the reaction mixture decreases the conductivity to 10^{-13} Ω^{-1} cm^{-1}, probably owing to loosening of the polymer structure by bulky molecules of the iron compounds.

Uniaxial compression slightly (by a factor of 1.1–1.26) increases the electrical conductivity of all the structural modifications of polyacetylene. Clearly, this is due to an increase in the charge carrier mobility owing to shortening of the distance between the macromolecules and hence a decrease in the energy barrier between the polyconjugated fragments. The pressure dependence of the electrical conductivity of polyacetylene flattens out at a pressure of 0.2 GPa (Fig. 3, curves *1–3*). In this region the electrical conductivities of structurally different samples are almost the same. The conductivity of polyacetylene samples modified with the organoiron compounds grows from 10^{-13} to 10^{-12} Ω^{-1} cm^{-1} with increasing pressure (curve *4*).

ing of the distance between conjugated sections of the macromolecules, which occurs during heat treatment [3]. As a result, the electrical conductivity of the polymers containing and not containing the organoiron compounds increases upon heat treatment. The electrical conductivity of the thermolysis products depends on the history of a sample. The conductivity of pyrolized crystalline samples is higher than that of amorphous samples throughout the tested pressure range (Fig. 3, curves *1*' and *2*'). The influence of the supramolecular structure of polyacetylene is preserved in products of pyrolysis at temperatures <500°C of samples containing ferrocene and $Fe(acac)_3$. Despite the high iron content in the product of pyrolysis at 500°C of amorphous-crystalline polyacetylene prepared in the presence of $Fe(acac)_3$, the curves of the pressure dependence of its electrical conductivity lie lower than those for the pyrolysis products of the amorphous-crystalline polymer containing no iron additive (Fig. 4, curves *2*, *2*'). The curve for the thermolysis product of crystalline polyacetylene doped with $Fe(acac)_3$ runs higher than that of the polymer with mixed structure, although the iron content in these samples is virtually the same (7.80 and 7.6%, respectively).

The influence of the dopant nature on the conductivity was studied for amorphous-crystalline polyacetylene thermolyzed at 500°C (Fig. 4). The electrical conductivity of the polymer prepared in the presence of $Fe(acac)_3$ and containing 6.6–7.8% Fe is lower upon the heat treatment, and the electrical conductivity of the polymer doped with ferrocene and containing 0.03% Fe after thermolysis, higher than that of the thermolysis product of undoped polymer. The electrical conductivity of the pyrolysis product of polyacetylene prepared by dehydrochlorination of polyvinyl chloride in the presence of an $Fe(acac)_3$–ferrocene mixture exceeds that of the sample prepared in the presence of ferrocene only. No correlations between the iron content in the pyrolysis products and their conductivity were revealed. The electrical conductivity of the iron-containing samples thermolyzed at temperatures higher than 500°C depends mainly on the iron concentration. For example, the conductivity of polyacetylenes with different supramolecular structures, thermolyzed at 600°C, correlates with the iron content in the samples (Fig. 3, curves *1*''–*3*'').

Clearly, the electrical conductivity of pyrolyzed polyacetylenes depends on their history (supramolecular structure), the polymer structure formed during heat treatment in the presence of additives and their transformation products, and the nature of the iron additives.

The polyacetylene structure undergoes pronounced changes during thermolysis. Dehydrogenation of the crystalline polymer starts at 250–300°C to form completely carbonized products at 1200–1300°C via a number of intermediates. The temperature dependence of the C/H ratio characterizing the degree of sample dehydrogenation (Fig. 5) indicates that dehydrogenation of crystalline polyacetylene (curve *1*) is faster than that of the amorphous sample (curve *3*). Dehydrogena-

tion of the amorphous sample is complete at temperatures higher than 2000°C. The organoiron compounds sensitize this process: dehydrogenation of doped polymers is faster and occurs at lower temperatures (Fig. 5). In the presence of both the additives, a synergistic effect is observed: dehydrogenation of polyacetylene doped with a ferrocene–$Fe(acac)_3$ mixture is faster than that of a polymer doped with any one of the components (curves *1*, *1*', *1*"). Probably, the organoiron compounds loosen the polymeric structure and increase its porosity, thus promoting hydrogen elimination from closed pores.

Thermal degradation of crystalline polyacetylene, occurring with appreciable weight loss, is more difficult as compared with that in the amorphous sample. The weight loss curves are shifted to higher temperatures in going from amorphous polymer containing 20% crystalline phase to a crystalline sample (Fig. 6, curves *1* and *2*). The iron compounds catalyze thermal degradation of the macromolecules. The thermal degradation curves of polyacetyeles prepared in the presence of ferrocene, $Fe(acac)_3$, and their mixture are shifted to lower temperatures (Fig. 6). The synergistic effect was observed for a sample doped with a ferrocene–$Fe(acac)_3$ mixture: thermal degradation of the polymer is faster than that of the polymers doped with either ferrocene or $Fe(acac)_3$.

We found that the organoiron compounds affect the nucleophilic properties of polyacetylenes. High reactivity of this polymer in reactions with electrophilic agents, for example with oxygen, is due to the nucleophilic properties of polyacetylene. The stability of polyacetylenes against atmospheric oxygen depends on their supramolecular structure. The rate of oxygen uptake, corresponding to the oxidation rate, decreases in going from amorphous to crystalline structure: the weight gain in 24 h is 2.3 and 1.1 wt %, respectively. Probably, the oxidation is controlled by oxygen diffusion which is slower in dense crystalline samples as compared with amorphous polyacetylene. The oxidation of Fe-containing polyacetyelenes is faster as compared with the undoped samples.

The weight gain in 24 h for amorphous and crystalline polymer prepared in the presence of $Fe(acac)_3$ is 2.7 and 2.5%, respectively. The stronger influence of the iron-containing additive on the oxidation of crystalline polymer, compared with the amorphous sample, is probably due to stronger structural loosening of the crystalline sample. Upon doping, the porosity of the crystalline sample becomes equal to that of amorphous polyacetylene and the samples take up equal amounts of oxygen.

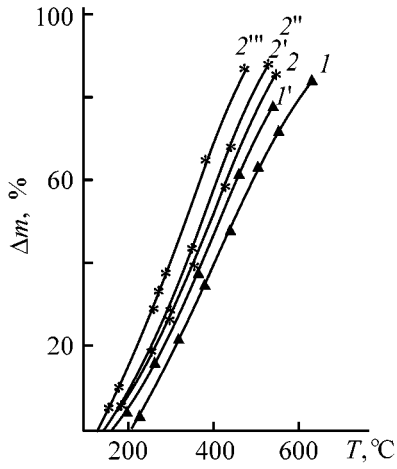

Fig. 6. Weight loss Δm from (*1*, *1*') crystalline and (*2*, *2*', *2*", 2''') amorphous-crystalline polyacetylenes prepared (*1*, *2*) in the absence and in the presence of (*1*', *2*') $Fe(acac)_3$, (*2*") ferrocene, and (*2*''') $Fe(acac)_3$–ferrocene mixture vs. temperature *T*. Iron content (wt %): (*1*, *2*) 0, (*1*') 6.03, (*2*') 5.34, (*2*") 0.03, and (2''') 8.16.

Thus, the organoiron compounds affect the chemical, magnetic, and electrophysical properties of polyacetylene.

CONCLUSIONS

(1) A sensitizing effect of ferrocene and iron acetylacetonate both on oxidation by oxygen of polyacetylenes prepared by phase-transfer dehydrochlorination of polyvinyl chloride and on high temperature dehydrognetation and degradation of these polymers was revealed.

(2) Introduction of ferrocene and iron acetylacetonate into polyacetylene decreases the electrical conductivity of both nonthermolyzed and thermolyzed samples and promotes transformation of the diamagnetic polymer to the paramagnetic state.

Metal Transfer in Polyethylene Films Oxidized on Copper Supports

D. G. Lin and E. V. Vorob'eva

Skorina State University, Gomel, Belarus

Received February 19, 2001

Abstract—Contact oxidation of polyethylene films on copper was studied as influenced by their thickness. An oxidation mechanism is proposed.

Contact oxidation of polyethylene films on copper is accompanied by diffusion of copper compounds—products of contact reactions, in the bulk of the film [1–3]. At low concentrations, these compounds catalyze oxidation, and at high concentrations they inhibit it [4, 5]. In this connection, we suggest [1] that the catalytic oxidation of polyethylene (PE) on copper is a homogeneous process catalyzed by transferred copper compounds.

Transfer of copper (copper compounds) strongly depends on the thickness of a polymeric film. With increasing thickness, the oxygen uptake grows. As a result, the region of intensive polymer oxidation is shifted from the near-support layer to the film surface [1], and two-stage copper accumulation is observed not only in the boundary PE layer, but also in the bulk of the film [6]. However, the nature of copper transfer in the bulk of PE being oxidized is not understood. To gain insight into these processes, systematic studies are required. In this work, we studied PE oxidation and copper transfer in a PE film as influenced by the film thickness.

EXPERIMENTAL

We used nonstabilized high-density PE prepared at low pressure using complex organometallic catalysts [GOST (State Standard) 163338–85, brand 20306-005]. Two types of samples, supported and filled polymeric films, were prepared from a polymer powder by hot pressing. The support and filler were, respectively, M1 copper foil and M1 copper powder with grain size ranging from 50 to 70 μm. Filled PE was prepared by mechanical mixing of the polymer and copper powders. Unfilled and copper-filled polymers were applied to copper supports by hot pressing at 150°C for up to 5 min. The resulting samples were oxidized in ovens in air and cooled under natural conditions. Then a copper support was separated, and the obtained polymeric film was studied.

The degree of PE oxidation was estimated by IR transmission and MATIR spectroscopy. We suggested that the degree of oxidation is proportional to the optical density of the band at 1720 cm^{-1} assigned to the carbonyl groups, or to the extinction coefficient K calculated as the ratio of the optical density to the film thickness expressed in centimeters. The IR spectra were recorded on a Specord 75-IR spectrophotometer. The MATIR spectra were recorded with a KRS-5 element (θ = 45°C, n = 2, 4; N = 14).

The amount of copper compounds accumulated in a PE film was evaluated by separating it from the support and ashing by two-stage thermal treatment in air [7]. The residue was dissolved in water. The copper content in these solution was determined by polarography. The procedure was described in detail in our previous communication [8].

The time dependences of the extinction coefficient and the copper concentration in 30- and 500-μm PE films oxidized on copper are shown in Fig. 1. These specific parameters characterize, respectively, the average number of carbonyl groups and copper in a unit volume of the polymer. As seen from Fig. 1, these dependences for the films with the same thickness flatten out after almost the same oxidation time (curves *2*, *4*), i.e., PE oxidation and copper transfer are interrelated processes. As noted above, copper compounds both catalyze (at low concentration) and inhibit (at high concentration) the PE oxidation. The

inhibition of oxidation (plateau in the kinetic curves of accumulation of carbonyl groups) is due to the accumulation of copper compounds in the polymer in amounts sufficient for suppression of oxidation.

The time required for accumulation of the critical concentration of copper compounds in PE grows with increasing film thickness (Fig. 1, curves *3*, *4*). Correspondingly more time is required for the extinction coefficient curve to flatten out (Fig. 1, curves *1*, *2*).

The dependences of the limiting extinction coefficient and the limiting metal concentration in the film on the film thickness are presented in Fig. 2. The oxidation time was enough for complete stabilization of the oxidation processes in the sample. As seen from Fig. 2, the region of tested thicknesses can be divided in two sections: *I* from 0 to 70 and *II* from 80 to 170 μm, in which the extinction coefficient changes relatively slowly (Fig. 2, curve *2*). In the narrow region between these sections (the hatched section in Fig. 2) the content of carbonyl groups increases abruptly. The dependence of the limiting concentration of copper compounds transferred in the film is similar (Fig. 2, curve *1*). The minimum copper concentration required to inhibit PE oxidation can be determined by extrapolating curve *1* (Fig. 2) to zero thickness. This concentration is about 0.25 wt %. In this case, the degree of polymer oxidation is very low. The extinction coefficient determined by extrapolation of curve *2* (Fig. 2) is 5–10 cm^{-1}.

Similar results were obtained for PE filled with copper powder. The dependence of the limiting extinction coefficient K of the band at 1720 cm^{-1} in the IR spectra of PE films on the filler content C in the films (oxidation temperature 150°C, film thickness 100 μm) is presented below.

C, vol %	0.2	0.5	1.5	3	5	7
K, cm^{-1}	60	39	23	11	5	4

These data show that oxidation of films with copper content of 5 vol % and higher is inhibited at low degree of polymer oxidation (extinction coefficient is about 5 cm^{-1}). This is due to thinning of the polymer layer surrounding filler particles with increasing copper concentration in PE. Hence, the influence of thinning of the unfilled copper-supported PE films on PE oxidation is similar to that of an increase in the filler concentration in the film at constant film thickness.

To elucidate the reasons for the observed complex influence of the film thickness (Fig. 2, curves *1*, *2*), we studied the oxidation kinetics in different layers of a copper-supported PE film. The kinetic curves of accumulation of carbonyl groups in the surface and near-support layers of a PE film (thickness of analyzed layer about 2 μm) were obtained by means of MATIR spectroscopy [9]. The results of a study of both thin (50 μm, curves *1*, *2*) and thick (150 μm, curves *3*, *4*) films are presented in Fig. 3.

Polyethylene film is not uniformly oxidized across its thickness. Carbonyl groups start to form in the near-support layer (Fig. 3, curves *2*, *4*). Then PE oxidation in the surface layer is accelerated, and the optical density of this layer increases (Fig. 3, curves *1*, *3*). The kinetic curves of accumulation of carbonyl groups in the surface and near-support layers of PE film flatten out irrespective of the film thickness. On the plateau, the degree of oxidation of the surface layer of polymer is always higher than that of the near-support layer, the film thickness being constant.

The film thickness affects the following parameters of the inhibition stage: the optical density corresponding to the saturation of the kinetic curves, D_0, and the oxidation time required for the optical density to reach saturation, τ_0. These parameters are indicated in Fig. 3, curve *3*. The parameters grow with increasing film thickness.

It should be noted that the ratio of τ_0 values for the surface and near-support layer depends on the film thickness. In thin films, the oxidation is stabilized faster in the near-support layer: τ_0 for this layer is lower (Fig. 3, curves *1*, *2*). This parameter for the near-support layer of thick films is higher than that for the surface layer. We believe that this difference in oxidation of thin and thick films (Fig. 3, curves *3*, *4*) is mainly responsible for the appearance of two ranges of film thickness in Fig. 2. It should be noted that thestabilization of the concentration of carbonyl groups in the surface layer of thick films does not mean that oxidation is complete in this layer (Fig. 3, curves *3*, *4*). Presumably, dynamic equilibrium is attained between the carbonyl groups formed in the surface layer and carbonyl groups of the low-molecular weight oxidation products diffusing from this layer of the sample inwards. Polymer oxidation is completely inhibited when the content of the carbonyl groups is stabilized across the whole thickness of the film.

We propose the following scheme for PE oxidation on a copper support. In the first stage, the oxidation is localized in the near-support layer. Copper compounds diffusing in a PE film catalyze PE oxidation to form low-molecular-weight products of thermal oxidative degradation. These products, in turn, react with the support to form copper compounds which again diffuse in the bulk of the film. As a result, a concentration of copper compounds that is enough to inhibit the oxidation is attained in the neat-support layer. As determined by MATIR spectroscopy, a layer of inhibited polymer is formed at the film–support interface after approximately 15 min of oxidation

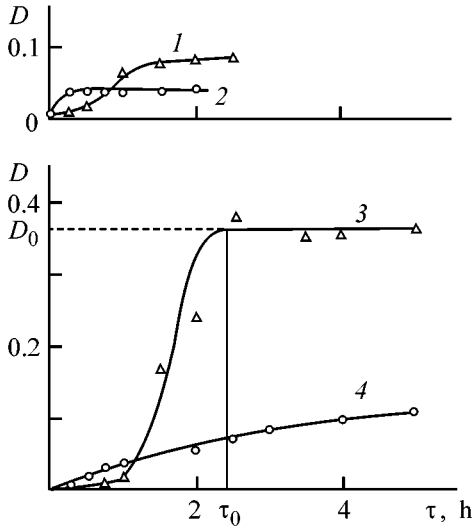

Fig. 3. Optical density D for the absorption band at 1720 cm^{-1} in IR MATIR spectra of (*1*, *3*) surface layer of PE film and (*2*, *4*) film layer adjacent to the support, vs. time τ of oxidation at 150°C on a copper support. Film thickness, μm: (*1*, *2*) 50 and (*3*, *4*) 150.

(Fig. 3, curve *2*). During further oxidation, this layer becomes thicker owing to diffusion of copper compounds through it. In the course of time, the entire polymeric film must be inhibited, with the oxidation stopped.

However, displacement of the zone of intensive oxidation from the near-support layer to the surface layer of the coating should also be taken into account [6]. In the course of oxidation, the oxygen uptake by the surface layer increases (which is promoted by diffusion of small amounts of copper compounds in this layer), thus decreasing oxygen penetration into the film. As a result, the oxidation is localized in the surface layer of the polymeric film and is suppressed deeper inside the film owing to oxygen deficiency. The metal transfer into the film is correspondingly decelerated. Low-molecular-weight products of thermal degradation, formed in large amounts in the surface layer diffuse through the film to the neat-support layer. These products react with the support to form copper compounds. In terms of our previous work [6], the second stage of metal transfer to PE being oxidized begins with diffusion of these compounds into the polymeric film. The metal transfer in this stage will continue until stabilization of oxidation in all layers of a film.

Thus, oxidation of a copper–supported PE film can be inhibited by both single- and two-stage-mechanism. The single-stage inhibition is only possible in thin films. In this case, the thickness of the inhibited

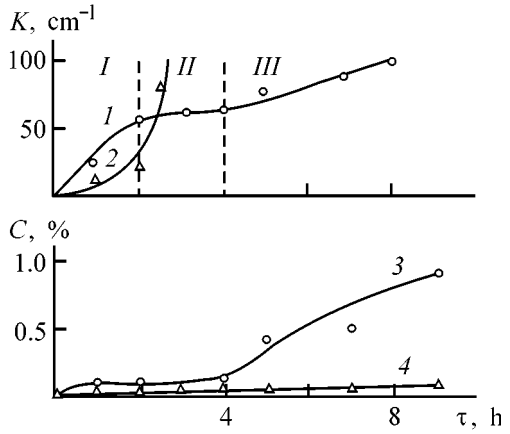

Fig. 4. (*1, 2*) Extinction coefficient K for the band at 1720 cm^{-1} in IR spectra and copper concentration C in (*3, 4*) surface and (*2, 4*) near-support layers of a 300-μm PE film vs. time τ of film oxidation at 150°C on a copper support.

layer gradually grows from the near-support layers toward the surface layer of the sample. Copper transfer into polymer is continuous. The two-stage inhibition of PE is typical of thicker films. In this case, the thickening of the layer of the inhibited polymer is interrupted owing to localization of the oxidation in the surface layer of the film. The metal transfer is interrupted simultaneously. However, it is resumed after diffusion of the oxidation products from the surface layer to the near-support layer. In this stage, the conversion of the polymer to the inhibited state is completed.

Kinetic studies of copper transfer in a 300-μm polymeric film (Fig. 4, curves *3*, *4*; Fig. 2, curves *3*) confirmed the proposed scheme of PE oxidation on copper support. The dependence of copper accumulation in the near-support layer (thickness of the analyzed layer is 10–15 μm) is characterized by two stage of metal transfer, which are separated by an interval of time. During this time, the metal content in a tested layer remains virtually constant (Fig. 4, curve *3*). The dependence of accumulation of carbonyl groups is similar (Fig. 4, curve *1*). The oxidation is stabilized when the degree of PE oxidation in the surface layer is low (extinction coefficient is about 20 cm^{-1}), but traces of transferred copper are clearly detected in it (Fig. 4, curve *4*). If the material of the near-support layer, oxidized for a time sufficient for stabilization, is heated with is free access of oxygen, the content of carbonyl groups increases slowly, i.e., PE oxidation in this layer is inhibited. The second stage of accumulation of carbonyl groups in the near-support PE layer is due to diffusion of low-molecular-weight products of thermal oxidation from the surface layer of the film, which by this time is characterized by high degree of oxidation (extinction coefficient exceeds 100 cm^{-1}). The second stage of copper transfer into PE films begins almost simultaneously with the onset of diffusion of the oxidation products in the near-support layer.

The two-stage mechanism of copper accumulation is typical of not only the near-support polymer layer, but also the film as a whole. The shape of the corresponding kinetic curves (Fig. 2, curve *3*) is similar to that of the dependence of the limiting copper concentration on the film thickness (Fig. 2, curve *1*). This similarity is due to features of copper diffusion in PE film. The initial portions of the curves (Fig. 2, curves *1*, *3*) correspond to the first stage of copper transfer without involvement of the thermal oxidation products formed in the surface layer. The next portion reflects the overall copper transfer in the first and second stages.

CONCLUSION

The area of intensive accumulation of the products of thermal oxidation of copper-supported polyethylene films shifts from the near-support layer to the surface layer of the polymer. This is the main reason for the change in the mechanism of metal diffusion in the film. As the film becomes thicker, the single-stage mechanism gives way to a two-stage mechanism. The mechanism changeover, in its turn, alters the parameters responsible for inhibition of oxidation processes in the polymer.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Modifying Reagents on Rheological Characteristics of Magnetite Dispersions in Transformer Oil

T. G. Lazareva, E. V. Shinkareva, and S. A. Prodan

Institute of General and Inorganic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received December 18, 2000

Abstract—Rheological properties of magnetite dispersions in transformer oil were studied in relation to the conditions of modification of the magnetite surface with water vapor and water-soluble polymers such as polyvinyl alcohol and carboxymethyl cellulose. Various modification modes are considered.

Directed preparation of various structures with prescribed mechanical properties is among the most important tasks of the modern physical chemistry of dispersed systems [1]. The commonly accepted approach is the optimal combination of mechanical dispersion with modification of the dispersed phase surface by, e.g., introduction of such modifying reagents as water-soluble polymers able to affect the strength of interparticle interactions and to be readily cross-linked in the presence of metal cations. The performance characteristics of such systems are largely controlled by their rheological parameters such as the viscoelastic, strength, and hyperelastic indices of solutions. In turn, these parameters are governed by the strength of macromolecular interaction responsible for the formation of a three-dimensional network structure. The basic factors controlling the viscosity of a structured suspension are the concentrations of the polymer and dispersed phase and temperature.

In this work, we studied the effect of sorption of water vapor and water-soluble polymers by magnetite particles on the structural and rheological characteristics of magnetite dispersions in transformer oil.

EXPERIMENTAL

Rheological measurements were carried out with a Rheotest-2 rotary viscometer for determining the dynamic viscosity of both Newtonian and non-Newtonian fluids over a wide range of the shear rates from 3 to 1312 s^{-1} at a temperature of 30–70°C.

As the continuous phase served transformer oil, and as the dispersed phase, magnetite Fe_3O_4 (pure grade), finely ground and dried at 105°C prior to use. The magnetite concentration in the oil dispersions varied from 5 to 25%. Sorption of water vapor on magnetite was studied as follows. A sample was placed in a desiccator and allowed to stand over saturated salt solutions at room temperature for 20 days at a fixed relative humidity of 30, 60, 80, and 100%. To obtain modified magnetite, it was brought in contact with solutions of water-soluble polymers such as 0.5% carboxymethyl cellulose (Na-CMC, 70/300) or 5% polyvinyl alcohol (PVA, 16/1). The liquor ratios were, respectively, Na-CMC/Fe_3O_4 = 2.5 and PVA/Fe_3O_4 = 5. The resulting mixtures were then allowed to stand at 105°C for 5 h and ground in an agate mortar.

The temperature and concentration dependences of the dynamic viscosity η of magnetite in transformer oil at 30, 40, 60, and 70°C and a shear rate of 81 s^{-1} are given in Fig. 1. With increasing temperature, η decreases from 16 to 3, from 22 to 7, from 32 to 16, from 50 to 30, and from 130 to 54 mPa s^{-1} in 5, 10, 15, 20, and 25% magnetite suspensions, respectively. With increasing magnetite concentration, η grows, which is due to the increasing number of contacting dispersed phase particles in unit volume, leading to intensive structurization and higher dynamic viscosity.

The fact that η strongly depends on the shear stress or rate (Fig. 2) indicates that magnetite dispersions in transformer oil are non-Newtonian fluids. In a 5% magnetite dispersion, η initially decreases rapidly with increasing shear stress (portion *I* of the curve), and then a uniform flow of a fluid anisotropically oriented in the field is established (portion *II*). Therefore, the system demonstrates the property of plasticity as a result of particle structuration and formation of a structure anisotropically oriented in the mechanical field. Sorption of water on magnetite

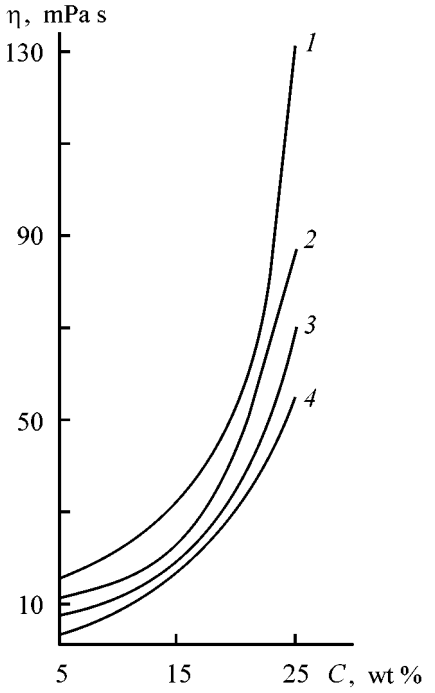

Fig. 1. Dynamic viscosity η of magnetite dispersion in transformer oil vs. the magnetite concentration *C*. Temperature (°C): (*1*) 30, (*2*) 40, (*3*) 60, and (*4*) 70.

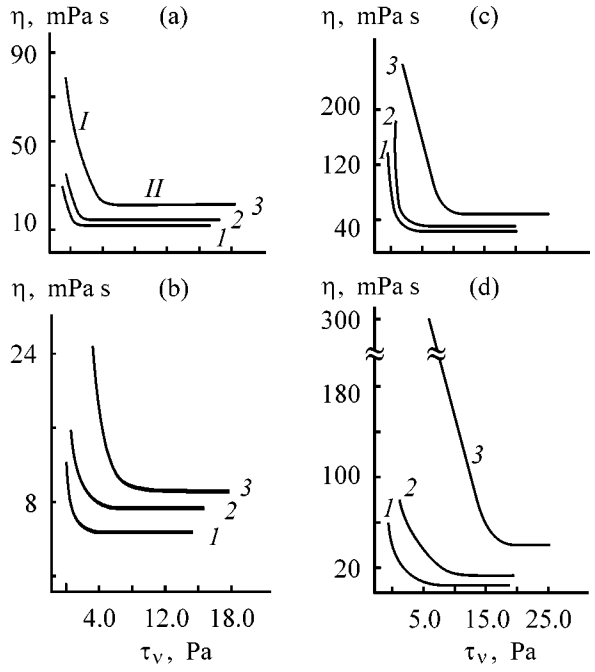

Fig. 2. Dynamic viscosity η of (a, b) 5 and (c, d) 15% magnetite dispersion in transformer oil vs. the shear stress τ_v. Temperature (°C): (a, c) 30 and (b, d) 70; the same for Fig. 3. Moisture content and relative humidity (%): (*1*) dried Fe_3O_4; (*2*) 0.7, 60 and (*3*) 5, 100.

leads to higher viscosity and shifs the viscosity curves toward higher shear stress (Fig. 2a, curves *2, 3*). With increasing temperature, the viscosity curves are shifted to higher shear stress, too. The effect of anisotropic structurization is observed in the 5% magnetite dispersion at 2.5 Pa, and in the dispersions containing 0.7 and 5% water, at 4.0 and 7.5 Pa, respectively.

In the presence of adsorbed water, the dynamic viscosity grows with increasing magnetite content. For example, in a 15% magnetite dispersion containing 0.7% water, η is 180 and 80 mPa s^{-1} at 30 and 70°C, respectively. At a moisture content of 5% the corresponding values are 250 and 300 mPa s^{-1} (Figs. 2c, 2d). In this case, the structurization is complete at higher shear stress as compared with the 5% magnetite dispersion (in dispersions with dried Fe_3O_4 this occurs at a shear stress of 2.5 and 5.0 Pa at 30 and 70°C, respectively; and in magnetite dispersions containing 5% water, at 9.0 and 19.0 Pa).

Therefore, the structurization of the magnetite dispersions can be controlled by varying the amount of sorbed water in the system.

Figure 3 shows the dependence of the dynamic viscosity on the shear stress in a 5% dispersion of magnetite modified with 0.5% Na-CMC and 5% PVA. Both the modifying reagents change the shape of the viscosity curves considerably: initially the viscosity increases and then levels off (Figs. 3a, 3b; curves *1*). The medium acquires the properties of a dilatant fluid [2]. Additional introduction of water into magnetite modified with a water-soluble polymer makes the dynamic viscosity higher (Figs. 3a, 3b; curves *3*). In this case the nature of flow changes, with both the plastic and dilatant types of behavior exhibited, which is manifested in the appearance of a maximum in the viscosity curves. For example, modification of magnetite with 5% PVA, followed by sorption of 8.1% water, results in an increase in η to 55 and 24.8 mPa s^{-1} at 30 and 70°C, respectively. Modification of magnetite with 0.5% Na-CMC, followed by sorption of 8.8% water, raises η to 550 and 240 mPa s^{-1} at 30 and 70°C, respectively.

Evidently, these effects are associated with a change, in the mechanical field, in the nature of the intermolecular interaction in magnetite containing sorbed water. In this case, water molecules strengthen the network of hydrogen bonds between the hydroxy groups of the polymers. Water sorption by the modified dispersions favors formation of a more developed network structure in the bulk of the dispersion, as demonstrated by a dramatic increase in the dynamic viscosity. With the shear stress increasing further (Fig. 3a, curve *3*,

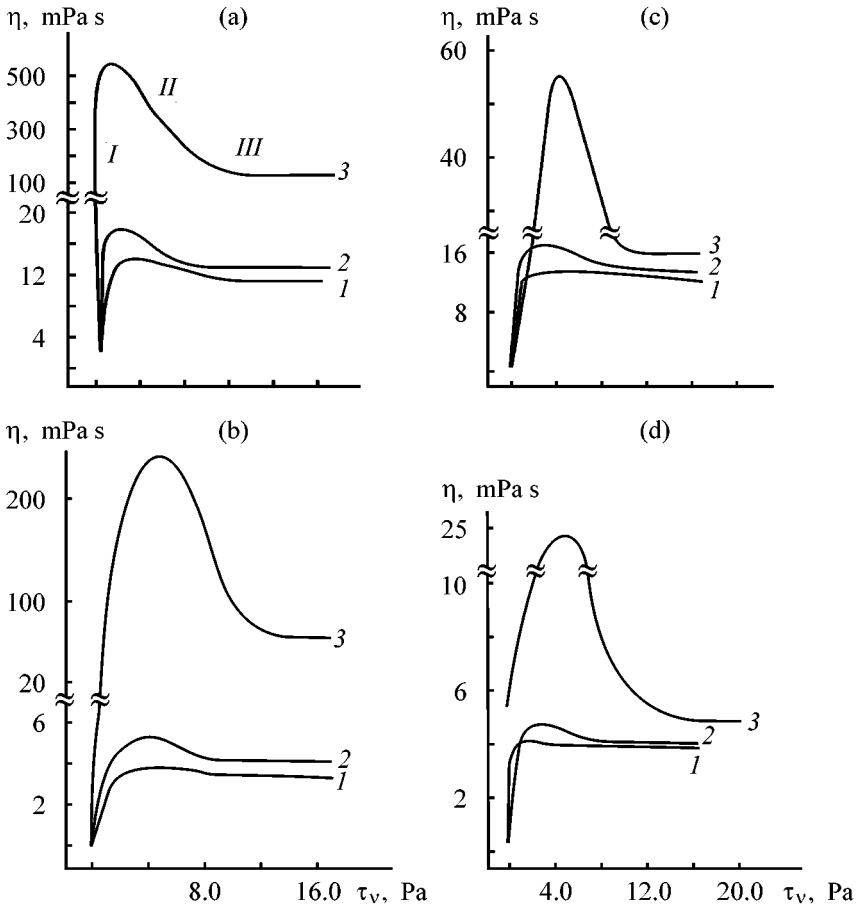

Fig. 3. Dynamic viscosity η of a 5% dispersion of magnetite modified with (a, b) 0.5% Na-CMC and (c, d) 5% PVA vs. the shear stress τ_v. Moisture content and relative humidity (%): (*1*) Dried Fe_3O_4; (*2*) (a, b) 0.6, 60 and (c, d) 0.4, 60; and (*3*) (a, b) 8.8, 100 and (c, d) 8.1, 100.

portion *II*), the binder undergoes structurization in the mechanical field, which results in the formation of anisotropically oriented magnetite particles (Fig. 3a, curve *3*, portion *III*).

CONCLUSIONS

(1) Modification of magnetite with water affects the nature of flow of magnetite dispersions in transformer oil in the mechanical field.

(2) Additional introduction of water into magnetite modified with water-soluble polymers results in the formation of media showing both dilatant and plastic properties, which is associated with the formation in the mechanical field of a network of hydrogen bonds and subsequent structurization of the disperse system with increasing shear stress through anisotropic orientation of magnetite particles.

(3) Depending on the modification conditions, fluid magnetite dispersions demonstrate both plastic and dilatant properties.

(4) The obtained results allow modification of binders of fluid formulations to be regarded as a method for preparing of media sensitive to mechanical fields.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Quantitative Refractometric-Spectrophotometric Analysis of Oil Solutions of Vitamins A and E

I. G. Zenkevich, V. M. Kosman, V. G. Makarov, and Yu. V. Dadali

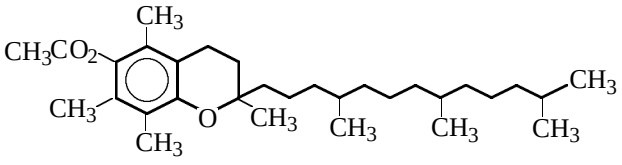
Adaptogen Inter-Regional Center, Close Corporation, St. Petersburg, Russia

Received November 23, 2000, in final form, February 2001

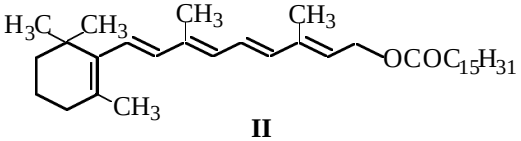
Abstract—A refractometric–spectrophotometric method is proposed for routine analyses for vitamins A and E in oil solutions, which is 3–4 times less time-consuming than HPLC. The determination procedure includes measurements of the refractive index n_D^{20} of samples and optical density of their solutions in hexane at 325 nm.

Modern requirements to routine analytical procedures, especially those used in industry, refer not only to the adequacy of analysis, but also cover such criteria as the time consumption, labor intensiveness, reagent consumption, cost, etc. [1, 2].

Solutions of vitamins E (α-tocopherol acetate **I**) and A (retinol palmitate **II**) in vegetable oils are commercially produced as drugs, including Aevit polyvitamin {FS (Pharmacopoeia Item) 42-1699–95 [3]}, and food supplements [4]. The difficulties arising in quantitative determination of such mixtures are caused by high hydrophobicity of all components, high viscosity of the samples, and variability of the properties of the matrix (like most natural products, it is a mixture of variable composition).



I



II

According to the modern views, the most accurate method of quantitative determination of compounds **I** and **II** in oil soilutions is HPLC with UV detection and external references. In this method, sample preparation includes preparation of test solutions and reference samples with concentrations of about 1 mg ml^{-1}. Each of these should be then analyzed at least twice. The intercalibration tests of this method for the example of analysis for vitamin A showed that the results may vary within 10–27 rel.% (about 15% on the average) [5]. Despite its simplicity, this technique appears to be non-optimal judging by the time consumption criterion (time required for analysis may be as long as 2–3 h and more). Therefore, a search for more rapid methods is an urgent task.

Oil solutions of individual vitamins A and E may be regarded formally as two-component mixtures, whose analysis requires measurement of only a single analytical parameter, e.g., the refractive index n_D^{20} [6]. The use of the refractometric method for determination of vitamin E in oil made it possible to cut the analysis time to 3–5 min, i.e., by a factor of 25–60 at absolute accuracy of $(+0.1 \pm 0.6\%)$, which is better than that in the case of HPLC. Since n_D^{20} of **II** is higher than that of **I** (1.555 ± 0.002 and 1.497 ± 0.001, respectively), and, e.g., this parameter varies from 1.467 [7] to 1.475 (data of the authors) between various lots of soybean oil, the expected accuracy of refractometric determination of vitamin A must be considerably higher.

Simultaneous determination of **I** and **II** in an oil solution, i.e., in a three-component mixture, requires measurement of one more independent parameter in addition to n_D^{20} [6]. However, none of the presently used combinations of analytical characteristics of ternary systems is suitable for accomplishing the task. For example, measuring the density as a second parameter is unsuitable because of the close similarity of this value for **I** and **II** and the need in large samples for analysis; measuring the refractive index at sev-

1070-4272/01/7406-1034 $25.00 © 2001 MAIK "Nauka/Interperiodica"

eral wavelengths [8] is difficult because of the lack of commercial instruments for this purpose; selective extraction of the one of the components [8] cannot be used because of the similarity of the physicochemical characteristics (including the hydrophilicity) of the target components and the matrix; and, finally, the refractometric–chromatographic method [6] has no advantages in time consumption over the ordinary chromatographic method.

Therefore, optimizing the procedure for quantitative determination of vitamins A and E in oil solutions requires, in fact, that new modifications of the refractometric analysis of ternary systems should be developed. In this work, we examine the potentialities of the refractometric–spectrophotometric method.

EXPERIMENTAL

As objects of study served model mixtures of vitamins E (**I**) and A (**II**), prepared by dissolving weighed portions of the corresponding concentrates in soybean oil, commercial samples of Aevit polyvitamin (rated concentrations of **I** and **II** are 50 and 30 wt %, respectively), and some other technological samples.

For comparison, the concentrations of **I** and **II** in the test samples were determined by HPLC on a Beckman Gold System liquid chromatograph with a Luna C_{18} column (4.6 × 150 mm; sorbent particle size 5 μm), a precolumn (4.6 × 20 mm) packed with the same sorbent, and a UV detector. As eluent served an 85 : 15 mixture of acetonitrile (HPLC grade) and dichloromethane (chemically pure grade). Elution was carried out in the isocratic mode at a rate of 1.0 ml min^{-1}. The target components were detected at 285 nm (18 min after the introduction of a sample) and then at 325 nm. The total time of analysis was 35–40 min; the retention time of **I** was about 12 min, and that of **II**, about 30 min. Samples for analysis were prepared by dissolution of weighed portions (40–100 mg) in 50 ml of isopropyl alcohol (chemically pure grade). Standard solutions were prepared gravimetrically from both the model samples (soybean solutions) and concentrates of vitamins A and E. No less than two chromatograms were recorded for each solution until the peak areas were reproducible within 3%. Data processing was performed using GOLDV402 program pack. The concentrations of **I** and **II** in samples C (wt %) were estimated by the external-reference method, using the relation

$$C = (kS_s m_{ref})/(S_{ref} m_s),$$

where S_s and S_{ref} are the peak areas (arb. units) for the test and standard solutions, respectively; m_s and m_{ref} are the weights of the test and reference samples (g), respectively; and k is a formally dimensionless coefficient accounting for the degree of dilution of all the samples and the recalculation of the concentrations from g ml^{-1} to %.

The refractive indices n_D^{20} were measured with an IRF 454B2M refractometer at room temperature (20 ± 1°C).

Spectrophotometric determination of **II** was carried out with SF-26 and SF-46 instruments in 1-cm quartz cells at 325 nm. Solutions of the samples in hexane (chemically pure grade) were prepared so that their optical density D was in the range 0.1–0.6. A weighed portion of a sample (about 25 mg) was dissolved in 50 ml of hexane, and the resulting stock solution was then diluted 50-fold with the same solvent. As reference solutions were used similarly prepared soybean oil solutions or hexane. In both cases, we obtained similar results, but sample preparation with hexane should be recommended as being simpler.

The working wavelengths were selected from analysis of the general UV spectra (Specord M40). The spectra showed peaks at 325.4 and 286.6 nm for **II** and **I**, respectively, which is well consistent with the reference data (324–326 and 285 nm). We also demonstrated that absorption of soybean oil at $\lambda >$ 322 nm is negligible.

The solutions prepared from individual samples of **I** and **II** were used to estimate (from D/C) the mass and molar extinction coefficients of **I** and **II** and also the specific extinction coefficient of **II**. The mass extinction coefficients ε_{mas} of **I** and **II** were found to be 98.0 ± 4.7 and (94.4 ± 6.6) × 10^3, and the molar extinction coefficients ε_{mol}, 46.0 ± 2.0 and (49.4 ± 3.5) × 10^3, respectively. The specific extinction coefficient of **II** at 325 nm $E_{1cm}^{1\%}$ = 949.4 ± 30.3. To estimate ε_{mas}, ε_{mol}, and $E_{1cm}^{1\%}$, the component concentrations in the solutions were expressed in g ml^{-1}, M, and %, respectively. Published data for retinol: ε_{mol} = 52.48 × 10^3 [9].

The retinol palmitate concentration C (wt %) in the model mixtures and Aevit polyvitamin was estimated by the relationships

$$C = (100kD)/(\varepsilon_{mas} m_s), \quad C = (kDM_r)/(10\varepsilon_{mol} m_s),$$

$$C = (100Dk)/(E_{1cm}^{1\%} m_s),$$

where D is the optical density of the test solution; ε_{mas}, ε_{mol}, and $E_{1cm}^{1\%}$ are the extinction coefficients; m_s is the sample weight (g); k is the coefficient reflecting the degree of dilution of the solutions; M_r = 524.87

is the molecular weight of retinol palmitate; 100 and 10 are the factors for recalculation of the concentrations from, respectively, g ml^{-1} and g l^{-1} to %.

To estimate the concentration of vitamin E and the sensitivity of results of its determination to slight variations in the experimental parameters, we used QBasic software.

The prerequisite for selecting just the refractometric method for analyzing the ternary systems under consideration was the fact that the molecules of **I** and **II** contain no active hydrogen atoms. Therefore, one may exclude the possibility of some specific interaction with the matrix components and consider the dependence of the refractive index of the mixtures to be nearly linear. Then, for the binary mixtures, n_D^{20} is proportional to the volume fraction of a component to be determined:

$$C_v(X) = (n_s - n_0)/(n_X - n_0), \quad (1)$$

where n_s, n_0, and n_X are the refractive indices of the sample, matrix (soybean oil), and the component to be determined, respectively (hereinafter the indications of the wavelength and temperature in the symbol for n_D^{20} are omitted for the sake of simplicity).

Passing from the volume to mass fractions requires taking into account the densities of the sample d_s and of the component to be determined d_X:

$$C_m(X) = (d_s/d_X)(n_s - n_0)/(n_X - n_0). \quad (2)$$

Contrary to [6, 8], in this work we were not restricted to calculations by Eq. (2), since estimation of the adequacy of the obtained results requires differentiation of the relationships to determine the random error of analysis. For example, when determining vitamin E in oil solutions, we demonstrated that the relative error of the obtained results depends primarily on $C_m(X)$ itself:

$$\delta C_m(X) \approx 2\Delta n[1 + 1/C_m(X)^2]^{1/2}/(n_X - n_0), \quad (3)$$

where $\Delta n \approx 10^{-4}$ is the limiting accuracy of determining the refractive index with critical-angle refractometers (Abbe refractometers).

For oil solutions of **I**, $(n_X - n_0) \approx 0.024$, so that $\delta C_m(X) \approx 1.9\%$ at $C_m(X) \approx 0.5$, but at $C_m(X) \approx 0.05$ the theoretical random error increases to 16.7%, indicating the inapplicability of the method. In other words, a certain minimum concentration of an analyte exists, which can be determined with a prescribed accuracy. In the case of ternary systems, such an analysis of the errors becomes even more necessary.

Since none of the existing techniques for refractometric analysis of ternary systems is applicable in our case, the required supplementary information about the composition of the samples can be obtained from spectrophotometric data. Because of the fact that the extinction coefficients of retinol palmitate at λ = 325 nm are higher by a factor of about 10^3 than those of α-tocopherol acetate, all the existing spectrophotometric methods for analysis of mixtures with known extinction coefficients (for example, the Fierordt method [10]), based on solving systems of linear equations, appear to be equally unsuitable, especially with account of the requirements to the evaluation of the random error component. Therefore, it is the combination of the refractometric and spectrophotometric data that can provide the required adequacy of analysis.

The refractive index n_s of the investigated ternary system can be written as a function of its composition as

$$n_s = n_A C_{m,A} d_s/d_A + n_E C_{m,E} d_s/d_E + (1 - C_{m,A} d_s/d_A - C_{m,E} d_s/d_E) n_0, \quad (4)$$

where n_A, n_E, and n_0 are the refractive indices of the components A and E and the matrix, respectively. It is noteworthy that this relationship does not include terms of the C_iC_j type, reflecting intermolecular interactions of the components [8].

Preliminary spectrophotometric determinations showed that at λ = 325 nm the absorption of **I** and the matrix can be neglected, i.e., one can directly determine the concentration of vitamin A in the samples (see Experimental). Next, rearranging (4), we obtain for the concentration of **II**

$$C_{m,E} = [(n_s - n_0)(d_E/d_s) - C_{m,A}(n_A - n_0)(d_E/d_A)]/(n_E - n_0). \quad (5)$$

The specific features of calculations by Eq. (5) are as follows. Similarly to the case of two-component mixtures, the necessary initial data, which should be determined preliminarily, are the refractive indices and densities of individual preparations of vitamins A and E and of the matrix (soybean oil). On passing to other batches of these components, the initial data should be rechecked. Five out of the six indicated parameters are known (n_E = 1.4965, d_E = 0.953, n_A = 1.554, n_0 = 1.4745, and d_0 = 0.916). We obtained no experimental data for the density of the concentrates of vitamin A, since its determination requires large samples (reference data could not be

* Errors are given as estimated relative to fixed concentrations of the components.

** For actual samples all the $C_{m,\,A}$ values are estimated by averaging the results of two determinations; as the errors are given the differences of the results obtained by the two methods.

found, either). Theoretically, it is possible to estimate the density of any compound from the relationship for the molar refraction MR_D: $d = (M_r/MR_D)(n^2 - 1)/(n^2 + 2)$, where M_r is the molecular weight of the compound. However, for retinol palmitate, the thus determined density appears to be substantially overestimated ($d_A = 0.995$) as a result of the presence of the system of five conjugated bonds in the molecule and the impossibility of taking account into correctly the optical exaltation. By contrast, estimation of this value using ACD software gives a clearly underestimated result ($d_A = 0.920 \pm 0.060$). In this case, d_A should be considered a conditional parameter allowing variation within certain limits in the course of the optimization procedure. As a first approximation, we adopted the average of the two above-mentioned estimates ($d_{A,\,arb} = 0.958$, which is close to d_E), since the sensitivity of the results to this parameter is rather low.

Similarly, one can consider the density of the test samples to be experimentally inaccessible, since their determination requires considerably larger samples, compared with those needed for measuring n_A only, and much longer analysis time. Therefore, it is preferable to use a modified algorithm of data processing. In this case, to obtain the initial value of n_E, one can take any (!) conditional value of d_s as a first approximation (e.g., 0.938, which is the average over all the samples studied). In the next step (after calculating the initial value of $C_{m,\,E}$) the indicated conditional value of d_s can be ascertained using the following linear relation

$$d_s = d_A C_{m,\,A} + d_E C_{m,\,E} + d_0(1 - C_{m,\,A} - C_{m,\,E}). \quad (6)$$

Then, the refined value of d_s is substituted into Eq. (5), and the calculation procedure is repeated to obtain reproducible results for $C_{m,\,E}$. Such iteration algorithms are typical of data processing in refractometric analysis of ternary systems, particularly in the case of uncertainty in some of initial parameters

[8]. To attain constant $C_{m,\,E}$, it is mostly sufficient to make one iteration cycle using the simplest computation programs.

Table 1 presents a data sample characterizing the accuracy of determination of vitamins A and E in soybean oil, using HPLC and the technique proposed in this work. The mean deviation of the results of refractometric determinations from the fixed concentrations is $-0.8 \pm 3.0\%$ (the value of 3% characterizes the random component of the determination error, which exceeds the absolute value of the systematic error, 0.8%) and from the HPLC results, $-0.4 \pm 1.8\%$ (the same relation between the components of the total error). Table 2 also lists the results obtained in analyzing actual industrial samples of Aevit polyvitamin and intermediates used in its production. In this case, the mean deviation of the refractometric–spectrophotometric data from the reference data is $+1.1 \pm 1.7\%$, i.e., again we observe an excess of the random component over the systematic error.

Possible errors in determining vitamin A by the proposed method depend only on the errors of spectrophotometric analysis [usually $\delta(D) < \delta(\varepsilon)$], being no less than 3%. Differentiation of Eq. (5), to estimate the error of vitamin E determination, gives cumbersome relations inconvenient for practical use. It seems more preferable to estimate the sensitivity of analytical results to variation of all the experimental parameters by a method like numerical differentiation. The estimates given in Table 2 indicate that the errors in determining d_0 have the minimum effect on the accuracy of $C_{m,\,E}$ determination. Variations in d_A within 0.10 (experimental values are inaccessible) can change the error of $C_{m,\,E}$ determination by no more than 1%, which is quite acceptable on the background of the estimated accuracy of analysis. The strongest effects are obtained for n_s and results of spectrophotometric determination of vitamin A. The relative error $\delta C_{m,\,A}$ is about 3% (at $C_{m,\,A} \approx 50\%$ this corresponds to $\Delta C_{m,\,A} \approx 1.5\%$), whereas the theoretically expected random error of $C_{m,\,E}$ determination may amount to ±6%. In fact, deviations of the parameters for all the samples studied varied from –6 to +2% (Table 1), suggesting high reliability of the proposed method. The proposed refractometric-spectrophotometric method for determining vitamins A and E in oil solutions is 3–4 times less time-consuming than HPLC. However, as in refractometric analysis of two-component systems [6], acceptable accuracy can only be attained when the concentrations of the components being analyzed exceed a certain critical value. To the greatest extent this refers to vitamin E (critical concentration is about 10%), since the difference between the refractive indices of vitamins E (1.4965) and the matrix (1.467–1.475) is considerably lower than in the case of vitamin A (1.554).

CONCLUSION

A refractometric–spectrophotometric method for determinig simultaneously vitamins A and E in oil solutions is proposed. The determination procedure includes measurements of the refractive index n_D^{20} of sample and the optical density of their solutions in hexane at 325 nm. The method meets the requirements to the accuracy of analysis of industrial samples, and the systematic error does not exceed the random error.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Type of Oligoisocyanate on the Properties of Thiourethane Compounds

A. D. Elchueva, I. V. Bortnikov, and A. A. Tabachkov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received October 5, 2000; in final form, February 2001

Abstract—Thiourethane sealants were developed on the basis of various ester and ether prepolymers. The possibility of replacing in sealants thiokol, whose production is ecologically unsafe, by thiopolyether was examined.

Thiourethane compounds, compared with thiokol materials, exhibit enhanced strength, elasticity, and adhesion; they have good low-temperature properties and are resistant to corrosive media. They can be prepared from a wide range of initial components by means of diverse curing procedures.

Among the drawbacks of composites based on oligothiols are low tensile strength, high residual deformation, and its fast accumulation under the action of a constant load. The adhesion of thiokol sealants to metals, glass, wood, plastics, and rubbers is 0.1–0.5 kN m^{-1}. At the same time, production of thiokol (polysulfide oligomer, PSO) is restricted by the short supply of the starting organic dichlorides and environmental problems in production of the initial monomers and thiokol itself (release of hydrogen sulfide and sulfur-containing gases into the atmosphere).

At present, the most promising way is chemical modification with preparation of a new generation of sealing compounds (SCs) surpassing in properties the commercial thiokol sealants. The best studied modifiers are reactive oligomers. The thiol group of PSO, reacting with the other functional groups of the oligomers, acts most frequently as a nucleophilic agent.

A prominent place among modified PSO-based compounds is occupied by polythiocarbamate materials, the so-called thiourethane compounds. In Russia, such elastomers have been prepared from polyfunctional polydiethylen glycol adipate, toluene 2,4-diisocyanate, and PSO [1]. This reaction can be regarded as primary extension of the oligomer chain, followed by cross-linking.

Of particular interest is modification of thiopolyether based on polyoxyalkylene [2]. Its composites exhibit a satisfactory set of physicomechanical properties but have a substantial drawback: strong swelling in water (800–1600 wt %) at 1–2°C, which makes them unsuitable as components of sealants to be used in outdoor building works. It was found that the swelling is mainly due to the presence in the polymer structure of the ethylene oxide block and dihydroxydisulfide groups formed in the course of curing. Therefore, it was proposed to modifyt the thiopolyether with macroisocyanates based on polyoxypropylenepolyol. The choice of this polyether was governed by such factors as the absence of the ethylene oxide block in the backbone polyol chain and the number-average content of hydroxy groups in the thiopolyether higher than 2, and that of thiol groups lower than 2, which excludes formation of disulfide bonds in the course of curing. It was noted that isocyanate groups react not only with hydroxy groups but also with thiol groups of thiopolyethers to give thiourethanes; therefore, dibutyltin dilaurate, mainly catalyzing the reaction of isocyanate and hydroxy groups, was chosen as catalyst. It is significant that the synthesis conditions (temperature, amount of catalyst) do not affect noticeably the viscosity of the final products. The activation energy of viscous flow is 9.2–11.1 kcal mol^{-1}.

As a rule, modification of thiokol SCs with oligoisocyanates increases the adhesion to 2–3 kN m^{-1} and improves the castability and processing properties of sealants [3]; hence, it shows considerable promise.

At present, the major problem is development of formulations of filled sealants with the use of cata-

1070-4272/01/7406-1040 $25.00 © 2001 MAIK "Nauka/Interperiodica"

lytic systems of the amine type for interaction of the reactive oligomers; a new approach to forming interpenetrating polymer networks is implemented [4].

For cross-linking of oligothiols through terminal mercaptan groups, we used urethane prepolymers with terminal isocyanate groups, based on ether, ester, and oligodiene polyols.

EXPERIMENTAL

As oligothiols were used grade 1 thiokol [GOST (State Standard) 12 812–80] and thiopolyether [TU (Technical Specifications) 38.403 431–82]. As catalysts served products of amine interchange in phenolic Mannich bases, ethylenediaminomethylphenols (EDAMPs) (TU 6.05.1663–74).

As oligoisocyanates were used commercial prepolymers: oligoesters of SKU-F-E4 brand (TU 38.403 506–84), based on oligoethylene butylene glycol adipate, and of OEDGA-50T brand (TU 38.103 446–79), based on oligoethylene diethylene glycol adipate, and oligoethers of SKU-PFL brand (TU 38.103 137–78), based on oligooxytetramethylene glycol (polyfurite), and of SKU-DF-2 brand (TU 38.103 451–79), based on oligobutadienepolyol.

As fillers served industrial carbon of P-803 brand (GOST 7885–77) and chalk (GOST 842–52).

To determine the deformation and strength properties, samples were prepared as plates of thickness 2 mm and width 25 mm. Tests were performed on an RMI-250 tensile testing machine in conformity with GOST 21 751–76.

It has been reported previously [5] that SCs prepared at the equimolar ratio of the reactive oligomers have the best physicomechanical properties. This fact indicates that in the systems under consideration the polymer network is formed by reaction of the oligomers through the terminal functional groups, with the homocuring of one or another oligomer being of minor or no importance, since even insignificant deviation from the equimolar ratio in any direction results in simultaneous decrease both in the nominal tensile strength and in the relative elongation of the composites.

For the formulations PSO + SKU-F-E4, the best properties are attained with 0.3 wt part of the catalyst per 100 wt parts of the oligothiol. In this case, the maximal nominal strength is as high as 5.6 MPa. The relative elongation of the composites at a catalyst content of 0.5 wt part is 680%. With the thiopolyether, the strength is 4.5 MPa, and the relative elongation, 480%.

With the OEDGA-50T prepolymer, the plots of the physicomechanical characteristics against catalyst content pass through extrema corresponding to the content of ethylenediaminomethylphenol of 0.3 wt part per 10 wt parts of oligothiol. With thiokol and thiopolyether, the optimal characteristics are as follows: strength 3.5 and 2.8 MPa; relative elongation 480 and 400%, respectively.

The thiourethane sealant based on SKU-PFL exhibits enhanced adhesion and elasticity but has a high deformation set (20–28%). The strength of the composites reaches 2.8 MPa, the elasticity is as high as 800%, and the adhesion at break is about 7.5 kN m^{-1}.

With the ether prepolymer SKU-DF-2, the best physicomechanical parameters are attained at EDAMP content of 0.5 wt part. These composites well compete with SCs based on OEDGA-50T.

The physicomechanical characteristics of the composites get worse on deviation from the optimal catalyst dosage, irrespective of the nature of the oligothiol and oligoisocyanate. This is due to the fact that, when present in large amounts, ethylenediaminomethylphenol causes cyclization of the prepolymer through isocyanate groups, along with activation of the mercapto groups of the oligothiol [6]. Formation of isocyanurate structures affects the ratio of the reactive groups of the oligomers in the sealant formulation, which has negative effect on the set of properties of the composites. Experiments proved that the mercapto groups form no disulfide bonds in the presence of isocyanurates.

Thus, with respect to the physicomechanical characteristics of sealants, oligoisocyanates can be ranked in the following order: SKU-F-E4 > OEDGA-50T > SKU-PFL > SKU-DF-2.

Also, the use of more polar thiokol for cocuring with prepolymers based on polyesters is more appropriate as compared to that of thiopolyether. The higher the polarity of the prepolymer (SKU-F-E4 compared with OEDGA-50T), the better the properties of SC.

Irrespective of the type of the oligothiol and oligoisocyanate, the properties of the composites as functions of the content of the active filler—industrial carbon—pass through extrema. With a mineral filler, chalk, the nominal strength increases and the relative elongation decreases with growing filler content (Table 1).

As objects for studying the chemical resistance we chose thiourethane sealants of the optimal composition. It is known [7] that urethane rubbers based on polyesters are less resistant to hydrolysis than rub-

bers based on polyethers. This is manifested in the behavior of thiourethane sealants in aggressive media (Table 2).

According to published data [8], swelling of thiokol sealants in seawater and tap water is somewhat lower than that in distilled water. Thiourethane sealants show the same trend, but, compared with thiokol sealants, their swelling is considerably stronger, which is probably due to hydrolysis of the ether and ester groups. With respect to water resistance, urethane prepolymers can be ranked in the order SKU-DF-2 > SKU-PFL > OEDGA-50T > SKU-F-E4.

SKU-F-E4	–38	119
U-30 M (commercial)	–60	120

The behavior of both thiokol and thiourethane sealants in solutions of acids and alkalis is the same: Samples relatively weakly swell in 20% solutions of KOH and H_2SO_4. The composites prepared from ester prepolymers are resistant to organic solvents and show the same swelling in benzine–benzene mixture and in toluene as the thiokol sealant U-30 M. The materials prepared from oligoethers are less resistant owing to enhanced swelling of the urethane block.

Thus, sealants based on SKU-PFL and SKU-DF-2 can be used instead of the thiokol material under conditions of contact with seawater and solutions of acids and alkalis, whereas the sealants based on poly-

esters show lower hydrolysis resistance but can be used as benzine-and-oil-resistant coatings.

It is known that the capability of elastomers to preserve at low temperatures their service properties, mainly elasticity, can be characterized by the glass transition point T_g. The glass transition point does not change significantly in going from thiokol to the developed oligoether-based materials (Table 3), but introduction of ester blocks strongly impairs the low-temperature properties of the sealants. The flow point T_f noticeably depends on the chemical structure of the urethane constituent. This parameter determines the limiting working temperature of the material under constant load; for the sealants based on oligobutadiene urethane T_f is as high as 170°C.

CONCLUSIONS

(1) The physicomechanical properties of sealant compounds prepared by catalytic reaction of oligothiols and oligoisocyanates were studied. As catalyst for curing the composites was used ethylenediaminomethyl phenol, the product of amine interchange in phenolic Mannich bases. The content of thiokol, whose production is ecologically unsafe, in the sealant formulation can be decreased by 37–42%; furthermore, thiokol can be completely replaced with thiopolyether.

(2) The influence of the chemical nature of oligoisocyanates on the properties of thiourethane sealants was studied. The main physicomechanical parameters and the resistance to benzine and oil grow in going from ether to ester prepolymers, whereas the composites prepared from oligoethers exhibit higher water resistance.

(3) In thiourethane sealants, oligothiol and urethane prepolymer are present in equimolar amounts; the output of thiokol-based sealing compounds can be thus increased by a factor of 2 and more. Such sealants can be used instead of thiokol sealants in virtually all cases. The process for sealant production is made simpler because of using oligoisocyanate as separate component. The traditional equipment used for production of thiokol sealants is suitable for commercial production of the developed compounds.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Photosensitivity and Physicochemical Properties of the Two-Layer Photoresist Based on Naphthoquinone Diazide and Cyclorubber

E. N. Gudymovich

Tomsk State University, Tomsk, Russia

Received April 25, 2000; in final form, February 2001

Abstract—The possibility was examined of preparing a model of a two-layer photoresist based on a photosensitive layer of naphthoquinone diazide (FP-383) and a planarizing layer of cyclorubber (FN-11) and enhancing the photosensitivity and physicochemical resistance of FN-11 films after irradiation through the naphthoquinone diazide layer and its removal by development in KOH.

The loss of the structure planarity in fabrication of integrated circuits requires preparation of multilayer resistive coatings eliminating many drawbacks of the single-layer systems. Also, with a multilayer structure of a resist it is possible to meet a set of mutually contradicting requirements: high resolving power at sufficient thickness of the planarizing layer, low film defectiveness at small thickness of the sensitive layer, etc. The common drawback of all masks based on multilayer resist films is more complex forming process involving numerous operations, in which the advantages of the idea of forming topological structures are lost in numerous process stages [1, 2].

The model of a two-layer photoresist based on naphthoquinone diazide (NQD) and cyclorubber (FN-11), proposed in this work, eliminates many labor-consuming operations of the lithographic process and provides a sharp pattern in the SiO_2 layer; the system needs no separating layer.

All experiments were performed on polished silicon wafers with 0.9-μm-thick SiO_2 layer. Wafers were degreased in acetone and ethanol. The two-layer resist was formed as follows. A planarizing layer of FN-11 was applied to a silicon wafer by centrifuging at 2600 rpm for 30 s. The film was dried in an oven at 90°C for 30 to 120 min. After cooling, a photosensitive layer of FP-383 was applied under the same conditions as for FN-11 and dried at 80°C for 20 to 60 min. Then FN-11 was hardened at 135°C for 20 min. The sample was exposed to the light of a DRL-250 mercury-arc luminescent lamp (continuous emission spectrum). Working phototemplates with element size from 5 to 1.5 μm were used. The openings in the FP-383 layer were made by treatment with 0.3% KOH, and those in FN-11, by treatment with xylene. The resist removal was monitored with an MMU-3 microscope (magnification from ×80 to ×476) and its being complete was judged from the disappearance of the characteristic supramolecular structure of FP-383. The transmission coefficient A was measured with an SF-46 spectrophotometer with an absolute error of ±1% at 365 nm. The IR spectra were obtained on a Specord-40 spectrophotometer (photometric accuracy ±0.2% A).

The use as planarizing layer of the negative photoresist FN-11 is due to its good physicochemical and physical properties [adhesion, viscosity, low polar constituent of the resist (χ^p = 2 dyne cm^{-1})], and also by the higher drying temperature (90–95°C) at which the FP-383 layer can partially lose the photosensitivity if used as the lower planarizing layer in drying the upper FN-11 layer.

Dioxane used as solvent for NQD causes cracking of a dried FN-11 film. The developers (KOH for NQD and xylene for FN-11) are inert toward dried films. Raising the film drying time to 60 min made both layers stable; the IR spectra of a purely FN-11 film were fully identical to those of the FN-11 film after removal of the upper photosensitive layer (Fig. 1). The spectrum of the latter contains no bands characteristic of FP-383. All the characteristic bands belong to FN-11 [3, 4] (cm^{-1}): 2940 and 2870,

1070-4272/01/7406-1044 $25.00

stretching vibrations of the C–H bond in the CH_3 and CH_2 groups of rubber; 2160–2120, asymmetric stretching vibrations of the $-N_3$ group of the bisazide; 1660–1650, vibrations of the C=O bond in the  group of bisazide; 1460, inplane vibrations of the C=C bond in the benzene ring of bisazide; 1375, bending vibrations of the C–C bond in the $C–CH_3$ group of rubber; and 615, vibrations in benzene derivatives.

The characteristic curves plotted for FN-11 in the coordinates film thickness–minimal irradiation time required for complete cross-linking (judged from the resistance of the films to development for more than 10 min) shows that the photosensitivity of the FN-11 film increases after application of naphthoquinone diazide. The irradiation dose for cross-linking of FN-11 through the upper sensitive layer of naphthoquinone diazide is considerably lower than the energy required for cross-linking of a single FN-11 layer (Fig. 2, curve *1*).

The times t_1 and t_2 corresponding to the ends of the intervals of proportional image transmission correspond to the same thickness of the cross-linked polymer, after which in both cases the rate of relief formation decreases steeply as the exposure energy increases. The identity of the transmission bands in the IR spectra of the single- and two-layer structures (Fig. 1) shows that these two layers do not react chemically under experimental conditions (simple physical contact of dried films 3 to 9 μm thick, with short UV irradiation). Probably, the photochemical activity of cyclorubber is initiated owing to multiple reflection from the layer boundaries upon completion of the photolysis in the upper sensitive layer of naphthoquinone diazide.

Since the absorption maxima of naphthoquinone diazide and cyclorubber coincide (365 nm) [5] and there is no separating layer, irradiation of the photosensitive layer through a phototemplate produces an image in the lower planarizing layer, too, after development (with 0.3% KOH and xylene, respectively). To describe the photochemical aspect of the photosensitivity of the FN-11 layer, we measured the transmission coefficient *A* as a function of irradiation time for various types of films (Fig. 3). Figure 3 shows that the FP-383 layer transmits a significant fraction of the incident radiation, sufficient to produce image also in the lower layer also.

The physicochemical aspect of the photosensitivity is characterized in the table by the irradiation dose

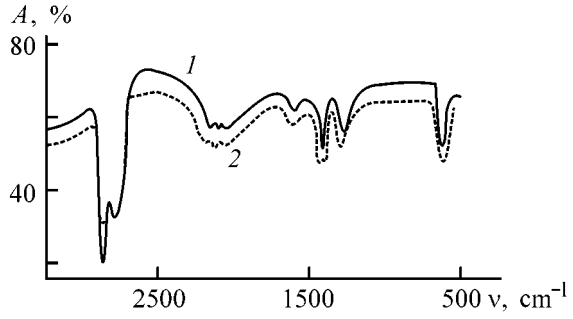

Fig. 1. IR spectra of (*1*) purely FN-11 film and (*2*) FN-11 film after removal of the naphthoquionone diazide layer. (*A*) Transmission coefficient and (ν) wave number.

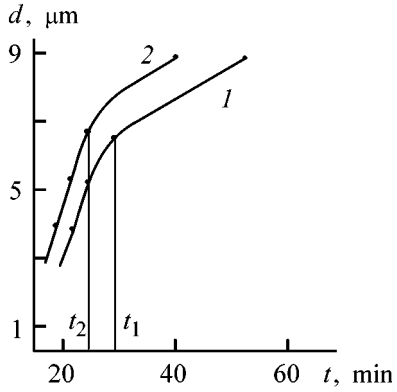

Fig. 2. Characteristic curves for the (*1*) purely FN-11 layer and (*2*) FN-11 layer irradiated through a layer of naphthoquinone diazide. (*d*) Film thickness and (*t*) minimal irradiation time.

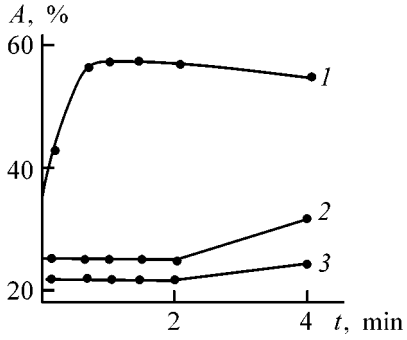

Fig. 3. Transmission coefficient *A* vs. the irradiation time *t* for (*1*) FP-383 film, (*2*) FN-11 film, and (*3*) FN-11 irradiated through a layer of FP-383, after removal of this layer.

required to make the film resistant to the developer. It is seen that the resistance of the FN-11 film appreciably increases when the image in this film is formed through a layer of FP-383, after removal of the latter in KOH solution. These results are fully consistent with the characteristic curves (Fig. 2).

Resistance of FN-11 films to the developer as influenced by the irradiation dose

t, s	Resistance of FN-11 films, s		*t*, s	Resistance of FN-11 films, s	
	single-layer	after removal of FP-383 layer		single-layer	after removal of FP-383 layer
40	15	20	120	25	> 600
60	20	25	150	> 600	> 600
90	25	> 600	300	> 600	> 600

Since the FN-11 photoresist is resistant to plasma, it is possible to obtain in this system an image using as planarizing layer a hardened (in the course of FN-11 drying) FP-383 layer, which can be subsequently broken down by plasmochemical etching. In this case a sharp image is formed in the FN-11 layer.

CONCLUSION

In the system FP-383–FN-11, it is possible to form a two-layer photoresist exhibiting significant advantages over other systems: the absence of a separating layer and the same radiation source for the planarizing and sensitive layers (UV, 365 nm); elimination of such operations as matching, repeated irradiation, and breakdown of the sensitive layers to make windows. FP-383 enhances the photosensitivity of the FN-11 layer and its physicochemical resistance to the developer.

CHEMISTRY OF FOSSIL FUEL

Homogeneous Pyrolysis of Anisole

V. V. Platonov, V. A. Proskuryakov, S. V. Ryl'tsova, and Yu. N. Popova

St. Petersburg State Technological Institute, St. Petersburg, Russia

Tolstoy State Pedagogical University, Tula, Russia

Received December 21, 2000

Abstract—Homogeneous pyrolysis of anisole in argon (1 : 25 volume ratio) at 750–900°C and contact time of 1.5–4.5 s was studied. The conversion and group composition of the tar and component composition of the gaseous pyrolysis products, phenols, and hydrocarbons were determined; asphaltenes and neutral oxygen-containing compounds were characterized. The kinetic parameters of formation of methane, hydrogen, and carbon monoxide and dioxide were calculated; mechanisms of their formation are proposed.

Intensifying high-rate pyrolysis of mineral oils and raising the yield of tars of prescribed qualitative and quantitative composition require detailed information on high-temperature conversion of the primary degradation products.

Since the primary tar and even its separate fractions are complex multicomponent mixtures of compounds of various classes, studying their high-temperature conversion is rather difficult. Therefore, analysis of the pyrolysis of groups of similar compounds and especially of individual components making the most pronounced contribution to the composition of liquid products is the best way to attack the problem.

Based on the latter approach, we can determine the mechanism and main pathways of the occurring reactions, together with their order and activation energies. The kinetic equations obtained in this case can be used to simulate the behavior of separate fractions of primary tars and the resulting tar as a whole in the course of pyrolysis.

Pyrolysis of individual compounds has been studied extensively [1–22], but in some cases data on the composition of secondary products are lacking [1–8]. Moreover, owing to different apparatus and experimental procedures used in these works, their results are difficult to compare.

The goal of this work was to study the homogeneous pyrolysis of anisole, to determine the composition of phenols, hydrocarbons, asphaltenes, and oxygen-containing compounds (NOCs), and to evaluate the kinetic parameters of formation of separate components of the gaseous pyrolysis products.

Pyrolysis of anisole was performed in a setup described in [23]; the tar composition was analyzed by the procedure described elsewhere [24].

The material balance of anisole pyrolysis, the group composition of liquid products, and the component composition of the gaseous pyrolysis products are given in Table 1. As seen, anisole decomposes to a significant extent at the temperatures and contact times used in the experiments.

Gases and tar are the main pyrolysis products at 750–800°C, whereas at 850–900°C the yield of pyrographite increases simultaneously with the yield of the gaseous pyrolysis products. For example, at a contact time of 1.5 s and 800°C the yield of gaseous pyrolysis products, tar, and pyrographite is 20.00, 52.00, and 18.80 wt %, whereas at 900°C it is 37.50, 24.90, and 32.80 wt %, respectively, based on anisole.

The yield of crude benzene, containing up to 90% benzene, is the highest at 800°C and contact time of 1.5 s (9.20 wt % based on anisole); under more severe conditions, the yield of benzene decreases.

The results of group analysis (Table 1) show that up to 850°C (1.5 s) phenols are the main component of the tar; their content varies from 63.50 wt % (750°C) to 29.50 wt % (850°C) at contact times of 4.5 and 1.5 s, respectively. Raising the temperature and contact time further strongly decreases the content of phenols. At 850°C and 3.0 s their content is 5.40 wt %, and at 900°C and 3.0 s the content of phenols in the tar decreases to 1.5 wt %. This is probably due to the degradation of phenols and to a certain change in the direction of pyrolysis reactions.

p-Cresol	0.398	0.542	0.119	0.037	0.045	0.013	0.015	0.016	0.004
m-Cresol	0.122	0.271	0.090	0.046	0.056	0.010	0.016	0.006	0.004

Note: Only trace amounts of xylenols are found in the phenol fraction.

Simultaneously with the decrease in the yield of phenols, the content of hydrocarbons and asphaltenes in the tar increases. At 750°C (4.5 s) the content of hydrocarbons in the tar is 17.50 wt %, and at 900°C (3.0 s) it grows to 50.30 wt %, and the content of asphaltenes increases from 9.40 to 43.10 wt % owing to intensification of the condensation processes. The content of NOCs varies insignificantly.

The main components of the gaseous pyrolysis products (Table 1) are hydrogen, methane, and carbon monoxide and dioxide. With increasing temperature and contact time, the yield of hydrogen steadily increases from 25.30 to 46.20 vol %, based on total gaseous products, at 800°C (1.5 s) and 900°C (3.0 s), respectively. Simultaneously the yield of methane and carbon monoxide decreases from 24.80 and 41.50 to 16.20 and 32.90 vol %, respectively.

To obtain a clearer pattern of thermochemical transformations of anisole, we studied the chemical composition of phenols, hydrocarbons, asphaltenes, and neutral oxygen-containing compounds.

The data obtained by means of capillary gas-liquid chromatography (CGLC) of phenols (Table 2) show that the main component of the tar is phenol, whose content changes from 14.632 to 0.085 wt %, based on anisole, upon heating from 750°C (4.5 s) to 900°C (3 s). The decrease in the phenol yield under more severe conditions of pyrolysis is due to intensification of the secondary processes of dehydration and condensation. The content of cresols is the highest at 750°C (4.5 s) and 800°C (1.5 s); the content of xylenols is insignificant.

Iodine number, g-equiv mol^{-1}	0.106	0.195	0.230	0.272	0.309	0.218	0.113	0.236	0.137

The component composition and yield of individual hydrocarbons are listed in Table 3. The main components of the hydrocarbon fraction are naphthalene, diphenyl ether, phenanthrene, and anthracene. The yield of naphthalene is the highest at 850°C (3.0 s) and the lowest at 900°C (3.0 s): 3222.40×10^{-3} and 1356.41×10^{-3} wt %, based on anisole, respectively. The yield of phenanthrene and anthracene is the highest under the same conditions. It should be noted that the above compounds are accumulated in the tar at temperatures up to 850°C and contact time of 1.5 s; under more severe conditions of pyrolysis these compounds are converted into more condensed hydrocarbons. This is confirmed by the steady increase in

the content of pyrene, benzophenanthrene, and fluoranthene in the tar.

Detailed data on the composition of NOCs and asphaltenes are necessary to study the most important stages of anisole degradation and to determine the fields of efficient utilization of the degradation products.

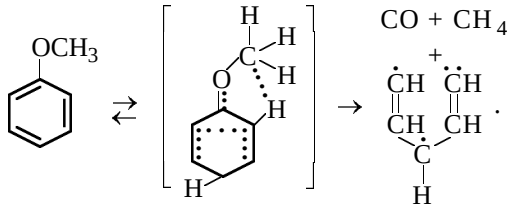
The molecular structure of asphaltenes and NOCs was studied by cryoscopy [25] and quantitative functional analysis [26–30]; the results are given in Table 4.

As seen, asphaltenes and NOCs differ in molecular weight and content of functional groups. For example, NOCs contain almost no phenolic hydroxy groups, which occur in asphaltenes where their content is the highest at 800°C and contact time of 1.5 s (0.335 g-equiv mol^{-1}). As the pyrolysis conditions are made more severe, the content of these groups decreases to zero through their complete degradation. The appearance of phenolic groups in asphaltenes is due to the large size of asphaltene molecules, which hinders attack of the reaction centers. By contrast, quinoid groups are concentrated in NOCs (0.505 and 0.266 g-equiv mol^{-1} in, respectively, NOCs and asphaltenes at 800°C and contact time of 1.5 s). With increasing temperature and contact time, the content of quinoid groups decreases, probably because of their higher lability as compared with that of other functional groups. The appearance of these groups in the products of anisole pyrolysis suggests the intermediate formation of quinoid or related structures in the course of pyrolysis. The alkoxy groups occur in the initial compound and can be formed by the attack of the radical fragments of ring degradation on the phenolic and quinoid groups; as a result, they are predominant in the NOC structures. Heterocyclic oxygen is the most thermodynamically stable form, and it is found in the asphaltenes under more severe conditions of pyrolysis at 900°C or at more prolonged contact. In the case of NOCs, heterocyclic oxygen is not formed only at 750°C (4.5 s), which suggests increased lability of heterocyclic fragments in oxygen-containing compounds as compared with asphaltenes. The degree of unsaturation of asphaltenes, which is characterized by the iodine number, is several times greater than that of the neutral oxygen-containing compounds.

To evaluate the overall thermal stability of anisole, we calculated the kinetic parameters of formation of components of gaseous pyrolysis products.

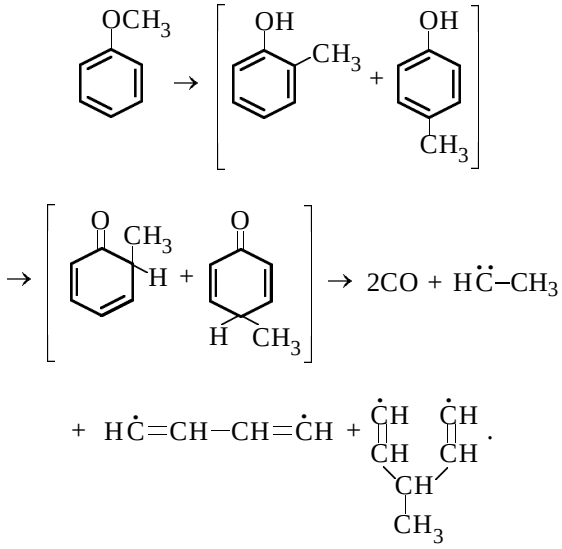
The formation of carbon monoxide is described by a 1.5-order kinetic equation with activation energy of 345.00 kJ mol^{-1}, which is of particular importance, since for most of the compounds studied this is a first-order process and the whole body of experimental data suggests intramolecular mechanism of CO liberation. In our case, the order of 1.5 is due to a more complex mechanism of formation, whereas the higher activation energy, compared with that in radical reactions, suggests their insignificant contribution.

The close activation energies of CO formation from anisole and phenols [21, 22] suggest that the structures of their activated complexes are similar. Since the activated complex of phenols has a quinoid structure, it would probably have a pseudoquinoid nature in the case of anisole. Then, the cleavage of CO from anisole can be described by the following reaction:



Based on the additivity of the bond energies in the activated complex [31], we calculated the activation energies for the above process. The resulting activation energy (368.30 kJ mol^{-1}) is close to the experimental value, which is slightly lower, probably owing to the contribution of secondary radical reactions.

Also, another mechanism of CO formation is possible:



The calculated activation energy of this process is 404.75 kJ mol^{-1}, and this mechanism accounts for the formation of cresols in the phenol fraction of the tar.

The formation of carbon dioxide is described by a second-order kinetic equation; at 850°C and contact time of 3.0 s the mechanism changes. At 800–850°C the activation energy is 92.18 kJ mol^{-1}, being as high as 206.15 kJ mol^{-1} at 850–900°C. Such small activation energies suggest the radical mechanism of the process, which can be described as follows: CO^* molecules formed by cleavage of the activated complex attack either the anisole molecules at the methoxy group (1) or the methoxy radicals in the gas phase (2):

$$CO^* + CH_3OC_6H_5 \rightarrow CO_2 + C_6H_5CH_3, \quad (1)$$

$$CO^* + CH_3O^{\cdot} \rightarrow CO_2 + {}^{\cdot}CH_3. \quad (2)$$

It is also possible that formation of CO_2 is accompanied by reactions catalyzed with pyrographite.

Methane can be formed simultaneously with carbon monoxide and also from methyl radicals in the course of formation of carbon dioxide. At equal contributions of these mechanisms the activation energy calculated by the Moin procedure [31] is 272.35 kJ mol^{-1}, in agreement with the experiment (256.43 kJ mol^{-1}). The smaller experimental value probably suggests occurrence of a less energy-consuming process. The accumulation of methane is described by a second-order equation.

Hydrogen is formed in anisole pyrolysis through condensation, degradation, and recombination reactions; its accumulation is described by a 1.5-order equation with activation energy of 98.88 kJ mol^{-1}.

The kinetic equations of formation of the gaseous pyrolysis products components are given in Table 5.

Table 5. Kinetic equations of formation of the gaseous pyrolysis products

Component	Reaction order	Kinetic equation
CO	1.5	$k_{ck} = 4.0 \times 10^{18}\exp(345000/RT)$
CH_4	2.0	$k_{ck} = 1.1 \times 10^{15}\exp(-256428/RT)$
H_2	1.5	$k_{ck} = 3.3 \times 10^{6}\exp(-98884/RT)$
CO_2	2.0	$k_{ck} = 8.3 \times 10^{7}\exp(-92180/RT)$ (800–850°C)
		$k_{ck} = 4.1 \times 10^{14}\exp(-206148/RT)$ (850–900°C)

CONCLUSIONS

(1) A study of homogenous pyrolysis of anisole showed that anisole is thermally unstable even at relatively low temperatures. The predominant liquid products obtained at 750–800°C and contact times of 1.5–4.5 s are phenols and hydrocarbons, and at 850–900°C, hydrocarbons and asphaltenes. Methane, hydrogen, and carbon monoxide and dioxide are the main components of the gaseous pyrolysis products.

(2) The phenol fraction of the liquid products consists of phenol, cresols, and trace amounts of xylenols; naphthalene and diphenyl ether are the main components of the hydrocarbon fraction. Asphaltenes and neutral oxygen-containing compounds are complex mixtures of predominantly aromatic compounds with various functional groups and alkyl chains.

(3) The kinetic parameters of formation of the gaseous pyrolysis products were calculated, and the mechanisms of their formation are proposed.

Abstract—Homogeneous pyrolysis of α-naphthol in argon (1 : 25 volume ratio) at 750–900°C and contact time of 1.5–4.5 s was studied. The conversion and group composition of the liquid products, and component composition of the gaseous pyrolysis products and hydrocarbons were determined; the asphaltenes formed were characterized. The kinetic parameters of α-naphthol degradation and formation of methane, hydrogen, and carbon monoxide were calculated; the possible mechanisms of these processes are proposed.

Phenols are significant component of the tars formed in semicoking (low-temperature carbonization) and high-rate pyrolysis of caustobioliths, and their content in the tar may be as high as 30–35 wt %. In high-temperature pyrolysis, the fraction of phenols in the tar decreases to 1.5 wt %, with the yield of neutral oxygen-containing compounds, hydrocarbons, and asphaltenes increasing simultaneously. Optimization of pyrolysis conditions to prepare products of prescribed composition requires detailed information on the behavior of various phenols, including naphthols, and on how high-temperature tars are formed.

It has been found [1–12] that the temperature and contact time strongly affect the yield and composition of the degradation products of phenols. However, owing to the lack of systematic data, small range of phenols studied, and significant differences in the experimental conditions, evaluation of the thermal stability in the phenol series is still difficult. Moreover, the kinetic parameters of pyrolysis and data on the group and component composition of liquid products are lacking. In [13–18], data on high-temperature conversion of phenol, cresols, xylenols, and dihydric phenols were presented, the group composition of the tars and the component composition of the gaseous pyrolysis products determined, the kinetic parameters of degradation of the initial raw material and of formation of the tar and gaseous pyrolysis products components calculated, and the reaction mechanisms proposed.

The aim of this work was to study the features of homogeneous pyrolysis of α-naphthol, determine the qualitative and quantitative composition of hydrocarbons and asphaltenes, and evaluate the kinetic parameters of formation of the gaseous pyrolysis products components.

Pyrolysis of α-naphthol was performed on a setup described in [19]; the tar composition was analyzed by the procedure described elsewhere [20].

The material balance for α-naphthol pyrolysis is given in Table 1 indicating a significant transformations of the initial compound at temperatures of 750–900°C and contact time of 1.5–4.5 s. Under the above conditions, the tar fraction decreases from 89.00 to 26.30 wt %, with the yield of gaseous pyrolysis products and pyrographite increasing from 6.50 to 26.50 and from 3.30 to 45.20 wt %, respectively. The content of benzene fraction remains almost constant and at 850°C (4.5 s) it does not exceed 2.55 wt % relative to α-naphthol. This is probably due to a rather complex pathway of formation of mononuclear aromatic hydrocarbons from the system of two fused aromatic naphthalene rings.

The result of group analysis of the liquid products and the component composition of the gaseous pyrolysis products are also listed in Table 1.

As seen, the content of the phenol fraction in the tar decreases, because the hydroxy group in phenol is the first to degrade. For example, the content of phenols in the tar is 58.5 wt % at 800°C (1.5 s) and only 5.3 wt % at 900°C (3.0 s). Simultaneously, asphaltenes and hydrocarbons are accumulated in liquid degradation products. The yield of hydrocarbons

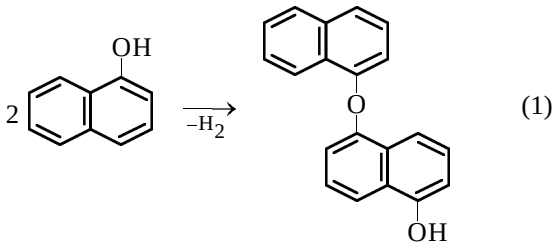
Table 1. Material balance of α-naphthol pyrolysis

Pyrolysis products	Yield of pyrolysis products (wt % based on initial α-naphthol) at indicated contact time, s								
	4.5	1.5	3.0	4.5	1.5	3.0	4.5	1.5	3.0
	750°C	800°C			850°C			900°C	
Benzene hydrocarbons	1.20	1.00	1.55	2.00	2.10	2.30	2.55	2.45	2.00
Tar, including (wt %):	89.90	85.50	74.50	61.90	73.05	51.90	39.85	37.30	26.30
phenols	48.20	58.50	43.20	20.80	36.10	16.40	8.20	12.20	5.30
hydrocarbons	17.20	15.00	22.20	19.00	25.40	43.40	50.30	28.90	36.50
neutral oxygen-containing compounds	0.40	1.60	2.00	0.80	1.30	1.10	0.60	0.80	0.60
asphaltenes	22.00	15.70	22.30	18.57	22.80	31.00	35.00	40.00	50.00
resins	12.20	9.20	10.30	2.73	14.40	9.10	5.90	18.30	7.60
Gaseous pyrolysis products + losses, including (wt %):	6.50	7.20	12.95	18.30	13.00	17.70	20.50	24.95	26.50
H_2	32.50	24.80	46.10	42.50	41.30	49.40	57.70	52.90	58.30
CH_4	4.60	3.50	5.70	5.80	5.90	7.10	7.50	6.70	7.30
CO	62.90	71.70	48.20	51.60	52.80	43.50	34.80	40.40	34.40
Pyrographite	3.30	6.30	11.00	17.80	12.85	28.10	37.10	35.50	45.20

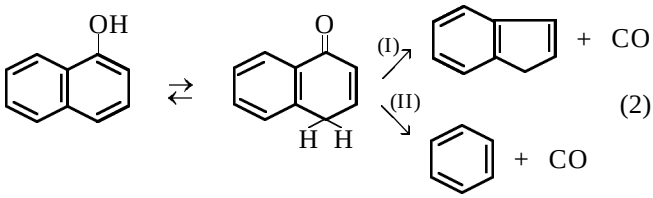
strongly depends on the contact time. This is probably due to the prolonged period of their formation from hydrocarbon fragments generated in degradation. The content of neutral oxygen-containing compounds (NOCs) is insignificant. Their highest content in the tar (2.00 wt %) is attained at 800°C (3.0 s); further decrease in the NOCs content is due to instability of the resulting structures and their degradation on heating.

Simultaneously, with decreasing yield of phenols, the content of asphaltenes in the tar increases to become 15.70 wt % at 800°C (1.5 s) and 50.00 wt % at 900°C (3.0 s). This is due to the structure of α-naphthol, containing two aromatic rings whose condensation gives macromolecular compounds.



(1)

The main component of the gaseous products formed at 750–800°C is carbon monoxide yielded by the following reactions:



(2)

$$+ H\dot{C}{=}\dot{C}H + \ddot{C}H_2$$

$$\ddot{C}H_2 + 2\dot{H} \rightarrow CH_4$$

With increasing temperature and contact time, the content of hydrogen and methane in the gaseous pyrolysis products grows, with the yield of carbon monoxide decreasing simultaneously. This is probably due to the fact that CO is formed by mechanism (I) in the initial stages of pyrolysis and by mechanism (II) under more severe conditions, with the formation of radical fragments.

To determine the contribution of α-naphthol to the formation of individual phenols, hydrocarbons, and neutral oxygen-containing compounds, the phenol and hydrocarbon fractions were studied by the capillary gas-liquid chromatography (CGLC). The phenol fraction consists of unchanged α-naphthol; other low-boiling components are almost absent.

The component composition of hydrocarbon fraction of the tar formed in α-naphthol pyrolysis is shown in Table 2. This fraction contains naphtha-

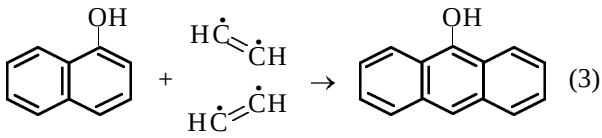
lene, its methyl and dimethyl homologs, acenaphthene, fluorene, phenanthrene, anthracene, fluoranthene, pyrene, benzophenanthrene, and high-boiling hydrocarbons. The main components of the hydrocarbon fraction are naphthalene and benzophenanthrene. Under more severe conditions, the yield of these compounds increases. For example, the yield of naphthalene grows from 250.19×10^{-2} at 800°C (1.5 s) to 526.08×10^{-2} wt % at 900°C (3.0 s); under the same conditions, the yield of benzophenanthrene increases from 142.41×10^{-2} to 205.44×10^{-2} wt %, respectively.

The content of hydrocarbons boiling out after benzophenanthrene is rather significant at 800– 850°C and contact time of 1.5 s (741.83×10^{-2} and 777.25×10^{-2} wt %) and rapidly decreases on heating to 900°C at a contact time of 3.0 s (56.64×10^{-2} wt %). These high-boiling hydrocarbons can be used to prepare low-molecular-weight hydrocarbons and asphaltenes, whose yield grows with increasing temperature and contact time.

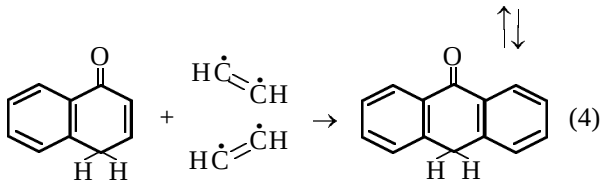
Detailed data on the structure of asphaltenes are necessary to analyze the most important stages of α-naphthol degradation and to determine the contribution of these compounds to the formation of the qualitative and quantitative composition of the "secondary" tars.

The molecular structure of asphaltenes was studied by cryoscopy [21] and quantitative functional analysis [22–26]; the obtained results are given in Table 3.

The content of phenol groups is the highest at 800°C and contact time of 3.0 s (1.47 mg-equiv g^{-1}); under more severe conditions their content decreases, which is due to the degradation of phenol hydoxy groups of both α-naphthol and the resulting asphaltenes.



(3)



(4)

The possibility of mechanism (4) is confirmed by the presence of quinoid groups in the asphaltene structures; their content is the highest at 800°C and contact time of 3.0 s and decreases under more severe conditions.

A significant fraction of oxygen is contained in heterocycles; its content increases at 800 and 850°C

Table 3. Properties of asphaltenes

T, °C	Contact time, s	Molecular weight	Content of functional groups, mg-equiv g^{-1}				Iodine number, mg-equiv g^{-1}

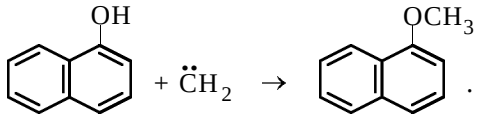
Table 4. Kinetic equations of degradation of α-naphthol and formation of components of gaseous pyrolysis products

Process	Reaction order	Kinetic equation
Degradation of α-naphthol	1.5	$k_{ck} = 1.96 \times 10^{14}\exp(-233\,800/RT)$
Formation of:		
CO	1.0	$k_{ck} = 7.34 \times 10^{17}\exp(-319\,280/RT)$
CH_4	1.5–2.0	$k_{ck} = 2.12 \times 10^{10}\exp(-256\,850/RT)$
H_2	1.5–2.0	$k_{ck} = 5.30 \times 10^{11}\exp(-270\,260/RT)$

and decreases at 900°C, which may be due to limited thermal stability of the resulting rings.

The content of alkoxy groups is small because of the low concentration of the fragments able to attack the phenol hydroxyl or quinoid group:



(5)

At 850°C and contact time of 3.0–4.5 s, formation of unsaturated fragments is the most intensive; under more severe conditions, high concentration of hydrogen (Table 1) promotes hydrogenation of unsaturated bonds. This is confirmed by the variation of the iodine number (mg-equiv g^{-1}) 0.25 at 800°C (4.5 s), 2.82 at 850°C (4.5 s), and 0.91 at 900°C (3.0 s).

To evaluate the total thermal stability of α-naphthol, the kinetic parameters of formation of gaseous pyrolysis products were calculated.

The degradation of α-naphthol is described by a 1.5-order kinetic equation with activation energy of 233.80 kJ mol^{-1}, a 20% higher value as compared with phenol [13], which may be due to a stronger stabilizing effect of two more rigid condensed naphthalene rings. The energy barrier of this process is two times lower than the energy of any bond in the α-naphthol molecule, which suggests a significant contribution of rapid radical processes with low activation energies. Moreover, similarly to phenols [13–18], pyrolysis of α-naphthol probably proceeds through an intermediate labile quinoid form [scheme (2)]. However, owing to the lower mobility of the phenolic hydrogen in α-naphthol, formation of the quinoid structures requires much more energy.

Formation of carbon monoxide is described by a first-order equation with activation energy of 319.28 kJ mol^{-1}; this process is primary and determines the pyrolysis rate.

The activation energies of methane and hydrogen formation are 256.85 and 270.26 kJ mol^{-1}, respectively; their lower values are due to the contribution of the secondary radical reactions proceeding with almost zero activation energy:

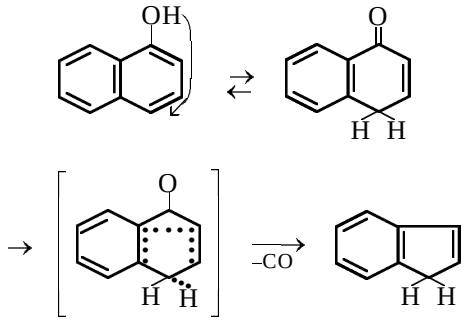
$$:CH_2 + 2H\cdot \rightarrow CH_4,$$

$$\cdot H + \cdot H \rightarrow H_2.$$

The reaction order varies within 1.5–2.0.

The kinetic equations of α-naphthol degradation and formation of the components of the gaseous pyrolysis products are listed in Table 4.

To test the proposed mechanism describing the formation of carbon monoxide, we calculated the activation energy by a procedure based on the additivity of bond energies in the activated complex [27].



The theoretical activation energy of 322.63 kJ mol^{-1} is in good agreement with the experimental results and confirms the proposed mechanism.

CONCLUSIONS

(1) Homogeneous pyrolysis of α-naphthol undergoes significant changes in the temperature range studied. With increasing temperature and contact time, the content of hydrocarbons and asphaltenes in the liquid products grows, whereas the content of phenols decreases. Hydrogen and carbon monoxide are the main components of the gaseous pyrolysis products.

(2) The hydrocarbon fraction contains mostly naphthalene and benzophenanthrene; asphaltenes are complex mixtures of predominantly aromatic compounds with various functional groups and alkyl chains.

(3) The kinetic parameters of α-naphthol degradation and formation of components of gaseous pyrolysis products are calculated, and mechanisms of their formation are proposed.

BRIEF COMMUNICATIONS

Some Characteristics of Synthetic Hydroxyapatite

E. B. Yarosh, B. A. Dmitrevskii, V. P. Naryzhnyi, and S. K. Tsvetkov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received January 30, 2001

Abstract—Physicochemical, morphological, and crystal-chemical characteristics of several calcium phosphates are given. The effect of various parameters of manufacturing process on the product quality is described.

Hydroxyapatite $Ca_{10}(PO_4)_6(OH)_2$ is identical in composition to the bone tissue of living organisms and has similar physical, mechanical, and other properties. It shows high biocompatibility, does not give rise to inflammatory phenomena, and is non-toxic. Therefore, articles made from synthetic $Ca_{10}(PO_4)_6(OH)_2$ are used in stomatology, traumatology, orthopedy, and cosmetology for regeneration of bone tissues [1].

$Ca_{10}(PO_4)_6(OH)_2$ exhibits no tendency toward destabilization in an organism; by contrast, it promotes aggregation and absorption of substances from the medium of the organism. Bioactive materials stimulate bone formation and restore bone tissues of a human body. Therefore, implants made of calcium phosphates are the most promising. It is known that $Ca_{10}(PO_4)_6(OH)_2$ samples with the same initial stoichiometric composition may differ in both the biological stability and the tendency toward biodegradation [1]. Samples of nonstoichiometric $Ca_{10}(PO_4)_6(OH)_2$ form a biologically stable phase in a living organism. An ion-exchange equilibrium can take place between a living tissue and $Ca_{10}(PO_4)_6(OH)_2$. To reduce the induction period required for binding between articles made of $Ca_{10}(PO_4)_6(OH)_2$ and a living tissue, nonstoichiometric $Ca_{10}(PO_4)_6(OH)_2$ can be used as a material for artificial bones [2].

When calcium phosphates are synthesized from solutions, the kinetics of the process and the microstructure of the crystalline material depend on the process parameters. The synthesis of $Ca_{10}(PO_4)_6(OH)_2$ crystals is complicated by the formation of intermediate and attendant phases—pseudo-apatites with the ratio $Ca/P \le 1.5$ [3] or calcium phosphates of varied composition [4]. Therefore, we studied the effect exerted by the amount of a calcium-containing reagent, the concentration of working solutions, pH (degree of neutralization), and temperature on the chemical and crystalline characteristics of the resulting salts. The experiments were carried out over a wide range of parameters of the manufacturing process.

Quite a number of researchers have synthesized $Ca_{10}(PO_4)_6(OH)_2$ from aqueous solutions [5–16]. Physicochemical properties [5–8] of $Ca_{10}(PO_4)_6(OH)_2$ and precursor salts and also conditions for their precipitation from $CaCl_2$ and NaH_2PO_4 solutions at low [9, 10], medium [11], and high [12] oversaturation and constant composition of liquid phase [13–16] have been studied. In this work, we used solutions of calcium nitrate and chloride and orthophosphoric acid. To maintain a specified value of pH, we applied solutions of ammonium and sodium hydroxides. The synthesis temperature was varied from 25 to 75°C. Liquid and solid phases were identified by standard procedures [17]. The solid phase was identified by X-ray phase analysis and IR spectroscopy.

The experiments were carried out at constant pH. The size of crystals and the amount of forming $Ca_{10}(PO_4)_6(OH)_2$ grow with increasing duration of syntheses (Fig. 1). It is necessary to note that an amorphous product is formed first, then it is converted to crystalline $Ca_8(HPO_4)_2(PO_4)_4 \cdot 5H_2O$ and(or) $Ca_{10}(PO_4)_6(OH)_2$ (Fig. 2). With increasing pH, the du-

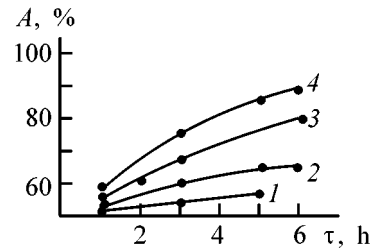

Fig. 1. Effect of synthesis duration τ on the yield *A* of $Ca_{10}(PO_4)_6(OH)_2$. Temperature 25°C, concentration of reagents 0.25 wt %. pH: (*1*) 6, (*2*) 8, (*3*) 10, and (*4*) 11.

ration of $Ca_{10}(PO_4)_6(OH)_2$ synthesis decreases (Fig. 1). If ammonium hydroxide is used, the amorphous phase is only formed at pH 6 and 8. In the presence of sodium hydroxide, amorphous $Ca_{10}(PO_4)_6(OH)_2$ is precipitated as a solid phase up to pH ~ 10. Small crystals up to 1 μm in size are formed on its recrystallization, whereas 3–5 μm crystals are formed when ammonium hydroxide (10% solution) is used.

Characteristics of calcium phosphates precipitated from initial solutions with various compositions are given in Fig. 3. These products were dried at 80°C. It was found that the product obtained from dilute solutions (CaO and P_2O_5 concentrations in initial reagents ranging from 0.25 to 1 wt %) is crystalline $Ca_{10}(PO_4)_6(OH)_2$ (Fig. 3, *a*), with crystal formation becoming slower at higher concentrations. Raising the initial concentration of solutions to 5 wt % CaO and 5 wt % P_2O_5 (stoichiometric ratio of the reagents) in a synthesis at constant pH 6 results in the formation of calcium-deficient $Ca_{10}(PO_4)_6(OH)_2$. The IR spectrum of this salt is given in Fig. 2b. Raising the pH to 8–10 gives poorly crystallized $Ca_{10}(PO_4)_6(OH)_2$. Raising the concentration of the initial solutions yields a finely crystalline product with crystal size of up to 1 μm. Thermal treatment of the products obtained at 800°C results in recrystallization of finely crystalline $Ca_{10}(PO_4)_6(OH)_2$ to give a macrocrystalline product (with crystal size increasing by a factor of 1.5–3). Calcium-deficient $Ca_{10}(PO_4)_6(OH)_2$ is converted into a mixture of calcium β-phosphate and diphosphate. Thermal treatment of the precipitates allows formation a crystalline salt. The IR spectra of the calcined products are more clear-cut, with the intensity of peaks increasing dramatically as compared with the spectra of dry salts. An X-ray phase analysis confirmed that the quality of crystals depends on the conditions of thermal treatment. The diffraction lines of a dry $Ca_{10}(PO_4)_6(OH)_2$ salt (3.44, 2.81, 2.77, 1.92, 1.84, and 1.74 Å), are broadened, their peaks are indistinct. In the X-ray diffraction patterns of calcined samples, the height of peaks grows and they become narrower, i.e., the diffraction lines become better pronounced.

A thermal analysis of salts synthesized at pH 8–10 demonstrated that, with increasing pH, a more stable salt is formed. The endothermic effect (125–135°C) is related to loss of water. At 295–320°C, CO_3^{2-} ions adsorbed by the salt from air are removed. The salt obtained at constant pH 8 is converted to β-$Ca_3(PO_4)_2$ on heat treatment (820°C). Raising the pH to 10 yields a product stable up to 850°C. Synthesis at pH ~ 11 favors formation of a salt stable up to T ~ 1000°C.

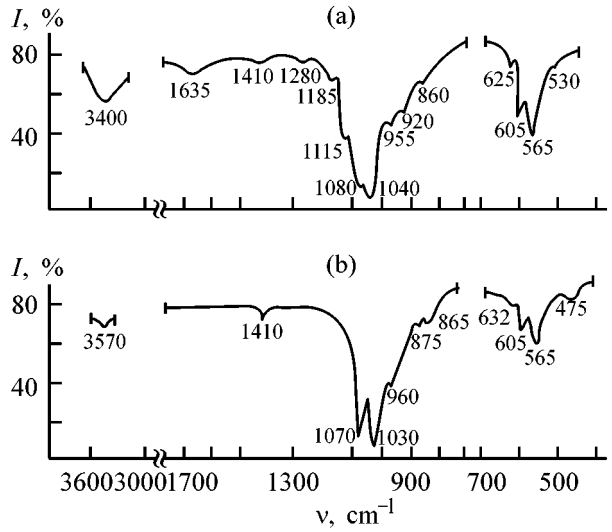

Fig. 2. IR spectra of (a) $Ca_8(HPO_4)_2(PO_4)_4 \cdot 5H_2O$ and (b) calcium-deficient $Ca_{10}(PO_4)_6(OH)_2$. (*I*) intensity and (ν) wave number.

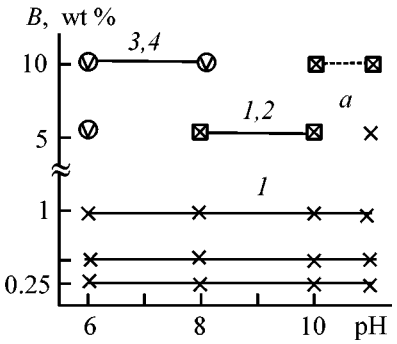

Fig. 3. Characteristics of calcium phosphates precipitated from solutions with various concentrations. (*B*) Initial concentration of CaO and P_2O_5. (*1*) $Ca_{10}(PO_4)_6(OH)_2$, (*2*) poorly crystallized $Ca_{10}(PO_4)_6(OH)_2$, (*3*) calcium-deficient $Ca_{10}(PO_4)_6(OH)_2$, and (*4*) mixture of calcium β-phosphate and diphosphate. (*2*) and (*3*) are only characteristic of an uncalcined material; (*4*) only calcined material.

The synthesis temperature essentially affects the crystallization of salts. We found that stoichiometric $Ca_{10}(PO_4)_6(OH)_2$ is formed in the range 25–75°C at pH 10–11. As temperature increases, the crystal size decreases from 3–5 to less than 1 μm. However, the salt is better crystallized in this case. The IR absorption bands of salts obtained at 75°C are more intensive than those of salts obtained at 25°C. The products have a clear X-ray diffraction pattern with reflections characteristic of $Ca_{10}(PO_4)_6(OH)_2$. According to thermal analysis, salts obtained at a higher temperature are less stable.

CONCLUSION

(1) The obtained data make it possible to forecast conditions for synthesis of calcium phosphates with specified chemical and crystalline structure.

(2) Lowering the concentration of initial solutions and raising the pH and synthesis duration within the limits under study give larger crystals of the products. Thermal treatment of the precipitates results in their structuring and improves the product quality.

BRIEF COMMUNICATIONS

Reactions of Lower Titanium Chlorides with Molten Magnesium-containing Chlorides of Alkaline Metals

V. A. Oleinikova and N. A. Loginov

Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia

Received February 19, 2001

Abstract—Conditional equilibrium constants K_n^* of reactions between titanium chlorides and molten magnesium were calculated.

Various admixtures, particularly metallic magnesium, are removed from chloride wastes of titanium-magnesium industry in the course of their electrochemical processing.

Chloride wastes have various compositions: these may be salts from a titanium chlorinator or waste electrolyte from the carnallite technique for magnesium production with composition (wt %): KCl 78, NaCl 14, $MgCl_2$ 6, and $CaCl_2$ 2, containing magnesium chloride upon reduction of titanium tetrachloride with solidified drops and regulus of metallic magnesium, and also slams from continuous refining furnaces containing more than 15 wt % magnesium [1, 2].

It was of practical interest to calculate the conditional equilibrium constants for the reactions of $TiCl_2$, $TiCl_3$, and $TiCl_4$ with magnesium in molten chlorides of alkaline metals (mp 650°C) in the range 1000–1250 K.

The aim of the calculations was to show that metallic magnesium can react chemically with titanium chlorides in addition to its electrochemical recovery from titanium-magnesium industry wastes.

We calculated temperature dependences of the conditional standard electrode potentials Ti(II)/Ti, Ti(III)/Ti and Ti(IV)/Ti, using equilibrium redox potentials of titanium in alkaline metal melts. The conditional standard electrode potential Mg(II)/Mg was taken from [3].

Equations for $E^*_{M^{n+}/M}$ (V) are shown in Table 1. The conditional equilibrium constants were calculated for the following reactions

Table 1. Temperature dependence of $E_{M^{n+}/M}$ in molten chlorides of alkaline metals (chlorine reference electrode)

1200	2.31×10^6	146.2	1.5×10^{18}	417.8	3.3×10^{16}	379.7

$$TiCl_{2(melt)} + Mg_{(l)} = MgCl_{2(melt)} + Ti_{(s)}, \quad (1)$$

$$\log K_1^* = \frac{2 \times 10^4}{1.984\,T}\,(E^*_{Ti(II)/Ti} - E^*_{Mg(II)/Mg});$$

$$TiCl_{3(melt)} + 3Mg_{(l)} = 3MgCl_{2(melt)} + 2Ti_{(s)}, \quad (2)$$

$$\log K_2^* = \frac{6 \times 10^4}{1.984\,T}(E^*_{Ti(III)/Ti} - E^*_{Mg(II)/Mg});$$

$$TiCl_{4(melt)} + 2Mg_{(l)} = 2MgCl_{2(melt)} + Ti_{(s)}, \quad (3)$$

$$\log K_3^* = \frac{4 \times 10^4}{1.984\,T}(E^*_{Ti(IV)/Ti} - E^*_{Mg(II)/Mg}).$$

The calculated data for various salt systems are shown in Table 2 and, in more detail, for reactions (1) and (2), in Table 3, where the changes in Gibbs energy (J mol^{-1}) are also given, as calculated by the expression:

$$\Delta G_r^* = -4.576 \times 4.184\,T \log K_n^*.$$

Values of K_n^* for reactions (1), (2), and (3) decrease with temperature. For the series (NaCl–KCl)–KCl–CsCl the values of K_1^* at 1100 K are 6.98×10^6, 7.95×10^6, 8.53×10^6, and those of K_2^* are 4.0×10^{21}, 1.5×10^{21}, and 2.7×10^{20}, respectively, K_2^* being greater than K_1^* by 14–15 orders of magnitude.

The value of K_3^* for a NaCl–KCl melt in the range 1000–1200K varies from 1.3×10^{20} to 1.1×10^{16}, for a KCl melt at 1100–1250 K—from 5.2×10^{18} to 1.0×10^{16}, and for a CsCl melt at 1000–1200 K—from 7.3×10^{20} to 3.3×10^{16}, i.e., the process may occur to a rather great extent (Table 3).

The interactions of the components are rather complicated, the above equations of reactions are only stoichiometric relationships. The melt contains complex ions (MCl_4^{3-}, $TiCl_3^-$, $TiCl_4^{2-}$, $TiCl_5^{2-}$, $TiCl_6^{3-}$, $TiCl_5^-$, $TiCl_6^{2-}$, $MgCl_4^{2-}$, etc.), which can variously affect each other and react with each other. These com-

plex ions have different bonding energies Ti^{4+}–Cl^-, Ti^{3+}–Cl^-, and Ti^{2+}–Cl^- and vibrational frequencies.

CONCLUSIONS

(1) The conditional equilibrium constants for the reactions of titanium chlorides with magnesium in various salt media were calculated using experimental and published data on conditional standard electrode potentials $E^*_{M^{n+}/M}$.

(2) The reactions are rather complicated and depend on a number of factors such as concentrations of components, temperature, nature of salt-solvent, etc.

High-Performance Gas Diffusion Electrode

A. Gawdzik, S. Gaida, N. M. Yurchuk, and A. N. Sofronkov

University of Opole, Poland
Odessa State Academy of Food Technology, Odessa, Ukraine

Received May 17, 1999; in final form, January 2000

Abstract—A high-performance gas diffusion electrode is fabricated by hot pressing with an asbestos laying used to provide uniform load in the process. The electrode was studied in cathodic reduction of oxygen in acidic electrolyte at various temperatures.

In fabrication of high-performance gas diffusion electrodes, the necessary condition is to ensure the maximal efficiency of a supported catalyst, particularly in the cases when electrocatalysis proceeds at a low rate. It is known [1–3] that the polarization can be diminished and the rate of an electrochemical reaction raised by making larger the surface of the catalyst–gas–electrolyte interface.

To raise the activity of oxygen reduction electrodes, we fabricated a composite with a porous structure, including two types of pores: hydrophilic pores formed by a carbon-supported catalyst and hydrophobic pores formed by a mixture of carbon black and fluoroplastic. As a carbonaceous support we used acetylene carbon black with a specific surface area of 200 $m^2 g^{-1}$. The electrodes were tested in sulfuric and phosphoric acid solutions. Carbon black was pretreated by roasting at 873°C, followed by boiling for 3 h in nitric acid for hydrophilization. Hydrophobization of acetylene carbon black was performed by mixing with a suspension of fluoroplastic in Sintanol (Sintanol-10 : fluoroplastic = 3 : 1). After intimate mixing, the surfactant Sintanol-10 was removed by heating. The catalyst was applied by impregnation of the electrode with a soluble salt of a metal of variable oxidation state, followed by treatment with an alkaline solution (pH ~13.0) of sodium borohydride [4].

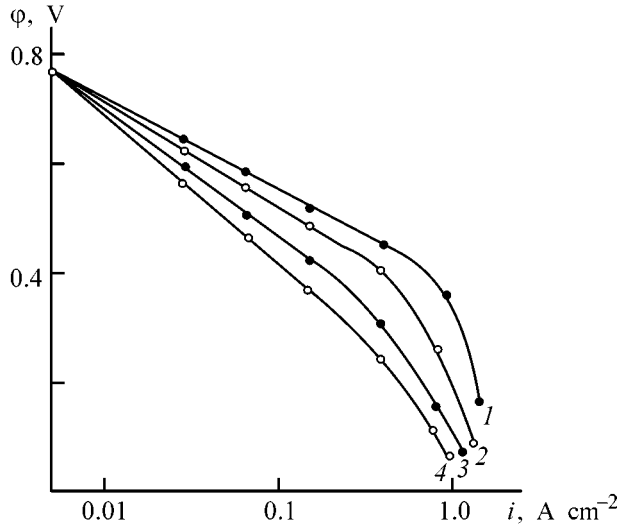
The electrode was formed by hot pressing of the hydrophobic and hydrophilic layers at 773°C under a pressure of 5 kg cm^{-2}, using an asbestos laying to ensure uniform load over the entire electrode area. A currentcollecting copper grid (annealed in hydrogen) was arranged within the hydrophilic layer. The catalyst surface density in the reaction zone was 0.5 mg cm^{-2}.

The polarization curves of cathodic oxygen reduction were recorded in the potentiostatic mode at 298 and 333°C under atmospheric pressure. Typical polarization curves are presented in the figure. For all of the tested electrodes we observed a linear dependence of φ on *i* over the entire polarization range.

The effective surface area *S* (μF m^{-2}) of the catalyst and the number of active sites *n* were estimated from the charging curves [5] as

$$n = \frac{Q}{96\,500} \times 6.023 \times 10^{23}, \quad S = \frac{C}{C_S} = \frac{C}{1120},$$

where *C* is the capacitance of the working electrode.



Polarization curves of cathodic oxygen reduction in sulfuric acid. (φ) Polarization and (*i*) current density. Hydrophilic to hydrophobic constituent ratio: (*1*) 2 : 3, (*2*) 7 : 3, (*3*) 5 : 5, and (*4*) 3 : 7.

1070-4272/01/7406-1064 $25.00 © 2001 MAIK "Nauka/Interperiodica"

The catalyst efficiency was defined by

$$\Pi = S/S^0,$$

where S is the effective surface area of the catalyst and S^0 is the total catalyst surface area obtained either for the supported electrode (1 : 1) or for a carbon-supported electrode hydrophobized with fluoroplastic (9 : 1), in which all the clusters are wetted by the electrolyte.

The amount of the electrolyte in the reaction zone of the electrode was estimated from the electrode weight before and after testing.

The electrodes fabricated using the proposed technique are formed of a mixture of the supported catalyst and fluoroplastic in which individual pores are not wetted by the electrolyte because of their high hydrophobicity. As a result, catalytic clusters are formed that are not involved in the reaction (their content may be up to 30% of the total). The proposed electrode fabrication technique ensures easy access of the electrolyte to the catalyst. In this case, the degree of filling with the electrolyte is well consistent with the experimental Π. The shares of the hydrophobic and hydrophilic structures of the active layer were chosen so as to ensure the minimum thickness of the reaction zone to minimize the diffusion component of the polarization. The figure shows that the electrode efficiency strongly depends on the hydrophilic to hydrophobic layer thickness ratio, reaching the maximum at the ratio of 2 : 3.

Cathodic oxygen reduction in a sulfuric acid electrolyte has been extensively studied previously [6–8]. Two portions were found in the Tafel curves. The first is described by the dependence $d\varphi/d\log i = -2.3RT/F$, and the second (for more positive potentials), by $2(-2.3RT)/F$. The transition point is at $\varphi = 0.85$ V, which corresponds to a changeover of the adsorption isotherm type from that described by the Temkin equation to the Langmuir isotherm [9].

For the electrodes under study the slope of the polarization curves is about 0.65 V at $\varphi > 0.85$ V. If oxygen reduction is kinetic- and diffusion-controlled, the slope is higher by a factor of 2.0–2.5 as compared to the purely kinetic mode.

To conclude, the maximum electrode efficiency is attained by minimizing the thickness of the reaction zone at the gas–electrolyte interface. This is ensured by the structure of the active layer containing a carbon-supported catalyst and hydrophobic pores formed in a mixture of carbon black and fluoroplastic taken at certain ratios.

7-Aminoheptanoic and 8-Aminooctanoic Acid Esters

A. Hrabálek, P. Doležal, and M. Mahacek

Pharmaceutical Faculty, Karlov University, Gradec Kralowe, Czechia

Received April 6, 2001

Abstract—A procedure was developed for preparing esters of secondary alcohols with 7-aminoheptanoic and 8-aminooctanoic acids.

Esters of primary alcohols with 7-aminoheptanoic and 8-aminooctanoic acids raise the permeability of skin [1, 2]. Also, such compounds are of interest as starting substances in synthesis of dendrimers by the convergence scheme when the dendrimer branches (dendrons) are prepared first and are then linked to the dendrimer core [3].

Proceeding with studies of compounds of this class, we developed a simple route to esters of secondary alcohols with 7-aminoheptanoic and 8-aminooctanoic acids, involving treatment of appropriate alcohols with amino acid chloride hydrochlorides in dry chloroform, followed by conversion of the resulting hydrochlorides to free amino esters by treatment with triethylamine:

$$\bar{Cl} \cdot H_3\overset{+}{N}(CH_2)_nCOOH + SOCl_2 \rightarrow \bar{Cl} \cdot H_3\overset{+}{N}(CH_2)_nCOCl$$

$$\xrightarrow[2.\,(C_2H_5)_3N]{1.\,CH_3(CH_2)_mCHOHCH_3} H_2N(CH_2)_nCOOCH(CH_2)_mCH_3,\ \ CH_3$$

I–VIII

where $n = 6$, $m = 4$ (**I**), $m = 5$ (**II**), $m = 6$ (**III**), $m = 7$ (**IV**); $n = 7$, $m = 4$ (**V**), $m = 5$ (**VI**), $m = 6$ (**VII**), $m = 7$ (**VIII**).

The required acid chlorides were prepared from the corresponding amino acid hydrochlorides, since conversion to the hydrochloride is the simplest and the most efficient way to protect the N–H bond [4]. The amino acid hydrochlorides were treated with thionyl chloride at 30–35°C (at higher temperatures the reaction is accompanied by polymerization). Esters of 7-tetradecanol with 7-aminoheptanoic (**IX**) and 8-aminooctanoic (**X**) acids were prepared similarly.

After being purified by column chromatography, all the esters are colorless highly viscous oils; yield 55–75%.

Tests performed according to [5] showed that amino esters **I**–**X** are less active, compared with the corresponding esters of isomeric primary alcohols, as agents raising the permeability of skin.

EXPERIMENTAL

The starting hydrochlorides of 7-aminoheptanoic and 8-aminooctanoic acids were prepared by acid hydrolysis of the corresponding lactams [6]. The IR spectra were taken on a Nicolet Impact 400 IR spectrophotometer in $CDCl_3$, and the ^1H NMR spectra, on a Tesla BS 497 spectrometer in $CDCl_3$ (internal reference TMS).

7-Tetradecyl 8-aminooctanoate (X). A solution of 1.96 g (0.01 mol) of 8-aminooctanoic acid hydrochloride in 15 ml of thionyl chloride was stirred for 0.5 h at 30–35°C. Excess thionyl chloride was removed in a vacuum, and the residue was treated with absolute toluene (30 ml). After removal of toluene, 2.14 g (0.01 mol) of 7-tetradecanol in 40 ml of absolute chloroform was added, the mixture was refluxed for 3 h with stirring, the solvent was removed, and the residue was dried in a vacuum desiccator over KOH. The crude amino ester hydrochloride was dissolved in 50 ml of water, and the aqueous phase was washed with diethyl ether (3 × 20 ml) and treated with 20 ml of triethylamine. Amino ester **X** was extracted with diethyl ether (3 × 20 ml), the combined extract was dried over magnesium sulfate, the solvent was removed, and the residue was purified chromatographically on crystalline cellulose (0.02–0.05 mm, 50 g); eluent diethyl ether. Yield of amino ester **X** 2.21 g

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Production of High-Purity Potassium by Vacuum Distillation with Dephlegmation

E. P. Lokshin

Tananaev Institute of Rare Element and Mineral Chemistry and Technology, Kola Research Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received January 31, 2000; in final form, May 2001

Abstract—A procedure was developed for evaluating the efficiency of substance purification by vacuum distillation with vapor dephlegmation in a heated condenser. A technology and apparatus are proposed for obtaining high-purity potassium by this method. The potassium quality is assessed using a set of chemical and physical techniques.

High-purity potassium is necessary for manufacture of photoelectric devices, illuminating lamps, high-temperature heat pipes, and low-melting heat carriers. The quality of technical-grade potassium, produced in conformity with GOST (State Standard) 10588–75 and containing up to 2 wt % Na and 0.8 wt % heavy metals (in terms of lead), gives no way of using it in manufacture of some kinds of materials and apparatus and performing precision scientific investigations. In addition to the controlled impurities, technical-grade potassium contains oxides, carbonates, calcium, organic impurities, chloride and hydroxide ions, and a number of other impurities.

For purifying potassium to remove oxygen, hydrogen, calcium, magnesium, iron, titanium, and other impurities, it has been proposed to make impurities pass into metallic lithium, which is poorly soluble in potassium [1, 2]. However, the achieved purification level (Ca 0.003, Mg 0.003, Fe 0.0005 wt %) was insufficient, and the consumption of lithium (in volume ratio of 1 : 1 to potassium to be purified), high, with its content in the purified potassium not determined. Zone smelting was found to be inefficient for deep purification of potassium [3].

Although the distillation methods are more versatile, equilibrium distillation cannot ensure, judging from the separation coefficients calculated with account of component activities of sodium–potassium alloys [4], deep purification of potassium to remove sodium impurity. Introduction of oxygen into technical-grade potassium in an amount no less than that stoichiometrically necessary for sodium oxidation makes higher the degree of potassium purification to remove sodium in subsequent distillation; however, the residual content of sodium is in this case more than 0.01 wt % [5].

It has been reported that distillation in a column was used to obtain potassium with Na impurity content less than 1%, from which 99.99% purity potassium was produced by further purification. However, no information about the employed technology of deep purification and analytical procedures was given. For the potassium manufactured abroad, its guaranteed content is at the level of 99.95 wt % (see catalogs of Aldrich, US; Fluka, Switzerland, etc.) Distillation of potassium containing 0.3–1.0 wt % sodium at residual gas pressure of 100 Pa in a column filled to a height of 1000 mm with steel ring packing gave a product containing (wt %) Na 0.015–0.05, Fe $\geq$0.002, SO_4^{2-} $\geq$0.004, and Cl 0.0013–0.0064 [7].

The aim of this study was to develop an industrial technology for manufacture of high-purity potassium with content of sodium impurity not exceeding 0.01 wt % at the minimum possible amount of other impurities. As starting materials were used technical-grade potassium and potassium–sodium alloys obtained as wastes in distillation of cesium–rubidium–potassium–sodium alloys of varied composition [8]. The possibilities of the previously proposed method of vacuum distillation with equilibrium dephlegmation of vapor in a heated condenser were studied. In this process, the temperature and vapor pressure of the substance being purified markedly vary between different apparatus zones. Since the procedure for evaluating the efficiency of component separation in this process has not been reported previously, it is

1070-4272/01/7407-1069$25.00

described here for the example of potassium–sodium alloys.

EXPERIMENTAL

The composition of the initial vapor in the equilibrium distillation process is determined by the composition of the starting alloy and the process temperature. In condensation of an infinitely small amount of vapor, the material balance equation has the form [10]

$$yG = (G - dL)(y + dy) + x dL,$$

whence follows

$$dy = dL(y - x)/G. \quad (1)$$

Equation (1) allows evaluation of the content of the low-boiling component (LBC) in the vapor at varied fraction of the condensed product on the basis of the known analytical dependence $f(x)$. This equation has been used previously in the cases when vapor dephlegmation was performed at constant pressure, since in this case it can be solved using the graphical dependence $y = f(x)$. If the distillation process with dephlegmation is performed in a vacuum, with the vapor temperature and pressure steadily decreasing, this way of solving Eq. (1) is inapplicable.

Let us assume that the initial vapor contains an insignificant amount of impurity. Then it may be considered that the molecular weight of the vapor after dephlegmation is equal to that of the initial vapor, and the vapor pressure is determined by the vapor pressure of the basic component of the alloy. The vapor pressure of pure alkali metals is described with high precision by the equation

$$\ln P = A - B/T. \quad (2)$$

The amount of vapor coming in unit time to dephlegmation is given by the Langmuir equation

$$G = \alpha SP(M/2\pi RT)^{1/2}, \quad (3)$$

where M is the molecular weight of vapor, S is the evaporation (condensation) surface area, P is the vapor pressure at temperature T, R is the universal gas constant, and α is the coefficient of evaporation (condensation). Eliminating T from expression (3) with the use of relation (2), we obtain

$$G = \alpha SP[M(A - \ln P)/2\pi RB]^{1/2}, \quad (4)$$

whence follows

$$dL = -dG = \alpha SP(M/2\pi RB)^{1/2} \times [(A - \ln P) - 0.5](A - \ln P)^{-1/2} dP. \quad (5)$$

Substituting (4) and (5) into Eq. (1), we have

$$dy = \frac{-(A - 0.5) + \ln P}{P(A - \ln P)}(y - x)dP. \quad (6)$$

At low impurity contents, the Henry law is valid, and, consequently, in the case of LBC purification to remove a high-boiling component (HBC),

$$y = \beta x + (1 - \beta),\ 0 < \beta < 1; \quad (7)$$

and in the case of HBC purification to remove LBC,

$$y = \beta x,\ \beta > 1. \quad (8)$$

In Eqs. (7) and (8), $\beta = f(P)$.

With x eliminated from Eq. (6) with the use of relations (7) and (8), the equation

$$\ln\frac{1 - y_2}{1 - y_1} = -\int_{P_1}^{P_2} \frac{(A - 0.5) - \ln P}{P(A - \ln P)} \frac{1 - \beta}{\beta} dP \quad (9)$$

is valid for the case of LBC purification to remove HBC, and

$$\ln\frac{y_2}{y_1} = -\int_{P_1}^{P_2} \frac{(A - 0.5) - \ln P}{P(A - \ln P)} \frac{\beta - 1}{\beta} dP, \quad (10)$$

for the case of HBC purification to remove LBC. Indices 1 and 2 denote, respectively, the initial and final stages.

Equation (9) makes it possible to calculate by how many times decreases the HBC content in the vapor $[(1 - y_2)/(1 - y_1) = 1/K]$, and Eq. (10), by how many times the vapor is enriched with LBC. $y_2/y_1 = K$, depending on the dephlegmation process parameters.

Equations (9) and (10) were applied to evaluate the efficiency of sodium purification to remove potassium impurity and potassium purification to remove sodium impurity.

The temperature dependences of the vapor pressure, obtained by processing of the recommended experi-

Table 1. Coefficients in Eq. (2)*

* Pressure given in pascals.

mental values [11] and used in our calculations, are presented in Table 1.

The approximate interpolation equations $\beta = f(P)$ (Table 2) were obtained from the $y = f(x)$ diagrams calculated for the sodium–potassium system with account of the component activities in the melt.

The equations obtained upon substitution of the dependences $\beta = f(P)$ into formulas (9) and (10) were integrated approximately, using the method of trapezoids.

The results of calculations are presented in Figs. 1a and 1b. Figure 1a shows how grows the logarithm of the content of potassium impurity in sodium, and Fig. 1b, how decreases the logarithm of the content of sodium impurity in potassium, in equilibrium dephlegmation of saturated vapor in the case of cooling of a saturated vapor in a prescribed temperature range. For this purpose, it suffices to subtract from the ordinate corresponding to the higher temperature that corresponding to the lower temperature.

As seen from Figs. 1a and 1b, the purification efficiency depends on the degree of dephlegmation. In cooling a vapor by a certain temperature difference, it also depends on the initial vapor temperature: the lower the initial temperature, the more efficient the separation (concentration) of the impurity in dephlegmation. However, on lowering the initial temperature of the vapor, its amount decreases, as also does, consequently, the process productivity.

With the content of impurity in the starting metal increasing beyond the limits in Table 2, the process efficiency must decrease because of the unfavorable change in the coefficients *K* in Eqs. (9) and (10). Indeed, in the case of LBC purification to remove HBC, β grows with the impurity content increasing beyond the limiting value, and, consequently, falls the factor $(1 - \beta)/\beta$ in Eq. (9), i.e., the numerator decreases remaining positive and the denominator increases. In a similar way decreases the factor $(\beta - 1)/\beta$ in Eq. (10) with increasing LBC content, because of the decrease in the β value in this case.

With a knowledge of how the impurity content varies with (or, in fact, the separation coefficients depend on) the conditions under which the equilibrium dephlegmation is performed, we can find the composition of the products formed in the process. Let us denote by x the mole fraction of LBC in the metal being distilled, by y the mole fraction of LBC in the vapor remaining after dephlegmation, and by W the amount of the metal being distilled.

Let dW of vapor be removed from the process in an infinitely short time. If the amount of metal present in the dephlegmator in the form of vapor and reflux is neglected, then the material balance equation has the form

$$xW = (W - dW)(x - dx) + y dW,$$

whence follows

$$dW/W = dx/(y - x). \quad (11)$$

Equation (11) is virtually identical to the Rayleigh equation [10] for equilibrium distillation, differing only in the type of the $y = f(x)$ dependence. In calculations, the purification in the metal evaporation stage was disregarded since the efficiency of equilibrium distillation is low at high temperatures.

It was shown above that the change in the impurity content in the course of vapor dephlegmation is only

Table 2. $\beta = f(P)$ dependences

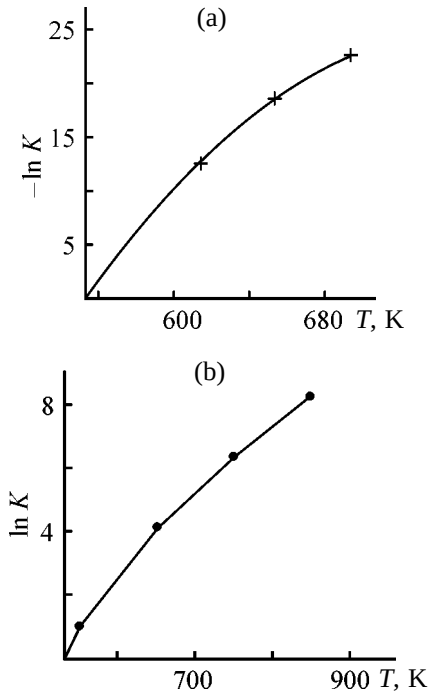

Fig. 1. Concentrations of (a) sodium impurity in potassium and (b) potassium impurity in sodium upon vapor cooling from temperature T to 553 K. (K) Separation coefficient.

determined by the initial and final temperatures of the vapor, but is independent of its composition in a wide range of impurity concentrations, which makes it possible to solve Eq. (11). Let us consider these solutions separately for the cases of LBC purification to remove HBC impurity and HBC purification to remove LBC impurity.

In the case of LBC purification to remove HBC impurity, we obtain, assuming that the composition of the vapor coming to dephlegmation is identical to the composition of the metal being purified and disregarding the purification in the evaporation stage, that

$$1 - x = K(1 - y). \quad (12)$$

If the initial amount of metal is W_0, and its impurity content, $1 - \varphi$ (φ, mole fraction), then, substituting (12) into (11) and solving the obtained equation, we find

$$\ln(W/W_0) = -\frac{K}{K-1}\ln\frac{1-y}{1-\varphi}$$

or

$$1 - y = \frac{1-\varphi}{K}(W/W_0)^{(K-1)/K}. \quad (13)$$

Equation (13) makes it possible to find the content of impurity in the condensate formed at the given instant of time. If Q is the fraction of metal that passed into the distillate, then the average content of impurity in it is given by

$$(1 - y)_{av} = Q^{-1}\int_0^Q (1 - y)\,dQ.$$

Since $W/W_0 = 1 - Q$,

$$1 - y = \frac{1-\varphi}{K}(1 - Q), \quad (14)$$

$$(1 - y)_{av} = Q^{-1}\int_0^Q (1 - \varphi)K^{-1}(1 - Q)^{(1-K)/K}\,dQ$$

$$= (1 - \varphi)[1 - (1 - Q)^{1/K}]Q^{-1}, \quad (15)$$

Equation (15) can be used to determine the average content of impurity in the distillate in relation to the impurity content of the starting metal, process conditions, and fraction of evaporated metal.

The composition of the first, purest vapor portion can be calculated using Eq. (13), provided that $W = W_0$:

$$(1 - y)_0 = \frac{1-\varphi}{K}, \quad (16)$$

In LBC evaporation in a still, the LBC impurity accumulates. As seen from Table 2, Eq. (13) and other equations obtained on its base are applicable if the content of HBC in the still does not exceed the limiting values listed in Table 2. The corresponding limiting impurity concentration in the distillate is given by

$$(1 - y)_{lim} = \frac{(1 - x)_{lim}}{K}, \quad (17)$$

Substituting (17) into (14), we obtain

$$\ln(1 - Q)_{lim} = \frac{K[\ln(1 - y)_{lim} - \ln(1 - \varphi) + \ln K]}{K}. \quad (18)$$

Equation (18) enables calculation of the extent of alloy evaporation at which the impurity content in the bottoms does not exceed the maximum permissible value.

To obtain potassium containing no more than 0.001 wt % sodium (0.0017 at. %) at a sodium content in the bottom alloy of 25 at. %, a coefficient is necessary $K \geq 25/1.7 \times 10^{-3} \approx 1.5 \times 10^4$, which, as seen from Fig. 1a, must not pose any difficulties. Below are given Q_{lim} values in relation to the content of sodium in the starting alloy, calculated at $K = 1.5 \times 10^4$ by Eq. (18) (the content of sodium in the purified metal does not exceed 0.001 wt %):

Content of sodium in the starting potassium, wt %	Q_{lim}, % relative to the initial value
0.05	99.7
0.5	96.95
1.0	93.9
1.5	91.5
2.0	88.8

In HBC purification to remove a low-boiling impurity, the impurity concentrations in the distillate and the starting metal are related by

$$y = Kx. \quad (19)$$

If the initial amount of metal is W_0, and the content of impurity in it is φ, then, substituting (19) into (11), we obtain

$$\ln(W/W_0) = (K - 1)^{-1} \ln(x/\varphi) \text{ or } x = \varphi(W/W_0)^{K-1}. \quad (20)$$

Equation (20) can be used to find the content of impurity in purified metal, which, as in the preceding case, depends on the impurity content in the starting metal, process conditions, and amount of unevaporated metal. Equation (20) is applicable at $x \leq x_{lim}$ (Table 2). At these x values, Eq. (19) is also applicable. We assume that, at $x > x_{lim}$, an alloy is evaporated containing y_{lim} of LBC. Then we have from the material balance equation

$$y_{lim} Q'_{lim} + x_{lim}(1 - Q'_{lim}) = \varphi,$$

$$Q'_{lim} = \frac{\varphi - x_{lim}}{y_{lim} - x_{lim}} - \frac{\varphi - x_{lim}}{x_{lim} - (K - 1)}, \quad (21)$$

where Q'_{lim} is the fraction of metal which is to be evaporated in order that Eq. (20) should be applicable to the remaining metal.

After evaporation of Q'_{lim}, Eq. (20) is applicable to the remaining metal, which makes it possible to determine what part of it, Q_{lim}, can be obtained under the given process conditions with a prescribed impurity content x:

$$Q'_{lim} = (x/x_{lim})^{1/K-1}. \quad (22)$$

The total yield of metal of prescribed purity is given by the product

$$Q_{lim} = Q_{lim}(1 - Q'_{lim}) \times 100. \quad (23)$$

Table 3. Expected minimum yield of products in purification of technical-grade sodium (potassium content 0.25 wt %) by distillation with vacuum dephlegmation

K	Yield of sodium, %, at indicated content of potassium in purified product, wt %		
	10^{-2}	10^{-3}	10^{-4}
27	88.43	80.98	74.17
220	98.56	97.54	96.54
1170	99.68	99.48	99.28

The obtained equations were used to evaluate the efficiency of sodium purification in vapor cooling from temperature T (653, 753, and 853 K) to 553 K. As seen from Fig. 2, the respective values of $K = y_2/y_1$ are 27, 220, and 1170.

As seen from Table 3, sodium can also be thoroughly purified to remove potassium impurity, since the temperatures at which the K values used in calculations can be achieved are quite practicable.

Thus, the calculations demonstrated that the method of vacuum distillation with equilibrium dephlegmation of vapor can be used to obtain pure metals in sufficiently high yield from technical-grade sodium and potassium. The process is the most efficient in purification of LBC to remove HBC impurity and it was used for purifying technical-grade potassium to remove sodium impurity.

The investigations were carried out on an installation shown schematically in Fig. 2. It comprises a still *1*, dephlegmator *2* with a pouring-in extension *3*, cover *4*, still heating furnace *5*, melting device *6*, container *7* for collecting the metal being distilled from condenser *8*, and the main *9* and auxiliary *10* vacuum lines. The still could be charged with 15 kg of potassium. Pockets *11–15* accommodating Chromel–Alumel thermocouples were welded to the bottom, middle, and top parts of the dephlegmator, and in the cover and bottom of the still. The dephlegmator case was heat-insulated with a layer of a clay-chamotte mixture, and the upper third and the cover of the

dephlegmator, with an additional layer of Sovelite. A steel crosspiece was mounted in the bottom part of the dephlegmator on a specially designed annular shoulder *16*, and packing *17* in the form of briquettes of cuttings was placed on the crosspiece. The packing bed height was 530 mm. Separate units of the installation could be shut-off by means of liquid–metal (*18–21*) or vacuum (*22*, *23*) valves. The main vacuum line was used for continuous evacuation of the distiller during the process, and the auxiliary line, for evacuating containers during their replacement.

Fractions of distilled metal were collected into specially designed metallic containers equipped with three level gages. The rate of metal evaporation was continuously monitored with batch meter *24* connected to the discharge extension and container.

To heat the installation in the course of distillation and in its final stage for complete removal of the metal from the dephlegmator packing, additional removable heaters were mounted onto the dephlegmator case. The metal poured in the still was heated by an electric furnace.

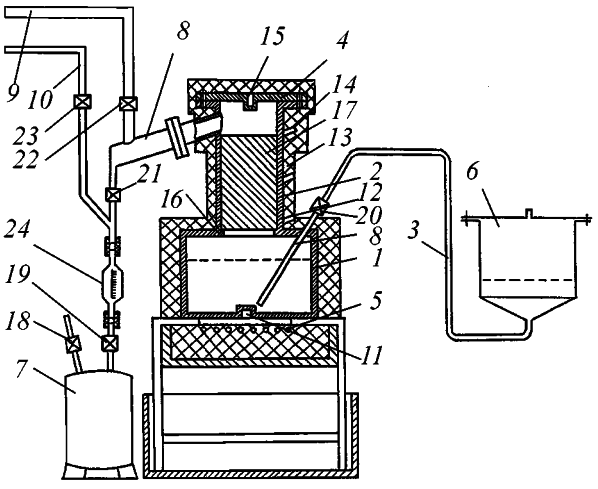

Fig. 2. Schematic of installation for potassium purification by distillation with dephlegmation. For explanations, see text.

To preclude the possible influence of oxygen [5] on the experimental results, technical-grade potassium was preliminarily distilled in a vacuum and then an additional amount of sodium metal was introduced to bring the impurity content to the required level.

The experiment was carried out as follows. An assembled installation was evacuated, tested for leaks, and heated. Potassium was charged through the pouring-in extension, and the valve in the pouring-in extension was closed. The metal poured in the still was heated to a prescribed temperature, with the evaporating metal gradually heating the dephlegmator to a certain temperature. The evaporated metal was collected in the condenser extension and discharged through the batch meter into the receiving container. The rate of metal evaporation was continuously monitored, together with the temperature regime. When filled with metal, the containers were replaced. For this purpose, the valves in the discharge extension of the distiller, auxiliary vacuum line, and container were closed and a filled container was disconnected. Then, the next container was connected, the valves in the container and auxiliary vacuum line were opened, the container was evacuated, and the valve in the discharge extension of the distiller was opened.

The exhaustion of metal in the still was inferred from a decrease in the apparatus cover temperature and in the rate of metal evaporation at invariable power consumed by the still-heating furnace. Then, additional heating furnaces were mounted on the dephlegmator, the apparatus was heated to 400–500°C to completely remove the metal from the packing, and the installation was cooled. The conditions and results of an experiment on potassium purification by vacuum distillation with partial dephlegmation in a heated condenser are listed in Table 4. It can be seen that the metal was obtained in about 70% yield, with the sodi-

um impurity content in the metal at the sensitivity limit of the available analytical methods. The main part of sodium did not find its way into the condenser, being "smeared" over the installation parts. Even though the efficiency of separation (K value) was less than expected (possible reasons: higher temperature of the central part of the vapor flow arriving at the condenser; poor metal agitation in the still, leading to enrichment of the surface layer of the melt with sodium; insufficient accuracy of determination of minor amounts of sodium because of sample contamination from the ambient), it was sufficiently high for practical purposes. Fraction 2, contaminated with sodium, was obtained in evaporating the metal from the packing.

Further, the charge was raised to 15 kg. After evaporation of 60–70% of the charged metal, 10–12 kg of technical-grade potassium was twice introduced additionally. At the end of the process, 0.4–0.5-kg fractions were obtained. With this experimental procedure, the yield of potassium into the pure fraction (sodium content 0.0005–0.002 wt %) was made as high as 98.2%, with sodium concentrated at the end of the process in an alloy containing 40–60% sodium.

The developed technologies and apparatus also allow successful separation of potassium–sodium alloys. For example, distillation of 12.35 kg of an alloy of this kind, containing 48.93 wt % sodium, gave in 99.78% yield potassium with sodium impurity content of 0.001 wt %. The evaporated sodium contained 0.03 wt % potassium, which is presumably due to contamination of distilled sodium in the condenser containing residual potassium.

The finishing purification of potassium was done by repeated distillation at 250–270°C and residual gas pressure of no more than 6.7×10^{-3} Pa. The purified metal was analyzed by atomic-absorption and spectral methods with preliminary chemical enrichment with impurities. The quality of potassium purified by the developed technology is characterized below (impurity; content, wt %): Na $<5 \times 10^{-4}$, Rb $<1 \times 10^{-3}$, Cs $<1 \times 10^{-3}$, Cu $<1 \times 10^{-6}$, Ag $<8 \times 10^{-7}$, Mg $<2 \times 10^{-5}$, Ca $<1.5 \times 10^{-4}$, Zn $<2.5 \times 10^{-5}$, Al $<1 \times 10^{-5}$, Ga $<2 \times 10^{-6}$, In $<2 \times 10^{-6}$, Tl $<4 \times 10^{-6}$, Ti $<5 \times 10^{-6}$, Sn $<5 \times 10^{-6}$, Pb $<5 \times 10^{-6}$, Sb $<1 \times 10^{-5}$, Bi $<2 \times 10^{-6}$, V $<1 \times 10^{-6}$, Cr $<5 \times 10^{-6}$, Mo $<5 \times 10^{-6}$, Mn $<1 \times 10^{-6}$, Fe $<1.4 \times 10^{-5}$, Co $<3 \times 10^{-6}$, and Ni $<1 \times 10^{-6}$.

The ratio of the residual electrical resistance ρ_0 (at $T \to 0$) of high-purity potassium to the resistance[1] at 293 K was 1.5×10^{-4}, which corresponds to a total content of impurities of about 0.001%.

CONCLUSIONS

(1) A procedure is proposed for calculating the efficiency of component separation by vacuum distillation with partial dephlegmation of vapor in a heated condenser. It is shown that this process must ensure effective purification of potassium to remove sodium impurity and sodium to remove potassium impurity.

(2) Apparatus designs and process regime ensuring efficient potassium purification to remove sodium impurity were developed.

(3) Additional purification by high-vacuum distillation gives potassium surpassing in quality the best of the available foreign commercial samples.

(4) The developed technology and apparatus made it possible to set up industrial manufacture of high-purity potassium in conformity with TU (Technical Specifications) 48-4-476–86.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Refractoriness and Phase Composition of ZrB_2–Si Materials

G. N. Gorbatova, I. B. Ban'kovskaya, N. S. Yuritsyn, and I. S. Malygina

Grebenshchikov Institute of Silicate Chemistry, Russian Academy of Sciences, St. Petersburg, Russia

Received December 21, 2000; in final form, March 2001

Abstract—The influence of silicon concentration and of the mode and time of heat treatment in air on the refractoriness and phase composition of ZrB_2–Si materials was studied. Recommendations are given for preparing refractory coatings on graphite in air using the given materials.

Coatings of ZrB_2 on a carbon material have been obtained in argon at 1900°C [1].

In this work we studied the feasibility of using ZrB_2–Si materials for obtaining refractory coatings on graphite in air at lower temperature. We studied how the silicon concentration and the mode and time of heat treatment influence the refractoriness and phase composition of the material.

Oxidation of ZrB_2 has been described in the literature [2–4]. Up to 1000°C ZrB_2 is oxidized only slightly, but at higher temperatures the oxidation accelerates sharply. The primary components of the oxide film are zirconium dioxide and hydrated boron(III) oxide, which evaporates at high temperatures. A scale formed on zirconium diboride shows no protective properties, because, owing to porosity, it does not impede oxygen diffusion into the sample. Zirconium diboride is used as refractory material. It is incorporated in a number of the composite alloys operating at high temperatures in an oxidizing medium. Also, it is a coating component. Thus, it is necessary to enhance its resistance to oxidants.

This is provided by addition of silicon-containing compounds [5–7]. Doping of the boride alloys with silicon or metal silicides yielding volatile oxides results in the formation of the oxide film that mainly consists of borosilicate glass and reliably protects the alloy from oxidation. According to the published data, boride materials with addition of silicon-containing compounds are prepared by hot pressing or sintering of the appropriate mixtures in inert medium. In this work, samples in the form of slip castings were used without additional heat treatment. The samples were dried to constant weight at room temperature.

The samples for studying refractoriness were heated in an electric furnace with silicon carbide heaters in air under the static conditions at 1400°C for 5, 15, 30, and 60 min. Three samples were heated for each time. The heat resistance was judged from the weight change (mg cm^{-2}) of the sample heated for the given time.

The open porosity of the samples was determined by water absorption. The phase composition of the surface after heating was studied on a DRON-2.0 diffractometer (CuK_α radiation, Ni filter). The microstructure of the samples was studied on an MIM-8M metallographic horizontal microscope. Zirconium diboride (pure grade) and silicon (KR-1 grade) were finely dispersed powders with particles no larger than 63 μm. The materials studied are presented in Table 1.

Each charge was mixed for 20 min. Then, slip casting was used for preparing the samples as castings. The binder was a 2% solution of carboxymethyl cellulose. The samples were $1.5 \times 1.5 \times 0.5$ cm in size. The samples were dried in air for 2–3 days.

We studied how the silicon concentration and the mode and time of heat treatment affect the refractoriness and composition of the ZrB_2–Si samples. The obtained results are plotted in the figure and given in Tables 1 and 2.

The figure shows the weight change of the samples heated in air at 1400°C as a function of the heating time. As seen, the silicon-containing samples are oxidized less intensely than zirconium diboride. Heating of the samples is accompanied by complex processes including oxidation of the initial components with atmospheric oxygen, interaction of the resulting compounds with each other, formation of borosilicate glass, volatilization of boron(III) oxide, and partial evaporation of silicon from the sample surface. The total contribution of all the occurring processes is reflected in the figure.

* Monoclinic ZrO_2.

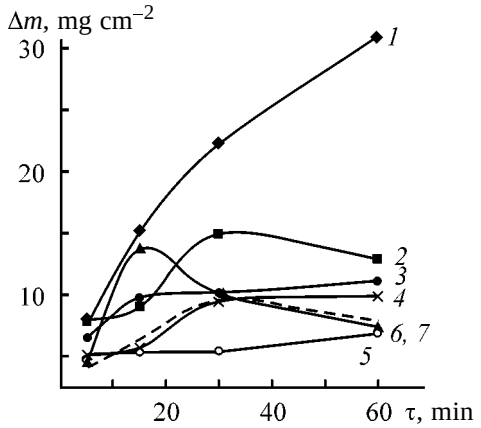
The new phases, ZrO_2 (monoclinic) and $ZrSiO_4$, are revealed on the surface of the ZrB_2–Si samples in the course of heat treatment (Table 1). In samples with 5 wt % silicon, zirconium silicate is formed after 5 h. At higher silicon concentrations the time of zirconium silicate formation is shorter: 1 h at 10–20% and even 30 min at 30%.

The open porosity of the heat-treated samples decreases with increasing silicon concentration and heating time. The porosity of the zirconium diboride samples kept for 5 min at 1400°C is 40%, and the porosity of those kept for 10 h, 29%. As the silicon concentration increases, the porosity of the samples kept for 5 min decreases to 26% and of those kept for 10 h at the same temperature, to 16%. Table 2 shows how the heat treatment mode affects the phase com-



Weight change Δm of ZrB_2–Si samples heated in air at 1400°C vs. heating time τ. The curve numbers are the same as the material numbers in Table 1.

position of the sample surface. Three modes were used for heating samples: (I) samples placed into the furnace preheated to 1400°C were kept there for 1 h, (II) samples placed into a furnace at room temperature were heated to 1400°C (with a rate of 10 deg min^{-1}), and (III) samples were placed into the furnace at room temperature, heated there to 1400°C, and then they were kept at this temperature for 1 h. In all cases, the heat-treated samples were withdrawn from the furnace and cooled in air.

Table 2 shows that modes II and III yield α-cristobalite having a high expansion coefficient, which is undesirable in preparing coatings on graphite.

The results of studying the material in air were used for preparing refractory coatings on graphite. The coatings are nonporous and strongly adherent to graphite. Their microstructure is heterogeneous. Crystalline grains of the initial zirconium diboride and new phases formed during heat treatment are distributed uniformly throughout the glassy matrix.

The coatings obtained can be recommended for use at up to 1600°C. The X-ray phase analysis of the coating surface revealed the crystalline phases of zirconium silicate and zirconium diboride.

CONCLUSIONS

(1) With increasing silicon concentration the refractoriness of the compound increases owing to formation of new crystalline phases and of the encapsulating matrix of borosilicate glass.

(2) The X-ray phase analysis of the samples heated at 1400°C revealed the crystalline phases of ZrB_2, ZrO_2, $ZrSiO_4$, and α-cristobalite on the surface.

(3) With the silicon concentration increased to 30%, zirconium silicate is formed on the surface even within 30 min.

Abstract—Oxidation of granulated polycrystalline zinc selenide (grain size 0.2–6.5 mm) with atmospheric oxygen at 430–700°C was studied. The optimal conditions for the oxidation were found. An installation for the oxidation of kilogram amounts of zinc selenide was designed and fabricated.

Published data on the oxidation of zinc selenide as single crystals, polished plates, and powders include estimates of the oxidation rate at 300–950°C, composition of the reaction products, and suggested equations for the oxidation [1–5]. However, there are a number of contradictions in the determination of composition of the nonvolatile oxidation products. For instance, according to [1–3], zinc oxide is the only nonvolatile product, but in [4] significant amounts (up to 18%) of zinc selenite were found in the range 490–560°C along with zinc oxide. According to [5], zinc selenite is the main product of the oxidation at 300°C; as the temperature increases, its fraction appreciably decreases as compared to zinc oxide. Volatile oxidation products either were not investigated at all [1, 2, 5] or only their qualitative composition as a mixture of selenium and selenium dioxide [3, 4] was established. The effect of the grain size of the initial zinc selenide on the rate of its oxidation is still obscure, and probable oxidation mechanisms were not discussed.

In this work the study was concerned with waste polycrystalline zinc selenide of various grain size, formed from production of optical parts for IR technique [6]. One of the ways of processing waste products is their oxidizing calcination. In this connection, the aims of this work were to study the oxidation kinetics of granulometric zinc selenide samples of various grain size, to identify the products of the oxidation at 430–700°C, and also to study the mechanism of the oxidation with atmospheric oxygen.

EXPERIMENTAL

First we carried out a thermodynamic analysis of the system zinc selenide–air. Though the oxidation conditions were far from equilibrium, the thermodynamic analysis is important for the estimation of the relative contents of products both in gas and condensed phases. The calculation was carried out at various stoichiometric ratios of the initial reactants. The calculated equilibrium concentrations of components (in moles per total number of moles of atoms in the initial substances) for the system zinc selenide–air in excess oxidant (molar ratio zinc selenide–oxygen in the experiments was 1 : 4.5) are given in Fig. 1. Apparently, within the whole temperature

range (500–1500 K) the main reaction product in the gas phase is selenium dioxide. The content of the other selenium species (Se, Se_2, Se_3, etc.) is lower by several orders of magnitude. In the condensed phase selenium dioxide exists only within a narrow temperature range.

The installation for oxidation consisted of an inclined quartz reactor (30 mm in diameter and 400 mm in length) and a condenser for volatile oxidation products. When the reactor is heated in a tubular electric furnace, a steady-state convection air stream arises. The temperature in the oxidation zone was varied from 430 to 700°C during experiments. The accuracy of temperature determination did not exceed 3%. The granulometric compositions of powders were determined by sieving. The particle size of zinc selenide varied from 0.20 to 6.50 mm. Samples of powders (18.00 ± 0.01 g) were placed in quartz boats ($60 \times 25 \times 15$ mm). The composition of the nonvolatile products remaining in the decomposition zone was determined by X-ray phase analysis. The qualitative composition of the volatile products condensed in the receiver was determined by chemical methods based on reactions with sodium thiosulfate, thiourea, and a mixture of concentrated potassium iodide and hydrochloric acid [7].

We found that the main nonvolatile product in the temperature range under study is zinc oxide, with the total content of zinc selenide, selenite, and selenate being lower than 5%. The volatile product is a mixture of selenium and its dioxide. To determine the amounts of individual components, the volatile products were dissolved in distilled water, the solution was filtered, and the precipitated selenium was dried and weighed. We found that the proportion of selenium and its dioxide in volatile products varies in the course of reaction [8]. This allowed us to offer the following equation for oxidation of zinc selenide:

$$ZnSe + (0.5 + y)O_2 \longrightarrow ZnO + xSe + ySeO_2,$$

In this equation factors *x* and *y* change in the course of the process, but the sum of them is equal to unity [9].

The variation of the molar ratio selenium : selenium dioxide in volatile oxidation products requires an independent study and was not considered in this work. To estimate the kinetic features, we studied only the nonvolatile oxidation products. The prevalence of zinc oxide in these products allowed us to estimate the degree of conversion of the initial zinc selenide by the gravimetric analysis. The time dependence of the zinc selenide conversion at 430–700°C is shown in Fig. 2.

To reveal the kinetic features of the oxidation, we examined the variation of the zinc selenide conversion (α) with the relative oxidation time τ/τ' (τ is current time and τ' is time of complete conversion). The dependences for 0.6–1.5-mm particles at 550 and 700°C are shown in Fig. 3. When studying the kinetics of processes in gas–solid systems, in particular of calcination of solid materials, it is common to take the model of a spherical particle with unreacted nucleus [10] as a basic model. According to this model, the limiting stage is characterized by the dependence of the conversion on the contact time, particle size, and temperature. The comparison of theoretical curves and our experimental data (Fig. 3) suggests that the oxidation process under consideration is controlled by internal diffusion [10].

The dependence of the time of 90% oxidation of zinc selenide (i.e., the reciprocal of the oxidation rate) on the particle size of the initial zinc selenide is plotted in Fig. 4. Particle sizes correspond to the mean values within the ranges (mm) 0.2–0.3, 0.3–0.4, 0.4–0.6, 0.6–1.5, 1.5–2.5, 2.5–3.5, 3.5–4.5, and 4.5–5.5.

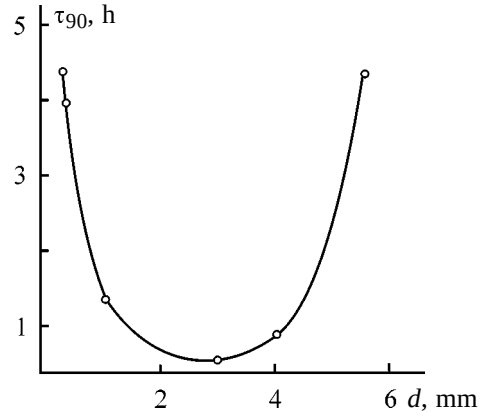

Fig. 4. Rate of zinc selenide oxidation as a function of its particle size *d*: (τ_{90}) time of 90% conversion.

It is evident that the reaction rate grows considerably with decreasing particle size (the right branch of the curve), which also confirms the assumption on the internal diffusion control of the process.

At the particle size decreased further (the left branch of the curve), the oxidation rate decreases, which seems to be due to the effect of another limiting stage, namely, diffusion of oxygen through a bed of the solid product [10]. This mechanism was discussed in the literature as applied to oxidation of FeS_2 in the industrial production of sulfuric acid [11].

From our experimental data we plotted the temperature dependence of the reaction time in the coordinates $\log(1/\tau)$–$1/T$ and determined the apparent activation energy of 83 kJ mol^{-1} for the range 430–700°C. It follows from the theory of diffusion kinetics of gas–solid phase interactions that the activation energy of processes controlled by internal diffusion is approximately a half of the activation energy of a chemical reaction [10]. The activation energy for the oxidation of polycrystalline plates of zinc selenide is known to be 170 kJ mol^{-1} [2]. In this case the activation barrier seems to be caused by the proper reaction between zinc selenide and oxygen, i.e., the reaction is kinetically controlled. The obtained apparent activation energy is approximately half of the value given in [2], which supports the assumption on the internal diffusion mode of the process.

The kinetic features allowed us to find optimal conditions for the oxidation of polycrystalline zinc selenide. This made it possible to design and fabricate an installation for the oxidation of kilogram amounts (0.6–1.5 kg) of zinc selenide [8].

CONCLUSION

Zinc oxide was found to be the main nonvolatile product of zinc selenide oxidation at 430–700°C. The oxidation is apparently controlled by internal diffusion. The temperature of 600°C and the particle size of 1.5–4.5 mm are the optimal for the oxidation of powdered polycrystalline zinc selenide by atmospheric oxygen.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Solubility in the Ternary System Water–Cadmium Bromide–Copper(II) Bromide

M. Yu. Skripkin, I. V. Zamyatin, and L. V. Chernykh

St. Petersburg State University, St. Petersburg, Russia

Received January 16, 2001

Abstract—Solubility in the system $CuBr_2$–$CdBr_2$–H_2O at 25°C was determined by the method of isothermal saturation. The obtained data were examined from the viewpoint of competitive formation of acido complexes in aqueous solutions.

Revealing relations between types of interparticle interactions in solutions and the corresponding solid phase is one of the most important problems of inorganic chemistry. Regular trends in these relations should form a basis for predicting types and properties of solid-phase compounds crystallizing in water–salt systems. These trends are useful for the development and improvement of hydrometallurgical processes and methods for concentrating mineral raw materials and separating elements. They can also form a basis for the development of procedures for directed synthesis of compounds with specified properties from solutions.

Previously we considered the formation of solid compounds in systems with dominating processes of association, hydration, and complex formation. The revealed regular trends were described in [1–3]. In this work we considered the solution–solid phase equilibrium in systems containing two complex-forming cations. Systems containing copper(II) and cadmium halides were selected as objects of the research. Solubility in the system $CuBr_2$–$CdBr_2$–H_2O was not studied previously. Data for the system $CuCl_2$–$CdCl_2$–H_2O were taken from [4].

The solubility was determined by the isothermal saturation method.

The systems were kept at prescribed temperature (±0.2°C) for 1 day. The copper content was determined by iodometric titration, and the total content of copper and cadmium, by EDTA titration. The cadmium content was calculated as the difference. The solid phase composition was determined by the Schreinemakers method. The results are given in the table and in Fig. 1.

The interactions occurring in solution can be judged from the presence or absence of crystallization branches of complex compounds in the solubility isotherm and from the lengths of the crystallization branches of initial compounds, the salting-in or salting-out effects; also, the interactions can be manifested as dehydration of the initial compounds.

Particular manifestations of the interactions depend on the contributions of their types, i.e., on the competition between them. In the systems under consideration the shape of the solubility isotherms is determined first of all by the competition between the complex formation processes.

Figure 1 shows that the solubility isotherms of the bromide and chloride systems differ considerably. The main principal distinction is the absence of the crystallization branch of a double halide in the bromide

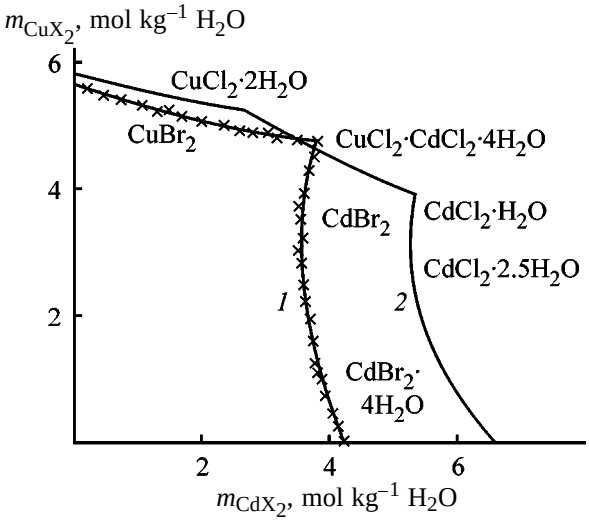

Fig. 1. Solubility in the systems (*1*) $CuBr_2$–$CdBr_2$–H_2O and (*2*) $CuCl_2$–$CdCl_2$–H_2O at 25°C. (m_{CuX_2}, m_{CdX_2}) Solubilities of CuX_2 and CdX_2, respectively.

system. According to the X-ray diffraction and spectral (Raman and IR) data, the compound $CuCl_2 \cdot CdCl_2 \cdot 4H_2O$ is a solid-phase heteronuclear complex of copper and cadmium with bridging chloride ligands. The copper and cadmium chloride complexes exhibit similar stability (the logarithm of the first-step stability constant $\log K_1$ is 1.55 for $CdCl^+$ and 0.98 for $CuCl^+$ [5]). This fact favors formation of precursors of the heteronuclear complexes in concentrated solutions (the similarity in the chemical species in saturated solution and solid phase was confirmed by Raman spectroscopy) and their further transition to the solid phase. The high stability of cadmium chloride complexes determines the uniformity of their coordination sphere in the solid compound, whereas copper ions are surrounded with both chloride and aqua ligans. As for the bromide system, the much greater stability of cadmium bromide complexes, as compared to copper(II) complexes {$\log K_1$ 0.32 ($CuBr^+$) and 2.30 ($CdBr^+$) [5]}, makes formation of heteronuclear bridged complexes unfavorable.

The different stability of copper and cadmium complexes in chloride and bromide systems also affects the length of the crystallization branches and the salting-in and salting-out of the initial compounds. In the system $CuCl_2$–$CdCl_2$–H_2O only salting-out of the components is observed, whereas in the system $CuBr_2$–$CdBr_2$–H_2O a clear transition from salting-out to salting-in takes place. The ratio of salting-out and salting-in of the components in the systems under consideration (Fig. 2) is determined by the hydration of ions and by the stability of acido complexes and fully corresponds to the ratio that could be predicted from the ratio of stability constants of the halide complexes.

The addition of the second electrolyte to a saturated solution of cadmium or copper halide is accompanied by two interdependent oppositely directed effects. On the one hand, the presence of an additional amount of halide ions will enhance the complex formation, which is accompanied by the detachment of water from the hydration spheres of the ions and increases the solubility [6]. On the other hand, the increase in the total concentration of ions results in greater binding of water and in decreasing solubility of the salt in the forming ternary solution, as compared to the binary solution. It should be expected that the first effect would make a greater contribution in the case of systems with stronger acido complex formation. In fact, the salting-out of copper chloride is weaker than that of copper bromide [$K_{st}(CuCl_n^{2-n}) > K_{st}(CuBr_n^{2-n})$]. In the case of cadmium halides, which are characterzed by even stronger acido complex formation, the salting-out of cadmium chloride is replaced by salting-out–salting-in of cadmium bromide [$K_{st}(CdCl_n^{2-n}) < K_{st}(CdBr_n^{2-n})$].

The greater stability of cadmium complexes, as compared to copper(II) complexes, results in a redistribution of ligands from copper to cadmium. “Vacant

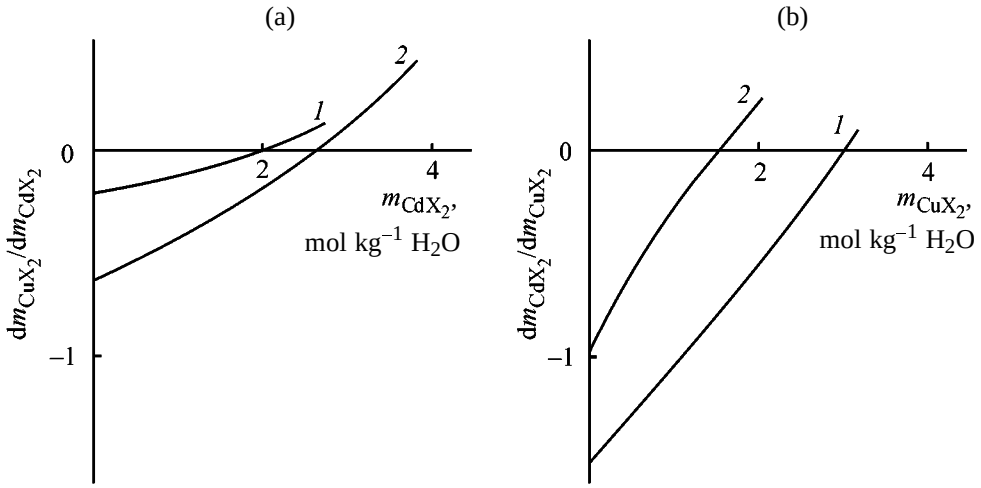

Fig. 2. Salting-out–salting-in of (a) CuX_2 and (b) CdX_2 in CuX_2–CdX_2–H_2O systems. X^-: (*1*) Cl^- and (*2*) Br^-.

positions" in the coordination sphere of copper ions are filled with water molecules, which results in decreasing content of "free" water in solution and in salting-out of the copper halide. In the bromide system this effect is stronger owing to the large difference in the complex formation of cadmium and copper. At the same time, because of the competition of copper and cadmium complex formation, the salting-out in the systems under consideration is stronger than in the ternary solutions CuX_2–MX_2–H_2O and CdX_2–MX_2–H_2O (M^{2+} is Mg^{2+}, Ba^{2+}) [7, 8].

The difference in the complex formation of cadmium halides also affects conditions of the dehydration of hydrates of these salts in the solid phases. The observed dehydration can be considered as a result of the replacement of water molecules in cadmium aqua halide complexes in solution by halide ions. This process should be more pronounced in the bromide system, as compared to the chloride system, which is observed experimentally. In this case the competition with copper(II) complex formation is manifested in that the point of the transition from the tetrahydrate to the anhydrous salt is displaced to larger concentrations of the second component, as compared to the systems containing double-charged noncomplexing cations.

Thus, solubility in the systems containing cadmium and copper(II) halides is determined by the competition of cadmium and copper complex formation. In the chloride system the similar contributions of these processes favor formation of solid heteronuclear complexes with chloride bridges and weaker salting-out of copper chloride dihydrate and stronger (compared to the bromide system) salting-out of cadmium chloride hydrate. Considerable redistribution of bromide ions in favor of cadmium bromide results in a change of the solid phase from the terahydrate to the anhydrous salt at relatively low concentrations of the second component.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Composite Silver Bromide Based T-Crystals of Epitaxial Type

Received December 7, 2000

Abstract—The process was studied in which heterocontact microcrystals based on silver bromide are obtained in bulk crystallization. The influence exerted by parameters of the crystallization process on the epitaxial growth was revealed. The conditions were determined for obtaining the AgBr/AgCl and AgBr/AgSCN epitaxial systems with the use of substrate-type tabular AgBr microcrystals (T-crystals of AgBr).

Epitaxial crystals constitute an extremely interesting system as regards both carrying out fundamental studies of the mechanism of microcrystal growth in bulk crystallization and solving practical problems of interaction between photographically active (sensitizing, stabilizing, antifogging, developing, etc. agents) substances with the surface of a heterophase microcrystal. That is why these crystals attract close attention of researchers all over the world [1–3]. Recently, numerous attempts have been made to create a material based on epitaxial microcrystals. Quite a number of rather unexpected effects have been revealed, with no scientific explanation provided so far [4, 5].

Here we made an attempt to reveal basic mechanisms and driving forces of the processes in which heterocontact microcrystals of epitaxial type are formed in bulk crystallization. Heterocontact systems were studied in bulk crystallization of AgBr/AgCl and AgBr/AgSCN epitaxial microcrystals. Simultaneously, we made an attempt to determine the possibilities opened up by the use of epitaxial systems in studying the fundamental problems of modern photographic chemistry.

EXPERIMENTAL

As substrate were used tabular AgBr crystals (T-crystals of AgBr) with average equivalent diameter $d = 2.0 \pm 0.2$ μm, coefficient of size variation C_v = 40%, and crystallographic uniformity S_T = 90%. The epitaxial systems were grown in the absence of any growth modifiers or organic dyes.

It is known from the literature that an important parameter of the epitaxial growth is the structural-geometric similarity of the planes growing together [6]. Thus, epitaxy of silver chloride and bromide is seemingly possible because of the isomorphism of these compounds and their close lattice constants.

However, it was found that no epitaxial growth is observed upon addition of a fine-grained emulsion (FGE) of AgCl to the substrate and subsequent co-crystallization at T = 60°C and pAg 7.6. Alternate introduction of $AgNO_3$ and KCl into an aqueous gelatin solution with substrate-type T-crystals of AgBr does not lead to epitaxial system growth, either.

It was established that addition of potassium iodide to the AgBr matrix and subsequent alternate introduction of $AgNO_3$ and KCl leads to growth of silver chloride epitaxial microcrystals on substrate-type T-crystals of AgBr. In the course of the experiment, the concentrations of the delivered reagent solutions were varied between 0.01 and 0.1 M. It was demonstrated that angular epitaxy of silver chloride is observed even at reagent solution concentrations of 0.02 M (Fig. 1).

Also noteworthy is the fact that, at high concentrations of the supplied reagent solutions, nonepitaxial growth of the chloride phase is observed over the

entire AgBr T-crystal surface that is not defect-free (Fig. 2). On separate parts of the surface of AgBr T-crystals, relatively large pyramidal structures are discernible, smoothly adjoining the surface of the substrate microcrystal. Possibly, this is due to the nonuniform deposition of silver iodide over the substrate surface. It may be assumed that those parts of the AgBr T-crystal surface which are covered with a layer of silver iodide serve as effective crystallization centers for AgCl epitaxial microcrystals. In this case, deposition of excess silver bromide from solution onto the silver iodide free parts of the surface and growth of the base microcrystal in the direction perpendicular to the {111} plane to form a pyramidal structure are possible when pAg increases steeply. Such a behavior of the system can, in our opinion, be accounted for by the fact that ion exchange occurs in cocrystallization of silver chloride and bromide: chlorine ions are introduced into the AgBr crystal lattice, whereas silver ions cannot form nuclei with chlorine ions because of the Coulomb repulsion from silver ions belonging to the substrate lattice.

Under the chosen crystallization conditions, iodide ions cannot penetrate inside the AgBr lattice because of the large difference between the solubilities of silver iodide and bromide. Therefore, they are adsorbed on the crystal lattice surface and serve as crystallization centers for silver chloride epitaxial microcrystals.

In this set of experiments, the optimal rate of reagent solution supply in crystallization was found to be 0.002 mmol min^{-1}.

Rather unexpected was the observed strong influence exerted by the crystallization process conditions (temperature, concentration of reagent solutions, and their delivery rate) on the epitaxial growth of AgSCN. It is known that silver thiocyanate is a good solvent for any silver halide [7] and, therefore, no significant dependence of the epitaxial growth on crystallization conditions would be expected. The observed dependence can be understood on making the following assumptions. It is known that formation of epitaxial microcrystals is preceded by the stage of solute adsorption on the substrate [6]. Therefore, differences in adsorption may lead to difference in epitaxial growth. In its turn, the adsorption is strongly affected by conditions in the sorption system (temperature, concentration of sorbates, etc.). In particular, the surface concentration of the adsorbate strongly depends on temperature and the solute concentration. It may be assumed that, on raising the concentration of silver thiocyanate in solution at 50°C, the adsorption of silver on the surface of AgBr T-crystals is unhindered. Naturally, the adsorption primarily proceeds in those areas where the surface energy is reduced to the maximum extent by adsorption. These places of preferential adsorption are the active elements of the AgBr T-crystal surface: edges and vertices. However, adsorption also occurs on the surface of basal (large) and lateral faces of the AgBr T-crystal because of the higher activity of {111} planes, compared with {100}. The edges and vertices are degenerate fast-growing faces of the crystal and, by the virtue of this fact, they are places of the most intensive mass exchange with the sorption medium. Local egress of ions may give rise to a surface with even higher effectiveness of silver thiocyanate adsorption.

In this case, the new surface becomes thermodynamically stable upon thiocyanate adsorption. Therefore, an effect similar to crystal etching is observed on repeatedly performing the given process (Fig. 3a). Silver bromide cannot fill the forming etching pits since the surface is protected by firmly adsorbed silver thiocyanate. In this case, deposition of silver bromide occurs in some other place of the crystal, in all probability on its basal planes, since under the crystallization conditions the growth of the {111} surface is rather effective. In the absence of silver thiocyanate, physical ripening of substrate crystals under the same conditions does not lead to formation of etching pits since there exists no hindrance to their being filled with silver bromide and the difference between the surface energies of the {111} and {100} faces is insufficient for effective mass transfer to occur. With increasing temperature, the situation changes. At 60°C, adsorption on the surface of the basal planes of the T-crystal becomes less effective. In this case, the edges and vertices of the T-crystal (where the matching of the AgBr and AgSCN lattices is the best) may primarily act as places of effective adsorption. Therefore, silver thiocyanate is accumu-

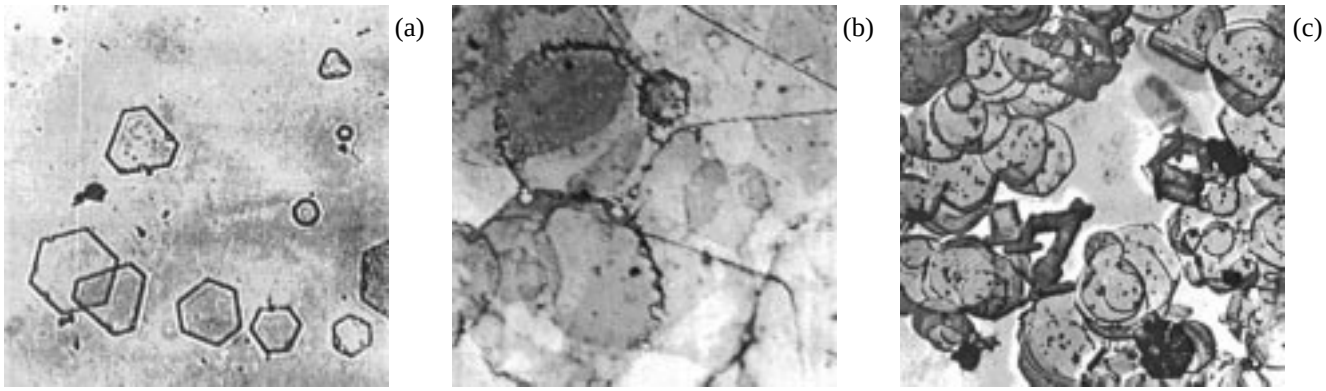

Fig. 3. Electron micrographs of carbon replicas of T-AgBr/AgSCN, obtained at different temperatures. Temperature (°C): (a) 50, (b) 60, and (c) 70.

lated in solution in the course of crystallization (supersaturation grows fast), which leads in the end to heterogeneous nucleation on the surface of the existing monolayer of AgSCN. In this way grows the epitaxial microcrystal, with the region of epitaxy limited to that of the effective adsorption of silver thiocyanate under the given conditions (Fig. 3b). However, in the case of a very low degree of supersaturation (low rate of reagent solution introduction), the adsorption on the surface of AgBr T-crystals becomes a more effective channel of silver thiocyanate consumption and the situation at 50°C is reproduced (Fig. 4). Finally, at 70°C, adsorption becomes ineffective even at vertices and edges. In this case, silver thiocyanate is accumulated in solution (supersaturation grows) until the critical level of homogeneous nucleation is reached. Under these conditions, AgSCN microcrystals nucleate and grow in the form of a separate independent phase (Fig. 3c).

A study of the influence exerted by epitaxial microcrystals of the indicated composition on the chemical sensitization of heterocontact systems AgBr T-crystal/AgCl revealed the following general features: for epitaxial systems, the time of chemical sensitization, i.e., the time in which the maximum light sensitivity is achieved, is shorter than that for the conventional emulsion-type AgBr T-crystals. When the maximum light sensitivity is achieved, the optical density of the fog of the epitaxial systems much exceeds that for the reference. It is shown that a smaller amount of a sensitizing agent is required for achieving the highest sensitivity of the epitaxial systems, and, therefore, photographic materials based on AgBr T-crystals with epitaxial microcrystals must be more stable in storage.

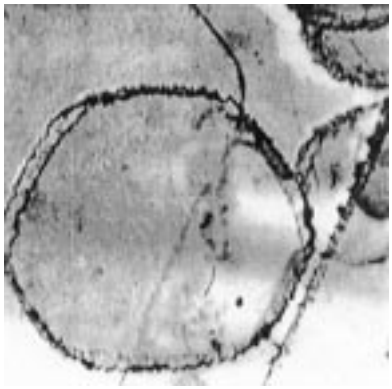

Fig. 4. Electron micrograph of a carbon replica of T-AgBr/AgSCN.

CONCLUSIONS

(1) A study of how heterocontact silver bromide based microcrystals are obtained in bulk crystallization revealed the influence of parameters of the crystallization process on the epitaxial growth.

(2) The effectiveness of epitaxial growth is determined by the possibility of adsorption of the material constituting the epitaxial microcrystals on the matrix of the AgBr T-crystal and by conditions in the sorption system.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of Ultradisperse Corundum from Industrial Waste

A. A. Khanamirova

Institute of General and Inorganic Chemistry, National Academy of Sciences of Armenia, Yerevan, Armenia

Received October 30, 2000

Abstract—The method is developed for fabrication of nonaggregated submicrocrystalline chemically active corundum from the production waste of capacitor aluminum foil. Such corundum is practically free of alkali metal impurities and has good rheological properties.

Many up-to-date technologies use corundum ceramics, which is hard, chemically inactive, and corrosion-resistant, has high compression strength and low friction coefficient, and is compatible with biological objects [1, 2]. Potentialities of corundum ceramics are highly appreciated [3]. However, the dynamic friability and low tensile strength limit its applicability. Studies showed that the properties of the ceramics could be appreciably improved by increasing diffusion coefficient and decreasing particle size. A universal route for preparing ceramics with prescribed properties is taking the components in the ultradisperse state (with no more than 100–150-nm particles). In such ultradisperse ceramics a unique combination of mechanical properties can be attained, including high hardness and superelasticity [2, 4–7].

To prepare such corundum ceramics, it is necessary to use α-Al_2O_3 as pure, nonaggregated powder with submicrorystalline (100–40 nm) or nanocrystalline (40–1 nm) particles. Its high dispersity and the minimal content of impurities facilitate mineralization in the course of formation of the ceramic structure, decrease the sintering temperature, retard particle growth, and increase the mechanical strength and heat resistance [1]. The necessity of disaggregating corundum powders is dictated by the fact that aggregated particles are sintered first, whereas between the aggregates coarse pores are formed, remaining in the ceramics, which decreases its density and results in nonuniform crystallization [8].

Ultradisperse monofractional powders can be obtained by various methods [2, 6–11]. Among them are the chemical and physical procedures, thermal decomposition of disperse chemical compounds with modifiers [12], and mechanical disintegration [13, 14]. Certain physicochemical methods allow attainment of a 100–10-nm dispersity. At the same time, they have a number of disadvantages, including complexity, high cost, and specificity. Mechanochemical treatment allows ceramic materials with the similar dispersity to be synthesized under milder conditions, provides control of their structure and properties, and intensifies sintering [15]. However, after the limiting particle size is attained, the disintegration ceases, and ultradisperse particles start to interact via van der Waals forces to form dense molecular aggregates [16, 17].

The final stage of high-temperature sintering of ceramic materials, when open (intergranular) porosity is mainly removed, is recrystallization [1, 18]. The studies showed that the original corundum crystals 1–3 μm in size start growing at 7.5–10% porosity. At a porosity of 2.5 and 0.5–1% their size increases to 6 and 18–8 μm, respectively [1]. Evidently, for preparing nonporous corundum, it is necessary to retard crystal growth till complete removal of pores from the cake.

To intensify sintering, decrease its temperature, and retain small ceramic grains, it is recommended to perform sintering in the presence of dopants protecting the crystals of the growing phase and retarding their fast growth [12, 19]. The sintering temperature of corundum can be decreased by mechanical activation [20]. For fabricating nanocrystalline nonaggregated corundum, a method has been developed including mechanical activation of α-Al_2O_3 at 40*g* load in the presence of disaggregating substance, removal of the latter by boiling of disintegrated corundum with hydrochloric acid, and sintering of purified corundum at 1270°C to obtain submicrocrystalline ceramics [21].

Fabrication of ultradisperse (0.5–1.0 μm) α-Al_2O_3 with a low content of alkali impurity (0.02–0.06 wt % Na_2O) in hydrochemical, thermochemical, mechanochemical, and radiation-thermal reprocessing

1070-4272/01/7407-1088$25.00

of aluminum hydroxides and oxides of different origin in the presence of dispersing and disaggregating inorganic and organic substances has been studied previously.

In this work, a method involving sequential thermochemical and mechanochemical activation was developed for preparing nonaggregated submicrocrystalline high-purity α-Al_2O_3 from cheap disperse industrial aluminum hydroxide.

EXPERIMENTAL

Anodic sludge, a large-tonnage residue of the production of capacitor foil by electrolytic pickling of aluminum, was the raw material. The composition of the initial anodic sludge was (wt %) 6.25 Na_2O, 0.056 SiO_2, and 0.006 Fe_2O_3 at a 60% moisture content. The aggregate size was 3–10 μm. and the size of the aggregate single crystals, 0.5–3 μm. The sludge was washed with distilled water and treated hydrochemically [22]. The resulting anodic aluminum hydroxide (AAH) had the bayerite structure and contained (wt %) 0.04 Na_2O, 0.053 SiO_2, and 0.006 Fe_2O_3 (based on Al_2O_3). The main part (~80%) consisted of individual single crystals (0.5–1 μm) and ~20%, of loose friable aggregates (3–5 μm).

The thermochemical activation of AAH was performed in the presence of ultradisperse mineralizers (ammonium fluoride, aluminum acetate, and aluminum citrate) and modifiers (manganese acetate tetrahydrate and manganese citrate hydrate). The mineralizers and modifiers were added to AAH as saturated solutions at pH 3–3.5. The mixture was thoroughly agitated and dried in air. Such a procedure assists the uniform distribution of the additive particles in the bulk of $Al(OH)_3$, which is preserved on further heating of the mixture, thus intensifying interaction of its components and decreasing the temperature of polymorphous transitions. The thermal decomposition of AAH containing additives was performed in an electric furnace with Silit heaters at 1000–1200°C (heating rate 7 deg min^{-1}) for 0.5–5 h.

The α-Al_2O_3 powder formed under the optimal conditions of the thermochemical treatment of bayerite was subjected to mechanical treatment for a short time (1–10 min) in the presence of microadditives (0.01–0.07 wt %) of OP-7 nonionic surfactant in a planetary mill at comparatively low centrifugal load, (8–15)*g*.

To confirm the feasibility of fabricating ultradisperse corundum ceramics from mechanochemically treated submicrocrystalline corundum, the latter was sintered at 1000–1350°C for 1–5 h in single tests with addition of magnesium acetate (0.2 wt % in terms of MgO) and citric acid (0.05 wt %) into the charge.

Content of mineralizers and modifiers for fabricating ultradisperse corundum with a low content of alkali impurities by thermochemical treatment of AAH (1025°C, 2 h)

Formulation*	Content, wt %		
	1	2	3
I	3.3	4.2	0.9
	3.5	3.6	0.8
	3.9	3.0	0.8
II	3.5	3.9	0.9
	3.8	3.3	0.8
	4.2	2.8	0.8

* Components: (I) (1) aluminum acetate, (2) manganese acetate tetrahydrate, and (3) ammonium fluoride; (II) (1) aluminum citrate, (2) manganese citrate hydrate, and (3) ammonium fluoride.

The content of impurities in the samples was determined by standard methods of analysis [23]. The phase composition and the size of the single crystals and aggregates were determined by the crystal optical method on a POLAM P-112 polarization microscope [23]. The size of submicrocrystallites was determined by X-ray diffraction on a DRON-4 apparatus from broadening of the reflection maxima *hkl* [24].

Based on the results obtained, we determined the optimal content of mineralizers and modifiers (see table) and the optimal conditions of thermochemical treatment of AAH (1025°C, 2 h). α-Al_2O_3 formed under these conditions contains about 0.008 wt % Na_2O and consists mainly (90%) of separate single crystals 0.200–0.003 μm in size, with the remainder (~10%) being unstable aggregates of 3–5 single crystals.

Such ultradisperse corundum subjected to mechanochemical treatment under the optimal conditions (centrifugal load 15*g*, 5 min, 0.07 wt % OP-7) contains virtually no aggregates and alkali impurities and consists of separate single crystals 0.080–0.085 μm in size. It is chemically active, shows good rheological properties, and forms dense submicrocrystalline corundum ceramics when sintered with the modifier and dispersant at 1350°C for 3 h.

Numerous studies showed that the solid phase formed in a multistep topochemical process inherits the structure of the preceding solid phase [25]. This suggests that the properties of the resulting submicro-

crystalline corundum were established in the stage of formation of the anodic sludge and AAH.

Because the anodic sludge was formed at electrochemical activation of aluminum, its particles have excess energy. They are colloid-polymeric discrete formations in the form of aggregates of aluminum hydroxide with the electrolyte (NaCl). The majority of electrolyte ions in the anodic sludge is physically sorbed in pores, and the remaining ions are incorporated into $Al(OH)_3$ micelles instead of the hydroxide ions and protons and are held there owing to chemical affinity [26]. After the hydrochemical treatment [22] with the dispersant, the activity and dispersity of AAH grow.

The thermochemical activation is caused by the presence of dispersing, disaggregating, and mineralizing thermally unstable chemical substances upon AAH decomposition. The organometallic compounds of aluminum and manganese decompose in the temperature interval of the bayerite–boehmite transformation when their most finely dispersed and active state is realized owing to formation of anionic vacancies upon water removal. In the process are formed nanometric particles of hydroxides and oxides of aluminum and manganese [27], which in the bulk of bayerite become centers of crystallization of ultradisperse α-Al_2O_3 and facilitate dispersion and disaggregation of its crystals. Manganese(II) oxide formed by transformation of the Mn^{2+} salt has enhanced reactivity (the Headwall effect), which favors formation of aluminum–manganese spinel $MnAl_2O_4$ above 1000°C [25]. With addition of Mn^{2+} ion whose radius (0.91 Å) is larger than that of Al^{3+} (0.57 Å), the γ-Al_2O_3 phase becomes less stable, and new vacancies are formed owing to tensile stresses [28]. As a result, diffusion is facilitated, which leads to the decrease in the apparent activation energy and temperature of the γ-Al_2O_3–α-Al_2O_3 transition and to the increase in the corundum dispersity.

The gases evolved upon decomposition of NH_4F and organometallic compounds are sorbed by $Al(OH)_3$, AlOOH, and γ-Al_2O_3 and diffuse into the space free from crystals and aggregates, which increases the γ-Al_2O_3 dispersity and accelerates its transformation into α-Al_2O_3 at lower temperatures. The gases react with the alkali metal ions migrated onto the surface of the bayerite and boehmite crystals with the formation of salts evaporating upon calcination.

The positive technological effect of the mechanical treatment of ultradisperse corundum subjected to thermochemical activation is attained owing to the change in its physicochemical properties [13, 14, 29, 30] resulted from the stress field relaxation after mechanical action. Due to mechanochemical activation, centers, predominantly of radical origin, are formed on the surface [31], and the near-surface layers of the particles undergo elastic deformation to form dense molecular aggregates. For the formation of nonaggregated α-Al_2O_3, apart from the mechanical action, the surface physicochemical phenomena responsible for the aggregation also play the important role [16]. Such physicochemical phenomena may be provided by introduction of surfactants [32]. The surfactant as monomolecular layer wets the whole surface of ground and activated α-Al_2O_3 grains and diffuses along the steric structural defects, thus facilitating disintegration under the action of capillary forces, preventing α-Al_2O_3 aggregation and assisting disaggregation of the initial powders [33]. The mechamism of such mechanosorption effect involves mechanical cracking of the sorbed surfactant molecules onto more active unsaturated free radicals [14, 29, 34, 35], their chemical interaction with active centers on the α-Al_2O_3 surface, diffusion along the structural defects, and formation of dense molecular aggregates from dispersed particles. The mechanosorption effect assisting corundum disintegration can attain 600–800% [17]. The mechanochemical activation in the presence of OP-7 assisted not only disintegration and disaggregation of α-Al_2O_3 particles, but also their passage into the nonequilibrium state characterized by enhanced reactivity, better plasticity, lower sintering temperature, and slower grain growth.

The submicrocrystalline corundum activated by mechanochemical treatment was sintered with the modifier (Mg) and dispersant (citric acid). Magnesium acetate added to the charge decomposes above 400°C with formation of nanosized highly reactive MgO [27]. The latter is distributed throughout the boundary of the α-Al_2O_3 phase as thin layer, and above 1000°C it forms aluminum–magnesium spinel $MgAl_2O_4$ impeding uncontrollable recrystallization of the corundum grains up to formation of a practically nonporous cake.

Like $MgAl_2O_4$, aluminum–manganese spinel $MnAl_2O_4$ entering the charge along with α-Al_2O_3 is the structural modifier of corundum ceramics. The presence of manganese(II) in the slip ensures formation of the melt wetting well α-Al_2O_3 crystals, decreases the sintering temperature, facilitates formation of the finely crystalline ceramic structure, and enhances the strength, plasticity, and endurance of the ceramics [36, 37]. Small amounts of citric acid control rheological properties of the molded masses on the basis of ultradisperse α-Al_2O_3 having the high surface

and bulk energy and high surface tension [38]. The citric acid molecules, being adsorbed on the corundum grain boundaries and diffusing into the intercrystal space, assist spontaneous disintegration of grains, facilitate disaggregation owing to break of intermolecular interactions, stabilize aqueous corundum dispersion, and decrease the sintering temperature.

CONCLUSIONS

(1) Submicrocrystalline corundum with high purity, low tendency to aggregation, good rheological properties, and high sinterability was prepared from the capacitor foil production waste sequentially subjected to hydrochemical treatment under mild conditions, low-temperature thermochemical activation, and low-intensity mechanochemical activation in the presence of dispersants and disaggregators (without additional operations for their removal).

(2) In reprocessing into submicrocrystalline corundum, anodic sludge and anodic aluminum hydroxide have undoubted advantages over technical-grade aluminum hydroxide and aluminum oxide, because anodic sludge is a cheap and ultradisperse material (3–10-μm grains against 20–150 μm in technical-grade aluminum hydroxide) from which alkali metal impurities can be almost completely washed out (95–98% against 20–50% in technical-grade aluminum hydroxide).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Improvement of the Iodine and Bromine Production Processes

Abstract—Ways to improve the existing process for iodine and bromine production from iodine-containing drill waters were studied.

Various types of mineral raw materials, such as seawater, brine of salt lakes, solutions from processing potassium-containing minerals, and underground waters and brines, are used in the iodine and bromine production. Depending on the type and characteristics of the raw materials, various methods and flowsheets are used, including highly expensive and obsolete. Therefore, it is urgent to improve the existing technology for processing of iodine- and bromine-containing raw materials and to develop new high-performance processes increasing the economic efficiency and environmental safety of the iodine and bromine production.

In the existing process [1] of treatment of drill water containing 9–10 mg l^{-1} of iodide ions and up to 750 mg l^{-1} of bromide ions as salts, first extracted is bromine and then iodine. The drill water after removal of bromine is directed to iodine extraction. It contains up to 60 mg l^{-1} of oxidants, including elemental bromine and chlorine and also iodate ions. For iodine adsorption on coal, iodate ions should be preliminarily reduced with sodium sulfite. Simultaneously, redox reactions of sodium sulfite with chlorine and bromine proceed in drill water, and the consumption of sodium sulfite in side reactions exceeds its amount required for the reduction of iodate ions.

The necessity of reducing iodate ions rises the cost of the iodine extraction from raw materials and makes the process of iodine production insufficiently profitable. Therefore, the development of efficient processes for treatment of drill water with primary extraction of iodine is of practical interest.

Conventional oxidants (compounds of active chlorine) failed to solve the problem of selective oxidation of iodide ions in drill water containing considerable amounts of bromide ions (compared to iodide ions), because of simultaneous oxidation of bromide ions (to elemental bromine). The use of sodium nitrite and nitrosylsulfuric acid, which selectively oxidize iodide ions in a weakly acid medium, results in the liberation of highly toxic nitrogen oxides, which should be recovered for reuse [1, 2].

A procedure was published [3] for the isolation of iodine from drill waters by oxidation of iodide ions to iodate ions in a part of drill waters with ozone at pH 7–8, subsequent acidification of this part of waters by sulfuric acid, and mixing with 4–5 parts of the initial drill water. The yield of iodine in this case reaches 96%. The drawbacks of this procedure are the formation of a precipitate on alkalization of the initially weakly acidic drill waters and also the liberation of elemental bromine in water oxidized with ozone due to partial oxidation of bromide ions.

Of interest are the data [4] on oxidation of iodide ions in a liquid medium containing up to 150 g of NH_4I per 100 g of water with oxygen or an oxygen-containing gas in the presence of compounds of transition metals [Fe(III), Co(II), Ni(II), Cu(II), etc.] and a weak acid or hydrophosphates. The oxidation is carried out at 20–100°C and oxygen partial pressure of 0.2–10 kg cm^{-2}. The yield of iodine is 50–82%.

Taking into account the goal of the study and the above-discussed processes, we examined selective oxidation of iodide ions to iodine in iodine- and bromine-containing drill water by atmospheric oxygen with ozone added to initiate oxidation, and also with iron(II) salt added to prevent the accumulation of bromine released from the oxidation of bromide ions in the drill water. As a reducing agent we used iron(II) chloride, which was obtained from 30% solution of $FeCl_3$ (a waste of bromine production) and iron shavings. Drill water was acidified with hydrochloric acid and oxidized with an ozone–air mixture containing 0.5–0.8 mg l^{-1} of ozone.

13	3.00	0.17*	9.6	0	0	0	0	0	0	0	0

* In run no. 13 drill water with $FeCl_3$ added and air without ozone were used.

We oxidized drill water from iodine–bromine production containing 750 mg l^{-1} of bromide ions and 10 mg l^{-1} of iodide ions as salts, and also prepared on its basis water samples containing 50 mg l^{-1} of I^- and 150 mg l^{-1} of Br^-. The experimental data are given in Table 1.

Table 1 shows that iodide ions are not oxidized in acidified drill water in air without ozone even in the presence of an iron(III) salt (Table 1, run no. 13), which is probably due to the extremely low reaction rate at low concentrations of iodide ions. Iodine appears in the drill water only after air bubbling for 1 h, which is unacceptable for processing large volumes of waters under production conditions.

When preliminarily acidified drill water is treated with ozone–air mixture, iodide ions are oxidized fairly actively at the rate of the mixture feeding of 0.1–0.17 $l\ l^{-1}\ min^{-1}$. Depending on the oxidation time τ, the yield of iodine reaches 80 (τ = 2 min) and 90–100% (τ = 3–5 min), which allows the process to be performed in the continuous mode. The consumption of ozone for the oxidation of iodide ions was much less than the stoichiometric amount required for the reaction

$$2I^- + O_3 + 2H^+ \rightarrow I_2 + O_2 + H_2O.$$

This fact suggests that iodide ions are oxidized with atmospheric oxygen, and ozone acts only as the oxidation initiator.

Table 1 shows that the addition of iron(II) chloride in the amount of 0.66 wt parts of Fe^{2+} per 1 wt part of I^- to drill water prevents the formation of elemental bromine, which suggests the occurrence of the fairly fast redox reaction

$$2Fe^{2+} + Br_2 \rightarrow 2Fe^{3+} + 2Br^-.$$

Without iron(II) chloride addition, free bromine appears in the oxidized drill water in the amount of 1–2 mg l^{-1}, which is not allowed by the existing technology of iodine sorption on coal.

Thus, our experiments proved that iodide ions can be selectively oxidized in drill water, and the process is quite suitable for the existing iodine–bromine production.

In bromine production gaseous bromine is absorbed from a bromine–air mixture by iron shavings periodically sprayed with water or solutions of iron bromides. A feature of this process consists in binding of bromine into iron(II) or (III) bromide. To liberate bromine from them, chlorine is used in the subsequent production stage, which results in the formation of a solution of iron(III) chloride as a liquid waste product simultaneously with the main product formation.

The drawbacks of using iron shavings as a bromine chemisorbent are the formation of the difficult-to-utilize by-product and also the accumulation of bromine-containing slimes in vessels for bromine chemisorption, which should be disposed of at regular intervals.

Table 2. Sorption of bromine from a bromine–air mixture (BAM) by aqueous solutions of *N*-(*n*-pentyl)pyridinium bromide (**I**) in a bubbling mode (time of gas–liquid contact about 1 s)

Initial concentration of **I** in absorbing solution		Averaged concentration of bromine in BAM, mg l^{-1}		Degree of bromine removal from BAM, %	Characteristics of resulting polybromide complex		
M	wt %	before reactor	after reactor		color	bromine content, wt %	density at 18°C, kg dm^{-3}
1	21.95	10.3	1.05×10^{-2}	99.9	Light cherry	40.5	1.659
2	42.05	9.5	9.8×10^{-3}	99.7	Cherry	53.7	1.907
3	60.69	11.8	1.02×10^{-2}	99.2	Dark cherry	66.0	2.136
4	78.23	7.7	8.3×10^{-3}	99.0	″	74.1	2.283

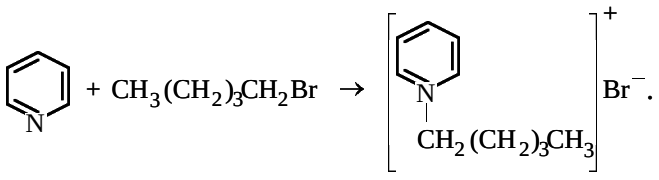
The application of soluble bromine sorbents is free of these drawbacks. Quarternary ammonium salts are of a special interest for the process of bromine production. They are safe in handling (nonvolatile, low-toxic, fire- and explosion-proof) and are not steam-distilled. They can be used as aqueous solutions binding bromine into polybromide complexes on contact with a bromine–air mixture. Bromine is readily desorbed from such complexes at moderate heating, and then it can be blown off with air or steam.

The preparation of quarternary ammonium salts by quaternization of tertiary amines with alkyl halides in polar solvents was studied in sufficient detail [5–9], and their application as bromine absorbents has been described in [10, 11].

Comparative examination of the data on the operation of liquid absorbents in bromine sorption–desorption showed that *N*-alkylpyridinium bromides show the most promise for bromine production [12–14].

In view of the aforesaid, we studied the absorbing properties of solutions of *N*-(*n*-pentyl)pyridinium bromide with respect to bromine in bromine–air mixtures under conditions close to those of bromine manufacturing. The choice of the salt was governed by the fact of production of *n*-pentyl bromide at the iodine–bromine plant.

N-(*n*-Pentyl)pyridinium bromide was prepared from equimolar amounts of pyridine and *n*-pentyl bromide in the presence of water (5–10 wt %) [5] in a quartz round-bottomed reactor with a reflux condenser at 90–95°C by the reaction



At the 2–3 h synthesis time the yield of the salt was 95%. The unchanged initial components were removed from the salt using a separatory funnel.

For the sorption of bromine from a bromine–air mixture we used 20–80% aqueous solutions of *N*-(*n*-pentyl)pyridinium bromide. The sorption was carried out in a quartz round-bottomed reactor at room temperature and the phase contact time of about 1 s. A polybromide complex formed from the bromine sorption was accumulated on the reactor bottom as a separate layer of a cherry-colored heavy oily liquid immiscible with the absorbing solution. The sorption of bromine vapor was terminated on complete saturation of the *N*-(*n*-pentyl)pyridinium salt in the absorbing solution. The data on the sorption of bromine vapor by *N*-(*n*-pentyl)pyridinium bromide solutions are given in Table 2.

Our experiment showed that the bromine content in the polybromide complex increases with increasing initial concentration of *N*-(*n*-pentyl)pyridinium bromide in the absorbing solution and reaches 40–75 wt % at the degree of bromine sorption from the bromine–air mixture equal to or greater than 99%. As the concentration of bromine in the polybromide complex increases, the color of the complex changes from light cherry through red-brown to dark cherry, and its density increases from 1.659 to 2.283 kg dm^{-3}.

Bromine was desorbed from the polybromide complex by heated air or steam in the same reactor in which bromine was sorbed from a bromine–air mixture. The bromine–air mixture (or a mixture of bromine vapor and steam) formed from the decomposition of the complex was directed to a reflux condenser with the aim to return water completely or partially (when steam was used) into the reactor, so as to keep a high rate of bromine desorption. The results of the experiments on the bromine desorption from the polybromide complex are given in Table 3.

Table 3. Desorption of bromine from the polybromide complex (initial concentration of bromine in the complex 49.81 wt %)

Weight ratio complex/water, m_{com}/m_w	Rate of air feeding for bromine desorption,* l min^{-1} g^{-1}	τ, min	Temperature, °C		Average concentration of bromine in BAM, mg l^{-1}	Degree of bromine desorption, %
			in reactor still	in dephlegmator		
1.66	1.50×10^{-2}	165	95–105	22–45	189	93.8
2.50	1.25×10^{-2}	150	96–105	22.45	232	87.2
1.66	1.80×10^{-2}	180	110–118	48–83	56	36.3
0.50	1.50×10^{-2}	180	96–105	21.24	222	40.1
1.66	2.30×10^{-2}	180	85–92	29–45	47	38.9

* In calculations of the rate of air feeding, m_{com} was expressed in grams.

Table 3 shows that the efficiency of bromine distillation from the polybromide complex depends on a number of factors: temperature in the still and in the dephlegmator, amount of solvent (water) for pyrydinium salt in the reaction mass, and space velocity of air (or steam) fed for the bromine desorption.

Our experiments showed that the maximal rate of bromine desorption, and also a high bromine concentration in a bromine–air flow, are observed at the beginning of bromine distillation when the content of polybromide complexes is high. As their concentration decreases in the course of bromine distillation, the rate of bromine desorption from the complex and the concentration of Br_2 vapor in the bromine–air flow decrease.

The optimal temperature of the complex decomposition is 95–105°C. Below this temperature the rate of bromine desorption starts to decrease, whereas at higher temperatures water is actively boiled off and removed through the dephlegmator, which results in the dehydration of the reaction mass and drastic deceleration of the bromine desorption rate.

The optimal temperature of the dephlegmator, intended for the complete (or partial) return of the condensed water into the reactor, is determined by the surface area of the dephlegmator and the space velocity of air (or steam) fed for bromine desorption.

The optimal weight ratio polybromide complex : water in the reactor approaches 1 : 1.5. The higher ratio (e.g., 1 : 0.5) results in decreased rate of bromine desorption, whereas at the lower ratio (1 : 2.5) the desorption rate does not increase further.

An optimal specific consumption of air or steam for the bromine desorption approximately corresponds to the ranges 1.25–1.75 m^3 (air) and 2–2.5 kg (steam) per kilogram of the polybromide complex and depends on the reactor design and also on the dephlegmator operation mode.

The 85–90% degree of bromine desorption from the complex was reached in 2.5–3 h of heat treatment of the complex. The bottom residue is a solution of pyridinium bromide containing 5–10 wt % bromine. It can be repeatedly directed to the sorption of bromine vapor from a bromine–air mixture.

To obtain liquid bromine, bromine vapor was blown off from the complex with steam. The resulting steam–bromine mixture was fed from the steam distillation column to a heat exchanger. Its condensation at 20–25°C gave crude bromine and bromine water containing about 3 wt % bromine. After separation of liquid bromine, the bromine water was fed to single-stage bromine extraction by the initial organic bromide. As a result, the bromine content in the bromine water sharply decreased (to 0.003 wt %).

In the case of air desorption of bromine from the complex, the content of bromine in the bromine–air flow gradually decreases from 1000–1200 (at the start of the process) to 100–150 g m^{-3} (at the end of desorption). Such a flow with a variable bromine content can be used for "mild" bromination in syntheses of various bromine-containing products (salts, certain organic compounds, etc.).

CONCLUSIONS

(1) The feasibility was confirmed for selective oxidation of iodide ions in the presence of bromide ions in acidified drill water by atmospheric oxygen with ozone added to initiate the oxidation of iodide ions and with an iron(II) salt added to prevent bromine liberation. The conditions eliminating bromine formation in the solution and simultaneously ensuring the yield of iodine in the range 70–100% were determined.

(2) The sorption of bromine from a bromine–air mixture by aqueous solutions of *N*-(*n*-pentyl)pyridinium bromide with the formation of a polybromide complex containing up to 75 wt % bromine was studied. The conditions of bromine desorption from the polybromide complex providing the yield of bromine in a gaseous or liquid product of no less than 85–90% was determined.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Extraction of Palladium(II) and Platinum(IV) from Hydrogen Chloride Solutions with 3,7-Dimethyl-5-thianonane-2,8-dione and Complexation of This Reagent with the Platinum Metals

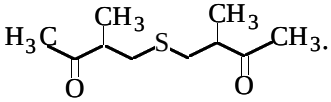
V. V. Potapov, R. A. Khisamutdinov, Yu. I. Murinov, L. A. Baeva, A. D. Ulendeeva, and N. K. Lyapina

Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Received December 26, 2001

Abstract—Extraction of palladium(II) and platinum(IV) from acidic chloride solutions with solutions of 3,7-dimethyl-5-thianonane-2,8-dione in toluene and chloroform and complexation of this reagent with platinum metals in aqueous acetone were studied by ^1H and ^{13}C NMR and IR spectroscopy. The possibility of extractive separation of palladium(II) from platinum(IV) and their separation from Cu(II), Ni(II), Co(II), Mn(II) and Fe(III) with solutions of 3,7-dimethyl-5-thianonane-2,8-dione in organic solvents was studied. The apparent concentration constants of extraction of palladium(II) and platinum(VI) with 3,7-dimethyl-5-thianonane-2,8-dione and the corresponding thermodynamic parameters were determined.

It is known that γ-oxo sufides are efficient and selective extractants for palladium(II), gold(III), and silver(I) [1]. For example, the reagents of this type allow selective separation of palladium(II) from platinum(IV) by extraction from acidic chloride solutions. A major portion of the works devoted both to synthesis of γ-oxo and γ,γ-dioxo sulfides by alkylthiomethylation of ketones and to study of their extraction power toward metals was performed at the Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences. However, extraction of platinum metals with γ,γ-dioxo sulfides practically was not studied. In this work we synthesized 3,7-dimethyl-5-thianonane-2,8-dione (DTD) and studied extraction of palladium(II) and platinum(IV) from acidic chloride solutions with this reagent and its complexation with the platinum metals.



3,7-Dimethyl-5-thianonane-2,8-dione can be readily prepared by thiomethylation of butanone with a mixture consisting of formaldehide and sulfur-containing reagents. Suitable sulfur-containing reagents are not only pure potassium hydrosulfide [2] and sodium sulfide and hydrosulfide [3], but also spent sulfite alkaline solutions from the gas- and petroleum-processing plants [4] containing various amounts of these compounds.

In this work DTD was prepared with the use of solutions containing 8.25 and 5.62 wt % sulfur in the sulfide and hydrosulfide forms, respectively, formed by treatment of the gas flow with 10–20% NaOH to remove hydrogen sulfide in production of additives to lubricating oils.

Synthesis of 3,7-dimethyl-5-thianonane-2,8-dione. 0.82 mol of formaldehyde (35% aqueous solution) and 0.82 mol of butanone (78 ml) were added to 100 g of a sulfite alkaline solution containing 13.87 wt % (0.82 mol) of sulfide and hydrosulfide (recalculated on S^{2-}). This mixture was stirred at room temperature for 1 h. The reaction progress was monitored by determination of the sulfide content by potentiometric titration with an $[Ag(NH_3)_2]NO_3$ aqueous solution [5]. After reaction completion the organic phase was separated and the aqueous phase was treated by contacting with chloroform. The chloroform extract was combined with the organic phase, washed successively with 10% HCl and water, and dried with magnesium sulfate. Thereafter chloroform was evaporated and the residue was distilled in a vacuum. The yield of DTD was 78% (68 g).

We studied extraction of palladium(II) and platinum(IV) chloride complexes from aqueous hydrogen chloride solutions of required concentration with the solutions of DTD in toluene and chloroform. The palladium and platinum chloride solutions were
