amorphous selenium in hydrocarbons. The integral form of this equation is as follows:

$$\ln X_{Se}^{sat} = \text{const} - \frac{\Delta H_{m.Se}}{RT},$$

where const is the integration constant, X_{Se}^{sat} is the selenium concentration (mole fraction) in a solution equilibrated with solid selenium, $\Delta H_{m.Se}$ is the heat of selenium melting, T is temperature, and R is the universal gas constant.

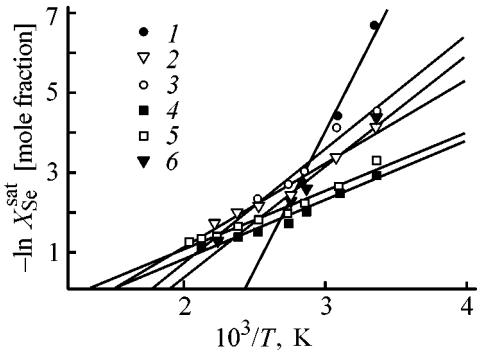

Fig. 3. $\ln X_{Se}^{sat}$–$1/T$ dependence for various solvents: (X_{Se}) concentration of dissolved substance; (T) temperature. Solvent: (*1*) *n*-heptane, (*2*) *n*-octane, (*3*) *n*-nonane, (*4*) *n*-decane, (*5*) *n*-undecane, and (*6*) *n*-dodecane.

The temperature dependences of the solubility of amorphous selenium in *n*-heptane, *n*-octane, *n*-nonane, *n*-decane, *n*-undecane, and *n*-dodecane are shown in Fig. 3. Similar dependences were obtained for metallic selenium.

The melting point of the solute can be found by extrapolation of straight lines in Fig. 3 to intersection with the abscissa ($\ln X_{Se}^{sat} = 0$), and their slope gives the molar heat of melting. However, Schroeder's equation is valid for ideal solutions, and data of Fig. 3 show that such an approximation is unjustified for solutions of selenium in hydrocarbons. A comparison of the reference value of the heat of selenium melting (6.7 kJ per mole of monoatomic selenium) and the values obtained in the experiment showed that Se_n molecules with n = 1–4 prevail in selenium solutions in *n*-alkanes at boiling point. It is usually believed that Se_8 rings are the main selenium species in organic solutions. In the gas phase, Se_8 molecules start to dissociate at 700–2000 K [8]. In this work, we estimated the average molecular composition of selenium in the solution from the temperature dependence of the selenium solubility: $Se_{3.4}$ in *n*-oktane, $Se_{3.4}$ in *n*-nonane, $Se_{2.6}$ in *n*-decane, $Se_{1.8}$ in undecane, and $Se_{1.8}$ in *n*-dodecane. A more precise determination of selenium

Table 3. Average molecular weight of selenium in liquid hydrocarbons (selenium concentration 1 mol per kg of solvent)

Hydrocarbon	$K_{e(calc)}$*	Δt_{boil}, °C	M_{av}
n-C_7H_{16}	3.15	14.3	258.89
n-C_8H_{18}	3.64	18.2	225.60
n-C_9H_{20}	4.80	23.4	224.80

* Ebullioscopic constant.

molecular weight in *n*-alkanes was performed by ebullioscopy.

A statistical processing of the equations $y = b_1x - b_0$ by the least-squares method gave the coefficients b_1 and b_0 of the linear regression equation and sample correlation coefficients r:

$y_1 = -16.56 + 6.82x$, $r = 0.99$, *n*-heptane, 298–365 K,

$y_2 = -5.00 + 2.83x$, $r = 0.98$, *n*-octane, 298–395 K,

$y_3 = -5.19 + 2.75x$, $r = 0.99$, *n*-nonane, 298–421 K,

$y_4 = -3.13 + 2.08x$, $r = 0.98$, *n*-decane, 298–450 K,

$y_5 = -2.14 + 1.45x$, $r = 0.98$, *n*-undecane, 298–472 K,

$y_6 = -1.90 + 1.45x$, $r = 0.98$, *n*-dodecane, 298–493 K.

As noted above, we calculated in [1] for the first time the slopes of the temperature dependence of the solubility of sulfur in various *n*-paraffins. It follows from these data that the temperature dependence of the sulfur solubility is substantially steeper for heptane and nonane, compared with their analogs having even number of carbon atoms in the chain.

This dependence is still more pronounced for the solubility of amorphous selenium in six *n*-paraffins: heptane, octane, nonane, decane, undecane, and dodecane (Table 2). The difference in the temperature dependence of the solubility in paraffins with odd and even number of carbon atoms in the hydrocarbon chain is well seen in Fig. 4. The solubility changes from 1.27 M for octane at 395 K to 3.47 M for dodecane at 493 K. For hydrocarbons of the odd series, the solubility is substantially higher and changes from 1.62 M for heptane (C_7) to 4.59 M for undecane (C_{11}) at 365 and 472 K, respectively.

Ebullioscopic data for selenium solutions in *n*-paraffins and calculated average molecular weights of selenium molecules in the solution are listed in Table 3.

Table 4. Characteristics of thermal dissociation of eight-membered molecular selenium rings

Number of carbon atoms in *n*-alkane chain	M_{av}*	Composition of thermal dissociation products	i	K_{av}
7	258.89	$Se_{3.28}$	2.44	3.24
8	224.80	$Se_{2.85}$	2.81	3.26
9	225.60	$Se_{2.86}$	2.80	4.94

* At maximal selenium solubility.

The low values of these molecular weights experimentally confirm the thermal dissociation of Se_8 rings in liquid alkanes in the range 372–424 K.

A linear correlation was also found between the number i of molecular selenium species formed from the initial Se_8 molecule and the solution dilution $1/C$:

$$i = K_{av} \times 1/C, \quad 1 \le i \le 8.$$

Regression analysis of this equation gives equations relating the empirical quantities x ($\log C$) and y ($\log i$).

$y = 0.510 - 0.703x$, $r = 0.994$, n-C_7H_{16},

$y = 0.513 - 0.586x$, $r = 0.993$, n-C_8H_{18},

$y = 0.510 - 0.582x$, $r = 0.986$, n-C_9H_{20}.

The closeness of the sample correlation coefficient r to unity indicates that the above linear regression $y = a + bx$ is adequate and meaningful.

The molecular weights, composition of products thermal dissociation of eight-membered selenium rings, average number of molecular species in solution, and equilibrium constants are listed in Table 4.

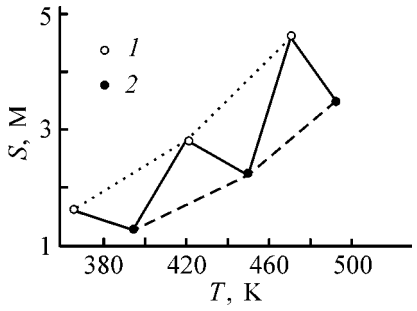

Fig. 4. Temperature trend of solubility S of amorphous selenium in *n*-alkanes with (*1*) odd and (*2*) even numbers of carbon atoms. (T) Temperature.

CONCLUSIONS

(1) The solubility of metallic and amorphous selenium in *n*-C_7–*n*-C_{12} paraffins was determined at 298–493 K by the method of immersion filtration.

(2) It was found from the molar heat of selenium melting, determined as the slope of solubility curves in the $\ln X_{Se}^{sat}$–$1/T$ coordinates (X_{Se}^{sat} is the selenium mole fraction), that Se_n molecules with $n = 1–4$ are the main selenium species in saturated solutions in *n*-paraffins.

(3) A saw-tooth dependence of the solubility of amorphous selenium in *n*-paraffins on the number of carbon atoms in the hydrocarbon chain was revealed.

(4) The average molecular composition of selenium in solutions in *n*-heptane, *n*-octane, and *n*-nonane in a wide concentration range was determined by ebullioscopy. Empirical equations describing the dependence of the average number of Se atoms in molecular selenium species on the selenium concentration in solution were obtained.

Abstract—The rheological properties of sodium alginate solutions were studied as influenced by the concentration of alginic acid, pH of the medium, and temperature. The probable structural and conformational transformations induced on varying these parameters were suggested. The effect of cations and anions of varied nature on the viscous characteristics of these solutions was discussed.

Brown sea algae have recently attracted attention as a source of various substances having wide range of consumer's properties.

Of special value is alginic acid underlying the manufacture of alginates. These are biologically active preparations exhibiting high antiviral, antibacterial, and immunomodulating activities and finding wide application in today's practical medicine [1].

The alginate production procedure is based on alkaline treatment of algae and subsequent separation of this polysaccharide. The drawbacks of this procedure are that the raw material is used ineffectively, as evidenced by production of much waste in the form of algal cellular tissue and large loss of the end product during centrifugation, when the process solution (fugate) is separated from the cellular tissue [2].

This work is a part of the studies of the physicochemical properties of sodium alginate solutions, aimed at gaining deeper insight into processes occurring in various stages of the process and at its further improvement.

In this study, we elucidated how the rheological properties of sodium alginate solutions are affected by the alginic acid concentration c, g dl^{-1}, ionic strength I, M, pH of the medium, and temperature T, °C. Also, we studied how the nature of anions and cations affects the properties of these solutions. The experimental dependences obtained in this study were used for explaining the structural and conformational transformations in these systems.

EXPERIMENTAL

The subjects of investigation were the process solution (fugate) sampled in the stage of centrifugation of algal galert whose main component is sodium alginate and which also contains organic and inorganic substances (chlorides, carbonates, as well as sodium, potassium, magnesium sulfates, etc.) and a sodium alginate solution prepared from the end product, sodium alginate, according to TU (Technical Specifications) 6-09-10-535–76.

The content of alginic acid in the fugate and sodium alginate was estimated by the procedure described in [3] to be 30 and 75% of absolutely anhydrous substance, respectively. The fugate solution yielded by the process had the following characteristics: alginic acid concentration 0.21 g dl^{-1}, pH of solution 10.2, and ionic strength due to Na_2CO_3 introduced in the algae cooking stage 0.053 M.

We measured pH of the solutions on an EV-74 universal ion meter with an ESL-43-07 glass electrode as measuring electrode and an EVL-1M silver chloride electrode as reference. We varied pH of the solutions studied by adding certain amounts of 0.01 M NaOH solution and 0.05 M HCl solution.

We studied the properties of the sodium alginate solutions as influenced by the electrolyte composition by adding inorganic salts; the same salts maintained a constant ionic strength. The influence of the nature of the anions was studied using sodium carbonate, sulfate, orthophosphate, and chloride. The influence of

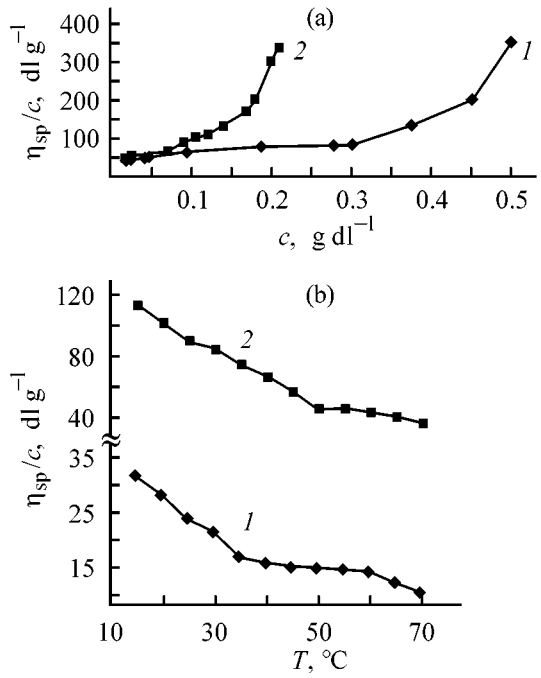

Fig. 1. Reduced viscosity η_{sp}/c, of (*1*) sodium alginate and (*2*) fugate solutions vs. (a) alginic acid concentration c, and (b) temperature T. (a) pH of solution 10.2, I = 0.053 M, T = 25°C and (b) alginic acid concentration in solution c = 0.21 g dl^{-1}.

the nature of the cations was investigated by introducing into sodium alginate solution sodium, potassium, ammonium, and magnesium chlorides. The viscosity was measured on a VPZh-1 glass viscometer with capillary diameter of 1.16, 0.99, and 0.53 mm at T = 25 ± 1°C. The temperature control was provided with a Typ Two thermostat. As the viscosity characteristic served the reduced viscosity η_{sp}/c, dl g^{-1}, which most adequately reflects the structural changes occurring in a system. The measurement error was within 0.5 dl g^{-1}.

To compare the rheological properties of the fugate and sodium alginate solutions, we studied how the concentration of alginic acid affects the reduced viscosity of these solutions (Fig. 1a). The $\eta_{sp}/c = f(c)$ dependence shows that, within the range of relatively low concentrations (c < 0.1 g dl^{-1}), the viscous characteristics of the fugate and sodium alginate solutions are similar. In this concentration range, the solutions are in the micellar state, predominantly in the form of Hartley micelles. With increasing concentration, solutions pass through several equilibrium states characterized by different aggregation numbers, sizes, and shapes of micelles. A sharp increase in the viscosity of solutions (c = 0.17 g dl^{-1} and c = 0.37 g dl^{-1} for the fugate and sodium alginate solutions, respectively) is probably due to the formation of more complex cylindrical or plate-like micelles (McBain micelles) which, in turn, are formed via successive transformations of several mesomorphic phases of different structures [4]. These extended micelles are further arranged into a two-dimensional-hexagonal continuous structure throughout the solution, thus forming a middle mesomorphic phase. With the concentration increasing further, the system converts to a plate-like or lamellar mesomorphic state [5].

The transition of the fugate and sodium alginate solutions from one mesomorphic phase to another at different concentrations can be accounted for by the influence of organic and inorganic impurities occurring in the fugate [2]. The concentration of these impurities is, evidently, sufficient for compressing the electric double layer, thus decreasing the energy barrier preventing the coalescence of colliding particles. Thus, in the fugate solution the interaction of the micellar particles is intensified, which is responsible for a more rapid transition from a less structured to a more structured phase and significantly increases the viscosity of the solution at lower concentrations [6, 7].

We showed that the viscosities of the fugate and sodium alginate solutions are also differently affected by temperature (Fig. 1b). First of all, it should be mentioned that the reduced viscosities of the fugate and sodium alginate solutions with the alginic acid concentration corresponding to that in the process solution (0.21 g dl^{-1}) differ. This suggests that the fugate solution occurs in a more structured (i.e., in one of mesomorphic phases) states than sodium alginate solution. This may be responsible for the different temperature dependences exhibited by these solutions.

For example, the viscosity of the fugate solution decreases with temperature increasing to 50°C; above this temperature a small gradient of the temperature dependence may evidence destruction of a stage in structuring and a transition of the system from micellar to a molecular-micellar state. In sodium alginate solution, an analogous transition occurs at 40°C. The inflection point in the temperature dependence at T = 65°C and the further steeper decrease in the viscosity of sodium alginate solution may be due to a transition of the system to the molecular state, which was not established for the fugate solution in the temperature range of interest.

Although the fugate and sodium alginate solutions markedly differ in the dependences obtained, we can reveal a similar trend in variation of the rheological properties of solutions of these polymers with their concentration and temperature.

To exclude the influence of impurities in the fugate solution, we used in subsequent experiments solutions of sodium alginate as process solution models. The plots of the reduced viscosity of sodium alginate solution against alginic acid concentration suggest that there are two regions of existence of the solutions, namely, the molecular ($c < 0.17 \times 10^{-2}$ g dl^{-1}) and micellar ($c > 0.17 \times 10^{-2}$ g dl^{-1}) regions, throughout the examined pH range (Fig. 2a). The inflection point in the plots discussed corresponds to the critical micelle concentration (CMC), at which micelles formed in solution are in thermodynamic equilibrium with the molecules. This is responsible for a drastic change in a number of properties of solutions and, above all, viscosity.

At close-to-CMC concentrations, the solution contains, for the most part, Hartley micelles, i.e., spherical formations consisting of a hydrocarbon nucleus and an electric double layer. The latter is lined from inside with COO^- ionic groups and from outside, with "bound" and "free" sodium counterions. With increasing concentration of alginic acid in solution the resulting micelles acquire another, namely, plate-like, structure (McBain micelles). Owing to the formation of plate-like micelles, sufficiently concentrated sodium alginate solutions ($c > 0.5$ g dl^{-1}; Fig. 1a, curve *1*) are able to convert into gel.

Our study of how the ionic strength of solution affects the reduced viscosity showed that, with the ionic strength increasing to 0.02 M, the reduced viscosity sharply decreases, while further increase in the ionic strength virtually does not affect the viscous characteristics of the solution (Fig. 2b).

In the case of solutions with alginic acid concentration $c = 0.94 \times 10^{-2}$ g dl^{-1}, corresponding to the micellar region, the influence exerted by sodium chloride taken to create the required ionic strength can be assessed from the viewpoint of the effect on the system of a supporting electrolyte, one of whose ions is identical to the counterions of the colloid particle. Evidently, with increasing content of electrolyte in the system, the electric double layer gets thinner owing to the compression of the diffusion layer. As a result, the ξ potential tends to decrease to zero (at $I = 0.02$ M), which corresponds to the isoelectric state of the system and the minimum reduced viscosity. Further increase in the electrolyte concentration does not affect the reduced viscosity.

The influence exerted by the concentration of the supporting electrolyte on the reduced viscosity of sodium alginate solution with the alginic acid concentration corresponding to the molecular region ($c = 0.15 \times 10^{-2}$ g dl^{-1}) can be accounted for conformational transformations of the alginate macromolecules in the system. The flexible macromolecules of this polymer can take different conformations. The conformations differ in free energy, since the repulsion of the charges of the COO^- groups will result in relatively high free energy for compact conformations, and relatively low, for unfolded conformations. Therefore, at low ionic strengths of solution, the macromolecules are unfolded to the greatest extent, which favors an increase in the viscosity of solutions (Fig. 2a, curve *1*). The increase in the ionic strength of solution, which causes the electric double layer to compress, is responsible for the fact that the shape of the macromolecule approximates the most statistically probable conformations corresponding to the globular state of the system as a whole, which, in turn, decreases the viscosity of solution.

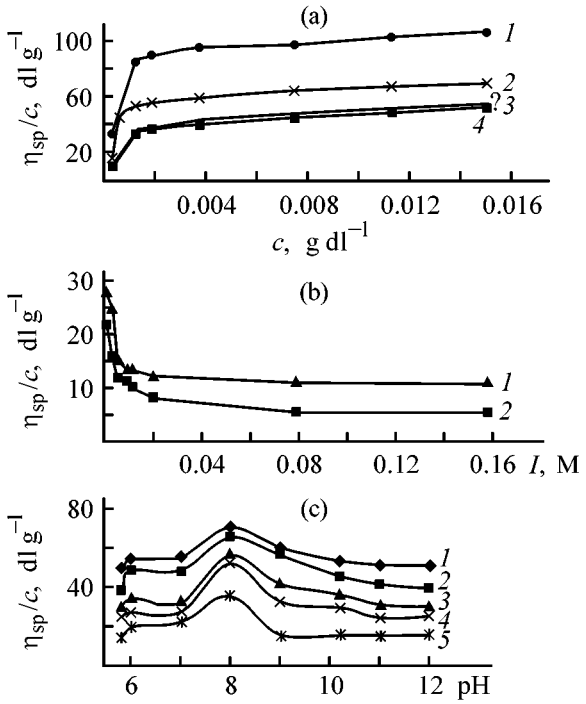

Fig. 2. Reduced viscosity η_{sp}/c of sodium alginate solutions vs. (a) concentration c, (b) ionic strength I, and (c) pH of the medium. (a, c) T = 25°C, I = 0.012 M and (b) pH of solutions 6.5. (a) pH: (*1*) 6.7 (without addition of NaCl electrolyte), (*2*) 8.0, (*3*) 7.0, and (*4*) 10.2. (b) Sodium alginate concentration, g dl^{-1}: (*1*) 0.0094 and (*2*) 0.0015. (c) Alginic acid content, g dl^{-1}: (*1*) 0.0150, (*2*) 0.0075, (*3*) 0.0019, (*4*) 0.0009, and (*5*) 0.0005.

The dependence of the reduced viscosity of sodium alginate solutions on the pH of the medium has a clearly pronounced maximum (Fig. 2c). We varied the pH of solution between 5.8 and 12; the lower boundary of

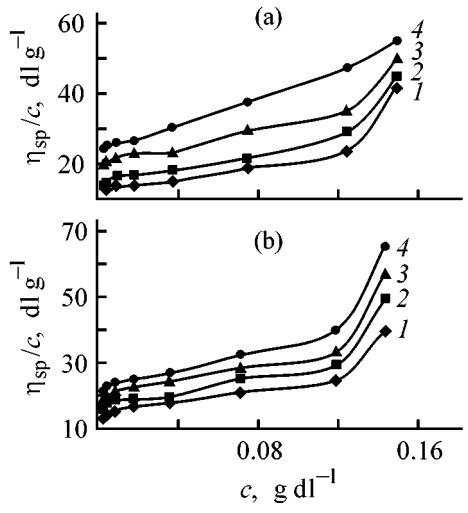

Fig. 3. Reduced viscosity η_{sp}/c of sodium alginate solution vs. the concentration c after introduction of (a) cations and (b) anions of varied nature. (a) Cation: (*1*) Mg^{2+}, (*2*) Na^+, (*3*) NH_4^+, and (*4*) K^+. (b) Anion: (*1*) Cl^-, (*2*) CO_3^{2-} (*3*) SO_4^{2-}, and (*4*) PO_4^{2-}.

this range was chosen in view of the fact that at pH < 5, alginic acid begins to precipitate from solution.

In the molecular concentration region (0.09×10^{-2} and 0.05×10^{-2} g dl^{-1}), the established patterns are quite explicable from the viewpoint of the ability of macromolecules occurring in solution to change their conformation by folding and unfolding.

In the acidic region (5.8 < pH < 6.5), the COO^- groups of sodium alginate molecules react with H^+ ions forming a weak alginic acid. As a result, the electrostatic repulsion forces in the segments of sodium alginate macromolecules weaken, which leads to folding of the macromolecule and, therefore, decreases the solution viscosity.

With increasing pH of sodium alginate solution (6.5 < pH < 8), the degree of dissociation of alginic acid increases, thus enhancing the electrostatic repulsion between the COO^- groups of the molecule. This, in turn, results in unfolding of the macromolecule and, consequently, increases the viscosity of the system. The highest viscosity is observed at pH 8. Further, at 8 < pH < 12 the viscosity of solution tends to decrease because the highly charged sodium counterion in the electrolyte introduced is attracted to the macromolecule surface and strongly shields it, thus decreasing the mutual repulsion of the segments of the molecule carrying negative charges of COO^- group and promoting partial folding of the chain [7].

In the case of micellar solutions (1.5×10^{-2}, 0.75×10^{-2}, and 0.19×10^{-2} g dl^{-1}), the influence of pH is less pronounced and is due to the colloidal-chemical transformations in the system. With increasing pH of the solution, the macromolecules constituting the micelle unfold owing to electrostatic repulsion forces, thus influencing the volume of the aggregate as a whole. Eventually, continuous micellar layers of the McBain micelle type are formed in the system (pH 8), thus increasing the viscosity of solutions.

The pronounced extremum in the plot of the reduced viscosity against pH of the medium in the molecular region is quite explicable by a more prompt response of the system to the state of individual molecules than to that of their aggregates.

We studied how cations of varied nature affect the rheological properties of sodium alginate solutions by introducing NaCl, NH_4Cl, KCl, and $MgCl_2$ salts into these solutions. We found that the reduced viscosity of the sodium alginate solutions tends to decrease in the order $K^+ > NH_4^+ > Na^+ > Mg^{2+}$ (Fig. 3a). The ions of interest form a lyotropic series in which the ion radius tends to decrease from K^+ to Mg^{2+}. This favors formation of less soluble and more compact sodium alginate structures, which, in turn, decreases the solution viscosity.

The same situation was observed with chloride, carbonate, sulfate, and orthophosphate ions introduced into sodium alginate solution. The viscosity of solutions increases in the lyotropic series $Cl^- < CO_3^{2-} < SO_4^{2-} < PO_4^{3-}$ (Fig. 3b). This can be explained in a way analogous to the case of the cations.

Our results can be used in production of alginic acid for regulating and controlling the structure formation processes and intermediate products and products with desired physicochemical properties.

CONCLUSIONS

(1) The molecular ($c < 0.17 \times 10^{-2}$ g dl^{-1}) and micellar ($c > 0.17 \times 10^{-2}$ g dl^{-1}) regions of existence of sodium alginate solutions were revealed.

(2) The influence of the ionic strength and pH of solutions on the viscous characteristics of sodium alginate solutions was established: the reduced viscosity decreases exponentially with increasing ionic strength. The dependence of the reduced viscosity of sodium alginate solutions on the pH of the medium has a maximum at pH 8.

(3) The influence of the cations of anions of different nature is in agreement with the known lyotropic series.

Abstract—The effect of thermal and steam treatment on the oxidation state of surface functional groups formed in preparation of granulated carbons from cotton lignin was studied by means of IR spectroscopy and titration with bases of varied strength.

Activated carbons prepared from vegetable raw materials (lignin, fruit kernels, sawdust, peat, nut shells, etc.) are widely used as sorbents. Compared with the known carbons (KAD-iodine, AG-3, and SKT), carbons of this type show higher activity in extraction of precious metals from process solutions after leaching of gravel concentrate.

The formation of the pore structure in active carbons has been studied in sufficient detail, but its chemical origin requires a more thorough study, since the polarity of active carbon surface, determined by surface oxides, and, consequently, the acid–base properties of the surface strongly affect carbon sorption of various substances.

The aim of this study was to analyze by means of IR spectroscopy [1, 2] and titration in various media [3–5] the chemical properties of the surface of activated carbon prepared from cotton hydrolytic lignin.

EXPERIMENTAL

Carbonized carbon samples were prepared at 400–700°C and then activated with superheated steam with addition of 2% oxygen at 800°C. Samples with different combustion losses were obtained by varying the activation time between 15 and 60 min. The total acidity was estimated by back titration with *n*-butylamine [3]. For this purpose, weighed portions (0.5 g) of granulated carbons under study were placed in flasks with ground stoppers, each containing 15 ml of a 0.01 N solution of butylamine in benzene. After periodic shaking for a few hours and clarification, an aliquot portion of the solution was titrated with a 0.005 N solution of acetic acid in benzene. The titration was performed until the Bromophenol Blue indicator changed its color, and then the amount of *n*-butylamine necessary for neutralization of the surface acidic centers was calculated.

It was found experimentally that, when the time of contact between a weighed portion of carbon and a benzene solution of a base is longer than 5 h, no further increase in the neutralization occurs. To differentiate between the acidic surface groups, the interaction of samples with aqueous basic solutions was studied by potentiometric titration. As in [4], we assumed that $NaHCO_3$ neutralizes the strongest acidic centers (H^+), Na_2CO_3 and weaker carboxyls (–COOH), NaOH, and phenolic hydroxyls. In addition to the above groups, C_2H_5ONa also reacts with alcoholic hydroxyls. Using the method of separate weighed portions, we found that under the conditions preventing CO_2 adsorption from air, the highest rise in neutralization is observed during the first 24 h of carbon contact with 0.005 N aqueous solutions of bases. Further, the concentration of acidic centers, especially those determined with $NaHCO_3$ and Na_2CO_3, changes only slightly. Therefore, in this stage of the study, we exposed the test samples to corresponding solutions for 1 day. The IR spectra of the activated carbons in KBr were recorded on a Pay Unicam spectrophotometer.

The IR spectra of the samples carbonized at 400°C contain a set of absorption bands in the interval 3600–430 cm^{-1}; the intensity of these bands markedly decreases with increasing carbonization temperature (see the figure). The absorption bands in the 3500–3330 cm^{-1} range can be assigned to (O–H) stretching vibrations of alcohols, phenols, carboxylic acids, and

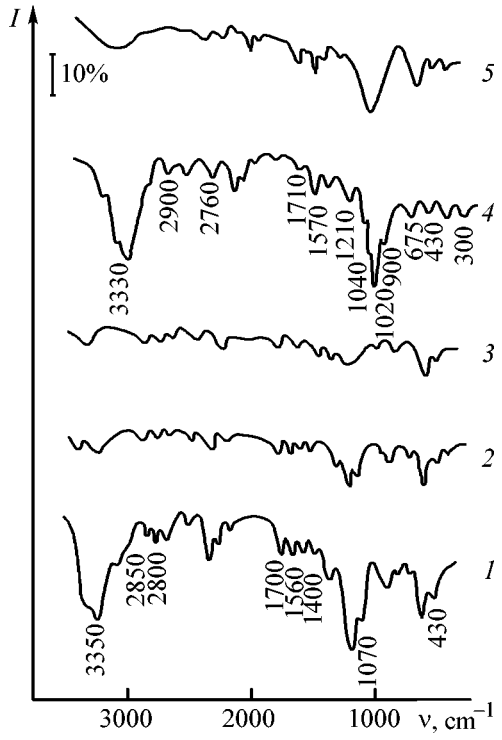
* Samples activated at 800°C following carbonization.

adsorbed water molecules. However, these frequencies are also a characteristic of stretching vibrations of free and associated (NH_2), (NH), and (C=NH) groups. Therefore, their presence, especially in samples containing up to 2% nitrogen and carbonized within 400–600°C, is rather probable. The weak bands at 2860 and 2800 cm^{-1} unambiguously characterize (C–H) vibrations of the methyl and methylene groups, which, along with a number of (C=O) vibrational bands in the range 1790–1625 cm^{-1}, points to simultaneous presence of compounds containing a carbonyl group in aldehydes and acids. A low-frequency shift of the (C=O) vibrations indicates the formation of intramolecular hydrogen bonds. The presence of oxygen-containing compounds at the surface is also confirmed by the bands at 1413–1440 cm^{-1}, related to bending vibrations of alcoholic hydroxyls, and bands at 1200–1070 cm^{-1} due to (C–O) vibrations of alcohols and phenols. The formation of the surface structures of aromatic type in the course of lignin carbonization can be judged, in particular, from the presence of skeletal vibrations, including (C=C) vibrations at 1600–1585 and 1500–1400 cm^{-1}, and from the out-of-plane bending vibrations of (C–H) in the range 900–675 cm^{-1}.

Analysis of the IR spectra of the carbonized lignin carbons indicates a gradual decrease in the intensity of vibrations of the hydroxyl-containing compounds with the carbonization temperature increasing from 400 to 800°C. This result correlates well with the measured concentration of acidic centers of varied nature (see the table) and confirms their close thermal stabilities. The total acidity of the carbonized samples decreases monotonically with increasing carbonization temperature. Before activation no basic centers are found. The estimate of the amount of surface groups titrated in aqueous media with bases of different strengths shows that high-temperature carbonization raises solely the concentration of the weakest acidic centers formed by alcoholic hydroxyls. At the same time, the number of strong protonic centers and weaker acidic centers decreases.



IR spectra of lignin carbons carbonized at (*1*) 400, (*2*) 600, and (*3*) 800°C and those activated at 800°C after carbonization at 700°C with combustion loss of (*4*) 12% and (*5*) 36.6%. (*I*) Absorption intensity and (ν) wave number.

The total acidity of the activated samples is the highest at a 36.5% combustion loss and, on the whole, is lower than that of carbonized samples. In the initial stage of activation, at a 12% combustion loss, a large amount of phenolic and alcoholic hydroxyls is formed. Correspondingly, the intensity of the IR bands at 3330 and 1089–1210 cm^{-1} due to (O–H) and (C–O) stretching vibrations reaches a maximum. It is in this sample that the maximum concentration of strongly acidic COOH and H^+ groups is observed. With increasing activation time, up to a 50% combustion loss, a part of alcoholic hydroxyls undergoes deeper oxidation to carboxyls and aldehydes. This follows from the gradual increase in the intensity of the absorption bands at 1700–1720 cm^{-1}, related to (C=O) stretching vibrations, and a decrease in the intensity of absorption bands at 3330–3350 cm^{-1}, associated with stretching vibrations of the (O–H) bond. Simultaneously, two new bands appear in the IR spectra: strong asymmetric band at 1570 cm^{-1} and a weaker band at 1400 cm^{-1}, due to symmetric stretching vibrations, which is characteristic of carboxylate ions [1].

In our opinion, burning out of organic substances in activation of lignin carbons releases alkali and alkaline-earth metal cations, which, interacting with carboxy groups, block part of strongly acidic centers. Thus, the unexpectedly low acidity of activated samples is due to partial neutralization of the surface carboxy and proton acidic groups by sodium, potassium, magnesium, and calcium ions produced in dissolution of ash particles in adsorbent pores under the action of steam in the course of activation. At higher combustion losses, corresponding to a (8–12%) ash content, the alkali and alkaline–earth metal compounds incorporated into the ash lead to the appearance of basic centers on the background of further decreasing acidity.

In addition to the bands related to various oxygen-containing compounds formed in preparation of active carbons, the IR spectra contain absorption bands whose assignment encounters certain difficulties. For example, a set of bands in the range 2600–2000 cm^{-1} can be attributed to acetylene compounds or to sulfur-containing compounds. The formation of the latter is rather probable in view of the fact that acid lignin containing sulfuric acid is used for preparing the carbons. Thus, the high-frequency bands in the range 2600–2490 cm^{-1} can be attributed to partial reduction of sulfate ions to hydrogen sulfide, present in chemisorbed state in the carbon pores. The strongest bands corresponding to (S–H) bond vibrations are observed at 2636 and 2423 cm^{-1} on a sample carbonized at 400°C. Their intensity falls with increasing carbonization temperature.

Several types of centers with different adsorption activities are formed at the surface in preparing activated carbons [5]. CO, CO_2, and other gaseous products of incomplete oxidation of lignin are physically and chemically adsorbed on the surface of freshly prepared carbon. Owing to the mobility of adsorbed molecules, the most active defect structures are saturated first and form secondary adsorption centers of different nature. According to [1], gaseous CO is characterized by absorption band at 2143 cm^{-1}, associated with stretching vibrations, and gaseous CO_2, by bands at 2349 and 667 cm^{-1} [1]. The surface structures responsible for the higher-frequency bands in the 2200–2140-cm^{-1} range are easily removed from the surface by roomtemperature vacuum treatment, and, consequently, are weakly bound to the surface by Van der Waals forces. Therefore, their appearance in the IR spectra can be attributed to the adsorbed carbon oxides.

CONCLUSIONS

(1) Functional groups whose acidic properties become weaker in going from H^+, to –OOH, and further to –OH groups of phenol-like compounds and alcohols are identified on the surface of active carbons prepared from cotton lignin.

(2) Raising the carbonization temperature from 400 to 800°C makes the concentration of the surface acidic centers lower.

(3) The activation of carbonized carbons with superheated steam at 800°C is accompanied by additional formation of carboxy groups up to 40% combustion loss.

(4) Lignin carbons containing only acidic functional groups, or those containing both acidic and basic centers simultaneously, can be prepared by varying the combustion loss in activation of lignin carbon.

SORPTION AND ION-EXCHANGE PROCESSES

Depassivation of Ion-Exchange Membranes in Electrodialysis

Abstract—Procedures were developed to prevent precipitation on the ion-exchange membrane surface in demineralization of natural hydrocarbonate water by electrodialysis.

Owing to the steadily growing consumption of pure water, its preparation by demineralization of natural water is of interest not only from the scientific and engineering, but also from the social and political standpoints [1]. At present, the most efficient and environmentally safe water treatment procedures are based on membrane processes [2]. In desalination of sea and ocean water, reverse osmosis membranes are the most appropriate. At the same time, in demineralization of the surface and underground brackish water, use of electrodialysis with ion-exchange membranes is preferable. A schematic of a five-compartment electrodialyzer including alternating anion- and cation-permeable membranes is shown in Fig. 1. In commercial electrodialyzers, the number of desalination and concentration compartments may be as large as several tens or even several hundreds. To prevent precipitation at the (anion-exchange membrane)–solution interface, caused by the increasing pH in this zone, the electrodialysis of natural water is performed at current density lower than the limiting diffusion current.

In standard electrodialysis modes, a concentration polarization occurs, resulting in alkalization of the aqueous solution at the boundary between the ion-exchange membrane and the aqueous phase owing to irreversible water dissociation. In particular, when the limiting diffusion current through the boundary layer between the anion-exchange membrane and solution is exceeded, the irreversible water dissociation is caused by selective electromigration of hydroxy anions across the membrane. These hydroxy anions are accumulated in the opposite boundary layer of the anion-exchange membrane in the concentration compartment *3* (Fig. 1). The increased concentration of hydroxy anions in compartment *3* results in the formation of precipitates of poorly soluble calcium carbonate, magnesium hydroxide, and calcium sulfate. According to [3], calcium sulfate does not affect the electrochemical characteristics of the ion-exchange membranes. As opposed to calcium sulfate, calcium carbonate and magnesium hydroxide, precipitating at the interface, shield the transmembrane current in the area of their deposition. At the same time, the current density through free surface increases to a level consider-

ably exceeding the limiting diffusion current density. These processes passivate the membranes, raise their electrical resistivity, reduce the membrane conductivity, and, finally, suppress the electrodialysis.

Deterioration of electrodialysis can be prevented by decreasing the current density to a level lower than the limiting diffusion current density. However, such a procedure decreases the output of demineralization and, what is more, the irreversible water dissociation can proceed at these current densities, too, owing to the catalytic effect of ionogenic groups of the ion-exchange membranes [4].

There are several ways to prevent precipitation. The passivated membranes can be regenerated by repeated (several times an hour) reversal of current [5]. The membranes can also be depassivated by treatment with a reagent capable of dissolving $CaCO_3$ and $Mg(OH)_2$ precipitates, e.g., by passing a dilute aqueous HCl solution with pH 4.5 through the concentration compartment [6]. One more, widely used technique for membrane depassivation is based on preliminary removal of calcium and magnesium from mineralized water by their precipitation in the form of poorly soluble hydroxides. The alkaline aqueous solution used for magnesium and calcium precipitation is prepared by electrodialysis of a salt solution with bipolar membranes [7], allowing simultaneous preparation of alkaline and acidic solutions. Calcium and magnesium hydroxide precipitates are filtered off, and the filtrate is passed through a column packed with cation exchanger in the H^+ form. This cation exchanger is regenerated by passing aqueous acidic solution prepared by electrodialysis of a salt solution with bipolar membranes. In this work, we developed an electrochemical technique for binding hydroxide and carbonate anions, which prevents formation of poorly soluble calcium carbonate and magnesium hydroxide on the ion-exchange membrane surface in electrodialysis of mineralized water.

In our experiments, we used Voronezh tap water containing 9 mM of magnesium and 1.43 mM of calcium ions. If the product of the concentration of the calcium cations and hydroxide anions exceeds the solubility product, a poorly soluble precipitate of magnesium hydroxide is formed:

$$[Mg^{2+}][OH^-]^2 > K_{s1} = 6.0 \times 10^{-10}. \quad (1)$$

This expression shows that at magnesium hydroxide can precipitate from the tap water at pH > 10.1.

Calcium carbonate precipitation is described by the expression

$$[Ca^{2+}][CO_3^{2-}] > K_{s2} = 3.8 \times 10^{-9}, \quad (2)$$

which shows that this process is more probable than magnesium hydroxide precipitation.

It is known that the carbonate concentration depends on pH (dissociation constant of bicarbonate anion $K_2 = 4.8 \times 10^{-11}$). At a bicarbonate concentration in supply water equal to 2.3 mM, precipitation of calcium carbonate starts at pH > 7.38. Therefore, even upon a small increase in pH of the initial water, calcium carbonate can precipitate in the concentration compartment *3* (Fig. 1).

Our experiments were performed with a five-compartment electrodialyzer with alternating anion- and cation-exchange membranes, platinum anode, and stainless steel cathode. MA-41I anion-exchange heterogeneous membranes were prepared from a composite containing AV-17 strongly basic isoporous anion exchanger (65%) with benzyltrimethylammonium monomeric units and polyethylene matrix.

It was found [8] that, in electrodialysis of carbonate solutions, anion-exchange membranes based on a strongly basic anion exchanger are preferable to membranes containing a resin with weakly basic ionogenic groups. These membranes provide higher current efficiency and smaller consumption of electric power. The commercial MA-40 anion-exchange membranes prepared from EDE-10P medium-basic anion exchanger contain, along with trimethylammonium groups (10–12%), secondary =NH and tertiary ≡N amino groups functioning as ionogenic groups in acidic media only. However, anions of weak acids are protonated in acidic media, and, as a result, the ionic transmembrane transfer decreases. Furthermore, MA-41I resin provides more complete removal of silica derivatives from natural water. Their removal is complete at pH > 12. In the neutral medium the removal of silica derivatives is also sufficiently high. Their transference number for MA-41I membrane is 0.39, which significantly exceeds that for MA-40 membrane (0.09) [9]. These facts were the main arguments in favor of the use of MA-41I membrane.

MK-40 cation-exchange heterogeneous membranes were prepared from a formulation containing KU-2 strongly acidic sulfonic cation exchanger and polyethylene. The electrodialyzer compartments are 120 cm high, 1 cm wide, with intermembrane spacing of 0.09 cm. The desalination compartments *2* and *4* were packed with anion-exchange gauze with granules of the anion exchanger in the cells. The concentration compartment *3* was packed in the same way with cation-exchange gauze and cation-exchange granules.

The way of packing of the intercompartment space with the ion-exchange materials is illustrated in Fig. 2. The ion-exchange gauzes and the corresponding ion-exchange membranes were prepared from the same material. The cells of the anionexchange gauze located in the desalination compartment were packed with AV-17 anion exchange granules. Similarly, the cells of the cation-exchange gauze in the concentration compartment were packed with KU-2 cation exchanger granules. The initial tap water with resistivity of 2 kΩ cm was clarified and then continuously passed through all the compartments at a velocity of 2.2 cm s^{-1}. The resistivity of the initial and desalinated water was determined on a VM-484 semiautomatic bridge in a flow-type conductometric cell with platinum platinized electrodes. A VSA stabilized rectifier was used as direct current source. The current was measured with an M-104 ammeter. The voltage across the electrodialyzer was measured with a V7-15 high-resistance voltmeter. The pH of the medium was measured with an EV-74 ionometer with a glass electrode. Calcium and magnesium were determined complexometrically. Carbonate anions were determined by acidometric titration.

Figure 3 shows the resistivity of desalinated water as a function of the current density. These data show that electrodialysis at current densities within the range $0.25 < i < 0.50$ mA cm^{-2} raises the resistivity from 2 kΩ cm in the initial water to 100–120 kΩ cm in the desalinated product. Electrodialysis at high current density allows preparation of water with characteristics similar to those of double-distilled water. However, to prevent precipitation in prolonged operation of an electrodialyzer, reversal of the water feed is required when the total resistance of the apparatus becomes high. Water demineralized in the first electrodialysis stage can be fed into the second stage of electrodialysis. In this case, the intermembrane space of the desalination compartments should be packed with a mixture of anion and cation exchangers. Such a two-stage treatment of tap water allows preparation of highly desalinated water with resistivity of 20 MΩ cm [10]. This water, with parameters similar to those of the double-distilled water, can be converted into ultrapure water by passing through a mixture of anion and cation exchangers.

Figure 4 illustrates the effect of the current density on the pH of water flowing out from both the desalination and concentration compartments. As seen from curve *2*, the water flowing out of the concentration compartment, where sedimentation is the most probable, has acidic reaction ensuring depassivation of membranes. On packing the desalination compartment with anion exchanger, we did not found any noticeable increase pH. This phenomenon is due to complicated electrochemical processes occurring in the course of electrodialysis with intermembrane space packed with ion exchangers.

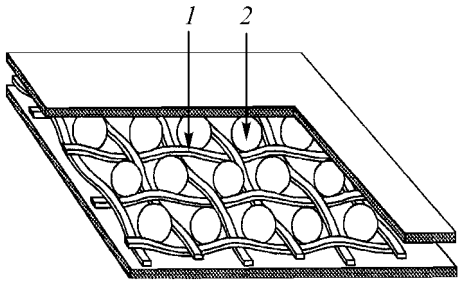

Fig. 2. Packing of the intermembrane space with (*1*) ion-exchange gauze and (*2*) granules.

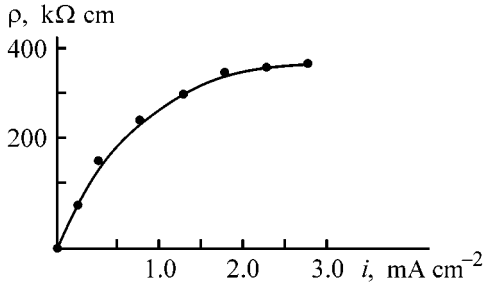

Fig. 3. Resistivity ρ of desalinated water vs. the current density *i* in the electrodialyzer with intermembrane space packed with ion-exchange gauze and granules. Velocity of water feed 2.2 cm s^{-1}.

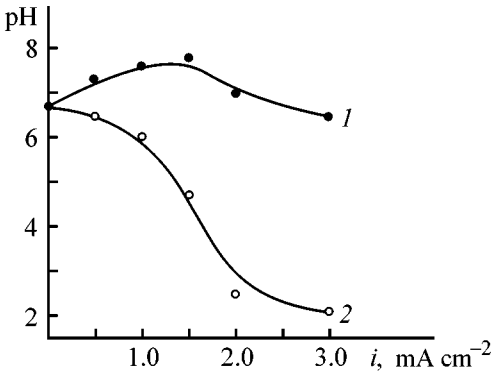

Fig. 4. pH of solutions flowing out of (*1*) desalination and (*2*) concentration compartments vs. the current density *i* in elecrodialysis of weakly mineralized calcium hydrocarbonate water.

The main processes responsible for desalination in electrodialysis occur at the heteropolar boundaries of anion-exchange granules and cation-exchange membranes (Fig. 5). It was established [11] that, in polarization indicated in Fig. 5, the features of the hetero-

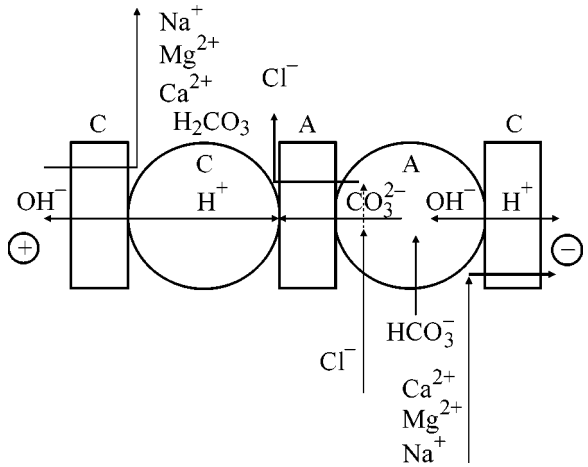

Fig. 5. Scheme of membrane depassivation in two adjacent compartments in electrodialysis of calcium hydrocarbonate water: (C) cation-exchange membranes and granules; (A) anion-exchange membranes and granules.

polar boundaries between the cation-exchange membrane and anion-exchange granules and between the anion-exchange membrane and cation-exchange granules are similar to those of the internal boundary of a bipolar membrane generating hydrogen and hydroxide ions. We believe that the following mechanisms are responsible for this similarity. The exhaustive desalination of water within the capillary heteropolar contact is reached even at very small current densities. Under these conditions, the current is maintained only by irreversible dissociation of water molecules. The high efficiency of this process is ensured by migration of protons and hydroxy anions across the cation-exchange membrane and through anion-exchange granules, respectively (Fig. 5).

In migration through the anion-exchange granule the hydroxy anions react with hydrocarbonate anions sorbed from water. As a result, the hydroxy anion concentration decreases and hydrocarbonate anions are converted into carbonate anions:

$$OH^- + HCO_3^- = CO_3^{2-} + H_2O.$$

Carbonate anions migrate toward the anode through the anion-exchange granules located within the desalination compartments *4* and *2* (Fig. 1) and also across the anion-exchange membranes separating compartments *4* and *3* and *1* and *2* into the concentration compartment *3* and anode compartment *1*, respectively. It was found [12] that the electromigration rate of carbonate anions exceeds that of bicarbonate anions [12].

Hydrogen ions formed by irreversible dissociation of water at the heteropolar contact between the cation-exchange membrane and anion-exchange granule migrate toward the cathode from the desalination compartment to the concentration compartment *3* and then through a cation-exchange granule to the heteropolar contact between the anion-exchange membrane and cation-exchange granule. At polarization indicated in Fig. 5, the following reaction occurs in the capillary space of this heteropolar contact:

$$2H^+ + CO_3^{2-} \rightarrow H_2CO_3 = H_2O + CO_2\uparrow.$$

By this reaction, carbonate anions are converted into weakly dissociating carbonic acid which partially decomposes to give water (target product) and carbon dioxide.

Figure 4 (curve *2*) shows that the pH in the concentration compartment grows with increasing electromigration of hydrogen ions across the cation-exchange membrane. This effect prevents precipitation of calcium carbonate and magnesium hydroxide.

What is more, even when calcium carbonate is precipitated under favorable local conditions, it is converted in any case into soluble calcium bicarbonate by the reaction with active carbon dioxide liberated in carbonic acid decomposition:

$$CO_2 + H_2O + CaCO_3 = Ca(HCO_3)_2.$$

Neutral or weakly alkaline medium in the desalination compartment can facilitate calcium carbonate precipitation. However, this precipitate is continuously dissolved owing to the transfer of calcium and carbonate ions from the saturated solution across the cation and anion-exchange membranes, respectively [13]. This electrochemical process prevents precipitation in the desalination compartment.

CONCLUSIONS

The following factors prevent precipitation in electrodialysis of calcium hydrocarbonate water: (1) conversion of hydroxy anions formed by nonlinear concentration polarization into water molecules by the reaction with hydrocarbonate anions, (2) localization of the reaction of carbonate anions with hydrogen ions within the capillary space of the heteropolar conrtact between the granular ion exchanger and ion-exchange membrane, (3) dissolution of calcium carbonate by the reaction with carbon dioxide, (4) control of pH in the desalination and concentration compartments by packing the intermembrane space with ion exchangers, and (5) electrochemical dissolution of calcium carbonate formed the desalination compartment.

SORPTION AND ION-EXCHANGE PROCESSES

Features of Preparation and Properties of FIBAN K-4 Fibrous Sorbents

G. V. Medyak, A. A. Shunkevich, A. P. Polikarpov, and V. S. Soldatov

Institute of Physical Organic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received February 5, 2001

Abstract—Liquid-phase graft polymerization of acrylic acid on polypropylene fiber after preliminary gamma irradiation was studied as influenced by the ratio of the concentration of peroxides formed during gamma irradiation (^{60}Co) of polypropylene in air to the Fe(II) concentration in the reaction solution. The ion-exchange and mechanical properties of monofunctional carboxylate cation exchanger prepared by the developed procedure were studied.

FIBAN K-4[1] fibrous cation exchanger is a polypropylene (PP) fiber with grafted acrylic acid (AA). Fibrous ion exchangers with carboxy groups are widely used to remove ammonia, amines, and alkali aerosols from air, and cations of nonferrous and heavy metals from water [1–5]. Commercial ion exchangers based on cellulose and polyamides are insufficiently stable in acid solutions, which complicates their regeneration. Fibrous polyacrylonitrile-based anion exchangers have good chemical and mechanical stability, but contain not only carboxy groups but also amidoamine, hydrazide, and ammonium groups. Hence, all technological prescriptions should be strictly followed in production of these ion exchangers and in their use for purification of tap water and also for medical and biological purposes.

From this standpoint, development of a simple and efficient procedure for preparing monofunctional carboxylate cation exchanger based on strong, chemically inert, and nontoxic fiber is an urgent problem. The initial polypropylene fiber chosen for this purpose was functionalized with carboxy groups by graft polymerization of acrylic acid. Granulated acrylic acid–methacrylic acid copolymers cross-linked with divinylbenzene and triacryloyltriazine are widely used in medicine and biology [6].

Several procedures for preparing PP fibers with grafted AA are known [7–9]. Tsetlin *et al.* [10] prepared these fibers by direct irradiation under AA vapor at reduced pressure. This fiber, named KATIOLAN, has good physicomechanical properties and is stable in repeated acid-alkali treatment. This fiber is successfully used in production of protective working outfit. At the same time, maintaining reduced pressure of AA in an installation exposed to gamma radiation is a complicated problem. Furthermore, the problem of efficient removal of the heat of grafting under these conditions has not been solved. This results in nonuniformity of fibers as regards the degree of grafting and exchange capacity. It should also be noted that grafting from an unsaturated AA vapor is a slow process.

EXPERIMENTAL

FIBAN K-4 sorbent was prepared by gamma irradiation of PP fiber with a ^{60}Co source in air, followed by liquid-phase graft polymerization of AA on peroxide groups of the PP in the presence of Fe(II) salts as reducing agents. We used the following starting materials: PP fiber (66-mm staple) with linear density of 0.33 tex, produced at Khimvolokno Kursk Production Association [TU (Technical Specifications) 6-06-535–76]; AA stabilized with Lauroks-9 (Shostka Chemical Plant); $FeSO_4$ and Mohr's salt of pure grade, ferrocene of technical grade; and iron(II) acrylate prepared from FeO and AA.

The starting PP staple was washed with benzene in a Soxhlet apparatus to remove the stabilizer and lubricant. The staple was irradiated on UGU-400 and RKhM γ-20 gamma irradiation units without tempera-

[1] This cation exchanger was developed at the Institute of Physical Organic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus.

1070-4272/01/7410-1658 $25.00 © 2001 MAIK "Nauka/Interperiodica"

ture control and without using additional equipment in the irradiation zone. The dose rate ranged from 0.5 to 4.7 Gy s^{-1}. The total radiation dose was 114 kGy. The content of peroxy and hydroperoxy groups in irradiated samples was determined by iodometric titration [11] after irradiation, during storage, and just before graft polymerization.

The graft polymerization was done from aqueous solutions of AA under nitrogen in the presence of iron(II) salts. The AA concentration ranged from 7.5 to 80 %. The iron(II) concentration was varied from 0.1 to 6.0 g l^{-1}, which corresponds to 0.05–0.60 g-equiv of iron(II) per 1 g-equiv of peroxy groups. The reaction temperature was varied from 353 K to the boiling point of the solution. The bath ratio (the ratio of liquid and solid phases) ranged from 7 to 100 ml g^{-1}. The degree of grafting was expressed as a percentage of the initial PP weight.

The properties of PP fibers were studied after both irradiation and grafting. The deformation-strength parameters of monofilament were measured on a UMIV-3 universal testing machine [12]. The acidity of the ion exchangers was determined by potentiometric titration [13]. The stability of the ion exchange fiber in aggressive media was characterized by GOST (State Standard) 10899–75 [14].

The synthesis of FIBAN K-4 cation-exchanger was performed as shown below

$$[-CH_2-\underset{\displaystyle CH_3}{\underset{|}{C}}H-]_n + O_2 \xrightarrow{\gamma\text{-ray}} [-CH_2-\underset{\displaystyle OOH}{\underset{|}{\overset{\displaystyle CH_3}{\overset{|}{C}}}}-]_m, \quad (1)$$

$$[-\underset{\displaystyle CH_3}{\underset{|}{C}}H_2-CH-OO-CH_2-]_p + CH_2=\underset{\displaystyle COOH}{\underset{|}{CH}}$$

$$\xrightarrow{Fe^{2+}} [-CH_2-\underset{\displaystyle COOH}{\underset{|}{CH}}-]_q + \text{PP-graft-AA (FIBAN K-4)}. \quad (2)$$

When PP fiber is irradiated with ^{60}Co gamma-rays (1), peroxy and hydroperoxy groups are formed in the sample. Their concentration was determined by iodometric titration on keeping the samples in a solution of sodium iodide in acetic anhydride at $T \geq 333$ K for no less than 10 min. Reaction (2) does not occur after this treatment, i.e., peroxy and hydroperoxy groups initiating this reaction are completely decomposed. After a similar treatment at room temperature for 0.5 h, as recommended in [11], the polymerization is still observed in the system, i.e., the initiating centers are preserved. In addition, the degree of grafting, *P*, and the amount of the homopolymer formed, *H*, are close to those for untreated PP fibers (e.g., *P* is 39 and 37%, and *H*, 1.0 and 0.8%, respectively).

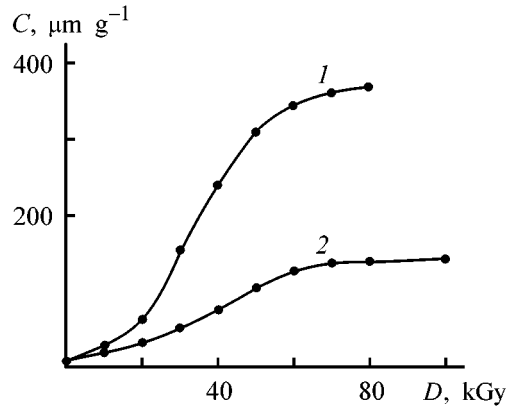

Fig. 1. Accumulation of peroxy and hydroperoxy groups in PP fiber at a dose rate of (*1*) 4.7 and (*2*) 0.5 Gy s^{-1}. (*C*) concentration and (*D*) radiation dose.

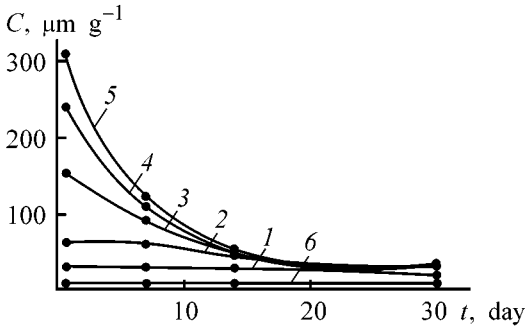

Fig. 2. Total concentration *C* of peroxy and hydroperoxy groups in PP fiber irradiated with (*1*) 10, (*2*) 20, (*3*) 30, (*4*) 40, and (*5*) 50 Gy and (*6*) in the unirradiated sample vs. time *t* of their storage in air at 277–278 K.

As seen from Fig. 1, the concentration of peroxy and hydroperoxy groups grows with increasing total radiation dose until equilibrium between their formation and degradation (individual for each dose rate) is attained. At a dose rate I = 0.5 Gy s^{-1}, the content of peroxy groups in the fiber levels off and reaches 120 μmol g^{-1} at a total radiation dose D = 60 kGy. At I = 4.7 Gy s^{-1}, the content of peroxy groups levels off at a total dose D = 70 kGy and reaches 360 μmol g^{-1}, which suggests the presence of a large number of reaction centers in the PP fiber.

Although peroxy groups are stable at ambient temperature [15], we found that their content in irradiated PP fibers decreases exponentially during their storage even in a refrigerator at 277–278 K (Fig. 2). The composition of irradiated PP fiber stored for 30 days approaches that of unirradiated samples. Hydroperoxy groups present in small amounts in the fiber are

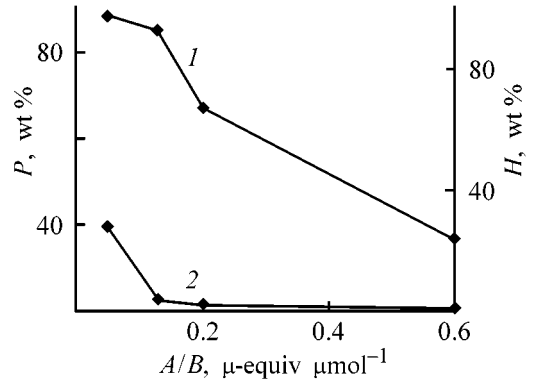

Fig. 3. (*1*) Degree of AA grafting, *P*, and (*2*) the amount of AA homopolymer, H, after polymerization from a 30% AA solution at 373 K for 3 h vs. the ratio of iron(II) concentration *A* to the content of peroxy groups in irradiated PP fiber, *B*.

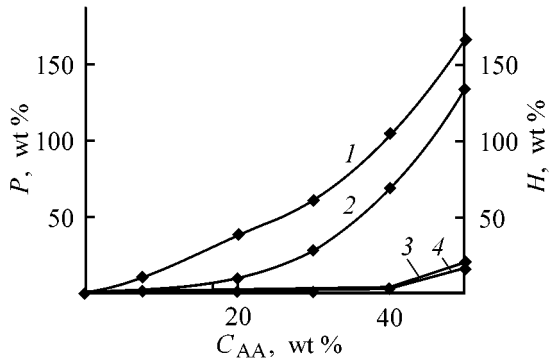

Fig. 4. (*1*, *2*) Degree of AA grafting, *P*, and (*3*, *4*) the amount of AA homopolymer, *H*, after graft polymerization at 373 K for 3 h vs. the AA concentration C_{AA} in the initial solution at a total concentration of peroxy and hydroperoxy groups of (*1*, *3*) 370 and (*2*, *4*) 269 μmol g^{-1}.

unstable even at low temperatures and decompose into radicals:

$$R\text{–}OOH \rightarrow RO^{\cdot} + OH^{\cdot}.$$

These radicals, in their turn, catalyze decomposition of the peroxy groups. To increase the efficiency of AA grafting, graft polymerization (2) should be performed as soon as possible after sample irradiation (1). Hence, the main features of graft polymerization (2) will be determined by the concentration of peroxy and hydroperoxy groups present in the sample by the time of grafting, rather than by the total radiation dose.

The graft polymerization and AA homopolymerization by reaction (2) strongly depend on the molar ratio of Fe(II) concentration in the solution, *A*, to the content of peroxy groups in irradiated PP fiber, *B*, and on the ratio of peroxy and hydroperoxy groups. As seen from Fig. 3, high degrees of AA grafting to PP at negligible formation of AA homopolymer are obtained in a narrow *A*/*B* range 0.1–0.2. If homopolymerization is initiated by OH radicals formed by decomposition of hydroperoxy groups, the content of peroxy groups initiating the graft polymerization should be 4–9 times higher than that of hydroperoxy groups which initiate to the same extent of both the graft polymerization and homopolymerization, even without taking into account the possibility of occurrence of chain-transfer reactions.

When ferrocene and Fe(II) acrylate were used as inhibitors, AA was grafted to PP fiber from an 80% aqueous solution of AA at 353 K [16]. With inorganic Fe(II) salts, the suitable AA concentration was 7.5–50 wt %. The homopolymer formation in the presence of ferrocene is 2–3 times more intensive than that in the presence of other Fe(II) compounds. Taking into account that Fe(II) acrylate is unstable in air, we used $FeSO_4$ and Mohr's salt for preparing experimental batches of grafted fiber.

Since the degree of AA grafting to PP fiber grows exponentially with increasing concentration of peroxy groups in PP, the influence of various factors on the graft polymerization was studied at rather high peroxy concentrations in a preirradiated PP fiber (C = 370 and 269 μg-equiv g^{-1}). The working concentration of AA in the solution ranged from 30 to 40% (Fig. 4). When the AA concentration is lower than 30%, the graft polymerization should be performed at higher content of peroxy groups in the starting fiber (about 400 μg-equiv g^{-1}). In solutions with AA concentration greater than, or equal to 50%, the homopolymer yield increases along with a sharp rise in the degree of grafting. In this case, it is difficult to wash out gelatinous polyacrylic acid (PAA) from the grafted fiber.

The theoretical static exchange capacities (SEC) of carboxylate ion exchangers were calculated from the degree of AA grafting to the PP fiber. The theoretical SECs for cations agree well with the experimental values. The difference between the theoretical and experimental SECs is no higher than 10% (SEC^t = 9.3 and SEC^e = 8.6 mg-equiv g^{-1}) even at high (200 wt %) degree of AA grafting to the PP fiber. This suggests the absence of cross-linking during the grafting and accessibility of all carboxy groups in the grafted fiber.

FIBAN K-4 fibrous carboxylate cation exchanger with SEC of up to 9 mg-equiv g^{-1} was prepared by the above procedure. The acid properties of the cation

exchanger were estimated by theoretical processing of the results of its direct and back potentiometric titration (Fig. 5). Polypropylene fiber with a degree of AA grafting of 98.0% was titrated by the single portion procedure at an initial HCl excess of 1.85 mg-equiv g^{-1} per gram of fiber, using 1 M KCl as the supporting electrolyte. The titrating agent was added at 20-min intervals. The results of calculation of the potentiometric titration curves by Soldatov's procedure [18] allow estimation of the number, quantitative content, and acidity of the functional groups of anion exchanger. This estimation can be performed even when the potentometric titration curve has no pronounced inflection points owing to a large number of functional groups of different kinds in the sorbent and and small difference in their acidities. In this case, it is possible to determine the properties of the functional groups with the same chemical composition but different acidities owing to their different positions or the influence of the adjacent functional groups.

A theoretical processing of the experimental results of potentiometric titration of FIBAN K-4 cation exchanger showed that this fiber is a moderately acidic monofunctional cation exchanger containing carboxy groups with pK 5.3 (ΔpK 2).

The good mechanical properties of FIBAN K-4 ion exchangers and their stable operation in repeated sorption–regeneration cycles and on exposure to aggressive media are of great practical importance. These properties of ion exchangers depend on the conditions of irradiation and grafting, degree of grafting, and nature of reagent.

As seen from Table 1, the deformation strength properties of PP fibers change mainly in the stage of preliminary irradiation. As seen from Fig. 6, the tensile strength σ and elongation at break, ε, of PP monofilaments decrease mainly in the initial stage of irradiation at a total dose D = 30 kGy, which may be due to radiative-chemical oxidation of the strongest chains in the ordered fibers. Further increase in the radiation dose to 70 kGy deteriorates the deformation strength properties of PP fiber only slightly. At a radiation dose of 114 kGy the main parameter of fiber elasticity, the elongation at break, ε, decreases further, to 7%, and the tensile strength, to 80 MPa, which complicates the use of this material as a fiber. Therefore, we used for graft polymerization a PP fiber irradiated at a dose rate of 4 Gy s^{-1} to a total dose of 70 kGy. The content of peroxy groups in the fiber

Untreated cation exchanger	6.2(100)*	16.8(100)	31(100)	NaOH, 5 g-quiv l^{-1}	5.1(82)	14.6(87)	18(58)
H_2SO_4, 5 g-quiv l^{-1}	5.4(87)	15.8(94)	12(39)	H_2O_2, 10 wt %	3.6(58)	10.9(65)	11(36)

* The percentage relative to the initial value is given in parentheses.

ranges from 200 to 400 μmol g^{-1}, depending on the storage time of the irradiated product.

As seen from Table 1, the diameter *d*, breaking force *F*, and elongation at break of the monofilament grow appreciably with increasing degree of AA grafting to PP fiber (up to a degree of grafting of 201 wt %), i.e., the grafted polymer located in amorphous regions of PP fibers improves their mechanical properties. Thus, although the tensile strength of the fiber containing carboxy groups decreases to 9 MPa, this fiber remains sufficiently strong, elastic, and suitable for processing and practical application. The tensile strength σ and the elongation at break, ε, of the fiber can be raised by using 30%, instead of 80% AA solutions in step (2) (Table 1).

The data on the chemical stability of FIBAN K-4 cation exchanger with 96.0 wt % grafted PAA are presented in Table 2. In accordance with the requirements of GOST (State Standard) 10 899–75, a sample was heated on a boiling water bath with 5 N sulfuric acid or 5 N sodium hydroxide for 30 min and then treated with 10 % hydrogen peroxide for 48 h at room temperature. The SEC and tensile strength σ change in concentrated acids and alkalis only slightly, whereas the elongation at break, ε, significantly decreases, especially after treatment with sulfuric acid and hydrogen peroxide. The low stability of the cation exchanger in 10% hydrogen peroxide may be due to low stability of both the PP matrix and grafted PAA in oxidative media. In an additional experiment, we found that the exchange capacity and deformation-strength parameters of FIBAN K-4 cation exchangers do not change after threefold treatment in regenerating solutions (0.5 N HCl and 0.5 N NaOH) at 293 K. The exchange capacity decreases by a factor of 1.3–2.3 after prolonged operation of the cation exchanger in actual sorptionregeneration processes, e.g., in iron removal from water, involving regeneration with 2 N HCl.

The enhancement of the chemical stability and mechanical strength of FIBAN K-4 fibrous cation exchanger is necessary for prolonged multicycle operation of the fiber in aggressive media. Nevertheless, FIBAN K-4 fibrous cation exchanger can be used for additional treatment of water to remove heavy metal cations.

An experimental batch of FIBAN K-4 fibrous cation exchanger with SEC = 4.5 ± 0.2 mg-equiv g^{-1} was prepared by the above procedure. Nonwoven needle-punched material was prepared from the fiber and used in composition of cartridges for Krynichka and Mifil filters for purification of potable water.

CONCLUSIONS

(1) FIBAN K-4 fibrous monofunctional cation exchanger containing carboxy groups with p*K* 5.3 (Δp*K* 2.0) was prepared.

(2) In graft polymerization of acrylic acid to the fiber at 373 K in inert atmosphere the best molar ratio of Fe(II) to peroxide groups in the irradiated polypropylene fiber is 0.1–0.2.

(3) Preferable inhibitors of acrylic acid homopolymerization are $FeSO_4$ and Mohr's salt.

(4) The ion-exchange and mechanical properties of the cation exchanger allow its use in filters for additional purification of potable water.

SORPTION AND ION-EXCHANGE PROCESSES

Extraction of Arsenic(V) with Hexabutylphosphoric Triamide

V. F. Travkin, Yu. M. Glubokov, E. V. Mironova, and V. V. Yakshin

Received December, 1999; in final form, May 2001

Abstract—The effects of the concentrations of sulfuric acid and arsenic in the aqueous phase, concentration of the extractant in the organic phase, temperature, and time of phase contact on arsenic(V) extraction with hexabutylphosphoric triamide were studied, and the arsenic(V) extraction constant was calculated.

Liquid extraction is widely used for recovery of arsenic from sulfuric acid solutions [1]. Various compounds, such as tributyl phosphate (TBP) [2, 3], amines [3] and tertiary ammonium [4] salts, trioctylarsine oxide [5], etc., have been proposed as extractants. The extraction of As(V) compounds from copper- and nickel-containing sulfuric acid solutions has been studied is most detail [6, 7], because the extractive purification of copper electrolyte to remove arsenic is performed on the industrial scale. At foreign plants, TBP is used as an extractant [8]. Presumably, other extractants may be more efficient for extractive recovery of arsenic.

In sulfuric acid solutions, arsenic(V) exists in the form of arsenic acid derivatives. The extractive recovery of As(V) can proceed by both anion-exchange and hydrate-solvate mechanisms. In the first case, extraction is performed with amines or substituted ammonium salts, and in the second case, with neutral organophosphorus compounds $X_3P{=}O$ (X = R, RO, R_2N). The stability of the extractable complexes strongly depends on the basicity of the oxygen atom in the phosphoryl group. Usually both the basicity and the extractive power of compounds with active phosphoryl group increase in the order $(RO)_3P{=}O < RP(O)(OR)_2 < R_2P(O)OR < R_3P{=}O$. High-molecular-weight phosphine oxides ($R \geq C_8H_{17}$) are the most efficient extractants of arsenic(V) in this series. The basicity of phosphoryl oxygen becomes even higher when phosphoric acid amides $(R_2N)_3P{=}O$ are used [8, 9]. This effect is due to a decreasing bond order in the phosphoryl fragment, as a result of competition of nitrogen atoms for 3*d* orbitals of the phosphorus atom and appearance of additional electron density at the phosphoryl oxygen. Yakshin *et al.* [8], determined experimentally the basicity of phosphoric acid amides by potentiometric titration with perchloric acid in nitromethane and found that pK_a increases from 8.75 for tributylphosphine oxide to 9.15 for hexabutylphosphoric triamide (HBPTA). Taking this circumstance into account, we can expect a greater extractive power of phosphoric acid amides with respect to As(V).

In this work, the main features of extraction of As(V) from copper-containing sulfuric acid solutions, with HBPTA as an extractant, were studied.

EXPERIMENTAL

The extractant contained no less than 98–99% of the main substance. The extraction was performed from sulfuric acid solutions containing 4–5 g l^{-1} As(V) at 1 : 1 organic to aqueous phase ratio, stirring time of 10 min, and temperature of $20 \pm 1°C$.

The distribution of As(V) between the aqueous phase and 1.1 M HBPTA solution in kerosene as a function of H_2SO_4 concentration is shown in Fig. 1.

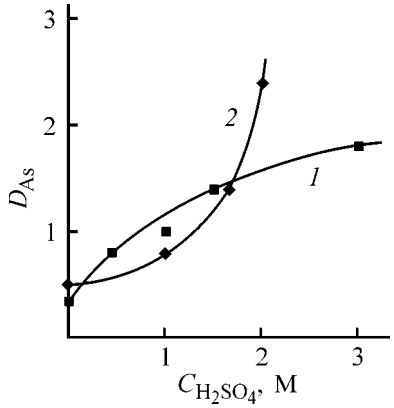

Fig. 1. Effect of sulfuric acid concentration $C_{H_2SO_4}$ on extraction of As(V) with (*1*) TBP and (*2*) 1.1 M HBPTA solution in kerosene. (D_{As}) As(V) distribution coefficient.

1070-4272/01/7410-1664 $25.00 © 2001 MAIK "Nauka/Interperiodica"

As seen, similarly to extraction with TBP, the As(V) recovery grows with increasing H_2SO_4 concentration. The greater basicity of HBPTA ensures As(V) extraction even from weakly acidic solutions. The As(V) recovery with HBPTA from H_2SO_4 aqueous solutions with concentration exceeding 1.5 M is greater than that in the case of TBP.

The dependence of the As(V) distribution coefficients D_{As} on the extractant (HBPTA, TBP) concentration in extraction from 1.7 M H_2SO_4 is shown in Fig. 2. The processing of the experimental data by means of the least-squares method gives the following dependences of D_{As} on the concentration of the unbound extractant:

$$\log D_{As} = 1.90 \log [HBPTA]_{ub} + 0.35, \quad (1)$$

$$\log D_{As} = 2.46 \log [TBP]_{ub} + 0.47, \quad (2)$$

where $[S]_{ub} = [S]_{in} - q[H_3AsO_4]_0 - [H_2SO_4]_0$.

The correlation coefficient for Eqs. (1) and (2) is 0.98.

It follows from Eqs. (1) and (2) that the solvation number q for HBPTA is lower than that for TBP. The obtained solvation numbers suggest that HBPTA recovers arsenic acid mainly in the form of disolvate, while TBP recovers it as a mixture of di- and trisolvates. In the latter case, extraction of a mixture of mono-, di-, and trisolvate is possible. Data of [3] confirm this possibility.

It should be noted that the increase in the As(V) extractive recovery with growing extractant concentration in the organic phase is limited by phase separation.

The reaction of As(V) extraction from sulfuric acid solutions with HBPTA can be represented as follows:

$$m(H^+ + HSO_4^-)_{aq} + nH_3AsO_{4(aq)} + q(HBPTA \cdot hH_2O)_o \rightleftarrows (nH_3AsO_4 \cdot mH_2SO_4 \cdot h_0H_2O \cdot qHBPTA)_o + (h - h_0)H_2O_{aq}. \quad (3)$$

The concentration constants of extraction of arsenic acid with HBPTA and TBP were determined as the slope of the extraction isotherms measured for As(V) dilute solutions at constant H_2SO_4 concentration (Fig. 3). The concentration extraction constants K_{ex} obtained by the least-squares method are listed in Table 1. The correlation coefficient for both extractants is 0.99.

The constant of extraction of arsenic acid from sulfuric acid solutions increases from TBP to HBPTA in parallel with a rise in the extractant basicity.

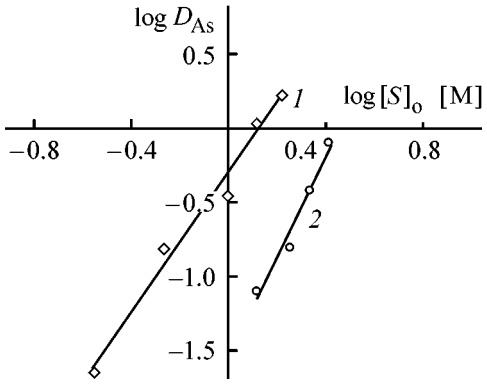

Fig. 2. As(V) distribution coefficient D_{As} vs. extractant concentration in kerosene $[S]_o$: (*1*) HBPTA and (*2*) TBP.

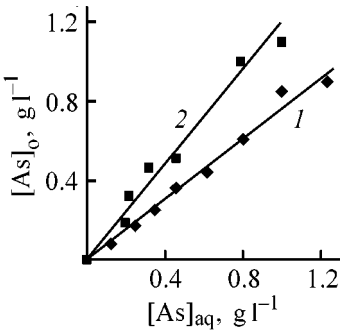

Fig. 3. Isotherms of As(V) extraction from 1.5 M H_2SO_4 with (*1*) TBP and (*2*) 1.1 M HBPTA solution in kerosene. ($[As]_o$, $[As]_{aq}$) As(V) concentrations in the organic and aqueous phases, respectively.

The IR spectrum of HBPTA contains two intense bands ν(P=O) at 1210 cm^{-1} and ν(C–N) at 1180 cm^{-1}. They shift to 1190 and 1170 cm^{-1}, respectively, when arsenic(V) and sulfuric acid are introduced. In addition, new bands characteristic of H-bonded hydroxy groups appear at 1640–1670 cm^{-1}. These changes result from the formation of arsenic acid hydrate-solvates in the organic phase. It is difficult to reveal the ν(As–O) bands because of the superposition of other bands and first of all those of ν(P–N) and ν(C–N). The data obtained show that amide groups hardly participate in coordination with As(V).

Table 4. Distribution of components of the initial sulfuric acid solution between raffinate and backwash in extraction of As(V) with HBPTA

Component extracted	Concentration, g l^{-1}		
	initial solution	raffinate	backwash
As(V)	4.10	1.68	1.81
H_2SO_4	209	201	6.9
Cu(II)	29.6	29.8	0.01
Fe(III)	1.10	1.12	0.01
Fe(total)	1.85	1.84	≤0.01
Sb(III)	0.07	0.07	0.001
Ni(II)	11.8	11.7	0.02
Zn(II)	1.50	1.52	0.005
Co(II)	0.60	0.59	0.001

One of important factors influencing the As(V) recovery is the extraction temperature. A special experiment showed that the arsenic distribution coefficient decreases with increasing temperature (Table 2); for instance, in the range from 20 to 60°C it decreases threefold.

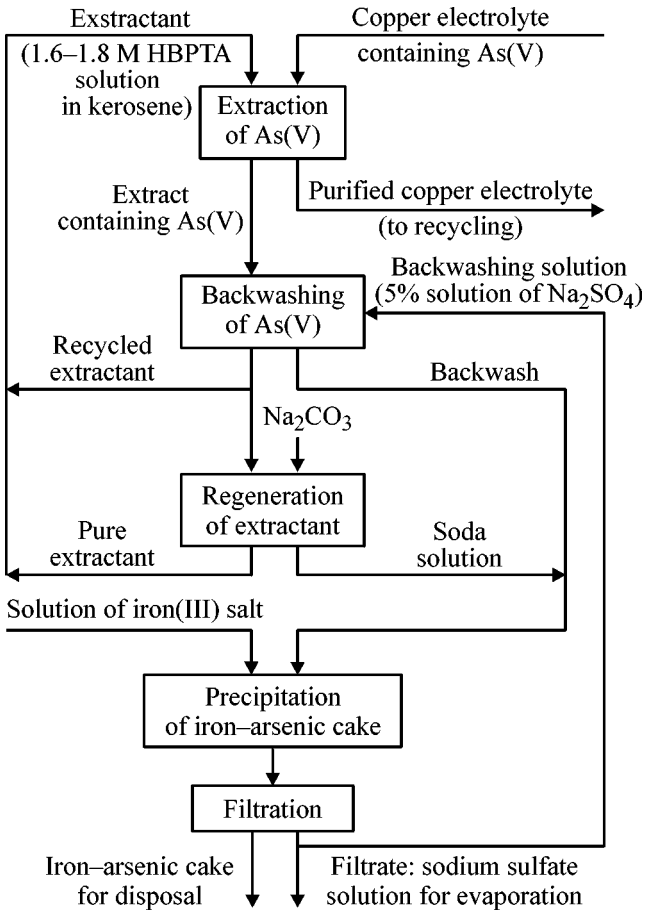
The kinetic parameters of As(V) extraction with HBPTA and TBP differ. Extraction with TBP is characterized by faster transfer of As(V) into the organic phase [10] (Table 3) which is probably due to a larger size of the HBPTA molecule as compared with TBP.

Our results show that the equilibrium of extraction with HBPTA is attained within 3 min.

Data on the extraction of concomitant metals present in the copper electrolyte with 1.5 M HBPTA in kerosene are presented in Table 4. Backwashing was performed with 5% aqueous solution of sodium sulfate at 1 : 1 volume ratio of aqueous to organic phase, stirring for 2 min, and 22 ± 1°C.

Thus, HBPTA, similarly to TBP, extracts only As(V) and sulfuric acid. Coextraction of H_2SO_4 does not exceed 3–4% in a single extraction stage. The counter-current regime of extraction ensures a high degree of purification to remove arsenic(V). For instance, in three stages of countercurrent extraction, the As(V) recovery from the aqueous phase under the above conditions amounts to 84%.

The studies performed allow recommendation of the following scheme for extractive purification of copper electrolyte to remove As(V), with HBPTA as extractant (see scheme).



The extraction process includes the following operations: extraction of As(V) with 1.6–1.8 M HBPTA solution in kerosene [3–5 stages of countercurrent extraction, volume ratio of the organic to aqueous phase (1–1.5) : 1, 25–30°C, time of phase contact 3 min], backwashing of As(V) from the organic phase with 5% aqueous solution of Na_2SO_4 [2–3 stages, volume ratio of the organic to aqueous phase (1–2) : 1, 30–40°C, time of phase contact 3 min], and separation of As(V) in the form of a poorly soluble product (e.g., calcium or iron arsenate) followed by its disposal or conversion to a commercial product (copper arsenate).

In this case, the degree of copper electrolyte purification is 80–90%. The electrolyte can be returned to copper electrolysis or directed to copper sulfate production. The optimal concentration of sulfuric acid in the aqueous phase for As(V) extraction with HBPTA is about 2 M.

Laboratory tests of the above process were performed with an electrolyte containing 11.2 g l^{-1} As and 220 g l^{-1} H_2SO_4 to give raffinates containing 1.2 g l^{-1} As(V) and 189 g l^{-1} H_2SO_4. The content of As(V) and H_2SO_4 in the backwash was 14.3 and 37 g l^{-1}, respectively. The recycling organic phase directed to extraction contained 0.3 g l^{-1} As and 1.1 g l^{-1} H_2SO_4. Thus, the process proposed ensures high degree of arsenic removal at small loss of sulfuric acid.

CONCLUSION

Hexabutylphosphoric triamide is more efficient extractant of As(V) than TBP in extraction from aqueous H_2SO_4 solutions with concentrations of 1.5 M and more. Arsenic is extracted with HBPTA solution in kerosene in the form of mixed hydrate-solvate. The degree of As(V) extraction decreases with increasing temperature. A flowsheet is proposed for As(V) extractive recovery from copper electrolyte with HBPTA solution in kerosene, ensuring high degree of arsenic removal from the electrolyte.

Abstract—Comparative analysis is made of the operation of an extraction block of the LG 35-8/300B benzene reforming unit (Kirishinefteorgsintez Production Association) before and after its upgrade (with triethylene glycol–sulfolane–water mixed extractant used instead of straight triethylene glycol).

It has been demonstrated previously [1–5] that the use of triethylene glycol–sulfolane–water mixed extractant instead of straight triethylene glycol (TEG) for extraction of aromatic hydrocarbons C_6–C_8 from reforming naphthas allows an increase in both the selectivity and solvency of the extractant. As a result of such a modification, the extractant : feed ratio can be decreased, and the degree of recovery of aromatic hydrocarbons from the reforming naphtha, increased.

In 2000–2001, the indicated mixed extractant was introduced in LG 35-8/300B benzene reforming unit (Kirishinefteorgsintez Production Association). The sulfolane content in the extractant was gradually brought to 15 wt %. In this communication, we report on a comparative analysis of the unit operation before and after upgrade.

Before the upgrade, watered crude TEG was used as an extractant. Its composition was as follows (wt %): water 6.0, ethylene glycol 0.7, diethylene glycol 4.4, TEG 88.4, and tetraethylene glycol 0.5.

The mixed extractant composition, extractant : feed ratio (stable reforming naphtha), and also parameters of extraction of aromatic hydrocarbons before and after upgrade are summarized in Table 1. The tem-

Note: (k) Extractant distribution coefficient and (α) degree of recovery.

perature in the extraction and extractant regeneration columns remained unchanged. The results show that the use of the mixed extractant allowed reduction of the extractant : feed and recycle : feed ratios by about 20%, with the total degree of recovery and the product quality remaining practically unchanged, which is due to increased selectivity and solvency of the mixed extractant with respect to arenes. The possibility of diminishing the recycle consumption is due to a stronger intermolecular interaction of sulfolane with arenes. As a result, the benzene and toluene concentrations in the recycle decrease. The decrease in the extractant and recycle consumption allows an increase in the extractor efficiency with respect to the feed by 20%, and also a decrease in the specific power consumption for recovery of arenes.

In another operation mode of the extraction block (March 2001), when the mixed extractant : feed and recycle : feed ratios were the same as with the use of straight TEG, the total degree of recovery of arenes increased by 2.1 wt %. The most significant increase was achieved with respect to recovery of toluene and xylenes (by 2.4 and 10.1 wt %, respectively), which is due to the lower molecular-weight selectivity of sulfolane and, correspondingly, of the mixed extractant as compared with TEG. For example, at 150°C the molecular-weight selectivity [logarithm of the ratio of the limiting activity coefficients of octane and heptane in the extractant $\log(\gamma^0_{oct}/\gamma^0_{hpt})$] is 0.08 and 0.13 for sulfolane and TEG, respectively [6]. The lower molecular-weight selectivity, along with an increased group selectivity with respect to arenes, allows more efficient extraction with the mixed extractant of not only benzene, but also higher-boiling arenes from fractions with relatively wider boiling ranges. At a potential output of 300 000 t with respect to the feed, an 85–87 wt % yield of stable naphtha, and a 40–45 wt % content of arenes C_6–C_8 in it [7], the unit can additionally produce 2.2–2.4 thousand tons of aromatic hydrocarbons annually.

In the initial period of operation of the unit on the mixed extractant, an increased loss of sulfolane, compared with that of TEG, was found in the raffinate and, to an even higher extent, in the extract, which, unlike the raffinate phase, is not subjected to aqueous washing. The increased sulfolane content in the extract is due to a number of factors. The first among these is the unfortunate flowsheet of the extraction block in the LG 35-8/300B unit, according to which the recycle and extract are steam-distilled not in separate columns (as is done in the process of arene extraction with individual sulfolane), but in a single column with removal of the extract as a sidecut distillate. The second factor is the flatter temperature dependence of the saturated sulfolane vapor pressure: at 150°C (temperature of regeneration of the extractants from the extract phase) the saturated vapor pressure of sulfolane is twice that of TEG, despite the virtually the same standard boiling points [8]. Finally, the third factor is the stronger positive deviation from the Raoult's law in the water–sulfolane system as compared with the water–TEG system (in the first system, the excess Gibbs energy ΔG^E_{max} exceeds 1 kJ mol^{-1} at 30°C [9]).

The efficiency of aqueous stripping of TEG and sulfolane was preliminarily tested on model hydrocarbon mixtures. As a system simulating the composition of the raffinate phase served a heptane–toluene mixture (99 : 1 by weight) containing small amounts of TEG and sulfolane. The extract was simulated with a benzene–toluene–*m*-xylene system with small amounts of the same extractants. The results show (Table 2) that TEG and sulfolane can be virtually totally recovered from the raffinate phase by single-stage stripping. The distribution coefficients of TEG and sulfolane between the simulated extract phase and aqueous phase are considerably lower, which is due to a strong specific interaction of arenes with the mixed extractant components. Correspondingly, the degree of recovery of TEG and, especially, sul-

Table 3. Parameters of aqueous stripping of extractants from the raffinate phase and also from xylenes (weight ratio water : raffinate phase = 0.05 : 1, water : xylenes = 1 : 1)

Solvent	Solvent content, wt %			
	raffinate phase	raffinate	xylenes before stripping	xylenes after stripping
Diethylene glycol	0.001	< 0.001	0.01–0.05	0.001–0.003
TEG	0.015	0.005	0.12–0.13	0.005
Sulfolane	0.09	0.004–0.010	4.3–5.7	0.008–0.02

folane from arene-containing mixtures is insufficiently high.

Since an increase in the water : extract weight ratio is undesirable because of the higher power consumption for the subsequent evaporation of excess water, the aqueous stripping block was upgraded so that it became possible to strip TEG and sulfolane not from the extract phase, but from the toluene column bottoms in which xylene and even higher-boiling TEG and sulfolane are concentrated. Since the xylene fraction in the extract is only 3–6 wt %, the volume of aromatic feed going to aqueous stripping is reduced by a factor of about 15–30. Another advantage is that aqueous stripping of polar solvents from xylene solutions is more efficient than that from mixtures with benzene or toluene, since xylene-containing systems are characterized by higher degree of nonideality. For example, at 35°C the limiting activity coefficients in the system oxylene (1)–sulfolane (2) are $\gamma_1^0 = 6.99$ and $\gamma_2^0 = 13.2$ [10], while the limiting activity coefficient of benzene in sulfolane is 2.4 [11].

In aqueous washing of concentrates of TEG and sulfolane in xylene, instead of those in the extract phase, the tendency of the system to form emulsions decreases as a result of, first, a decrease in the mutual solubility of xylenes, compared with benzene and toluene, in aqueous sulfolane and TEG solutions and, second, an increase in the difference between the phase densities from 130 to 150 kg m^{-3}.

The data on aqueous stripping of TEG and sulfolane after the upgrade of the unit show that, despite high sulfolane concentration in xylenes, their low consumption makes it possible to increase the water : xylenes ratio to 1 : 1 and to achieve a tolerable level of TEG and sulfolane losses (Table 3). Thus, at the rated feed load of the unit, the sulfolane loss with the raffinate and xylenes is estimated at 6–15 and 0.4–0.9 t per year, respectively; and the TEG loss, at 7–8 and 0.2–0.4 t per year. The estimated total loss of the extractants due to insufficiently effective aqueous stripping is 0.14–0.24 kg per ton arene product. A similar level of loss is typical of other arene extraction processes. For example, in the Aromex process with *N*-formylmorpholine, the loss is 0.16 kg extractant per ton of arenes [12]. If aqueous stripping of sulfolane were performed from the overall extract, instead of the xylene fraction, its estimated loss would be as high as 25–35 t per year, and, without aqueous stripping at all, as high as 170–250 t per year. Further reduction in the sulfolane and TEG loss in performing aqueous washing of xylenes with mainly the raffinate is possible by lowering the temperature of the extractant fed into the extractor. Compared with that of aqueous TEG, the increased solvency of the mixed extractant TEG–sulfolane–water with respect to arenes and its lower viscosity make it possible to lower the temperature in the upper section of the reactor from 145–150 to 120°C; in this case, the extractant content in the raffinate phase must decrease.

Further improvement of the efficiency of arene extraction is planned to be achieved by raising the sulfolane fraction in the mixed extractant.

CONCLUSIONS

(1) The extraction of benzene, toluene, and xylenes from the 62–105°C reforming naphtha fraction with mixed triethylene glycol–sulfolane–water extractant containing 15 wt % sulfolane, instead of straight triethylene glycol, at the LG 35-8/300B benzene reforming unit (Kirishinefteorgsintez Production Association) allowed an increase by 2.1 wt % in the total degree of recovery of aromatic hydrocarbons or reduction of the extractant : feed and recycle : feed ratios by 20%.

(2) The loss of sulfolane and TEG with the extract were reduced to a tolerable level as a result of the upgrade of the aqueous washing block, in which provision is made for stripping of TEG and sulfolane not from the extract phase, but from toluene column bottoms.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Redox Potentials of Samarium and Europium in Molten Cesium Chloride

A. V. Novoselova, V. A. Khokhlov, and V. Yu. Shishkin

Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciencesd, Yekatirenburg, Russia

Received March 19, 2001

Abstract—The method of direct potentiometry was applied to measure redox potentials of Sm^{3+}/Sm^{2+} and Eu^{3+}/Eu^{2+} in molten cesium chloride relative to chlorine reference electrode in the temperature range 973–1173 K. Changes in the Gibbs energy of the redox reaction $LnCl_{2(l)} + 1/2Cl_{2(g)} \leftrightarrow LnCl_{3(l)}$ were calculated.

Electrochemical methods for processing of rare-earth raw materials in salt melts have been acquiring increasing importance in view of the growing use of rare-earth metals (REM) and their alloys in high technologies. In electrochemical systems based on molten alkali metal halides and containing REM halides, the latter are, as a rule, present, by virtue of their chemical nature, in the form of ions in various oxidation states. There are only scarce published data on redox processes occurring in molten salt electrolytes containing lanthanide halides. As a rule, the available data are only estimates, which results from the use of indirect methods for determining electrochemical parameters [1] or proximate techniques [2] furnishing semiquantitative characteristics applicable only to solution of various technological problems. At the same time, use of methods making it possible to directly determine, e.g., decomposition voltages and redox potentials of halide systems containing rare-earth metals encounters severe difficulties. These are related to the fact that noticeable amounts of alkali metal start to deposit at the decomposition potentials, and the high affinity of lanthanides for oxygen requires an exceedingly clean experimental technique [3]. Meanwhile, successful development of such hi-tech schemes as processing of irradiated fuel [4–6] insistently demands that the occurring processes should be studied more thoroughly and in greater detail, which is impossible without systematic precision studies directly furnishing the required information.

The following most important problems of the electrochemistry of molten alkali metal halides containing lanthanide compounds can be distinguished, which have not been sufficiently well described in the scientific literature. To these belong in the first place the stability and type of REM ions in various oxidation states in these systems; quantitative characteristics of redox reactions (number of electrons involved in a reaction, equilibrium constants, etc.), their dependence on the ionic composition of the salt solvent, concentration of rare-earth halide, and temperature. Analysis of published data [7–9] and the results of previous studies [10, 11], convincingly demonstrates that samarium and europium have only two stable forms, Ln^{3+} and Ln^{2+}, and a reversible redox reaction involving these species is of single-electron type.

It is known that, in molten alkali metal halides, ions of polyvalent metals, including REM, form anionic complex groups whose stability grows on replacing the solvent-salt cation in the following order $Li^+ \rightarrow Na^+ \rightarrow K^+ \rightarrow Rb^+ \rightarrow Cs^+$ [12–14]. Their influence on the equilibrium of the reaction

$$Ln^{3+} + e \rightleftarrows Ln^{2+} \quad (1)$$

is especially strongly manifested in solutions dilute with respect to lanthanide chlorides, since, in this case, ions of rare-earth metals are completely incorporated into $LnCl_6^{3-}$ and $LnCl_4^{2-}$ [7, 13].

In the present study, the potentiometric technique is applied to study the equilibria of the redox reactions

$$SmCl_{2(l)} + 1/2Cl_{2(g)} \rightleftarrows SmCl_{3(l)}, \quad (2)$$

$$EuCl_{2(l)} + 1/2Cl_{2(g)} \rightleftarrows SmCl_{3(l)} \quad (3)$$

in a cesium chloride melt. In this case, by analogy with other salt systems containing polyvalent metals

1070-4272/01/7410-1672 $25.00 © 2001 MAIK "Nauka/Interperiodica"

[12], the stability of complex ions formed by samarium and europium, and their influence of on the equilibrium of trichloride reduction reactions, must be the highest.

EXPERIMENTAL

Cesium chloride of special-purity grade, used in the study, was preliminarily dried, melted, and subjected to zone refining [15]. Anhydrous samarium and europium trichlorides were prepared by chlorination of crystal hydrates by heating in carbon tetrachloride vapor [16]. Crystal hydrates of REM chlorides were obtained by dissolving an oxide in hydrochloric acid to pH 1–1.5 with further evaporation of the resulting solution on water bath. The prepared chlorides were stored, ground, and weighed in a box in an atmosphere of dry nitrogen.

REM chlorides readily decompose at elevated temperature in the presence of atmospheric oxygen and undergo hydrolysis as a result of interaction with moisture to form oxychlorides [17]. With account of this fact, $SmCl_3$ + CsCl and $EuCl_3$ + CsCl fusion cakes of eutectic composition, containing 17 mol % cesium chloride according to fusibility curves [14, 18], were preliminarily synthesized. Since it is known [19–21] that trichlorides of samarium, and especially europium, are thermally unstable at temperatures close to the melting point, the employed technique makes it possible to essentially decelerate the reaction of thermal decomposition of chlorides. The suppression of this process is due to lowering of the melting temperatures of trichloride-containing salt formulations and to occurrence of complexation reactions in the molten solvent-salt. To completely remove trace amounts of rare-earth metal oxychlorides, chlorine with admixture of carbon tetrachloride was bubbled through a melt contained in glassy-carbon or pyrolytic-graphite crucibles. A melt to be studied was prepared directly when carrying out an experiment by fusing a prescribed amount of a preliminarily prepared eutectic with the solvent-salt. In all experiments, the concentration of a rare-earth metal chloride in the salt phase was not higher than 4.5 mol %.

Glassy carbon served as indifferent material for the working electrode. As true values were taken such emf values which remained constant within ±1 mV for 0.5 h at a given temperature. All experimental emf values are given with account of the thermo emf between the platinum and carbon current leads to the cell electrodes.

The design of the experimental cell and experimental procedure were described in detail in [10]. Despite that samarium dichloride is a stable compound, it is exceedingly sensitive to presence of oxidizing agents and, in particular, oxygen in the system [3, 17]. In developing a procedure for measuring the redox potentials of samarium [10], it was shown that reproducible results can only be obtained with special measures taken against presence of oxygen in the gas atmosphere. Otherwise, the slope of experimental isotherms corresponded to a number of electrons much less than unity, and a precipitate was formed in dissolving solidified salt fusion cake in water. As shown by X-ray phase analysis, the chemical composition of the precipitate corresponded to samarium oxychloride, which could be formed in the melt by the reaction

$$SmCl_{2(l)} + 1/2O_{2(g)} = SmOCl_{(s)} + SmCl_{3(l)}. \quad (4)$$

Reaction (4) is even possible in the case of very small admixtures of oxygen in the gas medium or presence of residual amounts of oxygen adsorbed on the surface of crucible and other members of the measurement cell, not removed in thermal treatment. Therefore, special attention was given to argon purification. For this purpose, argon was pumped, during the entire experiment, by an RR 1-05 peristaltic pump through a getter composed of zirconium filings and heated to 1073 K.

The starting salt, containing rare-earth metal trichloride, was electrochemically reduced to a dichloride whose concentration was calculated from the quantity of electricity Q passed through a system under study, measured during the experiment with a copper coulometer.

After an experiment, the salt fusion cake solidified in the inert atmosphere was analyzed for the content of bi- and trivalent samarium or europium ions. The content of samarium dichloride was determined volumetrically from the amount of hydrogen evolved in dissolution of the fusion cake in an acidified aqueous solution, the content of europium dichloride was analyzed by potentiometric titration of its aqueous solution with potassium dichromate. The total content of trivalent ions of rare-earth metals was found by titration with ethylenediamine tetraacetate (EDTA) by the known procedure [22].

The experimental values of redox potentials obtained on an indifferent glassy carbon electrode in molten CsCl are presented in Fig. 1 for the systems Sm^{3+}/Sm^{2+} and Eu^{3+}/Eu^{2+}. In both the systems, the redox potential $E_{Ln^{3+}/Ln^{2+}}$ linearly depends on the logarithm of the trichloride to dichloride concentration ratio $\ln([Ln^{3+}]/[Ln^{2+}])$. The experimental $E_{Ln^{3+}/Ln^{2+}}$ (V) values are described by linear equations at confidence

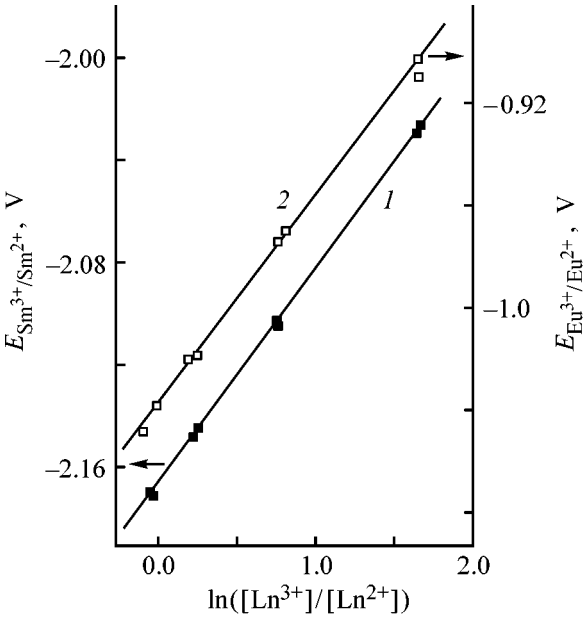

Fig. 1. Redox potentials (*1*) $E_{Sm^{3+}/Sm^{2+}}$ and (*2*) $E_{Eu^{3+}/Eu^{2+}}$ vs. concentration ratio Ln^{3+}/Ln^{2+} at 973 K in CsCl melt. Ln^{3+}/Ln^{2+}: (*1*) Sm^{3+}/Sm^{2+} and (*2*) Eu^{3+}/Eu^{2+}.

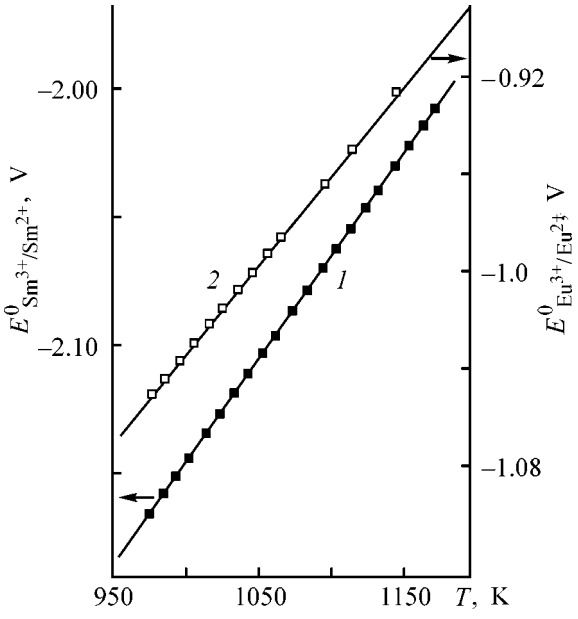

Fig. 2. Conditional standard redox potentials (*1*) $E^0_{Sm^{3+}/Sm^{2+}}$ and (*2*) $E^0_{Eu^{3+}/Eu^{2+}}$ in molten cesium chloride vs. temperature *T*.

probability of 0.95. For 973 K these dependences have the form

$$E_{Sm^{3+}/Sm^{2+}} = -(2.1667 \pm 0.0006) + (0.0833 \pm 0.0006)\ln([Sm^{3+}]/[Sm^{2+}]) \pm 0.001, \quad (5)$$

$$E_{Eu^{3+}/Eu^{2+}} = -(1.036 \pm 0.002) + (0.082 \pm 0.002)\ln([Eu^{3+}]/[Eu^{2+}]) \pm 0.004, \quad (6)$$

where $[Sm^{3+}]$, $[Sm^{2+}]$, $[Eu^{3+}]$, and $[Eu^{2+}]$ are the concentrations of samarium and europium ions in different oxidation states (mol fraction).

The number *n* of electrons involved in the electrochemical reduction of a rare-earth metal trichloride by reaction (1) was determined from the pre-logarithmic coefficients. The *n* value is 1.01 ± 0.01 for samarium and 1.02 ± 0.03 for europium.

A chemical analysis of solidified salt fusion cakes for the content of samarium or europium dichloride, performed after the experiments, confirmed the measurement results. The discrepancies between the coulometric (i.e. that calculated from the quantity of electricity expended for reduction of REM trichloride) and analytical determinations were 2–2.5%. Apparently, the electroreduction reaction in the melt under study proceeds by scheme (1).

The temperature dependence of the conditional standard potential $E^0_{Ln^{3+}/Ln^{2+}}$ (V), obtained on a glassy carbon electrode, is presented in Fig. 2. In the temperature range of the experiment, the dependence is linear for both samarium and europium. The data processed by a least-squares procedure are described in the temperature range 973–1173 K by the equations

$$E^0_{Sm^{3+}/Sm^{2+}} = -(2.943 \pm 0.003) + (79.8 \pm 0.3) \times 10^{-5}T \pm 0.0008, \quad (7)$$

$$E^0_{Eu^{3+}/Eu^{2+}} = -(1.764 \pm 0.003) + (73.0 \pm 0.3) \times 10^{-5}T \pm 0.0009. \quad (8)$$

Equations (5)–(8) involve the rms scatter of the experimental data.

The results obtained in the study indicate that, at one and the same temperature and concentration ratio of electrically active species, the redox potential $E_{Sm^{3+}/Sm^{2+}}$ is more negative than $E_{Eu^{3+}/Eu^{2+}}$, in good agreement with the available data for samarium and europium chloride solutions in a eutectic LiCl–KCl mixture [3] and equimolar NaCl–KCl mixture [2, 10].

Changing the salt solvent strongly affects the conditional standard potentials $E^0_{Ln^{3+}/Ln^{2+}}$. For example, at 1073 K, these potentials were –1.880 and –0.742 V in molten equimolar mixture [10], –1.966 and –0.844 V in molten KCl [17], and –2.087 and –0.981 V in molten CsCl, for samarium and europium, respectively. A linear, within the experimental determination error, dependence of $E^0_{Ln^{3+}/Ln^{2+}}$ on the inverse of the crystal-

chemical cation radii of the solvent-salt is observed (Fig. 3). The radii of the alkali metal cations are taken according to Goldschmidt [23]. For 1073 K this dependence is described by the following empirical equations

$$E^0_{Sm^{3+}/Sm^{2+}} = -(2.57 \pm 0.02) + (0.80 \pm 0.02)/r_R^+ \pm 0.004, \quad (9)$$

$$E^0_{Eu^{3+}/Eu^{2+}} = -(1.54 \pm 0.01) + (0.92 \pm 0.01)/r_R^+ \pm 0.002. \quad (10)$$

The obtained linear dependences of the conditional standard redox potentials on the inverse of the cation radii allow estimation of the $E^0_{Ln^{3+}/Ln^{2+}}$ values for those salt media in the series LiCl–NaCl–KCl–RbCl–CsCl (or mixtures of these) in which these potentials are not determined experimentally.

Table 1 presents conditional standard redox potentials $E^0_{Sm^{3+}/Sm^{2+}}$ and $E^0_{Eu^{3+}/Eu^{2+}}$ for molten NaCl and RbCl and for the LiCl–KCl eutectic mixture at different temperatures.

Johnson and Mackenzie [3] reported redox potentials $E_{Sm^{3+}/Sm^{2+}}$ and $E_{Eu^{3+}/Eu^{2+}}$ for 1 : 1 ratio of oxidized and reduced forms of rare-earth ions, measured on tungsten (for samarium-) and platinum (for europium-containing melts) indicator electrodes in a LiCl–KCl eutectic at 723 K relative to a platinum reference electrode. Recalculated to the chloride reference electrode, these potentials are, respectively, –2.035 and –0.860 V, whereas our data, extrapolated to this temperature, give –1.966 and –0.753 V. With account of the extrapolation error, the results are in satisfactory agreement.

The experimentally determined redox potentials were used to calculate the changes in the conditional standard Gibbs energy, ΔG^0, and the equilibrium constants K_c for the reaction

$$LnCl_{2(l)} + 1/2Cl_{2(g)} \rightleftarrows LnCl_{3(l)}. \quad (11)$$

The ΔG^0 value varies with the cation radius of a solvent-salt and temperature. For the salts studied these dependences are presented in Table 2.

Table 3 lists equilibrium constants for the reaction of samarium and europium trichloride formation in molten NaCl–KCl, KCl, and CsCl at different temperatures. It can be seen that the equilibrium constant decreases with increasing temperature. At equal temperatures, K_c grows with increasing cation radius of the solvent-salt. This indicates that, with decreasing

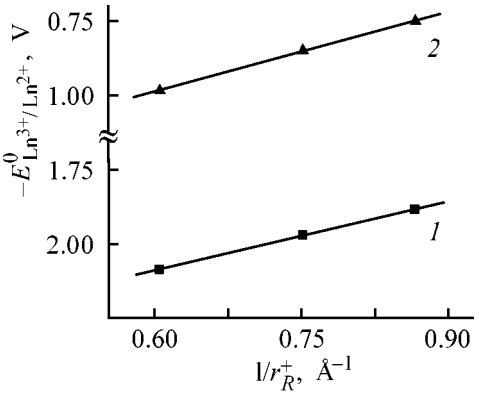

Fig. 3. Conditional standard redox potentials $E^0_{Ln^{3+}/Ln^{2+}}$ vs. cation radii r_R^+ of the solvent-salt at 1073 K in molten alkali metal chlorides. (*1*) $E^0_{Sm^{3+}/Sm^{2+}}$ and (*2*) $E^0_{Eu^{3+}/Eu^{2+}}$.

temperature and increasing cation radius of the solvent-salt, reaction (11) shifts toward formation of rare-earth trichloride.

The shift of the conditional standard potentials $E^0_{Ln^{3+}/Ln^{2+}}$ to more electronegative values and the change in the conventional standard Gibbs energy of the redox reaction in passing from (Na–K)Cl to CsCl are associated with complexation in melts. It is known [7–13] that, in dilute solutions of alkali metal chlorides, rare-earth metal ions Ln^{3+} and Ln^{2+} form complex groups $LnCl_6^{3-}$ and $LnCl_4^{2-}$ whose stability depends both on the ionic potential of the complexing agent [24, 25] and on the size of solvent-salt cations.

Melt	$E^0_{Sm^{3+}/Sm^{2+}}$			$E^0_{Eu^{3+}/Eu^{2+}}$		
	V, at indicated temperature, K					
	1073	1123	1173	1073	1123	1173
NaCl	–	–1.720	–1.683	–	–0.572	–0.542
RbCl	–2.033	–1.995	–1.956	–0.923	–0.885	–0.850
LiCl–KCl	–1.719	–1.686	–1.649	–0.561	–0.533	–0.504

Table 2. Conditional standard changes in Gibbs energy for reactions (2) and (3) in molten chlorides of alkali metals

Melt	$\Delta G^0_{Sm^{3+}/Sm^{2+}}$	$\Delta G^0_{Eu^{3+}/Eu^{2+}}$
	J mol^{-1}	
NaCl–KCl	–260317 + 73.5T	–136767 + 60.7T
KCl	–265623 + 70.7T	–150131 + 64.1T
CsCl	–283955 + 77.0T	–170200 + 70.4T

Table 3. Constants of equilibrium between di- and trichlorides of samarium, K_c(Sm), and europium, K_c(Eu), in molten alkali metal chlorides

Melt	K_c(Sm)			K_c(Eu)		
	at indicated temperature, K					
	1073	1123	1173	1073	1123	1173
NaCl–KCl	6.81×10^8	1.86×10^8	5.67×10^7	3.07×10^3	1.55×10^3	8.31×10^2
KCl	1.73×10^9	4.60×10^8	1.37×10^8	9.13×10^3	4.32×10^3	2.17×10^3
CsCl	6.33×10^9	1.53×10^9	4.20×10^8	4.06×10^4	1.74×10^4	7.98×10^3

It may be stated, on the basis of the available published data on crystal-chemical radii of doubly and triply charged samarium and europium ions [26, 27], that the stability of the $SmCl_6^{3-}$ and $EuCl_6^{3-}$ complexes much exceeds that of $SmCl_4^{2-}$ and $EuCl_4^{2-}$ groups. At the same time, account should be taken of the influence of the salt-solvent cation, which is the stronger, the smaller its radius. As a result, the relative stability of the complex species $LnCl_6^{3-}$ and $LnCl_4^{2-}$ decreases in order $Cs^+ \rightarrow K^+ \rightarrow (Na–K)^+$. Elevated temperature also favors weakening of interparticle bonds in the complex groups because of the more intensive thermal motion of molten salt particles. As also in other salt systems containing chlorides of polyvalent metals, the decrease in the extent of complexation (weakening of intracomplex interparticle bonds) shifts the redox potentials $E^0_{Sm^{3+}/Sm^{2+}}$ and $E^0_{Eu^{3+}/Eu^{2+}}$ to more positive values.

CONCLUSIONS

(1) Redox potentials of samarium and europium were for the first time measured potentiometrically in molten cesium chloride at 973–1173 K.

(2) The redox potentials $E_{Ln^{3+}/Ln^{2+}}$ depend linearly on $\ln([Ln^{3+}]/[Ln^{2+}])$ in accordance with the Nernst equation. The number of electrons involved in the electrochemical reaction is unity.

(3) The conditional standard potentials $E^0_{Sm^{3+}/Sm^{2+}}$ and $E^0_{Eu^{3+}/Eu^{2+}}$ become more electropositive with decreasing cation radius of the solvent-salt and increasing temperature.

(4) In molten alkali metal chlorides and mixtures of these, the redox potential $E_{Sm^{3+}/Sm^{2+}}$ is more negative than $E_{Eu^{3+}/Eu^{2+}}$ at equal temperatures and concentration ratios of electrically active species.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Deposition, Structure, and Properties of Electroplated Zinc Coating Alloyed with Cobalt

Abstract—Specific features of deposition, structure, physicomechanical (microhardness, wear resistance), corrosion-protective, and electrical properties of an electrochemical zinc–cobalt coating containing 0.05 to 28 wt % alloying metal.

Electrodeposition of zinc coatings alloyed with other metals is one of methods to improve their service characteristics. Among additives most widely used for alloying are iron subgroup metals: nickel [1–6], cobalt [6–10], and iron [6, 11], and also other metals—manganese [12], molybdenum [13], lead [14], and tin [14]. In alloying, modification of zinc coating properties is achieved both through formation of a finer, more perfect structure of a deposit in joint deposition of zinc and a minor amount of alloying metal and as a result of deposition of more corrosion-resistant phase structures—alloys Zn–Ni, Zn–Fe, Zn–Co, Zn–Mn, Zn–Sn, etc.

Zinc–cobalt coatings are commonly obtained in weakly acid zinc-plating electrolytes with various organic formulations, which yield, even without brightening (chromating), high-quality shining coatings with improved corrosion-protective properties in salt or sea fog. However, the problem of solution composition and deposition conditions of electrolytic Zh–Co deposits with required set of functional properties is for the most part solved empirically. Published data on electrochemical deposition of zinc–cobalt coatings are scarce, especially in what refers to the effect of various factors on the chemical and phase composition, structure, corrosion-protective, and physicomechanical properties.

The aim of this study was to develop a composition of a weakly acid electrolyte and conditions for obtaining a functional zinc–cobalt coating with fine decorative outward appearance and to study the effect of various factors on the chemical and physical composition of the coatings, and also on physicomechanical, electrical, and corrosion-protective properties.

EXPERIMENTAL

Zinc–cobalt coatings were electrodeposited from the developed weakly acid chloride solution onto the copper or steel surface with the use of a B5-49 dc power supply. Zinc of TsO brand was used as anode. The amount of cobalt and zinc in a coating was determined upon its dissolution on a Spectro Flame Modula atomic-emission spectrometer (FRG). The analysis error was not higher than 1%. As brightening additives to the zinc–cobalt plating electrolyte were used formulations of Dipo-tsink and ABC brands. The phase composition and structure of the obtained coatings were studied by means of X-ray diffraction analysis. Xray diffraction patterns were measured on a DRON-3 diffractometer with Co_{K_α} radiation at a recording rate of 1 deg min^{-1} in the angle range $2\theta = 16–110°$. The crystal lattice parameters and sizes of coherent-scattering regions (CSR) were found by the method of Cauchy's approximating function. Auger spectra were recorded from the surface of zinc–cobalt coatings, and also in various stages of ion etching, to study the element distribution across the entire thickness of electroplated coatings. The corrosion tests of the coatings under study (thickness 8.5 ± 0.05 μm) were performed at elevated relative humidity and temperature [GOST (State Standard) 9.308–85] by completely submerging samples in a 3% NaCl solution and subsequent gravimetric determination of the mass loss and also by a method based on measuring polarization curves of anodic dissolution of a coating and cathodic evolution of hydrogen. The polarization curves were measured with a PI-50-1 potentiostat in the potentiodynamic mode at potential sweep rate of 2 mV s^{-1}, with the use of fresh portions of a 3% NaCl

1070-4272/01/7410-1678 $25.00 © 2001 MAIK "Nauka/Interperiodica"

solution (50 ml) and a new working electrode. The potentials are given relative to a saturated silver chloride reference electrode.

The auxiliary electrode was made of platinum; as working electrode served steel plate onto which a zinc–cobalt coating with varied content of the alloying metal was electrodeposited. The measurements were done at 20 ± 1°C with natural aeration (without stirring the solution). The obtained results were presented in the form of a E–log i plot. Extrapolation of linear portions of the anodic and cathodic curves to the stationary metal potential was used to determine the current density and the corrosion potential. The microhardness of a coating about 30 μm thick was measured on a PMT-3 microhardness meter with indenter load of 20 g. The electrical resistance of coatings was measured at dc current of 50 mA under a load of 40 g. The wear resistance was evaluated by the method of reciprocal motion of a sphere (ShKh-15 steel, R = 3 mm) over the surface of a sample under study at a velocity of 25 mm s^{-1} under 50-N load without lubricant, with 1000 cycles executed at a 22-mm path length and the width and depth of the friction track measured, and the volume wear per cycle determined, subsequently.

The study was concerned with the effect of various factors—cathode current density, temperature, pH value, concentrations of the salts of the main metal (zinc chloride) and alloying metal (cobalt chloride) on the coating deposition rate, current efficiency by metal, and chemical composition of electroplated zinc–cobalt coatings. It was found that the deposition rate and the current efficiency are virtually independent of temperature, pH value, and concentration of the alloying metal salt in the zinc plating electrolyte and constitute 30 ± 2 μm h^{-1} and 95 ± 3%, respectively, at i_c = 2 A dm^{-2}. With the temperature increasing from 8 to 50°C, the pH value, from 3.3 to 6.5, and the Co(II) concentration in the electrolyte, from 0.02 to 0.22 M [at constant Zn(II) ion concentration of 0.45 M], the amount of cobalt codeposited with zinc grows, on the average, from 0.05–0.12 to 0.25–0.29 wt % (Fig. 1). The deposition rate, current efficiency by metal and chemical composition of a coating are more strongly affected by the cathode current density. With i_c increasing from 1 to 5 A dm^{-2}, the coating deposition rate grows linearly from 18 to 70 μm h^{-1}, the current efficiency decreases from 98 to 70–75% because of the simultaneously occurring reaction of hydrogen reduction, and the amount of cobalt codeposited with zinc becomes higher. It should be noted that at small current densities (0.5 to 2.0 A dm^{-2}) the mass fraction of cobalt grows at a much lower rate, from 0.12 to 0.18 wt %, than it does at higher current densities (2 to 5 A dm^{-2})—from 0.18 to 0.6 wt % (Fig. 1). The decisive influence on the chemical composition of a zinc–cobalt coating at fixed i_c and Co(II) concentration of 0.15 M is exerted by the ratio of metal salt concentrations in solution. The largest amount of cobalt (up to 28 wt %) is codeposited into a coating at a ratio Zn(II) : Co(II) = 0.3 : 1 [Zn(II) ion concentration 0.05 M] at low alloy deposition rate (~9 μm h^{-1}) and current efficiency (~30%). This is presumably due to the occurrence of concentration polarization: at low zinc salt concentration in the electrolyte and predominant discharge of zinc ions at the cathode, the near-electrode layer is rapidly depleted of Zn(II) ions, and, therefore, the share of cobalt in the coating is rather large. With increasing concentration of Zn(II) ions (to 0.15 M) and decreasing Zn(II) : Co(II) ratio (from 0.3 : 1 to 1 : 1, the amount of cobalt codeposited with zinc decreases dramatically, from 28 to 1.2 wt %, the coating deposition rate grows from 9 to 25 μm h^{-1}, and the current efficiency, from 30 to 85% (Fig. 2). Zn–Co coatings with the finest outward appearance—uniform, dense, and shining, were obtained at Zn(II) : Co(II) ratio in the electrolyte of 2 : 1 and more. The cobalt content in these coatings is 0.18–0.25 wt %, the deposition rate and current efficiency reach their maximum values of 30–32 μm h^{-1} and 98%, respectively (Fig. 2).

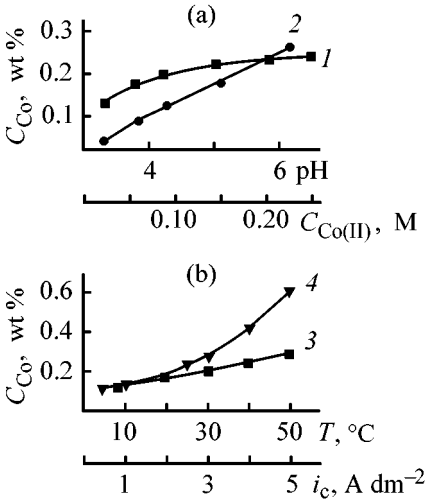

Fig. 1. Amount of cobalt in a Zn–Co coating, C_{Co}, vs. (*1*) pH; (*2*) concentration of Co(II) ions in the electrolyte, $C_{Co(II)}$; (*3*) temperature T; and (*4*) cathode current density i_c. In each curve one parameter varies with the other three remaining constant: T = 20°C, i_c = 2 A dm^{-2}, $C_{Co(II)}$ = 0.15 M, pH 5; the same for Fig. 2.

Thus, the content of cobalt in a coating can be varied in a sufficiently wide range (0.05–28 wt %)

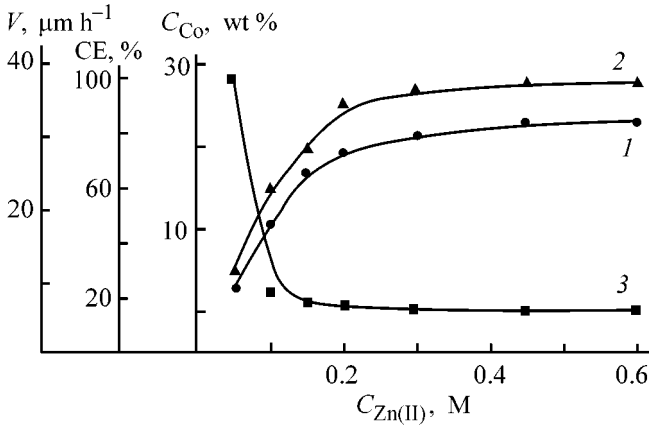

Fig. 2. (*1*) Deposition rate V of a zinc–cobalt coating, (*2*) current efficiency CE, and (*3*) amount of Co in a Zn–Co coating vs. concentration of Zn(II) ions in the electrolyte, $C_{Zn(II)}$.

by changing the concentration ratio of Zn(II) and Co(II) ions in the electrolyte, and in a much narrower range (0.12 to 0.6 wt %), by changing the electrodeposition conditions—cathode current density, pH value, and temperature.

An X-ray study of electroplated Zn–Co coatings with varied content of cobalt demonstrated that, at small content of the alloying metal (<1.2 wt %), only the phase of crystalline zinc is revealed with a full set of diffraction reflections 002, 100, 101, 102, 103, 110, 112, and 201, and lattice constants $a = b = 0.2665$, $c = 0.4947$ nm, which, according to [15] correspond to hexagonal closest packing. The CSR of the forming grains is 25–30 nm in size (see table). With the content of cobalt in a coating increasing to 2.5 wt %, the intensities of separate reflections change together with the crystal lattice constants: an increase in a and b to 0.2682 and a decrease in c to 0.4920 nm indicate the formation of a solid solution of cobalt in zinc. With the content of cobalt increasing to 28 wt %, no further changes in crystal lattice occur, with only the intensities of some reflections (002, 101, 102, 112) decreasing and that of others (100, 110) increasing, and the CSR size decreasing to 15–17 nm (see table).

Thus, depending on the chemical composition of a Zn–Co coating, either a solid solution of cobalt in zinc can be obtained if the content of the alloying metal exceeds 2.5 wt %, or crystalline zinc, if the content of the alloying metal is less than 1.2 wt %.

Auger spectra of Zn–Co coatings containing 0.18 wt % cobalt indicate that oxygen is incorporated into the coating in very small amounts (<1%) and is uniformly distributed across the entire thickness of the electroplated coatings (Fig. 3). This means that, contrary to the assumptions made in [1], no difficultly soluble hydroxo compounds of Zn(II) and Co(II) ions discharging at the cathode are formed as a result of alkalinization of the near-electrode layer, although the pH grows in the course of electrolysis from 4.5 to 5.0–5.5. At small content of cobalt in a coating, the cobalt phase is observed neither on the outer surface of electroplated Zn–Co deposits, nor on the inner surface adjacent to the iron substrate (Fig. 3). This suggests that cobalt atoms are introduced at defects of the crystal lattice of zinc.

A corrosion-electrochemical study of Zn and Zn–Co coatings with varied content of the alloying metal

Microstructure and phase composition of Zn–Co coating

Co concentration, wt %	Phase composition	CSR size, nm	Crystal lattice constants, nm
<1.2	Crystalline Zn	25–30	$a = b = 0.2665$, $c = 0.4947$*
2.5	Solid solution of Co in Zn	25–30	$a = b = 0.2682$, $c = 0.4920$
28	The same	15–17	$a = b = 0.2682$, $c = 0.4920$

* According to published data [15], $a = b = 0.2665$, $c = 0.4947$ nm.

in a 3% sodium chloride solution demonstrated that alloying of zinc with cobalt improves the corrosion resistance of Zn coatings: in particular, the corrosion current density decreases from 7.4 μA cm^{-2} for zinc coating to 0.7–4.2 μA cm^{-2} for Zn–Co coatings containing from 0.15 to 2.5 wt % cobalt, respectively (Fig. 4). The lowest corrosion current density is observed for coatings containing minor amounts of cobalt: (0.2 ± 0.05 wt %). This is presumably due to the uniform distribution of alloying metal atoms over defect sites in the crystal lattice. The increase in the corrosion current density to 4.2 μA cm^{-2} on raising the amount of the alloying metal in the coating to 2.5 wt % is probably due to the formation of a solid solution of cobalt in zinc. The corrosion potentials of Zn and Zn–Co coatings differ only slightly (–1.05 ± 0.05 V) and correspond to the cathodic steel protection range.

Accelerated corrosion tests of zinc and Zn–Co coatings in a climatic chamber in the course of 30 days (T = 40 ± 2°C, relative humidity 93 ± 3%) demonstrated that, under severe climatic treatment, the zinc coating shows centers of attack on the substrate (red rust) on the background of a white layer of corrosion products having the form of a mixture of ZnO, $6Zn(OH)_2 \cdot ZnCl_2$, and $4Zn(OH)_2 \cdot ZnCl_2$ (white rust) [7]. At the same time, only a very thin film of firmly adhering and difficultly removable corrosion products appeared on coatings containing less than 1 wt % cobalt (the coating became dull), whereas on coatings with 2.5 wt % cobalt the layer of corrosion products was the most pronounced. In both these cases, there were no centers of attack on the base metal.

Tests with samples completely submerged in a 3% NaCl solution with subsequent gravimetric determination of the coating mass demonstrated that zinc coatings alloyed with cobalt have better protective properties than zinc coatings. The average relative loss of mass in 30 days (%) was 5–10 for Zn coating, 2–3 for Zn–Co coatings with 2.5 wt % cobalt and 1–2 for those with 0.18 wt % cobalt.

A study of the physicomechanical (microhardness, wear resistance) and electrical (electrode resistance) properties of zinc and Zn–Co coatings demonstrated that the Zn–Co coatings have higher microhardness, compared with zinc coatings [H_{20}(Zn) = 850 N mm^{-2}]. With the content of cobalt in a coating increasing at low concentrations of the alloying metal (0.05 to 0.25 wt %), the microhardness grows linearly from 900 to 1050 N mm^{-2}. Further increase in the content of cobalt has little effect on the microhardness (1100 N mm^{-2}, Fig. 4). Zn–Co coatings exhibit firm adhesion to the base, with no flaking-off observed on

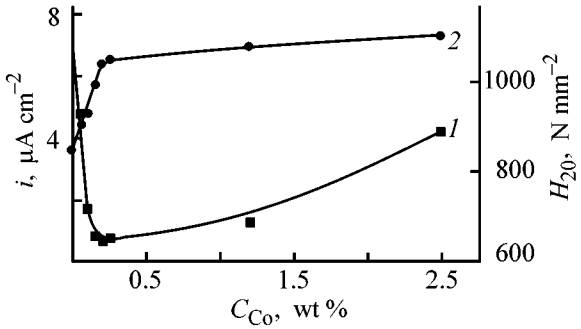

Fig. 4. Effect of the cobalt content C_{Co} of a Zn–Co coating on (*1*) corrosion current density i_c in a 3% sodium chloride solution and (*2*) microhardness H_{20}.

repeated bending of a steel band coated with Zn–Co. When thicker than 3 μm, the zinc coating alloyed with cobalt is nonporous and has a fine, decorative outward appearance—uniform, bright, and shining. It much surpasses the zinc coating in wear resistance. The specific volume wear in 1000 cycles of abrasion under dry friction conditions is (1.8×10^{-7} mm^3 for the Zn–Co coating and 6.5×10^{-7} mm^3 for the zinc coating. In contrast to purely zinc coatings, those alloyed with cobalt require no treatment in chromate solutions, which diminishes the labor-intensity of the process and eliminates the problem of wastewater purification to remove Cr(VI) ions. The resistance of zinc coatings and Zn–Co coatings with small content of cobalt (up to 2.5 wt%) is 4–5 mOhm. With the content of the alloying metal growing to 28 wt %, the resistance increases to 8– 12 mOhm. Presumably, this increase may be due to a twofold decrease in grain size (see table) and growing area of grain boundaries. The intergrain space has higher electrical resistance than the grain bulk, and, therefore, electron transport is hindered in finely crystalline coatings, compared with coarsely crystalline layers.

CONCLUSIONS

(1) A weakly acid (pH 5.0 ± 0.5) chloride solution for electrodeposition of Zn–Co coatings onto a steel or copper substrate was developed, which yields functional Zn–Co coatings with fine, decorative outward appearance in the presence of Dipo-tsink or ABC brand brighteners.

(2) Varying the ratio of Zn(II) and Co(II) ion concentrations in the electrolyte and the electrolysis conditions, one can obtain Zn–Co coatings containing 0.05 to 28 wt % cobalt.

(3) X-ray phase analysis demonstrated that the coating is composed of crystalline zinc at cobalt con-

tent less than 1.2 wt %, with cobalt presumably distributed among defects of the closest hexagonal packing of zinc, and a solid solution of cobalt in zinc at cobalt content exceeding 2.5 wt %.

(4) The best service characteristics: enhanced corrosion resistance and protecting capacity, higher microhardness and wear resistance, and low electrical resistance, are characteristic of zinc–cobalt coatings containing 0.2 ± 0.05 wt % cobalt.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrochemical Polishing of SrM925 Silver Alloy by Means of Pulsed Current

S. I. Galanin, A. V. Chekotin, and M. V. Nikonova

Kostroma State Technological University, Kostroma, Russia

Received March 21, 2001

Abstract—Electrochemical polishing of jewelry silver alloy SrM925 by means of microsecond-pulse current in ammonia-nitrate, thiosulfate, and chromate electrolytes is considered.

Stringent requirements are presently imposed on the outward appearance of jewelry. Manufacture needs effective technological processes for finishing treatment of the surface of composite-profile articles. As a process of this kind can be used electrochemical polishing, which has a number of indisputable advantages over mechanical treatment. The use of electrochemical polishing is hindered by the fact that silver alloys are conventionally polished in hazardous and ecologically unsafe cyanide electrolytes similar to Shpital'skii's electrolyte [1–5]. Also possible is use of non-cyanide electrolytes, e.g., thiosulfate [6], ammonia-nitrate [7], and chromate [5]. However, the quality of the resulting surface gives no way of using electrochemical polishing in these electrolytes as industrial finishing procedure.

According to the theory of electrochemical polishing [5], high quality of the resulting surface is ensured when the rates of anodic dissolution and passivation are comparable and rather high. Investigations have shown that the processes develop at different rates [8], with the difference observed on the microsecond time scale. Therefore, use of pulsed currents with microsecond pulse duration comparable with the time of development of anodic processes allows a certain extent of control over their course at the anode–electrolyte interface in order to achieve high rates of smoothing of the microroughness on a surface being treated [9, 10]. It was recommended in [6] to treat the surface with pulsating current in order to improve the process efficiency.

The aim of the present study was to analyze the possibility of electrochemical polishing of samples cast from SrM925 jewelry silver alloy in non-cyanide electrolytes with the use of microsecond current pulses.

The experiments were carried out using a transistor source of rectangular pulses, with independent control of the output amplitude-and-time parameters [11]. As samples served cast cylinders pressed in fluoroplastic. The cathode was made of 12Kh18N9T steel. The electrolyte in the electrochemical bath was continuously stirred mechanically. The electrolyte temperature was 18–20°C.

The effectiveness of surface microroughness smoothing was judged on the basis of the following criteria: outward appearance of the surface, metal loss Δm, reflectivity factor k_r, relative smoothing ΔR_z, and smoothing efficiency factor λ_{eff}. The coefficient k_r (%) was defined by

$$k_r = (O_{tr}/O_m) \times 100, \quad (1)$$

where O_{tr} and O_m are the intensities of light reflected from a sample under study and a mechanically mirror-polished sample, respectively.

To determine the coefficient k_r, a device was fabricated, measuring the intensity of light reflected perpendicularly to the sample surface. As a source of light served an electric lamp, with the beam of light from the lamp focused onto the sample surface by a lens. The intensity of reflected light was measured with a photographic exposure meter. The relative smoothing of surface microirregularities (the irregularity height R_z was determined with the use of an MII-4 interference microscope) ΔR_z (%) was defined as the ratio of the difference of microirregularity heights before, $R_{z(in)}$, and after treatment, $R_{z(fin)}$ to the value prior to treatment:

$$\Delta R_z = \frac{R_{z(in)} - R_{z(fin)}}{R_{z(in)}} \times 100. \quad (2)$$

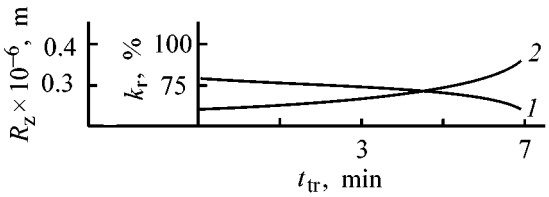

Fig. 1. (*1*) Microirregularity height R_z and (*2*) surface reflectivity factor k_r vs. time t_{tr} of treatment in ammonia-nitrate electrolyte. Electrolysis conditions: i_a = 15 A dm^{-2}, q = 2, t_p = 3000 × 10^{-6} s.

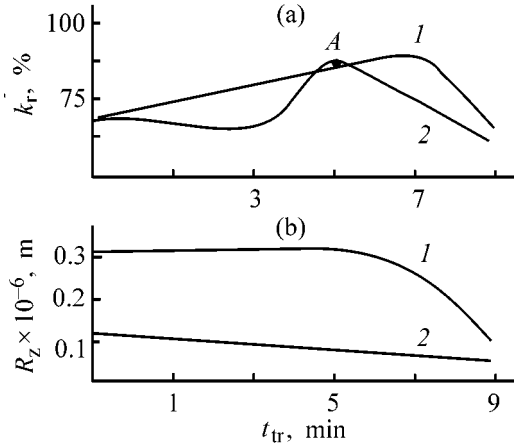

Fig. 2. Effect of the time t_{tr} of treatment in a thiosulfate electrolyte on (a) reflectivity factor k_r and (b) microirregularity height R_z. Electrolysis conditions: (*1*) i_a = 5 A dm^{-2}, q = 4, t_p = 100 × 10^{-6} s; (*2*) i_a = 5 A dm^{-2}, q = 4, t_p = 1000 × 10^{-6} s.

The coefficient λ_{eff} was defined as the ratio of the height of dissolved microprojections to the mass Δm of dissolved metal [5]:

$$\lambda_{eff} = \frac{R_{z\,(in)} - R_{z\,(fin)}}{\Delta m}. \quad (3)$$

The higher λ_{eff}, the more effective the smoothing. A change in reflectivity is a measure of the polishing properties of an electrolyte, whereas the relative smoothing, combined with λ_{eff}, characterizes electrolytes and electrolysis modes from the standpoint of smoothing ability and technological feasibility.

Electrolytes of the following compositions (g l^{-1}) were studied [5–7]: no. 1, ammonia-nitrate (NH_4NO_3, 360; NaOH, 120); no. 2, thiosulfate ($Na_2S_2O_3 \cdot 10H_2O$ 809); and no. 3, chromate (CrO_3, 220; $CaCl_2 \cdot 2H_2O$, 86).

The samples were treated in the following modes: pulse anode current density i_a (A dm^{-2}) (chosen on the basis of recommendations of [5–7] as the most effective for treatment) for electrolyte no. 1: 15, 30, 200; no. 2: 5, 7; no. 3: 5, 10, 15; time of treatment t_{tr}: 1, 3, 5, 7 min; current pulse duration t_p (100, 1000, 3000) × 10^{-6} s; off-duty factor (pulse repetition cycle to pulse duration ratio) q = (2; 4).

Before and after treatment, the microirregularity height, sample mass, and surface reflectivity were measured for each of the above modes.

Let us now consider successively the electrolytes studied.

Electrolyte no. 1. At i_a 30 or 200 A dm^{-2}, the obtained results are unsatisfactory at any pulse lengths and off-duty factors. The surface is subject to pitting etching, with the metal uniformly removed at a rate of 0.003–0.005 g min^{-1}. At i_a = 200 A dm^{-2}, q = 4, the surface is covered with a dense dark brown film, and the sample mass increases by 0.01 g min^{-1}. A shining surface was obtained in the following mode: i_a = 15 A dm^{-2}, q = 2, and t_p = 3000 × 10^{-6} s (Fig. 1), with λ_{eff} = 1.59 × 10^{-6} m g^{-1} and ΔR_z = 22.5%.

Electrolyte no. 2. A shining surface was obtained in the following modes. First mode: i_a = 5 A dm^{-2}, q = 4, and t_p = 100 × 10^{-6} s. The surface acquires mirror shine. At treatment time of 1 to 7 min the reflectivity grows linearly, upon further treatment (up to 9 min) the surface becomes matte (Fig. 2a, curve *1*): λ_{eff} = 2.99 × 10^{-6} m g^{-1}, ΔR_z = 66.7%. Second mode: i_a = 5 A dm^{-2}, q = 4, t_p = 1000 × 10^{-6} s. After treatment for 5 min, the sample surface becomes glossy (as shown by visual inspection; Fig. 2a, curve *2*, point *A*), but the microirregularity height remains unsatisfactory: λ_{eff} = 3.89 × 10^{-6} m g^{-1}, ΔR_z = 35.5%. Thus, a surface is obtained, which possesses rather high reflectivity at considerable microroughness. Such a result is possible in the case of regular surface texture [5].

The smoothing efficiency factor in the second mode is nearly 2 times greater than that in the first one. In any other mode, the surface reflectivity was lower, or pitting etching of the surface was observed and dense dark films were formed.

Electrolyte no. 3. Surface polishing could not be achieved in any mode. Pitting etching and formation of solid gray, brown, yellow, or black films were observed. The films could not be removed by washing with water or acetone. Raising the temperature to 80°C and use of dc current failed to improve the results.

CONCLUSIONS

(1) The surface of silver is not polished in the chromate and ammonia-nitrate electrolytes. The most

promising is the thiosulfate electrolyte used in the optimal electrolysis mode (pulse current density i_a = 5 A dm^{-2}, off-duty factor q = 4, pulse duration t_p = 100×10^{-6} s).

(2) High reflectivity can be obtained not only with a substantially smoothed surface, but also with a surface characterized by regular texture.

(3) Exceeding the optimal treatment duration leads to surface etching. Therefore, a thorough mechanical pretreatment of the surface is necessary to make shorter the final stage of electrochemical polishing.

CATALYSIS

Catalytic Properties of Platinum(II, III) Oxide in Ammonia Oxidation

N. I. Zakharchenko

Zhukovskii National Aerospace University, Kharkov, Ukraine

Received April 16, 2001

Abstract—Catalytic properties of Pt_3O_4 platinum oxide were studied in the high-temperature range. The optimal parameters of ammonia oxidation on the oxide catalyst and kinetic characteristics of the reaction were determined.

Catalytic oxidation of ammonia to nitrogen(II) oxide is the basis of the industrial method for production of nitric acid [1]. Industrial catalysts (Pt, Rh, and Pd alloys) undergo physicochemical transformations in the course of technological processes, with the surface structure and chemical composition changed [1–5]. A set of such transformations of platinoid catalysts results in the loss of difficult-to-obtain and expensive platinum metals. The mechanism of platinum metal loss remains debatable [1, 4–7]; the conversion products widely differ according to data of different authors [1, 4–8]. The catalytic properties of platinum compounds in ammonia oxidation have not been determined (except for PtO_2 [8]), which hinders the understanding of how ammonia is oxidized on platinoid catalysts and platinoids lost at elevated temperatures.

The present study is concerned with the catalytic and physicochemical properties of platinum(II, III) oxide Pt_3O_4 as a catalyst for ammonia oxidation, which has not been studied in the given process [1–8].

The catalyst was obtained by thermal treatment of ground hydrated platinum dioxide $PtO_2 \cdot nH_2O$ of chemically pure grade in inert medium (nitrogen) at 933 K. The reaction product was purified to remove the remaining platinum and PtO_2 in, respectively, boiling aqua regia and 48% HBr solution at 293 K [9] (with Pt_3O_4 not dissolved). The compound obtained was identified on a Siemens D-500 powder diffractometer in diffracted beam configuration, with Cu_{K_α} radiation and graphite monochromator. The phases observed in the obtained diffraction patterns were identified using the JCPDS file contained in the software package of the diffractometer. In parallel, the compound was subjected to chemical analysis [5, 9].

The content of oxygen in the oxide was determined from the mass loss in decomposition of samples in inert medium (nitrogen) in quartz ampules at 1173 K [10].

IR absorption spectra were measured on a Perkin–Elmer spectrophotometer in the spectral range 200–2000 cm^{-1} with KBr pellets as matrices.

The selectivity of the catalysts with respect to NO was determined on a flow-through setup with quartz reactor 2×10^{-2} m in diameter [11]. The bed of catalyst grains of size $(2 \times 3) \times 10^{-3}$ m was $(4–12) \times 10^{-2}$ m high; the time of contact was 6.50×10^{-2} s under standard conditions, i.e., the optimal according to previously obtained data [12]; and the pressure was 0.101 MPa. The temperature was varied within 813–1273 K, depending on the purposes of studies.

The composition of the products formed in ammonia oxidation and thermal decomposition of nitrogen(II) on the catalysts was determined chromatographically by means of the known technique [13] by analyzing the gas mixture for the content of NH_3, O_2, N_2, NO, and N_2O before and after the catalysts. The sensitivity of the employed analytical procedure was (vol %): 3.0×10^{-3} for NH_3; 3.5×10^{-3} for NO; and 5.0×10^{-3} for O_2, N_2, and N_2O.

The limiting load A of the catalysts with respect to NH_3 was determined by the procedure consisting in that the catalyst load was raised to a critical "decay" state, i.e., the state in which the thermal balance of a catalyst was disturbed when the reaction passed from the diffusion region into the kinetic one [14].

The catalyst particle size was determined on a JEM-7Y electron microscope [15]. A suspension of catalyst samples was prepared by ultrasonic disper-

1070-4272/01/7410-1686 $25.00 © 2001 MAIK "Nauka/Interperiodica"

sion of weighed portions of the substance in distilled water in a UZDV-2 device. As substrates were used carbon films obtained by thermal evaporation of graphite.

The specific surface area of the catalyst was determined from the low-temperature adsorption of nitrogen and calculated by the BET equation, using the standard procedure [16].

The synthesized catalyst (main lines in the X-ray diffraction pattern with interplanar spacings of 0.397, 0.253, 0.231, 0.1630, 0.1567, 0.1413, 0.1236, 0.1053, 0.0845 nm) corresponded to a cubic structure of Pt_3O_4 platinum oxide [17].

The IR spectrum of the compound contains absorption bands at 706, 590, 367, and 230 cm^{-1}, characteristic of platinum(II, III) oxide [18].

Chemical analysis was applied to determine the atomic ratio O/Pt = 1.31, which is in good agreement with the stoichiometry of the Pt_3O_4 compound.

The cubic structure of Pt_3O_4 is composed of square oxygen prisms filled with Pt atoms and perpendicular to one another (Fig. 1). Oxygen ions are arranged at cube corners. The Pt atoms center each oxygen square of these prisms. The cubic voids formed by the intersection of the prisms are empty. Such a structure corresponds to the ideal composition $PtO_{1.33}$ [17]. Deviations from the ideal composition can be attributed to formation of interstitial solid solutions. The excess, compared with the $PtO_{1.33}$ composition, platinum atoms can occupy (together with impurity ions Na^+, K^+, Ca^{2+}, Mg^{2+}, etc.) the cubic voids to form stable nonstoichiometric interstitial compounds of the type $Na_xPt_3O_4$ [9, 19].

The temperature dependence of the catalyst selectivity is shown in Fig. 2. The maximum selectivity of platinum(II, III) oxide (96.1%) is shifted to lower temperatures (953 K) as compared with most of other oxide catalysts [1, 12]. According to X-ray phase and chemical analyses, the catalyst starts to dissociate at 963–973 K with the formation of platinum, which corresponds to the following overall equation of the process [10, 20]

$$Pt_3O_4 = 3Pt + 2O_2. \quad (1)$$

According to X-ray phase analysis, the components of the system form no solid solutions under the given experimental conditions, being present as a mixture of two compounds. The formation of an interstitial solid solution in the system Pt_3O_4–Pt to give a stable structure of platinum oxide $Na_xPt_3O_4$ is slow [9, 17, 19]. The catalytic properties of the system Pt_3O_4–Pt at $T \geq 963$ K are determined by the physicochemical characteristics of the individual components and their relative amounts.

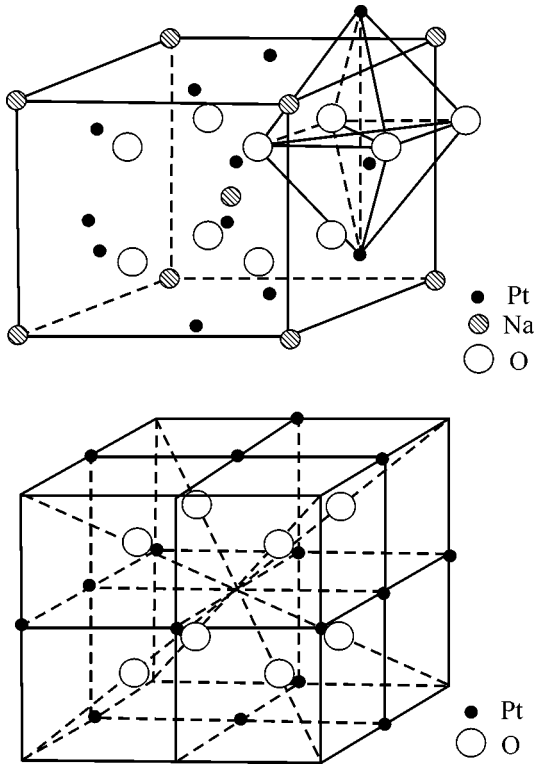

Fig. 1. Structure of Pt_3O_4 and $Na_xPt_3O_4$ by Muller [17].

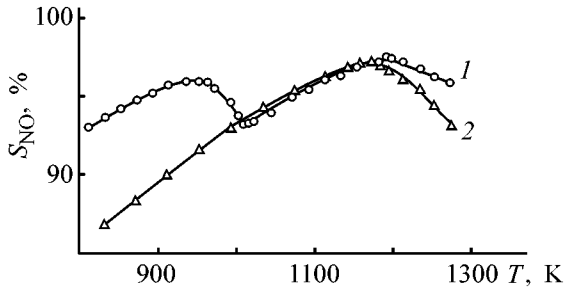

Fig. 2. Catalyst selectivity S_{NO} vs. process temperature T. Linear velocity of ammonia–air mixture 0.77 m s^{-1} (w.c.). (*1*) Pt_3O_4 (3 h of operation) and (*2*) catalyst after 170 h of operation.

Phase transformations of the catalyst at T ≥ 963 K make its selectivity lower, since a component (platinum) is formed whose selectivity at 963–973 K is not higher than 90.0–91.0% [1]. The catalyst selectivity was commonly determined after 2–3 h of operation at a given temperature. According to X-ray phase and chemical analyses, the catalyst partly dissociates at 1063–1073 K during this time, i.e., becomes a two-phase system Pt_3O_4–Pt. However, already after 7 h of

tests at 1063–1073 K the catalyst completely decomposes into the components, with only one condensed phase (platinum) found in the system. In the range 1113–1273 K, the curve describing the temperature dependence of the catalyst selectivity (Fig. 2) coincides with a similar curve for Pt [1], i.e., after 2–3 h of tests the catalyst completely decomposes into simple substances at the given temperature. Consequently, the catalyst is only stable as an individual compound at $T \le 963$ K. The main characteristics of the catalyst are presented in the table.

Only two nitrogen compounds, NO and N_2, were found in the products of ammonia oxidation on the given catalyst: no "breakthrough" of ammonia was observed under the conditions that are far from critical. The total conversion of the starting substance is

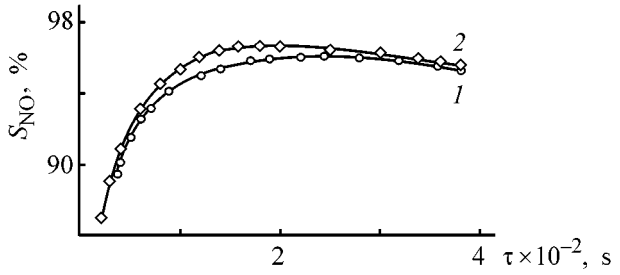

Fig. 3. Catalyst selectivity S_{NO} vs. contact time τ (w.c.). Linear velocity of ammonia–air mixture (m s^{-1}, w.c.): (*1*) 0.77 and (*2*) 1.19.

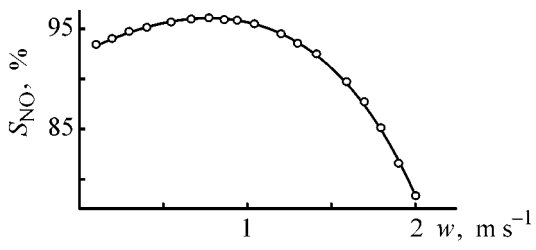

Fig. 4. Selectivity S_{NO} of platinum oxide vs. linear velocity of the ammonia–air mixture, w. Time of contact $\tau = 6.50 \times 10^{-2}$ s; T = 953 K.

100.0%, with only the ratio between the amounts of nitrogen(II) oxide and molecular nitrogen varying in the catalytic process, i.e., the catalyst selectivity with respect to NO (or nitrogen) changes. Thermal dissociation of NO makes lower the apparent selectivity of the catalyst with respect to nitrogen(II) oxide

$$2NO = N_2 + O_2. \quad (2)$$

According to experimental data, the degree of thermal dissociation of nitrogen(II) oxide on platinum oxide is 1.2% at 953 K and the optimal contact time $\tau = 6.50 \times 10^{-2}$ s. Thus, thermal dissociation of NO leads to a decrease in selectivity of platinum(II, III) oxide with respect to nitrogen(II) oxide by 1.1%. With increasing linear velocity of the components, i.e., the time of contact decreasing to 1.1×10^{-3} s (critical conditions of catalyst "decay"), no thermal dissociation of nitrogen(II) oxide is observed, in agreement with data for other oxide catalysts for ammonia oxidation [1, 21].

The fact that the catalyst selectivity depends on the contact time (Fig. 3) points to a kinetically complex mechanism of ammonia oxidation on platinum oxide [1, 12, 21].

The steep decrease in the catalyst selectivity at contact time $\tau < 8.0 \times 10^{-3}$ s (working conditions) is due to the occurrence of a side reaction of nitrogen defixation by the equation [1, 22]

$$4NH_3 + 6NO = 5N_2 + 6H_2O. \quad (3)$$

The gradual decrease in selectivity at contact time $\tau > (2.8–2.9) \times 10^{-2}$ s is mainly due to NO dissociation by scheme (2) [1]. The optimal contact time for platinum oxide is 2.46×10^{-2} and 1.58×10^{-2} s (w.c.) at linear velocities of the ammonia–air mixture of 0.77 and 1.19 m s^{-1} (w.c.), respectively.

The influence of the linear velocity of the reactants on the catalyst selectivity (Fig. 4) points to the outer-diffusion mechanism of the process [1, 12, 14, 21], in which the reaction rate is limited by diffusion of ammonia from the flow core to the platinum oxide surface.

The optimal linear velocity of the ammonia–air mixture for platinum oxide is 0.77 m s^{-1} (w.c.) at contact time $\tau = 6.50 \times 10^{-2}$ s (s.c.). With increasing linear velocity of the reactants, the "hot zone" shifts to the end of the catalyst bed, i.e., the temperature of its "frontal" layer becomes lower (Fig. 5). For example, at w = 1.80 m s^{-1} the temperature of the front layer of the catalyst falls to 803 K, which favors the occurrence of side reactions; in particular, the rate of nitrogen defixation by Eq. (3) is the highest at 673–873 K

[1, 22]. In addition, the low temperature of the front layer favors a parallel process

$$4NH_3 + 3O_2 = 2N_2 + 6H_2O, \quad (4)$$

which makes lower the selectivity of platinum oxide with respect to NO [1]. Low linear velocities of the ammonia–air mixture favor [1] the occurrence of a side reaction of NO dissociation, which leads to a gradual decrease in the catalyst selectivity with respect to nitrogen(II) oxide, since the rate of NO decomposition at 953 K is not high [1, 23]. Raising the linear velocity of the reactants to critical values ($\tau = 1.1 \times 10^{-3}$ s) leads to catalyst decay, i.e., to disturbance of the heat balance of the process because of a dramatic rise in heat losses. The heat losses can be compensated for by an increase in the amount of heat of the chemical processes occurring on platinum oxide in accordance with the heat balance equation [24]

$$Q_1 k C_S^n = \alpha(T_S - T_0) + Q_2, \quad (5)$$

where Q_1 is the heat effect of the reaction; k the reaction rate constant; C_S the ammonia concentration at the catalyst surface; n the reaction order; α the heat-transfer coefficient; T_s and T_0 the temperatures of, respectively, the catalyst surface and gas flow; and Q_2 the heat loss.

The increase in the heat effect of chemical processes occurring on the catalyst is ensured by faster rate (higher rate constant) of the reaction on the platinum oxide surface, with the grain surface temperature becoming higher. As follows from Eq. (5), the efficiency of the catalyst at constant temperature in the bed of platinum oxide grains strongly depends on the hydrodynamic characteristics of the ammonia–air mixture, and primarily on the linear velocity of the flow of reactants. The optimal linear velocities of the ammonia–air mixture lie within a limited range (Fig. 4).

The influence exerted by the ammonia concentration in the ammonia–air mixture on the selectivity of platinum(II, III) oxide is illustrated in Fig. 6 (w = const, h = const). At $[O_2]/[NH_3] > 1.6$–1.7 the catalyst surface is entirely covered with oxygen, and, consequently, mass transfer of NH_3 molecules to the platinum oxide surface is the rate-determining stage of the reaction [1, 14]. The ammonia oxidation rate r_{NH_3} per unit catalyst volume is equal to the rate of ammonia diffusion from the flow core to the platinum oxide surface [1, 14, 24].

$$r_{NH_3} = \beta S(C_0 - C_S), \quad (6)$$

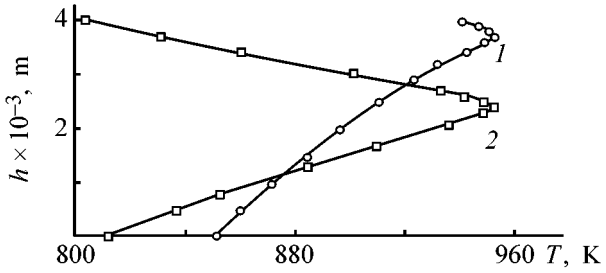

Fig. 5. Distribution of temperature T along the catalyst bed height h at the testing temperature of 953 K. Linear velocity of ammonia–air mixture (m s^{-1}; w.c.): (*1*) 0.77 and (*2*) 1.80.

Fig. 6. Selectivity of platinum(II, III) oxide with respect to NO, S_{NO}, vs. ammonia concentration C_{NH_3} in the ammonia–air mixture. Linear velocity of ammonia–air mixture w = 0.77 m s^{-1} (w.c.), T = 953 K; the same for Fig. 7.

where β is the mass-transfer coefficient; S the surface area of unit catalyst volume; and C_0 and C_S the ammonia concentrations in the flow core and at the catalyst surface, respectively.

Denoting $\beta_S = k$ and assuming that $C_0 >> C_S$ (deep-diffusion region of the process), we obtain

$$r_{NH_3} = KC_0. \quad (7)$$

At $[O_2]/[NH_3] < 1.5$ (C_{NH_3} = 12.3 vol %) the catalyst surface is insufficiently covered with oxygen and a possibility appears of a direct interaction between ammonia and the platinum oxide surface, which leads to reaction (4) with the formation of molecular nitrogen [1, 14].

In this case, the catalyst selectivity with respect to NO falls dramatically (Fig. 6).

The kinetic characteristics of the reaction were determined using the temperatures of "ignition" and "decay," i.e., the temperatures at the critical points, of an oxide catalyst pellet. The reaction rates were calculated using the method for determining the temperature limits of the outer-diffusion region with the use of the effect of catalyst pellet decay at lowered temperature of the ammonia–air mixture

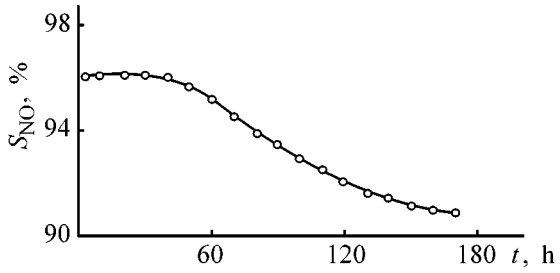

Fig. 7. Selectivity of Pt_3O_4 catalyst, S_{NO}, vs. operation time t.

[25]. The catalyst surface temperature was measured with a Chromel–Alumel thermocouple pressed in the pellet on the front surface of the pellet (with respect to the ammonia–air mixture flow direction). To prevent heat losses, a layer of platinum oxide grains $(2.0–3.0) \times 10^{-3}$ m was placed between the pellet and the reactor walls. The kinetic parameters of the process were calculated using the equation proposed by Buben [26] and solved for two reaction rates at constant concentration of oxygen. The Buben equation has the form

$$(1 + a)^2\left[1 + (m - 1)\frac{a}{b}\right] - \frac{a}{\varepsilon}\left(1 - \frac{a}{b}\right) = 0, \quad (8)$$

$$a = \frac{T}{T_0} - 1, \; b = \frac{Q\beta C_0}{\alpha T_0}, \; \varepsilon = \frac{RT_0}{E},$$

where m is the reaction order with respect to ammonia; T the catalyst surface temperature at the critical point (K); T_0 the temperature of the ammonia–air mixture; C_0 the concentration of ammonia in the flow; α and β the coefficients of, respectively, heat and mass transfer; Q the heat effect of the reaction; and E the activation energy of the reaction.

The coefficients α and β were calculated using the known equations [27].

The kinetic parameters of ammonia oxidation on platinum oxide are as follows:

Temperature of catalyst ignition	500
Ammonia concentration in the ammonia–air mixture, vol %	10.0
Activation energy E of the reaction, kJ mol^{-1} NH_3	9.06
Reaction order with respect to ammonia	0.17

A study of how the catalyst selectivity depends on the time of operation at the optimal temperature (953 K) demonstrated (Fig. 7) that the catalyst is stable during 40 h of operation and then undergoes deactivation. After 170 h of operation, the catalyst selectivity decreases by 5.2%. To reveal the causes of the deactivation, the chemical and phase composition of the catalyst and its structure (especially that of the surface layer of the catalyst, in view of the heterogeneous-catalytic nature of the reaction) were studied. According to X-ray phase and chemical analyses and X-ray photoelectron spectroscopy (XPS), the surface layer of a deactivated catalyst contains platinum and a nonstoichiometric compound $M_xPt_3O_4$ ($M = Na^+$, K^+, Ca^{2+}, Mg^{2+}, Fe^{3+}) of the $Na_xPt_3O_4$ structural type [9, 17, 19]. Compounds of such metals are present in the catalyst in the form of impurities and, in part, arrive with the ammonia–air mixture as contaminants, despite the purification of the reactants to remove them [1, 6]. According to XPS, the surface layers of catalyst grains are enriched (to a depth of 10–20 nm) in the above metal ions, compared with deeper lying layers. The appearance of platinum can be accounted for by the redox mechanism of the reaction occurring at the surface [1, 28], and by interaction of a strong reducing agent—ammonia, directly with parts of the catalyst surface that are characterized by low catalyst–oxygen binding energies [1, 28, 29]. Also, the temperature at which the catalyst was tested was close to the temperature of its dissociation. Partial dissociation of the catalyst is possible in the reaction medium at places of local catalyst surface temperature rise [9, 17, 20]

$$Pt_3O_4 = 2PtO_2 + Pt. \quad (9)$$

The forming platinum dioxide readily decomposes into simple substances (T_{dis} = 853–873 K) by the reaction [20]

$$PtO_2 = Pt + O_2. \quad (10)$$

Part of platinum dioxide sublimates and is carried away by the gas flow of the reaction medium [1, 6–8, 20].

Conditions are created for introduction of platinum atoms into the voids of the cubic structure of platinum(II, III) oxide to form a stable compound of the $Na_xPt_3O_4$ structural type. In this case, the atomic ratio O/Pt of the compound (170 h of operation) falls to 1.17 according to chemical analysis data. The crystal lattice constant of stabilized platinum oxide grows from 0.5633 to 0.5644 nm. The x value in a compound of the structural type $Na_xPt_3O_4$ may vary between 0 and 1 in the formation of stable interstitial structures [9, 19, 20]. The rate of formation of the variable-composition compound $Na_xPt_3O_4$ (in particular, upon introduction of platinum into platinum oxide) is low [9, 17]. For example, $Na_{0.1}Pt_3O_4$ is formed after 130–150 h of synthesis from sodium carbonate and α-PtO_2 [5, 9], and $CaPt_3O_4$, after 300–340 h of synthesis from calcium nitrate and α-PtO_2 [17, 30].

Probably, the concentration of platinum in the surface layer of the catalyst much exceeds the amount that can react with Pt_3O_4 under a given process conditions, i.e., part of platinum remains in the form of a separate phase. Both the interstitial solid solution ($M_xPt_3O_4$) and part of unreacted platinum are present in the surface layer of the catalyst as separate phases. The properties of the catalytic system at the chosen test parameters are determined by the composition and physicochemical characteristics of separate components and by the nature of their interaction. The selectivity of platinum at 953–973 K does not exceed 90–91% [1], i.e., the appearance of this phase in the surface layer makes the catalyst selectivity lower. The composition of the $M_xPt_3O_4$ compound varies with nature and concentration of interstitial ions in the structure and with the time of catalyst operation (at constant process parameters).

Under the action of elevated temperature the catalyst recrystallizes, with its specific surface area decreasing (see table). The rms size of particles of platinum oxide grows upon its conversion into a nonstoichiometric interstitial compound $M_xPt_3O_4$ from 170 to 230 nm (after 170 h of catalyst operation). Electron-microscopic studies of the surface of a catalyst that operated for a certain time demonstrated that the two-phase system $M_xPt_3O_4 + Pt$ contains both fine $M_xPt_3O_4$ particles and large, strongly recrystallized particles of platinum uniformly distributed over the surface. The $M_xPt_3O_4$ compound only slightly recrystallizes at the given temperature. The specific surface area of the catalytic system decreases in the course of operation from 12.5 to 8.7 $m^2 g^{-1}$ (mainly because of the recrystallization of platinum particles). Since the reaction proceeds under far-from-critical conditions, i.e., is limited by the diffusion of ammonia to the outer surface of the catalyst, the specific surface area exerts no decisive influence on the selectivity of platinum oxide with respect to NO [1, 12, 14, 21, 29]. This means that the decrease in the selectivity of the catalyst in the course of its operation at 953 K is mainly due to phase and chemical transformations of the catalyst. Under the critical conditions of the reaction (catalyst decay), the recrystallization and the decrease in the specific surface area of the catalyst decrease the limiting load on platinum oxide, i.e., diminish its activity [1, 14], from 13.8×10^3 to 9.58×10^3 $m^3 NH_3/(h\ m^2)$ 170 h of operation). The limiting load depends on the rate of the chemical reaction on the surface, which is, in turn, determined by the chemical composition of the catalyst. When the process is performed under the critical conditions ($\tau = 1.1 \times 10^{-3}$ s), no successive reaction of nitrogen(II) oxide decomposition by scheme (2) is observed, but part of unreacted ammonia is found after the catalyst, i.e., there occurs ammonia breakthrough.

The decrease in the specific surface area of the catalyst in the course of its operation is accompanied by an increase in ammonia breakthrough from 0.14 to 0.32%, which is due to the drop in the catalyst activity.

Thus, the whole set of chemical and phase transformations of the catalyst, leading to the formation of less active and less selective components ($M_xPt_3O_4$, Pt) with changed structure (recrystallization and decreasing specific surface area), is the reason for deactivation of platinum(II, III) oxide at 953 K.

A study of how the selectivity of a catalyst that undergoes phase and chemical transformations (170 h of operation) depends on temperature (Fig. 2) demonstrated that the peak selectivity of the catalyst (97.2%) is shifted to higher temperatures (1173 K), compared with platinum(II, III) oxide. The $M_xPt_3O_4 + Pt$ catalyst is thermally stable and does not undergo dissociation in the temperature range 953–1173 K. At $T > 1173$ K the compound $M_xPt_3O_4$ starts to decompose to give platinum and low-active oxides of the corresponding metals. At $T > 1173$ K the selectivity of the catalytic system decreases with increasing temperature.

The $M_xPt_3O_4$ phase can also be formed on the platinum surface in operation of the platinum catalyst in ammonia oxidation in view of the surface processes of high-temperature platinum oxidation and the presence of impurities of metal compounds in the ammonia–air mixture and the catalyst. In fact, the catalytic properties of platinum will be determined in this case by the composition and properties of the surface interstitial phase of platinum(II, III) oxide, i.e., $M_xPt_3O_4$. The assumptions that the key role in ammonia oxidation on platinum is played by PtO_2 [8] or PtO [31] are rather questionable, since both these compounds are unstable in the high-temperature region [5, 9, 17, 20].

The only possible candidate is the thermally stable modified platinum(II, III) oxide, i.e., $M_xPt_3O_4$. Studies of the catalytic properties of variable-composition compounds $M_xPt_3O_4$ (with account of the nature and concentration of the interstitial ions) give new insight into the mechanisms of high-temperature ammonia oxidation on platinum and deactivation and regeneration of the catalyst.

CONCLUSIONS

(1) The catalytic properties of platinum(II, III) oxide were studied in the temperature range 813–1273 K.

(2) The optimal parameters of the process of ammonia oxidation on oxide catalyst and the kinetic characteristics of the reaction were determined.

(3) It was established that at $T \geq 953$ K the catalyst undergoes structural (recrystallization, decreasing specific surface area), phase, and chemical transformations to give a nonstoichiometric compound $M_xPt_3O_4$ (Me = Na^+, K^+, Ca^{2+}, Mg^{2+}, Fe^{3+}, Pt^{2+}) and platinum. The reasons for the catalyst deactivation at $T \geq 953$ K are considered.

(4) Data on the catalytic properties of platinum(II, III) oxide can be used, in particular, in analyzing the mechanisms of high-temperature oxidation of ammonia on platinum and deactivation and regeneration of platinum catalysts.

CATALYSIS

Effect of Sulfur Compounds and Higher Homologues of Methane on Hydrogen Cyanide Production by the Andrussow Method

N. V. Trusov

Kharkov State Polytechnic University, Kharkov, Ukraine

Received June 6, 2000; in final form, March 2001

Abstract—The influence of sulfur compounds and higher homologues of methane on the parameters of oxidative ammonolysis of methane was studied.

In [1, 2], the results obtained in technological calculations in terms of the empirical model of HCN production by the Andrussow method (the so-called oxidative ammonolysis of methane, OAM) were considered. The next step in a comprehensive study was to analyze the influence exerted by technological impurities present in natural gas on hydrogen cyanide formation.

The influence of sulfur compounds and higher homologues of methane—unavoidable components of natural gas—on the OAM parameters has been studied in sufficient detail [3–5]. A detailed analysis of patents and other published evidence was made in a monograph [6]. However, quite a number of questions, answers to which are exceedingly important from the standpoint of applications, remain unanswered. In particular, the effect of the time τ of contact with platinoid grids on the loss of catalytic activity upon prolonged action of technological impurities on a catalyst, has not been studied at all. A search of answer to this and other questions was the aim of the present study.

The author has collected during a long time data characterizing the operation of an industrial installation for HCN synthesis. The obtained body of evidence was used to compile a database, part of which is given in Table 1 (total number of measurements 116).

Table 1. Influence exerted by the concentration of sulfur compounds and higher homologues of methane in natural gas on the content of HCN in synthesis gas (selected data)

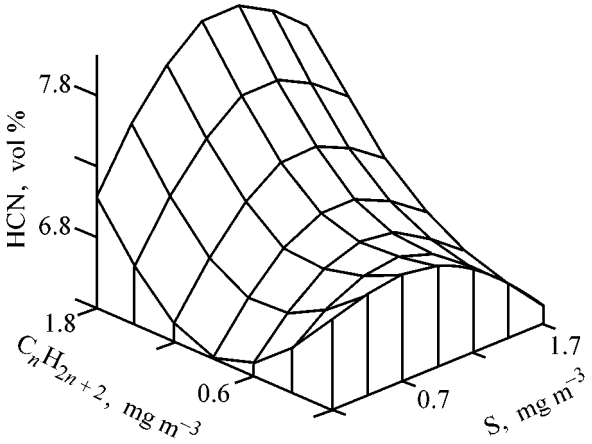

Fig. 1. Hydrogen cyanide concentration in the synthesis gas vs. content of sulfur compounds, S, and higher homologues of methane, C_nH_{n+2}, in natural gas.

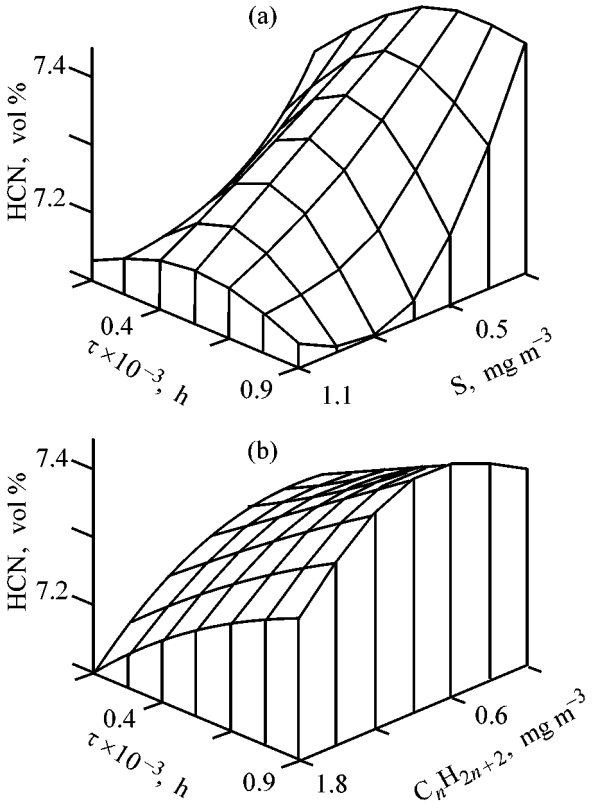

Fig. 2. Hydrogen cyanide concentration in the synthesis gas vs. (a) content of sulfur compounds, S, and (b) higher homologues of methane, C_nH_{n+2}, in natural gas at different times τ of contact with platinoid catalyst.

A preliminary processing of the entire body of information (representation in two-dimensional space) revealed a rather clearly pronounced correlation between the amount of sulfur compounds in natural gas and the volume concentration of hydrogen cyanide in the synthesis gas. There is no relationship between the content of HCN and the amount of C_nH_{n+2}. Therefore, it was suggested that the influence exerted by technological impurities present in natural gas has combined nature. This suggestion was confirmed by plotting the corresponding dependence in three-dimensional space (Fig. 1).

Noteworthy is the fact that the effect of sulfur compounds has extremal nature with a maximum at 1.0 mg m^{-3}: minor amounts block intermetallic compounds inevitably present in the alloy, thereby enhancing its selectivity; further increase in the content of sulfur in the gas leads to poisoning of platinum itself. The obtained results are in full agreement with the data of [7–9]. The influence of higher homologues of methane is on the whole positive in the investigated range of their concentrations, but, with this range expanded further, an abrupt drop in the output of hydrogen cyanide would be expected, as found experimentally by S.S. Bobkov [6]. A virtually similar conclusion is given in a patent [10].

Analysis of the data in Fig. 2 shows that the content of HCN exhibits extremal behavior with the time contact with the platinoid catalyst increasing at fixed content of sulfur compounds; at constant concentration of methane homologues the content of hydrogen cyanide grows with increasing time of passage.

The subsequent processing of the entire body of input data cast some doubts on the existence of a direct dependence of the volume content of HCN in the synthesis gas on the concentration of technological impurities in natural gas. A graphical interpretation of the averaged data of Table 1 (Fig. 3) indicates that this relationship cannot be considered in isolation from the changing flow rate of the starting mixture $Q \times 10^3$ (m^3 h^{-1}) and the spontaneously attained autothermic temperature T (°C) of the process. Anyway, none of the considered parameters (content of sulfur and C_nH_{n+2}, and also Q and T) correlates with the content of hydrogen cyanide in the reaction products.

In this regard, the following assumption seemed to be well justified. The problem in question can only be solved, with an empirical model adequate to the input data constructed, when the concentrations of technological impurities in a mixture supplied to conversion, rather than in natural gas (as it was done before [3–5, 7–10]), are used as control parameters.

A graphical presentation of the results of a representative sampling characterized by constant flow rate of the starting mixture (7550 m^3 h^{-1}) indicates

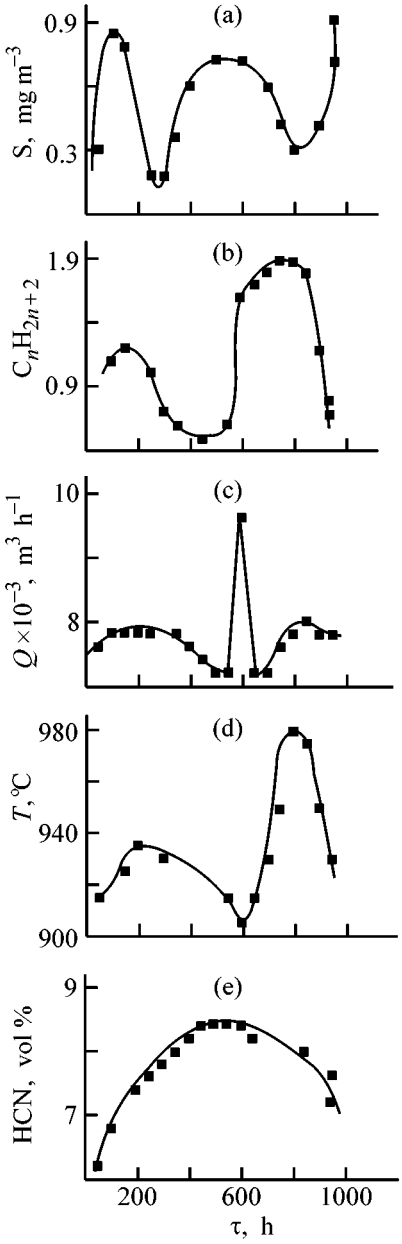

Fig. 3. Selected control parameters and response functions vs. time τ. (Q) Flow rate of the starting mixture and (T) temperature.

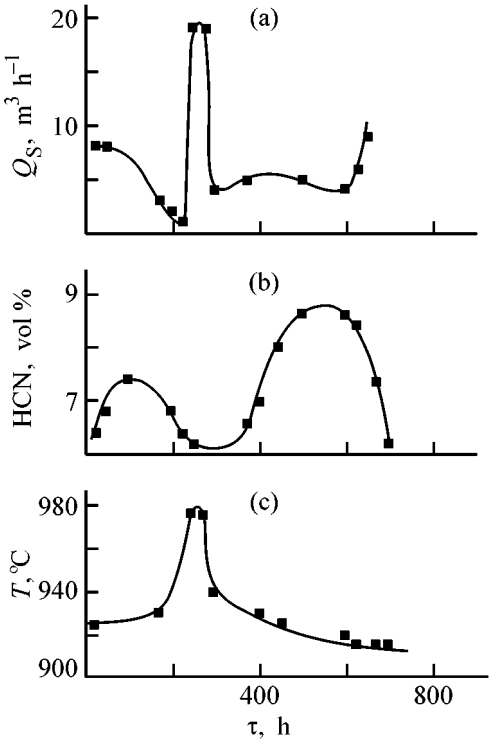

Fig. 4. Selected control parameters and response functions vs. time τ at constant flow rate of the starting mixture (7550 m^3 h^{-1}). (Q_S) Amount of sulfur and (T) temperature.

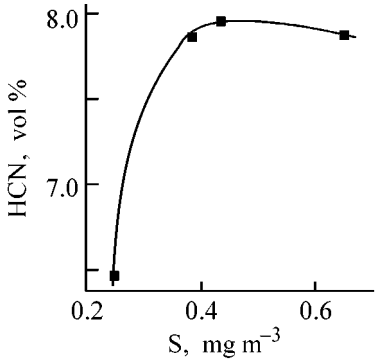

Fig. 5. Effect of the content S of sulfur compounds on the content of hydrogen cyanide in the synthesis gas. Load 7550 m^3 h^{-1}, temperature 915°C.

(Figs. 4a and 4b) that an abrupt increase in the amount of sulfur, Q_S (m^3 h^{-1}), fed into the reactor for HCN synthesis is accompanied by a virtually instantaneous, but not prolonged in any way, decrease in the content of hydrogen cyanide in the synthesis gas.

At the same time, the processing revealed a correlation between the content of sulfur compounds and the autothermic temperature of the process (Figs. 4a and 4c). For example, experiments with approximately constant temperature gave a dependence (Fig. 5) virtually coinciding with Warren's data, with the form of presentation of the content of sulfur compounds—as their concentration in natural gas or in the starting reaction mixture—being of no importance.

The entire body of the obtained data gave new insight into the problem of the influence exerted by technological impurities on the course of the OAM process. The revealed correlation between the content of sulfur compounds and the autothermic temperature suggested a similar relationship for higher homol-

ogues of methane, too, the more so as the calorific value of these latter much exceeds the same characteristic for sulfur compounds [11].

Therefore, an assumption was made that the entire body of the previously obtained information reflects the accumulation of sulfur on the surface of a platinoid catalyst, rather than the prolonged nature of the influence of sulfur compounds. To verify (or reject) this hypothesis, a sample was formed (Table 2), characterized by constant flow rate of the starting mixture (7550 $m^3\ h^{-1}$). As an additional restrictive condition served the following: all the experiments belonged to the same run. The volume of sulfur compounds in a given period of the run is understood as the current amount of sulfur compounds passed through the reactor, and their progressive total volume, as the integral amount.

The graphical representation of the data of Table 2 indicates that there is no integral effect of sulfur on the course of the OAM process. No prolonged nature of this influence is observed either. Detailed analysis of the obtained data shows that sulfur compounds are to be regarded as catalytic poisons of instantaneous action.

Thus, it became apparent that it is only possible to construct an empirical model of the OAM process that would adequately describe not only the effect of the main technological parameters (as it was done in [6]), but also the influence exerted by sulfur compounds and higher homologues of methane if the following condition is satisfied. Deviations of calculated volume concentrations of methane from experimental values should be regarded as a direct consequence of the unaccounted-for effect of sulfur compounds and higher homologues of methane.

The subsequent statistical processing aimed at developing an empirical model (derived by the Brandon method in the form of a polynomial) took this factor into account and yielded a system of equations, including several submodels. These were the following: (a) calculation of the volume concentration of reagents in the starting mixture (ammonia, methane, oxygen), depending on its preparation conditions; (b) determination of the spontaneously attained process temperature; (c) finding the output parameters of the process (volume content of HCN in the synthesis gas, conversion of reagents into the target product, yield of the target product, etc.).

The results of a technological calculation performed using the derived system of empirical equations indicate (Fig. 6) that, with natural gas containing equal amounts of sulfur compounds and higher homologues of methane, an increase in the amount of impurities leads to a gradual rise in the process temperature, and this dependence passes through a maximum with increasing flow rate of the starting mixture.

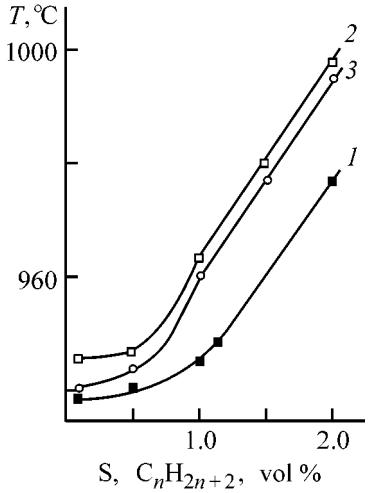

Fig. 6. Process temperature T vs. content of sulfur compounds, S, and higher homologues of methane, C_nH_{n+2}, in natural gas at their equal concentrations. Flow rate ($m^3\ h^{-1}$): (*1*) 7000, (*2*) 8000, and (*3*) 9000.

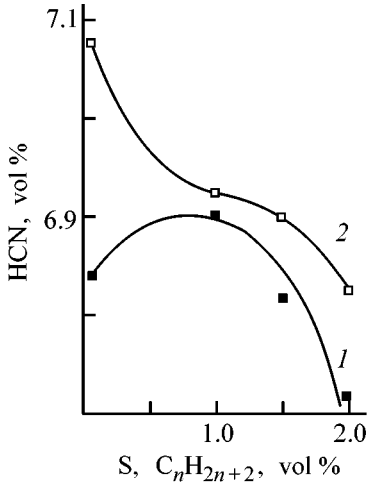

Fig. 7. Effect of the content of (*1*) sulfur compounds, S, and (*2*) higher homologues of methane, C_nH_{n+2}, on the concentration of hydrogen cyanide in the synthesis gas. Content (vol %): (*1*) C_nH_{n+2} 1.03 and (*2*) S 0.56.

An indisputable advantage of the proposed model is that it clearly demonstrates the effect of sulfur compounds and homologues of C_nH_{n+2} in "pure" form. The database in Table 1, characterized by exceedingly wide ranges of variation of all parameters of the OAM process, cannot do this by definition. It can be seen from Fig. 7 that the influence exerted by the content of sulfur compounds has extremal nature; the effect of higher homologues of methane on the content of hydrogen cyanide in the synthesis gas is negative (in calculations, the content of one of the natural gas components under consideration was fixed at the statistical-mean level).

It may be stated that only technological calculations based on the empirical model of the OAM process made it possible to avoid an erroneous conclusion that impurities contained in natural gas affect the HCN formation, drawn in the stage of preliminary processing of the initial database.

CONCLUSIONS

(1) Preliminary processing of experimental data was used to determine the nature of the influence exerted by technological impurities inevitably present in natural gas on parameters of oxidative ammonolysis of methane.

(2) Technological calculations performed using the constructed empirical model of oxidative ammonolysis of methane demonstrated an extremal influence of sulfur compounds and negative effects of higher homologues of methane on the content of hydrogen cyanide in the production gas.

(3) An increase in the time of contact with a platinoid catalyst in the case of presence of sulfur compounds and higher homologues of methane in natural gas exerts negative influence on the volume content of HCN in the synthesis gas.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Deep Purification of Aqueous Solutions to Remove Chromium(III) with Industrial Carbonate-Containing Wastes

T. G. Lupeiko, M. O. Gorbunova, and E. M. Bayan

Rostov State University, Rostov-on-Don, Russia

Received November 17, 2000; in final form, April 2001

Abstract—The possibility of diminishing chromium(III) ion concentration in aqueous solutions to a MPC (maximum permissible concentration) level with the use of industrial carbonate-containing wastes was studied. The influence exerted by the chromium(III) ion concentration in a starting solution, duration of sorbent contact with the solution, anion composition of the solution, temperature, and other conditions on the degree of recovery of Cr(III) ions and on the sorbent consumption was investigated.

The problem of effective and inexpensive purification of wastewater of galvanic industry to remove heavy metals and, in particular, chromium(III) ions is of great importance for the national economy. Presently, the main technique for removal of chromium(III) ions from solutions is their neutralization and precipitation in the form of $Cr(OH)_3$. The afterpurification to an MPC level (0.5 mg l^{-1}) usually requires expensive synthetic cation exchangers [1]. It has been proposed to use inorganic carbonate-containing sorbents for recovery of heavy metals [2]. The use of industrial wastes as sorbents is of particular interest from the standpoint of cost efficiency and ecological safety.

The cumulative, embryotoxic, and mutagenic effects of chromium(III) ions have been well studied. The possibility of removing these ions from wastewater is the subject of the present study. We propose to use for this purpose an industrial waste containing calcium and magnesium carbonates as a readily accessible and inexpensive sorbent (for brevity, referred to as sorbent in what follows). The sorbent is a finely disperse white powder with creme tinge. According to the histogram in Fig. 1, the main fraction (49.2%) used in the study contains particles of size 0.25–0.5 mm.

The following elements were found in the sorbent (%): Ca 26.5 ± 0.1 (titrimetry), Mg 2.69 ± 0.05; Fe 2.00 ± 0.02; Al 1.10 ± 0.05 (spectrophotometry, KFK-2 apparatus), Si 2.4 ± 0.1 (gravimetry), Na 0.19 ± 0.01 (flame photometry, Flapho-4 photometer); Ni 0.0010 ± 0.0005, Pb 0.0013 ± 0.0005, Cu 0.0047 ± 0.0005 (spectral analysis, LMA-10 spectrograph).

Using an X-ray analysis (DRON-2 apparatus, Cu_{K_α} radiation), we found the following phases: $CaCO_3$ (calcite), $MgCO_3 \cdot 3H_2O$, β- and γ-$Fe_2O_3 \cdot H_2O$.

A water extract of the sorbent at dry substance to water ratio of 1 : 5 has pH 8.74 ± 0.05 (the pH values were measured with an I-120M ionometer).

Hydrolytic equilibria for chromium(III) ions were calculated for the 100 mg l^{-1} concentration, which corresponds to the average content of chromium ions in real wastewater [3]. As a result, the pH ranges

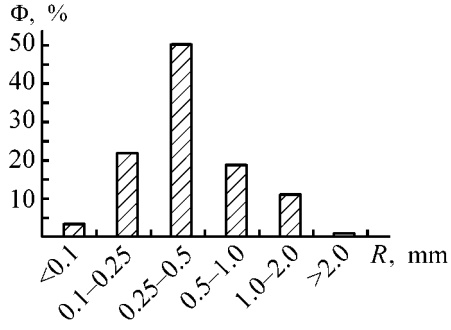

Fig. 1. Granulometric composition of the sorbent. (Φ) Content of a fraction in the sorbent and (*R*) particle size.

with the following predominant species were established: Cr^{3+} (pH < 4.0), $Cr(OH)^{2+}$ (4.0 < pH < 5.7), $Cr(OH)_2^+$ (5.7 < pH < 5.9), $Cr(OH)_3$ (5.9 < pH < 9.4), and $Cr(OH)_4^-$ (pH > 9.4). The range of maximal chromium(III) recovery at pH 6.5–10 was experimentally found by direct precipitation with sodium hydroxide solution. This pH range is in good agreement with the theoretically calculated range of $Cr(OH)_3$ predominance (Fig. 2a).

The calculated and experimental data, and also the fact that the solution above the sorbent has pH > 7, suggest that the industrial carbonate-containing waste can be used in purification of wastewater to remove chromium(III) ions.

The degree of chromium(III) recovery was monitored during the experiments by determining spectrophotometrically with diphenyl carbazide the concentration of chromium(III) ions in solution before and after contact with the sorbent [4]. The optical density was measured on a KFK-2 photometer with an error of no greater than 4%. Model solutions were prepared from analytically pure $CrCl_3 \cdot 6H_2O$. The sorption was carried out under static conditions with stirring.

We found experimentally for a model solution with chromium concentration of 100 mg l^{-1} and pH 3.41 (Fig. 2b, curve *3*) that purification to the MPC level is achieved at sorbent consumption of 10 g l^{-1} (pH 7.57). It is seen from how the pH value varies that the sorption is accompanied by neutralization of the initially acid solutions.

To optimize the sorbent consumption, we studied the effects of time, temperature, and other factors on the degree of chromium recovery. To assess the effect of contact duration, the sorbent (20 g l^{-1}) was placed in a solution to be purified (solution volume 100 ml) at 20°C. The obtained data (Fig. 2c) show that 20 min is sufficient for purification to the MPC level to be complete. In further experiments, the optimal duration of the sorbent–solution contact was 20 min.

The degree of chromium(III) recovery as a function of sorbent consumption at 20, 35, 50°C is shown in Fig. 2b. It can be seen that the sorbent consumption required for purification of aqueous solutions to the MPC level decreases dramatically with increasing temperature. For example, the sorbent consumption is about 10 g l^{-1} at 20°C and only 1 g l^{-1} at 50°C. Apparently, this is a consequence of the higher solubility of carbonates contained in the sorbent and increased degree of chromium(III) ion hydrolysis at elevated temperature.

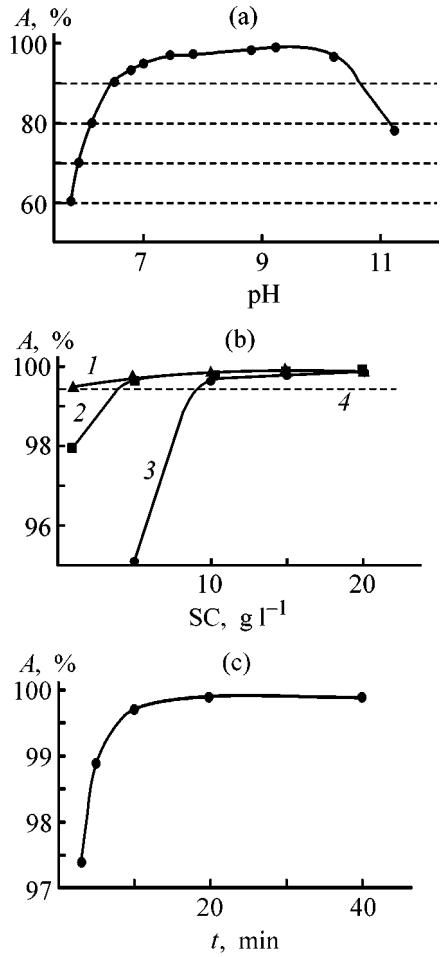

Fig. 2. Degree of Cr(III) recovery *A* vs. (a) pH value, (b) sorbent consumption SC, (c) time *t*. Temperature (°C): (*1*) 50, (*2*) 35, (*3*) 20; (*4*) MPC level.

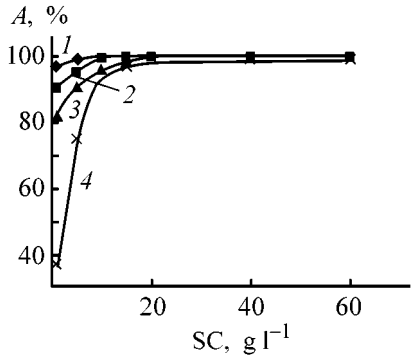

Fig. 3. Degree of Cr(III) recovery *A* vs. sorbent consumption SC at 20°C. Sorbent consumption RC (mg g^{-1} Cr): (*1*) 50, (*2*) 100, (*3*) 200, (*4*) 500.

To expand the possibilities of sorbent application, namely to purify spent electrolytes with chromium(III) content of up to 500 mg l^{-1}, we studied how the degree of chromium(III) recovery depends on the sorbent consumption at various initial concentrations of

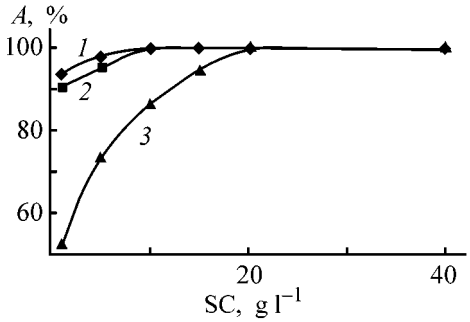

Fig. 4. Degree of Cr(III) recovery *A* vs. sorbent consumption SC for solutions of chromium (*1*) nitrate, (*2*) chloride, and (*3*) sulfate at 20°C.

chromium(III) in solutions (Fig. 3) and determined the sorbent consumption required to attain the MPC level in these cases. As expected, the sorbent consumption grows with increasing initial solution concentration and attains 60 g l^{-1} in the case of solutions with chromium(III) content of 500 mg l^{-1}.

Industrial chromium plating involves a stage of product pretreatment (mechanical cleaning, degreasing, etching, and rinsing) and direct electrolytic chromium deposition. Various acids can be used in etching. Thus, the galvanic sewage may have varying composition. Therefore, it is necessary to consider the effect of the anionic component of the solution on chromium sorption. For this purpose, we carried out additional experiments with chromium(III) nitrate and sulfate solutions (C_{Cr} = 100 mg l^{-1}). Comparison of thus obtained data (Fig. 4) and data on sorption from chloride solutions shows that the processes of sorption from chromium(III) chloride and nitrate solutions differ only slightly, although the degree of chromium(III) recovery from the nitrate solution is somewhat higher at the same sorbent consumption. The efficiency of chromium(III) recovery from the sulfate solution is essentially lower (Fig. 4). For example, when chromium(III) is removed from this solution, the MPC_{Cr} value is attained on adding 20 g l^{-1} of the sorbent. This can be accounted for by sorbent "gypsuming" in the course of chromium(III) sorption from sulfate solutions, i.e., a part of calcium ions of the sorbent becomes bound in the form of calcium sulfate. Moreover, a layer of difficulty soluble calcium sulfate appearing on the sorbent surface prevents diffusion of calcium ions into the solution and penetration of chromium(III) ions into the sorbent.

To verify the conclusions based on studying the sorption from model solutions, we carried out tests with real wastewater from electroplating shops of various plants. The wastewater compositions and analytical data are shown in the table. It follows from a comparison of the data for sample no. 1 and for the model solution with a similar concentration and the same sorbent consumption that the degree of chromium(III) recovery from sample no. 1 is much lower. This results from the presence of iron(III) and zinc(II), along with chromium(III), in the sorbent. The sorbent is presumably consumed for recovery of these ions. Moreover, in the case of sample no. 1, the pH value is much lower and part of the sorbent is consumed for neutralization of the acid medium. In fact, in the case of sample no. 4 with pH 3.34, the solution purification to remove chromium(III) to about the MPC level is attained on adding 20 g l^{-1} of the sorbent, whereas for sample no. 3 with pH 1.87 a similar result is obtained on addition of 60 g of the sorbent to 1 l of the solution. This conclusion is also well confirmed by the experimental data for samples nos. 5 and 6.

CONCLUSIONS

(1) A study of the chemical (elemental), phase, and granulometric composition of carbonate-containing industrial waste demonstrated the possibility of its use

Purification of real wastewater

Sample no.	Wastewater parameters			Sorbent consumption, g l^{-1}	C_{Cr}, residual, mg l^{-1}	Degree of Cr(III) recovery, %
	cations	pH	C_{Cr}, initial, mg l^{-1}			
1	Cr(III), Zn(II), Fe(III)	1.87	217.7	20	50.8	76.7
2	Cr(III), Zn(II), Fe(III)	1.87	217.7	40	11.6	94.7
3	Cr(III), Zn(II), Fe(III)	1.87	217.7	60	0.4	99.8
4	Cr(III), Zn(II), Fe(III)	3.34	217.7	20	0.7	99.7
5	Cr(III), Fe(III)	3.21	154.7	20	0.4	99.9
6	Cr(III), Zn(II), Fe(III)	3.51	275.2	20	0.4	99.9

as a sorbent in removal of chromium(III) ions from wastewater.

(2) Sorbent consumption decreases with increasing temperature and grows with increasing initial concentration of chromium(III) ions in the solution and also on passing from nitrate solutions to chloride, and especially to sulfate solutions.

(3) The results of the study were confirmed by tests with wastewater from electroplating shops of various plants. The efficiency and expediency of wastewater purification with the use of the carbonate-containing sorbent studied were demonstrated.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Ways to Develop Low-Waste Technology for Purification of Wastewater Containing Heavy Metal Compounds

N. E. Manvelova, I. V. Vol'f, and M. A. Sinyakova

Maikop State Technological Institute, Maikop, Russia

St. Petersburg State University of Plant Polymers, St. Petersburg, Russia

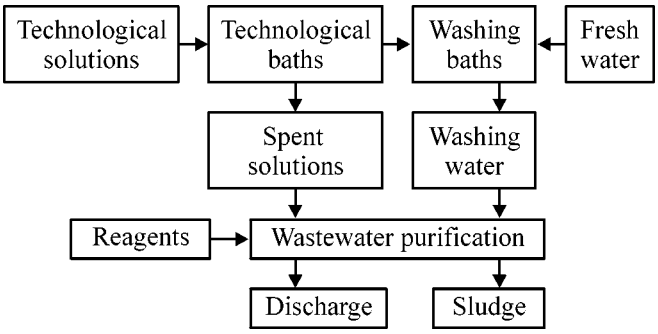
Received February 6, 2001

Abstract—A scheme is proposed for purification of wastewater of galvanic and printed circuit board shops. The scheme using reverse osmosis, ion exchange, and electrolysis techniques involves recycling of purified water and recovered metals.

Contamination of natural water with sewage water of galvanic industries is an ecological challenge. Discharge of this wastewater, containing highly toxic salts of heavy and non-ferrous metals, has a severe impact on the environment and leads to irretrievable loss of valuable metals in amounts of tens of thousands of tons.

The discharge of metals into water bodies of St. Petersburg was 3310.53 tons in 1999 [1]. The decline in galvanic manufacture in the succeeding years did not result in a proportional decrease in the environment contamination.

Most of domestic galvanic enterprises make use of outdated wastewater treatment facilities of 30–40-years-old conventional design. These bulky and cost-inefficient facilities fail to meet modern requirements to water recycling and heavy metal recovery. An essential drawback of such systems is the formation of a common wastewater flow including waste electrolytes, acidic and basic wastes, and rinsing water (see scheme). Mixing of wastes containing different ions in various concentrations hampers extraction of pollutants, and the mixed flow cannot be recycled even after reagent purification [2]. Purified wastewater is discharged into a sewer system or directly into a water body. Sediments formed in wastewater purification, i.e., sludges containing a combination of various heavy metal compounds, are transported to sludge stores, wherefrom these compounds are gradually washed out by ground waters and, all the same, find their way into the environment. Sludge processing is technologically complicated and economically inefficient.



Scheme of water use in degreasing, etching, and electroplating.

Owing to the absence of water recycling, most of domestic galvanic plants consume fresh water in amounts of 2 m^3 and more per 1 m^2 of treated surface area, whereas in Sweden the same parameter is 0.05 $m^3\,m^{-2}$. A promising engineering solution of the problem under discussion consists in passing at galvanic shops to local purification systems recycling purified wastewater and recovering heavy metals. Local systems are intended for purification of wastewater with relatively invariable composition, produced by a certain technological line or separate installation, which allows use of compact purifying systems based on more effective and expensive purification techniques. The recoupment of such systems can be ensured by reduction of charges for the intake of pure water and disposal of wastewater and sludges. Moreover, wastewater produced by a particular technological line or separate installation usually contains ions of a single metal, rather than a mixture of metal ions, which significantly simplifies

1070-4272/01/7410-1702 $25.00 © 2001 MAIK "Nauka/Interperiodica"

its purification and creates new possibilities for further use of the recovered metals.

There are several efficient methods of purification, namely: adsorption and ion exchange [2–4], isolation of impurities by changing their aggregative state (distillation and freezing) [1, 2], and membrane techniques (electrodialysis, ultrafiltration, and reverse osmosis) [2, 5–9]. Comparative data [1] on capital investments and degree of nickel(II) removal from washing water are given in Table 1. The consumption of washing water was 0.2 $m^3 h^{-1}$, and the initial concentrations of Ni(II) and organic compounds, 32 and 54 mg l^{-1}, respectively. The cost of wastewater purification by ion exchange was conditionally taken to be unity.

Naturally, the relative costs and residual concentrations may vary with discharge parameters.

EXPERIMENTAL

The aim of this work was to study the possibility of, and conditions for creation of a low-waste technology for purification of wastewater produced by galvanic industry and printed circuit board manufacture.

The proposed purification scheme involves use of reverse osmosis for washing water purification, ion exchange for concentrating metal ion solutions, and electrochemical methods for metal recovery from concentrates of washing water and spent technological solutions.

The advantages of reverse osmosis consist in that no chemical reagents are required, the installations are compact, and water can be purified to remove impurities of varied nature.

Membranes used for reverse-osmosis purification retain any particles larger than 0.001 μm: inorganic ions, molecules of organic substances, and colloid particles. This leads to a high degree of purification and water becomes suitable for recycling.

Among disadvantages of reverse osmosis are the possibility of precipitate formation on membranes owing to the concentration polarization and the resulting necessity for periodic regeneration of the membranes.

We determined the most favorable conditions of reverse-osmosis purification of washing water of galvanic shop on a pilot installation comprising filters for rough and fine mechanical pre-purification and a reverse-osmosis apparatus with roll elements (see figure).

Table 1. Relative costs of purification of nickel-containing the washing waters by various methods and the attained degree of purification

Method	Relative cost	Residual concentration, mg l^{-1}	
		Ni(II)	organic substances
Ion exchange	1	0.008	–
Reverse osmosis	2–3	0.05	1.2
Electrolysis	3–4	0.3	–
Electrodialysis	5–10	0.55	6.7
Evaporation	8–12	0.1	4.1

Table 2. Reverse-osmosis purification of local washing water discharges

Source of washing water	Metal ion	$C_{M^{n+}}$, mg l^{-1}		Selectivity, %	pH
		initial solution	filtrate

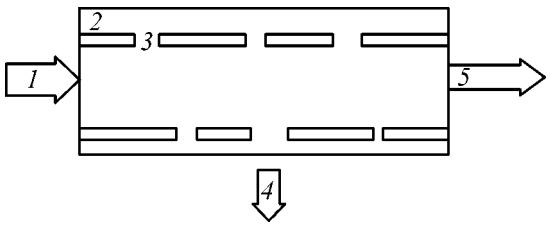
Comparative tests of the most widespread cellulose acetate membranes MGA-70, MGA-80, MGA-90, and MGA-100 demonstrated that MGA-100 membranes are the most effective under the test conditions, and these membranes were used in further studies. The possibility was established of purifiyng washing water containing various metal ions (Table 2). In all the experiments, the selectivity of a membrane, characterizing its separating ability, exceeded 90%, and the low residual content of metal ions in filtrates allowed their recycling as washing water.



Schematic of a reverse-osmosis element: (*1*) wastewater input, (*2*) reverse-osmosis apparatus, (*3*) membrane, (*4*) purified filtrate, (*5*) concentrate.

The experiments demonstrated that the residual content of metal ion in the filtrate, $C_{M^{n+}}$, is in inverse relationship with the effluent concentrate fraction—the ratio of the concentrate volume to the volume of washing water to be purified. In most cases, this fraction was maintained at a level of 10–15%.

Our study of the efficiency and selectivity of membranes in relation to reverse-osmosis purification determined the following optimal parameters: pressure 2.0–2.5 MPa, velocity of purified water flow along membrane 0.8–1.2 m s^{-1}, water temperature 12–27°C. In this case the degree of purification to remove salts of heavy metals is no less than 90%, and the extent of recycling of purified water, no less than 90%.

Comparative tests of the efficiency of membrane regeneration with solutions of oxalic, citric, and malic acids allow us to recommend a 2% solution of oxalic acid for practical use. A complete restoration of the initial properties of membranes can be achieved if regeneration with this solution is carried out once a month.

In most cases, more effective isolation of metals from concentrates obtained in reverse-osmosis purification can be performed if the concentration of metal ions is no less than 4–10 g l^{-1}. In this case, concentration can be carried out in the second stage of a reverse-osmosis installation or on an ion-exchange installation.

Heavy metal ions can be recovered from primary concentrates using various types of ion-exchange resins. We have shown previously [10] that carboxylic cation-exchange resins in Na form are extremely selective in sorption of copper(II) and other metal ions forming sparingly soluble hydroxides in hydrolysis. If hydroxides or basic salts of the metals being extracted are poorly soluble in alkalis, they can be accumulated in a cationite phase in amounts exceeding severalfold the exchange capacity in a single sorption by treating a cationite alternately with primary concentrates containing ions of a metal to be extracted and with alkali solutions.

$$2R\text{–}COONa + Cu^{2+} = (R\text{–}COO)_2Cu + 2Na^+, \quad (1)$$

$$(R\text{–}COO)_2Cu + 2NaOH = 2R\text{–}COONa \cdot Cu(OH)_2, \quad (2)$$

$$2R\text{–}COONa \cdot Cu(OH)_2 + Cu^{2+} = (R\text{–}COO)_2Cu \cdot Cu(OH)_2 + 2Na^+, \quad (3)$$

$$(R\text{–}COO)_2Cu \cdot Cu(OH)_2 + 2NaOH = 2R\text{–}COONa \cdot 2Cu(OH)_2. \quad (4)$$

For example, a triple sorption of copper(II) ions on a KB-4P-2 cationite, following equations (1)–(4), allowed us to raise the copper(II) concentration in the cationite matrix to 10 mg-equiv g^{-1} or 320 mg g^{-1} (in terms of dry cationite) [10].

At a comparatively small (in terms of volume or weight) required of amount ionites, it may be expedient to use relatively expensive new-generation ion-exchange resins. These resins have high exchange capacity, good kinetic characteristics, and granules of uniform size; the last factor ensures low hydraulic resistance of an ionite layer in filtration.

To recover metal ions from concentrates formed in purification by reverse osmosis and ion-exchange and containing about 4–4.5 g l^{-1} of metal ions, we used direct electrolysis on installations equipped with metal cathodes and graphite anodes. Discharge of metal ions (Cu, Ni, Zn, or Cr) and deposition of a metal occurred on the metal cathode. The current efficiency by metal was determined by gravimetry.

The experiments demonstrated that use of cathodes with smooth surface at a cathode current density of 0.3–1.5 A dm^{-2} allows recovery of up to 80–85% of metals at current efficiency of 30–70%. In this case, the specific energy consumption for metal recovery is 4–8 kW h kg^{-1}.

With bulk flow-type complex-shape cathodes, the current density can be decreased to 0.02–0.5 A dm^{-2}, with the degree of metal recovery of 95–98% and current efficiency of 50–80%.

Metals deposited at the cathode had relatively high purity (up to 99.5%), and, therefore, could be used as soluble anodes in metal plating.

Spent etching solutions formed in printed circuit board manufacture can be recovered by direct electrolysis with cooled titanium cathodes and graphite anodes at 40–45°C, current density of 9.5–11 A dm^{-2}, and rate of spent solution supply of 5–10 l min^{-1}.

In this case, cathode deposition of copper and anode recovery of etching reagent occur simultaneously. The productivity of copper recovery was 3 kg h^{-1} at a current efficiency of 85%.

The results of the investigations performed allowed us to design an automated compact (required area of 95 m^2) installation for physicochemical purification of wastewater containing heavy metals.[1]

[1] The project will be implemented at the galvanic shop of Krasnoe znamya plant (Ryazan).

CONCLUSIONS

(1) Conditions were found for the effective joint use of reverse osmosis, ion exchange, and electrolysis for deep purification of wastewater containing heavy metal ions and for recovery of these metals.

(2) A low-waste technology for purification of wastewater of galvanic industry and printed circuit board manufacture, assuming recycling of purified water and recovered metals, was proposed for practical implementation.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Formation of Optimal Working Space in Adsorbers with Fixed and Moving Adsorbent Beds

N. A. Samoilov

Ufa State Technical University of Oil, Ufa, Bashkortostan, Russia

Received April 5, 2001

Abstract—The possibility of improving the adsorbent efficiency by means of transverse and longitudinal sectioning of adsorption apparatus is substantiated. Results of an experimental and calculation study of sectioned apparatus are presented. A number of designs of sectioned adsorbers with the optimal working space were developed.

Adsorption apparatus with fixed and moving adsorbent beds have rather widely varying designs [1–3]. For example, adsorbers with fixed adsorbent bed may have vertical, horizontal, multishelf, annular, or some other arrangement of the adsorbent bed in an adsorber [2, 3]. The bed shape is frequently defined by technology (e.g., annular adsorbent beds are used in the case of limitations on the loss of head in purification of a raw material), whereas the relative geometric dimensions of the bed receive much less attention. For example, the ratio of the bed height H to adsorbent bed diameter D in industrial vertical adsorbers varies rather widely—between 0.5 and 15, without any convincing substantiation of the adopted H/D values.

The aim of this study was to analyze the effect of the working space configuration of the adsorber on the working activity of the adsorbent and the purity of the obtained products.

Adsorption apparatus with fixed adsorbent bed. An important thing in improving the operation efficiency of an adsorption apparatus is to make higher the main performance parameter of the process—the breakthrough activity of the sorbent, a, reached by the instant of breakthrough of the component being extracted into the purified product, since it largely determines the adsorber size, adsorbent consumption, and energy expenditure for adsorbent regeneration.

In batch adsorption apparatus, a part of the adsorbent bed, which corresponds to the height of the mass-transfer zone, is saturated with the adsorbate to a lesser extent than the spent bed. This makes on the whole lower the integral activity of the adsorbent, regarded in experiments and calculations as real breakthrough activity. Let us introduce the coefficient of efficiency of adsorbent use under working conditions, K_e, characterizing the extent to which the sorbent is spent:

$$K_e = a_b/a_e,$$

where a_b is the dynamic activity of the adsorbent to conditional breakthrough (g of adsorbed substance per 1 g of adsorbent); and a_e is the total dynamic activity of the adsorbent under the conditions of equal adsorbate concentrations in the flow at the entrance into, and exit from the adsorbent bed, characterizing the potential adsorption activity of the sorbent (g of adsorbed substance per 1 g of adsorbent).

The K_e value strongly depends on the conditions under which the adsorption process is performed. For example, calculations show that, for apparatus with long absorption stage (e.g., 1 day) and the correspondingly large height of the adsorbent bed, the decrease in a_b relative to a_e is largely compensated for by the fact that the ratio of the bed height H_1 to the height L_0 of the mass-transfer zone is, as a rule, greater than 10 for apparatus of this kind. In these cases, the sorbent efficiency coefficient K_e is rather high and constitutes 0.95–0.99, depending on the symmetry factor f of the output curve of absorption dynamics. By contrast, for adsorbers used in short-cycle processes, the H_1 value exceeds L_0 only slightly. In these cases, the adsorbent activity under the working conditions is comparatively low and is much exceeded by the total dynamic activity, which reduces the efficiency coefficient K_e to 0.3–0.5.

* (n) Number of sections, (W) flow velocity, and (H_s) sorbent bed height.

Reducing the bed diameter n-fold at constant volume of the vertical adsorbent bed results in an increase by a factor of n^2 in the bed height and in the linear velocity of the flow being purified (Fig. 1), and by a factor of n in the mass-transfer zone length, which makes the efficiency coefficient K_e somewhat higher (Table 1). However, the adsorber dimensions change in this case to such an extent that the apparatus becomes less convenient in practice. For example, if the velocity of the flow being purified is raised 4-fold in an adsorber with bed diameter and height of, respectively, 2 and 10 m and mass-transfer zone length of 5 m, the apparatus will be 40 m high at bed diameter of 1 m and, although the mass-transfer zone length will increase to 10 m, the coefficient of adsorbent use efficiency, K_e, in the new design will, nevertheless, increase from 0.65 to 0.85. However, an adsorber with such a bed height is inconvenient since the low mechanical strength of the adsorbent will result in crushing of sorbent grains and loss of a part of ground sorbent with the flow of the product being purified. In addition, the hydraulic resistance of the sorbent bent increases dramatically. Such a high column is to be divided into several beds, which will make the apparatus more expensive and the operations of adsorbent charging and discharging more difficult.

One of variants of improving the working space of an adsorber is its design in the folded "telescopic" form, when a system of n shells inserted one into another leads to conditional longitudinal sectioning of the apparatus, with equal cross-sections of each of the annular zones and the central zone (Fig. 2). This ensures a constant flow velocity in each sections, which is $n + 1$ times that in the initial apparatus.

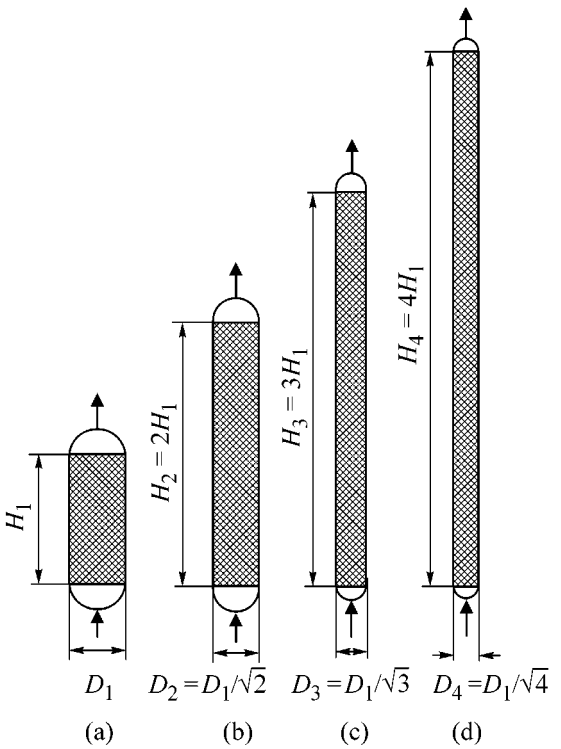

Fig. 1. Design variants of vertical adsorbers with the same charge of fixed adsorbent bed and varied height H and bed diameter D. H/D: (a) H_1/D_1, (b) $2.83H_1/D_1$, (c) $5.19H_1/D_1$, and (d) $8.0H_1/D_1$.

Adsorber: (a) of base type with bed height $H = H_1$, (b) with two sections with bed height $H = 2H_1$, (c) with three sections with bed height $H = 3H_1$, and (d) with four sections with bed height $H = 4H_1$.

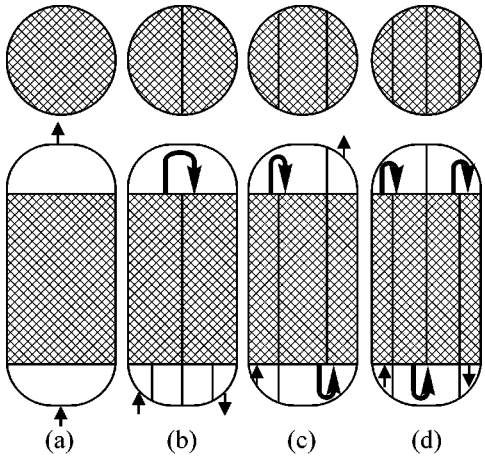

Fig. 3. Design variants of sectioned adsorbers with vertical partitions and the same charge of fixed adsorbent bed.

The telescopic design of the apparatus leads to a more perfect working space of the adsorber (Table 1), but has such disadvantages as high steel intensity and complicated systems for adsorbent charging and discharging.

This disadvantage is eliminated when the adsorbent bed is divided along the height by partitions parallel to the motion direction of the raw material being purified into several in-series connected sections (Fig. 3), which leads to an increase in the breakthrough activity of the sorbent [4–7]. This can be achieved because of the different effects of the section geometry on the flow velocity of a raw material being purified and on the mass-transfer zone length (Table 1).

Let us consider how the use of apparatus with adsorbent bed sectioned into n sections with $n + 1$ partitions parallel to the flow of a product being purified leads to intensification of short-cycle adsorption process.

With increasing number of sections, n, the path of a flow being purified along the apparatus becomes longer, i.e., the adsorbent height grows:

$$H_n = H_1 n, \tag{1}$$

where H_1 and H_n are, respectively, the path lengths of a flow in the adsorber through an adsorbent bed without sectioning and with n sections (m).

Simultaneously with the adsorbent bed height, grows the flow velocity

$$W_n = W_1 n, \tag{2}$$

where W_1 and W_n are, respectively, the velocities of adsorbate transport along apparatus without sectioning and with n sections (m s^{-1}).

The mass-transfer zone length L_0 depends on the flow velocity [8]:

$$L_0 = B\sqrt{W}, \tag{3}$$

which was also confirmed experimentally in [9, 10]. As applied to the operation conditions of a sectioned adsorber, relation (3) takes the form

$$L_{01}/L_{0n} = \sqrt{W_1/W_n}. \tag{4}$$

The mass-transfer zone length L_0 can be calculated using the equation [11]

$$L_0 = H_1 \frac{a_e - a_b}{a_e - (1 - f)a_b}, \tag{5}$$

where f is the symmetry factor of the output curve of the adsorption dynamics.

Writing Eq. (5) for the operation conditions of a conventional adsorber with bed height H_1 and n-sectioned adsorber with bed height H_n, we obtain an equation for calculating the efficiency coefficient

$$K_e = \frac{a_b}{a_e} = \frac{H_n - L_0\sqrt{W_n/W_1}}{H_n - L_0(1 - f)\sqrt{W_n/W_1}}. \tag{6}$$

Since the mass-transfer zone height is virtually independent of the adsorbent bed height and is proportional to $\sqrt{W}$, and W grows in sectioning in proportion to the height of the n-sectioned adsorber, this leads to

an increase in K_e, which intensifies the adsorption process because of the approach of a_b to a_e. The coefficient of adsorber operation efficiency depends on the number of sections in the apparatus, the symmetry factor of the output curve, and the H_n/L_0 ratio (Fig. 4); $K_e \to 1$ at $H_n/L_0 \to \infty$.

The effect of sectioning on the adsorbent efficiency was verified experimentally in separation of a 20% toluene–*n*-heptane mixture in liquid phase with NaX zeolites. A set of laboratory columns with adsorbent bed height of 0.27, 0.57, and 0.90 m allowed adjustment of the operation conditions of a sectioned adsorber by varying the total adsobent bed height in a set of in-series connected columns and the raw material flow rate equivalent to the necessary number of stages. The mass-transfer zone length was calculated by Eq. (5) and determined experimentally by sampling the product along the column height. The data presented in Fig. 5 and Table 2 confirm that sectioning makes it possible to raise the dynamic activity of the NaX zeolite with respect to toluene to a conditional breakthrough, and the efficiency coefficient K_e by 12–14 rel.%, with good qualitative and quantitative agreement between the experimental and the calculated values prognosticating the operation of a sectioned apparatus on the basis of experimental results obtained for the base unsectioned apparatus.

For concrete conditions of the adsorption process, the optimal number of sections forming the working space of an apparatus can be calculated; as a rule, the optimal number of sections is within 2–5 [12].

Adsorption apparatus with moving adsorbent bed. Adsorption apparatus with moving bed—hypersorbers, serve for separating multicomponent mixtures into fractions markedly enriched in one of components [2, 3, 13, 14]. In separating a multicomponent (e.g., four-component) mixture, the least readily sorbed component is discharged in the vapor phase from the upper zone of the adsorption section of the hypersorber, and the best sorbed component, as desorption product from the upper zone of the desorption section. Other components being separated are also discharged in vapor phase in succession along the height of the adsorption section operating in the chromatographic mode (Fig. 6a). The better a particular intermediate component is sorbed, the lower, along the adsorber height, lies the zone with the maximum concentration of the given component [14].

The indisputable advantages of the process with a moving adsorbent bed are as follows: lower adsorbent consumption (since the height of the adsorption section of the process exceeds only slightly the mass-transfer zone length and is several times smaller than the adsorbent bed height in apparatus with fixed sorbent bed), lower energy expenditure in the desorption stage, small size of the installation, and possibility of high-level automation of the process.

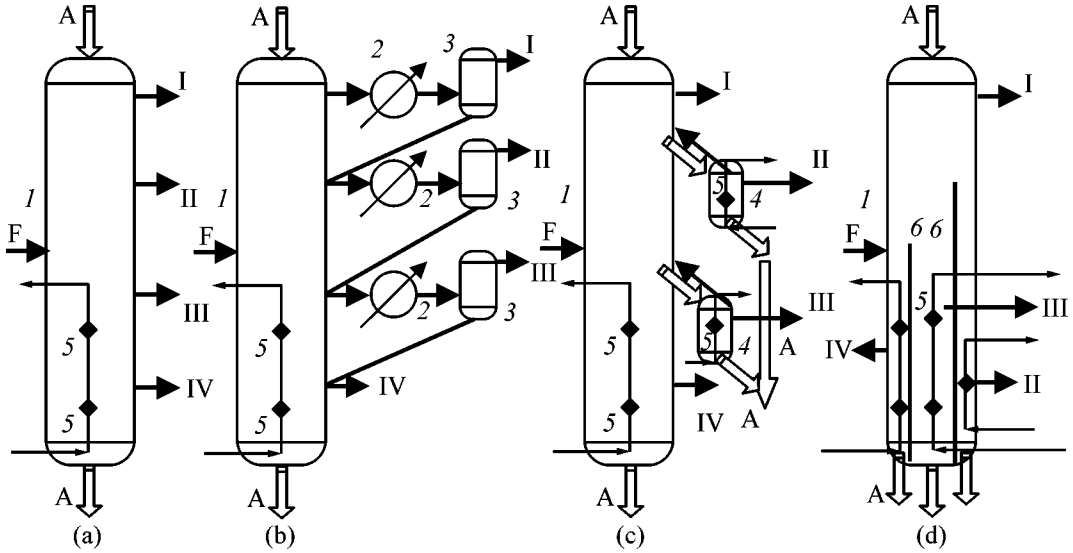

Fig. 6. Variants of separation of a four-component mixture in various designs of adsorbers with moving adsorbent bed. Hypersorber: (a) conventional; (b) supplemented with systems for cooling of discharged fractions with partial condensation of high-boiling components; (c) supplemented with system of stripping desorbers for removal of low-boiling components from the effluent fractions, with subsequent desorption of target fractions; and (d) with vertical sectioning partitions, equivalent to the system in variant (c). F, raw material; A, adsorbent; I–VI close-cut effluent fractions; (*1*) hypersorber, (*2*) condensers, (*3*) condensate collectors, (*4*) desorbers, (*5*) heat supply systems, and (*6*) sectioning partitions.

A disadvantage of the hypersorption process is the comparatively low purity of the intermediate components discharged at different heights along the adsorption section [13, 14], associated with the limitations on the column height. Improving the purity of products in side fractions requires a significant increase in the mass-transfer zone length and the resulting substantial increase in the number of theoretical plates with very low concentration gradient of a component being extracted in both the vapor and solid phases just at those parts of the bed where the efficiency of separation is markedly impaired [15]. As a consequence, the apparatus size, mass of circulating adsorbent, and energy expenditure for desorption grow dramatically.

Such an imperfection of the hypersorber operation can be eliminated, by analogy with the rectification process, by directing the products taken-off at different heights along the hypesorber in vapor phase to cooling with partial condensation of high-boiling components (Fig. 6b), which makes it possible to lower the concentration of these components in the discharged fractions and to increase the concentration of target products. In the limiting case, the system of single evaporation (condenser and evaporator vessel) can be replaced with an incomplete rectifying column, if the target component and impurities have markedly different volatilities. In some cases, it is necessary to remove low-boiling components from the effluent fraction and to increase thereby the concentration of the target components. Then the hypesorber can be equipped with a system of desorbers working as stripping columns (Fig. 6c) into which adsorbent saturated with the target product is delivered, since, according to the phase equilibrium laws, the concentration of the target component in the adsorbed phase is higher than that in the vapor phase. The admixture of a low-boiling component will be desorbed in the upper part of the "stripping" desorbers by the supplied heat and then returned into the hypersorber, and the target product will be discharged in their bottom part. Thus, in the two considered ways to solve the problem at hand, the intensification of the adsorption process with improvement of the quality of the discharged fractions is ensured by installing additional devices, and in the second of these by redistribution of the adsorbent mass and heat supply in the system. In this case, the velocity of adsorbent motion will decrease dramatically in the lower part of the base hypersorber, which will impair the operation of the already rather inefficient system of heat transfer from the heat transfer agent to the adsorbent in the desorption zone, or make necessary fabricating an apparatus with narrowed bottom part.

These shortcomings can be eliminated with the stripping desorbers placed directly in the adsorber with moving bed by mounting additional vertical sectioning partitions with lateral and bottom edges in contact

with the casing. The upper edges of the partitions must be higher than the feeding zone of the adsorption column. [16–19]. The number of partitions leading to parallel sectioning of the apparatus is equal to the number of discharged side fractions. Each section plays the part of a stripping desorber. In separating, e.g., a four-component mixture, mounting two additional partitions makes it possible to divide the adsorbent spent in the adsorption section into three flows delivered into chromatographic sections with individually optimal temperature modes. The component with the highest sorbability, absorbed by the adsorbent, is released into sections with higher desorption temperature, and that with intermediate adsorbability, into sections with lower temperature (Fig. 6d). Such a differentiated distribution of the adsorbent heating temperature over sections allows reduction of energy expenditure, compared with that in a conventional hypersorber, when the entire body of adsorbent is heated to the maximum temperature. The flow chart for a sectioned adsorber is shown in Fig. 7.

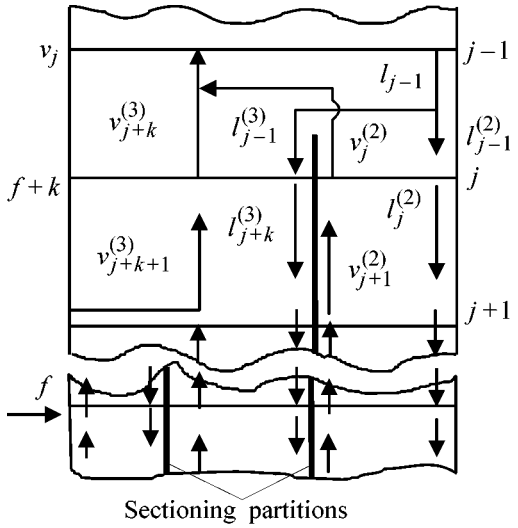

Fig. 7. Flows in a sectioned adsorber with moving adsorbent bed in separating a four-component mixture.

Previously [20, 21], the efficiency of a sectioned adsorber in extraction of two impurities from the base flow has been evaluated. The operation of a sectioned adsorbent column with moving adsorbent bed has been studied in detail and an analysis was made of the effect of sectioning on the quality of the extracted narrow-cut fractions—products of separation of a three-component mixture [22] As raw material was used a hypothetical three-component raw mixture fed into the column at component ratio of 30 : 40 : 30. The relative desorbabilities of the components, α_i (reciprocal of the relative adsorbability and equivalent of the relative volatility of components in rectification processes), were represented by the ratio $\alpha_1 : \alpha_2 : \alpha_3$ of 9 : 3 : 1, 16 : 4 : 1, or 25 : 5 : 1 and covered a rather wide range of variation of the sorbent adsorption properties and affinities of substances being separated for the sorbent. The discharge of the separation products was done with account of the balance relation of the main components: the first fraction had a yield fr_1 = 30; the second, fr_2 = 40; and the third, fr_3 = 30 kg per 100 kg of raw material.

A mathematical model of an adsorption column with moving adsorbent bed assumed a successive plate-by-plate calculation of the apparatus (from one stage of phase equilibrium to another) with account of the equilibrium and material balance equations at the contact device by means of the modified relaxation method which allowed a rather effective comparison of different variants of mass-exchange apparatus operation [23]. A specific feature of the model is that it relies in analyzing the phase equilibrium upon the notion of the relative desorbability of components of the mixture being separated, similar to relative volatility of components in calculating a rectification column.

The composition of the adsorbed mixture of components, which "flow down" together with a conditionally inert mass of adsorbent from j-th plate after contact on this plate of the countercurrent nonequilibrium flows of adsorbent from (j – 1)-th plate and vapor from (j + 1)-th plate and possible supply of raw material to j-th plate, can be determined from the material balance equation

$$x_{j,i} = \frac{l_{j-1}x_{j-1,i} + v_{j+1}y_{j+1,i} + f_j x_{f,j,i}}{l_{j-1} + v_{j+1} + f_j}, \quad (7)$$

where l_{j-1}, $x_{j-1,i}$ are the amount of flow descending from (j – 1)-th plate (flow absorbed by the adsorbent) and the content of i-th component in it; v_{j+1}, $y_{j+1,i}$ are the amount of vapor ascending from (j + 1)-th plate and the content of i-th component in it; f_j, $x_{f,j,i}$ are the amount of raw mixture and the content of i-th component in it. The composition of the vapor that is in equilibrium with the adsorbent being spent and ascends from j-th plate is found from the relation

$$y_{j,i} = \frac{\alpha_i x_{j,i}}{\Sigma\, \alpha_i x_{j,i}}, \quad (8)$$

where α_i is the relative desorbability of i-th component.

Table 3. Comparison of the quality of fractions discharged in operation of a hypersorber and sectioned adsorber in purification of a three-component mixture to remove admixtures of the second (2%) and third (3%) components

Composition of discharged fractions, %	Base hypersorber	Sectioned apparatus
Fraction 1 (95%):

component 3	9.08	0.29
Fraction 3 (3%):		
component 1	0.00	0.00
component 2	6.07	0.25
component 3	93.93	99.75

A calculation analysis of the operation of a three-section adsorber revealed the following main factors associated with the formation of the optimal working space in sectioned adsorbers with moving adsorbent bed with respect to flows and geometric parameters: distribution of adsorbent flow among sections, distribution of the cross-section areas of the sections, positions of upper edges of sectioning partitions in the adsorbent bed, place of raw material input into the adsorber, possibility of adjusting the working space characteristics upon a change in the flow rate or composition of the raw material.

Let us consider the operation of a sectioned adsorber in separation of a four-component mixture in the region of flow distribution between the first section, in which the second component is to be extracted (the first component is discharged at the top of the adsorber) and other sections. As follows from the flow chart of a sectioned adsorber (Fig. 7), part of sorbed substances, $l_{j-1}^{(3)}$, is diverted, together with the sorbent descending from a fixed (j – 1)-th plate, into the discharged zone of the third and fourth fractions by the sectioning partition. The remaining part of the sorbed flow, $l_{j-1}^{(2)}$, is moved to the discharge zone of the second ("intermediate") separation product, with $l_{j-1} = l_{j-1}^{(3)} + l_{j-1}^{(2)}$. The amount of sorbent discharged into this zone and, correspondingly, the flow $l_{j-1}^{(2)}$, and its composition were determined by the following two conditions: (1) the concentration of the third component in the flow $l_{j-1}^{(2)}$ should be as low as possible, and that of the fourth component should be virtually zero, which determines the purity of the second fraction with respect to the third component; and (2) the amount of adsorbed product in the flow $l_{j-1}^{(2)}$ descending into the second section (into the discharge zone of the second component) should be such that a balance amount of the second fraction is formed. In the case when the rate of the adsorbent flow arriving at the second section exceeds the balance value, the excess amount of the second component will ascend with the vapor flow into the first section and, as a result, the first fraction will be contaminated with the second component. In the case of the optimal formation of the working space of a sectioned adsorber, narrow-cut fractions are obtained in the apparatus, having much higher purity as compared with that achieved in the hypersorber (Table 3).

A mathematical modeling of the operation of the sectioned adsorber with a moving adsorbent bed demonstrated that the flow rate of spent adsorbent, G_i, arriving at an arbitrary stripping section, must ensure supply of the balance amount of the component discharged in this section and have the minimum content of the component next in order of increasing sorbability. The optimal positions of the sectioning vertical plates in the adsorber volume are governed by the relation

$$G_i/G_\Sigma = S_i/S, \quad (9)$$

where G_Σ is the total flow rate of separation products in all sections of the lower part of the adsorber, S_i is the cross-section area of the adsorber section between two adjacent sectioning partitions or between the extreme plates and the corresponding part of the shell, and S is the cross-section area of the adsorber.

The calculated position of the upper edge of the sectioning partition in the working space of the adsorber is found from the condition of minimizing the content of the component next in order of increasing sorbability, $x_{j,i+1}$, in the adsorbent flow arriving at the given section from j-th plate and is given by the relation

$$\frac{x_{j,i}}{x_{j,i+1}} = \frac{y_{\text{fin},i}}{(y_{\text{fin},i+1})_{\min}}, \quad (10)$$

where $x_{j,i}$ and $y_{\text{fin},i}$ are, respectively, the concentration of i-th component in the flow from j-th plate and its final concentration in the fraction discharged from the given section; and $(y_{\text{fin},i+1})_{\min}$ is the minimum admissible concentration of (i + 1)-th component in the fraction discharged from the given section.

The prescribed flow rates of the adsorbent, and, consequently, the flow rates of substances absorbed by the adsorbent (Fig. 7, e.g., $l_{j-1}^{(3)}$ and $l_{j-1}^{(2)}$) can be adjusted and maintained by varying the speeds of rotation of sector feeders mounted in lines discharging regenerated adsorbent from sections. In addition, an adsorber design with sliding partitions, allowing control over the volume of the adsorption space in each section separately, has been patented [18].

The raw material feed zone in the sectioned adsorption apparatus is somewhat shifted downwards along the column height, compared with the hypersorber, and, in optimizing the process, its position should be adjusted to achieve the maximum possible concentration of the target components in the discharged fractions (Fig. 8).

Calculations demonstrated that, as also in the case of any other mass-exchange processes, the purity of the fractions obtained in the sectioned apparatus depends on the flow rates of vapors being separated and adsorbent (Fig. 9). Results of mathematical modeling of hypersorbers and sectioned adsorbers indicate that mathematical processing of the information fields obtained in numerous kinds of apparatus calculations can be used to develop rather simple dependences relating the operation parameters of the sectioned adsorber and the base hypersorber [22]. The energy efficiency of the sectioned adsorber increases especially strongly when the content of the most difficultly desorbed component in the raw material is low. In these cases, the heat saving may be as high as 25–50%.

CONCLUSIONS

(1) It is shown that, with the working space of adsorbers divided by vertical partitions, it is possible to form in a single apparatus a conditional chain of in-series connected adsorbers with fixed adsorbent bed or parallel "stripping" zones in adsorbers with moving adsorbent bed.

(2) The possibility of optimizing the working space of adsorbers with fixed and moving adsorbent bed is substantiated theoretically.

(3) Optimization of the working space of an adsorber with fixed adsorbent bed makes it possible to find the optimal number of sections in the apparatus and raise the dynamic activity of the adsorbent.

(4) Optimization of the working space of an adsorber with moving adsorbent bed makes it possible to improve the quality of discharged fractions and reduce the energy expenditure for the process.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Kinetics of Liquid-Phase Redox Reactions Involving Hydroxy- and Aminoalkanesulfinates

Yu. V. Polenov, V. V. Budanov, and E. V. Egorova

Ivanovo State Chemical Engineering University, Ivanovo, Russia

Received November 14, 2000; in final form, July 2001

Abstract—The mechanisms and kinetics of practically important redox reactions proceeding under the action of hydroxy- and aminoalkanesulfinates are analyzed. The general features allowing forecasting of the rates of reactions involving the above reducing agents are elucidated.

Hydroxy- and aminoalkanesulfinates are widely used as reducing agents in various branches of engineering and technology. The best known compounds, hydroxymethanesulfinate (HMS, technical name rongalite) and thiourea dioxide (TUDO, aminoiminomethanesulfinic acid), are used in textile industry, production of synthetic rubber, stabilizers for polymeric materials, uranium salts and salts of transuranium elements, electroless metal plating of polymeric materials, and other processes [1].

By now the experimental data on the kinetics and mechanisms of redox reactions involving the above compounds are quite extensive and, in our opinion, sufficient to generalize and elucidate the general features.

Based on an analysis of the concentration dependences of the reaction rates and the effect of various additives on the reaction rate, the reactions in hand can be divided into three groups. The reactions of the first group are characterized by the occurrence of an induction period, zero reaction order with respect to oxidizing agent for a long reaction time, first reaction order with respect to reducing agent, and abrupt decrease in the reaction rate, even to the point of complete inhibition, upon addition of formaldehyde. This group includes reduction of disodium 5,5'-indigotindisulfonate (indigocarmine) with sodium hydroxy- and aminoalkanesulfinates [2], 2-nitro-2'-hydroxy-5'-methylazobenzene (NAB) with HMS and TUDO [3, 4], Direct Red 2C azo dye with HMS and TUDO [5], uranyl acetate with TUDO [6], and iodine, bromine, and chlorite ions with HMS and TUDO [7]. Typical kinetic curves characteristic of this group of reactions are shown in Fig. 1.

The reactions of the second group have zero induction period, fractional reaction order with respect to the oxidizing agent, and first order with respect to the reducing agent. Addition of formaldehyde also inhibits the reaction, but to a lesser extent than for the reactions of the first group. The second group includes reduction of vat dye precursors with sodium hydroxy- and aminoalkanesulfinates [8], nickel and cobalt salts with HMS and TUDO [9], and ethylenediaminetetraacetatoferrate ($FeEDTA^-$) with TUDO [10].

The reactions in which formaldehyde exerts weak or practically no effect on the reduction rate belong to the third group. These reactions are first-order with respect to the oxidizing agent at moderately low temperatures, and a fractional reaction order is observed with increasing temperature; in all cases, the reaction order with respect to the reducing agent is 1. The ex-

amples of these reactions are reduction of $FeEDTA^-$ [11] and 4-nitrosodiphenylamine (4NDPA) [12] with rongalite and of *p*-benzoquinone with rongalite and TUDO [2].

Studies of decomposition of HMS and TUDO showed [13, 14] that the induction period is caused by the autocatalytic decomposition of molecules of the reducing agent, proceeding with rupture of the C–S bond (with HMS molecules as an example) in neutral

$$HOCH_2SO_2^- = HSO_2^- + CH_2O \quad (1)$$

or in alkaline medium:

$$HOCH_2SO_2^- + OH^- = SO_2^{2-} + CH_2(OH)_2. \quad (2)$$

To pass from the induction period to a steady state, it is necessary to accumulate a sufficient amount of decomposition catalysts ("active sulfur" and sulfide), which are by-products of processes (1) and (2). When the excess of the reducing agent is sufficiently high, the reactions of the first group proceed in quasi-steady-state mode to 90% and higher conversion of the oxidizing agent. The inhibiting effect of formadehyde is caused by a shift to the left of the equilibrium of reactions (1) and (2) and the resulting decrease in the quasi-steady-state concentration of the intermediates, anions of sulfoxylic acid (HSO_2^- and SO_2^{2-}) [1, 2].

The kinetic data suggest that the reduction with derivatives of aminoalkanesulfinic acids proceeds by two concurrent pathways: with preliminary cleavage of the C–S bond, accompanied by the formation of sulfur-oxygen intermediates by reactions (1) and (2), and by direct reaction between molecules of the oxidizing and reducing agents [i.e., with stages (1) and (2) by-passed]. The first pathway is arbitrarily named the dissociative pathway, and the second, the associative pathway [15].

Thus, as regards the nature of the reducing effect, the reactions of the first group can be classed with dissociative-autocatalytic reactions.

For the second group of reactions, the absence of the induction period in the kinetic curves suggests that the reduction rather easily proceeds by the dissociative pathway without accumulation of active sulfur able to catalyze stages (1) and (2).

For the third group of reactions, along with the reduction with HSO_2^- or SO_2^- anions, there occurs direct reaction of the oxidizing agent with molecules of the initial reducing agent (associative pathway).

The relative contribution of associative and dissociative pathways to the total process can be estimated from the corresponding reaction rates r_a and r_d determined in experiments with and without addition of formaldehyde. The rate r_a for the reactions proceeding by two pathways was determined under the condition $r_d = 0$, i.e., when an increase in the concentration of added formaldehyde did not affect the reaction rate. The rate r_d was evaluated on the basis of experimental data obtained in the absence of formadehyde addition, from the difference between the apparent reaction rate r and r_a. It should be noted that the ratio $r_a : r_d$, characterizing the contribution of the individual pathways, is governed by the following factors: (a) chemical nature of the oxidizing and reducing agents; (b) reaction conditions, primarily temperature and pH; and (c) process duration.

Let us consider the effect of each factor separately. Data on the kinetics and mechanisms of reactions involving HMS and TUDO are summarized in Tables 1 and 2.

According to the experimental data, associative mechanism is of the greatest importance in reduction of $FeEDTA^-$ with HMS (at a temperature below 303 K the reaction proceeds completely by the associative pathway).

In reduction of organic compounds, the dissociative pathway is dominant. For example, the ratio $r_a : r_d$ is 1 : 6 for 4NDPA (T = 308 K, C_{NaOH} = 1 M), and 1 : 380 for NAB (T = 308 K, C_{NaOH} = 1 M). Reduction of indigocarmine proceeds completely by the dissociative autocatalytic pathway.

The $r_a : r_d$ ratio depends on the nature of the reducing agent. In reduction with TUDO, reactions with an appreciable contribution of the associative pathway are less common than in reduction with HMS. This is apparently caused by the presence of sulfoxylates, which are more readily formed under conditions of reduction with TUDO, i.e., in alkaline media.

The temperature and acidity of the medium govern the degree and rate of cleavage of the reducing agent molecules and thus affect the ratio $r_a : r_d$. The temperature effect is particularly noticeable in reaction of $FeEDTA^-$ with HMS [16]. In this process the reaction proceeds below 303 K by the associative pathway ($r_d = 0$), and by both pathways above 303 K ($r_a : r_d$ = 1 : 2.5 at T = 308 K, $C_{HMS} = 6.5 \times 10^{-3}$ M, pH 10.8).

This fact is accounted for by stronger temperature dependence of the reaction rate in the case of dissociative mechanism (Table 1), which follows from a comparison of the activation energies E^I and E^{II}. There-

fore, in all reducing reactions involving hydroxy- and aminoalkanesulfinates, the contribution of the associative pathway must grow with increasing temperature.

An increase in pH facilitates cleavage of TUDO molecules by the scheme

$$NHC(SO_2H)NH_2 + OH^- = HSO_2^- + (NH_2)_2CO. \quad (3)$$

Thereby, the contribution of the dissociative pathway to redox processes involving TUDO increases. The acidity of the medium affects the degree of dissociation of HMS and other derivatives of sodium alkanesulfinates in two ways. On the one hand, their dissociation becomes more pronounced with decreasing pH, owing to autocatalysis by the products of decomposition of the reducing agents [13, 14] and,

** $UO_2(CH_3COO)_2$.

on the other hand, a decrease in pH shifts the equilibrium of reaction (2) to the left, which decreases the contribution of the dissociative pathway when it is present. It is evident that the first factor plays a decisive role in this case. Previously, it has been shown [2] that in the reaction of *p*-benzoquinone with rongalite the reaction order changes from 1 to a fractional value with decreasing pH. It can be suggested that the contribution of the dissociative pathway of the reduction increases.

The following problems are very important for both elucidating the general features of the kinetics of the redox processes and solving the practical problems: (1) demonstration of the adequacy of the proposed reduction schemes, (2) goal-seeking control of the reduction rates, (3) forecasting of the rates and selectivity of the reduction depending on the nature of a reducing agent and an atom or a group of atoms to be reduced.

To prove the adequacy of the reduction schemes, we identified the intermediates of the redox reactions proceeding by the dissociative pathway, using polarography. It was found that the quasi-steady-state concentration of the intermediate active species ($S_2O_4^{2-}$, SO_2^{2-}, and SO^{2-}) varies in parallel with the reduction rate [17, 18]. As additional argument, we checked experimentally in a series of the reactions the kinetic equation obtained from the conditions of the quasi-

steady-state approximaton, which demonstrated a satisfactory agreement between the experimental and calculated reaction rates.

In the general form the reaction rates in the quasi-steady-state mode of many reactions involving HMS and its analogs can be described by the following equation (in alkaline medium):

$$\frac{dC_{Ox}}{d\tau} = \frac{k_1 k_2 C_{Red} C_{Ox} C_{OH^-}}{k_{-1} k_{CH_2O} + k_2 C_{Ox}} + k_3 C_{Red} C_{Ox}, \quad (4)$$

where k_1 is the constant of direct decomposition of the reducing agent (Red), k_{-1} is the constant of the reverse stage, k_2 is the rate constant of the reaction of the reducing agent with reduction intermediates, and k_3 is the rate constant of the associative pathway.

The first term in the right-hand side of Eq. (4) accounts for the reaction rate by the dissociative pathway, and the second, by the associative pathway.

For the reactions involving TUDO, the equations for the reaction rates have a more complicated form as a result of the presence of the stage of rearrangement and irreversible decomposition of the reducing agent molecules. However, in many cases, the experimental verification of the linear forms of the kinetic equations allows conclusion about the suitability of the quasi-steady-state approximation for reduction processes involving TUDO [4, 6, 10].

In the case of reduction of NAB, Ni^{2+},[1] and *N*,*N*' derivatives of binaphthylhexylcarboxylic acid diimide, we determined the kinetic parameters using the procedures of mathematic simulation with criterial selection of possible process schemes [19–21]. This approach makes it possible to determine the rate constants of individual stages or combination of these, estimate errors, and correlate the parameters with sufficient reliability.

The constants for NAB and Ni^{2+}, evaluated by the above procedures, are listed in Table 1.

It should be noted that the rate constants of the individual stages can be reliably determined only when the information content of the experimental data corresponds to the complexity of the system. When experimental data are scarce and the kinetic model is complex, a large number of parameter sets providing the same adequate description of the experimental data can be selected. Therefore, for some of reactions (Tables 1, 2) we determined not individual constants but their combinations.

Of some interest is to compare the rate constants of the same stages in different reduction reactions. It turns out that at 308 K the rate constant of the stage of HMS cleavage involving OH^- ions, k_1, determined from the kinetic data for reduction of NAB [$(0.32 \pm 0.07) \times 10^{-6}$ $M^{-1}\,s^{-1}$], is close to the k_1 value determined for reduction of 4NDPA [$(0.47 \pm 0.08) \times 10^{-6}$ $M^{-1}\,s^{-1}$]. The rate constants of the stages of HMS cleavage without OH^- ions involved in the reduction of $FeEDTA^-$ and indigocarmine are also comparable: $(0.14 \pm 0.01) \times 10^{-5}$ and $(0.17 \pm 0.03) \times 10^{-5}$ s^{-1}, respectively.

The k_1 values[2] for indigocarmine were recalculated from 333 to 308 K using the values E_{app} = 114 kJ mol^{-1} and $\ln p_{app}$ = 37. The kinetic parameters of the reaction of vat dye precursors of varied structures with HMS were evaluated in [22]. It was shown that for various hydroxyalkanesulfinates the rate constants of the stages of reaction of the same vat dye precursor with sulfoxylate anions [which corresponds to constant k_2 in Eq. (4)] agree within the order of magnitude. These facts additionally prove the adequacy of the proposed reaction schemes to experimental data.

The control of the reduction rate by addition of catalysts and formadehyde is only possible when the dissociative mechanism is dominant. For example, cobalt dioximines [23] and sodium sulfide [24] accelerate the process. It was found that cobalt dioximines exhibit high catalytic activity in reduction of azo dyes with rongalite and in reductive cyclization of nitroazobenzene to give light stabilizer of polymers, benzene P. The mechanism of the effect of dioximines consists in substitution of hydroxymethanesulfinate anion for one of the axial ligands, with its subsequent inner-sphere cleavage and release of sulfoxylate anions.

The effect of sodium sulfide is caused by an increase in the steady-state concentration of SO_2^{2-} owing to the inhibition of sodium hydroxyalkanesulfinate decomposition [13].

The selectivity of the reduction effect of alkanesulfinates of various structures is well seen in reductive cyclization of binaphthylhexacarboxylic acid der-

[1] The reduction of Ni^{2+} is arbitrarily considered homogeneous since it yields nickel in the solid state. However, owing to the irreversibility of the stage of solid nickel formation we can use the equations of homogeneous kinetics for mathematical description of the process.

[2] For reduction of Ni^{2+} ion, this rate constant is four orders of magnitude higher, which is caused by, first, the difference in pH and, second, different character of cleavage of reducing agent molecules, as mentioned above.

Table 3. Kinetic parameters of reduction of transition metal compounds

Oxidant + reductant	k_{app} (333 K), min^{-1}	E_{app}, kJ mol^{-1}	ln *p*	$\Delta_f H^0$ (298 K), kJ mol^{-1}
Co^{2+} + HMS	0.08×10^{-2}	74 ± 8	19 ± 1	–56.6
Ni^{2+} + HMS	0.11×10^{-2}	134 ± 12	42 ± 4	–53.1
$CuEdta^{2-}$ + HMS	13.3	189 ± 19	71 ± 6	1643.9
Co^{2+} + TUDO	0.52×10^{-2}	78 ± 7	22 ± 1	–56.6
Ni^{2+} + TUDO	12.5×10^{-2}	149 ± 15	51 ± 5	–53.1
$CuEdta^{2-}$ + TUDO	0.96	96 ± 10	35 ± 3	1643.9
UO_2^{2+} +TUDO	3.1×10^{-4}	39 ± 5	6 ± 2	–1024.9

ivatives. In this case, the final products of the reaction in solution are di- and tetraanions of perylenetetracarboxylic acid derivatives [25]. It was shown that the most probable process is concurrent formation of these derivatives from the corresponding initial compounds. For all of the studied derivatives of binaphthylhexacarboxylic acid, the relative yield of the product with four reduced carbonyl groups increases in the series of the reducing agents sodium dimethylaminomethanesulfinate < sodium diethylaminomethanesulfinate < sodium hydroxymethanesulfinate < sodium hydroxyethanesulfinate < sodium hydroxypropanesulfinate. It was shown [2] that the stabilities of the first three reducing agents are much the same, whereas introduction of alkyl substituent to α-carbon atom drastically decreases the stability of the reducing agent. The rise in the reducing power is due to an increase in the quasi-steady-state concentration of sulfoxylate anions, which, in turn, accelerates formation of products with four reduced groups.

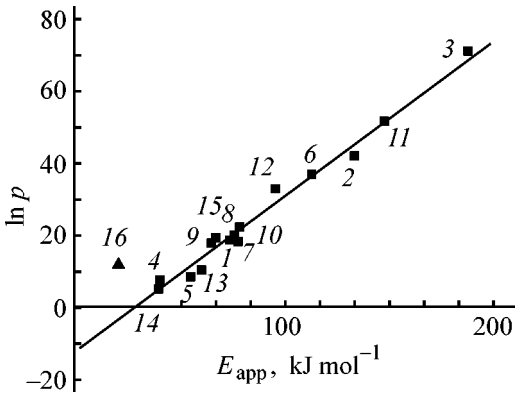

Fig. 2. Correlation between the Arrhenius parameters for reduction of various compounds with HMS and TUDO. (*p*) Pressure and (E_{app}) apparent activation energy. (*1*) Co^{2+} + HMS, (*2*) Ni^{2+} + HMS, (*3*) $CuEDTA^{2-}$ + HMS, (*4*) NAB + HMS, (*5*) 4NDPA + HMS, (*6*) $IC(CO)_2$ + HMS, (*7*) Direct Red 2C + HMS, (*8*) $CoEDTA^{2-}$ + HMS, (*9*) $NiEDTA^{2-}$ + HMS, (*10*) Co^{2+} + TUDO, (*11*) Ni^{2+} + TUDO, (*12*) $CuEDTA^{2-}$ + TUDO, (*13*) NAB + TUDO, (*14*) UO_2^{2+} + TUDO, (*15*) $IC(CO)_2$ + TUDO, and (*16*) $FeEDTA^-$ + HMS (by the associative pathway).

The correlations obtained on the basis of kinetic data for reduction of a wide variety of reducing agents may be useful for forecasting the rates of reduction of various compounds with rongalite and TUDO.

The kinetic parameters of reduction of transition metal ions and complex compounds with rongalite and TUDO are presented in Table 3. Comparison of the apparent rate constants and enthalpies of formation of oxidizing agents suggests that these parameters vary in parallel for both the reducing agents.

Figure 2 shows the compensation relation between the Arrhenius parameters, which is described by the equation

$$\ln p = 0.43E_{app} - 12.06 \quad (R = 0.987).$$

This dependence is observed for those reactions in which the dissociative mechanism of reduction is predominant. Therefore, the point with the coordinates E_{app} = 21 kJ mol^{-1} and ln *p* = 12, obtained for the reduction of $FeEDTA^-$ with rongalite proceeding at low temperatures by the associative pathway, falls out of this dependence. The observed compensation effect suggests the occurrence of the limiting stages of the reactions through transition states with similar configurations [26]. In the stages of decomposition of reducing agents, transition states are likely to form by protonation or deprotonation of hydrated molecules, as shown by quantum-chemical calculations for tautomeric conversion of TUDO as an example [2].

In conclusion, it should be noted that the data presented make it only possible to determine schemes of stoichiometric mechanisms of the processes. The existing experimental data are insufficient to come to reliable conclusions on the structure of transition states in particular stages.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Determination of Methylphosphonic Acid and Its Esters as Chemical Markers of Organophosphorus Chemical Warfare Agents

Abstract—The feasibility of isolation and quantitative determination by gas chromatography of methylphosphonic acid and its mono- and dialkyl etsers, which originate from destruction of organophosphorus chemical warfare agents and have been detected in bitumen–salt compounds is examined.

Organophosphorus chemical warfare agents (OPCWAs), the most known of which are tabun, sarin, soman, and VX-group compounds, are extremely strong cholinergic antagonists.

By now, basic principles of OPCWA analysis have been developed and recommended for use in the practice of international examinations [1–3]. For practically all of the known OPCWAs, the physicochemical constants are known, and therefore their "confirming" identification involves no problems. However, the experience of chemical appraisals of the consequences of emergencies involving OPCWAs shows that, in most cases, the initial OPCWAs cannot be detected at sites of their application. Decomposition products of OPCWAs, formed in various media, cannot be predicted *a priori*, the more so as the type of the weapons used may be unknown. Therefore, it is very important to reveal long-lived "witness" compounds that would be always present among products of OPCWA decomposition and would retain information about the initial compound.

Such "witnesses," or markers, should also be revealed for setting up analytical and sanitation-chemical monitoring of processes used for destruction of chemical weapons. First, it is necessary to study the composition of degradation products of war gases and of intermediates released into the contact medium in the process. This stage involves identification of OPCWA conversion products and revealing of chemical markers. The next stage should involve examination of the emission of markers to various media and assessment of possible pathways of their further transformation. These results can serve as a basis for environmental monitoring of potentially hazardous sites.

At present, a two-stage flowsheet is being put into operation in Russia for destruction of OPCWAs, with chemical decomposition and subsequent bituminous grouting of the resulting solid wastes to obtain so-called bitumen–salt compounds (BSCs) [4, 5].

It has been shown previously that among the products of yperite decomposition, including its decomposition within BSCs, a versatile marker is 1,4-dithiane [6]. In this work, with the aim to reveal chemical markers, we studied by GC–MS the composition of BSCs containing the products of sarin, soman, and VX breakdown, and also that of gases released from, and aqueous extracts of BSCs. With respect to their origin, BSC components can be subdivided in three groups: products of OPCWA breakdown, deactivating agents, and bitumen components. The chemical markers should belong to the first group; in individual determinations, they should correspond to specific types of OPCWAs. They should also be stable in the matrix and selectively detectable against the background signals.

After disposal of BSCs, emergency seal failure of containers is possible, accompanied by washout of soluble BSC components by groundwater. To estimate the extent of marker emission into an aqueous-salt system simulating the chemical composition of groundwater at the site of a repository to be constructed, it was necessary to develop procedures for recovery of the markers from aqueous solutions and for their quantitative chemical analysis. For this purpose, we used gas chromatography (GC).

To reveal chemical markers, we initially identified components always present in gases released from,

Table 1. Procedures of sample preparation for analysis

Procedure	Analysis object	Analysis procedure
A	BSCs	Static head-space analysis
B	Aqueous extracts of BSCs	Extraction with dichloromethane (pH 7)
C	Aqueous extract after procedure B	Evaporation to dryness, redissolution in dichloromethane–acetonitrile (1 : 1), silylation
D	"	Saturation with NaCl, extraction with acetonitrile (pH 2), drying, redissolution, silylation

and aqueous extracts of, BSCs. The sample preparation procedures are summarized in Table 1. Such a fourstep scheme allowed us to expand to the maximum possible extent the group of BSC components determinable by GC analysis: from the most volatile (head-space analysis) to non-volatile (derivatives of aqueous extracts).

In the systems BSC–sarin and BSC–soman, the main decomposition products of sarin and soman are, respectively, isopropyl and pinacolyl alcohols, diisopropyl and dipinacolyl methylphosphonates, isopropyl and pinacolyl hydrogen methylphosphonates, and also methylphosphonic acid itself. The system BSC–VX is considerably more complex and includes several tens of volatile organic compounds; the major components are mono- and disulfides containing diethylaminoethyl group but lacking the phosphorus atom. The mass spectra of these compounds are difficultly discernible and in most cases contain only a single strong peak corresponding to the $(Et_2N{=}CH_2)^+$ ion. The major phosphorus-containing products are methylphosphonic acid and its mono- and dibutyl esters [by VX we mean *O*-isobutyl *S*-(2-diethylaminoethyl) methylphosphonothioate, whereas in the United States and some other countries its isomer, *O*-ethyl *S*-(2-diisopropylaminoethyl) methylphosphonothioate, is more widespread].

Thus, among products of sarin, soman, and VX decomposition by the two-stage process, we can distinguish homologous series of alkyl hydrogen and dialkyl methylphosphonates. Specifically these compounds, together with their hydrolysis product, methylphosphonic acid, seem to be the most suitable chemical markers for assessing the possible environmental pollution. Additional advantages of these compounds are the possibility of their selective detection and low probability of false positive results, because compounds with a P–C bond are very rare in nature.

Table 2 gives mass spectra of phosphorus-containing compounds that originate from the breakdown of OPCWAs and are present in BSCs. Among the compounds given in Table 2, only methylphosphonic acid diesters $MeP(O)(OR)_2$ can be determined by direct gas-chromatographic analysis. As compared with methylphosphonic acid and alkyl hydrogen methylphosphonates, dialkyl methylphosphonates are considerably more seldom mentioned in the literature as OPCWA decomposition products, although they are included in the lists of compounds to be monitored according to the Convention on the Prohibition of the Development, Production, Stockpiling, and Use of Chemical Weapons and on Their Destruction [7]. Under conditions of the existing process for OPCWA destruction, they can form by reaction of the monoester MeP(O)(OH)(OR) with the alcohol ROH (R = *i*-Pr, pinacolyl, or *i*-Bu for sarin, soman, and VX, respectively). Also, diesters of methylphosphonic acid can be present as impurities in the initial OPCWAs, especially after their prolonged storage. A scheme for classification of these compounds according to their mass spectra was proposed in [8]. Comparison of the intensity of the peak at m/z = 47, corresponding to the $[P{=}O]^+$ fragment, with the preset threshold is the first step of the algorithm. If the threshold is not exceeded, this fact is regarded, according to [8], as the absence of the compounds under consideration in a sample. However, according to our experience, the intensity of this signal in the mass spectra of alkyl methylphosphonates is so low that at their low concentrations (especially in such matrices as soil) it can hardly be detected.

Under the experimental conditions, the content of diisopropyl and diisobutyl methylphosphonates in BSCs was determined with sufficient reproducibility by static head-space analysis. Dipinacolyl methylphosphonate present in BSCs can be quantitatively determined only in extracts. Table 2 shows that the strongest peak in the mass spectra of all these three diesters is that at m/z = 97. Group analysis of dialkyl methylphosphonates in groundwater and soil by GC–MS is possible in the selective ion monitoring mode. Samples were prepared for analysis by procedure B. The sensitivity of the analysis is high: the de-

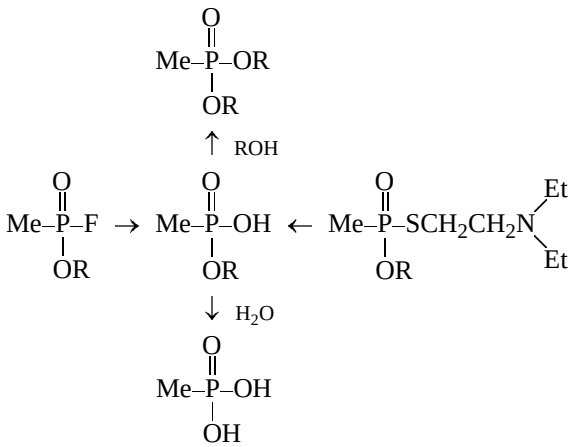
tection limit in water is as low as 0.1 μg l^{-1}. At the same time, esters of dibasic carboxylic acids, alkenes, alkylthiophenes, and some other compounds often present in soils also give in mass spectra a strong peak at *m*/*z* = 97. Therefore, if the concentration level does not allow analysis of the total mass spectrum, identification of dialkyl methylphosphonates, especially in soil, requires additional confirmation. Dialkyl methylphosphonates fully meet the requirements to BSC chemical markers. Their main advantages are simple recovery from matrices and the possibility of direct selective gas-chromatographic determination. At the same time, it is known [9] that, in the presence of water, dialkyl methylphosphonates are hydrolyzed to give alkyl hydrogen methylphosphonates and then methylphosphonic acid. Thus, just alkyl hydrogen methylphosphonates and methylphosphonic acid, initially present in BSCs and formed by hydrolysis of dialkyl methylphosphonates, can be considered "long-lived" BSC markers. Alkyl hydrogen methylphosphonates in which the alkyl group is specific to a particular OPCWA can be regarded as individual chemical markers, and methylphosphonic acid, as group marker (Table 2):



where R = *i*-Pr (sarin), pinacolyl (soman), or *i*-Bu (VX).

Methylphosphonic acid and alkyl hydrogen methylphosphonates are readily soluble in water; therefore,

they will migrate into groundwater in the case of a seal failure of BSC containers. At the same time, being polar and nonvolatile, these compounds are difficult objects for chemical analysis. However, they can be readily determined by HPLC. In this case, it is necessary to ensure efficient detection, which can be provided by introducing groups imparting UV absorption to a substance [10] or enhancing its electrical conductivity [11]. The feasibility of direct analysis of alkyl hydrogen alkylphosphonates by liquid chromatography, combined with mass spectrometry in the electrospray mode, was demonstrated in [12]. The main limitations of the procedures involving HPLC separation are problems with obtaining narrow peaks [10, 11] and the high cost of the equipment [12].

The majority of the methods developed for analysis of alkyl hydrogen alkylphosphonates are based on GC with various modification procedures for increasing the volatility of the compounds being analyzed. To prepare a sample for GC analysis, it is necessary to quantitatively recover it from aqueous solution and convert to a volatile form. These tasks are solved successively, since extractive alkylation procedures are inapplicable to these compounds. To recover alkyl hydrogen alkylphosphonates, Soderstrom *et al*. [9] evaporated aqueous solutions and biological fluids to dryness; Minami *et al*. proposed an alternative approach: extraction with acetonitrile [13].

In this study, we used both the procedures. To find the best conditions for recovery and modification of methylphosphonic acid and isopropyl, isobutyl, and pinacolyl hydrogen methylphosphonates, we used GC with a flame-ionization detector. The areas of the chromatographic peaks of the trimethylsilyl esters were measured, and their ratios to the area of the peak of tetradecane, used as internal reference, (relative peak areas) were determined.

The average relative peak areas S_{av} for each component in calibration solutions and in samples after evaporation and extraction are given in Table 3. The reproducibility of the analysis was characterized by the root-mean-square deviation S_x, and the efficiency of sample preparation, by the degree of recovery R. Data in Table 3 were obtained for the analyte concentration range 1–100 mg l^{-1}.

Table 3 shows that, in analysis of alkyl hydrogen methylphosphonates, satisfactory results are obtained only in extraction with acetonitrile (method D). We found that methylene chloride (method B) does not recover methylphosphonic acid and its acidic esters from both neutral and acidic (pH 1–6) aqueous solutions to a noticeable extent (R < 1%). Thus, there is practically no loss of methylphosphonic acid and its acidic esters in stage B of sample preparation (Table 1).

Methylphosphonic acid is recovered from aqueous solutions most difficultly. At the same time, with methylphosphonic acid, satisfactory analytical parameters are achieved by evaporation of the aqueous sample. Thus, the best procedures for analysis of methylphosphonic acid and its acidic esters are C and D, respectively (Table 1). However, in analysis of large

volumes of natural waters expected to contain methylphosphonic acid in low concentrations, procedure C is very power-consuming. In this case, procedure D becomes more appropriate, with correction made for the actual degree of recovery.

To choose a procedure for conversion of methylphosphonic acid and its acidic esters to volatile derivatives, we compared, using solutions of the corresponding reference samples in dichloromethane, the efficiencies of methylation (with diazomethane and methyl iodide) and silylation [with *N*,*O*-bis(trimethylsilyl)acetamide (BSA) and bis(trimethylsilyl)trifluoroacetamide (BSTFA)]. The highest relative yields, at a minimum of false positive results, were achieved with silylation (irrespective of the silylating agent used). The effect of trimethylchlorosilane (TMS) addition on the yield of silylation with BSTFA was studied in [13]; the highest yield was achieved at the ratio BSTFA : TMS = 1 : 9. Under our conditions, addition of TMS had no significant influence on the silylation efficiency and resulted only in sample contamination. As already noted, when choosing the optimal conditions for recovery from aqueous solutions and modification of alkyl hydrogen methylphosphonates, we used as recording device a gas chromatograph equipped with a flame-ionization detector, which was very convenient as applied to model, relatively concentrated (0.1–100 mg l^{-1}) solutions. However, for actual water samples, the sensitivity and selectivity of this procedure were insufficient. In this case, we used in GC analysis a thermoionic detector, with the same recovery and modification procedures. The detection limit of methylphosphonic acid and its esters was as low as 0.1–1 μg l^{-1}, approaching the sensitivity level of GC–MS with selective ion monitoring (m/z = 153 for alkyl hydrogen methylphosphonates and 225 for methylphosphonic acid).

EXPERIMENTAL

Head-space analysis (method A) was performed in the static mode: 1 g of a BSC sample was kept for 40 min in temperature-controlled 10-ml vessels with a Teflon membrane at 70°C, and 1-ml samples of the equilibrium vapor were taken for analysis.

Aqueous BSC samples were prepared as follows.[1] A bitumen–salt compound was poured into molds made of a chemically inert material and kept for 24 h, after which an aqueous-salt solution simulating the composition of natural waters at the site of intended BSC disposal was added, and the system was kept for 4 days at 25°C.

Neutral extracts from BSC aqueous extracts (method B) were prepared by treatment of 10 ml of an aqueous sample with methylene chloride (3 × 2 ml) at pH 7. The combined extract was dried, concentrated, and analyzed.

The aqueous residue was divided in two portions. An aliquot of the first portion was evaporated to dryness and dissolved in 10 μl of methylene chloride–acetonitrile (1 : 1), 20 μl of a methanolic solution of BSA or BSTFA was added, and the mixture was kept for 20 min at 60°C; after that it was diluted (if necessary) and analyzed (method C). The second portion was used for preparing acidic extracts from aqueous extracts. It was acidified to pH 1 with dilute sulfuric acid, saturated with sodium chloride, and extracted with acetonitrile (3 × 2 ml). The combined extract was dried, concentrated, again dried, and redissolved in 10 μl of methylene chloride–acetonitrile (1 : 1); 20 μl of a methanolic solution of BSA or BSTFA was added, and the mixture was kept for 20 min at 60°C (method D).

The solvents (methylene chloride and acetonitrile) were purified by standard procedures and distilled in a column; pure-grade anhydrous sodium sulfate was calcined in a muffle furnace at 400°C before use. BSA, BSTFA, and methyl iodide were purchased from Merck (Germany); diazomethane was prepared by decomposition of N-nitrosomethylurea.

The GC–MS analysis was performed on a Shimadzu device comprising a GC-17A gas chromatograph, a QP 5000 mass spectrometer equipped with a quadrupole analyzer, and a data processing system. The ionization was performed by electron impact at an ionizing electron energy of 70 eV. The ion source temperature was 280°C. The device was calibrated in the automated mode against perfluorotributylamine reference. A DB-5 25000 × 0.2-mm capillary column of fused quartz was used; the thickness of the stationary phase film was 0.33 μm. The flow rate of the carrier gas (He) was 1 ml min^{-1}. Liquid samples (0.5–1 μl) were injected in the splitless mode (0.3 min), and gas samples (1 ml), in the split mode. The injector temperature was 250°C. The column was heated from 40 to 270°C at a rate of 5 deg min^{-1} and kept at the final temperature for 15 min.

Compounds were separated on a Kristall-2000 gas chromatograph equipped with a flame-ionization de-

[1] The procedure was developed at the State Research Institute of Organic Chemistry and Technology (GosNIIOKhT); reference samples of methylphosphonic acid and its isopropyl, isobutyl, and pinacolyl esters were prepared and submitted by GosNIIOKhT staff members.

tector or a thermionic detector and a quartz capillary column (25 000 × 0.2 mm). The thickness of the stationary phase film (SE-54) was 0.2 μm. The flow rate of the carrier gas (nitrogen) was 1 ml min^{-1}; hydrogen and air were fed into the detector at rates of 15 and 250 ml min^{-1}, respectively. The temperature schedule was the same as in the GC–MS analysis.

Quantitative GLC analysis was performed with external reference.

CONCLUSIONS

(1) Methylphosphonic acid and its mono- and dialkyl esters present in bitumen–salt compounds as decomposition products of organophosphorus chemical warfare agents can be considered chemical markers.

(2) Dialkyl methylphosphonates can be quantitatively determined by gas chromatography. For determination of methylphosphonic acid and its acidic esters, they should be preliminarily extracted with acetonitrile from acidic solutions and silylated.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Monodisperse Microspheres Based on Acrolein Copolymers

Abstract—Emulsifier-free emulsion copolymerization of acrolein with styrene and methyl methacrylate in the presence of potassium persulfate was developed to prepare microspheres with surface aldehyde groups. The kinetics of monomer copolymerization was studied and the conditions for preparing monodisperse microspheres 370–1000 nm in diameter were determined.

Monodisperse polymer microspheres are widely used in immunology as supports of biologically active compounds (BACs) [1]. These BACs are either simply sorbed on the support surface or bound to it by various chemical reactions with reactive groups on the microsphere surface. For example, surface aldehyde groups react with BAC amino groups yielding Schiff bases under mild conditions. As a rule, polymer microspheres with aldehyde groups are prepared by homopolymerization of unsaturated aldehydes (e.g., acrolein, formylstyrene) [1]. The monodisperse polyacrolein particles are often prepared by the anionic or radiation-induced radical polymerization in aqueous solutions [2–5]. However, these procedures give significant amounts of oligomeric products, which, in the course of storage of the latexes and preparations on their base, migrate to the particle surface, making its surface structure unstable. At the same time, only in few works, microspheres were prepared by radical copolymerization of acrolein and styrene [6–8], though such a procedure allows control over the fraction of acrolein units in the surface layer and, probably, over the degree of polymer cross-linking via aldehyde groups. Therefore, we studied in this work the copolymerization of acrolein with more hydrophobic monomers, such as styrene and methyl methacrylate (MMA), to prepare monodisperse microspheres containing surface aldehyde groups. Data on the synthesis of poly(styrene/acrolein) (PSAC) and poly(MMA/acrolein) (PMMAAC) latexes by emulsifier-free emulsion copolymerization are of particular interest for revealing the effect of water-soluble acrolein on the course and mechanism of particle formation.

EXPERIMENTAL

Preliminarily, styrene, MMA, acrolein, dimethylformamide (DMF), methyl ethyl ketone (MEK), and methylene chloride were purified by distillation according to standard procedures. Double-distilled water served as dispersion medium. Sodium chloride NaCl, sodium tertaborate $Na_4B_2O_7$, potassium dihydrogenphosphate NH_2PO_4, analytically pure hydroxylamine hydrochloride, and HCl and NaOH standard solutions were used without additional purification.

The emulsion radical emulsifier-free copolymerization of the monomer mixtures was carried out in the presence of potassium persulfate [9]. In order to obtain monodisperse microspheres of widely varying size, the molar ratio of the initial monomers, concentration of the monomer mixture in water, *w* (wt %), temperature, and concentrations of the initiating agent and buffer salt were varied (Table 1). The residual monomers were separated from the resulting latexes by distillation with steam. The monomer conversion was determined by gas chromatography with internal reference (butanol).

The measurement error was 5%. The particle size of the resulting latexes was measured with a JEM 100 S electron microscope (JEOL, Japan). Water-soluble admixtures were removed from the latex by three cycles of centrifugation and dispersion in double-distilled water. Then the surface concentration of the carboxy and aldehyde groups was determined by conductometric titration [8]. The aldehyde groups were analyzed after preliminary treatment of the latex with

1070-4272/01/7410-1728 $25.00 © 2001 MAIK "Nauka/Interperiodica"

hydroxylamine hydrochloride [9]. The content of the sol fraction in the copolymers was determined by fractional extraction with methylene chloride for 3 days. The IR spectra of the sol fraction solutions were registered in the 400–4000 cm^{-1} range. The thin-layer chromatograms of the sol fraction of the resulting polymers were studied on the silica support in comparison with the homopolymers: polystyrene (PS) and polymethyl methacrylate (PMMA). Polyacrolein is insoluble in the solvents used because of the strong intermolecular cross-linking [1] and thus cannot be used as reference. In the case of PS and PSAC, the mobile phase was toluene, whereas for PMMA and PMMAAC the mixture of toluene and MEK (5 : 7 volume ratio) was used. The chromatograms were developed using a mixture of sulfuric acid and potassium permanganate.

The procedure of the microsphere surface modification with protein is presented elsewhere [10]. As adsorbate protein we used the native bovine serum albumin (BSA); this protein is widely used in immunoassay as a carrier of small antigens and as a blocking agent, which fills the hydrophobic surface and thus hinders nonspecific interactions. The procedures for purification and analysis of serum albumin were given in [10].

The solutions of BSA before and after their interaction with the polymer particles were studied by both the traditional Lowry procedure and modern high-performance monolithic chromatography (HPMC) [11] on a CIM® Disk DEAE anion-exchange membrane (BIA Separations, Ljubljana, Slovenia). The gradient elution was performed using solution containing tris(hydroxymethyl)aminomethane hydrochloride (0.02 M) and sodium chloride (0.5 M), pH 8.0 at a rate of 3 ml min^{-1}. Albumin was detected at λ = 229 nm.

Monodisperse latexes with particle size of 370–670 nm were prepared by radical copolymerization of acrolein and styrene (Table 1). It was found that at equimolar monomer ratio the reaction proceeded most completely, whereas at a styrene : acrolein molar ratio of 2 : 1 the conversion was only 75 and 57% (Table 1, run nos. 2 and 11). These data agree with published results [8]. With the preparation temperature decreasing from 60 to 55°C, the diameter of the resulting monodisperse microspheres increases (Table 1, run nos. 1 and 3), which is due to the decrease in the decomposition rate of the initiating agent. However, upon additional decrease in the initiating agent concentration (Table 1, run no. 4), the size of the resulting microspheres did not increase further because of the significant decrease in the monomer conversion.

** The resulting latexes along with the main fraction of coarse particles contain finer particles.

In contrast, with increasing monomer concentration in the reaction mixture, their conversion reached 90%; in this case, coarser monodisperse microspheres 610 nm in diameter were formed (Table 1, run no. 5).

To make larger the resulting microspheres, we also raised the ionic strength of the reaction mixture. It was found, that with the NaCl concentration increasing to 0.02 M, the particle size grows somewhat (Table 1, run nos. 1 and 6), whereas in a more saline solution the resulting latex becomes polydisperse (run no. 7). It is well known that, during emulsion polymerization, the persulfate initiating agent reacts with water to form hydroxy radicals, and the reaction mixture becomes more acidic [12]. In our case, the pH of the resulting polymer dispersions was 2.5 after the reaction termination. The aggregation stability of the polymer–monomer particles (PMPs) in the dispersion medium with low pH and high ionic strength was insufficient owing to a decrease in the ionization of the surface sulfate and carboxy groups which can be formed during oxidation of the surface aldehyde groups in the acrolein units with persulfate.

To enhance the aggregation stability in the synthesis of coarse particles at high ionic strength of the dispersion phase, we used potassium dihydrophosphate buffer salt, which ensures a weakly acidic state of the reaction mixture. In the presence of this

salt, a monodisperse latex with particle diameter of up to 670 nm was prepared (Table 1, run nos. 8 and 11). In this case, the size of the resulting microspheres also increased with decreasing temperature (Table 1, run nos. 9 and 10), but finer particles were detected along with a coarse fraction.

Copolymerization of acrolein with a less hydrophobic MMA was carried out under the conditions providing, in the case of acrolein and styrene, polymerization formation of coarse monodisperse particles and the most complete monomer conversion (Table 1, run no. 8). Since data on the emulsion copolymerization of acrolein with MMA are lacking, the effect of the monomer ratio on their conversion and the properties of the resulting latexes were studied in more detail. It was found that the acrolein conversion decreases with its increasing concentration in the reaction mixture (Fig. 1a), whereas the MMA conversion remains at a level of about 90%.

With increasing acrolein content in the initial mixture, the number of the polymer particles decreases and thus their size increases (Fig. 1b). With increasing acrolein content, the content of the surface aldehyde groups grows in parallel (Fig. 1c) with the number of acrolein units in the latex structure (Fig. 1a). However, there is no clear correlation between the concentration of the surface carboxy groups and the content of acrolein (Fig. 1c).

We found that the resulting microspheres are partially cross-linked systems and the content of the sol fraction increases with decreasing content of acrolein in the initial mixture (Table 2). These data confirm that the radical polymerization is accompanied by intermolecular cross-linking via the C=C and C=O groups of acrolein [1]. Thin-layer chromatograms (silica) of the sol fractions of the polymers prepared at equimolar MMA : acrolein or styrene : acrolein ratio show that these samples differ from, respectively, MMA and styrene homopolymers. For example, in the chromatograms with toluene eluent, PS moved in the front, whereas PSAC remained at the start. In the toluene/MEK mixture, PMMA advanced with the β-front and PMMAAC remained at the start. At the same time, in the case of MEK eluent, the PSAC and PMMAAC samples moved at the front. IR spectra of the PSAC and PMMAAC samples are shown in Fig. 2 in comparison with those of MMA and styrene homopolymers. The IR spectrum of the PSAC sample contains a strong absorption band at 1725 cm^{-1} (C=O vibrations) and a weak band at 2740 cm^{-1} (C–H asymmetric vibrations of the aldehyde group), which are absent in the IR spectrum of the PS sample. The IR spectrum of the PMMAAC sample contains a strong band at 1730 cm^{-1}, which can be attributed to vibrations of the carbonyl bond in both acrolein and MMA. A weak absorption at 2740 cm^{-1} confirms the presence of the aldehyde groups in this polymer. Hence, the PSAC and PMMAAC samples are copolymers of styrene or MMA with acrolein.

The copolymerization kinetics of acrolein with MMA and styrene at equimolar monomer mixtures is illustrated in Fig. 3. The kinetics of MMA conversion (Fig. 3a) shows that, at the start of polymerization, the contribution of this monomer is significantly smaller as compared with that of acrolein. Based on the slope of the conversion curves, the polymerization rates of MMA and acrolein during this induction period are 0.3×10^{-5} and 2.4×10^{-5} mol l^{-1} s^{-1}, respectively. The copolymerization constants for the MMA/acrolein system in dioxane are 10 and 0.2, respectively [13]. Thus, at equal concentrations of the required monomers in the reaction zone the rate of MMA polymerization must be significantly higher. The above result is probably due to the fact that the solubility of acrolein in water exceeds that of MMA: 3.7 and 0.15 M, respectively [14]. Gas chromatographic data show that, at the start of the process, nearly 70% of acrolein is in the aqueous solution. In the presence of water-soluble initiating agent, various oligomers and oligomeric radicals enriched with acrolein units are formed in solution; this provides their high solubility in water. Moreover, these compounds must possess low surface activity because of the low content of the MMA units and insignificant difference in polarity between the comonomer units. As a result, they form PMP later and their stabilization effect is smaller. Hence, we obtain coarser microspheres than in the case of acrolein copolymerization with more hydrophobic styrene (Fig. 4). Such a mechanism of PMP formation is confirmed by the fact that, at increased content of acrolein in the mixture with MMA, coarser particles are formed (Fig. 1b). In the second stage of polymerization, the rate of MMA consumption increases from 0.8×10^{-5} to 2.1×10^{-5} mol l^{-1} s^{-1}, whereas the rate of acrolein conversion remains constant. In this stage, polymerization proceeds predominantly on the PMP surface and thus the mole fraction of MMA in PMP may increase in the course of the experiment and acrolein consumption.

When the MMA conversion reaches nearly 35%, a gradual increase in the rate of MMA polymerization gives way to a pronounced gel effect: the rate of MMA consumption increases from 2.1×10^{-5} to 7.5×10^{-5} mol l^{-1} s^{-1}. Si-multaneously, the rate of acrolein consumption increases to 4.8×10^{-5} mol l^{-1} s^{-1}. This confirms the formation of a copolymer of acrolein and MMA in PMP. It should be noted that in this stage of polymerization the increase in the viscosity of the polymer-monomer mixture in the particles, which provides coexistence of several growing radicals and causes the gel effect, may be enhanced by cross-

linking of macromolecules via acrolein units (Table 2). After the exhaustion of the monomers in PMPs, the copolymerization rate significantly decreases and plateaus are observed in the conversion curves. The acrolein conversion is incomplete, probably because its certain fraction is retained in water.

In the course of polymerization with styrene, acrolein is consumed at a constant rate of 2.7×10^{-5} mol l^{-1} s^{-1} (Fig. 3b), which is higher than the rate of its copolymerization with MMA before gelation (2.4×10^{-5} mol l^{-1} s^{-1}). This is due to the fact that copolymerization with styrene yields smaller particles, and, thus, the concentration of growing PMPs is higher. In this case, the induction period in the conversion curve of styrene is less pronounced than in the case of MMA copolymerization with acrolein. This suggests rapid formation of diphilic PMPs, which thus involve the surface-active oligomers and oligomeric radicals containing fragments of hydrophobic styrene (3.7×10^{-3} M solubility in water [14]) and hydrophilic acrolein. At moderate conversion of monomers, when copolymerization proceeds predominantly in PMPs, the rate of styrene consumption (2.6×10^{-2} mol l^{-1} s^{-1}) is close to that of acrolein. It was found [8] that, despite equal copolymerization constants of styrene and acrolein in dioxane (0.25 [13]), the number of acrolein fragments in the copolymer in the course of emulsion copolymerization grows only slightly with its increasing content in the reaction mixture and does not exceed 30% at styrene/acrolein molar ratio of 1 : 2. By contrast, we prepared in our case PSAC copolymer microspheres with acrolein content of 53 mol % even at the equimolar monomer ratio (Table 2). The similar reactivities of styrene and acrolein in this case can be accounted for by the presence of potassium dihydrogenphosphate in the reaction mixture, which decreases the acrolein solubility in water and shifts the polymerization predominantly into PMPs. As a result, the conversion of styrene in the course of copolymerization is slightly smaller than that of acrolein, which allows preparation of copolymer microspheres with high content of aldehyde groups.

To study the sorption of proteins by the surface of PSAC and PMMAAC copolymer microspheres, we performed binding of BSA with their surface aldehyde groups in alkaline medium. The residual concentration of BSA after chemisorption was determined by HPMC; the results suggested that, simultaneously with the formation of the Schiff bases on the particle surface, the polymeric chains enriched with carboxy and aldehyde groups can be washed out of the particles into solution, with their further binding with BSA in solution. As a result, broad peaks of BSA conjugates with the most soluble copolymer chains appear in the chromatograms in analysis of the residual BSA in the dispersion system after chemisorption (Fig. 5a). Their retention time is longer than that of the initial BSA, which is due to an increase in the number of anionic groups in this protein. This trend is the most pronounced under the chemisorption conditions at high concentration of the surface aldehyde groups and protein solution (pH > 9.0). This effect was eliminated when the microspheres were washed with borate buffer solution (pH 10.0) before chemisorption (Fig. 5b).

The data on the BSA chemisorption in several samples of copolymer microspheres with different copolymer compositions and surface concentrations of the functional groups are listed in Table 3. It was found that the BSA chemisorption on PSAC copolymer microspheres is somewhat stronger than that in the case of PMMAAC. This is probably due to higher surface hydrophobicity of the acrolein-styrene copolymer. The chemisorption efficiency depends on the pH of the dispersion medium. It was found that, with the pH of the albumin solution increasing in the course of chemisorption, the amount of BSA bound to the PMMAAC microspheres increases significantly,

Table 3. Conditions of albumin chemisorption

* The concentrations of albumin and other polymers were determined by Lowry and HPMC procedures, respectively.

whereas in the case of PSAC microspheres the trend is reverse. It is obvious that certain fraction of BSA is physically sorbed on the surface of PSAC microspheres through the hydrophobic interactions. With increasing pH, the microsphere surface and albumin globules acquire a larger negative charge owing to ionization of their carboxy groups, and the albumin sorption must decrease because of the electrostatic repulsion and decreasing hydrophobic interaction [15]. The contribution of this mechanism to the BSA interaction with the surface of PSAC microspheres is confirmed by the fact that, with decreasing surface concentration of the carboxy groups, the albumin binding becomes more efficient (Table 3, sample nos. 3, 8); similar results were obtained in [16]. By contrast, the formation of the Schiff base becomes facilitated with increasing pH, which is observed in the course of BSA binding with the less hydrophobic surface of the PMMAAC microspheres. With increasing surface concentration of the aldehyde groups in the PMMAAC microspheres, the chemisorption efficiency also increases.

CONCLUSIONS

(1) Emulsifier-free emulsion copolymerization of acrolein with styrene and methyl methacrylate to prepare microspheres with surface aldehyde groups was developed. The copolymerization kinetics at the equimolar monomer ratios was studied. The results obtained allow control over the size of monodisperse microspheres (370–1000 nm), hydrophobicity of their surface, and content of the aldehyde groups providing the covalent binding of biologically active compounds.

(2) The albumin binding to the microsphere surface becomes stronger with increasing hydrophobicity of the polymer support, i.e., on passing from poly(methyl methacrylate/acrolein) to poly(styrene/acrolein). However, the contribution of chemisorption to the binding of the native bovine serum albumin is greater for poly(methyl metacrylate/acrolein) microspheres, because the efficiency of the albumin binding to the surface of this copolymer grows with increasing surface concentration of the aldehyde groups and the albumin solution pH.

Abstract—The kinetics of radical copolymerization of magnesium and calcium 2-acrylamido-2-methylpropanesulfonates with *N*-vinylpyrrolidone in aqueous solutions at pH 9 and 50°C in the presence of an initiator, potassium peroxodisulfate, were studied dilatometrically, and the molecular characteristics of the resulting copolymers were determined.

The kinetics of radical (co)polymerization of unsaturated acid salts in ionizing media are largely affected by the nature of the cation, as demonstrated for polymerization of salts of acrylic, methacrylic [1, 2], *N*-vinylamidosuccinic [3], *p*-styrenesulfonic [4, 5], and 2-acrylamido-2-methylpropanesulfonic (H-AMS) [6, 7] acids and copolymerization of salts of acrylic acid [8, 9] and H-AMS with acrylamide [10, 11] and of lithium, sodium, and potassium salts of H-AMS with *N*-vinylpyrrolidone (*N*-VP) [12]. In this study, we examined the influence of the cation on the copolymerization of magnesium and calcium salts of H-AMS with *N*-VP. Such studies are stimulated not only by unusual, from the viewpoint of the classical theory, trends in copolymerization of ionic monomers, but also by practical significance of the copolymers, which are effective flocculants [13], antistatic agents, adhesives [14], etc.

EXPERIMENTAL

H-AMS was purchased from Lubrizol (UK); mp 185°C. H-AMS salts of alkaline-earth metals were prepared by neutralization of H-AMS in aqueous solutions to pH 9 with suspensions of $Mg(OH)_2$, CaO, and $Ba(OH)_2 \cdot 8H_2O$ with stirring and cooling with water; the insoluble residue was removed by filtration. *N*-Vinylpyrrolidone (Merck, Germany) was purified by double distillation in a vacuum in the presence of 0.1% KOH; n_D^{20} 1.5119. Potassium peroxosulfate (PP) was twice recrystallized from aqueous solutions; the content of main substance, determined by the redox procedure, was 97.8%. In all the experiments, we used distilled water. The other chemicals were of chemically pure grade.

The copolymerization kinetics was monitored dilatometrically at low conversions ($X < 3\%$). The procedures of copolymerization and dilatometric measurements and the techniques used were similar to those described in [15].

After copolymerization, the resulting copolymers were precipitated from aqueous solutions into acetone, washed with acetone, and vacuum-dried at 50°C to constant weight.

The yield of the copolymers was determined gravimetrically, and the content of ionic units, by elemental analysis for sulfur [16]. The molecular weight M of the copolymers was evaluated by the Mark–Houwink relationship $[\eta] \sim M$ from the intrinsic viscosity $[\eta]$, which was measured using a VPZh-3 capillary viscometer with d_c = 0.56 mm in 0.5 M NaCl at 30°C.

Degradation of Mg-AMS–*N*-VP copolymers was performed at 50°C under the action of PP in a glass vessel equipped with a temperature-contol jacket, a magnetic stirrer, and a VPZh-3 capillary viscometer, d_c = 0.56 mm. The viscometer was equipped with a jacket to keep the same temperature as in the reactor.

Copolymerization of H-AMS salts (M_1) with *N*-VP (M_2) was performed in water in the presence of PP initiator ($[PP] = 1.2 \times 10^{-3}$ M) at pH 9 and 50°C. At this pH, the hydrolysis of *N*-VP was prevented [17], and the initiation rate was insensitive to changes

1070-4272/01/7410-1735 $25.00

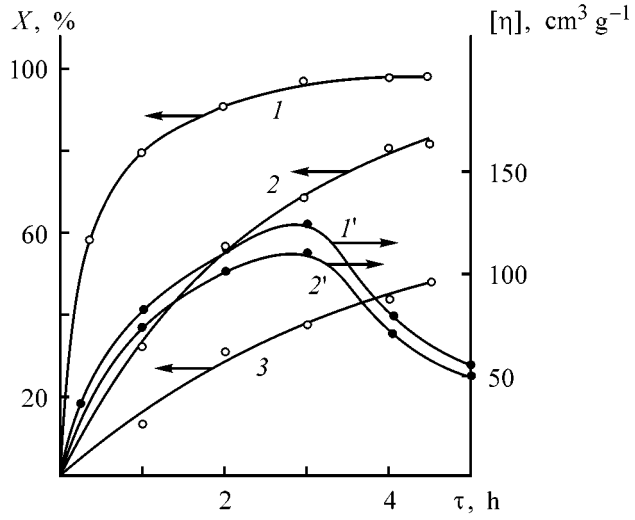

Fig. 1. Variation of (*1*–*3*) conversion *X* and (*1*', *2*') intrinsic viscosity [η] of the copolymers with time τ in the course of copolymerization of (*1*, *1*') Mg-AMS, (*2*, *2*') Ca-AMS, and (*3*) Ba-AMS with *N*-VP. $[M_1] + [M_2] = 14.7\%$; initial molar ratio $[M_1] : [M_2] = 7 : 3$.

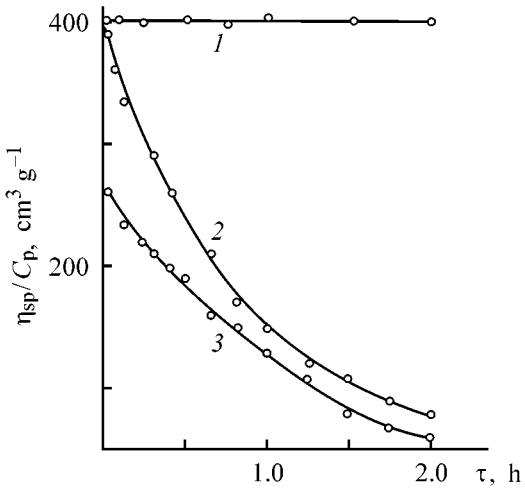

Fig. 2. Variation of the reduced viscosity η_{sp}/C_p of Mg-AMS–*N*-VP copolymers in water with time τ in the course of degradation at 50°C (*1*) in the absence and (*2*, *3*) in the presence of PP. $C_p = 0.1$, [PP] = 0.04%. Polymer samples: (*2*) C ([η] = 127 $cm^3 g^{-1}$, 49.5 mol % ionic units) and (*3*) D ([η] = 54 $cm^3 g^{-1}$, 42.0 mol % ionic units).

in the ionic strength [18] due to variation of the concentration of the ionic monomer in the course of copolymerization. Changes in the ionic strength had no effect on the reactivity of *N*-VP and the corresponding propagating radical [19]. Under the chosen conditions, no spontaneous copolymerization was observed in the absence of initiator.

Figure 1 shows the kinetic curves of copolymerization of H-AMS salts with *N*-VP, obtained with gravimetric monitoring of the reaction, and the intrinsic viscosities of the resulting copolymers. Copolymerization of Mg-AMS with *N*-VP and of Ca-AMS with *N*-VP occurred under homogeneous conditions to deep conversions, whereas copolymerization of Ba-AMS with *N*-VP was a heterogeneous process even at low conversions. Since phase separation considerably complicates copolymerization, our subsequent experiments were only concerned with homogeneous copolymerization of Mg-AMS and Ca-AMS with *N*-VP. Figure 1 shows that the initial rate of copolymerization with Mg-AMS is higher than that for Ca-AMS (curves *1*, *2*), and the molecular weight of the resulting copolymer with Mg-AMS is higher too (curves *1*', *2*'). Figure 1 also shows that, with increasing conversion, the intrinsic viscosities of the Mg-AMS–*N*-VP (curve *1*') and Ca-AMS–*N*-VP (curve *2*') copolymers pass through a maximum observed at a reaction time of 3 h. The increase in conversion had no noticeable effect on the composition of the Mg-AMS–*N*-VP copolymer: the content of the ionic units in the product was 50.8 mol %.

The decrease in [η] after the maximum of the function $[\eta] = f(\tau)$ (Fig. 1) may be due to occurrence under the experimental conditions of polymerization–degradation processes (under the action of radicals generated from PP), with the degradation becoming prevalent as the molecular weight grows. This suggestion is confirmed by monitoring of the variation in time of η_{sp}/C_p at C_p = const for Mg-AMS–*N*-VP copolymers in water under the action of PP at 50°C (Fig. 2). Figure 2 shows that η_{sp}/C_p does not change in the absence of PP (curve *1*) but decreases with time under the action of PP (curves *2*, *3*). These results are due to degradation of the macromolecules with cleavage of the C–C bonds in the backbone chain under the action of radicals generated from PP. Figure 2 also shows that the degradation of the macromolecules becomes more pronounced with increasing *M* (curves *2*, *3*).

The influence of the cation on the copolymerization of Mg-AMS and Ca-AMS with *N*-VP was examined in a wide range of compositions of the initial monomer mixture at $[M_1] + [M_2] = 14.7\%$ and fixed other parameters. The process kinetics was monitored dilatometrically. The inital sections of the kinetic curves were linear, and the initial copolymerization rate v_0 was determined from their slopes at low conversions ($X < 3\%$). The rate v_0 determined in these runs is plotted in Fig. 3 as a function of the content of ionic monomers M_1 in the initial mixture. For both systems

under consideration, $v_0 = f(M_1)$ passes through a maximum at the equimolar ratio of the monomers. The dependences plotted in Fig. 3 are well consistent with published data [12, 19] and suggest the donor–acceptor interaction between the H-AMS and *N*-VP salts. Figure 3 also shows that v_0 varies in the order $Mg^{2+} > Ca^{2+}$ (curves *1*, *2*) in a wide range of compositions of the initial monomer mixture. This sequence is consistent with the data in Fig. 1 (curves *1*, *2*).

Figure 4 shows how [η] and the conversion in copolymerization of Mg-AMS and Ca-AMS with *N*-VP depend on the mole fraction of the ionic monomer M_1 in the initial monomer mixture. It is seen that, in both systems, [η] and conversion drow with increasing M_1. Figure 4 also shows that, in a wide range of monomer ratios in the initial mixture, the intrinsic viscosity and conversion are higher for Mg-AMS, compared with Ca-AMS, which is well consistent with the data in Fig. 1 (curves *1*', *2*').

To explain the influence of the cation on v_0 in copolymerization of H-AMS salts with *N*-VP, let us consider the scheme of the equilibrium between the ionic groups in aqueous solutions

$$\underset{\mathbf{I}}{A^-X^+} \leftrightarrow \underset{\mathbf{II}}{A^-||X^+} \leftrightarrow \underset{\mathbf{III}}{A^- + X^+}, \qquad (1)$$

where A^- is the anion of the monomer and of the macroradical; X^+ is the cation; **I**, **II**, and **III** are, respectively, the contact and solvent-separated ion pairs and free ions.

It is known that the sulfonate groups in H-AMS salts and their units in copolymers of H-AMS salts with *N*-VP are totally ionized in aqueous solutions. However, with decreasing ionic strength of solutions (because of the varying concentration of the ionic monomers in the initial mixture and in the course of copolymerization) and with binding of cations with the polysulfonate anions, the ionization equilibrium (1) is shifted to the left. As a result, the intensity of intra- and intermolecular electrostatic interactions in the system decreases, and the reactivity of H-AMS salts and their macroradicals in copolymerization changes. Thus, the shift of the ionization equilibrium (1) results in that various ionic species of the monomers and radicals, differing in reactivity, are involved in the copolymerization. Because the reaction system is multicomponent and the conditions are not isoionic, the copolymerization "constants" $r_1 = k_{11}/k_{12}$ (for H-AMS salts) and $r_2 = k_{22}/k_{21}$ (for *N*-VP) change in the course of the process, which makes description of the reaction by classical equations [4] with fixed r_1 and r_2 impossible.

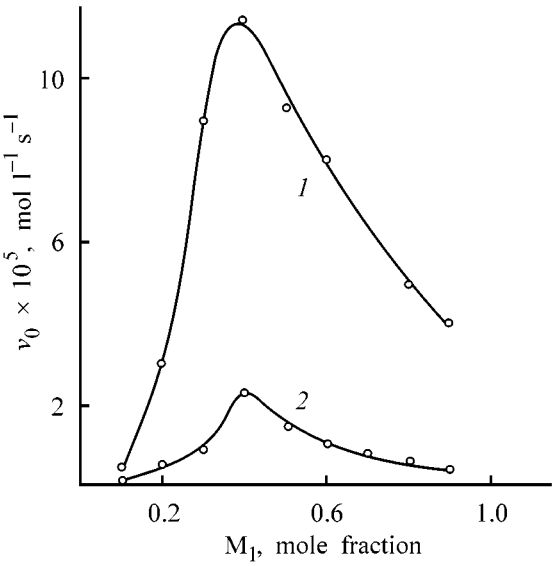

Fig. 3. Initial rate v_0 of copolymerization of (*1*) Mg-AMS and (*2*) Ca-AMS with *N*-VP in aqueous solution vs. the mole fraction of H-AMS salts in the initial monomer mixture M_1. $[M_1] + [M_2] = 14.7\%$; the same for Fig. 5.

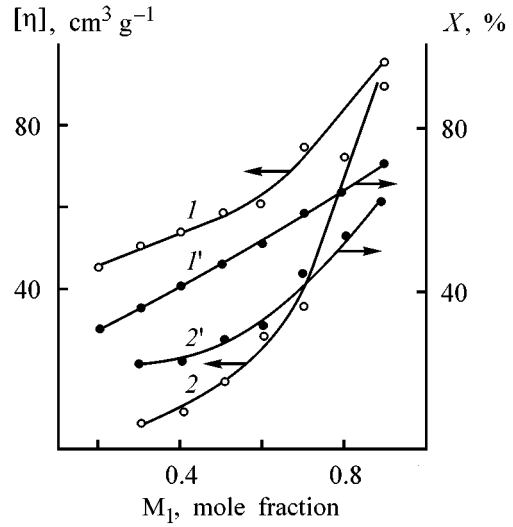

Fig. 4. (*1*, *2*) Intrinsic viscosity [η] at τ = 2h and (*1*', *2*') conversion *X* in copolymerization of (*1*, *1*') Mg-AMS and (*2*, *2*') Ca-AMS with *N*-VP vs. the mole fraction of H-AMS salts in the initial monomer mixture M_1. $[M_1] + [M_2] = 14.7\%$.

The degree of the cation binding with polysulfonate anions of the copolymers of H-AMS salts with *N*-VP decreases in the order $Mg^{2+} > Ca^{2+}$ [20]. The higher the degree of metal cation binding with sulfonate anions of the macroradical, the weaker the electrostatic repulsion between the similarly charged monomer and the macroradical with a terminal ionic

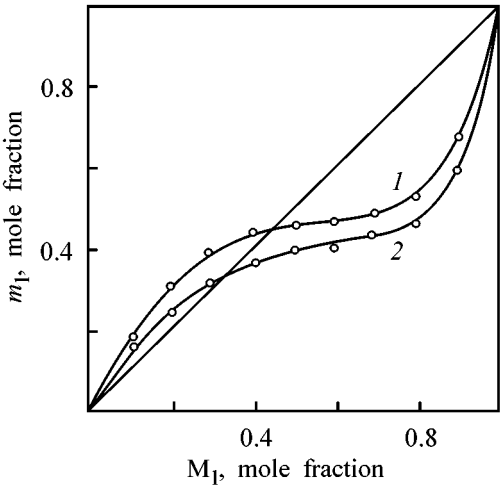

Fig. 5. Copolymer composition vs. the mole fraction of H-AMS salts in the initial monomer mixture M_1. Copolymerization of (*1*) Mg-AMS and (*2*) Ca-AMS with *N*-VP in aqueous solutions. (m_1) Mole fraction of ionic units in the copolymer.

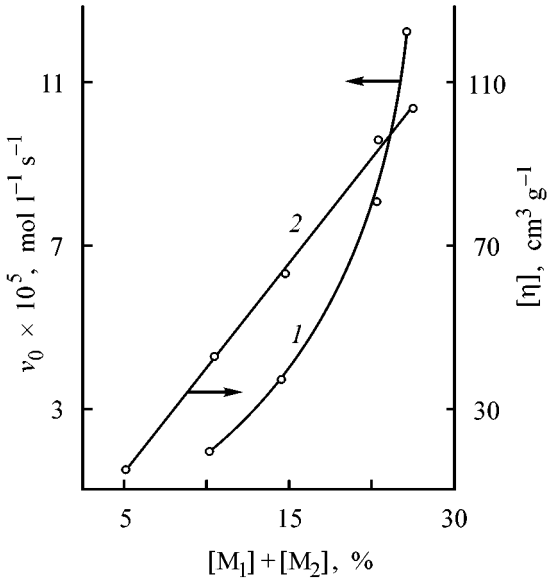

Fig. 6. (*1*) Initial copolymerization rate v_0 and (*2*) intrinsic viscosity [η] (reaction time 2 h) of Mg-AMS–*N*-VP copolymers in aqueous solutions as functions of the concentration of the initial monomer mixture $[M_1] + [M_2]$. Initial molar ratio $[M_1] : [M_2] = 1 : 1$.

unit, i.e., the higher the elementary propagation rate constant k_{11}. Therefore, v_0 (Fig. 3) and [η] (Fig. 4) decrease in the order $Mg^{2+} > Ca^{2+}$.

Figure 5 shows how the composition of the copolymers of Mg-AMS and Ca-AMS with *N*-VP depends on the composition of the initial monomer mixture at $[M_1] + [M_2] = \text{const}$. The dependences in Fig. 5 correspond to the relative activities of the monomers $r_1 < 1$ and $r_2 < 1$. We did not determine r_1 and r_2 for the systems in question, because r_1 and r_2 are apparent quantities for the copolymerization involving ionic monomers. Figure 5 shows that, in a wide range of compositions of the initial monomer mixture, the content of the ionic units in the copolymer increases in going from Ca-AMS to Mg-AMS (curves *1*, *2*). Obviously, the variation of the composition of the resulting copolymers is due to an increase in only one of four elementary propagation rate constants, k_{11}, describing the addition of the macroradical of H-AMS salts to the sulfonate anions of the monomer (H-AMS salt). This trend is due to a decrease in the degree of metal cation binding with the polysulfonate anions of the copolymers in the order $Mg^{2+} > Ca^{2+}$.

Also, we examined the effect on copolymerization of the concentration of the initial monomer mixture $[M_1] + [M_2]$ in the range 5–25%. Experiments were done at a fixed molar ratio $[M_1] : [M_2] = 1 : 1$ and invariable other conditions. The v_0 and [η] values obtained in this series of experiments are listed in Fig. 6. As seen from Fig 6, both v_0 and [η] grow with increasing concentration of the monomer mixture, which is consistent with fundamental aspects of radical copolymerization.

CONCLUSIONS

(1) The initial copolymerization rate v_0, conversion *X*, intrinsic viscosity [η] of copolymers, and the content of ionic units in them increase in the order $Ca^{2+} < Mg^{2+}$.

(2) The initial copolymerization rate v_0 grows with increasing concentration of the initial monomer mixture and, when considered as a function of the $[M_1] : [M_2]$ ratio, passes through a maximum at the equimolar monomer ratio.

(3) The intrinsic viscosity [η] drows with increasing concentration of the initial monomer mixture and content of the ionic monomer and passes through a maximum with increasing conversion.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Cryoozonolysis of Some Perfluoroolefins and Use of Perfluoro Ozonides as Polymerization Initiators

D. P. Kiryukhin, I. M. Barkalov, and I. L. Ismoilov

Institute of Problems of Chemical Physics, Russian Academy of Sciences, Chernogolovka, Moscow oblast, Russia

Received May 7, 2001

Abstract—Low-temperature (77–280 K) ozonolysis of perfluoro-4-methyl-2-pentene and perfluoro-2,4-dimethyl-3-ethyl-2-pentene by direct contact with ozone in the absence of solvents and oxygen was studied. The resulting perfluoro ozonides can be used as initiators of low-temperature polymerization and copolymerization.

Low-temperature ozonolysis of tetrafluoroethylene (TFE) and hexafluoropropylene (HFP) by direct contact of the reactants in the absence of solvents and oxygen was studied in [1–3]. At equimolar ratio of ozone and perfluoroolefin, the corresponding ozonides are formed at low temperatures (140–230 K) in quantitative yield by addition of ozone across the double bond. The resulting perfluoro ozonides are stable up to 250–290 K and decompose at higher temperatures, with TFE ozonide being more stable than HFP ozonide. The decomposition products of TFE and HFP ozonides *in statu nascendi* initiate polymerization of TFE [1, 2] and some other monomers [3, 4].

In this work, we studied the mechanism of cryochemical ozonolysis of perfluoro-4-methyl-2-pentene (HFP dimer, DHFP) and perfluoro-2,4-dimethyl-3-ethyl-2-pentene (HFP trimer, THFP) and examined the possibility of using the resulting ozonides as polymerization initiators. Our experimental procedure, including sample preparation, excluded the uncontrollable explosion mode of the reaction and allowed ozonolysis of DHFP and THFP to be studied in the absence of solvents and oxygen at direct contact of ozone and perfluoroolefin.

EXPERIMENTAL

DHFP and THFP were purified by double distillation (bp 323.2 and 383 K, respectively). Ozone was generated by passing an oxygen stream through an electric-discharge glass ozonizer equipped with external and internal electrodes. The resulting ozone–oxygen mixture was condensed in a trap cooled with liquid nitrogen. Then, we removed oxygen from the solution of ozone in liquid oxygen by vacuum distillation at 77 K, and the remaining crystalline ozone was additionally purified by sublimation.

The phase state of the systems and the kinetics of low-temperature ozonolysis and polymerization were studied calorimetrically [5]. Known amounts of a fluoroolefin and ozone were condensed in a vacuum at 77 K in special glass calorimetric cells and sealed. The reaction was performed in a slowly warming-up calorimeter, and the reaction course was monitored by the heat release.

The IR spectra of the fluoroolefins and reaction products were taken on a Specord IR-75 spectrometer using standard cells.

On cooling to 77 K, DHFP passes into a glassy state. In the course of heating of such a sample, we observe in the calorimetric curve a characteristic change in the heat capacity due to a transition from the glassy state to a supercooled liquid (T_g 110 K), crystallization of the supercooled liquid (exothermic peak at 120–140 K), and melting at 160 K (Fig. 1, curve *1*). The heat of melting of DHFP, determined calorimetrically, is 11.8 ± 0.5 kJ mol^{-1}.

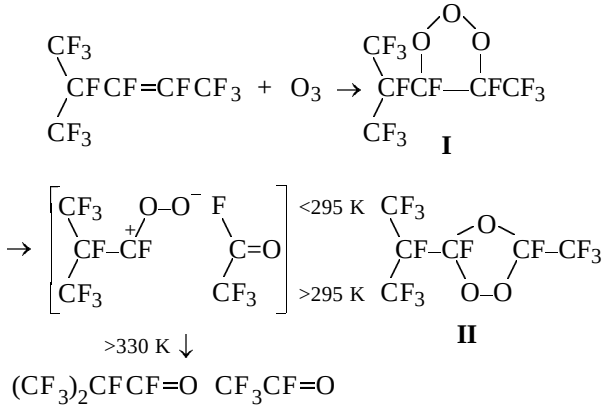
On heating a sample containing equimolar amounts of O_3 and DHFP, an exothermic reaction is observed starting from approximately 210 K (Fig. 1, curve *2*). The rate of cryoozonation (heat release) increases with temperature, reaching a maximum at 240–250 K. The total activation energy of the reaction in the range 210–240 K is 90 ± 5 kJ mol^{-1}. Upon further warming,

1070-4272/01/7410-1740 $25.00 © 2001 MAIK "Nauka/Interperiodica"

the ozonation rate decreases because of the exhaustion of the reactants. The thermal effect of DHFP ozonation, determined from a series of calorimetric runs, is 505 ± 5 kJ mol^{-1}.

In the IR spectrum of the ozonolysis products, compared with the initial DHFP, new bands appear at 1850 (R_f–FC=O bond [6]) and 1100 cm^{-1} (five-membered ring [7]).

These results suggest that, at low temperatures, ozonolysis of DHFP follows, similarly to that of TFE and HFP [1–3], the well-known three-stage Criegee mechanism [8], yielding the corresponding carbonyl compounds and DHFP ozonide. The primary reaction product is the so-called molozonide (**I**). It is unstable and rapidly decomposes to form a bipolar ion and a carbonyl compound. These intermediates couple again in another sequence, forming a more stable ozonide **II**:



The theoretical calculation of the heat released in these three stages (kJ mol^{-1}) [9] gave 240 for the formation of molozonide, 32 for the formation of the bipolar ion and carbonyl compound, 214 for the formation of the final ozonide, and 486 for the overall reaction. The last value is nicely consistent with that determined calorimetrically, 505 ± 5 kJ mol^{-1}, which confirms the suggested mechanism of low-temperature ozonolysis of DHFP.

The resulting ozonide **II** is in dynamic equilibrium with the bipolar ion and carbonyl compound. At low temperatures (<300 K) the equilibrium is shifted toward formation of **II**, but at higher temperatures (325–335 K) this ozonide irreversibly decomposes into perfluoroacyl fluorides $(CF_3)_2CFCF=O$ and $CF_3CF=O$. This conclusion was confirmed in studies of polymerization effectively initiated by the obtained perfluoro ozonides.

DHFP ozonide initiates, similarly to TFE and HFP ozonides, polymerization of a number of monomers, e.g., TFE. As shown previously [1–4], polymerization

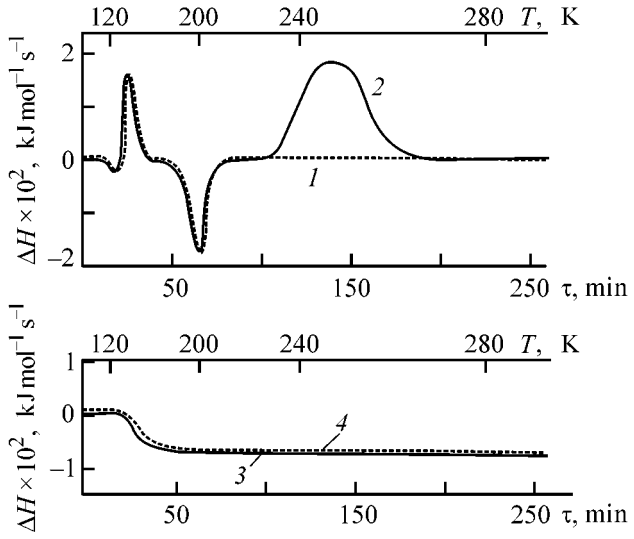


Fig. 1. Calorimetric heating curve: (ΔH) heat release, (τ) time, and (T) temperature; the same for Fig. 2. (*1*) DHFP, (*2*) system DHFP–O_3 (molar ratio 1 : 1), (*3*) THFP, and (*4*) system THFP–O_3 (molar ratio 1 : 1).

is initiated owing to the formation of a very reactive bipolar ion in the course of ozonide decomposition. Although ozonide **II** can be stored for a long time at room temperature, it initiates polymerization in the range 240– 300 K. If ozonide **II** formed by ozonolysis of DHFP is heated to 330 K, it irreversibly decomposes into perfluoroacyl fluorides, and these stable products do not initiate polymerization.

With increasing DHFP content in the initial samples (molar ratio DHFP : O_3 > 1 : 1), the thermal effect of ozonolysis in the temperature range 210–270 K remains unchanged (about 505 kJ mol^{-1}). This fact shows that, in the indicated temperature range, ozone molecules add across the double bond of DHFP in a 1 : 1 ratio only.

Also, we examined the possibility of cryoozonolysis of THFP. On cooling to 77 K, THFP fully turns into a glassy state. The calorimetric curve of heating of this compound shows only a characteristic change in the heat capacity due to transition from the glassy state to the liquid (T_g = 145 K; Fig. 1, curve *3*). No addition of ozone across the C=C bond is observed. No changes, compared with the case of pure THFP, are observed in the calorimetric curve recorded during warming of the system THFP–ozone (Fig. 1, curve *4*). Thus, THFP does not react with ozone in the range 77–300 K. Apparently, additional (compared with TFE, HFP, and DHFP) CF_3 groups in the THFP molecule shield the double bond and prevent access of ozone to this bond.

As already noted, ozonides of TFE, HFP, and DHFP initiate polymerization of many monomers.

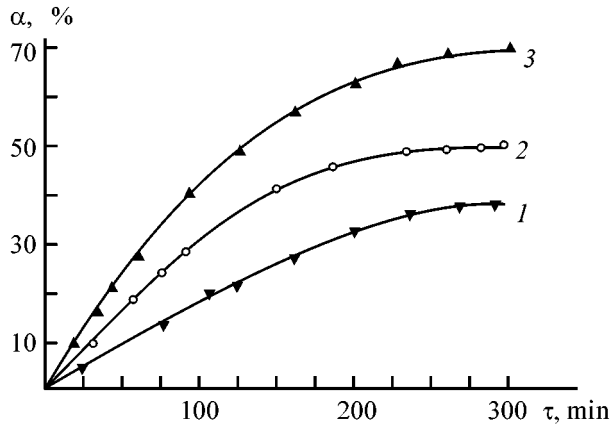

Fig. 3. Kinetic curves of TFE polymerization at different initial pressures of the monomer: (α) PTFE yield and (τ) time. *p*, mm Hg: (1) 250, (*2*) 500, and (*3*) 750 (295 K).

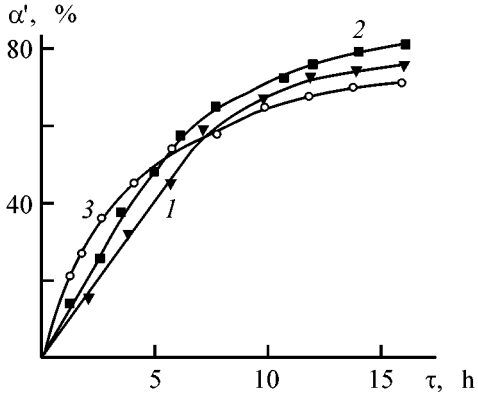

Fig. 4. Kinetic curves of MMA polymerization at different concentrations of the initiator (ozonide **II**): (α') polymer yield and (τ) time. *C*, mol %: (*1*) 2, (*2*) 2, and (*3*) 3 (295 K).

The polymerization initiated by fluoroolefin ozonides and the resulting products are of interest themselves; here, we only briefly discuss some features of the process.

As polymerization initiator, it is very convenient to use ozonide **II**, which is liquid at room temperature, is not dangerously explosive, and can be stored for a long time. Polymerization can be initiated in two ways: in slow cooling of the monomer and initiator in the range 77–300 K and in mixing of the monomer and initiator at constant temperature.

Figure 2 (curve *1*) shows a calorimetric curve of TFE heating in the presence of ozonide **II**. Ozonide **II** was prepared by warming the system DHFP–O_3 (molar ratio 2 : 1) from 77 K to room temperature. Actually, ozonide **II** was taken as a mixture with unchanged excess of DHFP. Then TFE was condensed into the calorimetric cell at 77 K, and the sample was slowly warmed. As seen from Fig. 2 (curve *1*), after thawing of TFE and a mixture of ozonide **II** with unchanged DHFP (endothermic peaks in the range 140–200 K in the calorimetric heating curve), heat release due to TFE polymerization is observed starting from approximately 230 K. The polymerization rate reaches a maximum at 275 K, and at 300 K the monomer is completely converted (yield of the polymer 100%).

Polymerization of TFE can also be initiated under similar conditions with ozonides of TFE and HFP [1–3] and occurs in the range 240–300 K. In the case when polymerization in the system TFE–HFP is initiated with HFP ozonide, a copolymer is formed, with the HFP content reaching 25 wt % [4].

Polymerization of TFE is initiated with ozonide **II** not only in the condensed phase on warming the system from 77 K to room temperature, but also in the gas phase at 295 K. Figure 3 shows kinetic curves of TFE polymerization at various initial pressures of the monomer. Experiments were performed in sealed ampules containing definite amounts of ozonide **II** and monomer. It is seen that, depending on the initial pressure of TFE, the conversion is 40–80% in 5 h.

It should be noted that perfluoro ozonides as polymerization initiators for fluoromonomers have fundamentally important advantages over the previously known initiators [10]. Ozonide **II** is not dangerously explosive and is safe in storage. The use of perfluoro ozonides allows polymerization of TFE under atmospheric pressure at room temperature with acceptable rate. Perfluoro ozonides enable, in principle, polymerization of fluoromonomers in the gas phase in the continuous mode. The use of gaseous TFE under normal pressure allows the process equipment to be significantly simplified, and abandoning the use of emulsions and water reduces the environmental impact of the process.

We also examined the possibility of initiating polymerization of monomers containing no fluorine. Ozonide **II** effectively initiates polymerization of liquid methyl methacrylate (MMA) and acrylonitrile (AN) at room temperature. Figure 4 shows kinetic curves of MMA polymerization at room temperature and various initial concentrations of ozonide **II**. The resulting polymer is insoluble in methyl ethyl ketone, which is untypical of polymethyl methacrylate. A chemical analysis showed incorporation of fluorine into the macromolecule in amounts significantly exceeding the content corresponding to addition of the initiator fragment in the initiation stage. Presumably, in the course of MMA polymerization, the decomposition products of the initiator or perfluoro-4-methyl-2-pentene are incorporated in the macromolecule. Preparation of polymethyl methacrylate containing perfluoro groups is also of practical interest.

Thus, ozonide **II** can be used as initiator for polymerization of various monomers; in contrast to usual initiators, it does not require use of elevated temperatures.

CONCLUSIONS

(1) Low-temperature ozonolysis of perfluoro-4-methyl-2-pentene involves addition of ozone across the double bond in equimolar ratio; cryoozonolysis of perfluoro-2,4-dimethyl-3-ethyl-2-pentene does not occur under these conditions.

(2) Perfluoro-4-methyl-2-pentene ozonide is stable at room temperature and can effectively initiate polymerization of commercial perfluoroolefins, methyl methacrylate, and acrylonitrile.

(3) Polymerization of methyl methacrylate initiated with ozonide yields a polymer containing perfluoro groups.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Epoxy Polymers Modified with Glycidyl Esters of Phosphorus Acids

L. M. Amirova and E. V. Sakhabieva

Tupolev State Technical University, Kazan, Tatarstan, Russia

Received April 16, 2001

Abstract—The softening point, heat and fire resistance, oxygen index, flammability, and smokiness of epoxy polymers modified with glycidyl esters of phosphorus acids were evaluated, and compression and bending tests of these materials were performed.

Epoxy polymers exhibit a set of valuable properties [1], but their major drawbacks are low fire and heat resistance and relatively low softening point. One of efficient ways to overcome these drawbacks, and also to make these polymers environmentally safer, is incorporation of phosphorus into their structure [2–5]. Among numerous organophosphorus compounds capable of incorporation into the structure of epoxy polymers, the most attractive are glycidyl esters of phosphorus acids (GEPs); their synthesis and properties are described elsewhere [6]. These compounds can be used as active diluents [7, 8]. However, studies of epoxy polymer compounds modified with GEPs are very limited and are reflected mainly in the patent literature [9].

In this work, we studied the properties of GEP-modified epoxy polymers.

EXPERIMENTAL

As investigation objects we chose epoxy–4,4'-isopropylidenediphenol oligomer ED-20 [GOST (State Standard) 10587–84); amine curing agent 4,4'-diaminodiphenylmethane [DADPM, TU (Technical Specifications) 6-14-415–70]; glycidyl esters of phosphorus acids of the general formula $RP(O)(OCH_2–\underset{\backslash O /}{CH}–CH_2)_2$, where R = $–OCH_2–\underset{\backslash O /}{CH}–CH_2$ (triglycidyl phosphate, **I**), $–OCH_3$ (diglycidyl methyl phosphate, **II**), and $–CH_3$ (diglycidyl methylphosphonate, **III**); and diglycidyl butanediol ether (**IV**).

The compounds were prepared as follows. ED-20 epoxy oligomer was mixed with various amounts of GEP, a stoichiometric amount of the curing agent was added, and the reaction was performed in a step mode. The completion of curing was judged from the attainment of a constant glass transition point T_g, from examination of the thermomechanical curves, and from the content of the gel and sol fractions. Thermomechanical curves were taken on a PTB-1 installation at a heating rate of 50 deg h^{-1}; a sample 8 mm in diameter and 11 mm high was compressed under a constant load in the range P = 9.8–39.2 N. The heat resistance of the compounds was evaluated with a Q-1500D MOM derivatograph (Hungary). The polymers were decomposed in air by heating at a rate of 5 deg min^{-1} to 350°C. The standard physicomechanical tests were performed on an FPZ tensile-testing machine following the prescriptions of GOST 4651–82 for compression tests and GOST 4648–71 for static bending tests.

To study the fireproofing power of the organophosphorus modifiers, we tested the polymeric materials for combustibility by evaluating the flammability according to GOST 21207–81 and determining the oxygen index (OI) according to GOST 12.1.044–89. The oxygen index is defined as the minimal content of oxygen in an oxygen–nitrogen flow moving at a velocity of 4 ± 1 cm s^{-1}, supporting the combustion of a sample for 180 ± 3 s or to a length of 50 mm, depending on what condition is fulfilled earlier.

To determine the smokiness in a wide range (2–70 units), we used a filtration procedure [10] based on deposition of the dispersed phase on the surface of filter paper, followed by photometry of the resulting carbon black spot. After passing a definite gas volume through a paper filter, we determined with an FM-56 photometer the reflection coefficient of the

1070-4272/01/7410-1744 $25.00 © 2001 MAIK "Nauka/Interperiodica"

carbon black spot on the filter R_S. Knowing the initial reflection coefficient of the clean paper filter R_W, we determined the smokiness number D:

$$D = \frac{R_W - R_S}{R_W}.$$

Figure 1 shows how the glass transition point of the compounds depends on the GEP content. It is seen that all the esters markedly raise the glass transition point of the epoxy–amine polymers. The modifier performance depends not only on the functional composition, but also on the chemical structure of GEP. For comparison, Fig. 1 (curve *4*) shows data for the ED-20–DADPM compound modified with **IV**.

Epoxy compounds modified with glycidyl esters of phosphorus acids were subjected to thermal oxidative degradation in air. Figure 2 shows the weight-loss curves for ED-20-based polymers cured with DADPM. Thermal degradation of the phosphorus-containing compounds (Fig. 2, curves *2–4*) occurs at higher temperatures as compared with the unmodified sample (curve *1*). For example, the temperature of 10% weight loss is 254°C for the unmodified compound and 281, 290, and 308°C for the compound modified with 15 wt % of **II**, **I**, and **III**, respectively. Introduction of the organophosphorus component somewhat inhibits degradation, especially with **III**; in order of increasing heat resistance the compounds can be arranged as follows: ED-20 < ED-20–**II** < ED-20–**I** < ED-20–**III**.

The modifier concentration also affects the resistance of epoxy compounds to thermal oxidative degradation. With increasing modifier content, the degradation temperature shifts to higher values, the process decelerates, and the coke yield increases.

Microscopic examination of the carbonized residues obtained in thermal oxidative degradation shows that the coke formed from the phosphorus-containing compounds exhibits higher crystallinity than the coke from the nonmodified compound. The coke residues from the compounds modified with the phosphates are looser and more foamed than those from the compounds modified with the phosphonate.

Thus, addition of GEPs enhances the heat resistance of epoxy compounds, and the effect depends on the concentration and structure of the modifier.

The combustibility of the epoxy compounds was evaluated by the combustion rate ϑ_c and oxygen index OI. The plots of ϑ_c and OI against the phosphorus content in the samples (Fig. 3) show that the oxygen index considerably increases on introduction of the organophosphorus component. The highest OI (up to 40%) is attained with the compounds modified with **III**. The compounds modified with **I** and **II** are somewhat more combustible, as indicated by lower OI.

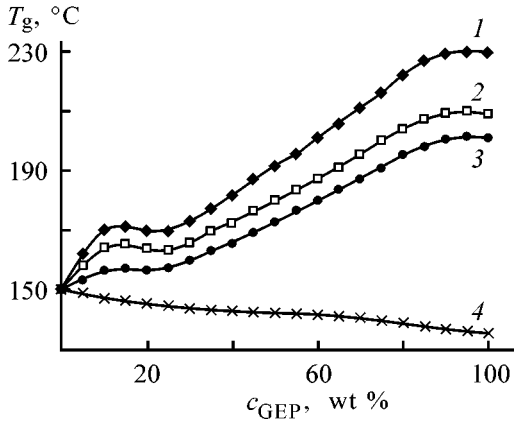

Fig. 1. Glass transition point T_g of ED-20–GEP–DADPM compounds vs. GEP concentration c_{GEP}. Modifier: (*1*) **I**, (*2*) **II**, (*3*) **III**, and (*4*) **IV**.

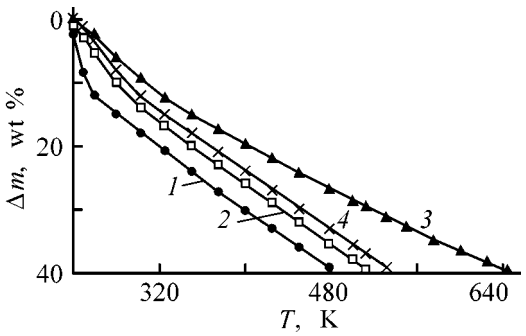

Fig. 2. Weight loss Δm on heating in air ED-20-based epoxy polymers cured with DADPM. (*T*) Temperature. Additive (15 wt %): (*1*) none, (*2*) **II**, (*3*) **I**, and (*4*) **III**.

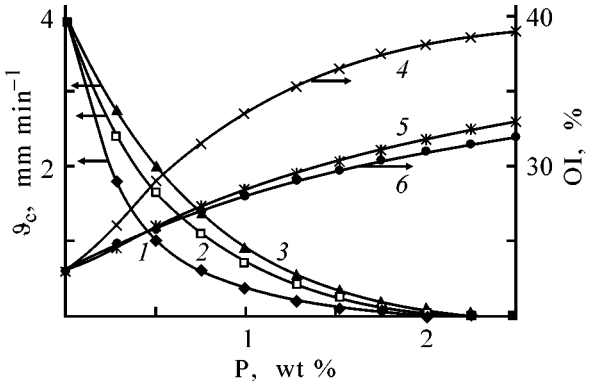

Fig. 3. (*1–3*) Combustion rate ϑ_c and (*4–6*) oxygen index OI of epoxy compounds cured with DADPM, vs. the content of the added GEPs in terms of phosphorus. Modifier: (*1*, *4*) **III**, (*2*, *5*) **I**, and (*3*, *6*) **II**; the same for Fig. 4.

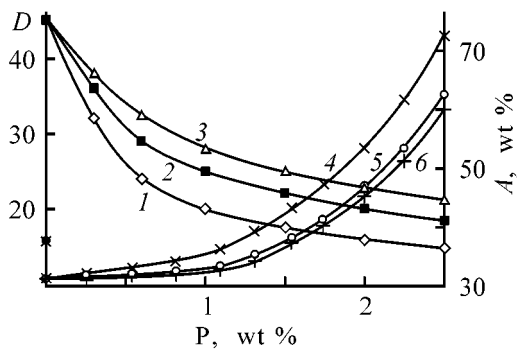

Fig. 4. (*1–3*) Smokiness number *D* and (*4–6*) coke yield *A* in combustion of epoxy compounds ED-20–GEP–DADPM vs. the phosphorus content P in the modified polymer.

Data on the combustion rate rather clearly correlate with the results of the OI tests. As seen from Fig. 3, phosphonate **III** is the most effective combustion inhibitor. Samples of compounds modified with phosphates show high ϑ_c. On the whole, experimental data allow the phosphorus-containing compositions to be classed with self-extinguishing compounds. The modified compounds burn to give a larger coke residue as compared with the initial formulation (Fig. 4); the higher the phosphorus content, the smaller the burnt-out fraction of the epoxy polymer. However, in this case, too, the coke yields for are different added phosphates and phosphonates at the same content of phosphorus in the compound. For example, at a 1.5% content of phosphorus the coke residue from samples modified with **III**, **I**, and **II** is 42, 38, and 37%, respectively (for the unmodified epoxy polymer it is 32%).

30	170	145	134	181	149	148

* (c_m) Modifier content.

When studying the fireproofing properties of GEPs, we noticed that addition of an organophosphorus component alters the character of the polymer combustion. The combustion of the unmodified samples is accompanied by the formation of carbon black, splashing of the polymer melt, and evolution of abundant smoke. By contrast, the phosphorus-containing polymers form a melt with a viscous surface layer, which is followed by carbonization. The combustion of phosphorus-containing epoxy polymers is accompanied by coke formation, with the coke yield and structure depending on the nature of GEP. The phosphate-modified compounds show strong foaming and intumescence. The phosphonate-modified compounds burn to give a large amount of dense coke, without intumescence. The coke yield grows with increasing phosphorus content.

Figure 4 shows that introduction of organophosphorus compounds considerably reduces the smokiness of epoxy compounds

The performance of fire retardants can be evaluated by the formula [11]

$$a = \Delta OI/(c + b), \quad (1)$$

where *a* is the coefficient of fire retardant performance; ΔOI is the change in the oxygen index; *c* is the concentration (wt %) of the element that diminishes the combustibility; and $b = 0.02A$ (*A* is the atomic weight of the element).

The coefficients *a* for the epoxy compounds studied are listed in Table 1; it is seen that phosphonate **III** exhibits the best performance.

Our results show that GEPs are effective fire retardants for epoxy polymers. Comparative analysis of the fireproofing powers of phosphonate and phosphates shows that, with the former, the oxygen index is higher and the combustion rate lower at the same content of phosphorus (Fig. 3).

The compression and bending tests of the modified polymers (Table 2) showed that the strength characteristics of the compound as functions of the modifier concentration pass through a maximum. The highest

values of σ_b and σ_c are observed at low GEP content, which is followed by a decrease in strength. The highest strength is shown by the compounds modified with trifunctional glycidyl phosphate; such compounds exhibit the highest crosslinking density and the highest glass transition point. Among the compounds modified with the bifunctional agent, those containing **II** are stronger. One of the major factors causing an increase in the strength of the GEP-modified epoxy polymers is, apparently, the lower content of structural defects, resulting from the lower viscosity of the initial formulation.

CONCLUSION

Our results showed that epoxy polymers modified with glycidyl esters of phosphorus acids exhibit, on the one hand, high levels of heat and fire resistance and high softening point and, on the other, increased strength and rigidity. A combination of such properties makes these compounds promising as versatile materials.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Oxidation Conditions in the System Dinitrogen tetroxide–Tetrachloromethane on Mechanical Characteristics of Viscose Threads

N. K. Yurkshtovich, A. K. Chekhovskii, N. V. Golub, and F. N. Kaputskii

Research Institute for Physicochemical Problems, Belarussian State University, Minsk, Belarus

Received May 24, 2001

Abstract—The relationship between the functional composition and mechanical characteristics of viscose cord threads with various linear densities, on the one hand, and oxidation conditions in the system N_2O_4–CCl_4 on the other, was studied. The effects of the oxidant composition and treatment time on the tensile strength of dry and wet threads, and those tied in a knot, and also on the stability in a phosphate buffer were analyzed. The optimal conditions for making threads with preset content of carboxy groups, having sufficient mechanical strength and stability in the phosphate buffer (pH 7.5) at 310 K, are determined.

Among cellulose derivatives, monocarboxycellulose (MCC), the product of cellulose oxidation with dinitrogen tetroxide, occupies a special place. Owing to its suitable biological and mechanical characteristics, MCC is widely used in medicine as a polymer carrier for drugs and also as a surgical suture material. However, large-scale employment of oxidized cellulose fibers in surgery has been limited till now by their insufficient mechanical strength and high biodegradation rate in living tissues.

It is known that the tensile strength of cellulose threads is controlled to a considerable extent by the preparation procedure, including chemical modification with dinitrogen tetroxide. It was demonstrated in [1, 2] that the loss of tensile strength on treatment with gaseous N_2O_4 of cellulose threads with a carboxy group content of 4.0–12.5% is 27.6–63.2%. In [2], effort was made to reduce the loss of tensile strength in cellulose threads by performing their oxidation in organic solvents (tetrachloromethane, trichlorofluoromethane, etc.) for a short time (15–30 min), with subsequent keeping at elevated temperature and pressure. In this case, the loss of strength in cotton and viscose threads with carboxy group content of 3.0–9.8% decreased to 19.9–28.9%. The threads thus treated lose their strength in living tissues in 5 ± 1 days. However, no detailed information is given in [2] on how the solution composition and oxidation time in each system affect the mechanical strength of the threads.

The purpose of this study was to optimize the process of oxidative treatment of viscose threads in the system N_2O_4–CCl_4 with respect to the mechanical strength and biodegradation rate in living tissues. Therefore, we studied the effects of the oxidant concentration, oxidation time, twisting of the threads, and the content of carboxy groups in them on the tensile strength of dry (P_d) and wet threads (P_w) and those tied in a knot (P_k), and also on the elongation $\Delta l/l$.

EXPERIMENTAL

In the study, we used twisted and untwisted viscose cord threads with linear density of 439 and 184 tex, respectively. The oxidative treatment was carried out in CCl_4 at 290 ± 1 K for 1–24 h with various concentrations of N_2O_4. Oxidation with gaseous N_2O_4 was performed at 318 ± 2 K and oxidant pressure of 2.5×10^5 Pa in the course of 15–30 min. After the oxidized samples were withdrawn from the reaction vessel, sorbed nitrogen oxides and CCl_4 were removed by passing an air stream for 30–45 min. Then the threads were thoroughly washed with distilled water to negative reaction for NO_2^- and NO_3^-. The carboxy group content in oxidized viscose threads was determined by the Ca-acetate method [3]. The tensile strength of dry (P_d) and wet (P_w) threads was measured on an RM-3-1 tensile-testing machine [4], and that of a thread tied in a knot (P_k), as for a dry thread. The thread was so arranged in clamps that the knot was at

1070-4272/01/7410-1748 $25.00

equal distances from the fixation points. The arithmetic mean of the results obtained and the coefficient of variation of the tensile strength of threads were estimated as in [4]. The relative tensile strength P_{rel} (cN tex^{-1}) was estimated to be

$$P_{rel} = P_a/T,$$

where P_a is the actual tensile strength (cN) and T is the linear density of the thread (tex).

The elongation was measured in parallel with determining the tensile strength on the elongation scale of the tensile-testing machine. The elongation of a thread is expressed in percent of its initial length.

Hydrolytic degradation of oxidized threads in living tissues was simulated using a phosphate buffer solution (pH 7.5) at 310 ± 1 K. After treatment for a fixed time, the threads were dried, and their tensile strength was measured.

Figure 1 demonstrates the effect of oxidation conditions in the system N_2O_4–CCl_4 on the content of carboxy groups in viscose threads. As seen, this parameter grows steadily with increasing oxidant concentration and oxidation time (within 12–16 h). For example, with the N_2O_4 concentration increasing from 5 to 30%, the carboxy group content in oxidized threads grows, depending on the oxidation time, from 0.3–6.3% [degree of substitution (DS) 1.1–23.0] to 1.6–15.5% (DS 5.9–58.5). In the oxidant concentration range 5–10%, the oxidation rate in the initial stage of the reaction is the most sensitive to the oxidant concentration. Use of N_2O_4 solutions with a concentration from this range allows fabrication of threads with $m_{COOH} \geq 3.0\%$, which well meets the medical and biological requirements to surgical suture materials. In this case, the dependence of m_{COOH} on t has a pronounced S-shaped form, suggesting that, in the initial stage of the reaction ($t < 5$ h), diffusion of dinitrogen tetroxide to the bulk of the fiber is hindered, and carboxy groups are accumulated preferentially in the surface layer. At a fixed N_2O_4 concentration in CCl_4 and fixed oxidation time, the carboxy group content in twisted and untwisted viscose threads is virtually the same, with the content of fixed nitrogen in all the samples not exceeding 0.1% of the initial weight of the threads.

Figure 2 demonstrates the influence exerted by the content of carboxy groups on the tensile strength of twisted and untwisted viscose threads oxidized in CCl_4 with various concentrations of N_2O_4. It should be pointed out that here we used experimental data corresponding to the initial stage of oxidation (rapid rise in the degree of oxidation) (Fig. 1). This is the optimal time interval for oxidation treatment, since,

with t growing further, the content of carboxy groups no longer increases, and P_w of the resulting threads and their stability in phosphate buffer solutions decrease dramatically.

The results obtained show that the tensile strength of oxidized viscose threads depends not only on the content of carboxy groups and degree of twisting, but also on the oxidant concentration. The decrease in the tensile strength of oxidized threads is the most significant with the content of carboxy group increasing to 1.8–3.6%, which is attained in 1–7 h. Further increasing degree of oxidation has practically no effect on the tensile strength, being manifested essentially in the changing stability of the threads in the phosphate buffer (Table 1). Presumably, the maximum drop in the strength in the initial stage of oxidation is associated with the higher rate of variation of the degree of structural ordering and decrease in the degree of polymerization.

Twisted threads					
5	2.8	21.8 ± 0.9	8.7	11.5	–

It follows from Fig. 2 that, with the N_2O_4 concentration increasing from 5 to 15%, the decrease in the tensile strength in untwisted threads with fixed content of carboxy groups is within the experimental error. At higher oxidant concentration the tensile strength decreases steadily with increasing N_2O_4 concentration. The supramolecular structure of the fibers degrades in parallel, as demonstrated by X-ray scattering data for the threads before and after treatment with N_2O_4 solutions (Fig. 3).

In the diffraction pattern of the initial viscose fiber, there is, instead of three distinct maxima typical of cellulose II, only one strong peak at $2\theta = 21–22°$, suggesting a relatively high degree of orientation in the initial fiber structure. With the oxidant concentration increasing from 5 to 10%, the extent of structural transformation in the oxidized threads with fixed m_{COOH} grows somewhat (peak intensity decreases). Therefore, the threads treated with a 10% N_2O_4 solution are characterized by a higher degree of disorientation and degradation of macromolecules, even despite the fact that the treatment time in this case is half as long as that for the 5% solution.

It can be seen from Fig. 4 that the increase in the elongation of oxidized threads with growing degree of oxidation, i.e., the effect of the oxidizing medium on the mechanical characteristics of viscose threads is similar to the effect of moisture. One may suggest that partial decomposition of the crystallites and disorientation of the macromolecules in amorphous regions in

* Oxidation time in CCl_4 is 7 h. Conditions of oxidation in the gas phase: T = 318 K, p = 2.5 10^5 Pa. $\Delta P = P_d^0 - P_d^{ox})/P_d^0$.

the course of oxidation and washing are accompanied by a decrease in the intensity of interaction between cellulose macromolecules.

Under the same oxidation conditions, the maximum loss of strength was observed for twisted threads (Fig. 2). In this case, the effect of the N_2O_4 concentration on the tensile strength of oxidized twisted threads is less pronounced as compared with untwisted threads. Table 2 shows that at the optimal oxidation conditions in CCl_4 the loss of tensile strength ranges for twisted thread from 15.9 to 38.5%, depending on the content of carboxy groups, and for untwisted thread, from 11.1 to 19.2%. The most probable explanation of the observed effect is that, both in solids and in polymers, simultaneous action of a mechanical stress and an aggressive medium provides more significant changes in strength [5]. Therefore, to reduce the loss of tensile strength of a cellulose-based material as a result of oxidation, it is necessary to use threads with low twisting density.

Comparison of the mechanical characteristics of cellulose threads having close degrees of substitution, but obtained under different oxidation conditions, shows that the loss of strength is more pronounced when oxidation is performed in the gas phase (Table 2). In this case, the tensile strength decreases by 37–63%, which is consistent with published data.

According to the results of [2, 5], the rate of strength loss in a phosphate buffer solution (pH 7.5) at 310 ± 1 K quite adequately reproduces that in living tissues, where hydrolytic degradation proceeds at a higher rate. It was demonstrated in [2] that the stability of the threads in the phosphate buffer depends on the oxidation conditions. However, we found no information on the effect of the content of carboxy groups in oxidized cellulose on its stability.

The results obtained in studying the influence exerted by the content of carboxy groups on the loss of strength in oxidized viscose threads under the action of the phosphate buffer are given in Table 1. After oxidation of the threads in 5% N_2O_4 to a carboxy group content of 0.4%, i.e., after introduction of one carboxy group per 60–70 glucoside residues, their stability against the action of the phosphate buffer strongly decreases. The strength loss in these threads after a 10-day storage in the phosphate buffer was found to be 31.7%, and that for the initial (untreated) threads, 8.9%. The primary reason for the loss of strength in the oxidized threads in a buffer solution at pH 7.5 is the hydrolytic degradation of macromolecules [6, 7]. With the degree of oxidation increasing further (by a factor of 7–8) to a carboxy group content of 3.3%, the decrease in the stability of the threads in phosphate buffer becomes less pronounced, ranging from 5.5 to 10.5%, depending on the storage time. At a still higher content of carboxy groups (4.2% and more) the loss of strength progressively increases with time of storage in the buffer solution. Comparison of the stability of threads with the same carboxy group content, but treated in 5% or 10% N_2O_4 solutions, shows that the hydrolytic stability is lower in the latter case, while the tensile stress is virtually the same.

CONCLUSIONS

(1) The optimal mechanical characteristics are demonstrated by viscose threads oxidized with 5–15% dinitrogen tetroxide solutions; the loss of tensile strength of the threads with a carboxy group content of 3.0–9.9% is about 11–42%.

(2) The stability of the oxidized threads in a phosphate buffer (pH 7.5) largely depends on the carboxy group content and oxidation procedure. After oxidation of viscose threads with 5% N_2O_4 to a carboxy group content of 3.5%, the loss of strength was 42.2% after 10 days of storage in the buffer solution. The oxidation in more concentrated N_2O_4 solutions, as well as higher degree of oxidation strongly diminishes the stability of the threads in the phosphate buffer solution.

(3) Preparation of a surgical suture material by oxidative treatment of viscose threads in the system N_2O_4–CCl_4 is recommended to be performed at oxidant concentration of 5%, oxidation time 5–10 h, and temperature 290 ± 1 K.

Abstract—Solubility of lead(II) nitrate in the system H_2O–$Fe(NO_3)_3$–HNO_3 was studied using the simplex-lattice method of experiment design.

Use of solutions containing nitric acid and iron(III) for oxidation and dissolution of various materials has been studied in sufficient detail. However, the available data mainly refer to the characteristics necessary for industry [1]. Published data on the solubility of lead nitrate in nitric acid in the presence of iron(III) nitrate are lacking.

In this work, the solubility of lead nitrate in the system H_2O–$Fe(NO_3)_3$–HNO_3 was studied by means of the isothermal method.

EXPERIMENTAL

We used lead(II) nitrate, iron(III) nitrate, chemically pure grade nitric acid, and water. The equilibration time (40–42 h) was established experimentally. The tests were performed during 50 h at 25 ± 0.1 and 55 ± 0.1°C. After the tests were complete, the liquid phase was sampled and the content of lead(II) was determined by atomic absorption spectroscopy and titrimetry [2, 3], and the concentration of nitric acid, by titrimetry [3]. The solid phase was filtered off, washed with water and ethanol to remove mother liquor, dried at 50–60°C, and subjected to X-ray phase analysis.

The obtained results were processed by the simplex-lattice method of experiment design [4]. The vertices X_1, X_2, and X_3 of the concentration triangles represented the components H_2O (55.56 M), $Fe(NO_3)_3$ (1.8 M), and HNO_3 (3.2 M), respectively. As functions served lead nitrate concentrations in solution. The simplex-lattice plan for incomplete cubic model of the dependence of lead nitrate concentration on the above solution parameters is presented in the table.

The obtained results were used to estimate the coefficients of the polynomials of incomplete third order, having the following form:

$$Y_{25} = 1.50X_1 + 0.15X_2 + 0.28X_3 - 1.84X_1X_2 - 0.04X_2X_3 - 1.31X_1X_3 + 3.04X_1X_2X_3 \quad (25°C),$$

$$Y_{55} = 2.00X_1 + 0.25X_2 + 0.38X_3 - 2.30X_1X_2 - 0.06X_2X_3 - 0.95X_1X_3 - 0.17X_1X_2X_3 \quad (55°C).$$

The root-mean-square error in determining Y was 3%. Substitution of the data of tests nos. 8–10 in the equations showed that they adequately describe experimental data with 97% probability.

The obtained equations were used to plot isoconcentration curves for lead nitrate (see Figs. 1a and 1b).

$Pb(NO_3)_2$–HNO_3–H_2O system. Various methods for precipitation of lead nitrate by addition of nitric acid are known [5]. However, the fundamental aspects of this process and the $Pb(NO_3)_2$ solubility have not been determined previously. The solubility data show that, with increasing nitric acid concentration in the system studied, the solubility of lead nitrate markedly decreases to reach a minimum at the point with the highest concentration of nitric acid (under the experimental conditions). This is due to an increase in the concentration of NO_3^- ions, which leads to salting-out of lead nitrate.

$Pb(NO_3)_2$–$Fe(NO_3)_3$–H_2O system. To our knowledge, no data are available in the literature for the solubility of lead nitrate in iron(III) nitrate solutions. The obtained data indicate that, in the system studied, the concentration of lead nitrate is considerably lower

than that in the case of its salting-out with nitric acid. The minimum concentration of lead nitrate is observed at the points 1.55 M $Fe(NO_3)$ at 25°C and 1.57 M at 55°C, with the lead salt concentration in solution reaching 0.12 and 0.22 M, respectively. An X-ray analysis of the deposits revealed no other compounds except lead nitrate.

$Pb(NO_3)_2$–$Fe(NO_3)_3$–HNO_3 system. A study of the $Pb(NO_3)_2$ solubility in the given system showed that the presence of iron(III) nitrate and nitric acid also decreases the concentration of lead nitrate in solution, and this effect becomes more pronounced with increasing iron(III) nitrate concentration.

$Pb(NO_3)_2$–H_2O–$Fe(NO_3)_3$–HNO_3 system. The calculated and experimental solubilities in the given quaternary system are presented in the isoconcentration triangles. When iron(III) nitrate and nitric acid are present in the solution simultaneously, the observed behavior is apparently the same as that in the ternary systems.

A comparison of the lead nitrate concentrations at 25 and 55°C showed that, with increasing temperature, the $Pb(NO_3)_2$ concentration grows and the general tendencies are preserved.

It should be noted that an X-ray analysis performed at all the points studied revealed only lead nitrate in the precipitate.

CONCLUSIONS

(1) A study of the lead nitrate solubility in the system H_2O–$Fe(NO_3)_3$–HNO_3 showed that the concentration of lead(II) ions decreases with increasing content of nitric acid and iron(III) nitrate in solution.

Abstract—The influence exerted by components introduced into the working solution and by the temperature of sludge treatment on hydration of dispersed aluminum particles formed in the course of spark erosion was studied.

The behavior of dispersed metal particles formed in spark erosion has been insufficiently discussed in the literature. The products formed in this process frequently have composition different from that of the employed electrodes. For example, metal carbides are formed together with metal powder in spark erosion of niobium in organic solvents (heptane, kerosene, transformer oil), with niobium carbides with varied carbon content formed depending on the process mode [1, 2]. Spark-erosion dispersion of aluminum in water gives aluminum hydroxide [3, 4]. Depending on the conditions of the spark-erosion process, the forming dispersed metal particles may partially or completely react with the working solution. Therefore, studying the influence exerted by the conditions of spark erosion on the composition of its products is important.

This study is concerned with spark-erosion dispersion of aluminum and the influence exerted by additives introduced into the working solution (ammonium nitrate, carbonate, or acetate) and by the temperature of sludge treatment on the composition of spark-erosion products.

The experiments were done in a cylindrical reactor made of an insulating material (acrylic resin or polyvinyl chloride plastic) with aluminum electrodes symmetrically arranged at reactor edges. The reactor was charged with aluminum grains 5–8 mm in size to 2/3 of its height. As working solution pumped through the reactor was used distilled water. The grains between the electrodes were stirred by shaking with the help of a mechanical stirrer. Voltage pulses of amplitude 180 V and repetition frequency of 1000 Hz from a 1-kW generator were applied to the electrodes.

At points of grain-to-grain and grain-to-electrode contacts there occurred spark discharges in water, and aluminum was dispersed. The sludge (mixture of the working solution and erosion products) was fed into a tank to be subjected to thermal treatment there.

The sludge was filtered, the filtrate was recycled, and the obtained precipitate was dried at 100°C. The phase composition, specific surface area, and metallic aluminum content of the obtained product were determined. The phase composition of the precipitate was performed with a DRON-2 X-ray diffractometer.

Some of the obtained diffraction patterns are shown in Fig. 1. Interplanar spacings used to identify the products (interplanar spacing $d = 10^2$ pm: bayerite: 1.33, 1.39, 1.44, 1.55, 1.60, 1.72, 2.23, 2.47, 2.72, 3.23, 4.40, and 4.80; pseudoboehmite: 1.42, 1.85, 2.34, 3.20, and 6.30; aluminum: 1.99) are indicated at the lines. The specific surface area was determined by the method of thermal desorption of argon on a special installation with the use of Tsvet-200 instrument.

As an example, we present in more detail the results obtained in studying the effect of addition of ammonium nitrate to the working solution. Figure 1 shows X-ray diffraction patterns of aluminum spark-dispersion products obtained with working solutions without additive and with ammonium nitrate additive at different temperatures of sludge treatment. It can be seen that, with distilled water used as working solution and sludge treatment temperature of 25°C, the erosion products are mainly composed of bayerite-type aluminum hydroxide and a minor amount of powdered aluminum whose content was not higher than 3 wt % in all experiments (Fig. 1a). On elevating the treatment temperature to 90°C, pseudoboehmite appeared in the erosion products together with bayerite (Fig. 1b). A similar behavior was observed at lower temperature of about 25°C on introducing ammonium nitrate into the working solution (Fig. 1c). The forma-

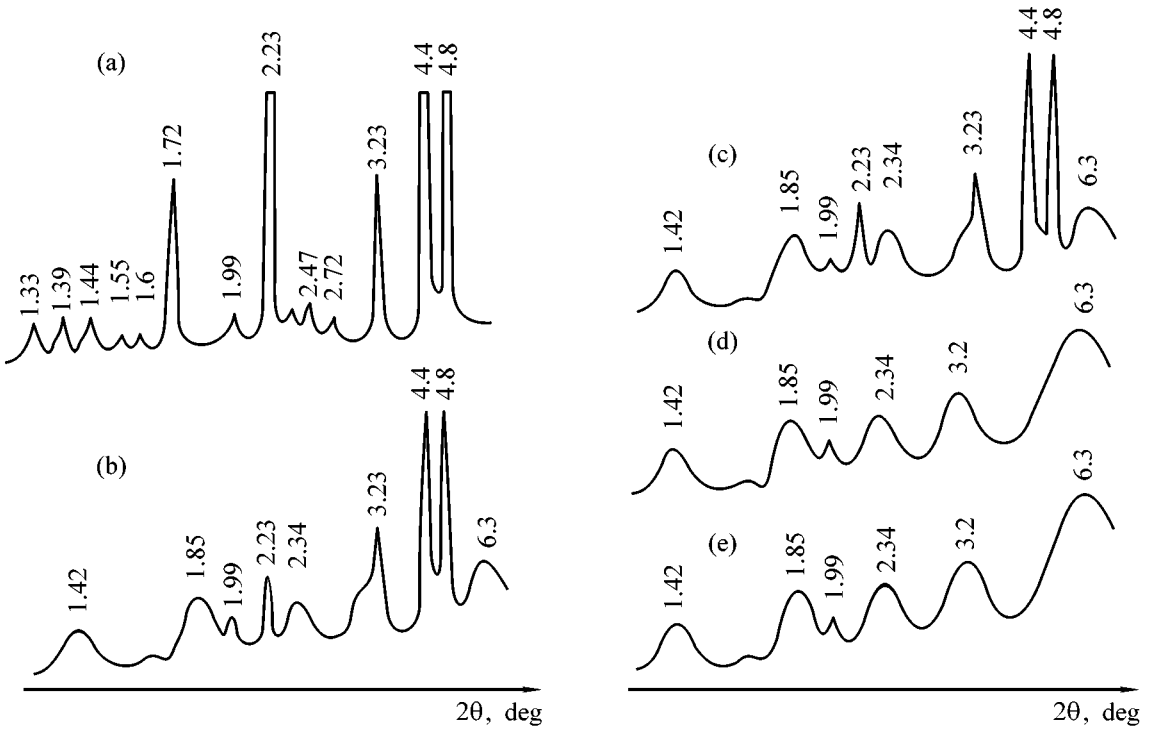

Fig. 1. X-ray patterns of products obtained in spark dispersion of aluminum in working solution (a), (b) without additive and (c)–(e) with addition of ammonium nitrate. (2θ) Bragg angle. Sludge treatment temperature (°C): (a), (c), (e) 25 and (b), (d) 90. Sludge treatment time (h): (a) 20, (b) 14, (c) 15, (d) 10, and (e) 6. NH_4NO_3 concentration (M): (c), (d) 0.017 and (e) 0.14.

tion of pseudoboehmite under these conditions is presumably not a consequence of bayerite dehydration, since the latter process onsets at 200°C [5]. On elevating the sludge treatment temperature to 90°C, dispersed metal is hydrated to give only pseudoboehmite (Fig. 1d). Raising the concentration of ammonium nitrate in the working solution also favors formation of boehmite, and, at concentrations exceeding 0.017M, pseudoboehmite is already formed at 25°C (Fig. 1e). Thus, a conclusion can be made that the hydration of dispersed aluminum is strongly affected by two factors: working solution composition and sludge treatment temperature.

The observed differences between the erosion products are presumably due to the fact that dispersed aluminum is hydrated to give both boehmite and bayerite. Figure 2 shows the effect of temperature on the specific surface area of aluminum oxides obtained from pseudoboehmite (curve *1*) and bayerite (curve *2*) formed in the course of spark erosion. The nature of the *S*–*T* curves is about the same for the given aluminum oxides and those obtained chemically from the corresponding aluminum hydroxide [5]. This also indicates that dispersed aluminum particles formed in spark erosion are hydrated to give bayerite and boehmite.

The following scheme of hydration of dispersed aluminum can be proposed on the basis of the obtained data:

$$Al + H_2O \rightarrow AlOH + 1/2H_2, \quad (1)$$

$$AlOH + H_2O \rightarrow Al(O)OH + H_2, \quad (2)$$

$$Al(O)OH + H_2O \rightleftarrows Al(OH)_3. \quad (3)$$

With distilled water as working solution and low treatment temperatures of sludge treatment, dispersed aluminum particles are hydrated to give bayerite,

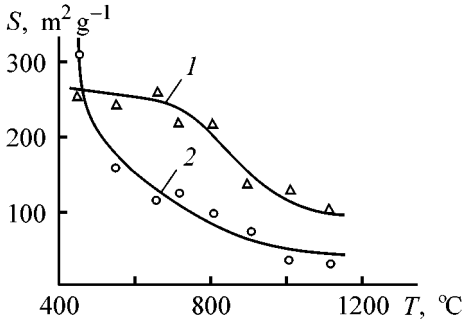

Fig. 2. Effect of temperature *T* on the specific surface area *S* of aluminum oxide obtained from (*1*) pseudoboehmite and (*2*) bayerite. Time of keeping at each temperature 6 h.

which is the final product of stage (3). Introducing certain additives into the working solution and elevating the sludge treatment temperature favor formation of boehmite.

CONCLUSIONS

(1) It is shown that, depending on the conditions under which the spark-erosion process is performed, the forming dispersed aluminum particles are hydrated to give bayerite or boehmite modification of aluminum hydroxide.

(2) Raising the temperature of sludge treatment and introducing ammonium nitrate, carbonate, or acetate into the working solution favor formation of boehmite-type aluminum hydroxide.

Abstract—The effect of additives introduced into the working solution on the behavior of dispersed aluminum particles formed in spark erosion was studied. The conditions under which products of a given composition are formed were determined on the basis of thermodynamic and kinetic factors.

Depending on the conditions under which the spark-erosion process is performed, the obtained dispersed aluminum particles, interacting with the working solution, form a bayerite or boehmite modification of aluminum hydroxide [1]. Aluminum hydroxide is obtained in those cases when the forming dispersed aluminum is free of an oxide film and exhibits high reactivity. It is of interest to enlarge the body of data on the influence exerted by various spark-erosion process conditions on the composition of the products.

In this study, the influence of acids introduced into the working solution (distilled water) on the composition of the spark-erosion process was analyzed. The experiments were done on the installation, and using the technique, described in [1]. The content of metallic aluminum in the erosion products was determined volumetrically [2].

Figure 1a shows an X-ray pattern of products obtained in spark dispersion of aluminum, with nitric acid introduced into the working solution. For comparison, Figs. 1b and 1c present X-ray diffraction patterns of erosion products obtained in the working solution (distilled water) and a solution of ammonium nitrate. It can be seen that addition of nitric acid results in that aluminum powder is the main product of spark erosion. The content of aluminum in the erosion products is about 97 wt %. In other cases, boehmite and bayerite forms of aluminum hydroxide are produced, differing in the number of water molecules per aluminum oxide molecule [1]. The differences in the composition of the erosion products are presumably due to the fact that introduction of ammonium nitrate into the working solution hinders access of water

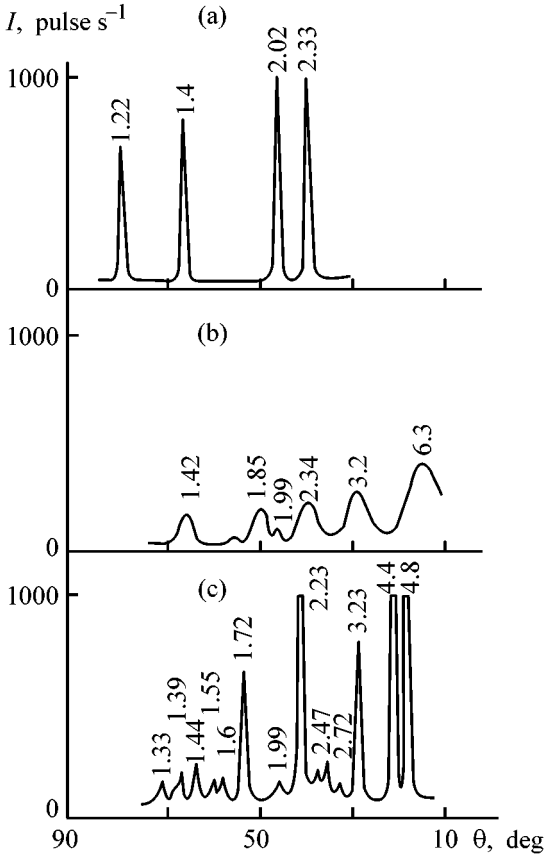

Fig. 1. X-ray patterns of products formed in spark dispersion of aluminum. Sludge treatment temperature 25°C. (*I*) Intensity and (θ) Bragg angle. Sludge treatment time (h): (a) 4, (b) 6, and (c) 20. Additive to working solution (M): (a) HNO_3 0.016, (b) NH_4NO_3 0.14, and (c) distilled water. molecules to dispersed aluminum particles. As a result, dispersed aluminum is hydrated to give boehmite. On adding nitric acid to the working solution, no hydration occurs. This is possibly due to formation of a protective oxide film on the surface of dispersed aluminum particles under the action of nitric acid. It should be noted that, at nitric acid concentration in the working solution of less than 0.003 M, aluminum hydroxide is formed in large amounts together with powdered metal. Raising the acid concentration leads to an increase in the amount of forming powdered metal, and, at solution concentrations exceeding 0.008 M, powdered metal becomes the main erosion product. Formation of aluminum powder was also observed upon introduction of other acids into the working solution [3]. The limiting concentrations of these acids, necessary for only powdered metal to be formed as the main erosion product, depend on the type of acid.

On the basis of [1], the scheme of hydration of dispersed aluminum in a working solution with addition of nitric acid can be represented as follows:

$$Al + H_2O \rightarrow AlOH + 1/2H_2, \quad (1)$$

$$2Al + 6HNO_3 \xrightarrow{t} Al_2O_3 + 6NO_2 + 3H_2O, \quad (2)$$

$$AlOH + H_2O \rightarrow Al(O)OH + H_2, \quad (3)$$

$$Al(O)OH + H_2O \rightleftarrows Al(OH)_3. \quad (4)$$

It is known that strongly diluted or cold concentrated nitric acid does not dissolve aluminum because of the formation of an oxide film [4]. Under the conditions of an electric spark discharge, when the released energy is, in principle, sufficient for atomization of oxygen of oxygen-containing acid residues, it is also not improbable that aluminum oxidation may proceed in dilute acid solutions [reaction (2)]. For this reason, other acids (phosphoric, chromic) can passivate aluminum in the course of spark erosion to give mainly powdered metal as a product [3].

Thus, at low temperatures of sludge treatment in distilled water, dispersed metal particles formed in the course of erosion are hydrated to give bayerite, which is the final product of stage (4). Introduction of salts into the working solution and raising the sludge treatment temperature [1] favor formation of boehmite, which is the final product of stage (3) or of reverse reaction in stage (4).

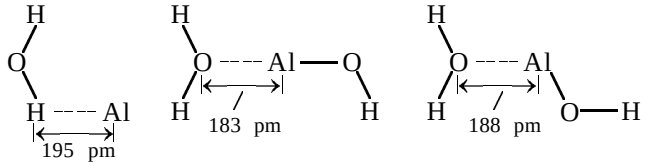
The change in the standard Gibbs energy, ΔG, calculated using the data of [5] for reaction (4), is about –4 kJ. This points to a slim, but still existing thermodynamic possibility of occurrence of the process. Calculation of the enthalpy and entropy factors of the given process indicates that, for the given reaction, the dependence of the change in Gibbs energy on temperature T (K) has the form

$$\Delta G = -18.8 + 0.005T.$$

At 90°C, ΔG = –0.65 kJ. As a result, passing from 25 to 90°C results in only a slight shift of the equilibrium toward boehmite formation. However, at 90°C the equilibrium of the system (4) may shift to the left in accordance with the Le Chatelier principle, because of the removal of water from the reaction sphere.

At the same time, it is not improbable that there may exist different rates of boehmite formation and consumption by reactions (2) and (4), respectively. Experimental verification of this assumption is difficult under the conditions of the experiment. Therefore, the relative reaction rates were evaluated on the basis of theoretical considerations. Let us assume that complexes between the substrate [i.e., Al, AlOH, or Al(O)OH] and water molecule are preliminarily formed near the transient states of the reactions in question. Then, the higher the energy gain in such a complexation, the lower must be the activation energy of the reaction and the higher its rate. Results of quantum-chemical calculations of the structure of the complexes by the PM3 method are presented below:

Complex 1 Complex 2 Complex 3



The complexation energy is (kJ mol^{-1}) 104 for complex no. 1, 185 for no. 2, and 96 for no. 3. The stabilization energy of complex no. 2 is the highest, which assumes fast conversion of aluminum monohydroxide into aluminum oxohydroxide [reaction (3)]. At the same time, aluminum oxohydroxide is the least stabilized in complexation with water, and, therefore, it is anticipated that its further hydration to give aluminum trihydroxide [reaction (4)] will proceed at lower rate than the rate of aluminum oxohydroxide formation. Consequently, it would be expected that boehmite is primarily accumulated in products via reactions (1) and (3), rather than as a result of bayerite

dehydration. This confirms the previous assumptions concerning the mechanism of boehmite formation [1].

Thus, the process can be directed toward formation a required product by varying the conditions of spark dispersion of aluminum.

CONCLUSION

Depending on the process conditions, different products can be obtained in spark erosion of aluminum; in particular, introduction of nitric acid into the working solution favors formation of metal powder. Changes in the composition of spark-erosion products with the process conditions may be governed both by thermodynamic and by kinetic factors of the process.

Abstract—The influence exerted by the nature of organic components of the working solution on the composition of products formed in spark dispersion of aluminum was studied.

In spark erosion of aluminum, the interaction of the forming dispersed metal particles with the working solution depends on the process conditions [1, 2]. The reaction products are bayerite, boehmite, and aluminum powder. The fact that mainly aluminum powder is obtained in the process is due to the formation of an oxide film on the surface of dispersed particles. The film formation may involve oxygen produced together with other elements in the decomposition of working solution components in the electric spark discharge zone. The possibility of occurrence of such a reaction is indicated by data obtained in studying the spark erosion of a metal in a working solution containing organic compounds (e.g., niobium in the presence of heptane etc.), in which metal carbides are formed together with the metal powder [3]. The carbides are products of the reaction of dispersed particles with carbon formed in destruction of organic compounds in the course of spark erosion.

This study is concerned with the influence exerted on spark erosion of aluminum by a number of organic compounds added to the working solution (distilled water). The experiments were carried out on an installation similar to that described in [1].

Figure 1 shows the results of a study of the effect of sludge treatment temperature (a) and concentration of introduced organic compounds (b) on the composition of the obtained products. It can be seen that the content of boehmite in erosion products obtained in the working solution and solutions containing organic components grows with increasing sludge treatment temperature. The thermal treatment of the sludge was carried out outside the spark-discharge zone (outside the reactor in the collector vessel) [1]. At the same time, approximately constant sludge temperature within the reactor (≤40°C) was ensured by controlling

* Sludge treatment temperature T (°C): (1–7) 90 and (8) 25.

the feed rate of the working solution. Since the thermal treatment mode affects the composition of spark-erosion products, the presented experimental data indicate the occurrence of "secondary" reactions in the sludge receiver. The difference in the compositions of products obtained upon thermal treatment of sludge at different temperatures are probably due to the varied, temperature-dependent extent of metal hydration. In particular, the extent of hydration of dispersed metal decreases with increasing temperature. This leads, in the end, to a higher amount of boehmite in spark-erosion products.

The fact that aluminum powder is obtained in the final product may be due to the formation in the spark-discharge zone of a uniform oxide film on the surface of dispersed particles (primary process) protecting the metal from further reaction with the working solution. Probably, partial formation of the oxide film on the surface of the dispersed metal may also occur in the spark-discharge zone in those cases when no metal powder is formed, e.g. with distilled water used as working solution. This film may play important role further, in secondary processes. The assumption made is most clearly confirmed when solutions containing various organic substances are used in the process (Fig. 1b). It can be seen that, with increasing concentration of organic substances used in the spark-erosion process, the content of boehmite in the product first grows steeply (portion *I*) and then gradually approaches the limiting value (portion *II*), which depends on the nature of the organic component of a working solution. The observed run of the ω–*C* curves suggests that the fraction of dispersed metal surface covered with oxide film grows in the spark discharge zone with increasing concentration of an organic substance in the working solution. This oxide film may be formed because of the appearance of atomic oxygen upon introduction of components into the working solution. In the spark-discharge zone, the temperature may be as high as several thousand degrees, which is sufficient for atomization of chemical elements. As a result, the fraction of aluminum surface occupied by oxygen grows with increasing concentration of an organic substance (portion *I*) and, as a consequence, the extent of hydration in the sludge receiver decreases. In the end, this leads to an increase in the fraction of the forming boehmite and a decrease in that of bayerite.

Thus, the differences in the compositions of spark-erosion products are associated with differences in the processes occurring in aluminum oxidation. It is known that oxidation of aluminum by water leads to hydrated forms of aluminum hydroxide. At the same time, no oxide phase is formed in this case. However, the influence exerted by the electric energy released in the spark discharge on the components of the medium leads to the appearance of atomic oxygen consumed for formation of the oxide phase of aluminum. As follows from the table, no metal powder is formed in electric spark dispersion in pure water. A quantum-mechanical calculation by the PM3 method [4] of the energy of formation of atomic oxygen from water

$$H_2O \rightarrow 2H + O, \quad \Delta E = 910 \text{ kJ mol}^{-1}; \qquad (1)$$

$$H_2O + e \rightarrow 2H + O^-, \quad \Delta E = 820 \text{ kJ mol}^{-1} \qquad (2)$$

points to a comparatively large energy expenditure, with reaction (2) involving electrons in the spark-discharge zone. However, in this case, too, the energy necessary for atomic oxygen to be formed from water remains high. Therefore, because of the deficiency of oxygen oxidizing aluminum, the main products of spark erosion in distilled water are various forms of aluminum hydroxide, with the predominance of the bayerite form.

To reveal the reasons for the increase in the fraction of boehmite in the reaction products formed in working solutions with organic substances, the possibility of their thermal decomposition to give atomic oxygen and organic radicals was considered on the basis of the results obtained in quantum-chemical calculations of the energy of formation of atomic oxygen from the additives introduced into the working solution. Account was only taken of the energy required to rupture bonds of a single oxygen atom with other atoms of a molecule. It was found that the energies of oxygen atomization from all of the used organic additives are less than that for atomization from water. For example, the energy of oxygen atomization from ethanol and ethyl acetate is 140–240 kJ mol^{-1} lower, and that from saccharose, urea, and ammonium acetate, 260–350 kJ mol^{-1} lower than that from water. A correlation between the fraction of boehmite in the reaction products and the energy of formation of atomic oxygen is observed. The easier the formation of atomic oxygen, the larger the fraction of boehmite. This may be a consequence of the appearance of a certain fraction of the oxide phase in metal dispersion, since boehmite can be regarded as an intermediate phase between aluminum oxide and the form hydrated to the maximum possible extent—bayerite. Thus, introduction of an organic additive into the working solution favors an increase in the fraction of oxygen consumed for aluminum oxidation to give boehmite.

The proposed scheme of hydration of dispersed aluminum [1] assumed that, only dispersed metal is formed in the spark-discharge zone and reacts with the working solution to give various forms of aluminum hydroxide. The analysis of experimental data, made in this study, suggests that dispersed metal with partly oxidized surface is also formed in the spark-discharge zone. This oxide film favors formation of boehmite in secondary processes occurring in solution. Thus, the hydration of dispersed aluminum can be represented as follows:

$$\left.\begin{aligned} &Al \rightarrow Al_d, \\ &Al \rightarrow Al_d[Al_xO_y], \end{aligned}\right\}\ \text{Processes occurring in the spark-discharge zone}$$

$$\left.\begin{aligned} &Al_d + H_2O \rightarrow AlOH + 0.5H_2, \\ &AlOH + H_2O \rightarrow Al(O)OH + H_2, \\ &Al_d[Al_xO_y] + H_2O \rightarrow Al(O)OH + H_2, \\ &Al(O)OH + H_2O \rightarrow Al(OH)_3 + H_2, \end{aligned}\right\}\ \text{Processes occurring in solution}$$

where Al is compact aluminum, Al_d dispersed aluminum, $Al_d[Al_xO_y]$ partly oxidized dispersed aluminum, Al(O)OH boehmite, and $Al(OH)_3$ bayerite.

CONCLUSION

Introduction of organic oxygen-containing additives into the working solution exerts strong influence on the spark erosion of aluminum. A plausible mechanism by which various forms of aluminum hydroxide are produced in spark dispersion of the metal is proposed.

Abstract—The optimal conditions for preparing activated carbons from polyethylene terephthalate polymer wastes were determined. The pore structure and sorption properties of the resulting product were studied.

Nonutilizable synthetic macromolecular man-made pollutants give rise to serious environmental problems. The removal, disposal, or incineration of these products as ways to diminish their environmental impact are often ineffective. Various procedures of their partial utilization [1–3] predominantly involve production of consumer's goods or intermediates for other cheap products. An alternative procedure allowing preparation of novel products is treatment of these wastes to obtain relatively cheap carbon sorbents whose working properties are comparable with the properties of common activated carbons prepared from wood, lignin, and coal dust.

In this work, we studied the possibility of preparing activated carbon from polyethylene terephthalate (PETP) plastic containers; accumulation of these containers only in the Ukraine reaches several million tons a year.

The treatment of this polymeric material is based on the thermal carbonization–activation in the presence of dehydrating agents [4, 5] improving the yield of the carbonized product and leading to the development of a microporous and transport pore system in the resulting material. Further steam activation provides additional development of the microporous structure (i.e., increases the volume of sorption pores and the specific surface area) and thus significantly improves the sorption properties.

EXPERIMENTAL

In our study, we used the PETP crumb intended for production of plastic containers and the polymer crumb obtained in utilization of used containers.

As modifying agents we studied a 30% $ZnCl_2$ solution and also concentrated orthophosphoric and sulfuric acids.

The preparation of a carbon sorbent by pyrolysis of the polymer crumb involves several stages. First, the samples were kept in solutions of the above modifying agents for 24 h. After impregnation, the crumb was dried at 150°C for 2 h.

The carbonization and activation were performed in a quartz reactor placed in a horizontal furnace. One side of the reactor was sealed, so that the process occurred almost without access of air, which in the course of heating promotes autocatalytic burning-out of the carbon-containing material. As a result, the crumb was heated in our process in the atmosphere of pyrolysis products. The heating rate was 20 deg min^{-1}; the maximum activation temperature was 800°C. Then, the carbon samples were additionally activated with steam at the same temperature for 1 h.

To confirm the effect of chemical modification, we performed simultaneously a pyrolysis of a sample without impregnation with modifying agents.

In all the stages, the pore volume of the carbon product was determined with respect to benzene W_s and methanol W'_s [6]. The size distribution of the macro- and mesopores was studied by the mercury porosimetry on a Pore-Sizer 9300 device (Cultronix, France). The sorption properties of the carbon sorbents were determined by sorption of Methylene Blue (A) and iodine (A') [6, 7].

24	28	0.36	420
48	28	0.37	427
24	23	0.27	318
24	33	0.36	424

Table 3. Pore characteristics of activated carbons prepared from polyethylene crumb by chemical and additional physical activation with steam

Activation	W_s, cm^3 g^{-1}	W'_s, cm^3 g^{-1}	A, mg g^{-1}	A', %	S_{sp} with respect to Ar, m^2 g^{-1}
Chemical	0.36	0.27	76	48	420
Chemical + steam	0.54	0.51	230	90	1230

in the presence of chemical modifying agents and without them are listed in Table 1. As seen, at a similar combustion loss the modifying agent strongly affects the sorption properties of the sorbents. The carbon sorbent modified with orthophosphoric acid exhibits the smallest sorption capacity with respect to Methylene Blue and benzene vapor; in this case, the sorption capacity is even smaller than that for sorbents obtained without use of modifying agents.

The highest sorption capacity is exhibited by activated carbons modified with concentrated sulfuric acid. The sorption capacity of such a sorbent with respect to benzene reaches 0.47 cm^3 g^{-1}, the sorption of Methylene Blue is 200 mg g^{-1}, which is comparable with AR, AG, BAU, and OU activated carbons, etc., widely used in industrial sorption processes.

In our further tests, we used concentrated sulfuric acid as a modifying agent.

The optimal conditions of PETP crumb pyrolysis were determined by varying the time of sample keeping in sulfuric acid and the impregnation coefficient K (%) calculated using the expression given in [4]:

$$K = (V_{imp}/V_{\Sigma}) \times 100,$$

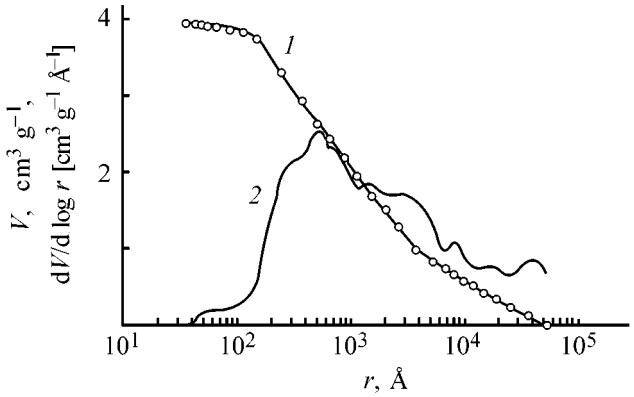
where V_{imp} is the volume of the impregnation solution (sulfuric acid) (ml) and V_{Σ} is the total volume of the impregnated crumb and modifying agent (sulfuric acid) (ml).

The data characterizing the development of the pore structure of the resulting activated carbons, as influenced by variation of the above parameters, are listed in Table 2. As seen, the best pore characteristics are achieved at a time of keeping in sulfuric acid of 24 h and an impregnation coefficient of 28%.

The pore characteristics of the activated carbons prepared from utilized crumb by chemical and subsequent physical activation with steam are listed in Table 3. The results suggest that the additional activation with steam significantly improves the sorption properties of the resulting carbons: the parameters characterizing the pore structure (pore volume with respect to benzene and methanol, and specific surface area with respect to argon) increase appreciably.

The resulting carbon sorbent is a highly porous carbon material with a developed system of macro-, meso-, and micropores. For example, upon chemical activation the pore volumes with respect to benzene and methanol are 0.36 and 0.27 cm^3 g^{-1}, whereas in the case of additional steam activation they increase to 0.54 and 0.51 cm^3 g^{-1}, respectively. In this case, the specific pore surface area increases by a factor of 3, which suggests predominant formation of the microporous structure.

The integral and differential curves of the mesopore and micropore volume distribution with respect to radius, determined from the mercury porosimetry data, are shown in the figure. As seen, the resulting activated carbon has a significant fraction of meso-



(*1*) Integral and (*2*) differential distribution curves of mesopore and macropore volume V with respect to effective pore radius r. (dV/d log r) Differential distribution of pore volume with respect to radius.

pores with effective radius of 500 Å. The total pore volume of activated carbons in question reaches 3.5 cm^3 g^{-1}.

CONCLUSIONS

(1) The optimal conditions for preparing activated carbons from polyethylene terephthalate polymer wastes were determined.

(2) Concentrated sulfuric acid is the most efficient chemical modifying agent for thermochemical carbonization–activation of polyethylene terephthalate wastes.

(3) The possibility was demonstrated of preparing activated carbons with developed structure, having pores of various types providing high sorption activity comparable with that of industrial activated carbons.

Effect of Sodium Chloride on Ultrafiltration of Aqueous Sulfonol Solutions

S. V. Kozlov

Karpov Physicochemical Research Institute, Moscow, Russia

Received November 23, 2000; in final form, June 2001

Abstract—Effect of NaCl on ultrafiltration of micellar aqueous Sulfonol solutions through a UFM-50 membrane is studied, including its effect on the permeate flux, retention factor, and hydrodynamic resistance of the membrane. Dependences of the hydrodynamic resistanse of dynamic membranes on the time of filtration are found.

Surfactants are widely used in everyday life and various branches of industry. Electrolytes improve surfactant performance characteristics, and, therefore, surfactants are often employed as mixtures with inorganic salts. Since ultrafiltration is an efficient method for surfactant concentration, it was of interest to study the effect of salts on this process. Previously, Yaroshenko *et al*. [1] have studied ultrafiltration separation of aqueous and aqueous-salt solutions of alkylpyridinium chloride on acetyl cellulose membranes. It was demonstrated that, at the same alkylpyridinium chloride concentration, the retention factor in 0.2 M NaCl is considerably higher as compared with that in a straight aqueous solution.

Recently, we have studied the ultrafiltration of aqueous Sulfonol solutions [2]. In the present study, we analyzed the effect of NaCl on the ultrafiltration of micellar Sulfonol solutions.

EXPERIMENTAL

The anionic surfactant Sulfonol is a mixture of sodium salts of alkylbenzenesulfonic acids $RC_6H_4SO_3Na$, where R = C_nH_{2n+1}, n = 12–18. In our experiments, the Sulfonol concentration C_1 was 10 g l^{-1}. The NaCl concentration C_2 was varied from 0.02 to 0.2 M. At these concentrations, the systems were homogeneous. The Sulfonol concentration was determined as the difference between the total weight of the solid residue and the amount of NaCl in it. In ultrafiltration experiments, we used several samples of a UFM-50 aromatic polyamide membrane with mean pore size of 30 nm.

The ultrafiltration was performed with a DKRI-021 nonflow-type module at 293 K without stirring. The pressure was set by compressed air. The working area of the membrane was 0.0117 m^2. The data scatter was 5%, and the within-sample variance, 0.6%.

For Sulfonol the critical micelle concentration (CMC) is 1.88 g l^{-1} [3], and, therefore the Sulfonol solution contained both micelles and surfactant molecules.

It is known that electrolytes make the CMC lower and the aggregation number and micelle weight higher [4], and also affect the adsorption of surfactants on the surface and in the pores of the membrane. Previously, it has been shown that the adsorption of cetylpyridinium chloride and sodium alkylbenzenesulfonate grows with increasing NaCl concentration [5]. Furthermore, electrolytes initiate compaction of the electric double layer around micelles [6]. All these factors can influence the ultrafiltration of surfactants.

In the course of ultrafiltration, Sulfonol molecules and micelles are accumulated and agglomerated on the ultrafilter surface, forming a dynamic membrane and making higher the hydrodynamic resistance to the permeate flow. The permeate flow velocity is given by the formula [7]

$$\frac{1}{J^2} = \frac{(R_m\eta)^2}{(\Delta P)^2} + \frac{2aC_s\eta R(1-K)}{\Delta P}t, \qquad (1)$$

where J is the permeate flow velocity, R_m is the hydrodynamic resistance of the ultrafilter, ΔP is the transmembrane pressure difference, η is the ultrafilter viscosity, a is the specific resistance to filtration, C_s is

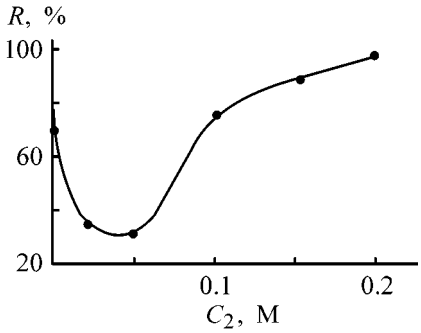

Fig. 4. Retention factor R vs. the NaCl concentration C_2 at a UFM-50 membrane.

the substance concentration in the solution, R is the retention factor, K is the fraction of the substance transferred from the membrane surface to the bulk of the solution by back diffusion, and t is time.

Let us introduce designation

$$q = \frac{2aC_s\eta R(1-K)}{\Delta P}. \quad (2)$$

The hydrodynamic resistance of a dynamic membrane is written as

$$R_d = \frac{aVC_sR(1-K)}{A}, \quad (3)$$

where V is the permeate volume and A is the membrane area.

From Eqs. (2) and (3) follows that

$$R_d = \frac{V\Delta P}{2A\eta}q. \quad (4)$$

Comparison of Eqs. (1) and (2) shows that the parameter q represents the slope of the time dependence of $1/J^2$. Since the retention factor decreases in the initial stage of filtration, it was averaged over the volume fractions in the filtrate. Sulfonol retained in filtration is found in the concentrate and, as a precipitate, on the ultrafilter. The coefficient K was determined as the ratio of the weight of Sulfonol in the concentrate to the total weight of retained Sulfonol. Knowing q, C_s, η, R, K, and ΔP, we could estimate the specific resistance a by means of Eq. (2). The hydrodynamic resistance of the dynamic membranes was estimated by Eq. (4) from data on q and the current permeate volume.

Figure 1 shows the time dependences of the permeate volume flux and retention factor of a UFM-50 membrane at an operating pressure of 0.05 MPa (Sulfonol concentration 10 g l^{-1}, NaCl concentration 0.02 and 0.2 M). The permeate flux is higher, and the retention factor, smaller at lower salt concentration. In the course of time, the permeate flux decreases, and the retention factor initially decreases and then remains unchanged.

Figure 2 shows the plots of $1/J^2$ vs. t. For 0.02 M NaCl, the specific resistance of the dynamic mem-

brane a was determined using Eq. (2) to be 3.44×10^{14} m kg^{-1} from the slope of curve *1* at $\eta = 1.005 \times 10^{-1}$ N s m^{-1}, $\Delta P = 5 \times 10^4$ N m^{-2}, $R = 0.179$, and $K = 0.17$. For 0.2 M NaCl (curve *2*, $R = 0.644$, $K = 0.33$), we estimated $a = 1.97 \times 10^{15}$ m kg^{-1}.

The time dependences of the hydrodynamic resistance of the dynamic membranes are presented in Fig. 3. The results show that R_d is much greater at high NaCl concentration.

Figure 4 demonstrates the effect of the NaCl concentration on the retention factor of Sulfonol (C_1 = 10 g l^{-1}, working pressure 0.05 MPa, t = 300 s). The retention factor initially decreases with increasing salt concentration, passes through a minimum at C_2 = 0.05 M, and then grows in the C_2 range 0.05–0.2 M. The increasing salt concentration initiates growth of micelles and simultaneous compaction of the electric double layer around Sulfonol particles [6]. The first circumstance makes the retention factor larger as a result of the screening effect. The second circumstance, conversely, causes a decrease in the retention factor by virtue of the decreasing electrostatic repulsion of the Sulfonol species from the membrane surface. Therefore, the shape of curve *2* in Fig. 4 is a result of the combined action of these two circumstance.

Let us examine the reliability of the results obtained. The membrane samples may have different permeabilities and selectivities. The hydrodynamic resistance of the dynamic membrane is proportional to the thickness of the Sulfonol layer on the ultrafilter. Therefore, somewhat different permeabilities of particular membrane samples are insignificant for determining the hydrodynamic resistance. The NaCl concentration has a strong effect on the Sulfonol retention factor, with changes in the retention factor under the action of sodium chloride much exceeding those caused by differences in the membrane selectivity.

The size of micelles is larger and their adsorption on the walls of pores of the ultrafilter is stronger at high salt concentrations. Therefore, the cross section of the membrane pores at an NaCl concentration of 0.2 M is lower than that at C_2 = 0.02 M. This circumstance accounts for the fact that the permeate volume flux at high NaCl concentrations is lower than that at low concentrations.

CONCLUSIONS

(1) Sodium chloride makes lower the Sulfonol retention factor on a UFM-50 membrane.

(2) With increasing salt concentration, the Sulfonol retention factor passes through a minimum.

(3) The specific resistance of dynamic membranes at a working pressure of 0.05 MPa, Sulfonol concentration of 10 g l^{-1}, and NaCl concentration of 0.02 and 0.2 M was found to be 3.44×10^{14} and 1.97×10^{15} m kg^{-1}, respectively.

Mathematical Model of the Membrane-Chromatographic Process

N. N. Smirnov, E. B. Aronova, and V. A. Konstantinov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received April 27, 2001

Abstract—A mathematical description of the membrane-chromatographic process and its experimental verification are presented.

The membrane-chromatographic process is one of the new, advanced processes for separation of substances, in particular, proteins [1]. However, methods for simulation and engineering calculations of the separating modules have been insufficiently worked out, which hinders further development of this process in both theoretical and practical aspects.

Based on the physical concepts of the membrane-chromatographic process [2], we developed a mathematical model which, following the geometry and shape of the membrane element, includes the system of equations in cylindrical coordinates

$$\left.\begin{aligned} \frac{\partial C_1}{\partial \tau} + \frac{\partial (C_1 \overline{W} r_1)}{\partial r} &= D_1^* \left(\frac{\partial^2 C_1}{\partial r^2} + \frac{1}{r} \frac{\partial C_1}{\partial r} \right) - \frac{C_1 b W_{z_1}}{S} \\ \frac{\partial C_2}{\partial \tau} \left[1 + \frac{K}{(1 + KC_2)^2} \right] &+ W_{z_2} \frac{\partial C_2}{\partial z} = 0 \\ \frac{\partial C_3}{\partial \tau} + \frac{\partial (C_3 \overline{W} r_3)}{\partial r} &= D_2^* \left(\frac{\partial^2 C_3}{\partial r^2} + \frac{1}{r} \frac{\partial C_3}{\partial r} \right) - \frac{C_3 b W_{z_3}}{S} \end{aligned}\right\} \quad (1)$$

and the corresponding initial and boundary conditions:

$$C_1(0, r) = 0, \quad C_2(0, r) = 0, \quad C_3(0, r) = 0,$$

$$C_1(\tau, 0) = \delta(\tau), \quad C_2(z = S_1, \tau, r) = C_1(\tau, r), \quad (2)$$

$$C_3(\tau, r_0) = C_2, \quad \frac{\partial C_1}{\partial r}(\tau, r_0) = 0, \quad \frac{\partial C_3}{\partial r}(\tau, 0) = 0.$$

Here, index 1 refers to the pressure channel; 2, to the membrane; and 3, to the filtration channel; C is the concentration, mg ml^{-2}, W is the flow velocity, m s^{-1}, D^* is the effective coefficient of longitudinal diffusion, m^2 s^{-1}; τ is the time of the process, s; H_i is the channel height (i = 1, 3), m; z is the coordinate along the normal to the module surface; S is the flow cross section, m^2; and K is the Langmuir constant.

The first equation in the system (1) describes the concentration field in the pressure channel of the membrane-chromatographic element. The second equation describes the process of selective absorption of the substance in the membrane. This equation was derived with account of the fact that sorption in the chromatographic membrane is characterized by the Langmuir isotherm. The third equation in the system (1) describes the concentration field in the filtration channel. By $\overline{W}_{r_i}$ is understood the velocity averaged over the coordinate z.

To solve the mathematical model proposed, we need to know how the axial velocity varies with the element radius. To this end, we separately considered the patterns of velocity distributions in the pressure and filtration channels.

The flow continuity equation in the cylindrical coordinates

$$\frac{1}{r} \frac{\partial (W_r r)}{\partial r} + \frac{\partial W_z}{\partial z} = 0 \quad (3)$$

after averaging the velocity over z

$$\overline{W}_{r_1} = \frac{1}{H_1} \int_0^H W_r \, dz \quad (4)$$

acquires the form

$$\frac{1}{r} \frac{\partial (\overline{W}_{r_1} r)}{\partial r} + \frac{1}{H_1} W_{z_1} \Big|_0^{H_1} = 0, \quad (5)$$

where H_1 is the channel height, m.

1070-4272/01/7410-1771 $25.00 © 2001 MAIK "Nauka/Interperiodica"

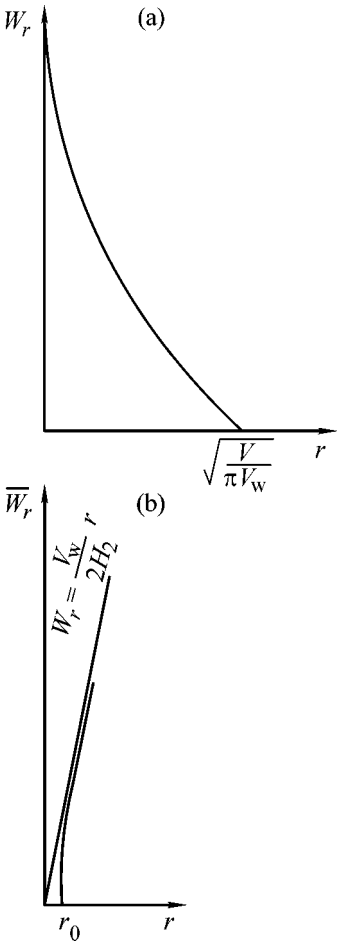

Fig. 1. Variation of the average radial velocity W_r along the radial coordinate r in (a) pressure and (b) filtration channels.

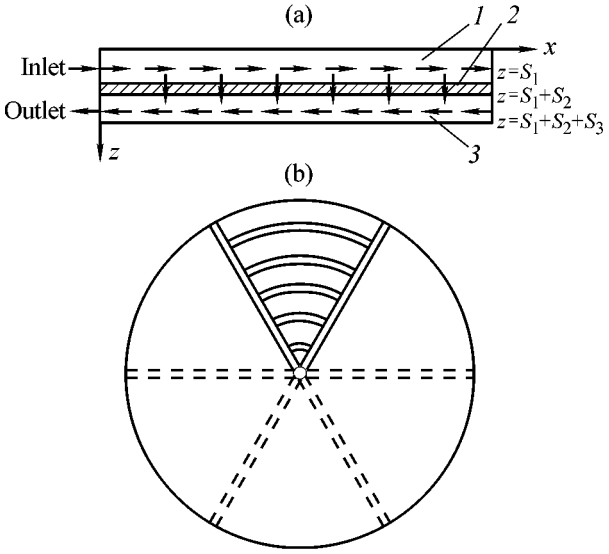

Fig. 2. Schematic of the flow movement in the membrane-chromatographic element: (a) Longitudinal cross section and (b) top view. (*1*) Pressure channel, (*2*) membrane, and (*3*) filtration channel.

Analytically, using the boundary conditions

$$z = 0,\ W_{z_1} = 0,$$
$$z = H_1,\ W_{z_1} = V_w, \quad (6)$$

where V_w is the filtration velocity, we obtained an ordinary linear inhomogeneous differential equation. The solution to this equation will be the dependence of velocity on radius, having the form

$$\overline{W}_{r_1} = -\frac{V_w}{2H_1} r + \frac{V}{2\pi H_1} \frac{1}{r}, \quad (7)$$

where V is the flow rate of the solution to be separated.

Similarly, we obtained the dependence for the filtration channel, by solving Eq. (8) with the boundary conditions (9):

$$\frac{1}{r} \frac{\partial(\overline{W}_{r_3} r)}{\partial r} + \frac{1}{H_3} \Big|_0^{H_3} = 0, \quad (8)$$

$$z = 0,\ W_{z_3} = V_w,$$
$$z = H_3,\ W_{z_3} = 0. \quad (9)$$

Here, H_3 is the filtration channel height, m.

As a result, we obtained the dependence

$$\overline{W}_{r_3} = \frac{V_w}{2H_3} r - \frac{V_w}{2H_3} r_0^2 \frac{1}{r}, \quad (10)$$

where r_0 is the module radius, m.

The obtained functions, describing the dependence of the axial velocity on radius were analyzed and graphically represented in Fig. 1. The plots in Fig. 1. suggest that the solution flow velocity in the pressure channel tends to vary monotonically along the channel from the initial value to zero and *vice versa* in the filtration channel. This will necessarily be manifested in nonuniformity of the velocity profile and a decrease in the substance separation efficiency owing to the blurring of the concentration field.

The system of Eqs. (1), (2), with account of the velocity distribution (7)–(10), describes the process of membrane-chromatographic separation.

The mathematical description developed in this study was tested experimentally for the case of protein separation in a cylindrical element (see flowsheet in Fig. 2 [3]). The flow distributors are represented by a series of concentric slits crossed by radial 1-mm-wide and 1-mm-deep slits in a metallic plate closely adjacent to the membrane. This design ensures

the most uniform and complete distribution of the substance being applied to the membrane surface.[1]

The proteins used in this work included lysozyme, ovalbumin, α-chymotrypsinogen, immunoglobulin, and hemoglobin; as components of the eluting systems served Na_2HPO_4, NaH_2PO_4, and NaCl (all of analytically pure grade, Russia). We used a JASCO (Japan) liquid chromatograph.

In this study, we developed on the basis of the physical model a mathematical description of the membrane-chromatographic process, including both the hydrodynamic and diffusion components. The theoretical and experimental data obtained by us show that the mathematical model makes it possible to calculate the concentration distribution in the separation module, estimate the separation efficiency, and determine the main geometric parameters of the module.

[1] Chromatographic membranes were manufactured by the Sorbopolimer Joint-Stock Company (Krasnodar); all the experiments were carried out at the Institute of Analytical Instrumentation, Russian Academy of Sciences.

Nitrogen-Containing Organomineral Fertilizer Based on Wood Waste

M. V. Efanov, A. I. Galochkin, P. R. Schott, D. V. Dudkin, and A. G. Klepikov

Altai State University, Barnaul, Russia

Received December 7, 2000; in final form, May 2001

Abstract—A new nitrogen-containing fertilizer was obtained by oxidative ammonolyis from wood waste. The chemical composition of the fertilizer was studied by functional chemical analysis. The fertilizer was tested in field conditions.

Recently, researchers' attention has been focused on methods for preparing new types of inexpensive organic fertilizers. Among raw materials suitable for this purpose are industrial lignin [1, 2] and lingo-carbohydrate materials, including wood-waste-based composts [3, 4].

As known, slow microbiological degradation of lignin from plant residues yields organic products exerting a physiological effect on plants [5]. Kodina and Aleksandrova showed [5] that, when considering decay in soil of organic substances from wood, lignin can be regarded as a starting material for production of humic acids forming the base of soil humus.

Soil-microflora-induced humification of lignin involves oxidation (demethoxylation), which yields polyphenol compounds, followed by condensation and oxidation processes giving humic (biologically active) substances responsible for soil fertility [5].

However, the natural microbiological degradation of lignin, yielding physiologically active humic substances, is a rather protracted process taking several years. It can be accelerated by oxidative degradation of lignin to produce physiologically active groups in its structure. Such functional groups include, in the first place, those containing nitrogen in a bound, slowly assimilable form, produced in oxidative ammonolysis of lignin molecules.

The authors of [6–8] developed various procedures for preparing slowly assimilable nitrogen-containing fertilizers by oxidative ammonolysis of lignins under the action of oxygen in an ammonia medium in severe conditions (120–180°C, 5–50 atm). The main drawbacks of the oxoammonolysis methods proposed are low yields of products and the complexity and long duration of the technological process. Zakis *et al.* [9] proposed that, for oxidative fixation of nitrogen, lignin should be oxidized with an ammonia solution of ammonium peroxodisulfate at 20°C [9]. However, this method also has major disadvantages, namely, duration of over 100 h and large amount of nitrogen-containing reactants consumed.

The aim of this study was to prepare new nitrogen-containing fertilizers by oxidation of lingo-carbohydrate materials (LCM, aspen wood) with an ammonia solution of ammonium peroxodisulfate and to analyze their properties. With LCM as the starting material for preparing the fertilizers, it is possible to significantly expand the range of raw materials and to make the process less expensive [10].

EXPERIMENTAL

The LCM-based nitrogen-containing fertilizers were prepared as follows. Air-dry chips (1.0–1.5-cm fraction) with weight of 1.5 kg were treated with a solution of ammonium peroxodisulfate (0.1 kg per kg of wood) in a 25% aqueous ammonia solution (liquid-to-solid ratio 10) at 120–130°C for 1 h in an autoclave under pressure of 2.5 atm. The resulting product was washed with water until negative reaction for the sulfate ion and dried in air to constant weight.

The nitrogen content was determined by the Kjeldahl semimicromethod [11], and the amount of COOH groups, by conductometric titration [12]. Oxidation of LCM with oxygen (0.05 g per g of wood) for 1 h in the presence of NH_3 (10.0 g per g of wood) yielded an ammonized product containing 10.9% organical-

1070-4272/01/7410-1774 $25.00

Action of hydrolyzing agents on the product of oxidative ammonolysis of LCM (hydrolysis time 3 h, hydrolysis temperature 100°C)

Hydrolyzing agent, 1 g-equiv l^{-1}	Yield of solid residue	Nitrogen content in treated product	Nitrogen eliminated, % of initial content	Content of COOH groups	Increase in the content of COOH groups
	%			%	
–	–	10.9	–	8.92	–
NaOH	71.6	7.08	35.1	11.6	30.1
H_2SO_4	83.4	9.25	15.2	10.1	13.2

ly bound nitrogen, 8.92% carboxy groups, and 4.13% methoxy groups. The product was obtained in 81.5% yield.

To elucidate how strongly nitrogen is bound to lignin, a sample of oxidized wood was boiled with 1 N solutions of NaOH and H_2SO_4 for 3 h. In the resulting solid residue, we determined the content of nitrogen and COOH groups (see table).

The table shows that hydrolysis of the product of oxidative ammonolysis of LCM involves elimination of 15–35% of the bound nitrogen. This is accompanied by the corresponding increase in the content of COOH groups in the hydrolyzed samples.

Zakis *et al.* [9] showed that, under the actual conditions, hydrolysis of R-$COONH_4$ and R-$CONH_2$ yields free carboxylic acids (acid hydrolysis) or their salts (base hydrolysis) and free NH_3.

Therefore, if the ammonia liberation is due to the presence of the functional groups mentioned, the content of carboxy groups in the samples after hydrolysis must increase (see table).

Thus, the resulting nitrogen-containing derivative of LCM contains 15–35% (25% on the average) of readily eliminated nitrogen in the ammonium and amide forms, which are readily available for plants. The remaining nitrogen (75%) is strongly bound chemically to LCM and is slowly assimilable (see table).

This state of LCM facilitates its further degradation in soil to humic substances, and, as the ammonized wood degrades in soil, the chemically bound nitrogen turns to forms accessible for plants.

The previous vegetation experiments [13] demonstrated the ability of the products of oxidative ammonolysis of LCM to stimulate the growth of cereals and leguminous plants. The effect of the product of oxidative ammonolysis of wood on the wheat productivity was studied in the year of 2000 on a testing field [14].

The field experiment demonstrated the accessibility of nitrogen from ammonized LCM to plants. Introduction of a nitrogen-containing derivative of LCM into soil in amounts of 60–90 kg N/ha enhances the wheat growth by 5.3–8.5% and favors increase in the biomass of plants by 19–47% relative to the reference. Eventually, the cereal productivity increases by 4.8–7.0 centner per ha, or by 26–47% relative to the reference. Similar results were obtained with ammonium sulfate taken in appropriate amounts.

CONCLUSIONS

(1) Oxidation of aspen wood chips with ammonia solution of ammonium peroxodisulfate yields a high-molecular-weight product containing 10.9% organically bound nitrogen, 8.92% carboxy, and 4.13% methoxy groups.

(2) The resulting nitrogen-containing product contains 15–35% nitrogen which is readily eliminated by acid and base hydrolysis and is readily available for plants.

(3) The new nitrogen-containing derivative of wood is suitable as effective organomineral fertilizer for cereals, which increases their productivity by 26–47%.

Use of Ozone for Preparing 4-Nitrobenzoic Acid in a Closed Process Cycle

A. G. Galstyan, N. F. Tyupalo, E. V. Patapenko, and P. Yu. Andreev

Rubezhnoe Branch, East Ukrainian National University, Rubezhnoe, Lugansk oblast, Ukraine

Received June 7, 2001

Abstract—The possibility of preparing 4-nitrobenzoic acid in a closed process cycle by oxidation of 4-nitrotoluene with an ozone–air mixture was examined. The optimal conditions of oxidation with multiple use of mother liquors were found, and the conditions for crystallization of 4-nitrobenzoic acid from the reaction mixture were determined. The effects of water, acetic anhydride, and catalyst on the oxidation performed in mother liquors after filtration of the target product were examined.

4-Nitrobenzoic acid is widely used in production of organic intermediates, dyes, and drugs [1]. In industry, it is produced by oxidation of 4-nitrotoluene with potassium dichromate in sulfuric acid [2], with dilute nitric acid [3], and with atmospheric oxygen in the presence of catalysts (metals of variable oxidation state and bromine compounds) [4]. Oxidation by mineral oxidants occurs under mild conditions but yields large amounts of toxic and difficult-to-utilize wastes. Oxidation by atmospheric oxygen occurs under rigorous conditions and, therefore, requires sophisticated equipment. In this context, low-temperature reaction of ozone with 4-nitrotoluene in acetic acid shows promise. In the presence of cobalt bromide catalyst, oxidation of 4-nitrotoluene by ozone–air mixture occurs under mild conditions (atmospheric pressure, 95°C), and the yield of 4-nitrobenzoic acid reaches 96% [5].

In this study, we developed a closed process cycle for production of 4-nitrobenzoic acid by oxidation of 4-nitrotoluene.

EXPERIMENTAL

Oxidation of 4-nitrotoluene was performed in a vertical cylindrical reactor equipped with a blade stirrer (7.5–13.3 rps) and a bubbler. The reactor was charged with 40 ml of glacial acetic acid, 4-nitrotoluene (0.5 M), cobalt(II) acetate (0.195 M), and potassium bromide (0.084 M). The stirring was switched on, and the mixture was heated to 95°C. After dissolution of the catalyst, an ozone–air mixture containing 4.7×10^{-4} M ozone was fed at a rate of 8.3×10^{-3} l s^{-1}. Oxidation was performed until complete exhaustion of 4-nitrotoluene and was monitored by GLC [6].

After oxidation, the reaction mixture was cooled to 13–14°C, and the precipitated carboxylic acid was filtered off, washed on the filter with hydrochloric acid, and recrystallized from water; yield 96%. The filtrate was returned to the oxidation stage. The wash

waters containing cobalt(II) chloride were evaporated, and the cobalt(II) salt was used as the reaction catalyst.

To optimize the crystallization conditions, we prepared standard mixtures consisting of 4-nitrobenzoic acid, cobalt(II) acetate, potassium bromide, and acetic acid taken in the same amounts as in the experiment on 4-nitrotoluene oxidation. The reaction solution obtained at 95°C was cooled with slow stirring. We found that the optimal conditions of quantitative isolation of 4-nitrobenzoic acid are cooling from 95 to 35°C at a rate of 1 deg min^{-1} and from 30 to 14°C at a rate of 0.5 deg min^{-1}. With this schedule, 30–60-μm crystals of the acid are formed.

Oxidation of 4-nitrotoluene by an ozone–oxygen mixture in a closed process cycle (95°C)*

Run no.	Degree of ozone utilization, %	4-Nitrobenzoic acid		
		yield, %	mp, °C	content, %
1	90.2	78.0	242.0	99.2
2	89.6	92.9	241.5	99.4
3	89.3	93.0	241.0	99.1
4	91.0	93.1	241.5	99.3

8	89.3	93.0	242.5	99.1
9	90.4	93.2	242.0	99.4
10	90.1	93.1	241.5	99.3

* Charged, M: 4-nitrotoluene 1.01, KBr 0.095 (in run no. 1, 0.126), Co(II) acetate or chloride 0.014 (in run no. 1, 0.023), acetic anhydride 3.7 (in run no. 1, 0); in run no. 1, CH_3COOH (40 ml); in run nos. 2–10, filtrate after filtering off 4-nitrobenzoic acid (36.3 ml) containing cobalt(II) and bromine compounds.

Then we studied the effect of the crystallization time at 14°C. Below are given the crystallization time (min) and acid yields (%): 0, 52; 3, 60; 6, 70; 10, 78; 15, 78; and 20, 78. Thus, it is appropriate to perform crystallization for 10 min.

After keeping for 10 min, 4-nitrobenzoic acid was washed with concentrated HCl to remove the absorbed cobalt(II) acetate. After fivefold use in the washing stage, hydrochloric acid was distilled off, and cobalt chloride was used in the oxidation stage without additional treatment.

When we used the filtrate from crystallization of the target product as the solvent, we noticed a progressing decrease in the accumulation rate and yield of the aromatic acid with increasing number of recycles (Fig. 1). This might be due to partial loss of the catalyst. However, even addition of a full portion of the catalyst in experiments with the filtrate had no noticeable effect on the oxidation results (Fig. 1, second and third runs of the cycle).

The oxidation deceleration may also be due to formation of oxidation inhibitors: phenols, nitrobenzene, and water. The effect of inhibitors on the oxidation was studied after compensating for the partial loss of the catalyst in the previous run. We found that the rate of 4-nitrotoluene oxidation in the presence of phenol and nitrobenzene does not change noticeably, whereas addition of water appreciably decreases the oxidation rate and the process selectivity (Fig. 2). Therefore, under conditions of multiple use of the filtrate, when the content of water formed by the reaction increases from run to run, the oxidation selectivity will decrease.

To bind the water formed by the reaction, we performed experiments with addition of acetic anhydride. We found that at a concentration of acetic anhydride in the primary filtrate of 0.495 M (provided that the catalyst loss is compensated for, see table), the oxidation rate becomes equal to the rate of 4-nitrotoluene oxidation in glacial acetic acid, and the yield of the aromatic acid reaches 93%. Further increase in the concentration of acetic anhydride decreases the oxidation rate and selectivity, because, when the water formed by the reaction is completely bound, excess acetic anhydride starts to react with intermediate 4-nitrobenzaldehyde to form 4-nitrobenzylidene diacetate, which is more resistant to ozone [7].

The amount of the catalyst lost in the cycle was determined in the presence of acetic anhydride (0.495 M). We found that, on adding potassium bromide (0.063 M, 75%) and cobalt diacetate (0.012 M, 61.5%) to the recycling filtrate, the selectivity of 4-ni-

trotoluene oxidation fluctuates about 93%, i.e., the amount of the added components corresponds to the catalyst loss.

To check the possibility of multiple use of mother liquors, we performed seven cycles, with ten runs in each, with addition of the catalyst, to compensate for its loss in the previous run, and acetic anhydride. The yield of 4-nitrobenzoic acid in oxidation of 4-nitrotoluene in the mother liquor was obtained at a level of 93% (see table).

CONCLUSION

It is feasible to prepare 4-nitrobenzoic acid by oxidation of 4-nitrotoluene in a closed process cycle with multiple use of mother liquors.

BOOK REVIEWS

Habashi, F., *Extractive Metallurgy Today: Progress and Problems*, Quebec City: Laval University, 2000, 312 pp.

Professor F. Habashi is a known Canadian scientist, a specialist in nonferrous metallurgy, and the author of a great number of books, part of which have been translated in Russia. His new review book makes an attempt to reflect, primarily for the example of Canada, the advance in metallurgy, made from 1960 till 2000, and to formulate the most currently pressing problems. During this period, new research centers concerned with various metallurgical processes appeared, the number of scientific conferences increased, and the dataware was improved. All these factors favored the development of energy-saving technologies, ensured a decrease in pollution, and promoted automation of both the technological processes themselves and methods for their control.

The book is excellently illustrated and contains numerous high-quality photographs and visual schemes. In the given case, this is an important constituent of the book, largely affecting the manner of presentation, since 21% of the entire book's volume is occupied by photographs, mainly colored, and further 14%, by various schemes. The information value of the book is even more increased by reference lists given at the end of each chapter.

The book comprises a brief introduction and 18 small chapters grouped into five parts. The first part, "General" (chapters 1, 2; pp. 3–14), contains most general evidence. In particular, the relationship between the most important sections of metallurgy—hydrometallurgy, pyrometallurgy, electrometallurgy—and their relations to other fields of science are discussed. The most important problems of metallurgy are indicated.

"Progress and Problems" (chapters 3–10; pp. 15–148) is the second, main part. The author considers a wide variety of issues, including processing of lean ores, recovery of metals from ores with complex composition (sulfide, oxide, oxide-sulfide), and manufacture of high-purity metals (modern analytical monitoring methods, electrolytic refining, chemical transport processes, physical methods). The entire material is illustrated by concrete examples. The same part of the book discusses the rise in production and consumption of a great number of metals during a long period from 1860 till 2000, the use of the metallurgical wastes and secondary raw materials, recovery of gaseous products and gas purification, and advances in application of new technologies.

The third part of the book, "Extractive Metallurgy at Laval University" (chapters 11–15; pp. 149–211) is concerned with investigations in metallurgy, performed at Laval University in Quebec (Canada). After a brief description of the history of the University and the Department of Mining and Metallurgy, the book considers the processes and systems studied there. As particular examples are discussed the reaction of chalcopyrite with hydrogen and chlorine and reduction of sulfates of a number of metals with hydrogen.

The fourth part of the book, "Industrial Minerals at Laval University" (chapters 16, 17; pp. 215–271), discusses the processing of phosphate ores containing compounds of rare earths and a number of silicate rocks.

The fifth part, "Literature Guide" (ch. 18; pp. 275–305), contains valuable evidence concerning the organizing and holding of metallurgical conferences of various levels and the relevant publications.

It should be noted once more that the book is excellently published, is written in a well-understandable manner, and contains a vast body of interesting and valuable information about processes of mainly nonferrous metallurgy.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Specific Features of the Composition of Solid Phases in the $Na^+K^+Ca^{2+} \,||\, CO_3^{2-}OH^-–H_2O$ System

V. A. Lipin

Russian Aluminum and Magnesium Institute, St. Petersburg, Russia

Received March 14, 2001

Abstract—The composition of solid phases in the $Na^+K^+Ca^{2+} \,||\, CO_3^{2-}OH^-–H_2O$ system at 95°C was studied. Triple carbonates of alkali metals and calcium, different from the known synthetic and natural compounds, were found in the system.

Complex carbonates of alkali metals and calcium in the $Na^+K^+Ca^{2+} \,||\, CO_3^{2-}OH^-–H_2O$ system can be formed in several processes involving treatment of carbonate solutions or calcium-containing wastes and intermediate products and separation of metals. Compounds of the $M_2CO_3 \cdot CaCO_3 \cdot H_2O$ type (M is an alkali metal) are formed by reactions of calcium-containing materials with solutions of alkali metal carbonates if their concentration exceeds the equilibrium concentration with respect to the corresponding carbonates. This process can be schematically represented by the reaction

$$Ca(OH)_2 + 2M_2CO_3 + nH_2O = CaCO_3 \cdot M_2CO_3 \cdot nH_2O + 2MOH.$$

Gaylussite $M_2CO_3 \cdot CaCO_3 \cdot 5H_2O$ is the solid phase stable in the Na_2CO_3–$CaCO_3$–H_2O system at temperatures lower than 40°C, and at higher temperatures pirssonite $M_2CO_3 \cdot CaCO_3 \cdot 2H_2O$ is stable. Natrofairchildite $Na_2CO_3 \cdot CaCO_3$ and shortite $Na_2CO_3 \cdot 2CaCO_3$ are also known as natural minerals. In the K_2CO_3–$CaCO_3$–H_2O system buetschliite $K_2CO_3 \cdot CaCO_3$ can be obtained, which is converted by heating over 500°C to fairchildite differing from buetschliite by its crystal structure. In the Na_2CO_3–K_2CO_3–H_2O system the so-called "double salt" $Na_2CO_3 \cdot K_2CO_3 \cdot nH_2O$ (n = 0–6) is formed. Its isolation as an intermediate product is used in production of soda products by sintering of alkali aluminosilicate raw materials [1–4].

Relatively recent studies of plutonic and volcanic formations [5–7] revealed the presence in them of triple carbonates of calcium and alkali metals along with the double carbonates. To date at least three mineral kinds of triple carbonates of sodium, potassium, and calcium, named natrocarbonatites, have been found in the nature, namely, nyerereite, gregoryite, and zemkorite. Nyerereite $(Na,K)_2CO_3 \cdot CaCO_3$, close in its structure to natrofairchildite, and gregoryite $(Na_2,K_2,Ca)CO_3$ were first found in essentially sodium carbonate lavas and ashes of Oldoinyo Lengai active volcano [5, 6]. Specific features of this volcano, located not far from Kilimanjaro at the Kenya and Tanzania border, are the low temperature of lava eruption (540–593°C) and also the leading role of alkali and volatile components and complete absence of aluminum and silicon compounds in the eruption products. Zemkorite $(Na,K)_2CO_3 \cdot CaCO_3$, differing from nyerereite by its hexagonal crystal system, was found in Yakut kimberlites at a depth of 400–450 m [5]. Up to now, there is no general opinion on the mechanism of natrocarbonatite formation. Two versions are suggested: plutonic action of carbon dioxide on alkaline massifs of alkaline nature and secondary reactions of the eruption products with atmospheric factors.

The range of conditions for the formation of triple carbonates of alkali metals and calcium seems to be rather wide, which suggests the formation of these compounds during processing of various alkali mineral raw materials as a result of homogeneous and heterogeneous reactions. The elucidation of such a possibility is important for both the technology of separation of alkali metal salts and for the explanation of the mechanism of natrocarbonatite formation in the nature.

The aim of this work was to study the effect of the ratio of alkali metals on the composition of solid phases in the $Na^+K^+Ca^{2+} \,||\, CO_3^{2-}OH^-–H_2O$ system.

* CaO is contained in minute amounts in the liquid phase.
** By the data of IR spectral and X-ray analyses.

EXPERIMENTAL

The initial mixtures for setting equilibria in the system under study were prepared from solutions of alkali metal carbonates and calcium oxide. We used pure grade salts of the corresponding alkali metals to prepare carbonate solutions. Calcium oxide was prepared by calcination of calcium carbonate at 1150°C. In most experiments the amount of calcined calcium oxide for preparing the initial mixtures was limited by the $Ca(OH)_2$ solubility in the system under study. We varied the concentration of carbonates and the ratio between sodium and potassium ions in solution. To reach equilibria, the mixtures were vigorously stirred at 95°C for 330 h. The equilibrium solid phases were separated from the liquid by filtration, washed with alcohol, and analyzed by X-ray diffraction and IR spectroscopy. The X-ray patterns were taken on a Philips automatic powder diffractometer using CoK_α radiation and a graphite monochromator. The IR spectra were recorded in KBr pellets on a Perkin–Elmer spectrometer in the wave number range 400–3800 cm^{-1}. The differential thermal analysis (DTA) was carried out on a Q-1500D derivatograph (Hungary) by heating samples to 1000°C at a rate of 7.5 deg min^{-1}. The content of cations in the solid and liquid phases was determined by flame photometry. The content of OH^- ions in the equilibrium liquid phases was determined volumetrically after preliminary isolation of CO_3^{2-} as $BaCO_3$.

The data obtained are given in Tables 1 and 2 and in Fig. 1–3. They show that the presence of sodium carbonate in the liquid phase results in formation of compounds containing sodium ions in the solid phase. They appear at lower K_2CO_3 concentrations than it is necessary for buetschliite formation from solutions free from sodium ions. Furthermore, the presence of Na^+ ions in the solutions affects the ratio of equi-

librium concentrations of K_2CO_3 and buetschliite: buetschliite is formed at lower concentrations from a mixed solution. The formation of sodium-containing compounds from mixed sodium–potassium solutions is preferable compared to buetschliite.

The formation of new sodium-containing phases is proved by the X-ray and IR data.

The IR spectra of solid phases obtained in the reactions of calcium oxide with carbonate solutions (buetschliite, pirssonite, and a double salt) and also of the phase obtained in run no. 14 (Table 1) are shown in Fig. 1. It is seen that the IR spectrum of the solid phase obtained in run no. 14 differs from the spectra of all the double salts known to exist in the $Na^+K^+Ca^{2+}||CO_3^{2-}OH^-–H_2O$ system at temperatures below 100°C. The absence of the stretching bands of OH^- groups suggests that this phase is a mixture of complex carbonates. Apart from the characteristic stretching bands of calcite (880, 1430 cm^{-1}) and buetschliite (865, 1090 cm^{-1}, stretching bands at 670, 710, 870, 1008, 1050, 1075, 1400, 1465, 1760, and 3150 cm^{-1} are observed in the IR spectra of these solid phases. Splitting of the stretching band of the carbonate groups (1400 and 1465 cm^{-1}) and also occurrence of the so-called forbidden bands at 1050 and 1090 cm^{-1} indicate that the CO_3^{2-} group is distorted owing to the formation of a triple salt or of its mixture with another complex.

The X-ray diffraction patterns reveal two triple carbonates X and Y in the solid phase. The X-ray diffraction characteristics of the X and Y carbonates and also of the known natural triple carbonates of alkali metals and calcium are given in Table 2.

If the mole fraction of sodium oxide exceeds 3% of the sum of alkali metal oxides, the Y phase is formed in the solid phase (Table 1, run nos. 5–10). The X phase is in equilibrium with solutions in which the mole fraction of sodium oxide exceeds 15% of the sum of alkali metal oxides (run nos. 11–19). To obtain the X phase free from the Y phase, the fraction of sodium oxide must be greater than 23% (run nos. 20–22). If the mole fraction of sodium oxide exceeds 60%, pirssonite prevails in the solid phase (run nos. 23, 24). Calcite-free X and Y phases were not obtained under the experimental conditions. As the concentration of OH^- ions in the equilibrium liquid phase increases, the solubility of complex carbonates increases in the order X < Y < $K_2CO_3 \cdot CaCO_3$.

The IR spectrum of the solid phase in run no. 14 is indicative of a mixture of the X and Y phases

(Fig. 1). The solid phase in run no. 6 consists of the complex carbonate Y in a mixture with calcite without an impurity of the X phase. Its IR spectrum (Fig. 2) contains characteristic adsorption bands of the Y phase (630, 670, 710, 1080, 1460, 1500, 2950, and 3150 cm^{-1}). The presence of several bands of stretching vibrations of water molecules (2950 and 3150 cm^{-1}) suggests that these molecules enter the Y salt structure. It is most likely that the Y phase is a layered structure in which charged layers of CO_3^{2-} ions are kept together by alkali metal cations. Water molecules in this structure are inserted between the layers to form hydrogen bonds with oxygen atoms of the anion layer, the structure of the carbonate compound being not affected.

The solid phase from run no. 6 consists mainly of the Y phase, and its DTA curve (Fig. 3a) has a deep endothermic peak of dehydration in the range 160–220°C, weak endothermic peaks of a polymorphous transition at 420–460°C, and also peaks of the material melting above 685°C. The solid phase from run no. 20 consists of the complex carbonate X in a mixture with calcite without an impurity of the Y phase. Its IR spectrum (Fig. 2) has absorption bands at 700, 730, 840, 1075, 1450, and 3470 cm^{-1}. The DTA curve of the solid phase from run no. 20, in which the X phase prevails (Fig. 3b), differs from that of the solid phase from run no. 6. It involves a small thermal effect of removal of unbound water at about 160°C, a number of polymorphous transitions in the range from 330 to 730°C, an endothermic effect of the X phase dissociation to $Na_2CO_3 \cdot K_2CO_3$ and $CaCO_3$ in the range from 730 to 830°C, and an effect of the $CaCO_3$ dissociation to CaO and CO_2 above 1000°C. The retention of double sodium potassium carbonate in the product of the X phase calcination at 1000°C, confirmed by the IR spectra, suggests that the structure of this phase is close to the structure of dolomite $CaCO_3 \cdot MgCO_3$, which dissociates to $CaCO_3$, MgO, and CO_2 at 680–800°C.

Therefore, structures of the X and Y phases belong to different types, i.e., the mechanisms of their formation in the carbonate solutions are different. Correlation of the chemical analysis and DTA data suggests that the Y phase has a composition close to $Na_2CO_3 \cdot 7K_2CO_3 \cdot mCaCO_3 \cdot nH_2O$ ($m, n > 1$). The X phase is a triple carbonate of the composition $Na_2CO_3 \cdot K_2CO_3 \cdot pCaCO_3$ ($p > 1$). These phases have no known natural analogs and have been found in the system under study for the first time.

Processing of alkali aluminosilicate by sintering involves operations associated with the reactions of calcium-containing compounds with mixed solutions of alkali metal carbonates. These operations include the regeneration of the belite slime after leaching of the cake and of the white slime after desilication with a solution of Na_2CO_3 and K_2CO_3, and also the causticization of carbonate solutions [1].

Our experiments revealed the presence of a triple carbonate of sodium, potassium, and calcium in the solid phases after treating the white slime of alumina

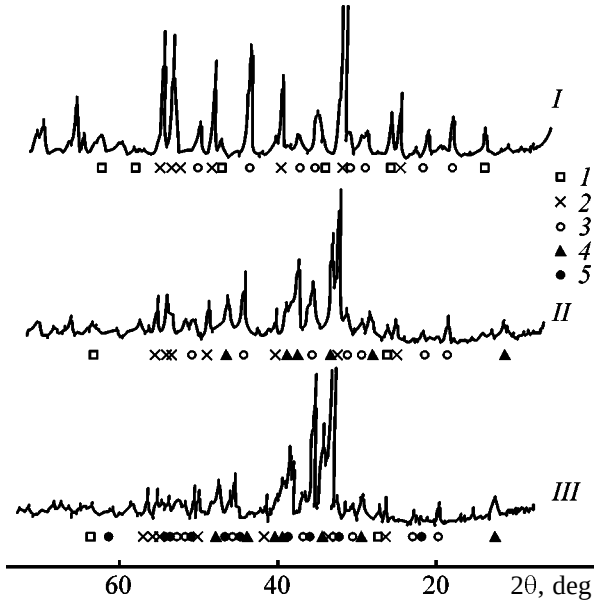

Fig. 4. X-ray patterns of (*I*) starting white slime of alumina production and the slime after treatment with K_2CO_3 solution at (*II*) 25 and (*III*) 90°C. (2θ) Bragg's angle. (*1*) Hydroaluminosilicates of alkali metals $Na_2O \cdot Al_2O_3 \cdot mSiO_2 \cdot nH_2O$ (m = 1.7–2.5, n = 1–3); (*2*) calcite $CaCO_3$; (*3*) calcium hydrogarnets $3CaCO_3 \cdot Al_2O_3 \cdot mSiO_2 \cdot (6–2m)H_2O$ (m = 0.1–0.8); (*4*) Y phase $Na_2CO_3 \cdot 7K_2CO_3 \cdot mCaCO_3 \cdot nH_2O$ (m,n > 1); and (*5*) buetschliite $K_2CO_3 \cdot CaCO_3$.

production with carbonate solutions. The slime of the composition (wt %) Na_2O 2.70, K_2O 1.20, CaO 40.66, Al_2O_3 12.49, and SiO_2 6.69 was treated with a carbonate solution containing (g dm^{-3}) Na_2O 19.6 and K_2O 570. The treatment was carried out for 2 h with stirring at 25–90°C. After separating the phases the solid phase was washed with ethanol and analyzed by X-ray diffraction.

The X-ray patterns of the starting and resulting solid phases (Fig. 4) point to the presence of the Y phase in the resulting products along with calcite, calcium hydrogarnets, and alkali metal hydroaluminosilicates. When the treatment temperature was increased from 25 to 90°C, buetschliite was also observed in the solid phase.

CONCLUSION

(1) Previously unknown triple carbonates of sodium, potassium, and calcium were found in the $Na^+K^+Ca^{2+} \,||\, CO_3^{2-}OH^- – H_2O$ system, and their main properties were described. The Y phase has a composition close to $Na_2CO_3 \cdot 7K_2CO_3 \cdot mCaCO_3 \cdot nH_2O$ (m,n > 1), and the X phase is the triple carbonate $Na_2CO_3 \cdot K_2CO_3 \cdot pCaCO_3$ (p > 1).

(2) The structure of the revealed compounds is different, which was confirmed by the IR spectral, X-ray phase, and thermal analyses.

(3) The possible formation of triple carbonates of sodium, potassium, and calcium in the intermediate products of processing mineral resources can significantly affect the distribution of alkali metal ions between the products. Therefore, the need in special process operations arises.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Composition of Solid Phases Isolated from Sulfuric Acid Solutions of Titanium(IV) by the Action of Phosphoric Acid

L. G. Gerasimova, M. V. Maslova, N. M. Zhdanova, and R. F. Okhrimenko

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received January 30, 2001

Abstract—The composition of titanium phosphates precipitated in the course of the hydrothermal sulfuric acid decomposition of sphene concentrate in the presence of phosphoric acid was studied.

Titanium phosphate compounds, or, more exactly, titanium(IV) hydrophosphates, are known as effective inorganic ion exchangers (sorbents) removing from wastewater the ions of cobalt, nickel, cadmium, and radioactive elements [1, 2]. Production of such sorbents from solutions of titanium intermediate products and the influence of solution acidity [3, 4], temperature [5], and conditions of washing and heat treatment of hydrated synthesis products [3] on their properties were actively studied in Russia.

Titanium(IV) phosphates are also used as fillers of paper and rubber and in compositions of weatherproof paint-and-varnish materials [6–8]. In this case the requirements to titanium phosphate products are different from those for the sorbents. In particular, they should have pigmentary properties, and also high weather resistance [9].

The aim of this work was to synthesize such compounds and to study their composition and properties.

EXPERIMENTAL

Titanium(IV) solutions obtained upon the sulfuric acid decomposition of sphene $CaSiTiO_5$ were used as titanium intermediate products. Such solutions contain ($g\ l^{-1}$) TiO_2 80–120, H_2SO_4 400–500, and also impurities of iron, silicon, and calcium compounds. The filtrate obtained from the apatite decomposition with sulfuric acid (P_2O_5 content 30%) was used as a phosphorus-containing component.

Experimental technique consists in the following. Phosphoric acid was added into titanium(IV) sulfuric acid solution in the ratio $TiO_2 : P_2O_5 = 1 : (1–10)$. The process was carried out with stirring under hydrothermal conditions (~100°C) for 1.5–2 h, and the resulting suspension was kept without stirring for 10 h. Then the precipitate was separated from the liquid phase and washed with water at the solid : liquid ratio of 1 : 10. The precipitation conditions and precipitate compositions are given in Table 1.

The degree of titanium(IV) precipitation from solutions increases with increasing consumption of phosphoric acid; the filtration rate of the resulting suspension also increases, which is indicative of the formation of agglomerates with the surface low-active toward the liquid phase.

The freshly precipitated substances are X-ray amorphous. Their thermal treatment (~750°C) yields products consisting mainly of a single phase $(TiO)_2 \cdot P_2O_7$. The endothermic effects at 170–350°C are due to dehydration and to the loss of adsorbed water and water of crystallization. The exothermic effect at 730–750°C is not accompanied by a change in weight and is due to crystallization of the amorphous substance (Fig. 1).

We have studied in more detail the production of titanium phosphate precipitates from titanium(IV) sulfuric acid solutions, when phosphoric acid was taken not in excess but in the amount corresponding to the weight ratio $TiO_2 : P_2O_5 = 1 : 0.5$. The acid was added not before heating the initial titanium(IV) solution, but after boiling it for 2, 7, and 14 h. The initial sulfuric acid solution of titanium(IV) contained 110 $g\ l^{-1}$ of TiO_2 and 500 $g\ l^{-1}$ of H_2SO_4. Such "titanic" system is very stable, and without external actions (dilution with water and addition of seeds) the titanic phase is not formed, though the speciation of the dissolved titanium(IV) changes. Thus, whereas in

				TiO_2	P_2O_5	
1 : 0.5	80.3	75	40.0	60.5	36.4	$3TiO_2 \cdot P_2O_5 \cdot 7H_2O$
1 : 1	95.0	100	31.6	52.2	42.4	$2TiO_2 \cdot P_2O_5 \cdot 8H_2O$
1 : 3	98.8	300	27.1	50.5	45.1	$2TiO_2 \cdot P_2O_5 \cdot 6H_2O$
1 : 5	99.0	400	26.2	51.8	46.5	$2TiO_2 \cdot P_2O_5 \cdot 5.5H_2O$
1 : 10	99.3	550	23.0	51.6	46.1	$2TiO_2 \cdot P_2O_5 \cdot 4H_2O$

the initial solution almost all titanium(IV) was in the reactive state, during heating the complexes form polymeric chains –Ti–O–, with the content of polymeric titanium(IV) increasing as the heating time increases. Such species seem to be a matrix for the formation of a solid phase under the action of external factors. In this case the system stability is disturbed owing to the addition of phosphoric acid to the solution. On the one hand, this addition gives rise to a decrease in acidity, and on the other hand, the presence of phosphate ions initiates the formation of an almost insoluble compound (titanium phosphate phase). It should be noted that the same amount of phosphoric acid added to the boiling suspension in different time after the start of boiling causes unequal decrease in the titanium(IV) concentration in solution. The longer the time of preliminary heating of the initial solution, the smaller the residual titanium(IV) content in the solution. This seems to be due to the fact that the mechanisms of the formation of titanium phosphate phases are different; therefore, the compositions of the resulting precipitates are also different. As fresh precipitates are X-ray amorphous, we determined their phase compositions after heat treatment at 750°C. The X-ray patterns of the precipitates under study are shown in Fig. 3. The most poorly crystallized is sample no. 3, in which the main phase is anatase and the impurity phase is oxotitanium diphosphate. The amount of anatase decreases, and sample nos. 1 and 2 consist mainly of titanium phosphate phases of the formulas $Ti_4P_6O_{23}$ and $(TiO)_2P_2O_7$. According to the chemical analysis of freshly precipitated samples, titanium phosphates precipitated under the above conditions correspond to the empirical formula (3–3.5)$TiO_2 \cdot P_2O_5 \cdot xH_2O$ (x = 1–5). The degree of hydration of the precipitates increases with increasing time of heat treatment of titanium(IV) sulfuric acid solutions before adding phosphoric acid.

We obtained white readily disaggregated products by thermal treatment of the precipitates under study

(700–750°C) and determined their pigmentary properties (Table 2).

The results obtained were used to develop a process for the synthesis of a lightfast titanium phosphate pigmentary composition from sphene concentrate [10].

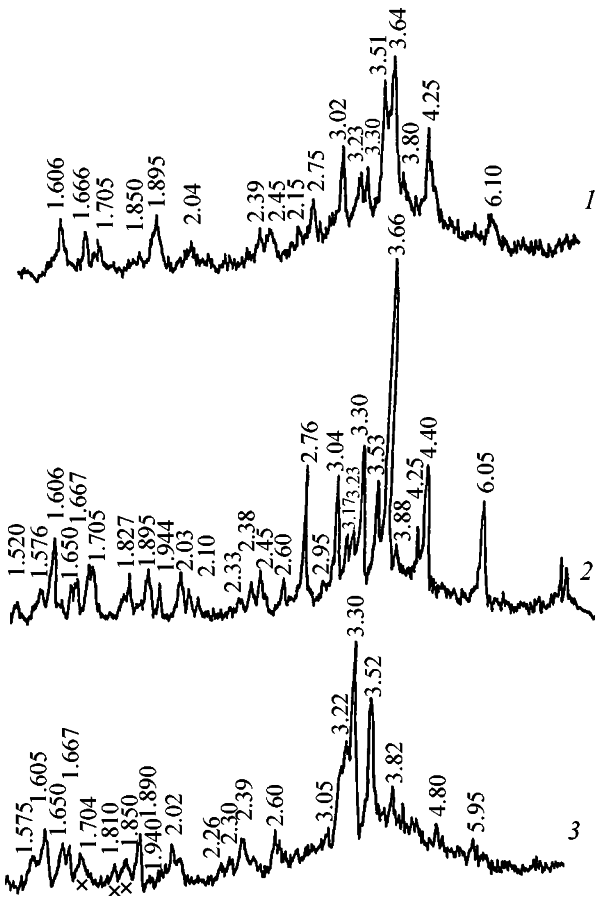

Fig. 3. X-ray diffraction patterns of titanium phosphate precipitates.

CONCLUSION

The titanium phosphate products synthesized have fairly good pigmentary quality and can be used for pigmenting filling of white paper, plastic, and rubbers. Taking into account high lightfastness of titanium phosphate, we can predict prolonged whiteness of materials filled with it.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Phase Formation in the Synthesis of Special Clinkers from Industrial Waste Products

O. A. Miryuk and I. G. Luginina

Rudnyi Industrial Institute, Rudnyi, Kazakhstan
Belgorod State Technological Academy of Building Materials, Belgorod, Russia

Received March 13, 2001

Abstract—Phase formation on the calcination of sulfated clinkers with the use of ironstone concentration rejects and the effect of the raw mixture composition on the formation of magnesium calcium aluminosilicate were studied.

Cements based on sulfated clinkers are effective sort of special binders characterized by a power-saving production process, intense setting, expansiveness, and high construction parameters. Because of the shortage of natural raw materials, substandard rocks and industrial wastes characterized by diverse chemical and mineral compositions find growing use. The performance of a new raw material is determined by its effect on processes of the clinker formation and structure.

In this work we studied the sequence of phase formation in the synthesis of sulfated clinkers from industrial waste products, namely, from a mixture of limestone, lignite-bauxite, and ironstone concentration rejects. Substandard lignite-bauxite, which is enriched with carbonized wood residues, contains (%) Al_2O_3 31–50, SiO_2 10–17, and Fe_2O_3 2–5. Ironstone concentration rejects contain silicates and aluminosilicates of various structures (diopside, grossularite, epidote, scapolite, chlorites, and feldspars). Their dominating chemical components are (%) SiO_2 40–42, Al_2O_3 10–12, Fe_2O_3 15–17, CaO 12–13, and MgO 5–7. The presence of pyrite FeS_2 in the rejects predetermines a possibility for their use as a sulfur-containing component of a charge. The charge composition was taken to ensure the following composition of the clinker (%): SiO_2 16, Al_2O_3 20, Fe_2O_3 6, CaO 50, MgO 4, and SO_4 4.

Samples of the raw mixture were burnt at 800–1300°C and studied by X-ray diffraction. Examination of the diffraction patterns allowed us to suggest the following pattern of the phase formation in the mixture under study (Fig. 1). Burning at 800°C transforms all the raw components. The active character of the low-temperature transformations results from the catalytic effect of the products of pyrite and lignite oxidation formed at 450–600°C. The pyrite decomposition yields anhydrite $CaSO_4$. The acceleration of the reactions yielding aluminum-containing compounds is promoted by a high dispersity of aluminum-containing minerals of lignite-bauxite and a rather low temperature of their decomposition. The oxide Al_2O_3 arising from the dehydration of hydrargillite $Al(OH)_3$ reacts with $CaSO_4$ and CaO even at 700–800°C [1]. The first portions of belite Ca_2SiO_4 formed from the silicates of the rejects react with $CaSO_4$ to give cal-

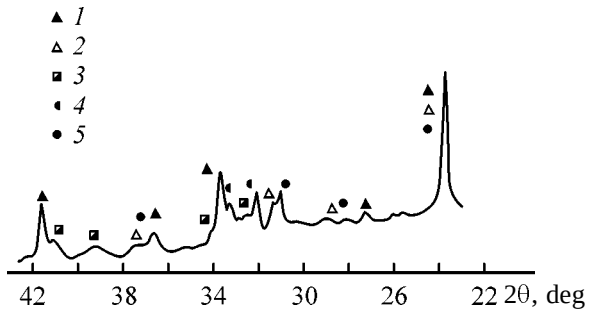

Fig. 2. Diffraction pattern of sulfated clinker. (θ) Bragg's angle; the same for Fig. 3. Phase: (*1*) $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$, (*2*) $2CaO \cdot Al_2O_3 \cdot SiO_2$, (*3*) Ca_2SiO_4, (*4*) $4CaO \cdot Al_2O_3 \cdot Fe_2O_3$, and (*5*) $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$.

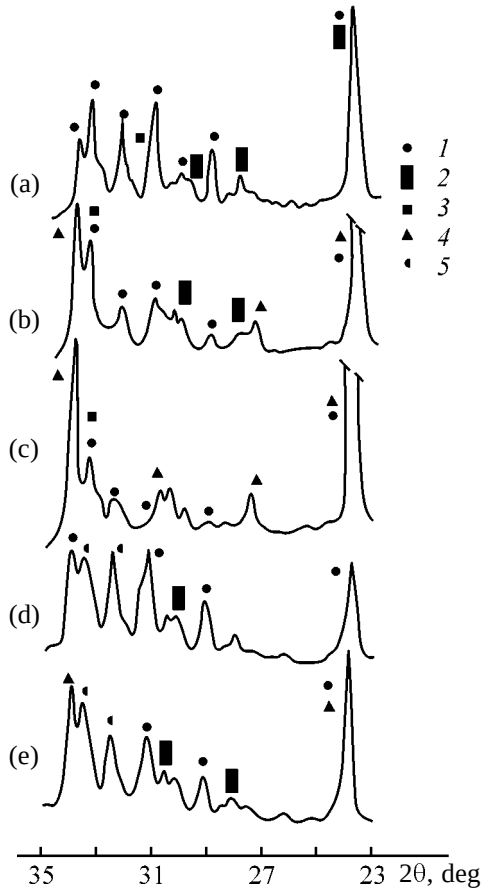

Fig. 3. Diffraction pattern of clinkers from alumina mixtures: (a) without additions and with additions of (b) 5% $CaSO_4$, (c) 10% $CaSO_4$, (d) 10% Fe_2O_3, (e) 5% $CaSO_4$, and (f) 10% Fe_2O_3. Phase: (*1*) $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$, (*2*) $CaO \cdot Al_2O_3$, (*3*) $12CaO \cdot 7Al_2O_3$, (*4*) $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$, and (*5*) $4CaO \cdot Al_2O_3 \cdot Fe_2O_3$.

cium sulfate silicate $2Ca_2SiO_4 \cdot CaSO_4$. This phase starts to decompose shortly after heating above 900°C to give the phases Ca_2SiO_4 and $CaSO_4$. The released $CaSO_4$ takes part in the formation of the main clinker phase calcium aluminate sulfate $3CaAl_2O_4 \cdot CaSO_4$.

Helenite $2CaO \cdot Al_2O_3 \cdot SiO_2$ is formed in the mixture under study from SiO_2, Al_2O_3, CaO, Ca_2SiO_4, and also from grossularite $3CaO \cdot Al_2O_3 \cdot 3SiO_2$, which is untroduced with ironstone concentration rejects according to the scheme

$$3CaO \cdot Al_2O_3 \cdot 3SiO_2 + 3CaO \rightarrow 2Ca_2SiO_4 + 2CaO \cdot Al_2O_3 \cdot SiO_2. \quad (1)$$

In the presence of $CaSO_4$ helenite is unstable [1]; its content decreases at temperatures higher than 1100°C. A smooth decrease in the amount of $2CaO \cdot Al_2O_3 \cdot SiO_2$ and its retention in the clinker are due to the restricted contents of CaO and $CaSO_4$ and the preferable reaction of $CaSO_4$ with $CaO \cdot Al_2O_3$ and $12CaO \cdot 7Al_2O_3$. The iron-containing part of the mixture forms calcium aluminate ferrites $4CaO \cdot Al_2O_3 \cdot Fe_2O_3$ in the clinker (Fig. 2).

The feature of the burnt mixture is the presence of magnesium calcium aluminosilicate $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$, which is also known as magnesia pleochroite or phase Q [2]. Its appearance is preceded by various reactions [3] including (2) and (3).

$$2CaO \cdot Al_2O_3 \cdot SiO_2 + CaO \rightarrow Ca_2SiO_4 + CaO \cdot Al_2O_3, \quad (2)$$

$$4CaO \cdot Al_2O_3 + Ca_2SiO_4 + MgO \rightarrow 6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2. \quad (3)$$

Magnesium oxide is formed in the burnt mixture by the decomposition of dolomite, which is introduced with chalkstone, and of magnesium silicates in ironstone concentration rejects.

Some authors [1, 2] consider the presence of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ in cements as undesirable, referring to weak hydraulic properties of this phase. However, the data [3–5] on the formation and hydration of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ point to its pronounced binding activity and high strength parameters of cements based on it. Therefore, it seems appropriate to convert inert helenite to a phase capable of active hydration [reactions (2) and (3)]. Furthermore, the origination of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ is accompanied by a decrease in the fraction of free MgO, the content of which in cements is strictly regulated.

Sulfated clinkers are diverse in qualitative and quantitative composition [1]. It is necessary to elucidate whether the aluminate phase $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ can be formed in sulfate aluminate clinkers of various compositions. Such determinations in a multicomponent system are rather difficult. For

Composition of alumina mixtures and clinkers

Mixture composition, %				Calculated contents of oxides in clinker, %				
calcite	technical alumina	chlorite	diopside	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO
56	35	9	–	3.5	47.9	1.1	42.3	4.2
53	35	–	12	8.7	44.7	0.5	40.4	4.1

such a study we chose a mixture of dolomitized chalkstone and lignite-bauxite in amounts corresponding to formation of the aluminate clinker containing $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$. Also we added $CaSO_4$ and Fe_2O_3, which are present in sulfated clinkers. The mixtures were burnt at 1200–1300°C to complete assimilation of calcium oxide. According to the diffraction patterns, the clinker made from the mixture without additions mainly contained $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$, $12CaO \cdot 7Al_2O_3$, and $CaO \cdot Al_2O_3$ (Fig. 3). Stepwise addition of $CaSO_4$ results in a proportional reduction of the $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ content at the expense of the $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$ formation. An addition of 10% Fe_2O_3 reduces the $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ content in the clinker and causes formation of calcium aluminate ferrites. This conclusion agrees with data of [3, 6].

When 5% of $CaSO_4$ and 10% of Fe_2O_3 are added into the mixture, the intensity of the diffraction peaks of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ is higher than that for a clinker with the addition of only 5% of $CaSO_4$. It suggests that the presence of Fe_2O_3 in an aluminate sulfate clinker creates preferential conditions for the formation of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$, as compared to $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$. Apparently, a decrease in the temperature of the appearance of a liquid phase in the iron-containing mixture accelerates the formation of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$.

The presence of MgO in the initial mixture favors the formation of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$. In industrial waste products magnesium silicates often serve as a source of MgO. Of magnesium-containing minerals, diopside $CaMg[Si_2O_6]$ and chlorite $Mg_5Al \cdot [AlSi_3O_{10}](OH)_8$ are present in ironstone concentration rejects. The formation of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ with the participation of natural magnesium silicates deserves attention. It is rather difficult to monitor transformations in a polymineral mixture. Therefore, to obtain clinkers with equal content of magnesium and with calcium aluminates present, we prepared alumina mixtures with various mineral compositions (see table).

The X-ray diffraction analysis reveals the effect of magnesium minerals on the phase composition of burnt mixtures (Fig. 4). The thermal transformations in a chlorite-containing mixture start with the chlorite decomposition. The dissociation of the mineral is multistage [7]: the removal of chemically bound water at 550–800°C and the decomposition of the chlorite structure followed by the formation of forsterite Mg_2SiO_4 from amorphous decomposition products (MgO and SiO_2) at 820–840°C. The reaction of forsterite with calcite yields diopside $CaO \cdot MgO \cdot 2SiO_2$ and MgO [8]. The enhanced activity of the resulting $CaO \cdot MgO \cdot 2SiO_2$ provides its saturation with calcium oxide up to the formation of mervinite $3CaO \cdot MgO \cdot 2SiO_2$ (Fig. 4). The release of free CaO in decarbonation of calcite promotes formation of low-basic calcium aluminates. At higher calcination temperatures the number and content of aluminate phases

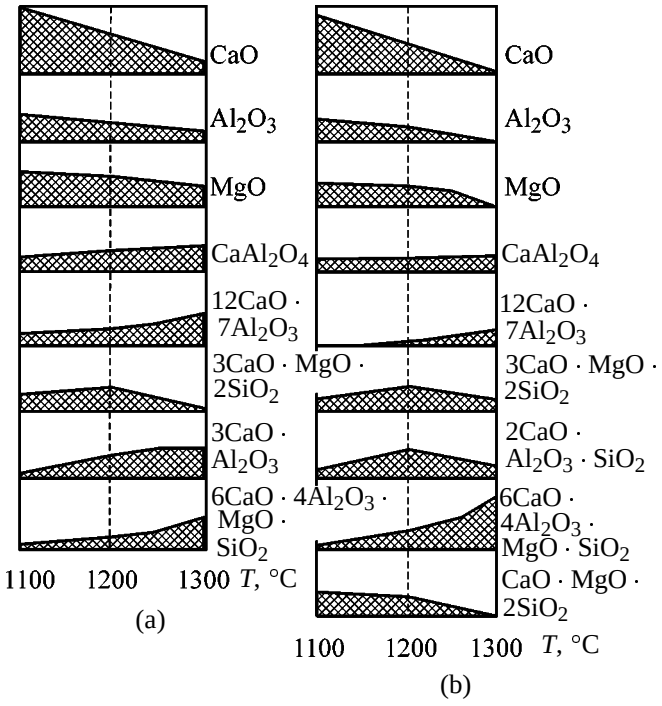

Fig. 4. Variation in the content of phases during calcination of mixtures: (a) chlorite-containing and (b) diopside-containing (by the intensity of diffraction reflections).

increase. The compound $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ is formed by the reaction

$$3CaO \cdot MgO \cdot 2SiO_2 + 4CaO \cdot Al_2O_3 + CaO \rightarrow 6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2 + Ca_2SiO_4. \quad (4)$$

This reaction is followed by reaction (3). An increased basicity of the chlorite-containing mixture is responsible for the formation of calcium-rich aluminate $3CO \cdot Al_2O_3$ and the retention of free CaO in the clinker.

The mineral $CaO \cdot MgO \cdot 2SiO_2$ in a diopside-containing mixture is gradually saturated with CaO up to the formation of $3CaO \cdot MgO \cdot 2SiO_2$ (Fig. 4). The other transformations in many respects are similar to those described above. However, an increased fraction of silica in the diopside-containing mixture predetermines the appearance of $2CaO \cdot Al_2O_3 \cdot SiO_2$ and the formation of a greater, compared to a chlorite-containing mixture, amount of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ completely binding MgO. The lack of free CaO is responsible for the stability of $2CaO \cdot Al_2O_3 \cdot SiO_2$ and $3CaO \cdot MgO \cdot 2SiO_2$ in the clinker.

Therefore, the presence of magnesium silicates in a raw material provides the formation of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ in aluminate clinkers. The natural minerals diopside and chlorite supply non-carbonate CaO and the additional amount of Al_2O_3. As a result, the raw materials that are in a short supply are saved, and the power consumption for the clinker formation is decreased.

The data obtained suggest that the appearance of the phase $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ and its amount in clinkers depend on the chemical composition of the initial mixture. The appearance of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ noticeably changes the ratio of phases in the clinker. However, the majority of known techniques for the calculation of the composition of charges do not take into account the presence of MgO in raw materials and the possibility of formation of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$. The calculation equations should be corrected to take into account complex compositions of clinkers and the variety of raw materials.

CONCLUSIONS

(1) The use of industrial waste products complicates the phase composition of sulfated clinkers at the expense of the formation of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$.

(2) The compound $4CaO \cdot 6Al_2O_3 \cdot MgO \cdot SiO_2$ can form in sulfated clinkers when the conditions for the formation of $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$ are limited. The formation of $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ is preceded by transformations involving aluminosilicates and calcium and magnesium silicates.

(3) Appropriate choice of the chemical composition of the charge with the aim to obtain $6CaO \cdot 4Al_2O_3 \cdot MgO \cdot SiO_2$ will make it possible to convert undesirable $2CaO \cdot Al_2O_3 \cdot SiO_2$ and MgO phases to a hydraulically active compound.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Analysis of Component Interaction in Liquid Alloys of the Potassium–Indium System

A. G. Morachevskii and M. A. Bykova

St. Petersburg State Technical University, St. Petersburg, Russia

Received July 10, 2001

Abstract— The thermodynamic properties of K–In liquid alloys were compared and discussed. The alternating positive and negative deviations from the ideal behavior were observed in the system.

Markedly different data are presented in the literature on the phase diagram of the potassium–indium system [1]. According to Thummel and Klemm [2], potassium and indium form the congruently melting compound K_5In_8 (mp 745 K) and incongruently melting compound KIn_4, with the peritectic horizontal lying at 698 K. In the composition range 50–90 mol % potassium the liquidus line is nearly horizontal, i.e., a tendency to separation is probable. According to Yatsenko *et al*. [3], the system has the phase separation region, and the compound K_5In_8 melts congruently at 753 K and has a very narrow homogeneity region. The composition KIn_3 was reported in that work for the incongruently melting compound. The presence of the homogeneity region in the system was confirmed by differential thermal [4] and magnetochemical [5] analyses and by electrical resistance measurements [6]. However, data on the upper critical temperature differ essentially. Bushmanov [4] reported 731 K, whereas Melekhov [5], 818 K. In Yatsenko's monograph [7], the immiscibility region is presented according to [5]. According to the later data [8, 9], the incongruently melting compound has the composition $K_{22}In_{39}$ (K_7In_{13}?), its melting point is 751 ± 6 K, and the upper critical temperature of separation does not exceed this value.

Thermodynamic properties of liquid K–In alloys were studied for the first time by the emf method using potassium glass (3.8 wt % K_2O) as solid cation-conducting electrolyte ($0.016 \le x_K \le 0.815$, 15 compositions, 720–810 K) [10]. It was found that the activity isotherm of potassium at 750 K has alternating deviations from the ideal behavior, and the corresponding curve for indium is located in the region of negative deviations from Raoult's law (Fig. 1). The integral molar excess Gibbs energy ΔG^{ex} is negative over the entire composition range (Fig. 2), with the curve extremum lying in the region of formation of intermetallic compounds.

More recently, Dergacheva *et al*. [11–14] studied, also by the emf method, the thermodynamic properties

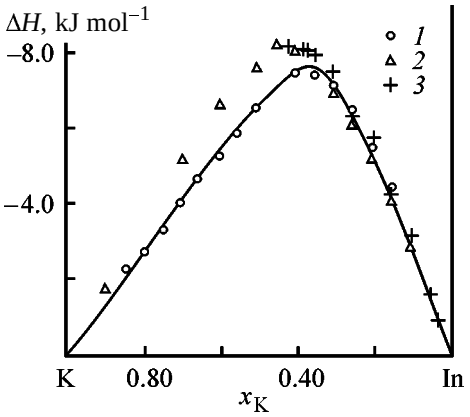

Fig. 3. Integral molar enthalpy of mixing ΔH vs. composition in the K–In system. Reference, T (K): (*1*) [16], 773; (*2*) [11], 753; and (*3*) [15], 773.

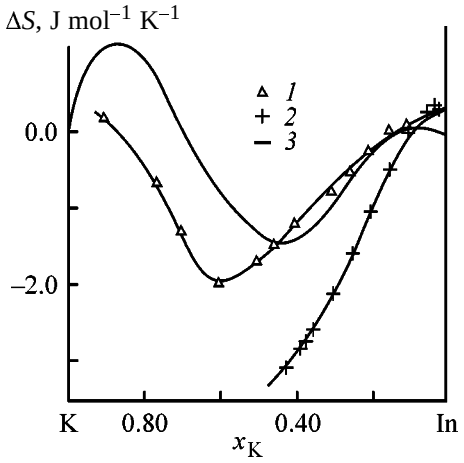

Fig. 4. Integral molar entropy of mixing ΔS vs. composition in the K–In system. Reference, T (K): (*1*) [11], 753; (*2*) [15], 773; and (*3*) the recommended values.

of the K–In liquid alloys ($0.10 \le x_K \le 0.90$, 11 compositions, 733–833 K). As seen from Fig. 1, the activity isotherms of potassium obtained in these studies reasonably agree with the data of [10]. The curves of the integral molar Gibbs energy are also close (Fig. 2). In these studies, the separation region at 750 K was not observed.

Takenaka *et al.* [15] used potassium β-alumina as solid electrolyte and the K–Bi alloy ($x_K = 0.08$) as reference in emf measurements. The alloy potential relative to pure potassium was known and was monitored at regular intervals in the course of the tests. The alloy composition was determined coulometrically with a potassium–lead liquid alloy ($x_K = 0.02$) as potassium source. The majority of tests were started with pure indium, and potassium was added in the course of the test. This made it possible to study the potassium-poor region of compositions (41 compositions, $0.030 \le x_K \le 0.520$, from the liquidus line to 823 K).

Takenaka *et al.* [15] noted that at very low potassium contents in the alloy ($x_K \le 0.001$) and at $x_K \ge 0.35$ the equilibrium is attained difficultly. As seen from Figs. 1 and 2, there are discrepancis between the data of [15] and the results of the previous studies. It is notable that the discrepancis are essential specifically at $x_K \ge 0.35$, i.e., in the composition range in which the equilibrium is attained difficultly.

The liquidus line of the K–In system ($x_K \le 0.42$), determined from the breaks in the $E = f(T)$ curves for the compositions studied [15], lies at somewhat higher temperatures than it was reported in [3, 6].

In [4, 16], a Calvet calorimeter was used to determine the enthalpy of mixing of liquid K–In alloys. The obtained values are in a reasonably good agreement with those calculated from the emf measurements [14, 15] (Fig. 3). At the same time, essentially different data were reported in [14, 15] on the integral molar entropies of mixing (Fig. 4).

Despite existing discrepancis, all the data on the thermodynamic properties of the K–In liquid alloys show that interaction between components is fairly strong. Even if a phase separation region does exist in the system, the upper critical temperature lies below 750 K.

The peak of the excess stability in the K–In system is close to $x_K = 0.35$ (55 kJ mol^{-1}) [15]. At the same time, the excess stability in the K–Pb and K–Bi systems at equiatomic compositions is 250 and 350 kJ mol^{-1}, respectively, [1], with the peak of the excess stability in the K–Bi system being even larger at the composition of the compound K_3Bi. The excess heat capacity was calculated from the emf measurements in [15], but the results are given without necessary clearness and are difficult to discuss.

Data on the electrical resistivity of liquid K–In alloys are available for the entire range of compositions at temperatures exceeding by 100 K the liquidus temperature of the system [6]. The resistivity reaches a maximum (480 ± 10 μΩ cm) at equimolar composition (723 K), with the temperature coefficient $d\rho/dT$ being minimal (–1.25 μΩ cm K^{-1}). The resistivity of liquid K–In alloys is considerably higher than that of the alloys with lithium or sodium, with the resistivity peak in the series Li–In, Na–In, and K–In shifting from the alkali-metal-rich region to the equimolar composition. In this case, the peak in the $\rho = f(x_K)$ curve should be ascribed to the corresponding groups

in potassium–indium liquid alloys. Their presence indirectly confirms the validity of the ideal associated solution model [17] for the given system.

The recommended values of the thermodynamic functions, obtained from treatment of the results of all studies on the liquid K–In alloys [10–16], are given in the table. In the potassium-rich part of the system our dependence of the entropy of mixing on the composition (Fig. 4) appreciably differs from the data of [11–14], but is similar to the analogous dependence for the Na–In system [1, 18]. Such a curve of the integral entropy of mixing is typical of systems with a fairly strong interaction between the components [19]. This result is confirmed by the thermodynamic characteristics [14, 20] of the solid phases formed in the K–In system: K_5In_8 (x_K = 0.385) and KIn_3 (x_K = 0.25). The saturated vapor pressure over K–In alloys in the solid state was measured by the molecular beam method. For the phase region K_5In_8 + KIn_3 the vapor pressure was measured in the temperature range 441–544 K, and for the phase region KIn_3 + In, in the 473–660 K range. For the phase region K + K_5In_8 the measured quantity is similar to the saturated vapor pressure of pure potassium. The integral thermodynamic characteristics of formation of the compounds from the pure liquid components at 540 K were estimated from the data obtained:

Compound	ΔG, kJ mol^{-1}	ΔH, kJ mol^{-1}	ΔS, J mol^{-1} K^{-1}
1/4 KIn_3	–(9.37 ± 0.55)	–(15.02 ± 1.76)	–(10.5 ± 2.9)
1/13 K_5In_8	–(11.18 ± 1.42)	–(18.41 ± 1.63)	–(13.4 ± 2.9)

Assuming that the difference between the heat capacities of the compounds and initial components ΔC_d is negligible, we calculated the standard thermodynamic characteristics of formation of the compounds from the solid components. For 1/4 KIn_3 ΔH^0_{298} = –(12.01 ± 2.76) kJ mol^{-1} and ΔS^0_{298} = –(2.85 ± 4.00) J mol^{-1} K^{-1}; for 1/13 K_5In_8 ΔH^0_{298} = –(15.48 ± 2.64) kJ mol^{-1} and ΔS^0_{298} = –(6.2 ± 4.2) J mol^{-1} K^{-1}. The difference between the ΔH values at 540 and 298 K is caused solely by the changed aggregation state of the pure initial components (potassium and indium).

As noted above, more recent studies of the K–In system revealed the compounds of somewhat different composition: $K_{22}In_{39}$ (x_K = 0.361) or K_7In_{13} (x_K = 0.350), and KIn_4 (x_K = 0.20). The correction of calculations taking into account the new boundaries of the phase regions does not alter significantly the integral thermodynamic characteristics, especially for the

congruently melting phase. It should be noted that the compounds are formed with considerable exothermic effects, and the entropies of their formation are negative. However, according to [15], in formation of potassium–indium liquid alloys from pure components, the change in the heat capacity ΔC_d is observed, reaching 12–14 J mol^{-1} in the composition range $0.35 \le x_K \le 0.42$ [15]. This suggests a deviation from the Neumann–Kopp rule for the solid phases, which affects the estimate of the standard parameters at 298 K.

Probably, the values obtained from calorimetric measurements in [21] for the enthalpy of formation of the potassium–indium compounds under the standard conditions are underestimated: $\Delta H^0_{298} = -(7.32 \pm 0.59)$ kJ mol^{-1} for 1/4 KIn_3 and $\Delta H^0_{298} = -(9.14 \pm 0.71)$ kJ mol^{-1} for 1/13 K_5In_8. In Yatsenko's monograph [7] the results of this study are given with no comments. The enthalpy of melting of 1/13 K_5In_8, determined calorimetrically, is 7.87 ± 0.54 kJ mol^{-1}. Presently available data on the thermodynamic properties of solid phases in the K–In system are insufficient for their optimization.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Interaction of Hafnium Chlorides with Magnesium, Aluminum, and Lead in Molten Alkali Metal Chlorides

N. A. Loginov and V. A. Oleinikova

Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia

Received July 30, 2001

Abstract—The thermodynamic characteristics of the interaction of hafnium(II) and hafnium(IV) chlorides with magnesium, aluminum, and lead in molten alkali metal chlorides were calculated.

In electrolytic preparation and refining of hafnium, dilute solutions of its chlorides in molten alkali metal chlorides and their mixtures attract a great attention. In this context, it was interesting to examine the possibility of interaction of $HfCl_2$- and $HfCl_4$-containing solutions with magnesium, aluminum, and lead at temperatures above their melting points (T_m 650, 660.2, and 327.4°C, respectively) and to calculate the apparent equilibrium constants of some reactions in the 3LiCl–2KCl, NaCl–KCl, KCl, and CsCl melts in the range 950–1250 K.

In a chloride melt, metallic hafnium is in equilibrium with its double- and quadruple-charged ions [1–3]. Relatively volatile (T_{sub} = 315°C) hafnium tetrachloride is the intermediate product of preparation of metal itself and its compounds. Hafnium in an electrolyte is present in the form of complex ions ($HfCl_4^{2-}$, $HfCl_5^{3-}$, $HfCl_6^{2-}$, $HfCl_5^{-}$, etc.), differing in the configuration, energy of the Hf(II)–Cl^- and Hf(IV)–Cl^- bonds, and characteristic vibration frequencies.

The goal of the calculations was to show that, along with electrochemical recovery of metal from the electrolyte, magnesium-assisted thermal reduction of its chlorides can also occur, by analogy with production of metallic titanium. For this purpose, we used the data of [1–6] on the temperature dependences of the apparent standard electrode potentials and on the formal redox potentials for those concentration intervals in which the activity coefficient f^* is constant to within probable errors of the emf measurements (Table 1).

The equilibrium potentials of hafnium were determined by taking the isotherms and subsequently treating the results by a rather complex coulometric procedure [1–3], in which, however, direct analytical determination of the concentration is not necessary.

The calculation formulas and the obtained temperature dependences of the apparent equilibrium constants

of reactions (1)–(8) are given in Table 2. The most practically significant reactions are (1)–(3). The K_n^* values and the change in the Gibbs energy for these reactions as functions of temperature are presented in Table 3 ($\Delta G_r^* = -4.576 \times 4.184T \log K_n^*$, J mol^{-1}). The calculation error is 10–12%. Hafnium tetrachloride interacts with magnesium more actively than hafnium dichloride.

With growing temperature K_n^* somewhat decreases in each salt system. At a fixed temperature (1100 K), the apparent equilibrium constant, e.g., K_2^*, also decreases in the series (3LiCl–2KCl)–(NaCl–KCl)–KCl–CsCl [1.01×10^{13}, 6.40×10^{13}, 3.44×10^{12}, and 1.7×10^{12}, respectively (Table 3)].

According to the autocomplexation model of the structure of alkali metal chlorides, in chloride solutions the bond U of the alkali metal cation M with chloride anion Cl^- (M^+–Cl^-) decreases in going from a salt system with a smaller cation to a system with a larger cation. Introduction into the melt of complexing component, the quadruple-charged hafnium ion in our case, should increase the difference between the energies of the Hf^{4+}–Cl^- and M^+–Cl^- bonds. When such a replacement of the outer cationic surrounding takes place, a large number of M^+–Cl^- bonds will transform into stronger Hf^{4+}–Cl^- bonds. The latter bonds will become stronger in melts with alkali metal ions of larger radius. An example is the redox potential of the system Hf^{4+}/Hf^{2+}, given for different temperatures and different molten salts in Table 1. With the cationic radius of the electrolyte increasing at the constant temperature, the potential acquires the more negative values. This is due to a more pronounced increase in the stability of Hf^{4+} complexes compared to Hf^{2+} complexes. Thus, reduction of Hf(IV) to Hf(II) becomes more difficult in the series LiCl–CsCl. The same phenomenon (Table 3) was also observed for reaction (3). At 1100 K the apparent equilibrium constant K_3^* decreases from 8.07×10^5

1050	2.74×10^7	149.50	3.97×10^{12}	253.3	1.48×10^5	104.0
1100	1.54×10^7	151.4	1.70×10^{12}	257.6	1.15×10^5	106.6
1150	9.12×10^6	153.24	7.84×10^{11}	261.9	9.13×10^4	109.2
1200	5.64×10^6	155.1	3.85×10^{11}	266.2	7.39×10^4	111.9

to 1.15×10^5 in the series (3LiCl–2KCl)–CsCl. At the same time, K_2^* is higher by 6–7 orders of magnitude than K_1^* and K_3^*. This relationship is not valid for the decrease in K_1^* of reaction (1) in the 3LiCl–2KCl and NaCl–KCl melts at the same temperature (Table 3).

Reactions (4) and (5) with molten aluminum occur to a negligible extent; therefore, Al cannot be used as reductant for preparing the metal.

A great deal of attention was given in Russia to electrolytic refining of heavy nonferrous metals, among which metallurgy and reprocessing of lead and lead compounds [7–9] and electrochemical behavior in molten ionic electrolytes, e.g., in NaCl–KCl–$PbCl_2$ [7–12], occupy the prominent place. Therefore, it was of interest to calculate the reactions of hafnium di- and tetrachlorides with molten lead and $PbCl_2$ in equimolar NaCl–KCl mixture (Table 2).

Reactions (6) and (7) do not occur to a noticeable extent: K_6^* at 1100 K is 3.37×10^{-7} and K_7^*, 8.3×10^{-15}. Reaction (8) occurs practically quantitatively. The apparent equilibrium constant at 1100 K is equal to 4.15×10^7.

Compared to similar reactions of titanium tetrachloride in the NaCl–KCl melt [13], the reactions of $HfCl_4$ with magnesium occur less intensely. At 1100 K the constant K_2^* and K_3^* of the reaction of $TiCl_4$ with magnesium are 7.6×10^{17} and 9.6×10^{12}, respectively, and those for the reaction of $HfCl_4$ with Mg are 6.4×10^{12} and 6.69×10^5, i.e., they differ by 5–7 orders of magnitude.

CONCLUSIONS

(1) The temperature dependences of the apparent equilibrium constants are calculated for eight reactions of hafnium di- and tetrachloride with magnesium, aluminum, and lead in various molten salt solvents.

(2) Reactions (2) and (3) occur to a lesser extent than the analogous reactions of titanium tetrachloride with magnesium in the NaCl–KCl melt.

(3) The reaction of $HfCl_2$ and $HfCl_4$ with liquid aluminum and lead does not occur, and that with $PbCl_2$ is rather intense.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Physicochemical Properties of Methyl- and Ethylhalosilanes

I. B. Sladkov

St. Petersburg State Technical University, St. Petersburg, Russia

Received January 30, 2001

Abstract—Published data on the main physicochemical constants of methyl- and ethylhalosilanes were summarized. The lacking parameters were calculated by the methods whose reliability was checked by calculating parameters for which the experimental values are available.

Organometallic compounds find growing use in organic synthesis, preparation of metallic films and semiconducting materials, etc. [1, 2]. At the same time, physicochemical properties of organometallic compounds are studied insufficiently.

In this work, we summarized available data on the physicochemical constants of alkylhalosilanes and calculated the lacking parameters. The reliability of our calculations was confirmed by calculating parameters for which the experimental values are available.

We studied the compounds formed by substitution of the hydrogen atoms in the silane molecule by methyl and ethyl radicals and halogen atoms. Such substitution generates the homologous series of the SiR_4–SiR_3Hal–SiR_2Hal_2–$SiRHal_3$–$SiHal_4$ type, where R is methyl radical CH_3 or ethyl radical C_2H_5 and Hal is halogen (F, Cl, Br, I). Such molecules can also contain hydrogen atoms.

Methods for approximate calculation of the boiling point are few, applicable to a limited range of substances, and low-accurate [3]. We found that for the above compounds the boiling point can be fairly reliable estimated by Kinney's method [4]. In this method, a definite characteristic quantity n_b connected with the boiling point is assigned to atoms and atomic groups of the molecule. The characteristic of the molecule as a whole N_b is the sum of n_b parameters of atoms and groups with regard to the molecular stoichiometry.

The stoichiometric formula of a compound can be presented as

$$SiR_\alpha H_\beta Hal'_\gamma Hal''_\delta, \qquad \alpha + \beta + \gamma + \delta = 4, \qquad (1)$$

where R is an organic radical (CH_3 or C_2H_5), H is the hydrogen atom, and Hal is a halogen.

In terms of this concept,

$$N_b = n_b(Si) + \alpha n_b(R) + \beta n_b(H) + \gamma n_b(Hal') + \delta n_b(Hal'').$$

The boiling point is calculated by the equation

$$T_b = 230N_b^{1/3} - 270. \qquad (2)$$

In [5, 6], the n_b values are presented for Si (4.20), Cl (3.40), and Br (5.88). All these values are related to tetrahedral coordination. We determined n_b from the known boiling points of the above compounds for the following atoms and radicals: H 1.20, F 0.65, I 8.35, CH_3 3.65, and C_2H_5 6.80.

The average (in absolute value) error of the boiling point calculation by Eq. (2) with the above n_b values for 53 substances was 2.0% (Table 1).

The enthalpy of vaporization at the boiling point ΔH_b (J mol^{-1}) for our compounds can be estimated by Trouton's rule [9]

$$\Delta H_b = 88T_b. \qquad (3)$$

For 30 compounds with known ΔH_b [10–13], the average (in absolute value) error of the ΔH_b calculation by Eq. (3) was 3.0%.

To determine the critical temperature T_c, we used the two-stage iteration procedure [14]. Initially, using Guldberg's rule, we found the first approximation:

$$T_{c,0} = 1.5T_b. \qquad (4)$$

Then, the enthalpy of vaporization was calculated by Eq. (3) at the boiling point, and the refined value of the critical temperature was determined

$$T_c = T_b[1 + f\ln(10.255T_{c,0}/b)], \qquad (5)$$

$$f = RT_{c,0}/\Delta H_b,$$

$$b = 1.27V_b - 6.$$

It was found that the critical volume well correlates with the parachor (the calculation of the latter for alkyl compounds is considered in detail in [6]). This correlation is linear (correlation coefficient 0.9961, root-mean-square error ±2.8%). As a result, the equation

$$V_c = 80\prod - 11 \quad (6)$$

can be used to calculate the critical volume.

The critical pressure can be found by the equation [10]

$$P_c = 1.039b/T_c. \quad (7)$$

Since experimental data on the critical parameters of halogen derivatives are very limited, we included in the data base the compounds that begin and complete each homologous series (SiR_4 and $SiHal_4$), and also alkyl compounds of the other Group IV elements (GeR_4, SnR_4, and PbR_4), whose thermodynamic similarity with the compounds discussed is doubtless. This improves the statistics and reliability of the calculation methods used. The errors of the calculation of the critical parameters are listed in Table 2.

Published data on the density of the compounds under consideration in the liquid state are extremely scarce. Experimental data on the temperature dependence of the density are available only for trichloromethylsilane [23]. For the other compounds, the density data are available only for separate temperatures (usually for room temperature). Initially, we consider prediction of the density (or molar volume) of a liquid at the boiling point.

When the density of a liquid is known at temperature T_1, its recalculation to the boiling point can be performed most precisely using the critical temperature of the substance by the equation [10]

$$\rho_b = \rho_1(2 - T_b/T)/(2 - T_1/T_c). \quad (8)$$

* The necessary data on T_b and V_b were taken from [15] and from Tables 1 and 3.

The critical parameters are known for only six alkylhalosilanes (Table 2). For these compounds, the volume properties at the boiling point can be calculated by Eq. (8). The densities and molar volumes of liquids at the boiling point, calculated by Eq. (8) from the density at T_1 = 293 K, are listed in Table 3. $Si(CH_3)Cl_3$, for which the experimental value is known [23], is the exception. For molecular inorganic compounds, the rms error of the calculation of ρ_b by Eq. (8) is ±0.7% [7]. Let us ascertain that for compounds considered this equation keeps the high accuracy. For this purpose, we should use the molar volume of a liquid at the boiling point for three substances that open and complete the homologous series: tetrachlorosilane, tetramethylsilane, and tetraethylsilane. The V_b values of these substances (cm^3 mol^{-1}) are equal to 121.1, 138.4, and 215.5, respectively [15, 19].

Using the listed set of nine substances, we can assess the reliability of data obtained by Eq. (8) by the method of comparative calculation. Variation of the molar volume of a liquid at the boiling point in the series of methyl- and ethylchlorosilanes is well described by the linear dependence (correlation coefficient 0.9993, rms error ±0.8%), which demonstrates high reliability of the data obtained. Thus, for substances with known critical parameters, recalculation of ρ at 293 K to T_b gives results close to the experimental data.

When the critical temperature of a substance is unknown, the recalculation of the density at a known temperature to that at the boiling point can be performed by the simpler equation [10]

$$\rho_b = \rho_1/[1 + 0.46(1 - T_1/T_b)]. \quad (9)$$

The high reliability of Eq. (9) as applied to alkyl compounds of Group II–VI elements was proved with a large data set [15]. Indeed, for the considered silicon compounds with known experimental ρ_b, such recalculation (from T = 293 to T_b) gives the error (%): +0.2 for $Si(CH_3)_4$, –0.1 for $Si(C_2H_5)_4$, –0.3 for $SiCl_4$, and +0.5 for $Si(CH_3)Cl_3$.

Thus, Eq. (9) also provides for recalculation of the density at arbitrary temperature T_1 to density at T_b with the error close to the experimental error. The results of calculation of the molar volume of a liquid at the boiling point by Eq. (9) for substances with known densities at room temperature are listed in Table 3.

When any data on densities of liquids are lacking, the molar volume at the boiling point $V_b = M/\rho_b$ can be calculated by two more methods. Earlier, we have found the following correlation for alkyl compounds of Group II–VI elements [6]:

$$V_b = 31\prod - 15. \quad (10)$$

In addition, it was found that the molar volume of liquid methyl- and ethylhalosilanes at the boiling point is well described by the additivity scheme. We determined the fractions of V_b for CH_3 and C_2H_5 radicals using the atomic fractions of V_b for silicon

Table 3. Volume properties of liquid methyl- and ethylhalosilanes

Substance	ρ_{293}, g cm^{-3} [8, 15, 23, 24]	T_b, K	V_b, cm^3 mol^{-1}
$SiMe_4$	0.646	300.1	138.4*

$SiEtHBr_2$	1.728	393.2	140.9

* Experimental values.
** Calculated by Eq.(8); the other values of V_b are calculated by Eq. (9).

Table 4. Atomic fractions V_b of CH_3 and C_2H_5 radicals

Compound	V_b, CH_3, cm^3 mol^{-1}	Compound	V_b, C_2H_5, cm^3 mol^{-1}
$SiMe_4$	25.7	$SiEt_4$	45.0
$SiMe_3Cl$	22.6	$SiEt_3Cl$	43.8
$SiMe_2Cl_2$	25.3	$SiEt_2Cl_2$	42.1
$SiMeCl_3$	25.0	$SiEtCl_3$	42.3
$SiMe_3Br$	25.3	$SiEt_2Br_2$	46.0
$SiMe_2Br_2$	25.2	$SiEtBr_3$	47.6
$SiMe_2Br_3$	25.2	$SiEtBr_2Cl$	49.9
$SiMeBr_2Cl$	28.3	$SiEtBrCl_2$	44.5
$SiMeBrCl_2$	27.9	$SiEtHCl_2$	45.8
$SiMeH_2I$	25.9	$SiEtH_2Cl$	45.8
		$SiEtHBr_2$	48.6
		$SiEt_3F$	44.2
Average	26.0		45.0

(35.5), hydrogen (2.8), fluorine (9.5), chlorine (21.6), bromine (27), and iodine (35) [10].

As seen from Table 4, the atomic fractions of V_b for CH_3 and C_2H_5 radicals found from data for various compounds vary within fairly narrow limits and amount to 26 and 45, respectively. This shows that the additive scheme can be used to calculate V_b of alkylhalosilanes:

$$V_b(SiR_\alpha Hal_\beta) = V_b(Si) + \alpha V_b(R) + \beta V_b(Hal). \quad (11)$$

The average (in absolute value) error of determining of V_b of halogen derivatives by Eqs. (1) and (11), calculated from data of Table 3, was 2.1 and 0.9%, respectively.

Another characteristic value of the density, especially important in applied chemistry, is the density at room temperature (293 K is considered as a standard temperature).

For alkyl compounds of Group II–VI elements, we proposed the equations [15]

$$\rho_{293} = [M/(31.5\prod - 15)](1.46 - 134.8/T_b), \quad (12)$$

$$\rho_{293} = M/(24.5\prod + 3.5). \quad (13)$$

To check the accuracy of Eqs. (12) and (13), we used data of Table 3 and found that the average (in absolute value) error is 2.1 and 3.0%, respectively.

CONCLUSION

Physicochemical properties of methyl- and ethylhalosilanes, not available from the literature, can be predicted fairly reliably by methods of approximate calculation.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Water-Soluble Copper(II) Compounds on Clinoptilolite

Yu. N. Makurin, A. V. Yuminov, and V. G. Berezyuk

Ural State Engineering University, Yekaterinburg, Russia

Received August 9, 2000; in final form, June 2001

Abstract—Copper(II) sorption on clinoptilolite from aqueous solutions with different pH was studied. The results were analyzed using the calculated distribution of water-soluble copper(II) species at different pH. The best conditions of copper(II) sorption on clinoptilolite from aqueous solutions were determined.

Over a 3–4-thousand-year period copper is used for production of implements, dishware, decorations, and dyes. At present heat exchangers, vacuum apparatus, pipes, and electric wires are produced from copper. Copper alloys are applied as structural materials. Copper compounds are used in production of glass and enamels and in electroplating and ore enrichment. They are also used as wood preservatives, catalysts, etc.

The scale of application of copper and its compounds gives rise to environmental problems. Copper, like other heavy metals, plays a dual role in biochemistry of plants and animals. On the one hand, copper is involved in the metabolism, and on the other hand, it is a toxic metal. The biological functions of copper in cells are determined by its coordination properties, possibility of reaction with oxygen, and reversible reduction of copper compounds. Copper(II) in a cell exists in the form of complexes with biologically active compounds such as amino acids, nucleic acids, biogenic amines, and hormones. The average human consumption of copper with food is 2–5 mg daily. In the case of hard physical activity this value increases to 7 mg daily. When the consumption exceeds the daily demand, the organism is poisoned. The toxicity is due to coordination of the S–H groups of proteins and especially enzymes to copper(II) ions. Copper compounds increase the permeability of mitochondrial membranes. Acute intoxication with copper compounds is accompanied by hemolysis of erythrocytes and disorder of monoamine metabolism. As a rule, a human being is poisoned with copper under industrial conditions. However, poisoning with potable water containing 444 mg l^{-1} of copper(II) cations which are probably washed out from copper water pipes has been described [1].

When the copper concentration in natural water exceeds the productivity of the natural regeneration, its concentration in potable water should be reduced by special procedures. To decrease excess copper content in tap water, natural sorbents including clinoptilolite are used. Clinoptilolite is a cheap and readily available sorbent with a high capacity for copper [2].

We used clinoptilolite from the Kholin deposit (Buryatiya). Its average composition is described by the formula $(K_2Na_2Ca)_3Al_6Si_{30}O_{72} \cdot 22H_2O$. The silicon/aluminum ratio ranges from 4.2 to 5.2. The cross section of clinoptilolite openings is 0.40×0.55 nm; the free pore volume is 0.34. The soprtion capacity and stability of clinoptilolite in various media are described in [3].

To determine the best sorption conditions, we studied copper(II) sorption from aqueous solutions with different pH, since the distribution of water-soluble copper species exhibiting different sorption properties strongly depends on pH. Copper(II) cations are hydrolyzed in aqueous solution to form the following hydroxo complexes: $[Cu(OH)]^+$, $[Cu(OH)_2]$, $[Cu(OH)_3]^-$, and $[Cu(OH)_4]^{2-}$. The concentrations of these species are denoted as C_1, C_2, C_3, and C_4. Their instability constants are as follows [4, 5]:

$$pK_1 = 7.0,\ pK_{1-2} = 13.7,\ pK_{1-3} = 17.0,\ pK_{1-4} = 18.5.$$

The fractions of copper species being in equilibrium in an aqueous solution are related to the instability constant and pH by the following equations [6, 7]:

$$\alpha_0 = C_0/C_\Sigma = 1/\beta, \quad (1)$$

$$\alpha_1 = C_1/C_\Sigma = K_w/(K_1[H_3O^+]\beta), \quad (2)$$

$$\alpha_3 = C_3/C_\Sigma = K_w^3/(K_{1-3}[H_3O^+]^3\beta), \quad (4)$$

$$\alpha_4 = C_4/C_\Sigma = K_w^4/(K_{1-4}[H_3O^+]^4\beta), \quad (5)$$

$$\beta = 1 + K_w/(K_1[H_3O^+]) + K_w^2/(K_{1-2}[H_3O^+]^2) + K_w^3/(K_{1-3}[H_3O^+]^3) + K_w^4/(K_{1-4}[H_3O^+]^4), \quad (6)$$

where K_w is the ionic product of water; C_Σ is the total concentration of water-soluble copper(II) species, $C_\Sigma = C_0 + C_1 + C_2 + C_3, C_4, C_0 = [Cu^{2+}]$.

The equilibrium compositions of aqueous copper(II) solutions with various pH, calculated by Eqs. (1)–(6), are presented in the table.

The stability of the copper(II) solution with respect to precipitation of copper hydroxide is of great practical interest, since this process can strongly decrease C_Σ. The equilibrium aqueous solution–$Cu(OH)_2$(s) is described by the equation:

$$[Cu^{2+}][OH^-]^2 = SP, \quad (7)$$

where SP is the solubility product of copper(II) hydroxide, equal to 5.6×10^{-20} [4].

Substitution of this value in Eq. (7) gives the following equation

$$pC_0^t = 2pH - 8.75, \quad (8)$$

where pC_0^t is the threshold concentration of C_0. At copper concentration higher than the threshold value $Cu(OH)_2$ starts to precipitate.

The diagram of stability of an aqueous Cu(II) solution with respect to $Cu(OH)_2$ precipitation is shown in Fig. 1. The dependence of the threshold concentration C_0^t described by Eq. (8) is represented by straight line *1*. Curve *2* determines the actual C_0 at $C_\Sigma = 3.9\times10^{-4}$ M. As seen from Fig. 1. copper hydroxide precipitates at pH > 6. These results will be used in interpretation of experimental data on copper(II) sorption form the tested solutions on clinoptilolite.

Copper(II) sorption on clinoptilolite from aqueous solutions with various pH was studied as follows. A weighed portion of clinoptilolite (10.0 ± 0.1 g) was placed in a round-bottomed flask. A buffer solution (10.0 ml) with pH ranging from 3 to 10 was added. Acidification to pH 1 and 2 was performed with 0.1 and 0.01 M hydrochloric acid solution prepared from standard samples. To adjust pH in the range 3–10, ammonia–acetate buffer was used [8].

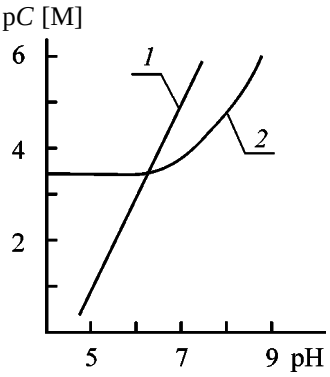

Fig. 1. Diagram of stability of a Cu(II) aqueous solution with respect to $Cu(OH)_2$ precipitation. (*C*) Copper(II) concentration. (*1*) pC_0^t and (*2*) pC_0.

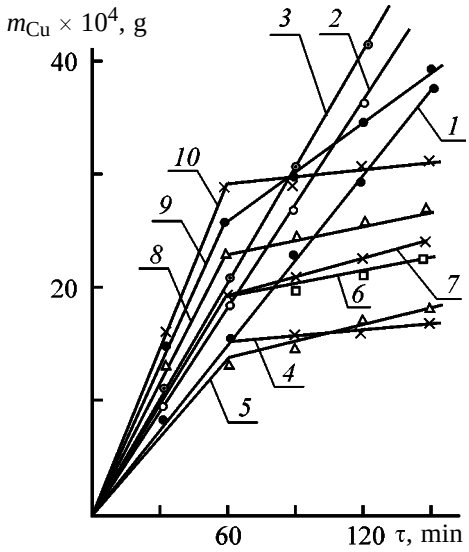

Fig. 2. Diagrams of Cu(II) accumulation on clinoptilolite m_{Cu} at pH (*1*) 1.10, (*2*) 1.85, (*3*) 3.0, (*4*) 4.05, (*5*) 5.0, (*6*) 6.0, (*7*) 7.10, (*8*) 8.0, (*9*) 9.06, and (*10*) 9.85. (τ) Time.

A 3.9×10^{-4} M standard copper(II) solution (10 ml) was added to the reaction mixture. The total volume of the system was 50 ml. The reaction mixture was shaken with a mechanical stirrer. Samples of the solution in contact with clinoptilolite were taken at 30-min intervals and analyzed for copper(II) by the procedure in [9]. The results are shown in Fig. 2. The copper(II) sorption was determined as the difference between the total copper(II) content and the copper(II) content in the solution.

As seen from the table, copper(II) in acidic solutions exists in the form of Cu^{2+} cations which can be rapidly sorbed both on the surface and in pores of clinoptilolite.

At higher pH copper(II) hydroxide precipitates. The copper(II) concentration in the solution sharply decreases (Fig. 1) and the sorption decelerates. In the first stages (t < 60 min) the sorption occurs by the globular mechanism and does not reach saturation (Fig. 2). As the sorption time increases (t > 60 min), zeolite pores are clogged with $Cu(OH)_2^s$ particles, internal diffusion is blocked, and the sorption sharply decreases. Globules of $Cu(OH)_2$ are weakly sorbed on the clinoptilolite surface and are readily washed off.

In alkaline solutions the soprtion is accelerated owing to intense nucleation of $Cu(OH)_2^s$ to form finely divided $Cu(OH)_2^s$ precipitate. The globular mechanism becomes more efficient.

CONCLUSIONS

(1) Speciation of water-soluble copper(II) forms at various pH was calculated. The stability of a Cu(II) solution with respect to precipitation of $Cu(OH)_2$ was analyzed.

(2) The kinetics of copper(II) sorption on clinoptilolite was studied as influenced by pH of the solution. The inflection point in the kinetic curves was assumed to be due to a change in the sorption mechanism depending on the copper(II) species present in the solution.

(3) At pH 1–3 copper(II) is efficiently sorbed by clinoptilolite for no less than 150 min. At pH 4–10 the sorption mechanism changes and the soprtion becomes efficient within the first 60 min.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Oligomers from Dilute Solutions on the Surface of Ferromagnetic Fillers

I. S. Rodzivilova, N. L. Zaitseva, S. E. Artemenko, S. G. Kononenko, and T. G. Dmitrienko

Saratov State Technical University, Saratov, Russia

Received May 14, 2000; in final form, January 2001

Abstract—The adsorption of oligomers from their dilute solutions on the surfaces of dispersed barium and strontium oxide ferrites and of neodymium–iron–boron alloy was studied. The main thermodynamic functions of the system components were evaluated. The features of their variation were established.

The adsorption processes on the surface of fillers in solutions of oligomers and polymers govern the features of production of composite materials. The interaction of polymeric components of solutions with the filler surface is the initial event in formation of the interphase contact in composites based on these components [1]. Therefore, the study of adsorption of polymers and oligomers from dilute solutions is of theoretical and practical importance. These data give insight into the features of the adsorption equilibria of polymer and oligomer molecules with the surface of solids.

As a rule, the results of studying adsorption equilibria are presented in the form of dependences of the oligomer or polymer excess in the adsorption layer relative to its content in the equilibrium solution on the concentration of the polymer or oligomer in the solution (Gibbs adsorption isotherm) [2, 3]. In the range of moderate and high concentrations of polymer solutions, these dependences are complicated. Therefore, there is no common interpretation of the results [4]. As shown in a series of papers [5, 6], the study of adsorption of polymers from dilute solutions allows rather simple determination of the adsorption isotherm, which allows evaluation of the parameters of the adsorption equilibrium.

The aim of this work was to study the adsorption equilibria of phenol–formaldehyde oligomer (PFO) in its adsorption from dilute solution in alcohol–acetone mixture on the surface of magnetic fillers.

EXPERIMENTAL

We studied model systems including the following substances: barium and strontium oxide ferrites, $BaO \cdot 6Fe_2O_3$ and $SrO \cdot 6Fe_2O_3$, and also neodymium–iron–boron alloy Nd–Fe–B, used as sorbents; PFO used in rubber ferrites as a matrix; and oligooxypropylene glycol (OOPG), and epoxy-4,4'-isopropylidenediphenol resin (ED-20) used as modifiers for PFO. The physicochemical characteristics of the fillers are listed in Table 1.

Adsorption was carried out in hermetically sealed pycnometers at $25 \pm 1°C$ and the weight ratio of the liquid and solid phases of 10 : 1. The equilibrium solution of the oligomer was separated from the adsorbent by centrifuging; the concentrations of the equilibrium solutions were determined refractometrically. The adsorption Γ (mmol g^{-1}) according to Gibbs is an excess of the number of moles of the second component in the volume of adsorption layer over the number of moles in the same volume in the bulk of the equilibrium solution. The difference of concentrations of the second component in the initial solution C_0 and in the solution equilibrated with the adsorbent

Table 1. Physicochemical characteristics of the fillers

Sorbent	Composition, %	Specific surface area, $S \times 10^{-3}$, $m^2\ kg^{-1}$

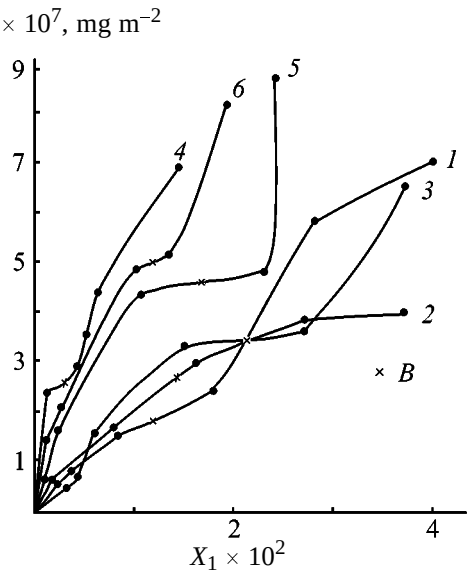

Fig. 1. Isotherm of PFO adsorption from its solutions in alcohol–acetone mixture on the surface of ferrite oxides and Nd–Fe–B alloy. (Γ_i) Excess adsorption and (X_1) PFO mole fraction in the mixture. PFO: (*1–3*) nonmodified and (*4–6*) modified with OOPG. (*1, 4*) Nd–Fe–B, (*2, 5*) barium ferrite, and (*3, 6*) strontium ferrite.

C_e is measured under static conditions. The excess adsorption was evaluated by the equation

$$\Gamma = \frac{(C_0 - C_e)V}{m},$$

where C_0 and C_e are the initial and equilibrium (after contact of the solution with the filler) concentrations of the oligomer (mM), respectively; m is the filler weight (g); and V is the solution volume (ml).

By recalculating on 1 m^2 of the sorbent surface, we obtain the absolute value of adsorption (mg m^{-2})

$$\Gamma = \frac{(C_0 - C_e)V}{mS},$$

where S is the specific surface area (m^2 kg^{-1}).

* Thickness of the adsorption layer.

The experimental isotherms of the excess adsorption of PFO from its dilute alcohol–acetone solutions on the surface of various sorbents is presented in Fig. 1. This shape of the isotherms of adsorption from dilute solutions is characteristic of specific interaction of oligomer molecules with the sorbent surface. In adsorption of macromolecules from dilute solutions, when all components of the mixture are sorbed concurrently, determination of the limiting adsorption of the oligomer Γ_{max} presents some problems. Various approaches to determination of the limiting adsorption are considered in the literature, but they mainly concern adsorption of simple molecules [7, 8].

In adsorption from solutions of components that separate into layers in saturation, an S-shaped isotherm similar to isotherms of adsorption of vapors is obtained.

The limiting adsorption Γ_{max} was evaluated from the position of point *B* [8] in the isotherms of adsorption of the oligomer from dilute solution (Table 2). As seen, the highest Γ_{max} is observed with strontium ferrite, which is caused by its more developed surface and the charge effect of the double-charged strontium cation.

On adding OOPG into solution, the limiting adsorption increases by 60%, which is explained by improvement of solvent characteristics. The development of view on sorption from solutions is based on the concepts of excess and absolute adsorption (the total content). Based on these data, thermodynamic functions of adsorption solution can be evaluated using two procedures of thermodynamic consideration of adsorption systems: Gibbs method of excess quantities and the method of total content.

Isotherms of Gibbs adsorption do not carry information on the true parameters of adsorption layers formed on the filler surface. Adsorption of macromolecules from solutions is commonly accompanied by displacement of solvent molecules from the sorbent surface. Therefore, macromolecules of the oligomer always compete with the solvent for adsorption centers. It was shown [8] that, when the competition of solvent molecules is weak, adsorption can proceed to form an adsorption layer of oligomer macromolecules extended along the surface. Thermodynamic

parameters evaluated by the method of total content depend on the particular model of the adsorption solution (pore volume and limiting values of adsorption). These values reflect the real characteristics of the adsorption solution provided that the selected model is correct. As adsorption solution model, we can use a model considering sorption as mutual displacement of components, provided that

$$S = \Sigma n_i^S w_i,$$

where S is the specific surface area of the sorbent ($m^2 g^{-1}$), n_i^S is the number of moles of ith component in the surface layer, and w_i is the landing surface area of the adsorbent.

To check the reability of the selected parameters of the adsorption layer model (values of the limiting adsorption), we estimated variations of the Gibbs energy ΔG evaluated by the method of excess quantities and the method of total content ΔG_{mod} [9]. ΔG and ΔG_{mod} were evaluated by the equations

$$\Delta G = -\Delta\Phi + n^0 RT\Sigma X_{i0} \ln (X_i\gamma_i/X_{i0}\gamma_{i0}),$$

$$\Delta G_{mod} = -\Delta\Phi + n^0 RT\Sigma X_{i0} \ln (X_i/X_{i0}) + n^0[g^E(X) - g^E(X_0)] + n^S[g^{ES}(X^S) - g^E(X)],$$

$$g^E = RT\Sigma X_i \ln\gamma_i,$$

$$g^{ES} = RT\Sigma X_i^S \ln\gamma_i^S,$$

where $\Delta\Phi$ is variation in the chemical potential of the sorbent in its wetting with binary solution ($J g^{-1}$); g^E and g^{ES} are the excess energies of mixing of components in the solution and in the adsorption layer; γ_i and γ_i^S are activity coefficients of components in the solution and adsorption layer; and X_i and X_i^S are compositions of the solution and adsorption layer (mole fraction), respectively.

The activity coefficients of components in the solution were determined from the saturated vapor pressure. The activity coefficients of components in the adsorption layers were evaluated by the equation [9]

$$\ln\gamma_i^S = \ln (X_i/X_i^S) + \Delta\Phi/(\Gamma_{max} RT),$$

where Γ_{max} is the limiting adsorption ($mmol g^{-1}$).

Sufficiently good agreement between ΔG and ΔG_{mod} (Fig. 2) serves as a criterion of the validity of the selected model of adsorption layer and reliability of the proposed parameters of the adsorption phase.

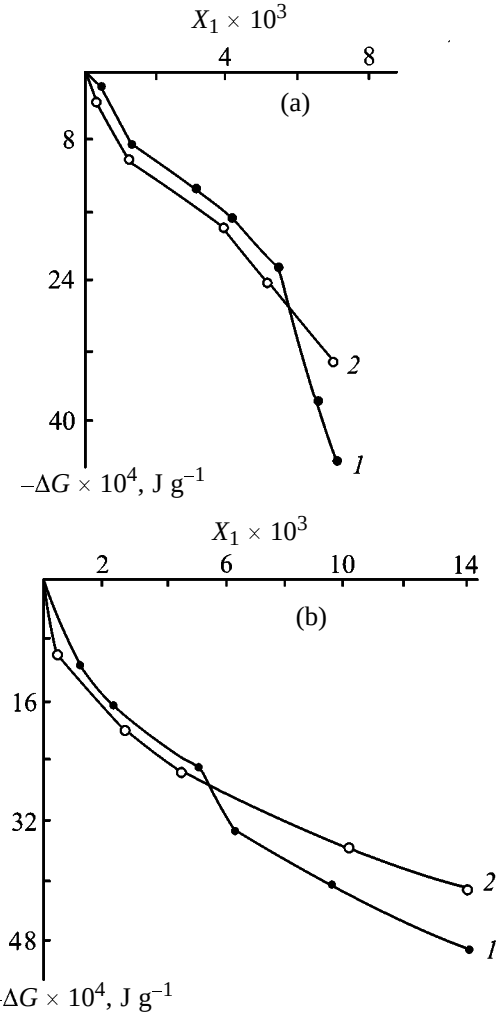

Fig. 2. Concentration dependences of variation of the system energy ΔG in adsorption of PFO modified with (a) ED-20 and (b) OOPG on the surface of Nd–Fe–B alloy, evaluated by the methods of (*1*) excess Gibbs parameters and (*2*) total content. (X_i) Mole fraction of PFO in the mixture.

The parameters of the adsorption phase Γ_{max} were used for evaluating the thickness of the adsorption layer and the equilibrium constant [10]. To estimate the thickness of the adsorption layer, we started from the assumption that the oligomer density in the adsorption state is identical to that in the samples. The thickness of the adsorption layer was evaluated by the equation

$$\tau = \overline{M}\Gamma_{max}/\rho,$$

where M is the reduced molecular weight of the oligomer, Γ_{max} is the limiting adsorption ($mg m^{-2}$), and ρ is the oligomer density ($g cm^{-3}$).

The thickness of the adsorption layer varied from 1

to 4 Å, which suggests parallel orientation of the adsorbed molecules extended along the surface.

In terms of the model of adsorption layer we evaluated the adsorption equilibrium constants (Table 2)

$$K_e = \frac{1}{1 - X_1^S},$$

were X_1^S is mole fraction of the component in the adsorption layer.

The resulting equilibrium constants suggest relatively weak interaction of oligomer macromolecules with the filler surface.

CONCLUSIONS

(1) Thermodynamic characteristics of adsorption systems were evaluated by the Gibbs method and the method of the total content. The features of their variation were established.

(2) The choice of the model of adsorption layer considering sorption as mutual displacement of components was substantiated.

SORPTION AND ION-EXCHANGE PROCESSES

Quaternization of 1,1-Dimethylhydrazine with Chloromethylated Polystyrene and Properties of Thus Prepared Anion-Exchange Resins

L. M. Antonik, V. A. Lopyrev, M. P. Tiunov, and G. V. Dolgushin

Abstract—Quaternization of 1,1-dimethylhydrazine with chloromethylated polystyrene is studied to optimize the procedure of preparation of new anion-exchange resins. Sorption characteristics of the resulting resins and their applicability to wastewater treatment to remove uranium are studied.

Cross-linked chloromethylated polystyrene (CMPS) is the basic intermediate for fabrication of anion-exchange resins. With primary and secondary amines, weakly basic anion exchangers are formed, and with tertiary amines, strongly basic anion exchangers [1]. 1,1-Dimethylhydrazine (DMH) shows promise as an aminating agent, since it can react with CMPS via both the primary and secondary amino groups to form anion-exchange resins with specific performance characteristics. Such resins are of particular interest in view of the fact that, being one of the basic components of propellants, DMH is accumulated in vast amounts in a number of countries. In context of the existing disarmament agreements this work is also of a social significance.

EXPERIMENTAL

Commercial CMPS (purchased from the OMIS Joint-Stock Company, Omsk) was washed with acetone and dried to constant weight. The chlorine content in the copolymer was found to be 16.1%. 1,1-Dimethylhydrazine was distilled at 63°C.

Quaternization of DMH with chloromethylated polystyrene was carried out as follows. The polymer (10 g) containing 0.43 mol of fixed chlorine was allowed to swell in 24 ml of dioxane for 15 or 60 min at room temperature. Then DMH in 50 ml of water was added. The amount of the aminating agent in the system is given in Table 1. The process was performed at 35–92°C. The resulting product was washed with distilled water and dried to constant weight.

The resulting resin was tested for the thermal and chemical resistance and anion-exchange performance according the standard procedures [2, 3]. The polymer samples in the H form (nitrogen content 8.4%) were placed in vials with distilled water and allowed to stand for 24 h at 80, 100, and 150°C. In studying the chemical resistance, 1 g of the air-dry resin was treated with 100 ml of 5 N NaOH, HNO_3, H_2SO_4, or 10% H_2O_2 at 20°C for 24 h or at 100°C for 1 to 90 h. Then the samples were washed, dried, and analyzed for the weight loss, nitrogen content, and exchange capacity. Sorption of the salts listed in Table 2 was studied with the resin in the corresponding salt and OH forms. A 1-g sample of the dry resin was stirred in 100 ml of 0.1 N salt solution until the equilibrium was reached (constant pH). The concentrations of Cu^{2+} and Mn^{2+} in the equilibrium solution were determined chelatometrically with Na_2EDTA and Murexide as an indicator, and that of Fe^{2+}, by titration with 0.1 N $KMnO_4$. The amount of absorbed metal was estimated from the difference between the metal concentration in the initial and equilibrium solutions. Sulfate was determined by titration with $Ba(NO_3)_2$ in the presence of the chelatometric indicator chlorophosphonazo III. The residual concentrations of MnO_4^-, $Cr_2O_7^{2-}$, $Fe(CN)_6^{3-}$, and AsO_3^- were determined by titration with 0.1 N $Na_2S_2O_3$ and $KMnO_4$. The amount of absorbed anions was determined from the difference between their concentrations in the initial and equilibrium solutions. The resin was tested as a sorbent for wastewater treatment to remove uranium. For comparison, several commercial sorbents were

tested under the same conditions (Table 3).[1] The wastewater composition was as follows (mg l^{-1}): U 0.09, surfactants 3.72, sulfate <40, and phosphate 82.4 (pH 9.2). The sorption capacity was determined by the static method with intermittent stirring (sample weight 2.5 g, liquid phase volume 0.25 l, contact time 4 days). The sorption power was estimated from the distribution coefficient Γ (ml g^{-1}):

$$\Gamma = A \times 10^3/C,$$

where *A* is the equilibrium sorption capacity for U (mg g^{-1}) and *C* is the U concentration in the equilibrium solution (mg l^{-1}).

The reaction of CMPS with hydrazine and some of its derivatives, including DMH, was reported previously [4–6]. However, we found no data on properties of the resulting products. Therefore, we studied the reaction of CMPS with DMH and characteristics of the resulting polymeric anion exchangers. The reaction was carried out in water or 32% aqueous dioxane. We studied the effects of the temperature, reagent ratio, and swelling time of CMPS in dioxane. We found (Table 1) that the reaction between CMPS and DMH proceeds at a noticeable rate at a temperature above 35°C and is completed in 1–4 h, the degree of

[1] Tests were carried out at the Novosibirsk Chemical Concentrates Plant, Joint Stock Company, Novosibirsk, Russia.

amination being dependent on the reaction time and DMH concentration, maximally approaching 71%. The static exchange capacity of modified CMPS (MCMPS) in 0.1 N HCl ranges from 1 to 3.4 mg-equiv g^{-1} (Table 1), indicating that it is a strongly basic anion exchanger whose macromolecules bear ionic groups formed via quaternization of DMH with CMPS. With increasing temperature to 92°C or DMH concentration the reaction accelerates, and the degree of amination approaches 8.5% in an hour. However, as the reaction time is further increased to 2.5 h the nitrogen content decreases to 7.9%. In this case we visually observed the decomposition of the initial CMPS granules at elevated temperatures.

It should be noted that the heterogeneous reaction of DMH with CMPS depends to a considerable extent on the swellability of the initial polymer in the reaction mixture. For example, the reaction in water at 92°C initially (in the first hour) is rather slow; the degree of amination in this case is as low as 12%, while after CPMS was preliminarily swollen for 15 min in an aqueous dioxane solution, all other reaction conditions being equal, the degree of amination increased by a factor of 4.7, whereas with increasing reaction time to 2.5 h it increased by a factor of only 1.8.

To reduce the effect of side reactions on the composition and properties of the anion exchangers, quaternization of 1,1-dimethylhydrazine with CMPS was performed at 55°C. However, in this case the degree of amination of CMPS gained in 2.5 h (38.8%) appeared to be lower by a factor of 1.7 as compared to the high-temperature reaction. With increasing reaction time to 4 h it increased to 70–71%, regardless of the swelling time of the initial CMPS.

Therefore, the optimal conditions for quaternization of DMH with CMPS are as follows: preliminary swelling of the initial polymer, aqueous dioxane as a reaction medium, temperature of 50–55°C, and reaction time of up to 4 h. All the data given below are related to MCMPS obtained under the indicated conditions.

The thermal and chemical resistance of anion exchangers is among the most significant criteria of their practical use. The test results showed that treatment of MCMPS with water at 80°C for 24 h causes only a slight weight loss (0.4%), the exchange capacity remaining practically unchanged (SEC 2.9 mg-equiv g^{-1}). Furthermore, these parameters remain unchanged even after treatment of the polymers with concentrated acids, alkalis, and hydrogen peroxide for 24 h at 20–30°C. However, at higher treatment temperatures (150°C for water or 100°C for the corrosive medium, τ 6 h) the exchange capacity decreases by 20–47% (in this case the nitrogen content decreases to 4–5%).

* (*C*) Concentration of U-containing pollutants in the solution.
** (*P*) Equilibrium concentration of U-containing pollutants in the sorbent phase.

A 90-h treatment of MCMPS with 5 N HNO_3 or NaOH provides a 20–46% weight loss, which is accompanied by total degradation of the polymer. Therefore, the operation temperature of the investigated anion exchanger should not exceed 80°C, and in the presence of strong acids or alkalis the temperature should be below 30°C.

The ion-exchange characteristics of the resin were studied by the static method. In the experiments we used the chloride and OH forms. The sorption was performed from metal sulfate solutions and also from solutions containing alkali metal salts with complex anions (Table 2). The results demonstrate that, depending on the metal, the sorption of sulfate with the resin in the chloride form is 24–45%, which is considerably higher than that with the OH form (4–12%) (Table 2). Simultaneously we observed that the resin sorbs cations from the metal sulfate solutions. The OH form sorbs more strongly the cations than the Cl form (by a factor of 2–10) (Table 2). It was demonstrated that the sorption of cations is pH-dependent to a considerable extent: the cations are not sorbed from strongly acidic sulfate solutions (pH 2–3).

In the case of alkali metal salts with complex anions it was demonstrated that the cations, being strongly hydrated, are less efficiently sorbed, whereas the anion-exchange efficiency reaches 97–99% (Table 2).

To conclude, ion exchange in the static mode with MCMPS appeared to be quite efficient method for concentration of metals contained in complex anions, since these anions are readily desorbed in regeneration.

This method, requiring no sophisticated equipment, proved efficient in U recovery and concentration from wastewater (Table 3). Comparative analysis of data obtained with various sorbents shows that MCMPS has the best sorption capacity for uranium (U distribution coefficient 8900 ml g^{-1}).

CONCLUSIONS

(1) A method for utilization of 1,1-dimethylhydrazine is proposed, based on its quaternization with cross-linked chloromethylated polystyrene. As a result, strongly basic anion exchangers are obtained. The static exchange capacity for chloride of the resulting resins, measured in 0.1 N HCl, is 1–3.4 mg-equiv g^{-1}.

(2) Results on the thermal and chemical resistance of the anion exchangers reveal that their operation temperature should be below 80°C, and in the presence of strong acids or alkalis, 20–30°C.

(3) Ion exchange in the static mode with MCMPS is a quite efficient method for recovery and concentration of metals, particularly, uranium.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Microdistribution in Electrodeposition of Tin–Antimony Alloy from Sulfate Electrolytes with Organic Additives

G. I. Medvedev, S. S. Kruglikov, and N. Yu. Fursova

Novomoskovsk Institute, Mendeleev Russian University of Chemical Engineering, Novomoskovsk, Tula oblast, Russia

Received April 12, 2001

Abstract—The process of microdistribution in deposition of a tin–antimony alloy from sulfate electrolytes with organic additives (Syntanol, formalin, butynediol, coumarin, and benzyl alcohol) was studied.

The electrodeposition of the Sn–Sb alloy from sulfate electrolytes with organic additives was studied in [1–5]. It was shown that lustrous alloy coatings are formed at current densities in the range 0.5–12 A dm^{-2} from electrolytes containing simultaneously Syntanol, formalin, and butynediol; or Syntanol, formalin, and coumarin; or Syntanol, formalin, and benzyl alcohol. The content of antimony in the alloy varies between 0.6 and 32.5 wt %, depending on the electrolyte composition. With increasing cathodic current density, the content of antimony in the alloy decreases. It was of interest to study the leveling power of the given electrolytes.

Sulfate electrolytes for electrodeposition of the tin–antimony alloy were prepared from $SnSO_4$ and H_2SO_4 (both of chemically pure grade). Antimony was introduced into the electrolyte as follows. Antimony was preliminarily ground to obtain a finely dispersed powder which was then dissolved in concentrated H_2SO_4 with heating. The obtained $Sb_2(SO_4)_3$ solution was added to the electrolyte. The following organic additives were used: Syntanol DS-10 [TU (Technical Specifications) 6-14-577–77], formalin [37% solution, GOST (State Standard) 1625–75], 1,4-butynediol 35% solution, TU 6-45-52–79), coumarin, and benzyl alcohol (the last two of chemically pure grade). The composition of the main electrolyte used in the study was as follows (g l^{-1}): $SnSO_4$, 10 and 30; $Sb_2(SO_4)_3$, 0.8; H_2SO_4, 100; Syntanol, 2; and also formalin, 6 ml l^{-1}. Additionally, the following organic agents were introduced into the electrolyte: butynediol, 40 ml l^{-1} (electrolyte no. 1); coumarin, 2 g l^{-1} (no. 2); and benzyl alcohol, 5 ml l^{-1} (no. 3). The study was carried out at 20–22°C. Polarization curves were measured on a rotating disk electrode with a P-5827 potentiostat in the potentiodynamic mode. Before measuring a polarization curve, a 10-μm-thick layer of the tin–antimony alloy was deposited onto the disk electrode surface. The leveling power (P) of the electrolytes was determined directly by profiling of the sample surface with a sinusoidal microprofile. P was calculated by the formula [6]

$$P = \frac{2.3a}{2\pi h_{av}} \log (H_0/H_\tau),$$

where a is the wavelength of the sinusoidal microprofile (μm); h_{av} is the average coating thickness (μm); and H_0 and H_τ are, respectively, the initial and final amplitudes of the sinusoidal microprofile (μm).

The electrodeposition was performed under stirring with a blade stirrer at a speed of rotation of 300 rpm. The deposit thickness was 10 μm.

To reveal the influence exerted by separate organic substances on the microdistribution process, the dependence P–i_c was studied in electrolytes with various organic substances. The presence of only Syntanol in the electrolyte leads to minor leveling (P = 0.25–0.15) only at i_c = 0.5–1.0 A dm^{-2}. With i_c increasing beyond these limits, antileveling is observed. Addition of formalin to an electrolyte with Syntanol enhances the antileveling at i_c = 0.5–4.0 A dm^{-2} (Fig. 1, curve *2*). With the current density increasing to 5–7 A dm^{-2}, the antileveling effect becomes weaker, and at i_c = 8 A dm^{-2} P = 0. In electrolyte nos. 1–3, surface leveling occurs (Fig. 1, curves *3*–*8*). Thus, the last three substances among the mentioned organic compounds (Syntanol, formalin, butynediol, coumarin, and benzyl alcohol) are leveling additives.

1070-4272/01/7411-1817$25.00

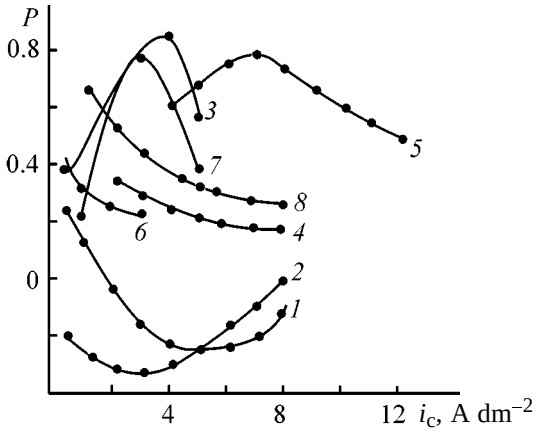

Fig. 1. Leveling power *P* of sulfate electrolytes in electrodeposition of Sn–Sb alloy vs. current density i_c. Electrolyte composition (g l^{-1}): $SnSO_4$ 30, $Sb_2(SO_4)_3$ 0.8, and H_2SO_4 100; the same for Fig. 2. (*1*) Electrolyte + Syntanol, 2 g l^{-1}; (*2*) *1* + formalin, 6 ml l^{-1}; (*3–5*) *2* + butynediol (40 ml l^{-1}), or coumarin (2 g l^{-1}), or benzyl alcohol (5 ml l^{-1}), respectively; (*6–8*) *3–5* with $SnSO_4$ (10 g l^{-1}).

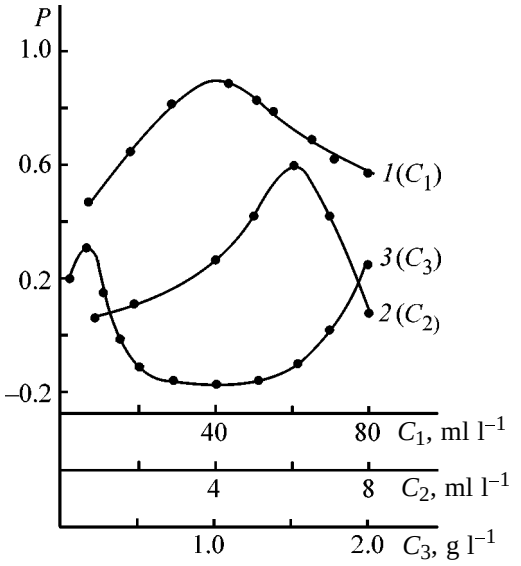

Fig. 2. Leveling power *P* of sulfate electrolytes for electrodeposition of Sn–Sb alloy vs. additive concentrations C_1, C_2, and C_3 at i_c = 4 A dm^{-2}. Additive: (*1*) butynediol, (*2*) benzyl alcohol, and (*3*) coumarin. Electrolyte + Syntanol (2 g l^{-1}) + formalin (6 ml l^{-1}); the same for Fig. 3.

Figure 1 shows that the dependence P–i_c is determined in electrolyte nos. 1–3 by the nature of a leveling additive and $SnSO_4$ concentration in the electrolyte. At $SnSO_4$ concentration of 30 g l^{-1} in electrolyte nos. 1 and 3 the dependence P–i_c passes through a maximum (curves *3*, *5*), and in electrolyte no. 2 *P* decreases with increasing i_c (curve *4*). In electrolyte nos. 1 and 3, containing 10 g l^{-1} of $SnSO_4$, the leveling power decreases with increasing i_c (curves *6*, *8*). In electrolyte no. 2, the dependence passes through a maximum, with the highest leveling power (P = 0.9) observed in the presence of butynediol (curve *3*).

The influence exerted by the concentrations of the leveling additives on *P* is illustrated in Fig. 2. It can be seen that, with increasing concentrations C_1 and C_2 of, respectively, butynediol (curve *1*) and benzyl alcohol (curve *2*), the *P* value passes through a maximum. For butynediol the highest leveling power (P = 0.9) is observed at concentration C_1 = 40, and for benzyl alcohol (P = 0.6), at C_2 = 6 ml l^{-1}. In electrolyte no. 2, the highest leveling power (P = 0.31) is achieved at C_3 = 0.1 g l^{-1} (curve *3*). Further increase in the coumarin concentration results in a dramatic decrease in *P*. At C_3 = 0.5–1.5 g l^{-1}, even antileveling of the surface is observed (P –0.1 to –0.18). At coumarin concentrations exceeding 1.5 g l^{-1} the degree of antileveling decreases, and at 2 g l^{-1} a weak leveling is again observed (Fig. 2, curve *3*).

Figure 3 presents cathodic polarization curves for alloy deposition from electrolytes with organic additives in relation to the speed of electrode rotation. It can be seen in Fig. 3a that raising the speed of rotation in electrolyte no. 3 to 200 rpm makes the cathodic polarization of the alloy deposition lower (curve *2*). However, with the speed of rotation increasing further, to 2000 rpm, the cathodic polarization grows somewhat (curve *3*). In electrolyte nos. 1 and 2 (Figs. 3b, 3c), a limiting-current plateau (I_{lim}) is observed in the cathodic polarization curves. With increasing speed of rotation, the i_{lim} value grows steeply and the cathodic polarization becomes lower (Figs. 3b, 3c, curves *1–6*). The i_{lim} value in these electrolytes is determined by adsorption of organic substances and formation on the electrode surface of polymolecular adsorption layers (Loshkarev effect) [7].

The mechanism of surface leveling is commonly explained in terms of the adsorption–diffusion theory [6] whose basic concepts are the following. All leveling additives inhibit electrodeposition of metals (alloys), with the extent of inhibition controlled by diffusion. Polarization curves measured with a rotating disk electrode at different speeds of rotation can qualitatively model the cathodic process at microprojections (high speeds of rotation) and in microdepressions (low speeds) [6]. The varied accessibility of the microprofile is the reason for nonuniform distribution of the rate of supply of organic substances to different parts of the microprofile. Since the inhibit-

ing influence exerted by leveling additives on metal (alloy) electrodeposition becomes stronger with increasing rate of diffusion of an additive toward the cathode (high speed of rotation), this influence is more pronounced at microprojections, and less so at microdepressions. This results in a nonuniform distribution of the metal electrodeposition rate. In view of the aforesaid, it was proposed to use for evaluating the influence of various additives the changes in cathodic polarization in going from one stirring mode to the other. If polarization grows with increasing speed of electrode rotation, then it would be expected that the additive should exert leveling influence under the given conditions.

Analysis of the polarization curves measured in electrolytes with organic additives shows that, in contrast to the cathodic polarization curves measured in electrolyte no. 3 (Fig. 3a), the polarization curves taken in electrolyte nos. 1 and 2 (Figs. 3b and 3c) in different stirring modes do not model the distribution of the alloy electrodeposition rate over the microprofile. The possible reason is that polymolecular adsorption layers are formed in this case. The hydrodynamic mode intensification affects the processes of formation and disintegration of such layers, with the rate of deposition of the alloy components changing in such a way that it outwardly looks like a manifestation of the antileveling effect. In view of this fact, the dependences P–i_c and P–C in electrolyte no. 3 can be accounted for as follows. With increasing i_c, first an increase in the leveling power is favored and then, at relatively high current densities, the high rate of surface renewal results in that the surface concentration of the additive and its inhibiting influence decrease even at microprojections, which must make the leveling effect weaker. At a too low content of an additive in the electrolyte, when the process of alloy electrodeposition is inhibited only slightly, it is unlikely that the leveling effect will be pronounced. At the same time, at too high additive concentrations the leveling power decreases, because the rate of supply of the additive and its inhibiting action are no longer diffusion-controlled.

It should be noted that the lower and upper limits of the concentration range with the maximum leveling power depend on (i) the electrolysis conditions (and current density, in particular) and (ii) the nature of leveling additives and presence of other organic substances in the electrolyte [6].

Electrodeposition from electrolytes in which polymolecular layers of organic substances are formed on the electrode surface has its specific features, e.g., the

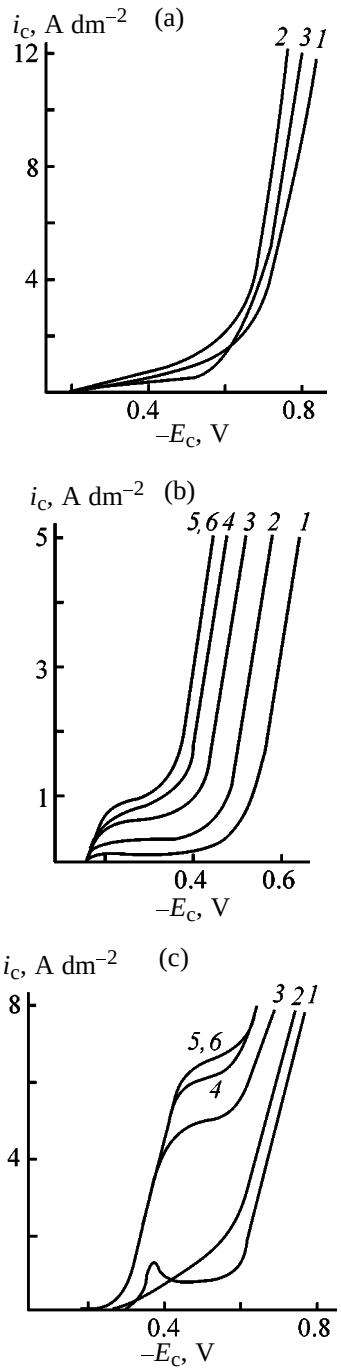

Fig. 3. Cathodic polarization curves of Sn–Sb alloy electrodeposition, measured in electrolyte nos. 1–3 at different speeds of electrode rotation. (i_c) Current density and (E) potential vs. standard hydrogen electrode. Electrolyte: (a) no. 3, (b) no. 1, and (c) no. 2. Speed of rotation (rpm): (*1*) 0, (*2*) 200, (*3*) 500, (*4*) 900, (*5*) 1500, and (*6*) 2000.

appearance of the adsorption-related limiting current. As seen from Fig. 3, this current markedly grows with increasing speed of rotation of the cathode. This is an indisputable proof of the influence exerted by the hy-

drodynamic mode on the properties of polymolecular layers. Their partial disintegration with increasing speed of rotation of the disk electrode leads to higher limiting current and lower cathodic polarization. At the same time, as indicated by direct measurements of the microdistribution of metal, the difference between the rates of supply of organic substances to microprojections and microdepressions, leading to the corresponding difference in their inhibiting influence, i.e., to positive leveling, is preserved at any particular hydrodynamic mode.

The change in the leveling powers of sulfate electrolytes with organic additives at $SnSO_4$ concentrations of 10 and 30 g l^{-1} (Fig. 1) shows that the adsorption–diffusion processes depend not only on the hydrodynamic conditions, but also on the metal ion concentration.

Thus, leveling of the surface microprofile is observed in electrodeposition of the Sn–Sb alloy from sulfate electrolytes with organic additives. Depending on the nature of organic substances, the cathodic polarization may either increase or decrease with increasing speed of rotation of the disk electrode. A decrease in the cathodic polarization with increasing speed of electrode rotation is observed in those cases when polymolecular adsorption layers are formed on the electrode surface. In systems of this kind, cathodic polarization curves obtained at different speeds of electrode rotation cannot model the distribution of the alloy electrodeposition rate over the microprofile because of the sensitivity of the adsorption layer, inhibiting the electrodeposition, to the hydrodynamic conditions. Apparently, measurements of cathodic polarization curves on a disk electrode at different speeds of rotation cannot be taken in this case as a basis for distinguishing between the leveling and nonleveling additives, as follows from the adsorption–diffusion theory of leveling [6].

CONCLUSIONS

(1) The microdistribution in electrodeposition of the tin–antimony alloy from sulfate electrolytes with organic additives (Syntanol, formalin, butynediol, coumarin, and benzyl alcohol) was studied. It is shown that, in electrolytes simultaneously containing Syntanol, formalin, and butynediol; or Syntanol, formalin, and coumarin; or Syntanol, formalin, and benzyl alcohol, the effect of leveling of the surface microprofile is observed.

(2) Depending on the nature of organic substances, the cathode polarization in alloy deposition may either increase or decrease with increasing speed of rotation of the disk electrode. The latter is observed in electrolytes in which polymolecular adsorption layers of organic substances are formed on the electrode surface.

(3) In the electrolytes in which polymolecular adsorption layers of organic substances are formed on the electrode surface, cathodic polarization curves obtained at different speeds of electrode rotation cannot model the distribution of the alloy electrodeposition rate over the microprofile and cannot serve as a basis for distinguishing between leveling and nonleveling additives.

Abstract—Specific features of formation of a "pyramidal" surface relief and [110] texture in "raw" electrolytic copper foil obtained in industrial electrolyzers with rotating titanium drum cathode at varied current density and electrolyte composition and temperature were studied. The effect of how the drum cathode is treated prior to deposition on the crystal structure and surface topography of the raw foil was analyzed.

Presently, electrolytic copper foil (ECF) is most widely used for fabricating printed-circuit boards for radioelectronics. The foil is produced from "raw" ECF, thin (18–100 μm) solid electrolytic deposit of copper, commonly obtained in the form of a ribbon "continuously" coming out of an electrolyzer with rotating drum cathode. The deposition is performed at very high current densities and electrolyte circulation rates. It suffices to mention that deposition under the same current densities from unstirred electrolytes of the same composition must give powders [1–3].

Studies of thin solid electrolytic deposits of copper have been largely stimulated by the problem of obtaining raw ECF with a prescribed set of physical and technological properties, such as, e.g., roughness of the inner ("glossy") and outer ("rough") sides (relative to the cathode), continuity, plasticity, strength, etc. Nevertheless, published data on the structure, surface topography, and physical and technological properties of deposits formed on cathodes moving in a high-rate electrolyte flow are scarce [1, 2]. In this work we studied the structure and surface topography of copper deposits formed directly in industrial electrolyzers with rotating titanium drum cathode. The data are of interest not only from the technological standpoint, but also for revealing the specific features of copper electrocrystallization under such specific conditions.

EXPERIMENTAL

The foil was obtained in commercial KFE 1200/320 (henceforth KFE) and BEL-12M (BEL) electrolyzers and AIST 1600 M (AIST) pilot installation differing from BEL only in cathode diameter. The diameters of drum cathodes made of VT-1.0 forge titanium were, respectively, 320, 900, and 1600 mm. The foil width was 1200 mm. Detailed schematics of electrolyzers of this kind and their operation conditions were reported in [1, 2]. It is noteworthy that an additional insoluble anode made of an alloy of lead with silver was mounted at the bath exit of the KFE electrolyzer. In addition, prior to deposition, the surface of the drum cathode was subjected to mechanical polishing and anodizing in the case of KFE and only to mechanical polishing for BEL and AIST. The thickness of the raw foil was 32 ± 2.5 μm in all experiments, which was ensured by adjusting the speed of rotation of the drum cathode.

The electrodeposition conditions are presented in the table, with average "geometric" current densities D_c given. Figure 1b shows "local" current densities $D(L)$ in different parts of the drum cathode, situated near its section, circle, at a distance L from the entrance into the electrolyzer bath. For convenience of comparison, D and L are normalized to the maximum current density in the distribution, D_{max}, and the total length S of that part of the circumference of the drum cathode which is submerged in the electrolyte. These dependences are individual characteristics of electrolyzers, and their shape is close to that reported in [12]. The absolute $D(L)$ values can be readily found using the data in the table (D_c) and D_c/D_{max} values presented in Fig. 1b.

* $C_{Cu^{2+}}$, $C_{H_2SO_4}$, and $C_{b.g.}$ are the concentrations of copper(II) ions, sulfuric acid, and bone glue, respectively, in the electrolyte; D_c is the ratio of the current load to the surface area of the cathode through which current is passed; T is the averaged electrolyte temperature at its entrance into, and exit from the interelectrode space (±1.5°C); P_{hkl}: data for the rough and glossy sides of ECF are given in the numerator and denominator, respectively.

The surface topography was studied using YCXA-733 and REM-100 U scanning electron microscopes at inclinations of the sample plane with respect to the horizontal plane of the microscopes equal to 0 and 30°. Outlines of projections (at base) were clearly seen in SEM surface images of the rough side of the foil, obtained without sample tilt (Fig. 2b). The conventional metallographic method of determining the average length of a segment intersecting a contour [4] was used to evaluate the average size of projection bases in the focal plane, d, and the averaged relative deviation of this value, $\Delta d/d$ (see table). The images obtained with inclined samples (Fig. 1) suggest that the projection height must not exceed substantially half their transverse size at base.

The surface topography was also studied using carbon–chromium replicas on an EMMA-4 transmission electron microscope (TEM) with a considerably higher resolution (Fig. 3). The results obtained in studying the surface topography were compared with TEM images of microstructure, obtained on the same microscope. For this purpose, ECF samples were thinned on both sides with a 66% aqueous solution of orthophosphoric acid.

The microstructure of ECF cross sections was

Fig. 1. studied on an Ynavert optical microscope (Fig. 4). To reveal the microstructure, the cross sections were thoroughly polished and then etched for several seconds in a mixture of aqueous solutions of ammonia (25%, 50 ml) and hydrogen peroxide (3%, 50 ml). It is noteworthy that the finishing polishing was always done along the foil surface.

The texture was studied using a DRON-2.0 X-ray diffractometer with CoK_α radiation and iron filter. The texturing coefficient P_{hkl} was found in the experiment [3, 5]

$$P_{hkl} = n(I_{hkl}/I_{r,\,hkl})[\Sigma\,(I_{hkl}/I_{r,\,hkl})]^{-1}, \qquad (1)$$

where I_{hkl} and $I_{r,\,hkl}$ are the intensities of X-ray reflections in the sample being analyzed and texture-free

(isotropic) sample, respectively; and n is the number of samples being analyzed.

For the texture-free sample, $P_{hkl} = 1$, whereas at full orientation of grains in a direction toward one of the (hkl) planes $P_{hkl} = n$. An analysis of P_{hkl} was made for the four strongest copper reflections (see table).

The thickness of the layer of 50–75% attenuation of the CoK_α X-ray radiation by copper in the considered range of Bragg reflection angles is 408 μm [6]. This makes it possible to trace changes in P_{hkl} across the foil thickness by successively removing from the foil surface layers 5–10 μm thick. To perform a layer-by-layer analysis, a foil sample was glued onto the surface of a diffractometer holder, and then polished mechanically on a Metapolan installation with controllable load on the ground section and time of polishing. The automated mode was used, ensuring chaotic motions of a sample in a suspension of GOI abrasive paste. The object thickness was determined with a micrometer with an accuracy of ±2.5 μm. For clarity, the reduced texturing coefficient was used (%) (Fig. 1a)

$$P^*_{220} = 100(P_{220} - 1)/3, \quad (2)$$

for the relative distance from the foil surface (depth) x/h, where h is the foil thickness. The value $x = 0$ corresponds to the glossy side.

It is known [5] that mechanical polishing of metals (including copper) gives rise to strains in the surface layer of thickness (0.5–1 μm) (Bilby layer), which lead to a profound change in its structure: grain becomes finer, deformation texture appears, etc. If the thickness of the object being analyzed is comparable with the Bilby layer thickness, the latter will make a noticeable contribution to the diffraction pattern, which is commonly the case in electron diffraction studies of mechanically polished samples. No noticeable broadening of X-ray reflections was observed in the present study on going from the initial glossy to a polished surface, which is the primary indication of the influence exerted by the fact that the grains become finer on the results of X-ray diffraction analysis. Even if the surface layer texturing does exist, the corresponding contribution to P_{hkl} at different analysis depth must be approximately the same in view of the identical polishing conditions.

For a foil from the KFE apparatus, the microprojections on the rough side have the form of pyramids or hemispheres (see table, Fig. 2). In more detail the structure of these surface units (growth forms) can be seen in TEM images of carbon–chromium replicas of the rough side of sample no. 2 (Fig. 3).

Two types of pyramids are clearly distinguished: pointed and truncated, with the former occurring more frequently than the latter (Figs. 3b and 3c). The pyramids have complex multifaceted relief of the lateral surface, characterized by the presence of a great number of reentering angles, which are presumably associated with the emergence of twinning planes to the lateral surface (Figs. 3a–3c). As a rule, the pyramids are much larger than hemispheres (Fig. 3b). Projections, represented by a single growth form, occur rarely. Elements of faceting are present on the lateral surface of the hemispheres (Fig. 3c). Presumably, with increasing size of separate projections, hemispheres turn into pyramids.

The size and relative content of projections of various shapes on the surface of ECF produced in the KFE apparatus strongly depend on the deposition conditions (see table). With decreasing current density or increasing volume content of copper ions in the electrolyte with prescribed content of additives, pyramids with rather close sizes and orientations relative to the normal to the surface occur as the main growth form on the surface (Figs. 2a, 2b, sample nos. 1, 3). Contrariwise, at higher current densities and low content of copper(II) in the electrolyte, the fraction of small hemispheres increases dramatically on the ECF surface, with larger pyramids also present (Fig. 3, sample no. 2). Correspondingly decreases the average size of projections and increases the averaged deviation $\Delta d/d$. It is noteworthy that increasing current density, decreasing concentration of discharging ions in the electrolyte bulk, and decreasing temperature of the electrolyte correspond to higher degree of concentration limitations on the course of the cathodic reaction (to a decrease down to zero of the concentration of ions discharging at the cathode surface) [7].

The texturing of the rough side of ECF strongly depends on its surface topography. The texturing coefficient P_{220} grows with increasing number of pyramids on the surface of the rough side, and falls with increasing number of hemispheres (see table). Lowering the content of bone glue in the electrolyte leads to a substantial decrease in projection sizes. The corresponding decrease in P_{220} may be due both to an increase in the fraction of hemispheres and to mutual misorientation of small pyramids, which make up large globular formations together with hemispheres (Figs. 2c, 2d).

According to [8], there exists a direct relationship

between the growth form on the surface and TEM images of the microstructure in the bulk of thin deposits of nickel, which is close to copper in crystal structure and electrochemical parameters. No clear-cut relationship of this kind was observed in the case of ECF. The electron-microscopic contrast in grains is a typical "twinning" contrast formed by a set of lines intersecting at multiple twinning sites or parallel to one another. It is only possible to distinguish elements of intragrain microstructure, corresponding to the established [8] twinned pentahedral pyramids with growth direction [110] (Fig. 3e). To the hemispheres presumably correspond microstructural elements shown in Fig. 3d. To truncated pyramids (with growth direction [211] [8]) must correspond grain microstructure with a set of equally spaced parallel twinning lines. Such elements can also be found in TEM images (Fig. 3f). Commonly, the intragrain structure is exceedingly complex and indicates the presence in a growing projection of several multiple-twinning axes (Fig. 3f). It is noteworthy that the TEM images of the microstructure of different ECF samples analyzed in this study are very similar. With increasing texturing of the rough side, only the number of twinning lines and nodes grows in the foil bulk.

The highly textured electrolytic deposits of copper must be characterized by "columnar" grain microstructure on cross sections [3]. It is of interest to correlate the data on the microstructure of cross sections of ECF obtained in the KFE apparatus (Figs. 4a, 4b) with changes in the texturing coefficient across the foil thickness (Fig. 1a). The pyramid growth presumably occurs only at a certain deposit height, nearer to the rough side of ECF. It is in this region that the columnar structural elements and the corresponding drastic increase in the texturing coefficient are most clearly observed (Figs. 4a, 1a, respectively). Sections of the texture-free sample no. 5 (Fig. 4b) show no elements of this kind. Fine randomly oriented pyramids (Fig. 2d) have no continuation in the bulk and, in all probability, are nuclei of this growth form on the surface of the rough ECF side.

ECF is formed in the KFE electrolyzer under the conditions when the spherulite and pyramidal growth forms coexist. It is known that, when concentration limitations are lifted, it is through the spherulites that the transition to solid textured copper deposits occurs [9, 10]. Spherulites [11] are three-dimensional (3D) nuclei developing in the radial direction. A solid deposit obtained under strong concentration limitations may be entirely composed of very fine spherulites [12].

The pyramid growth mainly occurs in the region where the foil exits the KFE electrolyzer bath. The appearance of the pyramidal growth form on the ECF surface as the main topographic element may be largely due to the presence of an additional anode at the KFE electrolyzer exit. Its presence makes longer the working path of the drum cathode with current flowing, thereby improving the electrolyzer efficiency, and, at the same time, ensures a delay in current density drop at the foil exit from the electrolyzer, as seen in Fig. 1. This presumably creates conditions for transition from the spherulite to the pyramidal growth form. Without an additional anode, the ECF has the same topographic characteristics as sample no. 4 (Fig. 2c). Concretions of fine pyramids and hemispheres are always present on its surface. The surface topography does not change significantly on varying the deposition conditions within the same limits.

The pyramids are the main structural element on the surface of the rough side of ECF obtained in BEL and AIST apparatus under any deposition conditions (see table). Lowering the current density (at fixed temperature) and elevating the electrolyte temperature (at fixed current density) equally lead to an increase in the pyramid size (see table, Figs. 2e, 2f). At the lowest current densities and elevated temperatures (sample no. 7), rather large polyhedra without clearly pronounced vertices appear together with the pyramids (Fig. 2e).

The optical cross-sectional images of foils produced in AIST and BEL apparatus clearly show "columnar" grains (Figs. 4d, 4e). Inside the grains, sets of parallel lines are present, intersecting the foil from both sides. Raising the current density and lowering the temperature leads to a more clearly pronounced microstructure of this kind over the entire section surface. It may be assumed that the formation of pyramids in the case of strongly textured foils produced on AIST and BEL apparatus begins in the immediate vicinity of the glossy side, and then the mechanism of their growth remains unchanged until the removal of the foil from the drum cathode. The observed intragrain microstructure may result from the presence within a pyramidal projection of several multiple twinning axes parallel to the direction of its growth and, correspondingly, from the intersection of the twinning surfaces with the section surface. The possible formation of such a kind of microstructure was mentioned in [8].

These results are in agreement with data on variation of the texturing coefficient across the ECF thickness (Fig. 1a). The most strongly textured foils are

characterized by a steep rise in P^*_{220} (x/h) already near the glossy side. The higher the current density and the lower the temperature, the higher the texturing coefficient at any distance from the surface (of those studied). Thus, in contrast to KFE, the deposition of foils with higher texturing coefficient in the BEL and AIST apparatus occurs under the conditions of enhanced concentration limitations on the cathodic reaction.

The variation tendencies displayed by the crystal structure and topography of ECF obtained in different apparatus under different deposition conditions are, on the whole, in agreement with the existing concepts of how various types of electrolytic copper deposits are formed [13, 14]. With increasing extent of concentration limitations, the structural types of solid electrolytic copper deposits must replace one another in the following order: BR $\rightarrow$ (Z $\rightarrow$ FT) $\rightarrow$ UD [14].

In experiments on AIST and BEL, the projection size grows, and even large polyhedra appear on the surface, with decreasing extent of concentration limitations. This presumably reflects a transition to layered deposits of the BR type, whose growth is commonly attributed to development of 2D nuclei.

Under virtually any deposition conditions, a foil is formed in AIST and BEL apparatus, whose cross-sectional microstructure is characteristic of deposits with twinning (Z) and fibrous (FT) types of texture. The growth of deposits of this kind may be related to development of "quasi-2D" layers whose growth rate in directions perpendicular to the cathode surface markedly exceeds the rate of their spreading along its surface [13].

The formation of solid fine-grained unoriented UD deposits is related to development of “3D” nuclei. In the case of the KFE apparatus, the UD structural type is the main constituent of the foil microstructure. With increasing extent of concentration limitations, the share of this component grows, whereas in the opposite case, with the concentration limitations becoming weaker, the fraction of the texture component grows. A transition to UD deposits must occur faster if the content of a surfactant in the electrolyte is raised [14]. This is well illustrated by the example of KFE foils obtained at different amounts of additives.

The shape of the pyramidal projections on the surface of deposits with [110] texture, studied in [3, 15–17], is in close agreement with that reported here. It should be emphasized that the problem of relationship between the shape of the pyramidal projection and the mechanism of its growth in the case of the [110] texture remains unsolved. Formation of pyramids with multifaceted relief of the lateral surface cannot be described in terms of a simple model of nucleation and growth of 2D layers [3, 14].

In the experiments, pyramids were formed under conditions close to (AIST, BEL), or exactly coinciding with (KFE) the conditions when the 2D nucleation is replaced by 3D nucleation. According to the obtained results, twinning may occur in the growth of a pyramidal projection not only on lateral (111) faces [3, 14, 18], but also with formation within the projection of multiple twinning axes in the direction of its vertical growth. It is the emergence of the twinning planes on the lateral face that possibly gives rise to its complex topography. In this study, the direction of preferred orientation was determined to be [110]. Nevertheless, a pyramidal projection may also be formed as a result of development of a multiply twinned quasi-2D nucleus of specific shape, e.g., with a [411]t twinning axis close to the [110] texture axis [15]. This issue invites further, more detailed investigation of the ECF texture by special diffraction techniques [5, 15].

The foil produced by the AIST and BEL apparatus markedly differs from that formed in KFE both in the surface topography of the rough side and in the microstructure and extent of its texturing, especially in the initial stages of growth. The difference between the growth mechanisms of deposits is clearly seen in SEM images of their glossy sides. The surfaces of the glossy sides of the AIST and BEL foils are identical (Fig. 4f), being an exact replica of the mechanically polished surface of the drum cathode. The presence of a minor amount of “nonlinkability” micropores indicates that atomic layers of the deposit spread over the cathode surface to the point of projection merging. The surface relief on the glossy side of the KFE ECF is much more pronounced. The obtained SEM images (Fig. 4c) indicate that a great number of 3D crystallites with faces of several micrometers in size grow in the immediate vicinity of the cathode. It should be emphasized that this difference between the topographies of the glossy sides of ECF was preserved under any deposition conditions, even in those cases when these conditions were close for all the three electrolyzers (sample nos. 1, 10, 15).

The observed difference in the ECF structure is possibly due to anodic oxidation of the drum cathode, which is an additional operation in surface treatment of the drum cathode of the KFE electrolyzer. Similar changes in the ECF surface topography and the texturing coefficient have already been observed previously

in studying the electrodeposition of copper onto stationary and submerged titanium cathodes with different types of surface treatment: mechanical polishing and anodic oxidation [16, 17, 19]. In the initial stage of deposit growth, anodizing the titanium cathode leads to greater number and smaller size of nuclei. Further effect of the layer formed in anodic oxidation is in all probability due to the increasing content of ions of titanium and its colloid particles, which are formed in cathodic reduction of an oxohydride titanium film [20].

CONCLUSIONS

(1) Electrolytic copper foil is obtained in electrolyzers with rotating titanium drum cathode under conditions close to, or exactly coinciding with the conditions of 3D deposit nucleation, which predetermines the texture and topography of the foil surface.

(2) The growth of a foil with [110] texture is accompanied by formation of pyramidal projections on its surface. The complex multifaceted relief of the lateral surface of these projections is presumably due not only to twinning at the crystallization front, but also to formation within a projection of [110] multiple twinning axes in the direction of the vertical growth of the projection.

(3) The deposition conditions under which the foil possesses the maximum extent of [110] texturing were determined. Anodizing the titanium drum cathode favors 3D nucleation and presumably accelerates the transition to electrolytic copper foil with unoriented microstructure and surface relief of fine hemispheres.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic Dissolution of Titanium Alloys in Hydrofluoric-Sulfuric Acid Electrolytes with Additives

E. A. Fedorova

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received July 2, 2001

Abstract—Anodic dissolution of VT1-0, VT6, and VT16 titanium alloys in hydrofluoric-sulfuric acid solutions with addition of alkali metal fluorides, glycerol, hexamethylenetetramine, and remantadine was studied in a wide range of potentials.

Commonly, the anodic behavior of "pure" metals, both in the range of limiting currents [1–3] and in the post-passive state [4], is accounted for in terms of diffusion mass-transfer [4, 5] and formation of a thin surface salt film on a metal [6]. The possibility that an anodic oxide film (AOF) is formed on the metal surface and is chemically dissolved in acid electrolytes for anodic treatment is not ruled out, either [1–4]. Specific features of anodic dissolution of alloys with varied extent of alloying are less understood. Of practical interest is anodic treatment of titanium alloys as a preliminary operation before depositing a titanium nitride layer on articles for aircraft, natural gas, and other industries [7–9]. As shown previously [8, 9], electrochemical treatment of the surface of VT1-0, VT6, and VT8 titanium alloys in the developed electrolytes made it possible to obtain the required functional characteristics of the surface of metalware: zero microstrain and relative leveling $K > 65\%$. Difficulties were encountered in anodic treatment of the VT16 alloy: the voltage across the electrolytic bath exceeded 10 V, samples were covered with a matte film, and the stressed-strained state of their surface was preserved [9].

In this work we analyzed the influence exerted by the extent of alloying of titanium alloys on their anodic behavior in electrochemical treatment in hydrofluoric-sulfuric acid solutions without additives and with addition of alkali metal fluorides, glycerol, hexamethylenetetramine, and remantadine at potentials E = 2–9 V (vs. s.h.e.), and the properties of the forming surface AOFs.

EXPERIMENTAL

The anodic treatment of VT1-0, VT-6, and VT16 titanium alloys containing various alloying components (Table 1) was done in hydrofluoric-sulfuric acid solutions of the following composition (M): H_2SO_4 11.2–11.7 and HF 11.5, without additives and with addition of potassium (or sodium) fluoride (0.5–0.52 M), glycerol (2 M), and hexamethyleneteramine and remantadine [$(2.0-4.0) \times 10^{-2}$ M] at 293 K. The solutions were prepared using double-distilled water from ultrapure and chemically pure grade chemicals.

Electrochemical measurements were carried out with a PI-50-1 potentiostat, an LKD-4 self-recorder, a three-electrode cell with separated electrode spaces,

Table 1. Content of alloying components and impurities in titanium alloys [according to GOST (State Standard) 19807–91]

Alloy brand	Alloying component, wt %			Impurities, no more than, wt %				
	Al	Mo	V	C	Fe	Si	H_2	O_2
VT1-0				0.05	0.2	0.08	0.015	0.1
VT6	4.3–6.2	–	3.8–4.3	0.1	0.1	0.1	0.1	0.1

and a saturated silver chloride reference electrode (with potential given relative to s.h.e.). The working electrodes, made of titanium alloys in the form of disks with reaction surface area of 1.256 cm^2, were mechanically cleaned and weighed prior to every experiment. Voltammograms were obtained at potential sweep rates V_s (V s^{-1}) of 0.01, 0.02, 0.05, 0.1, and 0.2.

Table 2. Current efficiency CE^{Ti} of anodic oxidation of VT titanium alloys in hydrofluoric-sulfuric acid solution and fraction of current, Q_{O_2}, consumed for evolution of gaseous O_2

j_a, A dm^{-2}	CE^{Ti}, %			Q_{O_2}, %		
	VT1-0	VT6	VT16	VT1-0	VT6	VT16
6.5	96.3	90.8	89.5	0	0	
7.5	88.9	88.2	85.6	3.7	5.2	2.8
9.5	86.7	85.7	79.6	5.9	7.6	4.6
10.5	78.0	77.5	75.2	11.6	12.8	9.3

The current efficiencies of alloy component ionization (methods for calculation of their electrochemical equivalents were described in [9]) were determined gravimetrically and by quantitative analysis of anolytes in an electrolyzer with separated electrode spaces. The content of ions of dissolving alloy components in the anolyte was determined quantitatively by atomic absorption analysis on an AAS-1 spectrophotometer with the detection limit of 0.05–0.1 mg l^{-1} [10] and by photocolorimetric analysis on a KFK-3 photoelectric photometer with the detection limit of 1.0 mg l^{-1} [11]. The fraction of current consumed for the partial process of oxygen evolution was estimated volumetrically.

The phase composition of anodically treated alloys was determined from X-ray diffraction patterns obtained on a DRON-3M diffractometer in CuK_α radiation. The elemental composition of the forming surface films was studied with a JXA-5A electronic X-ray fluorescence analyzer.

The anodic potentiostatic curves (Fig. 1a) obtained on VT1-0, VT6, and VT16 titanium electrodes in a hydrofluoric-sulfuric acid solutions exhibited, after a steep rise in current at $E \approx 2.0$ V, a deceleration of the anodic dissolution process in a wide range of potentials $2.0 < E < 8.5$ V. At $E > 8.5$ V, the VT1-0 and VT6 alloys passed into a transpassive state.

In the presence of alloying additions of aluminum and vanadium in the VT6 titanium alloy (Table 1), the run of the j_a–E curve was qualitatively about the same, but the currents in the oxide formation and transpassivation regions decreased as compared with technically pure titanium (Fig. 1a).

The presence of alloying additives (Al, V, and Mo) in the VT16 titanium alloy (Table 1) led to a significant change in the run of the potentiostatic curve (Fig. 1a): the current rise portion started much earlier, at $E = 0.6–0.65$ V, and did not reach the currents of anodic dissolution of "pure" titanium, and then the electrode passed into the passive state, up to potentials of 9.0–9.5 V. The appearance of a violet film was observed visually on the electrode surface.

The increase in the process overvoltage, exceeding 3–4-fold the overvoltage in, e.g., chromium steels [12], is due to the considerable ohmic resistance of the forming surface AOFs, which grows, as reported previously [9], with increasing extent of alloying of titanium alloys in the order VT1-0 < VT6 < VT16.

Experiments on determining the anodic current efficiencies demonstrated that, with the current density maintained constant, the current efficiency of

alloy component ionization decreases in the same order of alloys VT1-0 > VT6 > VT16 (Table 2). Thus, the film resistance presumably reflects in the given case mainly the ionic conduction, since only this mechanism assumes higher current efficiency of metal ionization.

In addition to ionic conduction, the surface AOF on titanium alloys exhibits electronic conduction, too, which is indicated by measurements of the photovoltaic effect on the surface of an anodically passivated VT1-0 electrode [9, 13, 14]. This enables oxygen evolution at the film–solution interface.

Monitoring of the evolution of oxygen formed on the surface of anodically polarized titanium electrodes (Table 2) suggests that the oxygen process involves two constituents: evolution of gaseous O_2 and consumption of oxygen for final oxidation of anodic products of alloy oxidation (subions migrating across the AOF at strong polarizations and recorded in anodic polishing of aluminum alloys [15]). The higher the ionic conductivity of a film (VT1-0 > VT6 > VT16), the larger fraction of oxygen must be consumed by the second constituent of the oxygen process. Part of ions in intermediate oxidation state do not have enough time to react with O_2, and they find their way into solution. For the VT16 alloy, the fraction of current consumed for evolution of gaseous oxygen is somewhat lower than that for the other alloys (Table 2).

Quantitative analysis of the anolyte in electrochemical dissolution of the VT1-0 alloy demonstrated approximately the same content of Ti^{3+} and Ti^{4+} ions in the supporting electrolyte, in agreement with the scheme of anodic dissolution of titanium in the presence of hydrofluoric acid acting as a catalyst of titanium ionization by the complexation mechanism [13].

Replacement of a part of hydrofluoric acid with equivalent amount of sodium or potassium fluoride, with the concentration of fluoride ions in the hydrofluoric-sulfuric acid solution maintained constant, led to significant changes in the run of the anodic curves j_a–E obtained on the VT1-0 and VT16 alloys (Fig. 1b). The Na^+ and K^+ ions present in the hydrofluoric-sulfuric acid solution in amount of 0.50–0.52 M accelerated anodic dissolution of titanium alloys. The most significant factors were the increase in the anodic dissolution currents, as compared to the electrolyte without added salts, and the appearance of a transpassive range of the process for the VT16 alloy (Fig. 1b).

The shape of the anodic voltammetric curves ob-

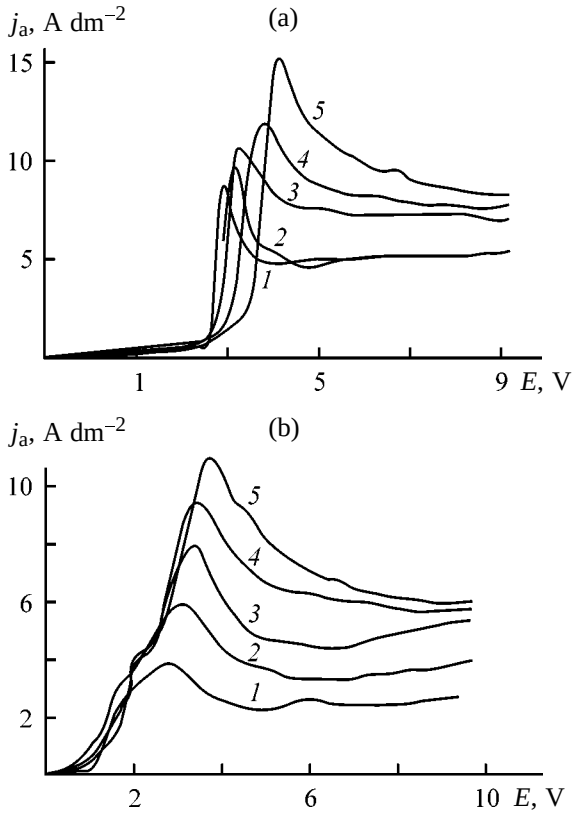

Fig. 2. Voltammetric curves of anodic oxidation of (a) VT1-0 and (b) VT16 titanium alloys at 293 K. Potential sweep rate (V s^{-1}): (*1*) 0.01, (*2*) 0.02, (*3*) 0.05, (*4*) 0.1, and (*5*) 0.2.

tained on the VT1-0 and VT16 titanium alloys (Fig. 2) was also largely determined by the presence of alloying additives, solution composition, and anodic polarization η_a.

The VT1-0 alloy in a hydrofluoric-sulfuric acid solution was characterized by a steep rise in current with increasing η_a up to the peak current j_p, whereas the VT16 alloy exhibited several successive current peaks (Fig. 2b. The appearance of these peaks in the anodic voltammetric curves is possible [16] in two cases: first, when there occurs step oxidation of reactants at the electrode, and, second, in the case of oxidation of several different substances.

Apparently, ionization of Ti in anodic dissolution of the VT16 alloy occurs in stages and is accompanied by preliminary anodic oxidation in stages of the alloying components contained in the alloy (Table 1) and possessing a more negative ionization potential, compared with the Ti base.

At potentials $E \geq 5.5$ V, corresponding to the electropolishing range, the voltammetric curves show characteristic inflections (Fig. 2) identified with peaks

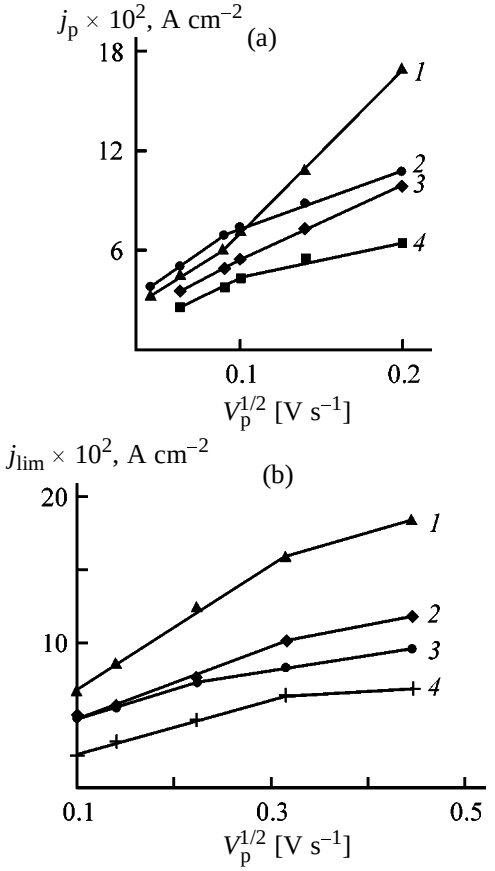

Fig. 3. Current densities (a) j_p and (b) j_{lim} vs. potential sweep rate V_s for titanium alloys (*1*, *3*) VT1-0 and (*2*, *4*) VT16. Solution (M): (*1*, *2*) H_2SO_4 11.5, HF 11.0, NaF 0.52; (*3*, *4*) H_2SO_4 11.5, HF 11.5.

of "limiting" current j_{lim} at anodic overvoltages of the process [17, 18]. Introduction of alkali metal cations into the hydrofluoric-sulfuric acid solution favored an increase in j_p and j_{lim} on titanium alloys, and especially on VT16.

At V_s = 0.01–0.05 V s^{-1} the currents j_p and j_{lim} linearly depend on the square root of the potential sweep rate (Fig. 3), which indicates diffusion control of the anodic dissolution of titanium alloys [16]. With the V_s values increasing further, to 0.1–0.2 V s^{-1}, the process of anodic dissolution of alloys passed first into the region of mixed diffusion–activation kinetics and then into that of purely activation control. Experimental studies demonstrated that solution agitation in measuring voltammetric dependences at V_s = 0.1–0.2 V s^{-1} has no effect on the curve shape, and, consequently, the ion diffusion must be limited to the solid-state oxide zone. Migration of ions of metals constituting the alloys, under the action of electric field in the surface oxide film, is the main driving force of the process.

Thus, the observed features of the anodic dissolution of titanium alloys—significant increase in overvoltage of transition of VT1-0 and VT6 titanium alloys into transpassive state as compared with, e.g., steels [13]; "deep" passivation of the VT16 alloy in the hydrofluoric-sulfuric acid solution; and also activation of anodic dissolution in the presence of alkali metal cations in the supporting electrolyte, especially pronounced for the VT16 alloy—cannot be related only to diffusion limitations on the process, but are also determined by properties of surface AOFs.

An analysis of the phase composition of a film formed on a VT16 titanium anode in the hydrofluoric-sulfuric acid electrolyte (Table 3) demonstrated the presence, in addition to TiO_2, of an amorphous phase containing MoO_3, δ-V_2O_5, and, in part, γ-Al_2O_3.

Partial substitution of Ti ions in the TiO_2 crystal lattice by Mo and V ions is possible if the atomic radii of the host and substituting metal ions differ by no more than 15%. This condition is satisfied for the VT16 alloy: Ti ion radius (r_{Ti} = 1.45 Å) is close the radii of the alloying components, Mo (r_{Mo} = 1.39 Å) and V (r_V = 1.34 Å) [19].

This suggests that Mo^{6+} and V^{5+} ions migrating through the oxide layer in anodic dissolution of the alloy substitute part of Ti^{3+} and Ti^{4+} in the crystal lattice of titanium oxide and thereby lead to lower rate of anodic dissolution of the VT16 alloy in the hydrofluoric-sulfuric solution and to surface passivation, with the thickness of the oxide film increasing; and this was, indeed, observed experimentally.

The observed acceleration of the anodic dissolution of titanium alloys on introducing alkali metal cations into the supporting electrolytes is apparently due to reduction of the diffusion resistance of the solid phase, caused by the possible introduction of Na^+ and K^+ ions into the film to form a substitutional solid solution. This process is possible if the atomic radii of the host and impurity ions are close, which is satisfied for Na^+ ions (r_{Na} = 1.90 Å). Introduction of Na^+ cations into aluminum oxide in cathodic activation and anodic dissolution of aluminum in chloride solutions was demonstrated in [20].

The atomic radius of K^+ ions (r_K = 2.35 Å) is 1.6 times that of Ti. An X-ray phase analysis of films formed on the VT16 alloy in a solution containing potassium fluoride revealed the presence of an amorphous phase of the type K_2O–MoO_3–V_2O_5 (Table 3). The fact that chemical compounds of elements contained in the electrolyte are present on the surface films formed on valve metals in the galvanostatic mode was demonstrated in [21].

Table 3. Elemental and phase composition of AOF on VT16 titanium alloy after electrochemical treatment at 5 A dm^{-2} for 5 min

Electrolyte, M	Elemental composition of film, wt %				Phase composition of film
	Ti	Al	Mo	V	
H_2SO_4, 11.5; HF, 11.5	86.2–87.0	2.8–3.0	5.2–5.4	3.7–3.9	TiO_2-rutile, amorphous phase MoO_3–δ-V_2O_5
H_2SO_4, 11.5; HF, 11.0; KF, 0.52	85.8–86.5	3.1–3.3	5.2–5.3	3.9–4.1	TiO_2-rutile, amorphous phase K_2O–MoO_3–δ-V_2O_5
H_2SO_4, 11.5; HF, 11.0; KF, 0.52; $C_3H_8O_3$, 2.0	86.5	3.3–3.5	5.0–5.2	3.9–4.0	TiO_2-rutile, amorphous phase K_2O–MoO_3–δ-V_2O_5–γ-Al_2O_3

The introduction of alkali metal cations into the hydrofluoric-sulfuric acid solution allowed intensification of the anodic dissolution of titanium alloys; however, the required leveling of VT16 alloy sample surface (K > 65%) and absence of surface microstrains could only be achieved on replacing water in the supporting electrolyte with another solvent, glycerol, taken in amount of up to 2 M, and additional introduction of hexamethylenetetramine additive [$(2.0–4.0) \times 10^{-2}$ M].

CONCLUSIONS

(1) Ionization of metals contained in titanium alloys subjected to anodic oxidation under strong polarization occurs in stages, with solid-phase limitations on the stage of ion migration through the forming anodic film.

(2) The surface semiconducting anodic oxide films may include components of dissolving titanium alloys and solutions for anodic treatment, which affect the process rate.

(3) It is recommended to use for electrochemical treatment of the VT16 titanium alloy a solution of the following composition (M): H_2SO_4 11.2–11.7, HF 11.0–11.5, KF (NaF) 0.50–0.52, $C_3H_8O_3$ 2.0, and $C_6H_{12}N_4$ $(2.0–4.0) \times 10^{-2}$.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Potentiometric Study of Oxidized Coals in Aqueous Solutions of Surface-Inactive Electrolytes

Abstract—Stationary electrode potentials of oxidized synthetic coals of the SCN type are determined in aqueous solutions. The contributions of redox reactions with participation of the surface oxygen-containing functional groups and the potential of unoxidized areas of the coal surface to the total potential of oxidized coals in aerated solutions are studied. The potentials of oxidized carbons in deoxygenated solutions are also measured.

The potentials of activated carbon (AC) in aerated aqueous solutions were studied in [1–9]. It was demonstrated that formation of the stationary potential of AC is associated with oxygen reduction. Measurements of the potential of AC in deoxygenated solutions allowed estimation of the zero-charge potential (ZCP) [1]. At the same time, there is only limited data on the potentials of oxidized AC, and the available information is contradictory [4, 9]. Data on the potentials of oxidized AC in deoxygenated solutions are lacking at all.

In this work we determined the stationary potentials E_{st} of oxidized AC having various degrees of surface oxidation and studied the pH dependences of E_{st} in aerated and deoxygenated electrolyte solutions.

EXPERIMENTAL

In the work we used synthetic spherical granulated AC of the SCN type obtained by carbonization of a copolymer of vinylpyridine resin and divinylbenzene with subsequent activation with water vapor [10].

Oxidized SCN carbon (SCN_o) was prepared by treatment of SCN with concentrated nitric acid. The degree of oxidation was estimated from the static exchange capacity (SEC) of the carbons with respect to alkali, reflecting the amount of oxygen-containing surface functional groups [11]. We measured the potentials of the carbons with SEC of 0.31, 0.41, 0.54, 0.69, 0.86, 1.10, 1.25, 1.32, 1.63, 2.0, and 2.5 mg-equiv g^{-1}.

As the working solution we chose 0.1 N sodium sulfate, because the specific adsorption of Na^+ and SO_4^{2-} ions is low enough to have no effect on the measured potentials [12]. The solution pH was varied from 1 to 12 by adding sulfuric acid or NaOH and controlled with an EV-74 pH meter.

The cell for measurement of the potential was a 250-ml round-bottomed flask with sealed-in ground-glass joints. Through these joints to the cell were introduced a Pt microprobe, an AgCl reference electrode, a pH-metric glass electrode, and a dropping funnel for feeding the acid or alkali.

Measurements were performed with a suspended sample using a magnetic stirrer, which allowed suspended carbon particles to strike against the Pt microprobe. In so doing we were able to measure just the surface potential of the AC granules, but not the potential of the Pt microprobe in the electrolyte solution [13]. The potentials were measured with a V7-35 high-resistance voltmeter and recalculated against the standard hydrogen electrode. All experiments were conducted at $20 \pm 2°C$.

Preliminarily we measured the potential of the Pt microprobe in the working solution. This potential appeared to be considerably different from the potentials of AC (Fig. 1). While measuring the potentials of AC we introduced various concentrations of a mediator, $Fe_2(SO_4)_3$, in the solution. We found that its presence has no effect on the AC potentials, suggesting that the measurement procedure used is adequate.

Deoxygenation of the solution in the measuring cell was attained by a 24-h bubbling of Ar thoroughly purified to remove oxygen. It was demonstrated in special experiments that this time is sufficient for

1070-4272/01/7411-1834$25.00

deoxygenation. To remove adsorbed oxygen, the AC samples were heated at 120°C in an Ar flow for 2 h.

As an example, Fig. 1 demonstrates the kinetics of formation of the stationary potential of the oxidized carbons having SEC of 0.41, 2.0, and 2.5 mg-equiv g^{-1}, and, for comparison, of SCN activated carbon in acidic (pH 1) and basic (pH 12) aerated solutions. The time dependence of the AC potential is represented by a curve slowly approaching the stationary value (Figs. 1a, 1b, curves *1*), which is consistent with the published data [5, 6].

The stationary potentials of AC and oxidized AC are attained differently. For example, weakly oxidized AC (SEC 0.41 mg-equiv g^{-1}) is characterized by a considerable growth of the potential from the initial to the stationary value, which, however, is lower as compared to activated SCN (Figs. 1a, 1b, curves *2*). For SCN_o with a higher degree of oxidation (SEC 2.0 mg-equiv g^{-1}) the difference between the initial and stationary potentials is small, being within 50 mV (Figs. 1a, 1b, curves *3*). Finally, for strongly oxidized carbon (SEC 2.5 mg-equiv g^{-1}) the potential decreases with time, i.e., E_{st} of this carbon is lower than the initial potential (Figs. 1a, 1b, curves *4*), which is consistent with data of [9]. Carbons with intermediate degrees of oxidation show intermediate patterns.

The stationary potentials of oxidized carbons and the initial SCN are also different. The correlations of the stationary potentials of oxidized carbons with SEC at pH 1 and 12 are presented in Fig. 2 together with E_{st} of SCN. Although the potentials in both acidic and basic solutions vary in rather narrow ranges (695–775 and 220–305 mV, respectively), some trends are nevertheless seen. Thus, with increasing SEC from 0.31 to 1.25 mg-equiv g^{-1} the potential slightly decreases. With further increasing SEC from 1.25 to 2.0 mg-equiv g^{-1} the stationary potentials of the oxidized carbons drift toward more positive values, approaching the potential of the initial SCN. The reproducibility of E_{st} in our experiments was within 2 mV.

Figure 3 shows the pH dependences of E_{st} for oxidized carbons with SEC 0.41, 2.0, and 2.5 mg-equiv g^{-1} and also for the initial SCN in aerated solutions. Here the specific feature is that for strongly oxidized carbons (SEC 2.0, 2.5 mg-equiv g^{-1}) E_{st} is a linear function of pH over the entire pH range. For weakly oxidized carbon and the initial SCN the pH dependences are curves with two linear sections.

The pH dependences of E_{st} of SCN and oxidized SCN (SEC 2.0 mg-equiv g^{-1}) in deoxygenated sys-

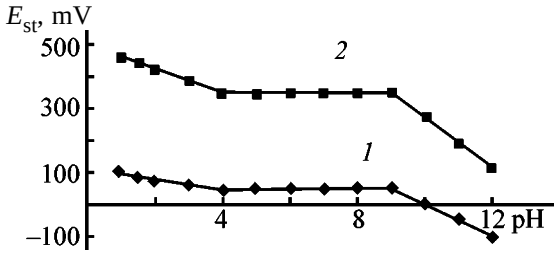

Fig. 4. Stationary potential E_{st} of (*1*) SCN and (*2*) SCN_o (SEC 2.0 mg-equiv g^{-1}) as a function of pH in deoxygenated solutions.

tems are given in Fig. 4. It is seen that the dependences are similar for the both types of carbons. Each of the curves has three linear sections; over the pH range from 4 to 9 the corresponding linear section represents a plateau. The plateau potentials of these samples are strongly different, being 350 and 50 mV for SCN_o and SCN, respectively. In the pH ranges below 4 and above 9 E_{st}, respectively, decreases and increases.

The observed considerable differences in the kinetic curves of the potential of SCN and SCN_o (Fig. 1) can be interpreted taking into account the chemical and energy heterogeneity of their surface [14]. The measured potentials are formed under the effect of several factors.

There are a wide spectrum of oxygen-containing functional groups (phenolic, alcoholic, carbonyl, carboxy, quinoid, lactone, etc.) on the surface of SCN_o, which are bound to the carbon matrix, as demonstrated by various physical (IR, NMR, ESR, etc.) and chemical methods used for identification of individual organic compounds [11, 15].

The surface of SCN_o has also unoxidized areas [8, 11] which can reduce chemisorbed oxygen.

Therefore, we can attribute the growth of the potentials of weakly oxidized carbons in aerated electrolyte solutions (Figs. 1a, 1b, curves *2*, *3*) to reduction of chemisorbed oxygen in unoxidized areas of the surface. The decrease in E_{st} of a strongly oxidized carbon (SEC 2.5 mg-equiv g^{-1}) relative to the initial SCN was assigned in [9] to dissociation of protonated oxygen-containing groups (their amount is higher in strongly oxidized carbons) and formation of a negative charge on the surface.

The effect of oxygen-containing groups on the stationary potentials of oxidized carbons is demonstrated in Fig. 2. The amount of these groups in weakly oxidized carbons is small, and in this case E_{st} is close to that of unoxidized SCN. The contribution of the redox potentials of these groups to E_{st} increases with increasing degree of oxidation of the carbons, being dependent not only on the amount of oxygen-containing groups, but also on their spectrum. According to the modern views [8, 16, 17], furan and phenol groups dominate on the surface of weakly oxidized carbons, which imparts a negative or weakly positive potential to the carbon surface [18]. With increasing degree of oxidation, in addition to the above-indicated groups, carboxy and lactone groups and branched chains with peripheral alcoholic groups are formed on the surface, which are characterized by high positive redox potentials [18, 19]. As a result, strongly oxidized carbons have higher potentials, which regularly increase with the degree of oxidation.

The pH dependences of E_{st} given in Fig. 3 for SCN and variously oxidized SCN_o confirm the common view that the electron-donor power of oxidized carbons is less pronounced. For SCN this dependence (Fig. 3, curve *1*) has two linear sections with the slopes of –29 and –58 mV per pH unit, which correspond to oxygen reduction on the surface, respectively, to hydrogen peroxide and to hydroxide ion in acidic and alkaline solutions by Eqs. (1) and (2).

$$O_2 + 2H^+ + 2e = H_2O_2, \quad (1)$$

$$O_2 + 2H_2O + 4e = 4OH^-. \quad (2)$$

For oxidized carbons with SEC of 2.0 and 2.5 mg-equiv g^{-1} the pH dependences of E_{st} are straight lines having a slope of –42 and –40 mV per pH unit, which can be regarded as a resultant of the processes of oxygen reduction on unoxidized areas of the surface by Eqs. (1) and (2) and redox reactions with participation of oxygen-containing functional groups.

The pH dependence of E_{st} of SCN_o (SEC 2.0 mg-equiv g^{-1}) in a deoxygenated solution (Fig. 4, curve *2*), given as an example, is similar to that for SCN (curve *1*). With the lack of oxygen the potential is unchanged over the pH range from 4 to 9 (plateaus in Fig. 4). However, the plateau potential of SCN_o is above that of SCN by 300 mV, which is due to a lower electron-donor power of the former [11]. The observed growth of E_{st} of SCN at pH <4 can be attributed to adsorption of hydrogen ions on the carbon surface and also to partial charge transfer from the carbon matrix, i.e., its oxidation, as was demonstrated in [1]. In this case the surface acquires a positive charge. The decrease in the potential at pH >9 is due to adsorption of hydroxide ions [8].

For SCN_o the observed pH dependence of E_{st} at pH <4 is evidently associated also with protonation of the surface acidic groups, and at pH >9, with their ionization with formation of negatively charged moieties [20].

One may say that the plateau potential of SCN_o (+350 mV) is an averaged (compromise) redox potential of oxygen-containing functional groups on its surface, which are lacking on the SCN surface. This potential is controlled by Eq. (3)

$$C + H_2O \rightarrow C(O) + 2H^+ + 2e, \quad (3)$$

where C(O) designates an oxidized state of carbon.

The plateau potential corresponds to E_{st} in the absence of electrochemically active gases.

CONCLUSIONS

(1) Stationary potentials of oxidized coals correspond to the averaged potentials of oxygen-containing functional groups chemically bound to the coal surface and of unoxidized areas. As the degree of oxidation of the coals increases, the potential grows, which is due to the transition from the furan and phenol groups, having negative or slightly positive redox potentials, to the carboxy and lactone groups with higher redox potentials.

(2) It follows from the pH dependence of the stationary potential that oxidized coals demonstrate less pronounced electron-donor power as compared to the activated coals. In deoxygenated solutions the pH dependences for both oxidized and activated coals have plateaus at pH 4–9. The plateau potential of the oxidized coal (SEC 2.0 mg-equiv g^{-1}) is +350 mV, which corresponds to the potential of the coal surface in the absence of electrochemically active gases in the solution, i.e., without specific adsorption.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodeposition of the Cr–Co Alloy from Acid Sulfate Electrolytes

A. I. Falicheva and B. A. Spiridonov

Voronezh State Technical University, Voronezh, Russia

Received July 4, 2001

Abstract—The kinetics of electrodeposition of Cr–Co alloys from sulfate electrolytes with monoethanolamine was studied. The influence of the dc and pulsed current modes on the composition and physicochemical properties of the Cr–Co coatings with cobalt content of 5–10% was examined.

Chromium coatings electrodeposited from electrolytes containing triple-charged chromium ions and iron-group metals have appreciably improved physicochemical properties: increased heat and oxidation resistance [1], lower fracturing [2, 3], and enhanced corrosion resistance. Sulfate [2–4] and chloride [1–5] electrolytes have been recommended for preparing electrolytic Cr–Co alloy. The previous studies have shown that Cr–Co coatings can be prepared from sulfate electrolytes with monoethanolamine (MEA) or hexamethylenetetramine in both static [3, 4] and pulsed [6] current modes. In this work, we continued the study of the electrodeposition of Cr–Co alloy from sulfate electrolytes.

EXPERIMENTAL

The electrolyte contained (M) 0.5 "modified" green chromium(III) sulfate (spectral characteristics: λ_1 = 415–416 nm and λ_2 = 582–583 nm; $\varepsilon_1 \approx \varepsilon_2 = 37$) [7, 8], 0.5 sodium sulfate, and 0.032 MEA. To the electrolyte, from 1 to 5 g l^{-1} of cobalt sulfate was added. For comparative studies on cobalt deposition we prepared electrolyte containing 2 g l^{-1} $CoSO_4$ and MEA.

The pulsed electrolysis was performed using a transistor generator of rectangular pulses. The pulse repetition frequency was varied from 0.1 to 10 Hz and the pulse length, from 0.1 to 50 s. Copper cathodes and platinum anodes were used.

The current efficiency (CE) by the alloy was determined gravimetrically using a copper coulometer with account taken of the alloy composition. The cobalt content of the alloy was determined spectrophotometrically with nitroso-R salt and the chromium content, by the persulfate–silver method. The cathodic polarization was studied galvanodynamically (6 mA min^{-1}) on a P-5827 M potentiostat with a KSP recording potentiometer. All the potentials are given vs. silver chloride reference electrode which served as reference; platinum was used as an auxiliary electrode. The partial polarization curves were obtained by resolution of the overall curves on the basis of data on the current efficiencies by hydrogen, chromium, and cobalt. The quality of the deposits was judged from outward appearance of the coatings; their reflectivity was studied with an FM-58 M photometer and the morphology, with an MIM-7 microscope. The phase analysis was done on the alloy films 500–1000 Å thick (separated from copper substrate) at a 100 kV voltage. The lattice period was determined according to [9]. The hydrogen content in the cathode deposits was determined by vacuum extraction [10].

Analysis of the partial polarization curves derived from the overall curve of Cr–Co deposition from sulfate electrolyte with MEA (Fig. 1) shows that chromium(III) is reduced to chromium(II) ($E^0_{Cr^{3+}/Cr^{2+}}$ = –0.41 V) simultaneously with the formation of hydrogen ($E^0_{H^+/H^0}$ = 0 V), cobalt ($E^0_{Co^{2+}/Co^0}$ = –0.277 V), and chromium ($E^0_{Cr^{3+}/Cr^0}$ = –0.71 V). The previous data show that, apart from hydrogen evolution, the formation of cobalt is the most probable from the thermodynamical standpoint. However, owing to the increase in the chromium(II) ion concentration and the shift of the $E_{Cr^{3+}/Cr^{2+}}$ potential toward negative region, chromium (curve *1c*) is deposited simultaneously with cobalt (curve *1d*), as revealed by analysis of the cathode deposits and partial curves. Reduction of chromium(III) ions during the alloy deposition occurs with lower polarization than deposition of pure

1070-4272/01/7411-1838$25.00

chromium (curve *2c*). From an electrolyte containing no cobalt(II) ions, chromium is electrodeposited at D_c = 25 A dm^{-2} (pH 0.75). At simultaneous deposition with cobalt, the necessary current density decreases to 15 A dm^{-2}, because the free energy decreases owing to formtion of the crystal lattice of the cathodic chromium–cobalt solid solution.

Electron-microscopic study of the chromium–cobalt deposits containing 10% cobalt showed that the simultaneous deposition of chromium and cobalt results in the formation of a solid solution with a lattice period of 2.87 Å. According to the phase diagram, the β-phase with a centered cubic lattice, which is a solid solution of cobalt in chromium [11], is formed in the chromium–cobalt system at cobalt content of up to 10%. The lattice period of chromium deposited from chromium-plating sulfate electrolyte with MEA under the similar conditions is a = 2.89 Å. Apparently, a slight decrease in the lattice period of Cr–Co alloy compared to chromium is explained by the decreased hydrogenation. For example, with the cobalt content of the alloy increased from 2.3 to 8.6%, the hydrogen content is decreased approximately 2.7-fold (Fig. 2). The decrease in the alloy hydrogenation with increasing cobalt content of the alloy can be explained by the decrease in the current efficiency by hydrogen in chromium-plating sulfate electrolyte with added $CoSO_4$. For example, with cobalt sulfate concentration increased from 1.0 to 5 g l^{-1}, the cobalt content of the alloy is increased from 1.8 to 12% and the CE by the alloy, from 6.2 to 10.3% (D_c = 20 A dm^{-2}, pH 0.75). Under these conditions the rate of hydrogen formation decreases simultaneously (see table), whereas that of cobalt formation increases approximately 4-fold.

The self-discharge of cobalt(II) ions occurs at a considerably higher rate (Fig. 1, curve *3*) than at simultaneous electroplating with chromium (curve *1d*). One of the reasons responsible for overpolarization of Co^{2+} discharge is the adsorption of colloidal surface-active $Cr(OH)_3$ on active sites of the cathode. As a result, the cobalt formation is hindered. This phenomenon is characteristic of codeposition of chromium with iron-group metals, for example, nickel [8] from sulfate electrolytes.

The alloy deposits containing up to 10–12% cobalt are lustrous and acquire a shadow typical of cobalt coatings at higher cobalt concentrations. With cobalt sulfate concentration increased from to 5 g l^{-1}, the D_c interval corresponding to deposition of lustrous coatings is broadened essentially (to 80 A dm^{-2}, pH 0.5).

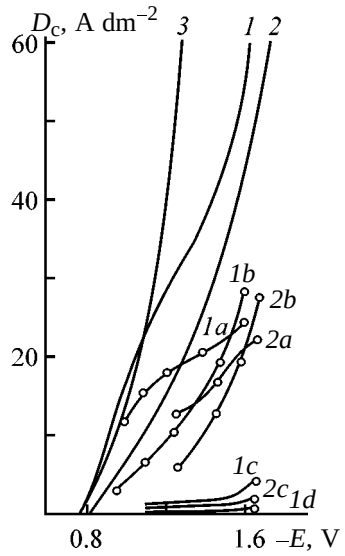

Fig. 1. Cathodic polarization curves of deposition of (*1*) Cr–Co alloy, (*2*) chromium, and (*3*) cobalt from sulfate electrolytes with MEA. (D_c) Current density and (E) potential. Partial curves of formation of (*1a*, *2a*) H_2, (*1b*, *2b*) Cr^{2+}, (*1c*, *2c*) Cr^0, and (*1d*) Co^0.

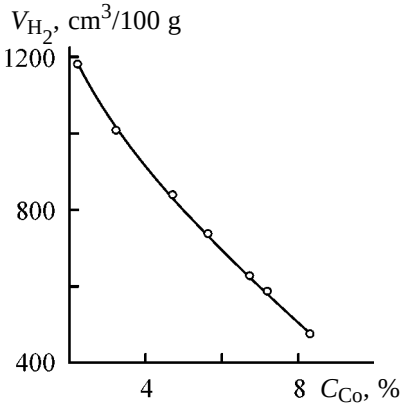

Fig. 2. Hydrogenation V_{H_2} of Cr–Co cathode deposits vs. cobalt content C_{Co} of the alloy. D_c = 30 A dm^{-2}, thickness 5 μm, pH 0.75, and T = 25°C.

With increasing electrolyte pH the rate of the alloy deposition increases. For example, with pH varied from 0.5 to 1.0, the hydrogen discharge current is decreased nearly twofold (from 19 to 10 A dm^{-2}) and the partial rate of the alloy deposition is increased approximately 9.50-fold (E = –1.4 V). Such a change in the electrolyte pH increases the current efficiency by the alloy (from 5 to 26% at D_c = 30 A dm^{-2}). Comparison of the partial current densities of the chromium(III) and cobalt(II) ion formation shows that with pH increasing in the given range the partial current density of the cobalt separation decreases from 6.2 to 1.8% (at D_c = 30 A dm^{-2}), and the alloy is

enriched with chromium. It should be noted that with decreasing electrolyte acidity the reflectivity of the coatings decreases, and at pH > 1.5 they become dull.

Increasing cathodic current density decreases cobalt content of the alloy. For example, as D_c is decreased from 10 to 60 A dm^{-2}, the cobalt content is decreased from 6 to 0.5%. One of the reasons of the appreciable dependence of alloy composition on D_c is the stronger polarization accompanying cobalt deposition into the alloy (Fig. 1, curve *1d*), which is ascribed to the increased pH_s and prevention of the Co^{2+} discharge by facilitated adsorption of $Cr(OH)_3$ on the cathode. To stabilize electrodeposition and make the dependence of alloy composition on D_c less appreciable, we studied the influence of the transient electrolysis mode using a rectangular pulsed current. It is seen from Fig. 3 that with the pulse to dead time ratio Q ($Q = \tau_p + \tau_d/\tau_p$, where τ_p is electrolysis time and τ_d is dead time) increased from 1.03 to 1.5, the cobalt content in the alloy is increased from 0.5 to 1.2% at D_c = 60 A dm^{-2}. This suggests that at high D_c the formation of chromium hydroxide film is hindered with increasing Q, thus creating the more favorable conditions for the Co^{2+} discharge compared to steady-state regime. At low D_c, the pH_s increase is slower, the chromium(III) ion concentration in the near-cathode space increases relative to cobalt(II) concentration, and the alloy is enriched with chromium. For example, at D_c = 10 A dm^{-2} the cobalt content in the alloy decreases from 4.6% (curve *2*) to 2% (curve *5*). The effect of the pulse repetition frequency on the alloy component ratio is less marked than that of the pulse to dead time ratio. For example, if f = 0.3 Hz, then at D_c = 10 A dm^{-2} the cobalt content in the alloy is lower by 0.8% (curve *5*) than at D_c = 60 A dm^{-2}. With f increasing to 0.35 Hz the cobalt content in the alloy decreases by 0.5% (curve *5'*). At f > 0.35 Hz and $Q \geq 2$ the current efficiency by the alloy is considerably lower (by ~ 12%), which can be explained by the cathode passivation at higher pulse repetition frequences typical of electrodeposition from sulfate electrolytes [12].

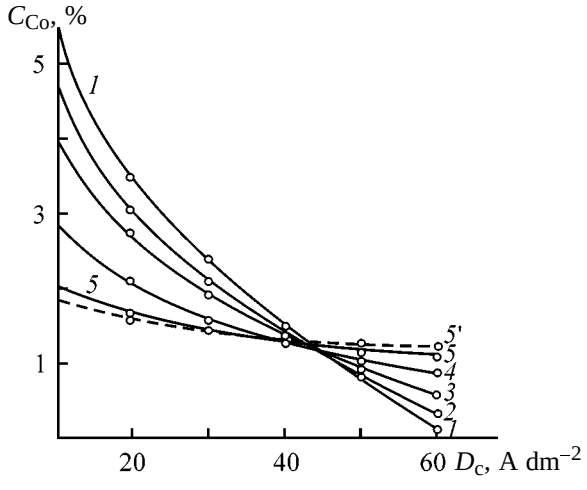

Fig. 3. Influence of the cathodic current density d_c on the cobalt content of the alloy C_{Co}. Electrolysis: (*1*) steady-state and (*2*–*5*) pulsed. Pulse to dead time ratio Q: (*2*) 1.03, (*3*) 1.1, (*4*) 1.2, and (*5*, *5'*) 1.5. Pulse repetition frequency f (Hz): (*2*–*5*) 0.3 and (*5'*) 0.35.

CONCLUSIONS

(1) Chromium and cobalt can be codeposited from electrolytes containing cobalt and chromium sulfates [the latter in the form of modified green chromium(III) sulfate] and luster-producing monoethanolamine.

(2) The method of partial curves has revealed that the electrodeposition of Cr–Co alloys occurs with depolarization, and that of cobalt, with enhanced polarization.

(3) The sulfate electrolyte with momoethanolamine is developed, allowing preparation of mirror-lustrous Cr–Co coatings (up to 10% Co) at D_c = 10–60 A dm^{-2}, T = 25°C, and pH 0.5–1.0. The current efficiency by the alloy is 15–25%.

(4) For the stabilization of the alloy composition, we recommend to perform electrolysis in the pulsed

current mode using rectangular pulses with a 0.3–0.35 Hz repetition frequency and the pulse to dead time ratio $Q = 1.5$.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodeposition of Tin from Sulfate Electrolyte with Organic Additives

G. I. Medvedev and N. A. Makrushin

Novomoskovsk Institute, Mendeleev Russian University of Chemical Engineering, Novomoskovsk, Tula oblast, Russia

Received June 7, 2001

Abstract—Electrodeposition of tin from sulfate electrolytes containing $SnSO_4$, H_2SO_4, Synthanol, formalin, and benzyl alcohol was studied.

It was shown in [1, 2] that dihydric alcohols (1,4-butynediol, 1,4-butenediol, and 1,4-butanediol), present in sulfate tin-plating electrolyte simultaneously with Synthanol and formalin, favor formation of lustrous tin coatings. Proceeding with these studies, we considered in this work electrodeposition of tin from a sulfate electrolyte in the presence of Synthanol, formalin, and benzyl alcohol.

The study was carried out in the electrolyte of the following composition (g l^{-1}); $SnSO_4$ 5–50, H_2SO_4 90–100. The organic substances were introduced in the following amounts: Synthanol DS-10 1–4 g l^{-1}; formalin (37% solution) 1–10 and benzyl alcohol 1–10 ml l^{-1}.

Tin coatings 6–24 μm thick were deposited onto copper samples. Polarization curves were obtained potentiodynamically with a P-5878 potentiostat. The leveling power of the electrolyte was measured on a flat sinusoidal microprofile. The leveling power P was calculated using the equation [3]

$$P = \log[(H_0 \times 2.3a)/(H_\tau \times 2\pi h_{av})],$$

where H_0 and H_τ are, respectively, the microprofile amplitudes before and after deposition of tin; a is the sinusoid wavelength, and h_{av} is the coating thickness (10 μm).

The coating luster was measured with an FB-2 photoelectric luster meter.

Our experiments showed that matte coatings with coarsely crystalline structure are formed in tin-plating electrolyte ($SnSO_4$ 30 and H_2SO_4 100 g l^{-1}) containing 1–4 g l^{-1} of Synthanol. In the presence of formalin and benzyl alcohol (in amount of 1–10 ml l^{-1} each), matte coatings with unsatisfactory quality are obtained. Addition of benzyl alcohol to an electrolyte with Synthanol does not lead to any significant change in the coating quality. In an electrolyte with Synthanol and formalin, silvery coatings are formed. The outward appearance of the coatings is much improved if benzyl alcohol (6–8 ml l^{-1}) is added to an electrolyte with Synthanol (2–3 g l^{-1}) and formalin (6–8 ml l^{-1}). In this case, lustrous tin coatings are obtained in the current density range i_c = 4–12 A dm^{-2}. When the concentrations of formalin and benzyl alcohol are beyond the above limits, semilustrous or silvery coatings are obtained, depending on i_c. At Synthanol concentrations lower than 2 g l^{-1}, the working range of current densities at which lustrous coatings are obtained becomes much narrower. At Synthanol concentrations exceeding 3 g l^{-1}, the interval of current densities in which lustrous coatings are obtained remains unchanged, but electrolyte foaming is much enhanced, which hinders the electrodeposition process. It should be noted that lustrous coatings can only be obtained with electrolyte stirring. We have examined the influence of the $SnSO_4$ concentration on the range of working current densities for preparing lustrous coatings. We found that raising the $SnSO_4$ concentration from 5 to 50 g l^{-1} in an electrolyte containing H_2SO_4 (90–100 g l^{-1}), Synthanol (2–3 g l^{-1}), formalin (6–8 ml l^{-1}, and benzyl alcohol (6–8 ml l^{-1}) makes higher the current density necessary for obtaining lustrous coatings. For example, lustrous coatings are formed in the following ranges of current densities (A dm^{-2}) at indicated $SnSO_4$ concentrations in the electrolyte: 1–7, 5 g l^{-1}; 1–8, 10–20 g l^{-1}; and 4–12, 30–50 g l^{-1}.

Data on current efficiency (CE) in tin-plating electrolyte with additives are presented in Fig. 1. It can be seen that CE grows with increasing $SnSO_4$ concentration in the electrolyte and decreases when i_c becomes

1070-4272/01/7411-1842$25.00

higher. The highest CE is observed in an electrolyte containing 50 g l^{-1} of $SnSO_4$. Lustrous tin coatings have finely crystalline structure and firmly adhere to the base metal.

To reveal the influence of organic substances on electrodeposition of tin, cathodic polarization curves were measured with immobile and rotating disk electrodes (Fig. 2). It can be seen that organic additives (curves *1* and *2*) make the deposition of tin slower and the cathodic polarization stronger. With increasing speed of electrode rotation, the overvoltage of tin deposition also grows (curves *2–4*).

The inhibiting action of organic substances in a tin-plating electrolyte is presumably due to their adsorption onto the electrode surface. This assumption is confirmed by measurements of the electrical double layer capacitance *C*. As seen from Fig. 2 (curves *5*, *6*), introduction of organic substances into the electrolyte leads to a decrease in the double layer capacitance in the potential range from –0.3 to –0.4 V from 32 to 8 μF cm^{-2}. At higher potentials, organic substances are desorbed from the electrode surface, which leads to higher capacitance of the double layer.

To reveal the effect of organic substances on the microdistribution of electrodeposited tin, we studied the dependence of the leveling power *P* of the electrolyte on the cathode current density upon addition of organic substance to the electrolyte. As seen from Fig. 3 (curve *1*), introduction of Synthanol into the tin-plating electrolyte leads to a certain leveling of the surface ($P = 0.1$) only at $i_c = 1$ A dm^{-2}. With the current density increasing further, surface antileveling is observed. On addition of formalin to an electrolyte with Synthanol (curve *2*), the leveling ($P = 0.14$–0.05) occurs at $i_c = 1$–10 A dm^{-2}. Introduction of benzyl alcohol into the electrolyte leads to more pronounced surface leveling (curve *3*). The leveling power of the mixture reaches its maximum value $P = 0.83$ at $i_c = 7$ A dm^{-2}.

Thus, the leveling additives in a mixture of organic substances are formalin and benzyl alcohol, with the latter ensuring the strongest surface leveling. A study of the influence exerted by the concentration of benzyl alcohol on the extent of leveling demonstrated that, with increasing concentration of benzyl alcohol (Fig. 3, curve *4*), the *P* value grows to reach a maximum of 0.69 at $C = 6$ ml l^{-1}. According to the adsorption–diffusion theory of surface leveling [3], the leveling additives inhibit electrodeposition of metals, with the extent of inhibition controlled by diffusion of an additive in the course of electrodeposition. The polarization curves measured on a rotating disk electrode at

different speeds of rotation can qualitatively model the cathodic process at microprojections (high speeds of electrode rotation) and at microdepressions (low speeds) [3]. The uneven accessibility of the microprofile is the reason for the nonuniform distribution of the rates at which additive is delivered to different parts of the microprofile. Since the inhibiting effect exerted by the leveling additives on electrodeposition

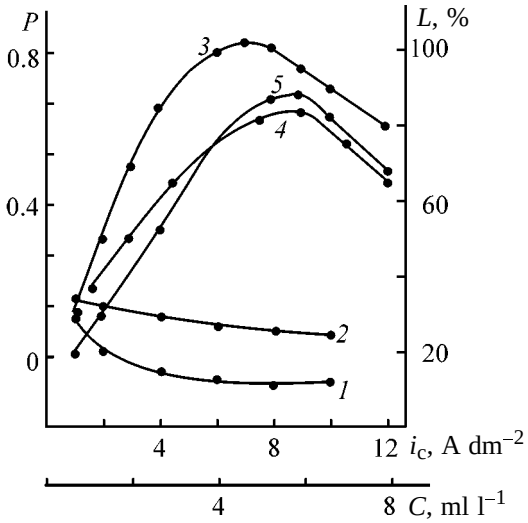

Fig. 3. Leveling power P vs. (*1–3*) current density i_c and (*4*) benzyl alcohol concentration C, and (*5*) coating luster L vs. current density for tin-plating electrolyte. (*1*) Electrolyte + Synthanol, 2 g l^{-1}; (*2*) *1* + formalin, 6 ml l^{-1}; (*3*, *5*) *2* + benzyl alcohol, 6 ml l^{-1}.

of metals becomes stronger with increasing rate of additive diffusion toward the cathode (high speed of rotation), this effect is more pronounced at microprojections, and less so at microdepressions, which leads to nonequilibrium distribution of the electrodeposition rates.

Analysis of the polarization curves measured in electrolytes with organic additives (Fig. 2, curves *2–4*) shows that the cathodic polarization curves measured at different speeds of rotation qualitatively model the distribution of the tin electrodeposition rate over the surface microprofile [3]. With increasing i_c, the leveling power first grows and then, at comparatively high current densities, the surface concentration of the additive and its inhibiting action decrease even at microprojections, which makes the leveling effect weaker. At too low content of additive in the electrolyte, when there occurs weak inhibition of tin electrodeposition, one cannot expect a pronounced leveling effect. At the same time, at too high concentrations of additive, the leveling power decreases because of the termination of the diffusion control over the rate of consumption of the additive and its inhibiting action. The phenomenon of leveling is related to the luster of electroplated coatings, since luster formation is also governed by leveling of submicrometer surface irregularities. According to [4], large microirregularities, from 0.2 to 100 μm and more in size, are eliminated in leveling, and very fine submicroirregularities of about 0.15 μm and less, in luster formation. Comparison of samples differing in luster and extent of leveling (Fig. 3, curves *3*, *5*) shows that these parameters are correlated: the higher the extent of leveling, the stronger the luster. Thus, leveling of submicro- and microirregularites on the cathode surface occurs in the course of electrolysis in a tin-plating electrolyte containing Synthanol, formalin, and benzyl alcohol.

On the basis of the performed investigations, a sulfate electrolyte of the following composition was developed for obtaining lustrous tin coatings (g l^{-1}): $SnSO_4$ 5–50, H_2SO_4 90–100, Synthanol DS-10 2–3; formalin 37% solution 6–8, benzyl alcohol 6–8 ml l^{-1}; deposition mode: i_c = 1–12 A dm^{-2}, CE = 65–98%. The process is carried out with mechanical stirring of the electrolyte. To obtain high-quality lustrous coatings, it is necessary to use anode made of pure tin. In order to prevent electrolyte contamination with sludge, the anodes are to be placed in sheaths made of polypropylene, before being submerged in the electrolyte. The electrolyte temperature is 20–25°C. At higher temperatures, the electrolyte rapidly turns turbid, and a large amount of precipitate is formed at the bath bottom, which impairs the coating quality. Long-term tests with the electrolyte demonstrated its high stability in operation. However, it should be noted that, during prolonged operation, a light yellow precipitate impairing the coating quality is formed on the bath bottom. The precipitate should be filtered off at regular intervals. The adjustment of the $SnSO_4$, H_2SO_4, and formalin content relies upon the results of chemical analysis [5]. The adjustment of the Synthanol content of the electrolyte should be done after passing 100 A h l^{-1} of electricity, by introducing 1 g l^{-1} of the additive into the bath. Since there is no technique for determining the concentration of benzyl alcohol in a tin-plating electrolyte, a spectrophotometric method was developed for this purpose. A 50-ml sample of a tin-plating electrolyte containing Synthanol, formalin, and benzyl alcohol was extracted with octanol (50 ml) under vigorous stirring in the course of 10 min. During this time, complete extraction was achieved. Part of the obtained organic phase was placed in a cell 10 mm thick, and spectra were recorded in the optical density–wavelength coordinates with an SF-26 spectrophotometer in the range 220–310 nm. As blank sample was used a solution obtained by extraction with octanol of a tin-plating electrolyte containing no benzyl alcohol. It was found that for all of the solutions studied the peak of the absorption band is observed at 252 nm, with the peak growing in height with increasing concentration of benzyl alcohol. It should be noted that the absorption is zero or very low in the employed wavelength range for all other components.

The obtained spectra were used to plot the calibration curve describing the dependence of the concentration of benzyl alcohol on the optical density at the maximum at 252 nm. This calibration curve can be used to monitor the concentration of benzyl alcohol in a tin-plating electrolyte. The scatter of measurement results in separate series does not exceed 5%.

CONCLUSIONS

(1) A study of tin electrodeposition from a sulfate electrolyte in the presence of organic substances demonstrated that high-quality lustrous deposits of tin are obtained in an electrolyte containing Synthanol, formalin, benzyl alcohol, $SnSO_4$, and H_2SO_4.

(2) A sulfate electrolyte and a deposition mode were developed for obtaining lustrous tin coatings with leveled surface.

Received May 7, 2001

Abstract—The acid and catalytic properties of Pentasil-type high-silica zeolites were studied as influenced by conditions of high-temperature treatment in the course of conversion of straight-run naphthas.

Zeolite-containing catalysts based on Pentasils are widely used in oil refining and petroleum chemistry. It was found [1–4] that the activity and selectivity of Pentasil-type high-silica zeolites (HSZs) in conversion of various hydrocarbons are determined by their not only acid, but also molecular-sieve properties. The efficiency of given catalytic process in conversion of hydrocarbon raw materials is determined by the optimal concentration ratio of the Brønsted and Lewis acid centers in the zeolite-containing catalysts. Along with modification using various additives, preliminary high-temperature treatment allows control of the catalytic and molecular-sieve properties of zeolite-containing catalysts.

In this work we studied the effect of high-temperature treatment on the acid and catalytic properties of Pentasil-type HSZs in the course of conversion of straight-run naphthas into lower olefins and arenes.

EXPERIMENTAL

High-silica zeolites of ZMS-5 type (silica ratio 30) were prepared from aluminosilicates by a hydrothermal procedure [5]. To convert Na-HSZs into the H form the samples were treated with 25% aqueous NH_4Cl at 90°C for 2 h, dried at 110°C, and calcined at 550°C for 8 h (Na_2O content ≤0.1%). The resulting HSZs were analyzed by IR spectroscopy and X-ray diffraction (XRD) (Mo anode, Ni filter). The effect of high-temperature treatment on the zeolite crystallinity was monitored by the comparing the interplanar spacings d (Å) and reflection intensities I (%) in the XRD patterns of the zeolite in question and reference compound.

The acid properties of HSZs were studied by thermal desorption of ammonia [6], and their catalytic properties were analyzed in the course of conversion of straight-run naphthas (from Surgut Gas Processing Plant) on a flow-type setup [7].

Data on the effect of high-temperature treatment on the activity and selectivity of HSZs in conversion of straight-run naphthas are listed in Table 1. With the initial NaHSZ (0.6 wt % Na^+), at 550–700°C and feed space velocity of 3 h^{-1}, the naphtha conversion increases from 85 to 88%. With increasing temperature the yield of gaseous hydrocarbons increases from 44.3 to 63.4%, the yield of C_2–C_4 olefins also increases from 19.8 to 39.1%, whereas the yield of aromatic hydrocarbons decreases from 47.9 to 31.1%.

After high-temperature treatment of an Na-HSZ sample at 800°C for 15 min its catalytic activity remains almost constant, and the yield of gaseous hydrocarbons and lower olefins increases in the temperature range studied. For example, at 650°C the yield of olefins (based on passed feed) increases from 29.3 to 39.0% and the yield of arenes decreases from 36.9 to 29.9% (Table 1). With the time of thermal treatment at 800°C increased to 30 min, high yield of C_2–C_4 olefins is retained. After treatment of an Na-HSZ sample at 900°C for 15 min, the yield of olefins at 550–600°C increases, but the catalytic activity decreases by 5% as compared to the initial sample. The selectivity of arene formation increases from 34.3 to 37.5 with increasing temperature.

Thus, our experimental data show that with increasing temperature of the catalyst thermal treatment from 750 to 900°C the yield of C_2–C_4 olefins increases; the

optimal time of thermal treatment is 15 min. The effect of thermal treatment on the catalyst performance is the most pronounced at the temperature of the straight-run naphtha conversion of 550 – 600°C; with increasing conversion temperature the effect of the catalyst thermal pretreatment on the selectivity of formation of lower olefins and arenes decreases.

These trends in the conversion and selectivity of formation of lower olefins and arenes are probably due to variations in the acidity of the HSZ samples. It is known that the Brønsted acid centers are zeolite hydroxy groups, and their interaction with ammonia yields NH_4^+ ions [8]. In the case of zeolite containing residual Na^+ cations, ammonia sorption involves

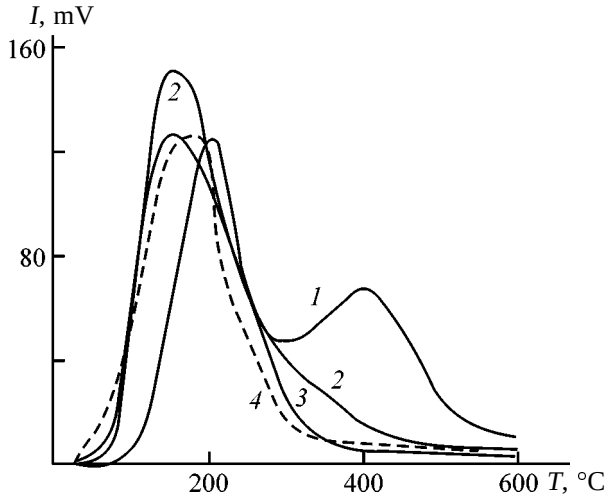
formation of the coordination bond between the lone electron pair of nitrogen and sodium cations [9].

Data on the acid properties of the HSZ samples subjected to high-temperature treatment are shown in the figure and listed in Table 2. The curve of temperature-programmed NH_3 desorption from the initial Na-HSZ contains two peaks: low-temperature peak (T_{max} 198°C) and high-temperature shoulder (T_{max} 380°C), which suggests the presence of acid centers of two types. This is confirmed by the ammonia desorption curve registered for the H-HSZ catalyst (figure, curve *1*).



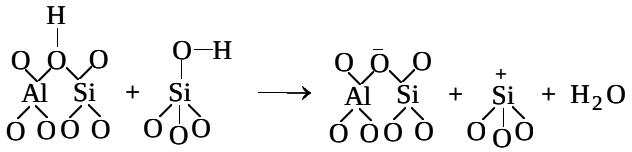
Curves of temperature-programmed ammonia desorption from HSZs. (*I*) intensity and (*T*) temperature. Sample: (*1*) H-HSZ, (*2*) Na-HSZ, (*3*) Na-HSZ (800°C), and (*4*) Na-HSZ (900°C).

High-temperature treatment of Na-HSZ at temperatures of up to 750°C does not affect its acid properties (Table 2). On further heating to 800°C and higher temperatures the strong acid centers almost completely disappear, and the content of more thermally stable weak acid centers slightly decreases. Moreover, on treatment at temperatures ≥900°C T_{max} of the low-temperature peak of ammonia desorption (form I) shifts to lower temperatures, i.e., the strength of the acid centers decreases. With increasing temperature of HSZ treatment the high-temperature form of ammonia desorption gradually disappears.

The XRD data on the initial HSZ and zeolite subjected to high-temperature treatment are listed in Table 3. The XRD patterns of the samples exhibit a set of Pentasil reflections typical for ZSM-5 [10]. Our

study of the thermal stability showed no changes in the HSZ structure at annealing of the zeolite samples for 15 min at 800 and 900°C. At more prolonged treatment (30 min) the reflection intensities slightly decrease.

Our experimental data on the acid and catalytic properties of HSZs allow evaluation of the role of the weak and strong acid centers in formation of C_2–C_4 olefins and arenes from straight-run naphtha. The activity of the zeolite catalyst is determined by the presence of both strong and weak acid centers. At high-temperature treatment the zeolite undergoes dehydroxylation. First of all at 750°C the content of strong acid centers sharply decreases, and at higher temperatures these acid centers completely disappear. Based on the IR data, it was supposed [1, 2] that high-temperature treatment of the zeolites (≥900°C) strongly decreases the content of the Brønsted acid centers (B-centers). At the same time, the Lewis centers (L-centers) are more thermally stable and start to degrade at higher temperatures. For example, in the case of Zn-Pentasils their L-centers are retained even after annealing at 1000°C. The L-centers of dehydrated zeolite [2] belong to two types: those of type I are three-coordinate Al^{3+} cations in the zeolite lattice with stronger acid properties, and those of type II are exchangeable Na^+ cations, coordination-unsaturated Al^{3+} ions outside the zeolite skeleton [8, 11], or three-coordinate Si^{4+}. The quantum-chemical calculations performed in [3] suggested the following scheme of zeolite dehydroxylation:



Thus, our experimental data show that, with the temperature of thermal treatment increased to 900°C, the strong acid centers completely disappear, the strength and concentration of the weak Lewis acid centers decrease, and the selectivity of formation of lower olefins from straight-run naphthas increases.

CONCLUSION

High-temperature treatment (up to 900°C) of high-silica zeolites of Pentasil type changes the ratio of the strong and weak acid centers in the catalyst. As a result, the weak Lewis acid centers become predominant, which increases the selectivity of formation of lower olefins from straight-run naphthas.

CATALYSIS

Direct Acid-Catalyzed Hydration of Camphene as a Route to Isoborneol

Received June 18, 2001

Abstract—Heterogeneous homophase hydration of camphene in the presence of $H_4SiW_{12}O_{40}$, $H_3PW_{12}O_{40}$, or $HClO_4$ was studied as a selective procedure for production of isoborneol.

Isoborneol, a bicyclic terpene alcohol, is widely used as initial substance in syntheses of biologically active substances for medicine, perfumery, cosmetics, and other fields. In particular, isoborneol is an intermediate in industrial synthesis of camphor, one of the main wood-chemical products.

The isomerization procedure used previously for producing camphor in Russia was multistage and involved catalytic isomerization of α- and β-pinene (turpentine) to camphene, esterification of camphene, saponification of the esters to isoborneol, and dehydrogenation of isoborneol to camphor [1]. The process was resource-, labor-, and power-consuming and gave rise to environmental problems; the quality of the target product was relatively poor. As a result, in the early 1990s the camphor production in Russia was fully stopped.

At the same time, it is known that China succeeded in improvement of the isomerization procedure and expanded the camphor production, so that at present it is practically the only producer and supplier of synthetic camphor to the world's market. Available publications suggest that the improved procedure for camphor production is based on the direct acid-catalyzed hydration of camphene to isoborneol, which allows not only reduction of the number of process stages but also improvement of the camphor quality. In the process, ion-exchange resins [2–4] or synthetic zeolites [5, 6] are used as catalysts.

Previous studies of homogeneous acid-catalyzed hydration of camphene in aqueous-organic media showed that effective catalysts are $H_4SiW_{12}O_{40}$ and $H_3PW_{12}O_{40}$ [7], and also $HClO_4$ [8]. Taking into account these results, we examined the behavior of these catalysts under conditions of heterogeneous homophase hydration.

Camphene hydration was performed in the presence of organic solvents immiscible with water (toluene or hexane), and also in the presence of dioxane and methyl ethyl ketone (MEK) added in amounts at which dissolution of the initial reactants was incomplete. In some cases, an emulsifier was used to improve the phase contact. In these experiments the organic phase was camphene or a solution of camphene in an organic solvent, and the aqueous phase was a solution of a catalyst in water.

The results of heterogeneous acid-catalyzed hydration of camphene in the absence of organic solvent are listed in Table 1. It is seen that the catalyst and reaction conditions strongly affect the composition and yield of the products.

With concentrated aqueous $HClO_4$ (40–60 wt %) as catalyst, the reaction yields exclusively camphene polymers (mainly a mixture of dimers). As the $HClO_4$ concentration is increased from 40 to 60%, the yield of the polymeric products at 65°C increases from 50 to 98%. As the reaction temperature is decreased to 50°C, with 40% $HClO_4$, the yield of the polymeric products appreciably decreases, becoming as low as 12%. No isoborneol or other alcohol is formed. Addition of ZnO to the catalyst (40% aqueous $HClO_4$, run no. 4) significantly increases the yield of the polymeric products, which reaches the level of 98% obtained with 60% $HClO_4$.

With less concentrated aqueous $HClO_4$ solutions, the camphene conversion considerably decreases, but isoborneol is detected in reaction products. As the $HClO_4$ concentration is decreased, the yield of the polymeric products regularly decreases, becoming zero with <11.6% $HClO_4$, whereas the content of isoborneol in the products remains constant down to

the $HClO_4$ concentration of 4.2%. The increase in the reaction temperature to 80°C, variation of the volume ratio of camphor to aqueous acid solution, and addition of an emulsifier have no significant effect on the reaction selectivity and product composition.

With $H_3PW_{12}O_{40}$ and $H_4SiW_{12}O_{40}$ as catalysts of heterogeneous homophase hydration of camphene, we obtained the same results as with dilute aqueous solutions of perchloric acid: the yield of isoborneol, which was virtually the only reaction product, did not exceed 6–7% (Table 1).

The results of heterogeneous acid-catalyzed hydration of camphene in the presence of various solvents are given in Table 2. It is seen that addition of solvents immiscible with water (toluene or hexane) increases the content of undesirable impurities in the reaction products: camphene hydrate, pseudoborneol, and minor amounts of fenchol and isofenchol (all products were identified by GLC using reference compounds). The yield of isoborneol, with both heteropoly acids and perchloric acid as catalysts, does not change as compared to the process performed without a solvent.

The yield of the target product and the process selectivity appeared to be considerably higher when the process was performed with dioxane or methyl ethyl ketone (MEK) as solvent. These solvents were added in amounts that were insufficient to fully dissolve the initial compounds; therefore, the reaction conditions were also heterogeneous homophase.

Table 2 shows that even at a water : dioxane ratio of 2 : 1 (by volume; run no. 14) the yield of isoborneol increases to 15.6%. At the content of dioxane or MEK increased further, the content of isoborneol in the reaction mixture increases, reaching 25–28 wt % at the reaction selectivity of 98–99%. The nature of the catalyst has practically no effect on the yield of isoborneol and the process selectivity.

The perchloric acid concentration (3.4 wt %) ensuring the same yield of isoborneol is by a factor of almost 7 lower than the required concentration of heteropoly acids (23%), which is very important, taking into account high cost of heteropoly acids.

The heterogeneous hydration of camphene in MEK in the presence of perchloric acid was chosen as a procedure for preparative synthesis of isoborneol. The reaction product, isolated in 25% yield, after recrystallization from ethanol had mp 210.8°C (the reference value [9] for pure isoborneol is 212°C) and a 98.5% purity (GLC data). Such a product fully meets the requirements imposed upon isoborneol to be used for commercial production of synthetic camphor [1].

* (V_o, $V_{aq\text{-}o}$) Volumes of the organic and aqueous-organic solvents, respectively.
** An emulsifier was used.

The spent perchloric acid can be used repeatedly; neither the yield of isoborneol, nor the selectivity of hydration are deteriorated.

EXPERIMENTAL

Hydration of camphene was performed in a temperature-controlled reactor equipped with a heated jacket, a stirrer, and a reflux condenser. The reactor temperature was maintained to within ±0.5°C. The stirring rate was controlled with a tachometer. To improve the contact of aqueous and organic phases, Pektanoks emulsifier [OE-15 brand, TU (Technical Specifications) 2453-006-25588394–99] was added in some experiments. At certain time intervals after the start of the reaction, the mixture was quickly cooled, the reaction products were extracted with hexane, and the extract was neutralized with 10% aqueous Na_2CO_3, washed with water to pH 7, and dried over $MgSO_4$. After removing excess solvent, the reaction products were analyzed by GLC with a Chrom-5 chromatograph (flame-ionization detector, 3-m stainless steel column, stationary phase 15% PFMS-5 silicone oil on Chromaton N-AW-DMSC, 0.20–0.25 mm; column and vaporizer temperatures 110–180 and 250°C, respectively; carrier gas N_2, flow rate 60 ml min^{-1}). The content of the components was determined using tridecane as internal reference. The relative error of single analysis at a confidence level of 0.95 was within ±2%. The results of five parallel runs were averaged.

The melting point of isoborneol was determined in a capillary according to [10] with a PTP-2 device for melting point determination.

A solution of perchloric acid in aqueous MEK, after isolation of hydration products from the reaction mixture, was adjusted to the required concentration and reused.

Received June 29, 2001

Abstract—The effect of ionic diffusion on parameters of redox electrical conductivity in poly-$[M(5\text{-Cl-phen})_3]^{2+}$ (M = Fe, Ru, Os) was studied.

Supramolecular chemistry studying ordered associations of coordination-saturated species is an urgent branch of the modern basic science showing promise for high technologies [1–3]. Electroconducting supramolecular structures that are formed from polymers based on organometallic and coordination compounds of transition metals are of special interest. As a rule, these are intensely colored substances with a series of practically important properties such as redox electrical conductivity of polymeric complexes, photosensitivity, photo- and electroactivity, electrocatalytic and electrochromic properties.

From the viewpont of the practical use, polymeric structures with a high rate of charge transfer in the bulk of the solid phase, stable to action of chemical and physical factors, are of the most interest. Such complexes can be promising materials for production of sensors, chemotronic, photo- and electrocatalytic devices, and solid converters of the light energy [1].

In this work, we studied the electrochemical properties of polymers based on Fe(II), Ru(II), and Os(II) complexes with 5-chloro-1,10-phenanthroline with the aim to reveal factors determining the rate of charge transfer in the polymer bulk.

EXPERIMENTAL

Complexes $[M(5\text{-Cl-phen})_3](ClO_4)_2$ (M = Fe, Ru, Os; 5-Cl-phen = 5-chloro-1,10-phenanthroline) were synthesized by methods described in [4] and indentified by elemental analysis and electronic absorption spectra [5, 6].

(4,7-Diphenyl-1,10-phenanthroline)bis(5-chloro-1,10-phenanthroline)iron(II) perchlorate $[Fe(4,7\text{-ph}_2\text{-phen})(5\text{-Cl-phen})_2](ClO_4)_2$ was prepared by successively mixing the initial reagents 5-Cl-phen (0.466 mmol), $FeSO_4 \cdot 7H_2O$ (0.233 mmol), and 4,7-ph_2-phen (0.233 mmol) in 50 ml of hot ethanol. The resulting dark red solution was vigorously agitated at moderate heating for 2 h. The claret-colored complex (perchlorate form) was filtered off, washed with water, hot benzene, and diethyl ether, and dried in a vacuum over phosphorus(V) oxide. Yield 85%. Analytical data:

Found (%): C 61.89, H 2.74, N 7.45.
Calculated (%): C 62.06, H 2.58, N 7.24.

The electrochemical synthesis of polymeric $[M(5\text{-Cl-phen})_3]^{2+}$ was performed in the potentiostatic mode. The optimal conditions of growth of polymeric layers were as follows [7]: polarization potential of the working electrode in 2×10^3 M acetonitrile solutions of monomeric complexes E_p = –1.6 V, polarization time 7 min.

The electrochemical properties of the polymeric complexes were studied by cyclic voltammetry. A PI-50-1 pulse potentiostat with incorporated *IR*-compensation system set the potential of the working electrode. The potential of the working electrode was scanned in the cyclic mode at a rate of 10, 20, 50, 100, 200, and 500 mV s^{-1}. Voltammograms were recorded on a 307 two-coordinate potentiometric recorder.

Voltammetric measurements were performed in a hermetically sealed three-electrode Pyrex cell with separated compartments of the working, auxiliary, and reference electrodes.

1070-4272/01/7411-1854$25.00 © 2001 MAIK "Nauka/Interperiodica"

A 1-mm platinum wire (99.99% Pt) with the 0.21 cm^2 surface area sealed into Pyrex glass was the working electrode, and a platinum gauze with the 2.5 cm^2 surface area was the auxiliary electrode. All potentials are given vs. Ag–AgCl reference electrode filled with saturated aqueous NaCl solution.

The low-temperature electrochemical experiments were performed in a special three-electrode glass cell placed into a small thermostat with the temperature control of the supporting solution within the 243–293 K range.

A 0.1 M Bu_4NClO_4 solution in acetonitrile (the solvent was purified according to [8]), aerated with argon, was used as the supporting electrolyte. 1 M solutions of Bu_4NBF_4, Bu_4NPF_6, and CF_3COOBu_4N in acetonitrile were used to study the effect of supporting electrolyte on the charge diffusion coefficient D_{ct} in the bulk of the polymeric phase. The values of D_{ct} were obtained with an error of $\pm 0.5 \times 10^{-10}$ $cm^2 s^{-1}$.

During the electrochemical reduction of the Fe(II), Ru(II), and Os(II) complexes with 5-chloro-1,10-phenanthroline, red, orange, and olive green films, respectively, are formed on the surface of the platinum electrode. The possible mechanism of film formation involves reduction of the ligand into a radical anion followed by chloride ion elimination. Recombination of the resulting radicals generates polymeric chains and initiates growth of poly-$[M(5\text{-Cl-phen})_3]^{2+}$ polymers [4].

The polymeric complexes are electrochemically active within the potential range of metal-centered M(III)/M(II) transition. The potentials of the poly-$[M(5\text{-Cl-phen})_3]^{3+}/[M(5\text{-Cl-phen})_3]^{2+}$ couples were calculated as the mean values of the potentials of the cathodic and anodic maxima. They amounted to +1.12 (Fe), +1.36 (Ru), and +0.92 V (Os) [9].

Transition of the redox polymers from the reduced to oxidized state and back involves the electron transfer to the electrode–polymer phase boundary, the electron self-exchange between chain fragments (redox centers), and diffusion of the supporting electrolyte ions into the polymer bulk (and back) to keep macroelectroneutrality [10].

The rate of the charge transfer in the polymeric phase is mainly determined by the nature of the initial monomeric complex, supporting electrolyte, and morphology of the resulting polymer. It can be quantitatively characterized by D_{ct}.

Depending on the nature of the limiting stage, this quantity characterizes the electron self-exchange between heterocharged fragments or diffusion of supporting electrolyte ions in the polymeric phase.

Published data on the electron self-exchange with participation of octahedral low-spin Fe(III, II), Ru(III, II), and Os(III, II) complexes with polypyridyl ligands (bipy, phen, and their derivatives) show that it is not the limiting process. The electron transfer within the outer coordination sphere between the redox centers is accompanied by small variation of the metal–ligand bond length, because the transferred electron is located on the energetically favorable $d\pi$ orbitals of the metal ion: $d_\pi^5 + e = d_\pi^6$ [11]. This causes the high rate of the electron exchange in the above systems. For instance, in aqueous solutions the self-exchange constants reach the diffusion limit of 10^9 mol^{-1} s^{-1} [12].

The cyclic voltammograms of the redox processes with participation of poly-$[Os(5\text{-Cl-phen})_3]^{2+}$ recorded at various rates of scanning of the electrode potential V_p are shown in Fig. 1a, and in Fig. 1b are presented the currents of anodic maxima of voltammograms I_p^a as functions of V_p. The linear dependence between the above parameters at $V_p \le mV$ s^{-1} is observed, which indicates complete oxidation and reduction of the polymeric complexes in each cycle of potential scanning. This is characteristic for compounds adsorbed on the electrode surface. At the rates of potential scanning exceeding 50 mVs^{-1}, both oxidation and reduction of the polymeric complex in each scanning cycle is incomplete. In this case, the linear dependence $I_p^a = F(V_p^{1/2})$ is observed, i.e., the redox processes proceed in the mode equivalent to the semi-infinite diffusion of the electroactive substance directed to the electrode surface. The D_{ct} values calculated by the Randles–Shevchik equation [13] were about 2.0×10^{-10} cm^2 s^{-1} for all polymers studied and were independent of the polymer thickness.

The charge transfer in the bulk of the polymeric phase is a thermally activated process. The typical dependence $\ln D_{ct} = F(T^{-1})$ for poly-$[M(5\text{-Cl-phen})_3]^{2+}$ is shown in Fig. 2. The low-temperature voltammetric measurements showed that the activation barriers of the charge transfer are independent of the metal center nature and amount to about 25 kJ mol^{-1} for all the polymeric complexes studied. The lack of correlation between the degree of π-dative metal–ligand interaction increasing in the Fe–Ru–Os series and the height of the activation barrier to charge transfer indicate that the D_{ct} values found characterize the mobility of counterions in the polymeric phase.

To confirm the crucial importance of ionic diffu-

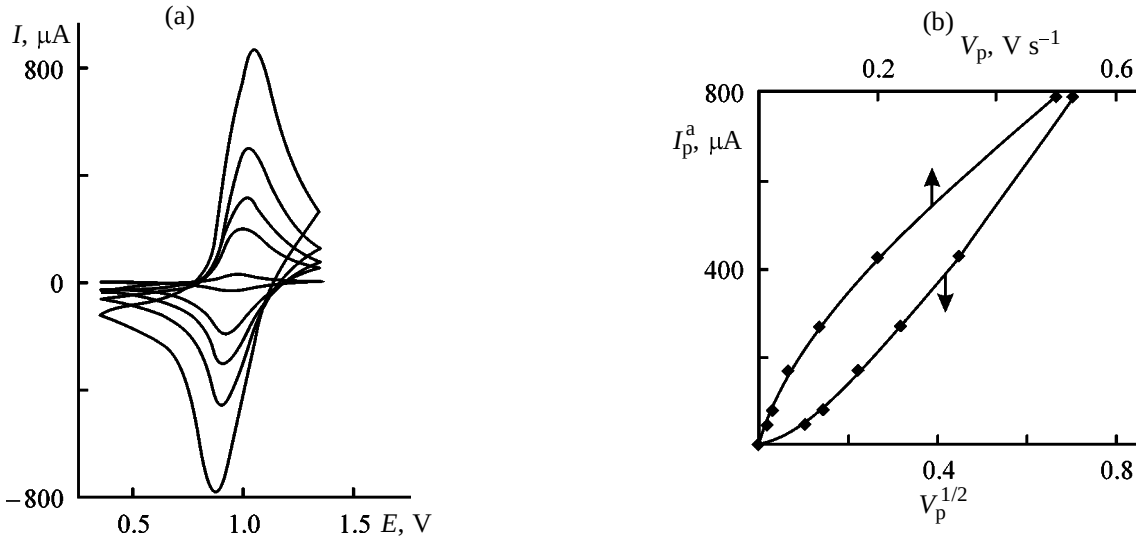

Fig. 1. (a) Chronoammograms of poly-$[Os(5\text{-Cl-phen})_3]^{2+}$ in the supporting electrolyte solution (0.1 M Bu_4NClO_4 in CH_3CN) and (b) dependence of the current of anodic maxima I_p^a in the chronovoltammograms on the rate of potential scanning V_p. (a) Rate of potential scanning (in the order of increase in chronovoltammogram current): 10, 20, 50, 100, and 500 mV s^{-1}. (*I*) Current and (*E*) potential; the same for Fig. 3.

sion in the charge transport in the poly-$[M(5\text{-Cl-phen})_3]^{2+}$ complexes, we examined the effect of the size and concentration of the supporting electrolyte ions on the charge diffusion coefficient. The diameters of ClO_4^-, BF_4^-, PF_6^-, and CF_3COO^- ions are 3.37, 3.70, 4.35, and 7.20 Å, respectively [14]. The experiment shows that the charge transfer activation energy regularly increases with increasing diameter of the counterion (to 37 and 46 kJ mol^{-1} for BF_4^- and PF_6^-, respectively). This can be explained as follows. The diffusion in the bulk of the polymer phase can be presented as a sequence of jumps occurring as a free volume is generated by segmentary motion near the moving particle [15]. The diffusion of bulkier particles involves larger energy consumption required to shift bulky polymeric fragments to form "holes" sufficient to accommodate the counterions.

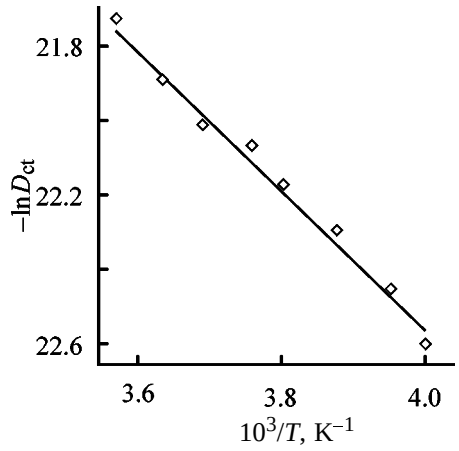

Fig. 2. Determination of the activation barrier of the charge transfer in poly-$[Ru(5\text{-Cl-phen})_3]^{2+}$. Supporting electrolyte 0.1 M Bu_4NClO_4 in CH_3CN. (D_{ct}) Charge diffusion coefficient and (*T*) temperature.

In the limiting case, mismatch of the sizes of the charge-compensating ions and holes of the polymer can cause polymer degradation. For instance, the use of 0.1 M CF_3COOBu_4N in CH_3CN as a supporting electrolyte leads to irreversible oxidation of the all polymers studied (Fig. 3, curve *2*) and practically complete loss of the electrical conductivity by these materials (Fig. 3, curve *3*) due to distortion of the π conjugation in the ligand system. This fact can be explained by impossibility of trifluoroacetate ions to penetrate deep into the polymer to compensate for the new charge state of the metal centers.

The rate of oxidation–reduction of poly-$[M(5\text{-Cl-phen})_3]^{2+}$ substantially depends not only on the nature of the supporting electrolyte but also on its concentration. The dependence of I_p^a on the Bu_4NClO_4 concentration C_S in acetonitrile for poly-$[Ru(5\text{-Cl-phen})_3]^{2+}$ is shown in Fig. 4. The dependence $I_p^a = F(C_S)$ is linear at $C_S \le 0.6$ M; within this concentration range D_{ct} increases by 25–30% owing to the growth of the gradient of the diffusing ion concentrations in the bulk of the polymer and in the supporting electrolyte solution. At $C_S > 0.6$ M, the linear character of the $I_p^a = F(C_S)$ dependence is broken, which reflects the transformations of the polymer morphology [16]. In concentrated solutions of the supporting electrolyte, the degree of shielding of the similarly charged centers of

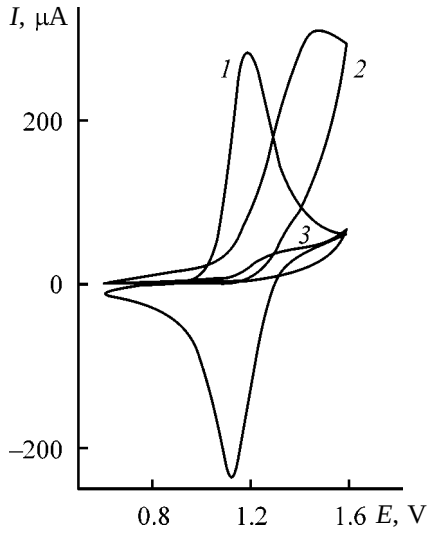

Fig. 3. Chronovoltammograms of poly-$[Fe(5\text{-Cl-phen})_3]^{2+}$ in supporting electrolyte solutions (*1*) 0.1 M Bu_4NClO_4 in CH_3CN and (*2*, *3*) 0.1 M CF_3COOBu_4N in CH_3CN. Rate of potential scanning 50 mV s^{-1}.

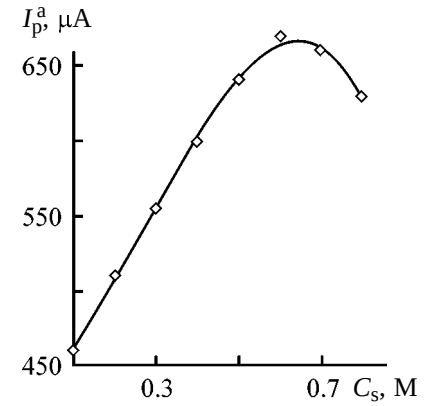

Fig. 4. Current of anodic maxima I_p^a for poly-$[Ru(5\text{-Cl-phen})_3]^{2+}$ as a function of Bu_4NClO_4 concentration in CH_3CN C_S. Rate of potential scanning 200 mV s^{-1}.

the polymeric complex increases, and therefore the macromolecule becomes more compact. As a result, the polymer free volume decreases, and ionic diffusion decelerates.

It should be noted that appropriate variation of the formation conditions and morphology of polymeric structures substantially increases the coefficient of the charge diffusion in the bulk of the polymer. For the polymer based on the heteroligand complex Fe(4,7-ph_2-phen)(5-Cl-phen)$_2$](ClO$_4$)$_2$, D_{ct} is equal to 4.7×10^{-10} cm^2 s^{-1}. Probably, bulky phenyl substituents in the inner sphere of the initial monomeric complex increase the polymer free volume and strengthen the mobility of counterions in the bulk of the polymer phase.

When a 0.1 M solution of CF_3COOBu_4N in CH_3CN is used as a supporting electrolyte in the synthesis of poly-$[M(5\text{-Cl-phen})_3]^{2+}$ with the subsequent transfer of the polymer into the 0.1 M solution of Bu_4NClO_4, D_{ct} increases to 7.5×10^{-10} cm^2 s^{-1}. Hence, these conditions of polymer formation provide the larger free volume of the polymer matrix.

CONCLUSION

The rate of charge transfer in polymers based on Fe(II), Ru(II), and Os(II) complexes with 5-chloro-1,10-phenanthroline is determined by the mobility of ions of the supporting electrolyte in the bulk pf the polymer phase.

Abstract—The selectivity of S-930 chelating sorbent with respect to nonferrous metals present in the wastewater from electroplating productions was studied. This sorbent is advantageous as compared to KU-2 universal cation exchanger in recovery of microamounts of nonferrous metals from wastewter containing up to 2 g l^{-1} of alkaline-earth chlorides and sulfates.

A division for centralized reprocessing of the spent solutions from electroplating productions was set up at the Moscow Promotkhody plant. According to the flowsheet, spent solutions from electroplating productions are neutralized with sodium hydroxide aqueous solution to precipitate nonferrous metals and iron in the form of their hydroxides. After separation of these precipitates by filtration, the remaining solution contains up to 25.5 g l^{-1} of the sum of water-soluble salts, including minor amounts of nonferrous metals and iron.

On compacting the precipitate and washing the equipment and pipelines, the wastewater is formed containing up to 2 g l^{-1} of the sum of alkali and alkaline-earth metals and microamounts of nonferrous metals and iron. The metal content in the wastewater is given in Table 1.

Sulfates and chlorides of alkali and alkaline-earth metals (Na^+, Ca^{2+}, Mg^{2+}) are macrocomponents of the wastewater. Their content in wastewater discharged to a sewer system is not restricted; therefore, wastewater should be decontaminated only from impurities of nonferrous metals [Cr(III), Fe(II), Cu(II), Zn(II), and Ni(II)] to the levels lower than the maximum permissible concentrations (MPC) [1].

It is known that in decontamination of dilute wastewater (in particular, washing water) with the salt content not exceeding 2 g l^{-1}, the ion-exchange sorption is the most preferable. It is this technique that provides environmentally safe decontamination of industrial wastewater [2].

To ensure high efficiency of ion-exchange decontamination of wastewater, it is necessary to use the ion exchanger exhibiting the required sorption power, fast sorption kinetics, high granule strength, and also high chemical and osmotic stability [3].

In sorption removal of nonferrous metals and iron from multicomponent solutions containing large amounts of alkali and alkaline-earth metals, the sorbent should be sufficiently selective.

Chelating ion exchangers with amino acid functional groups fully meet these requirements [4]. These sorbents exhibit selectivity owing to their capability of forming metal complexes of various stabilities and structures in the resin phase. The highest selectivity is exhibited by chelating polyampholytes with the iminodiacetate complexing groups. Their selectivity decreases in the order Cu > Ni > Zn > Co > Ca >

Table 1. Metal ion content in wastewater

Metal ion	Concentration		MPC in discharging to sewer system, mg l^{-1}
	mg l^{-1}	mg-equiv l^{-1}	
Cr(III)	15	0.865	1.0
Fe(II)	50	1.8	3.0
Cu(II)	12	0.38	0.5
Ni(II)	15	0.51	0.5
Zn(II)	12	0.37	2.0
Ca(II)	156.3	7.8	Not restricted
Mg(II)	72.9	6.0	〃

1070-4272/01/7411-1858$25.00

Mg > Sr > Ba > Na, which correlates with the strength of complexes of these metals with the iminodiacetate functional groups in the resin phase [4].

At present, ANKB-35 and ANKB-50 sorbents with the iminodiacetate functional groups are not commercially produced in Russia. Their most available imported analog is S-390 produced by Purolite Corporation (The United States, the United Kingdom) [6].

Our experience of using S-930 sorbent for recovery of copper from multicomponent process salt solutions showed that this chelating sorbent surpasses in selectivity both ANKB-35 (Russian analog) and well-known MC-50 polyampholyte (Germany) [7].

It is known that the group concentration of the metal impurities can be performed on weakly acidic carboxylic cation exchangers exhibiting high sorption capacity and selectivity with respect to polyvalent metals [8]. However, these cation exchangers are efficient in weakly acidic media only (at pH about 3). Also, these sorbents do not meet the modern requirements to the osmotic stability and resin strength; therefore, their service life is limited.

Thus, carboxylic cation exchangers of KB type seem to be of little promise for solving the problems under consideration.

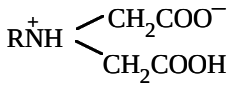
Selective sorption is a multifactor process depending not only on the ionic composition of solution but also on the ratio of the ions being recovered, pH, and the degree of protonation of the functional groups. Therefore, prior to the practical use, the sorbent with suitable characteristics should be experimentally chosen and conditions ensuring its highest performance should be found.

In this work the comparative study of sorption recovery of nonferrous metals [in particular, Cr(III)] and iron from wastewater from electroplating productions with both KU-2 × 8 strongly acidic sulfonic cation exchanger and S-930 selective chelating sorbent with the iminodiacetate functional groups was carried out to choose the sorbent ensuring the most efficient wastewater decontamination, suitable for industrial use.

EXPERIMENTAL

The sorption and desorption characteristics of KU-2 × 8 universal sorbent and S-930 selective sorbent were determined under dynamic conditions by passing appropriate solutions through columns packed with these ion exchangers.

S-930 sorbent is the monofunctional ion-exchange resin containing the iminodiacetate functional groups



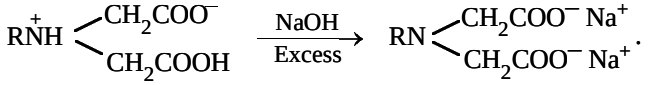
where R is the macroporous polymeric matrix based on styrene and divinylbenzene.

This sorbent consists of light yellow dull granules 0.4–1.0 mm in diameter exhibiting high levels of sorption capacity, chemical and thermal stability, mechanical strength, and osmotic stability.

The lack of standard recommendations for pretreatment of chelating polyampholytes hinders their use. The standard pretreatment is required to provide reproducibility of the sorption capacity and other characteristics of these sorbents.

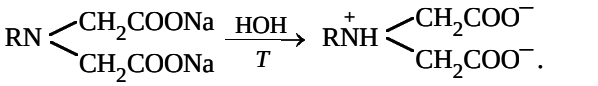
In this work S-930 sorbent was converted to the neutral form by passing a 5% sodium hydroxide solution through the column packed with the commercial resin. Such treatment was continued until the sodium hydroxide concentrations at the inlet and outlet of the column became equal. Then, the column was washed with water to weakly alkaline reaction of the eluate (pH 8–9).

Treatment of the commercial sorbent with aqueous sodium hydroxide solution converts the sorbent to the dibasic cation-exchange iminodiacetate form:

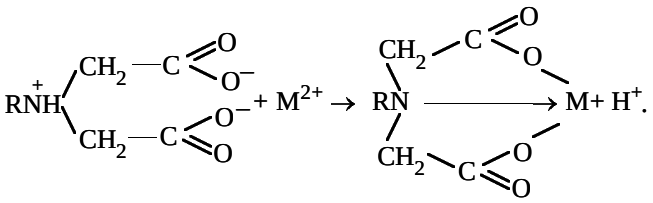


However, hydrolysis of this form of the sorbent makes the aqueous solution strongly alkaline, which is unacceptable for the practice.

To overcome this drawback, the cation exchanger in the Na form was washed with hot water to the weakly alkaline reaction of the eluate (pH 8–9). After such treatment the sorbent is converted to the stable neutral form:



This coordination-active form of the sorbent is capable of binding the metal ions by coordination and ionic bonds:



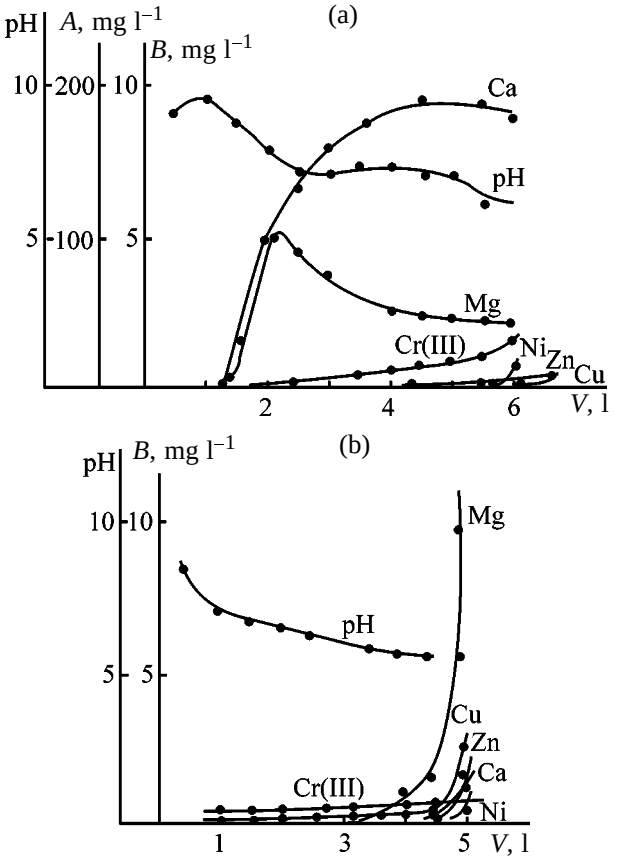


Fig. 1. Output curves of sorption of nonferrous metal [including (Cr(III)] cations on (a) S-930 selective sorbent and (b) KU-2 × 8 cation exchanger. (*A*) Ca and Mg content; (*B*) (a) nonferrous metal [including (Cr(III)] content and (b) metal content; (*V*) solution volume passed through column.

At the same time, this form of the ion exchanger does not sorb metals that do not form coordination bonds with the acetate functional groups or form weak complexes [9, 10]. Owing to these features, S-930 sorbent is selective to nonferrous metals and iron. To convert one volume of swollen polyampholyte to the Na form, six volumes of 5% NaOH are required. To wash one volume of this sorbent, four volumes of water are required.

KU-2 × 8 cation exchanger in the Na form was used as the reference sorbent.

Pretreatment of KU-2 × 8 cation exchanger and determination of its characteristics before testing were carried out in accordance with GOST (State Standard) [11, 12].

The sorbents were tested under dynamic conditions in standard glass columns 18 mm in diameter. The height of the swollen sorbent bed was 15 cm, and its volume, 40 cm^3.

In the tests, ten volumes of wastewater were passed through one sorbent volume per hour. The wastewater was passed through the column up to breakthrough of the least sorbable metals to concentration exceeding their maximum permissible concentration in water discharged to the municipal sewer system (Table 1). The initial and decontaminated wastewaters were analyzed for the metals by atomic-absorption technique on a Perkin–Elmer spectrophotometer [13].

The output curves of sorption of nonferrous metals [including Cr(III)] in the presence of macroamounts of Ca^{2+} and Mg^{2+} on S-930 and KU-2 × 8 cation exchangers are shown in Fig. 1.

As seen from Fig. 1, KU-2 × 8 cation exchanger absorbs the sum of the metals present in the wastewater, including Ca^{2+} and Mg^{2+}. In contrast to the sulfonic cation exchanger, S-930 sorbs alkaline-earth metal ions only at the beginning of the process. In further elution these metals are replaced by nonferrous metal [including Cr(III)] cations, and therefore their content in the eluate becomes equal to that in the feed. These results show that nonferrous metal [including (Cr(III)] cations are selectively sorbed on S-930 cation exchanger.

Table 2 shows that in sorption on KU-2 × 8 cation exchanger the nonferrous and alkaline-earth metals break through simultaneously. Thus, this sorbent exhibits no selectivity with respect to the metals concerned. In contrast to KU-2 × 8 cation exchanger, in sorption of these metals on S-930 cation exchanger chromium(III) and nickel break through first (among nonferrous metals), while zinc and copper cations are retained on the resin so that only traces of them are eluted. By breakthrough, as above, we mean the metal concentration in the eluate exceeding the maximum permissible concentration in wastewater discharged to a municipal sewer system (Table 1).

The fact that the volume of the wastewater decontaminated by one column volume of S-830 sorbent is twice that of KU-2 × 8 shows that the dynamic exchange capacity of S-930 is twice that of KU-2 × 8.

The averaged composition of wastewater passed through beds of S-930 and KU-2 × 8 resin, (water volumes are 6 and 5 l, respectively) are listed in Table 3.

The metals were desorbed from S-930 sorbent under dynamic conditions by passing 20% H_2SO_4 through the column at a filtration rate of 1–2 ml min^{-1}. Figure 2 shows that the eluate contains all nonferrous

metals [including Cr(III)] present in the initial wastewater. Magnesium was not detected in the eluate. As for calcium, this cation is precipitated in the first fraction of the eluate (10% of the total eluate volume) as calcium sulfate. In the case of KU-2 cation exchanger, to prevent calcium sulfate precipitation within the sorbent bed, the metals were sequentially desorbed with 2 and 10% sulfuric acid at a filtration rate of 1–2 ml min^{-1}. In these experiments copper, zinc, nickel, calcium, and magnesium were eluted, whereas Cr(III) was desorbed poorly (Fig. 2). In all fractions of the eluate calcium sulfate was precipitated. To prevent calcium sulfate precipitation in regeneration of KU-2 cation exchanger and increase recovery of chromium(III), we recommend to use as eluent nitric or hydrochloric acid. However, with these reagents the sorbent regeneration is significantly complicated. Figure 2 shows that in regeneration of S-930 sorbent

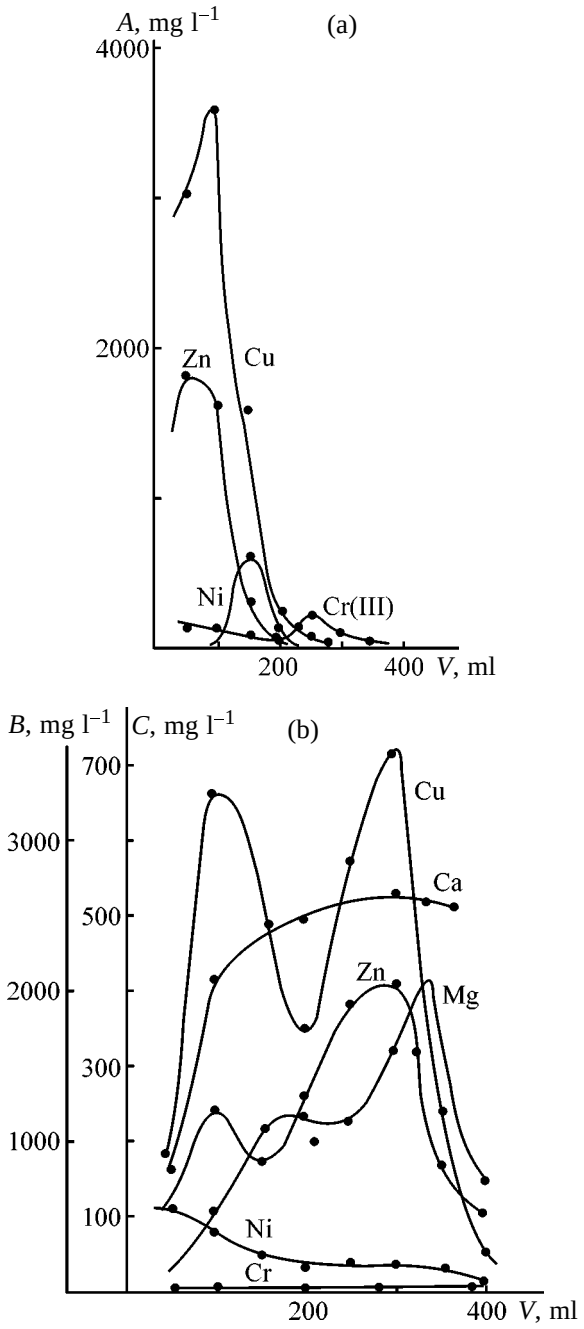

Fig. 2. Regeneration curves of (a) S-930 sorbent and (b) KU-2 × 8 cation exchanger. (*A*) Nonferrous metal [including Cr(III)] concentration, (*B*) Mg concentration, and (*C*) nonferrous metal [including Cr(III)] and calcium concentration; (*V*) eluate volume.

the main amount of nonferrous metals [including Cr(III)] is desorbed by the first portion of the eluent (40%). The remaining part of the eluate (60%) mainly contains chromium and traces of other nonferrous metals. This portion of the eluate is acidified with sulfuric acid to 20% concentration and reused in the first stage of S-930 regeneration after repeated sorption cycle. This procedure allows significant decrease of the sulfuric acid consumption.

All fractions of the eluate formed in the course of KU-2 × 8 regeneration contain calcium sulfate precipitate, which hinders their reuse for regeneration.

Comparison of S-930 selective sorbent and KU-2 × 8 universal cation exchanger in sorption of nonferrous metals [including Cr(III)] from wastewater and in regeneration of the spent sorbents shows advantage of the selective sorbent in both stages. Another advantage of S-930 is that it does not sorb the cations responsible for the solution hardness (Ca, Mg), which increases the filtration cycle and the sorption service life. With this sorbent it is possible to reuse the weakly concentrated eluate fractions (60% of the total eluate volume) after their adjustment with a small amount of sulfuric acid. This procedure decreases the consumption of sulfuric acid and the wastewater volume.

The technique developed by us for decontamination of the wastewater from electroplating productions by treatment with S-930 sorbent was put into operation at the Promotkhody plant.

CONCLUSIONS

(1) High selectivity of S-930 sorbent provides the required extent of decontamination of wastewater from electroplating productions and high degree of concentration of nonferrous metal impurities.

(2) The sorption capacity of S-930 in wastewater decontamination from microamounts of nonferrous metals is twice that of KU-2 × 8 cation exchanger.

(3) The use of S-930 sorbent for wastewater decontamination from nonferrous metals significantly decreases the reagent consumption in the regeneration stage.

(4) Testing of S-930 showed that this chelating sorbent can be recommended for decontamination of wastewater from electroplating productions. The use of this sorbent is promising from the viewpoint of both the process optimization and the environmental safety.

Received September 12, 2000; in final form, July 2001

Abstract—Gas-sensitive (sensory) properties of bismuth–tin oxide materials, including ceramic films with the $Bi_2Sn_2O_7$ composition and pyrochlore structure, were considered, as applied to the determination of H_2, CO, and CH_4 in an air mixture.

Carbon monoxide is known to be one of the main contaminants of the atmosphere. Its efficient monitoring requires development of highly sensitive selective chemical sensors. Doped tin dioxide is recognized as one of promising materials for manufacturing functional layers of such sensors [1–3]. Thin films based on tin dioxide with properly chosen dopants can selectively change electrical conductance when adsorbing various gases [4, 5].

The aim of this work was to study the possibility for the selective monitoring of carbon monoxide using bismuth-doped tin dioxide with a variable chemical composition.

EXPERIMENTAL

To study gas-sensitive properties of bismuth–tin oxide materials, we have manufactured adsorption-sensitive elements (ASEs). As an ASE substrate we used Polikor laminas of size $0.3 \times 0.3 \times 0.5$ mm. Comb-shaped measuring electrodes and zigzag-shaped heaters on the back side of substrates were formed by platinum magnetron sputtering with subsequent photoengraving. Sensitive ceramic layers of thickness 50 μm were made by covering measuring electrodes with a suspension of powdered bismuth stannates in an organic volatile binder and by subsequent sintering at 800°C in air for 1 h. The powders of bismuth stannates were synthesized by a hydrolytic procedure based on coprecipitation of bismuth(III) and tin(IV) from nitrate–chloride solutions by their neutralization with an alkali. The content of bismuth was varied from 5 to 90 at. %. The composition of the films was determined by X-ray and chemical methods [6, 7]:

Sn : Bi	Composition of thick films
20 : 1	$SnO_2 + Bi_2Sn_2O_7$
10 : 1	$SnO_2 + Bi_2Sn_2O_7$
5 : 1	$SnO_2 + Bi_2Sn_2O_7$
1 : 1	$Bi_2Sn_2O_7$
1 : 12	$Bi_2Sn_2O_7 + Bi_2O_3$

To study the temperature dependence of the adsorption response to gases (H_2, CO, and CH_4), ASEs were placed in a sealed quartz cell, through which filtered air with a constant humidity was passed using a PRB-2B gas flow booster. A sample containing a mixture of 100–1000 ppm of H_2, CO, and CH_4 with air (gas–air mixture) was fed to the measuring cell. The ratio R_a/R_g, where R_a is the film resistance in pure air and R_g is the film resistance in a gas–air mixture, was taken as a measure of the adsorption response to the gas action. The ASE resistance was measured with a VK-9 device accurate to within ±4% of the length of the working section of the ×10 Ω scale and to within ±2.5% on the other scales. The ASE temperature was varied by the corresponding variation of the heater power P_h from 0.1 to 4.0 W, which corresponded to the range from 100 to 500°C. The constant power of the heater was maintained during measurements with an accuracy of 5%.

The bismuth–tin oxide materials under study with tin–bismuth ratios from 5 to 1/12 have high resistance of the order of hundreds of MΩ, which decreased with increasing temperature, following an exponential law characteristic of semiconductors [8].

1070-4272/01/7411-1864$25.00

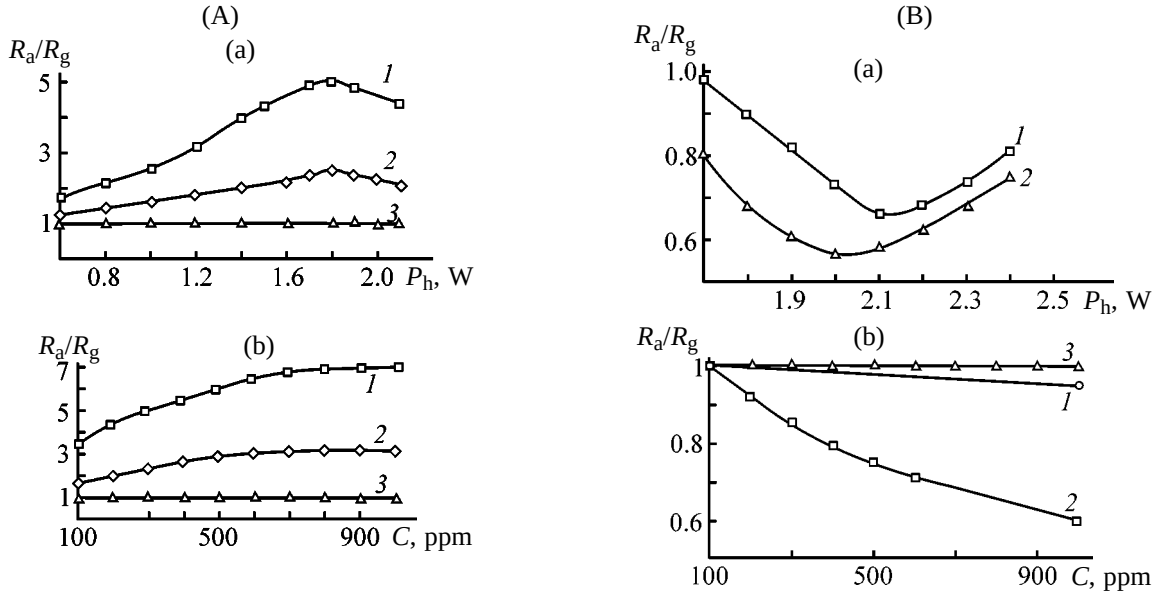

Fig. 1. Adsorption response R_a/R_g to the action of (*1*) H_2, (*2*) CO, and (*3*) CH_4 as a function of (a) heater power P_h and (b) gas concentration C. Composition of films: (A) SnO_2–$Bi_2Sn_2O_7$ (Sn : Bi = 20) and (B) $Bi_2Sn_2O_7$ (Sn : Bi = 1). (A, a; B, a) Concentration of gases 400 ppm; heater power P_h (A, b) 1.8 and (B, b) 2.0 W.

The adsorption-sensitive cells based on the bismuth–tin materials SnO_2–$Bi_2Sn_2O_7$, $Bi_2Sn_2O_7$, and $Bi_2Sn_2O_7$–Bi_2O_3 have an enhanced sensitivity to hydrogen and to carbon(II) monoxide and do not respond to methane up to 400°C. As follows from the concentration and temperature dependences (Fig. 1A), the ASEs under study based on thick films with the composition SnO_2–$Bi_2Sn_2O_7$ are sensitive to low concentrations of CO and H_2 (1.0×10^{-2} vol %). Their sensitivity to hydrogen is 1.5–2 times higher than to CO. At the atomic ratio Sn : Bi < 5 the sensitivity to H_2 and CO starts to drop, and at the Sn : Bi ratio of 1 and lower, the adsorption response is less than unity (Fig. 1B). In this case the concentration and temperature dependences of the adsorption response to the action of reducing gases are characteristic of the *p*-type semiconductor sensors. Hence, $Bi_2Sn_2O_7$, along with the known Bi_2O_3, are the *p*-type semiconductors.

These compounds are more sensitive to CO than to H_2. This difference is the most pronounced for the films with the composition $Bi_2Sn_2O_7$ below 380°C (which corresponds to $P_h \sim 2.0$ W). Thus, at such temperatures the $Bi_2Sn_2O_7$ films can be used in CO-selective sensors in a wide range of gas concentrations in the presence of H_2 and CH_4.

The adsorption response of ASEs passes through a maximum, which is reached at various temperatures depending on the chemical composition of the sensitive material and the nature of a gas under determination (P_h values; Figs. 1A, a and 1B, a). The temperature of the highest performance of sensors based on pure $Bi_2Sn_2O_7$ is maximal, being close to 380°C for CO and H_2. The value of T_m for $Bi_2Sn_2O_7$–Bi_2O_3 is much lower (~250°C). In the case of the SnO_2–$Bi_2Sn_2O_7$ ASEs with Sn : Bi from 5 to 20 T_m decreases with increasing content of the bismuth-containing component and reaches approximately 310°C at the Sn : Bi ratio equal to 5.

When detecting reducing gases, including CO and H_2 in air, gas molecules are oxidized on the surface of metal oxide semiconductors with adsorbed oxygen [3]. It is probable that gas-sensitive ASE characteristics essentially depend on the concentration of active oxygen, which is determined by the density of adsorption centers and also by the form of chemisorbed oxygen [9]. Our experimental data show that the adsorption response as a function of temperature passes through a maximum (when a reducing gas is introduced, the relative change in the electric conductance first grows with increasing temperature and then drops to zero at a fairly high temperature). Such a dependence, which is typical for a wide range of gas-sensitive cells, is presumably due to the formation of negatively charged adsorbed forms of oxygen. If the operation temperature of the sensor T_{op} is low, the reaction products (CO_2 in the case of CO and H_2O in the case of H_2) will not be desorbed, i.e., the regeneration of the oxygen adsorption centers will be impossible. If T_{op} is rather high, the adsorption of both oxygen and a reducing gas becomes impossible.

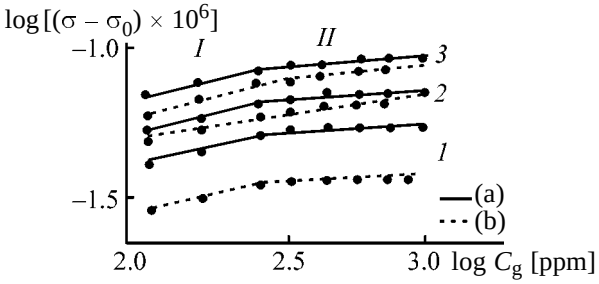

Fig. 2. Electrical conductance σ of SnO_2–$Bi_2Sn_2O_7$ films as a function of concentration C_g of (a) H_2 and (b) CO in air. (σ_0, σ) ASE conductance under normal conditions and specified temperatures, respectively. Atomic ratio Sn : Bi: (*1*) 5, (*2*) 10, and (*3*) 20. Heater power P_h, W: (*1*) 1.8 and (*2, 3*) 1.4.

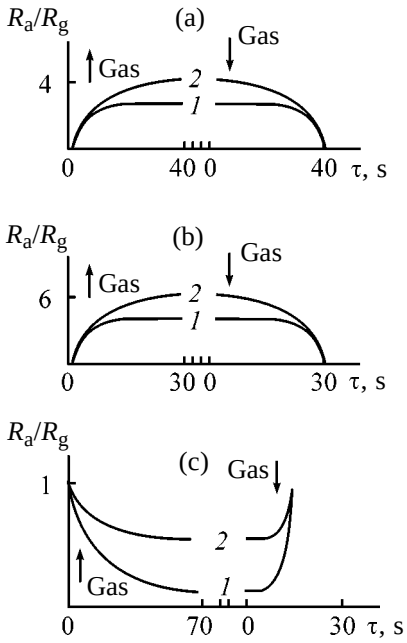

Fig. 3. Kinetic curves of adsorption response R_a/R_g for SnO_2–$Bi_2Sn_2O_7$ films (Sn : Bi = 10) in the presence of (a) CO and (b) H_2 in concentrations of (*1*) 100 and (*2*) 1000 ppm, and (c) for $Bi_2Sn_2O_7$ films in the presence of 1000 ppm of (*1*) CO and (*2*) H_2. (τ) Time. Heater power P_h, W: (a, b) 1.7 and (c) 2.0.

It is known that above 150°C O^- is the most stable oxygen species on the SnO_2 surface, and above 300°C the appearance of O^{2-} is probable [9]. As the temperature of the maximum response of ASEs under study is higher than 300°C, H_2 and CO can probably react with O^- and O^{2-}, except for the $Bi_2Sn_2O_7$–Bi_2O_3 film. The plots of the electric conductance of bismuth–tin oxide layers against concentrations of CO and H_2 in logarithmic coordinates are shown in Fig. 2. There are two clear linear segments *I* and *II* in the curves, which correspond to the power dependence $\sigma \sim P_g^m$ (P_g is the gas pressure) with different values of m (m_I and m_{II}). When H_2 and CO are detected, m_I and m_{II} values lie in the ranges 0.2–0.27 and 0.12–0.16, respectively, depending on the ratio Sn : Bi in the SnO_2–$Bi_2Sn_2O_7$ films. The parameter m changes at gas concentrations close to 400 ppm. A possible reason for low m values can be the lack of oxygen adsorption centers on the semiconductor surface [8]. At present the nature of these centers for bismuth–tin materials is unknown. It was found that Bi_2O_3 lowers the amount of adsorbed oxygen and supplies lattice oxygen for surface reactions [10]. Possibly $Bi_2Sn_2O_7$ also has such properties. It is the presence of $Bi_2Sn_2O_7$ in a mixture with SnO_2 that seems to considerably reduce the number of oxygen adsorption centers on the surface, which results in deceleration of the growth of adsorption response in the concentration curves (Fig. 1) as the H_2 and CO concentrations increase. We can assume that the high temperature of the maximum response (about 380°C) is caused by the dominating participation of lattice oxygen in surface reactions when "pure" $Bi_2Sn_2O_7$ is used for detecting CO and H_2. This assumption is also supported by the longer response time of the ASEs based on $Bi_2Sn_2O_7$ as compared to SnO_2–$Bi_2Sn_2O_7$ films (Fig. 3).

It is evident from Fig. 3 that increased concentration of a gas to be detected results in increased ASE response rate. It follows from the theory of semiconductors that the characteristics of a sensor depend on the value of the surface barrier U_s: the greater U_s, the lower the electron transfer rate and, hence, the response rate of the sensor. As the chemisorption of H_2 and CO reduces the surface barrier, the response rate increases with increasing CO and H_2 concentrations.

CONCLUSION

(1) Bismuth–tin compounds obtained by a hydrolytic procedure are promising materials for adsorption gas analyzers. At properly choosen compositions, they can be used in adsorption-sensitive cells of semiconductor sensors selective to carbon monoxide and hydrogen in the presence of methane, to hydrogen in the presence of carbon monoxide, and to carbon monoxide in the presence of hydrogen.

(2) $Bi_2Sn_2O_7$ in the composition of adsorption-sensitive cells is highly sensitive to low concentrations of CO and H_2 in air.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Suspension Separation in a Centrifuge with Biconical Rotor

Yu. P. Volkov and S. A. Svetlov

Biisk Technological Institute, Altai State Technical University, Biisk, Altai krai, Russia

Received June 7, 2001

Abstract—Separation of cellulose nitrate suspensions in a centrifuge with biconical rotor was studied. An empirical equation was derived, enabling calculation of the efficiency of purification of process water and wastewater to remove the solid phase in centrifuges of this kind.

At present, sedimentation tanks (wastewater ponds) are used to purify wastewater to remove polydisperse solid impurities [1]. These installations have strong adverse effect on the environment and safety of humans; their maintenance requires gross expenditure. At the same time, use of other techniques intensifying the purification process and, in particular, centrifugal separation is difficult from both economical and technological standpoints. This is so because there exist no sufficiently simple to operate and comparatively low-cost centrifugal machines with mechanized sediment discharge and high degree of separation [2–5].

Centrifugal apparatus [6] and centrifuges are known [7] in which suspensions are separated in a rotor comprising two truncated conical cowlings mounted on a fast-rotating shaft. Preliminary calculations and experiments on a cylindrical sedimentation centrifuge demonstrated that the centrifuge with a biconical rotor must exhibit high efficiency of separation of finely dispersed and low-concentration suspensions at relatively high centrifugate output capacity.

The aim of this study was to analyze the influence of basic process parameters (speed of centrifuge rotor rotation, flow rate and initial concentration of the starting suspension) on the final concentration of solid particles in the centrifugate; and to derive empirical equations for calculating the relative concentration of the solid phase in the centrifugate, which allows prognostication of the quality of suspension separation in centrifuges of the given type.

EXPERIMENTAL

To perform experimental studies, we designed an installation comprising a centrifuge *1* and accessory equipment. A prepared suspension was fed into the centrifuge from a vessel *2* by means of a centrifugal pump *3*, with the flow rate monitored with rotameter *4*, and the speed of shaft rotation, with tachometer *5*. The centrifuge power drive allowed variation of the speed of rotor rotation in the range from 1000 to 6000 rpm.

The centrifuge rotor (Fig. 2) comprised two conical cowlings, upper *1* and lower *2*, and disk *3* pressed to the lower cowling with a bushing. Apertures through which the suspension is fed into the centrifuge rotor were made in the bushing *5*. The impermeability of the cowling junction was ensured by nut *6*.

An aqueous suspension of nitrocellulose with solid particles 1 to 280 μm in size was separated. The experiments were carried out as follows. A nitrocellulose suspension was poured into the vessel apparatus and continuously agitated there with blade stirrers, and a uniform concentration of the solid phase was maintained in the working volume of the apparatus. A variable power drive ensured rotor rotation at a required speed. Then the suspension was fed into the rotor, and purified liquid was sampled at the centri-

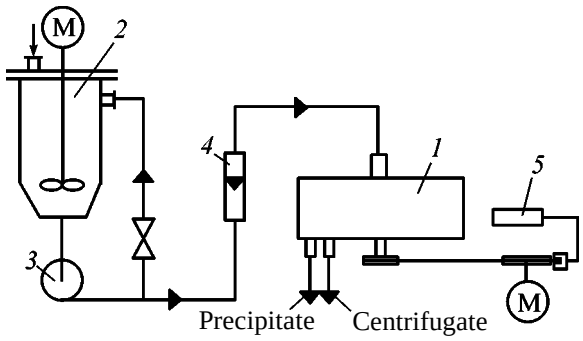

Fig. 1. Schematic of laboratory installation: (*1*) centrifuge, (*2*) apparatus with stirrer, (*3*) centrifugal pump, (*4*) rotameter, and (*5*) tachometer.

fuge outlet. The samples were filtered and the concentration of solid impurities in the centrifugate was determined.

The study was carried out at speeds of rotor rotation, n, equal to 3000, 4000, 5000, and 6000 rpm, initial suspension concentration C_{in} = 13.28, 6.64, 3.32, and 1.66 g l^{-1}, and suspension flow rate varying between 9 and 100 l h^{-1}.

The obtained experimental data were presented in the form of a dependence of the concentration C_{out} of the solid phase in the centrifugate on the flow rate Q of the suspension at the centrifuge inlet.

Figure 3 shows such dependences for speeds of rotor rotation of 3000, 4000, and 5000 rpm and initial suspension concentration of 3.32 g l^{-1}.

As a parameter that characterizes the separation capacity of sedimentation centrifuges and facilitates simulation of their operation is commonly used the output capacity index

$$\Sigma = 2\pi RHF, \quad (1)$$

where H is the height of the cylindrical sedimentation surface of the rotor (m), and F is the separation factor at a radius R.

Using the known equation [2, 8] based on the Godin–Andreev formula [2, 3, 8], we derived a regression equation approximating the experimental data and determined the coefficients of this equation. Equation (2) allows a rather accurate prognostication (mean relative error of about 25%) of the relative concentration of the solid phase in the centrifugate in a wide range of speeds of rotor rotation and suspension concentrations and flow rates (for the investigated type of suspension):

$$C_{out}/C_{in} = 6.16 \times 10^5 (Q/\Sigma)^x, \quad (2)$$

where Σ is the throughput factor of the centrifuge (m^2).

The coefficient x in Eq. (2) is defined by the formula

$$x = \exp(a \ln C_{in} + b). \quad (3)$$

The coefficients appearing in Eq. (3) are given by

$$a = -3.75 \times 10^{-6} n + 0.038, \quad (4)$$

$$b = -2.52 \times 10^{-5} n + 0.526. \quad (5)$$

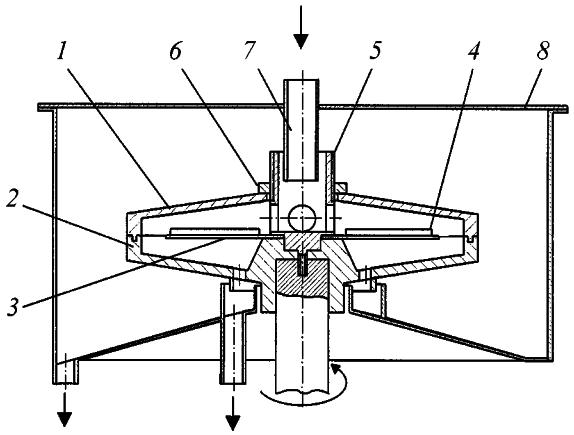

Fig. 2. Schematic of the centrifuge: (*1*) upper cowling, (*2*) lower cowling, (*3*) disk, (*4*) blades, (*5*) bushing, (*6*) nut, (*7*) pipe, and (*8*) case.

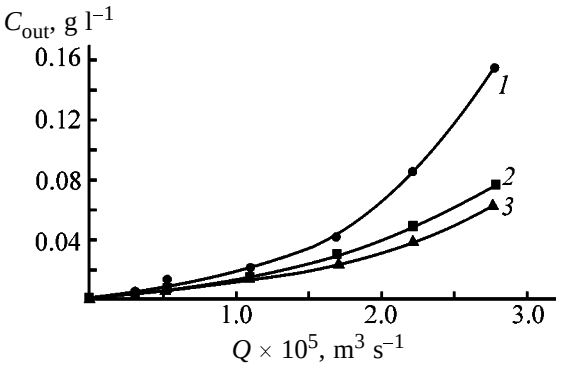

Fig. 3. Concentration of the solid phase in the centrifugate, C_{out}, vs. suspension flow rate Q. Initial concentration C_{in} = 3.32 g l^{-1}. Speed of rotor rotation n (rpm): (*1*) 3000, (*2*) 4000, and (*3*) 5000; the same for Fig. 4.

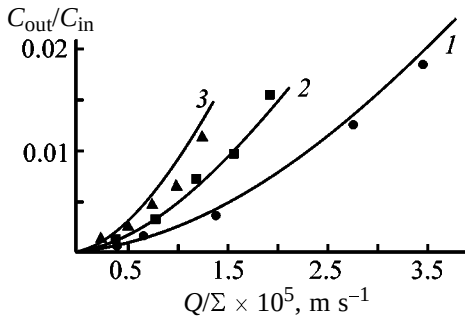

Fig. 4. Relative concentration C_{out}/C_{in} vs. parameter Q/Σ. Initial concentration C_{in} = 13.28 g l^{-1}.

Figure 4 shows by solid lines the calculated dependences of the relative concentration C_{out}/C_{in} on the parameter Q/Σ at different speeds of rotor rotation and initial suspension concentration of 13.28 g l^{-1}.

An analysis of the obtained experimental data

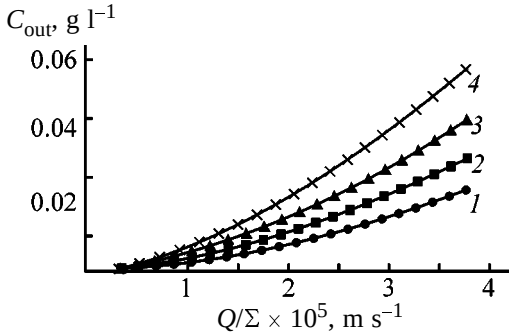

Fig. 5. Relative concentration C_{out}/C_{in} (calculated) vs. parameter Q/Σ. Number of rotor revolutions n = 3000 rpm. Initial concentration C_{in} (g l^{-1}): (*1*) 13.28, (*2*) 6.64, (*3*) 3.32, and (*4*) 1.66.

demonstrated that the separation efficiency grows with increasing concentration of the starting suspension (Fig. 5), in good agreement with the available published data [2]. At the same time, the separation efficiency falls with increasing speed of rotor rotation and decreasing concentration of the solid phase in the centrifugate (Fig. 4). This can be presumably accounted for by the presence of turbulence zones inside the centrifuge rotor, whose influence on the separation efficiency becomes more pronounced with increasing speed of rotor rotation [3], and also by the fact that the degree of destruction of solid phase particles and agglomerates of these grows with increasing angular speed of rotor rotation.

The following conditions should be satisfied in simulation of geometrically similar sedimentation centrifuges [4]: sedimentation of particles with close sizes in different centrifuges is ensured at the same separation factor; fluid flows are in the same automodel region. The equation for simulating geometrically similar centrifuges with the use of the output capacity index can be written as

$$Q/Q_m = \Sigma/\Sigma_m, \quad (6)$$

where Q_m is the output capacity of a centrifuge being simulated (m^3 s^{-1}), and Σ_m is the throughput factor of this centrifuge (m^2).

It may be considered that for suspensions with fibrous solid phase, in which the particle size changes significantly in the course of separation, the maximum ratio of centrifuge throughputs is equal to the ratio of cubed radii of rotor disks.

Based on the results obtained in processing the obtained experimental data and on methods of the similarity theory, an industrial variant of the centrifuge is designed. The centrifuge can be used for purification of process water and wastewater to remove solid impurities in manufacture of cellulose nitrates. Using the similarity theory [9–11], we calculated the basic geometrical parameters of the industrial centrifuge. The performance characteristics of the industrial centrifuge are as follows:

Throughput, m^3 h^{-1}	25
Number of rotor revolutions, rpm	5000
Rotor diameter, mm	600
Disk diameter, mm	500
Rotor height, mm	350

Use of centrifuges of this type makes it possible to improve, at low capital outlays, the efficiency of purification of industrial wastewater at the existing plants and ensure discharge to waste disposal plants of purified liquid with solid phase concentration corresponding to the maximum permissible concentration.

CONCLUSIONS

(1) The achieved degree of purification of low-concentration cellulose nitrate suspensions in a centrifuge with biconical rotor yields in certain separation modes a concentration of solid impurities in the centrifugate of no more than 20 mg l^{-1}.

(2) The derived empirical equation can be used to prognosticate with sufficient accuracy the relative concentration of the solid phase in the centrifugate in a wide rage of variation of the basic process parameters of the installation: initial concentration and flow rate of suspension and speed of rotor rotation.

(3) The obtained results demonstrate the possibility of using centrifuges of the given type in purification of industrial process water and wastewater to remove finely dispersed solid impurities.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Nitration of Chlorobenzene with Nitric Acid in a Continuous Installation

E. A. Veretennikov, B. A. Lebedev, and I. V. Tselinskii

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received June 28, 2000

Abstract—The procedures of production of mononitrochlorobenzene by nitration with 75–97% nitric acid with the yield of the target product of 97.5% were developed. A procedure of precipitation of crystalline *p*-nitrochlorobenzene from the reaction mixture without additional purification was proposed.

Nitration of chlorobenzene with sulfuric acid–nitric acid mixtures is the main procedure of mononitrochlorobenzene (MNCB) production [1]. The drawback of this procedure is large amount of dilute spent sulfuric acid as waste. The present-day procedures of recovery of spent sulfuric acid do not eliminate its environmental impact. The growing importance of environmentally safe processes requires a search for new nitration procedures without using sulfuric acid.

One of such procedures can be nitration of chlorobenzene with nitric acid alone, which can be recovered on the industrial scale by environmentally safer procedures, compared to sulfuric acid [2]. As seen from published data, the major attention was focused on the use of 67–68% nitric acid for nitration. For example, it was proposed to carry out nitration of chlorobenzene with a 20–30-fold molar excess of nitric aicd in a tubular reactor or cascade of reactors at 90°C [3] or by adding chlorobenzene to an excess of boiling nitric acid with simultaneous removal of the reaction water [4]. Apparently, long reaction time, large amounts of acids to be recovered, and difficulties in temperature control of the process hinder industrial implementation of these procedures.

Kinetic studies of mononitration of chlorobenzene with aqueous nitric acid showed [5, 6] that, contrary to nitration in sulfuric acid medium, the reaction proceeds in a homogeneous medium with the rates of nitration close to or exceeding the rates of nitration of chlorobenzene with sulfuric–nitric acid mixtures; the significant (three orders of magnitude) difference in the rate constants of mono- and dinitration suggests that the use of nitric acid alone as a nitrating agent allows reduction or elimination of formation of the by-product, dinitrochlorobenzene (DNCB), during nitration.

Based on these data, we examined the possibility of using nitric acid alone for production of MNCB.

Nitration of chlorobenzene was carried out in a continuous installation (Fig. 1) including (*1*) main and (*2*) surge reactors and (*3*) dilution vessel, equipped with reflux condensers, blade stirrers, coil pipes, and jackets. The volume of the apparatus made from 1Cr18Ni10Ti steel was 60 ml. The components were dosed by piston pumps. Before start-up, the installation was filled with nitric acid with a composition close to that of spent acid. The steady state of the system was reached after passing a 5–6-fold volume of the reaction mixture through the apparatus. The temperature was maintaned with an accuracy of ±0.5°C using thermostats. After nitration completion, the reaction mixture was a solution of MNCB in spent acid. To recover the nitro product, the reaction mixture

was diluted in apparatus *3* at 20°C with a calculated amount of water to the nitric acid concentration of 50.0%. The resulting nitro product, suspension of *p*-NCB crystals in the liquid mixture of isomers, was separated, washed with hot water, and dried. Dilute spent acid was extracted with chlorobenzene. The composition of the organic product was determined by gas–liquid chromatography. The concentration of nitric acid was determined by alkalimetric titration.

After reaching the steady state, the reaction mixture in the main reactor is heterogeneous and in the surge reactor, homogeneous. It is well known that in heterogeneous nitration of chlorobenzene with sulfuric acid–nitric acid mixtures the diffusion of the components into the reaction area affects substantially the nitration process, and stirring of the reaction mixture is one of the factors providing mass exchange in the reaction system, dispersity of phases, and, hence, the required residence time of components in the reaction zone [7]. Studying the effect of the strirring rate on nitration of chlorobenzene with nitric acid alone showed that in this reaction system variation in the stirring rate from 200 to 3000 rpm does not affect the reaction rate in the entire range of nitric acid concentrations studied. This fact suggests that the nitration occurs in the bulk of the acid phase and the rate-determining stage of the process is the reaction of chlorobenzene with nitric acid. Therefore, in the subsequent experiments the mixture was stirred at a rate of 400 rpm. The experimental results are listed in Table 1.

As seen from Table 1, the use of a 1.5–2-fold molar excess of nitric acid does not ensure complete

conversion of chlorobenzene to MNCB, and an attempt to increase the yield of the target product by increasing reaction temperature or time is accompanied by formation of 2–4% DNCB (run nos. 1–7). An increase in the amount of nitric acid to 2.5–3.0-fold molar excess results in practically complete conversion of chlorobenzene; in this case, the resulting nitration product contains no DNCB (run nos. 8, 13, 14, 16–18, and 24–26). It should be noted that at 55–75°C the reaction was complete in 7.5–10 min.

To elucidate the effect of the acid concentration on the yield of MNCB, we studied nitration of chlorobenzene with 90–68% nitric acid. The results are listed in Table 2.

The experiments showed that a decrease in the acid concentration below 85% is accompanied by noticeable increase in its molar excess, reaction temperature, and reaction time required to reach the maximum yield of MNCB. However, despite higher temperature and longer process time, DNCB was formed in none of the runs. For example, in nitration of chlorobenzene with 75% nitric acid at 95°C, fourfold molar excess of nitric acid, and the reaction time of 180 min, the yield of MNCB was 97.5% (run no. 39). A decrease in the nitric acid concentration to the composition of aqueous azeotrope (68% HNO_3) results in significant increase in the excess of nitric acid (more than eightfold by moles) and inhibition of the nitration process.

Thus, it was established that in a wide concentration range nitric acid can be used for producing MNCB in a nearly quantitative yield; the resulting product contains no DNCB impurity.

Based on this study, we developed two procedures for nitration of chlorobenzene with both concentrated and dilute nitric acid. With 90–97% nitric acid, the total amount of the nitrating agent required for attainment of the maximum conversion is lower, but the spent acid cannot be used for preparing nitrating mixture. On the contrary, with 75–85% nitric acid a part of spent acid can be used in production of MNCB.

We found that for nitration with 95% HNO_3 the optimum conditions are as follows: molar ratio HNO_3 : chlorobenzene 2.5, reaction temperature 65°C, and residence time in the main and surge reactors 45 min. The yield of MNCB was 97.5%.

The nitration process with partial acid circulation was tested with 75% HNO_3 as an example. The optimum conditions are as follows: molar ratio HNO_3 : chlorobenzene 4, reaction temperature 95°C, and residence time in the main and surge reactors 180 min. The acid mixture was prepared in the main reactor by dosing of 98% HNO_3 and spent 50% HNO_3. The yield of MNCB was 97.5%.

The MNCB formed by nitration has the following isomeric composition (%): *p*-NCB 68.0–70.0, *o*-NCB 29.5–31.9, and *m*-NCB 0.1–0.5. In nitration of chloro-

* Isomeric composition, %: [a] *p*-NCB 46.4; *o*-NCB 14.6, *m*-NCB 39.0; [b] *p*-NCB 16.5, *o*-NCB 41.7, *m*-NCB 41.8; [c] *p*-NCB 18.9, *o*-NCB 35.5, *m*-NCB 45.6; [d] *p*-NCB 44.3, *o*-NCB 55.6, *m*-NCB 0.1.

benzene with sulfuric acid–nitric acid mixtures the amount of *m*-NCB reaches 2.0–2.5% [1].

We found that during dilution a significant part of *p*-NCB (up to 60% of the total amount in the mixture of isomers) precipitates from the reaction mixture in the crystalline form and can be separated by filtration. A high degree of purity of *p*-NCB isolated by this procedure (98.5–99.0%) allows this product to be used without additional purification, which undoubtedly facilitates the labor-consuming stage of isomer separation. The residual liquid mixture of isomers, containing on the average 20% *p*-NCB and 80% *o*-NCB, is separated from the spent acid and washed with water. Taking into account high solubility of MNCB in nitric acid, we studied the dependence of the yield of the nitro product on the temperature and degree of dilution of the reaction mixture with water.

We found that with increasing concentration of spent acid and temperature the solubility of MNCB in the spent acid noticeably increases, and the amount of the *para* isomer precipitated from the reaction mixture decreases (Table 3).

To substantiate the choice of the conditions for isolation of the nitro product, we studied the solubility of MNCB isomers in nitric acid of various concentration. As seen from Figs. 2a–2c, the solubilities of the isomers in 47–63% nitric acid in the range 0–80°C somewhat increase with increasing temperature and are comparable, but with increasing acid concentration to 74% the solubility of *p*- and especially *m*-NCB abruptly increases. Contrary to *para* and *meta* isomers, the solubility of *o*-NCB in 74% nitric acid decreases with increasing temperature.

The study of the interrelated effect of isomers on their solubility in nitric acid showed that in 47% HNO_3 the minimum solubility of all three isomers of MNCB is observed at 20°C; in this case, the concentration of both *ortho* and *meta* isomers in the solution

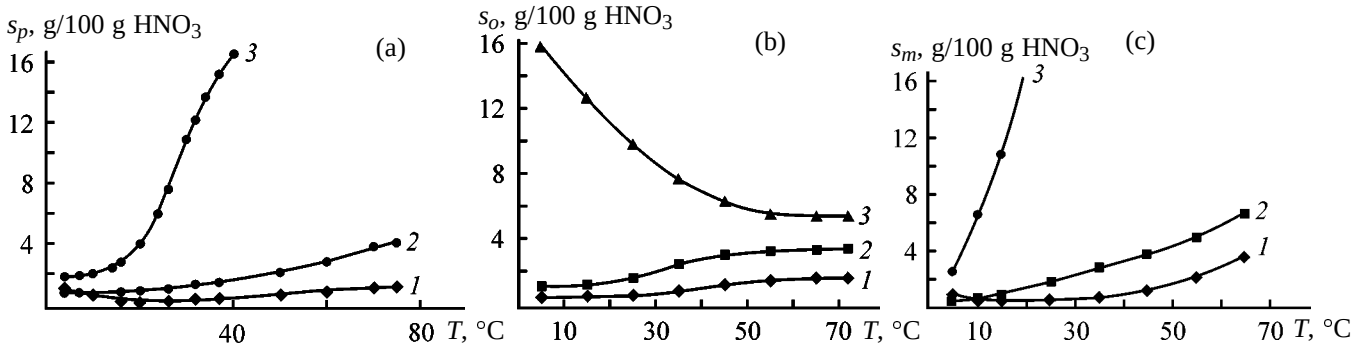

Fig. 2. Solubility of (a) *p*-NCB s_p, (b) *o*-NCB s_o, and (c) *m*-NCB s_m in nitric acid as a function of temperature T. Concentration of HNO_3 (wt %): (*1*) 47, (*2*) 63, and (*3*) 74.

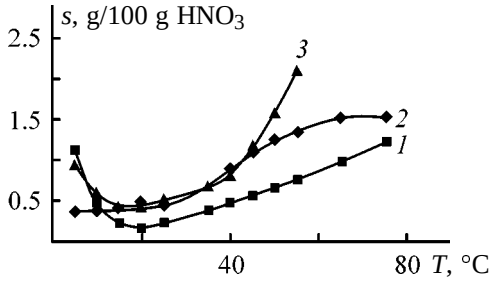

Fig. 3. Solubility *s* of MNCB isomers in 47% nitric acid as a function of temperature *T*. Isomers: (*1*) *para*, (*2*) *ortho*, and (*3*) *meta*.

is approximately two times greater than that of *p*-MNCB (Fig. 3). The mixture of isomers precipitated from nitric acid solution contains *o*- (40.5), *m*- (42.0), and *p*-NCB (17.5%), and its composition is close to that of the product isolated from the spent acid (Table 3, run no. 2). These data provide an explanation for the effect of temperature on the dilution process: an increase in the solubility of nitro compounds in spent acid with decreasing temperature (Table 3, run no. 1) and increase in the content of *ortho* and *meta* isomers of MNCB in spent acid with increasing temperature (Table 3, run no. 3).

Thus, the study of the solubility of MNCB isomers in nitric acid showed that, to increase the recovery of *p*-NCB from the mixture of isomers and to prevent the loss of the nitro product with the spent acid, the reaction mixture should be diluted at 18–22°C to a nitric acid concentration below 60%.

CONCLUSIONS

(1) Two methods were developed for production of mononitrochlorobenzene by nitration of chlorobenzene with 75–79% nitric acid, ensuring practically quantitative yield of the target product and the absence of dinitrochlorobenzene in the reaction products.

(2) Based on the study of the solubility of mononitrobenzene isomers in nitric acid, a procedure for isolation of *p*-mononitrobenzene from the reaction mixture in the crystalline form was proposed, which simplifies isomer separation.

Received January 26, 2001

Abstract—The calorimetric method was applied to study the kinetics of chlorobenzene mononitration with 74.9 and 95.8% nitric acid and a kinetic model of the process was developed. A comparison of the thermodynamic parameters of nitration led to a conclusion concerning the limiting stage of the reaction.

The basic method for obtaining nitrochlorobenzene is nitration of chlorobenzene with a mixture of sulfuric and nitric acids. A specific feature of this technique is that it produces large amounts of dilute sulfuric acid whose regeneration cannot prevent at present its detrimental environmental effects.

To eliminate this shortcoming, it has been proposed to use for obtaining aromatic nitro compounds solely nitric acid as nitrating agent [1–3]. In [3], nitration of chlorobenzene with 68–97% nitric acid was studied and two versions of a procedure for producing nitrochlorobenzene with 75 and 95% nitric acid used for nitration were developed. These methods gave nitrochlorobenzene in nearly quantitative yield. The process was carried out in a cascade of two 60 cm^3 continuous reactors. To solve the problem of whether these results could be reproduced on industrial scale, it is necessary to develop a mathematical model of the process and study the possible choice of optimal and safe conditions under which the process can be performed in industrial nitration reactors.

The kinetics of the process was studied using the calorimetric method with a heat-flow calorimeter which makes it possible to obtain, together with data on the process kinetics, necessary information about the heat effect and thermal properties of the reaction mixture. As starting conditions were chosen those under which chlorobenzene is nitrated with 75 and 95% nitric acid [3].

EXPERIMENTAL

Chlorobenzene containing 99.0% main substance and 98% nitric acid were used in kinetic experiments. Prior to being used, nitric acid was distilled in a vacuum from a mixture with sulfuric acid and diluted at 0°C with distilled water to a prescribed concentration. The acid concentration was determined by alkalimetric titration. Deionized water was used to evaluate the thermal effects and relative rates of hydration.

The reaction kinetics were studied on a C-80 Setaram automated heat-flow calorimeter in special two-chamber chromium–nickel ampules. Nitric acid was placed in the bottom chamber and, after weighing, the necessary amount of chlorobenzene in the upper chamber was calculated. Prior to the reaction, the reactants were separated with a high-strength fluoroplastic film, which is stable against the action of corrosive media. A hermetically sealed ampule was placed in the sensitive zone of the calorimeter. At the beginning of an experiment the membrane was ruptured with a special-purpose rod stirrer and the components were subjected to primary agitation. Further agitation in the course of the experiment was provided by 180° rotation of the calorimetric unit together with the ampule fixed in it. After the experiment was complete, the reaction mass was diluted with water to nitric acid concentration of 35–40% and extracted with chloroform; the extract was washed with water and analyzed by gas–liquid chromatography. The yield and isomeric composition of the nitration product were in agreement with the data reported in [3]. The analytically obtained chlorobenzene conversions corresponded to the values found from the heat-release curve in each experimental series.

The C-80 calorimeter is automated with the use of an IBM-compatible computer and an appropriate interface. The experiments were carried out, experimental

Table 2. Kinetic parameters of chlorobenzene mononitration with 74.9 and 95.8 wt % nitric acid

HNO_3, wt %	$\ln k_0$	E	ΔH	n_1	n_2
		kJ mol^{-1}			
95.8	–1.9519	8.003	154.12	1.0	2.0
74.9	12.2716	57.642	141.75	1.0	2.0

data collected, and the results of the experiments preprocessed using Eksperiment software (v4.3).[1] Preliminarily, the thermal characteristics and temperature calibration coefficients were determined for the given type of ampules.

The kinetic experiments were carried out in the isothermal temperature mode. In preparing data for kinetic analysis, true nonisothermal temperature modes were reconstructed for each experiment, with account taken of the overheating of the reaction mass, resulting from the considerable heat effect of the reaction and high rates of heat release. Such a temperature mode refinement is rather essential since the calculated overheating of an ampule with the reaction mass was several degrees relative to the temperature of the calorimetric unit. The experimental conditions are presented in Table 1.

The kinetic analysis was made with the use of MKF software.

[1] The Eksperiment and MKF software was developed at the Prikladnaya Khimiya Russian Scientific Center.

The obtained kinetic curves of heat release were described in terms of a reaction of nth order with respect to the reactants:

$$-\frac{dc_{CB}}{d\tau} = \exp\left(\ln k_0 - \frac{E}{RT}\right) c_{CB}^{n_1} c_{HNO_3}^{n_2},$$
$$\frac{dT}{d\tau} = \frac{\Delta H}{C_V}\left(-\frac{dc_{CB}}{d\tau}\right), \quad (1)$$

where k_0 is the pre-exponential factor of the reaction constant (l mol^{-1} min^{-1}); E is the activation energy (kJ mol^{-1}); n_1, n_2 are the reaction orders with respect to the components; ΔH is the heat effect of the reaction (kJ mol^{-1}); and C_V is the heat capacity of a unit volume of the reaction mixture (kJ l^{-1} K^{-1}).

The obtained kinetic parameters are listed in Table 2.

The obtained results indicate that the temperature dependences of nitration with 74.9 and 95.8% nitric acid differ so significantly that these reactions are to be regarded as two different processes in terms of a simple kinetic model. For example, the activation energy of chlorobenzene nitration with 74.9% nitric acid is 57.64 kJ mol^{-1}, which is close to values characteristic of reactions in which the rate of nitration of aromatic compounds is limited by the reaction of the nitrating agent with the substrate [4], whereas the activation energy of nitration with 95.5% nitric acid is 8.00 kJ mol^{-1}. Presumably, formation of a nitrating agent, nitronium cation, through self-protonation of nitric acid, rather than nitration proper, is the rate-determining stage under the given conditions. At the same time, there exists strict correlation between the chlorobenzene conversion and heat release in nitration with both 95.8 and 74.9% acid, and, thus, the rate of the chemical reaction can be expressed in terms of the experimentally measured rate of heat release.

It was impossible to take into account in terms of such a simple kinetic model the role played by the forming water and to generalize the description of experiments at different nitric acid concentrations, since the fundamentally different natures of these processes and temperature dependences of their rates suggest that the rate-determining stages are also different in these two cases. Therefore, the kinetic analysis was made separately for experiments with 74.9 and 95.8% nitric acid. The system of equations (1) with the determined values of the kinetic parameters, listed in Table 2, describes satisfactorily the obtained experimental data.

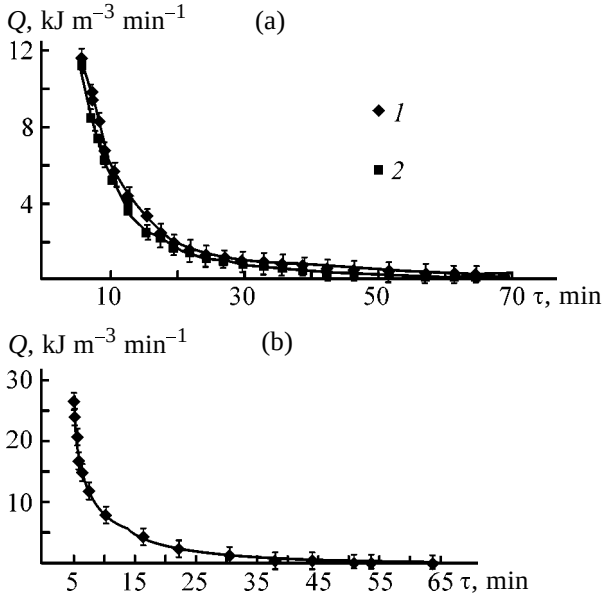

Fig. 1. Experimental and calculated curves describing heat release Q in chlorobenzene nitration in terms of a single-stage concentration model. (τ) Time. Nitrating agent: (a) 94.9% nitric acid, run nos. (*1*) 2 and (*2*) 7, joint kinetic description of runs nos. 1–8 (Table 1); (b) 74.9 nitric acid, run no. 10, joint kinetic description of run nos. 9–12 (Table 1).

Figures 1a and 1b present experimental and calculated data for kinetic experiments performed under the conditions given in Table 1.

Thus, the obtained kinetic equations can be used in developing a mathematical model of chlorobenzene nitration in a reactor in order to determine the safe process conditions.

CONCLUSIONS

(1) The kinetics of chlorobenzene nitration with nitric acid was studied on the basis of heat release rate. The obtained kinetic equations can be used in developing a mathematical model of chlorobenzene nitration in order to determine the safe process conditions.

(2) The presumed rate-determining stage in chlorobenzene nitration with 95.8% nitric acid is formation of the nitronium cation, which accounts for the low observed activation energy of the process, whereas in nitration with 74.9% nitric acid the rate of the process is determined by the rate of reaction between chlorobenzene and the nitrating agent.

Abstract—A mathematical model of processes occurring in a continuous flow-through reactor was developed on the basis of data obtained in a calorimetric study of the kinetics of chlorobenzene nitration with 74.9 and 95.8% nitric acid. The parameters of safe nitration modes were found.

Conditions of chlorobenzene (CB) nitration to nitrochlorobenzene, determined on a laboratory flow-through installation with 75 and 95% nitric acid used as nitrating agents, were reported in [1]. However, industrial implementation of these processes requires that the possibility of their scaling should be determined as regards heat removal and maintenance a prescribed temperature mode, on the one hand, and process stability and safety, on the other. To solve this problem, it is necessary to develop a mathematical model of processes occurring in a continuous flow-through reactor commonly used for nitration under industrial conditions.

The mathematical model of the process was developed using the kinetic model of the nitration reaction, obtained on the basis of a calorimetric study of the nitration kinetics [2]. The following assumptions were made in developing the model: (i) the intensity of stirring is rather high and the reactor operates in the ideal mixing mode, (ii) the mixture densities at the reactor inlet and outlet are different, and (iii) the mixture density and the volume and mass of liquid in the reactor remain unchanged.

With account of the assumptions made, the mathematical model of nitration in the ideal mixing reactor has the form

$$\frac{dC_j}{dt} = G_t(C_i^f/\rho^f - C_i/\rho)V_r^{-1} + R_j(C), \quad (1)$$

$$c_p\frac{dT}{dt} = \sum_s(-\Delta H_s)r_s(C) + \frac{1}{V_r}\frac{G_t c_p^f(T^f - T)}{\rho^f} - h\frac{S(T - T^c)}{V_r},$$

where C_i are the component concentrations in the reactor (kmol m^{-3}), C_j^f are the component concentrations at the reactor inlet (kmol m^{-3}), c_p is the volume heat capacity of the mixture in the reactor (kJ m^{-3} K^{-1}), c_p^f is the volume heat capacity of the feed (kJ m^{-3} K^{-1}), G_t is the total mass flow (kg min^{-1}), h is the heat transfer coefficient (kJ m^{-2} min^{-1} K^{-1}), $-\Delta H_s$ is the heat effect of a stage (kJ kmol^{-1}), V_r is the reactor volume, T is the temperature in the reactor (K), T^f is the feed temperature (K), T^c is the coolant temperature (K), R_j are the reaction rates with respect to different components (kmol m^{-3} min^{-1}), r_s are the rates of different stages (kmol m^{-3} min^{-1}), S is the heat exchange surface area (m^2), t is time (min), ρ^f is the feed density (kg m^{-3}), and ρ is the mixture density in the reactor (kg m^{-3}).

The heat capacities of the feed and mixture in the reactor were found using the additivity rule from the heat capacities of the components and their mass fractions. The reaction rate was calculated using the equation [2]

$$r = K(T)C_{HNO_3}^{n(HNO_3)}C_{CB}^{n(CB)}, \quad (3)$$

where n is the kinetic coefficient (Table 1), and

C_{HNO_3} and C_{CB} are the concentrations of nitric acid and chlorobenzene, respectively.

The developed model was verified using the results of experiments on chlorobenzene nitration on a laboratory installation comprising a cascade of two flow-through reactors equipped with blade stirrer and heat-exchange jacket [1].

The reaction mixture densities at the outlet of each reactor, necessary for determining the residence time of the reaction mass in the apparatus and component concentrations in unit volume of the reaction mixture in relation to its composition and temperature, were calculated using equations based on the principle of additivity of the total density. The component densities at different temperatures were calculated on the basis of the properties of pure components: nitric acid, water, chlorobenzene, and nitrochlorobenzene, using the developed interpolation formulas. Verification of the obtained calculation formulas confirmed their precision, sufficient for studying the process.

The simulation was done with the use of the MKF software package[1] for processes in reactors of different types. Table 2 compares the results of calculation in terms of the mathematical model with experimental data.

It is seen that the error in calculating the chlorobenzene conversion is less than 4% and can be regarded as integrated characteristic of the simulation precision. A conclusion can be made that the kinetic model obtained on the basis of experiments in a heat-flow calorimeter is adequate and can describe satisfactorily the nitration process in a flow-through reactor with vigorous stirring. As shown in [1], chlorobenzene nitration with nitric acid does proceed under homogeneous conditions and a heat-flow calorimeter can be used to obtain an equation describing both the conversion rate and rate of heat release in this reaction.

The mathematical model developed for describing the nitration on a laboratory installation was used to construct a mathematical model of nitration in a flow-through reactor used in the industry for nitration of aromatic compounds. Commonly, vertical cylindrical resctors with spherical bottom, equipped with a stirrer, heat-exchange jacket, and coils, are used for these purposes. To describe chlorobenzene nitration in an apparatus of this kind, it is necessary to supplement the system of equations (1) with a heat balance equation that takes into account the heat removal through the heat-exchange jacket and coils and with equations for calculating the coefficients of heat transfer across the surfaces of the coil and heat-exchange jacket [3].

In simulation, the possible output capacity of a 2 m^3 reactor was determined together with the necessary intensity of heat exchange and parameters of the heat-exchange agent. As shown by simulation of nitration in a cascade of two reactors of the specified volume, the key factor is the operation mode of the first reactor, in which the chlorobenzene conversion is as high as 83–84%. Calculations demonstrated that, in nitration with 95.8% nitric acid, the output capacity of the reactor in terms of chlorobenzene may be as high as 100 kg min^{-1}, whereas with 74.9% nitric acid the maximum output capacity is 48 kg min^{-1}.

Thus, the developed model of the reactor makes it possible to either determine the reactor volume necessary for achieving a prescribed output capacity (in designing a new process) or find the maximum possible output capacity of a reactor (in developing a process in an existing shop). Of importance in solving both these problems is the safety of the newly revealed working modes, which is particularly important for the process in question, whose heat effect is about 150 kJ mol^{-1}. To find the safe mode parameters, the

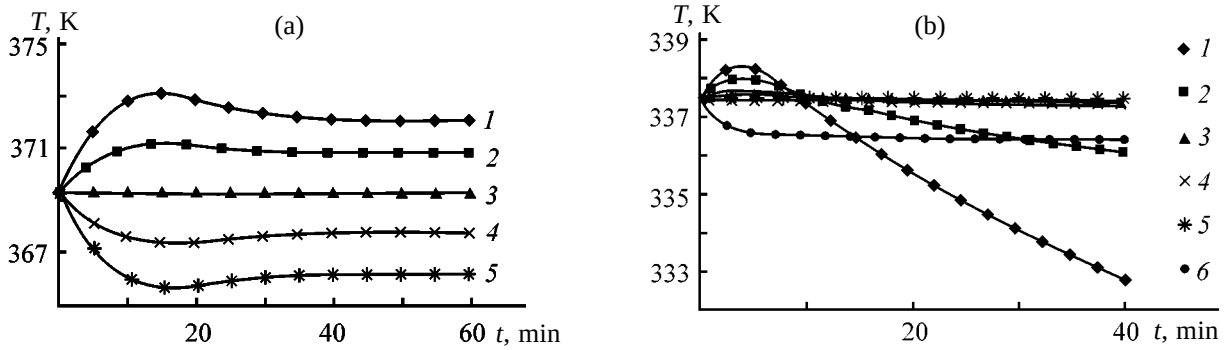

Fig. 2. Effect of changes in nitric acid flow rate on the temperature T in the reactor. Factor by which increases (decreases) the mass flow rate of nitric acid at the reactor inlet at constant flow rate of chlorobenzene: (a) (*1*) 0.6, (*2*) 0.8, (*3*) 1.0, (*4*) 1.2, and (*5*) 1.4; (b) (*1*) 0.4, (*2*) 0.6, (*3*) 0.8, (*4*) 1.0, (*5*) 1.2, and (*6*) 1.4.

sensitivity of the obtained modes to deviations from the optimal process parameters was studied.

Figures 1 and 2 show the parametric sensitivity of the given process to deviations of the parameters from the nominal values listed in Table 2.

As seen from Fig. 1, a decrease in the mass flow of chlorobenzene leads to a slight lowering of temperature in the reactor, whereas on raising the mass flow the temperature increases temporarily and then falls and tends to a new stationary level. These changes in temperature are more pronounced (up to 20°C) in nitration with 95.8% nitric acid.

Calculations also demonstrated that a decrease in the mass flow of nitric acid is accompanied by a short-time insignificant rise in the reactor temperature, which is more pronounced in nitration with 74.9% acid, and its subsequent fall. By contrast, raising the acid flow rate makes the reaction mass temperature lower.

Thus, the data obtained in studying the parametric sensitivity demonstrate that the process of chlorobenzene nitration with both 95.8 and 74.9% nitric acid is rather stable, with a transition to a new steady state occurring without any heat explosion upon steplike perturbations of the main parameters. This can be accounted for by the fact that, despite having high heat effect, the process is characterized by rather low activation energy (especially in nitration with 95.8% nitric acid). Therefore, the process passes to a new steady state rather gradually upon parameter perturbation.

Thus, the simulation results demonstrate that the process can be scaled and is rather stable.

CONCLUSIONS

(1) A mathematical model of nitration in a flow-through reactor with vigorous stirring was developed.

(2) The kinetic model developed in a calorimetric study of the nitration can be used to describe the process in a flow-through reactor.

(3) A study of the parametric sensitivity demonstrated that the process is stable at widely varying reactant concentrations.

(4) The simulation results can be used to determine the conditions for safe operation of the reactor.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

On the Possibility of Using SPARK-1M Portable X-ray Spectrometer for Studying the Chemical Bond

B. D. Kalinin, R. I. Plotnikov, and Yu. P. Kostikov

Received July 10, 2001

Abstract—The possibility of using SPARK-1M spectrometer for studying the shift of emission lines belonging to the *K* series of X-ray spectra of transition metals (chemical shift of the lines) was studied. The possibility of using the spectrometer for measuring the chemical shift and evaluating the relative amounts of transition metals in different oxidation states is analyzed.

In studying the composition and properties of various materials, a necessity occasionally arises for analyzing the electronic structure of constituent atoms. To problems of this kind belongs, e.g., determination of the structure of various, and in the first place complex, compounds and refinement of the oxidation state of the constituent atoms. Another set of relevant problems includes quantitative determination of the relative contents of compounds containing some element in different oxidation states (e.g., the relative content of sulfate and sulfide sulfur in coal; Fe^{2+} and Fe^{3+} in kimberlite clays, micas, and other minerals; UO_2^{2+} and U^{4+} in process materials of nuclear power industry, etc.). One of the most promising methods for solving problems of this kind is to analyze the fine structure of emission X-ray spectra and to measure the shift of X-ray spectral lines (chemical shift). As a rule, the chemical shift of spectral lines does not exceed 0.1–1 eV and its measurement involves some difficulties.

The chemical shift of lines in X-ray emission spectra is commonly studied using special-purpose precision X-ray spectrometers characterized by high spectral resolution on the order of 1 eV and better (e.g., double-crystal spectrometers [1, 2]) or focusing spectrometers with large focal circle radius [3]. Nevertheless, numerous studies have employed conventional industrial scanning spectrometers with the Soller geometry, intended for analysis of the elemental composition of materials [3–5], or microanalyzers [6].

Despite the low spectral resolution of these devices (angular resolution is, as a rule, no better than 10–15′, to which corresponds, e.g., energy resolution of about 40–60 eV in the first order spectrum of iron in the *K* range), their high aperture ratio, combined with good reproducibility of angular settings, allows recording of spectral line shifts associated with the valence state of oxidation of the emitting atoms by hundredths of an electron volt.

Also, attempts have been made to study the chemical shift with a spectrometer based on a semiconductor detector with resolution of about 150 eV [7].

The present communication is concerned with the possibility of studying the chemical shift of lines belonging to the *K* series of transition metals with SPARK-1M portable X-ray spectrometer, which has been successfully used to analyze alloys and environmental objects [8, 9] and is distinguished by small size and low cost.

The SPARK-1M instrument is an automated short-wavelength scanning X-ray spectrometer with the Johansson geometry and focal circle radius R = 300 mm. X-ray spectra of chemical elements constituting a sample were excited using a BKh-7 X-ray tube with anode voltage of up to 45 kV, power of up to 10 W, and anode coating of (as a rule) Ag, deposited directly onto the beryllium window. This tube design makes it possible to bring a sample under study as close as 3–5 mm to the focus spot, which ensures high counting rates which are only 5–10 times less than those in conventional instruments with X-ray tubes having power of about 3 kW.

The scanning mechanism driven by a stepping motor ensures synchronous rotation of the crystal-

1070-4272/01/7411-1884$25.00

analyzer and detector (proportional xenon detector) at angles 2θ 24–88°. With the commonly used LiF |200| crystal, to this angular range corresponds wavelength interval 0.83–2.8 Å in which lie the *K* series of elements with *Z* 21(Sc)–51(Sb) (with the first and second reflection orders used) and *L* series of elements with *Z* 56(Ba) and more. The kinematic scheme of the spectrometer ensures the minimum scanning step of 0.125 mÅ in the entire wavelength range.

The angular resolution of the spectrometer with standard slits (input slit 0.2 mm wide, output slit 0.4 mm) is 6–8′ (15 eV for the CrK_β line) in the range of the *K* series of transition metals, which is at least twice better than the resolution of Soller-geometry spectrometers.

It should be noted that the angular resolution of the Johansson-geometry spectrometer can be substantially improved by making the slits narrower. For example, with 0.1-mm-wide input and output slits, it is possible to achieve, at the expense of a 2–3-fold decrease in intensity, a resolution of 1–2′, which ensures in the wavelength range 1.6–2.8 Å an energy resolution of 3–8 eV, comparable with the intrinsic width of the lines (~3 eV).

According to the technical documentation, the main instrumental error of the spectrometer does not exceed 0.5 rel. %; however, with the number of pulses exceeding 10^6, the actual reproducibility of measurement results is 0.1–0.15%.

The reproducibility of goniometer settings, evaluated by the reproducibility of intensity measurements at the wing of the FeK_α line under conditions of repeated setting of a prescribed wavelength, was about 0.0001° (0.015 eV).

To illustrate the possibilities of the spectrometer, Figs. 1a and 1b compare the spectra of iron oxide Fe_2O_3 and iron oxalate FeC_2O_4 (Fig. 1a) and chromium oxide Cr_2O_3 and potassium dichromate $K_2Cr_2O_7$ (Fig. 1b) for K_β lines of iron and chromium. In the measurements, the anode voltage was 35 kV, and the anode current, 0.2 mA. The counting rates at maximum were about 20000 pulse s^{-1} for iron and about 6000 and 2000 for chromium in, respectively, oxide and dichromate. The spectral scanning was done with a step of 0.0005 Å, with 10-s exposure at a point. Three sets of measurements were done for each preparation, with the obtained results averaged. After normalization (for each spectrum all ordinates were divided by a sum of ordinates), differences of counting rates $J_1 - J_2$ were determined and plotted against wavelength together with the profiles of the corresponding lines. For clarity, the differences for chromium and iron were multiplied by 5 and 50, respectively.

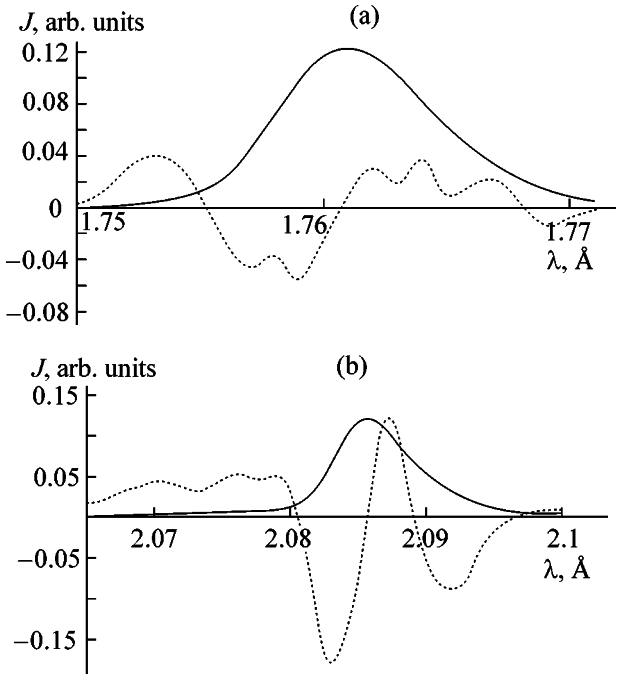

Fig. 1. Comparison of X-ray spectra of (a) Fe_2O_3 and FeC_2O_4 and (b) Cr_2O_3 and $K_2Cr_2O_7$. (*J*) Counting rate and (λ) wavelength. Dashed line: differential spectrum (×50).

As seen from Fig. 1a, the dependence of the difference $J_{Fe^{3+}} - J_{Fe^{2+}}$ (dashed line) on the wavelength is complicated. The S-shaped curve indicates the observed shift of the main Fe$K_{\beta_{1,3}}$ peak.

The peak at 1.753 Å and additional peaks superimposed on the main curve in the interval 1.755–1.76 Å are associated with the presence of the Fe$K_{\beta_{2,5}}$ line whose intensity and position depend on the oxidation state of iron. A similar structure in the long-wavelength part of the spectrum (1.76–1.77 Å) is due to the presence in the spectra of preparations of an Fe $K_{\beta'}$ line whose position and intensity strongly depend on the oxidation state of the metal (on the number of unpaired electrons).

Of similar nature is the differential curve $J_{Cr^{3+}} - J_{Cr^{6+}}$ (Fig. 1b). In this case, owing to the absence of the Cr $K_{\beta'}$ line in the spectrum of potassium dichromate, the long-wavelength part of the curve shows a single peak corresponding to the presence of this line in the spectrum of chromium(III) oxide.

The shift can be evaluated by comparing the abscissa of the point of intersection of the differential

Evaluation of the error in determining compounds with different oxidation states of metals in relation to counting rate in two spectral regions

Metal	Compound	Wavelength, Å		$R = J_1/J_2$	σ_R		σ_c, %
		λ_1	λ_2		calculation	statistical values	
Fe	Fe_2O_3	1.758	1.762	0.07107	0.00005	0.00003	2.8
	FeC_2O_4	1.758	1.762	0.06310	0.00002	0.00002	2.8
Cr	$K_2Cr_2O_7$	2.088	2.092	4.235	0.039	0.02	4.3
	Cr_2O_3	2.088	2.092	3.290	0.014	0.02	4.3

curve and the X axis with the position of the $K_{\beta_{1,3}}$ peak or, more precisely, by the amplitude of peaks in this curve. For example, in the case of approximation of the line shape with a Gaussian curve and small, compared with the peak half-width $H_{1/2}$, shift Δ, the shift can be determined using the approximate formula obtained in approximation of the line shape with a normalized Gaussian function:

$$\Delta = 0.35(A_d/A)H_{1/2}, \quad (1)$$

where A_d/A is the ratio of the difference of peak amplitudes in the S-shaped differential curve to the amplitude of the main peak.

Calculation by formula (1) for the examples presented in Figs. 1a and 1b demonstrated that the shift is 0.25 eV in passing from Fe_2O_3 to FeC_2O_4 and 0.53 eV, in reasonable agreement with the known data, in going from Cr_2O_3 to $K_2Cr_2O_7$.

The curves in Figs. 1a and 1b can be used not only in studying X-ray emission spectra of transition metal compounds, but also for determining quantitatively the relative contents of compounds with different metal oxidation states. Such an evaluation can be made, e.g., on the basis of position or height of peaks in the differential curves. The ratio of concentrations of compounds with different metal oxidation states, contained in a sample, can be evaluated more accurately by the ratio of the counting rates in two parts of the spectrum (after subtraction of the background). It is advisable to use points at the peak of the $K_{\beta_{1,3}}$ line and near the maximum or minimum in the differential curve.

As an example, table presents such ratios for the spectra of iron and chromium, shown in Figs. 1a and 1b, and evaluates the anticipated analysis error. In each case, six measurements with 10-s exposure were done with independent wavelength setting. Further, average values R and their rms deviations σ_R were calculated. The table also lists statistical errors of the ratios.

The anticipated error in determining the metal content, σ_c (%), was calculated using the expression

$$\sigma_c = (\sigma_{R_1} + \sigma_{R_2})^{1/2}/(R_1 - R_2) \times 100.$$

As follows from the data presented in the table, at a total measurement time on the order of $2 \times 6 \times 10$ s = 2 min and high metal contents, the error in determining metal forms in varied oxidation state on a SPARK-1M spectrometer is 3–4%, which corresponds to the results obtained in determining the iron oxidation state from the shift of lines belonging to the L series on a CAMEBAX microanalyzer [6].

The presented results suggest that the commercial SPARK instrument allows reliable measurements of the chemical shifts of X-ray emission lines. The information about the chemical shift of lines is important in solving chemical-analytical, geochemical, and environmental problems.

The dependence of the wavelengths (energies) of X-ray lines on the chemical state of an element being determined may also affect the results of quantitative analyses in the cases when the chemical states of an element being determined in a sample being analyzed and in the reference are different. For example, the error in determining titanium in titanium-containing oxide materials may be as high as 0.3–0.4% with metallic titanium used as reference. Therefore, in our opinion, any precise analytical studies should be started with evaluation of the chemical shift of analytical lines in a material under study with respect to references, with subsequent introduction, when necessary, of appropriate corrections.

CONCLUSION

The high reproducibility of angular settings of the SPARK-1M spectrometer allows this instrument to be

used in studying the chemical shift of spectral lines. Comparison of *K*-line spectra of transition metals, obtained using the instrument, makes it possible to study their oxidation state. If compounds of transition metal in different oxidation states are present in a sample being analyzed, the contents can be evaluated on the basis of the ratios of counting rates at wings of the K_β peak with an error not higher than 3–5 rel. %. The possibility that the chemical shift may affect the results of analysis should be taken into account in precise quantitative measurements.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Perfume Characteristics of Acetals Containing an Aromatic Ring

O. G. Vyglazov, V. A. Chuiko, L. V. Izotova, Zh. V. Vintarskaya, and R. Ya. Yudenko

Institute of Physical Organic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus
Tereza-Inter Limited Liability Company, Moscow, Russia

Received March 15, 2001

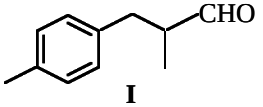
Abstract—Aromatic acetals were prepared by condensation of 2-methyl-3-(4-R-phenyl)propanals (R = Me, *i*-Pr, *i*-Bu) with ethanol, methanol, ethylene glycol, 1,2-propanediol, methyl Cellosolve, and Cellosolve. The perfume characteristics of the acetals were studied.

Thanks to active development of synthetic organic chemistry, the set of available synthetic perfumes is rapidly extended, with new classes of compounds being involved. The use of new synthetic perfumes is characterized by two features: (1) as a rule, substances with interesting scent are discovered empirically; (2) the perfume characteristics are studied for as many structurally related compounds as possible, with the aim to apply the developed processes to synthesis of a wide set of perfumes.

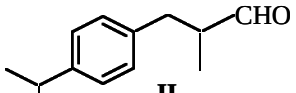
Such an approach inevitably sets a task of revealing the structure–scent relationship for perfumes, with the aim to make a search for new perfumes purposeful. At the same time, to find such a relationship, it is necessary to prepare as many structural analogs as possible.

Such studies were performed previously [1] but became more active in the past years. For example, the structure–scent relationship was studied for the series of 7-oxanorbornanes [2], monoterpene lactones [3], and bicyclo[2.2.*n*]oximes [4].

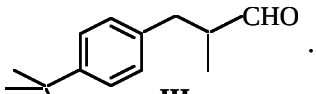
In this work, starting from aldehydes in which the carbonyl group is located in a side chain of an aromatic ring, we prepared aromatic acetals and studied their perfume characteristics. The initial compounds were the aldehydes widely used in perfumery: jasmorange [2-methyl-3-(4-methylphenyl)propanal, **I**], cyclamenaldehyde [2-methyl-3-(4-isopropylphenyl)propanal, **II**], and lilial [2-methyl-3-(4-*tert*-butylphenyl)propanal, **III**]:



I



II



III

Acetals are widely used are synthetic perfumes. This mostly concernes diethyl, dimethyl, and ethylene acetals, although derivatives of some other alcohols (geraniol, isoamyl alcohol, 2-phenylethanol) are also used [5]. To systematically study the structure–scent relationship in the series of acetals derived from **I**–**III**, we prepared the acetals with methanol, ethanol, ethylene glycol, 1,2-propanediol, and also with methyl Cellosolve and Cellosolve (the two latter compounds were not used previously for these purposes).

The reaction is usually performed in the presence of an acid catalyst; from the viewpoint of process simplicity, it is convenient to use cation-exchange resins, e.g., granulated KU-2 cation exchanger. The reaction was performed in benzene in the presence of FIBAN K-1 fibrous sulfonic cation exchanger as catalyst. This resin was prepared by radiation-induced grafting ot styrene (98%)–1,4-divinylbenzene (2%) copolymer to a polypropylene thread, followed by sulfonation with sulfuric acid.

With this catalyst, owing to its developed surface [6], the reaction time was reduced by a factor of 1.5–2 as compared to KU-2. Furthermore, the fibrous ion exchanger did not noticeably lose its activity in repeated use, as demonstrated by the example of the reaction of aldehydes **I**–**III** with Cellosolve (Table 1).

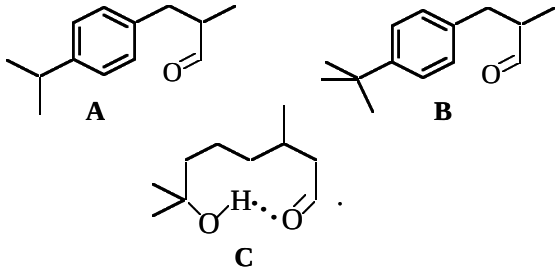
The reaction progress was monitored by GLC. The structure of the acetals was confirmed spectroscopically. In the ^{1}H NMR spectra, a characteristic doublet

1070-4272/01/7411-1888$25.00

at 4.3–4.8 ppm (J 5–8 Hz) corresponds to the $HC(OR)_2$ proton. The IR spectra exhibit a characteristic acetal pattern consisting of five bands in the range 1185–1030 cm^{-1}.

The synthesis conditions and yields of the target products are given in Table 2, and the perfume characteristics of the acetals,[1] in Table 3.

Certain similarity of the scents of the initial aldehydes **I**–**III** is undoubtedly due to their similar molecular structure, not only topological but also steric. It was suggested [7] that all these molecules have a "rolled-up" conformation of the side chain (**A**, **B**), which is stabilized owing to conjugation of the π orbitals of the aromatic ring and carbonyl group. This factor is also responsible for the similar scent of these aldehydes and of 7-hydroxy-3,7-dimethyloctanal (hydroxycitronellal, **IV**). As suggested in [7], the molecule of **IV** in the vapor phase can take the rolled-up conformation **C** owing to hydrogen bonding:



A **B**

C

However, optimization of the molecular geometry of **I**–**III** in the MM-2 approximation [8] shows that for each aldehyde the energies of the molecule in all the possible conformations differ by no more than ± 0.8 kJ mol^{-1}. Thus, the rolled-up conformation affords no additional stabilization of the aldehyde molecule. Furthermore, calculation shows that the angle between the planes of the aromatic ring and CHO group in **I**–**III** in the rolled-up conformation is 41.3°, 43.2°, and 44.5°, respectively. Such orientation excludes any overlap "through space" of the orbitals of the two nonbonded molecular fragments. It should be noted also that in conformation **C** of **IV** the distance between the hydroxyl hydrogen and carbonyl oxygen is 4.87 Å, which is too long for hydrogen bonding, especially in the gas phase when the molecule acquires additional energy.

[1] The perfume characteristics of acetals, tested as 10% solutions in purified 96% ethanol, were evaluated by the Tasting Council (eight experts) at the Accredited Control and Analytical Laboratory of Perfumes and Cosmetics, Tereza-Inter Limited Liability Company (Accreditation Certificate of the State Committee for Standards of the Russian Federation no. ROSS RU.0001.512.312, July 6, 2000).

These data cast doubt on the "conformational" approach to scent analysis. The obtained set of acetals allows us to correlate variations of the scent with variations of, e.g., the number of alkyl substituents, with the conformation of the molecular core being preserved.

When considering the relationship between the scent of the initial aldehydes and their molecular structure, it should be noted that, in going from the methyl to isopropyl and then *tert*-butyl substituent, the scent changes from fresh fruit to fresh flower. In the series of the corresponding dimethyl acetals, the

Table 3. Scent characteristics of the synthesized acetals

Compound	Scent
2-Methyl-3-(4-methylphenyl)propanal dimethyl acetal	Green, flower, with a bittery tint
2-Methyl-3-(4-isopropylphenyl)propanal dimethyl acetal	Green, of cyclamen, with a bitter grassy note
2-Methyl-3-(4-*tert*-butylphenyl)propanal dimethyl acetal	Strong, flower, with a cold note of cyclamen and lily of the valley, light ozone
2-Methyl-3-(4-methylphenyl)propanal diethyl acetal	Green, fresh watermelon, with a note of spice herbs
2-Methyl-3-(4-isopropylphenyl)propanal diethyl acetal	Flower, of cyclamen, with a wood note
2-Methyl-3-(4-*tert*-butylphenyl)propanal diethyl acetal	Flower, of cyclamen and lily of the valley, with a wood note
2-Methyl-3-(4-methylphenyl)propanal di(2-methoxyethyl) acetal	Fresh, flower, of peony with a bright watermelon note
2-Methyl-3-(4-isopropylphenyl)propanal di(2-methoxyethyl) acetal	Fresh, of cyclamen, with a watermelon–ozone note
2-Methyl-3-(4-*tert*-butylphenyl)propanal di(2-methoxyethyl) acetal	Flower, with notes of cyclamen, lily of the valley, and sweet lime blossom
2-Methyl-3-(4-methylphenyl)propanal di(2-ethoxyethyl) acetal	Flower, grassy, with a fresh note of watermelon and heady anise and wood tint
2-Methyl-3-(4-isopropylphenyl)propanal di(2-ethoxyethyl) acetal	Flower, of cyclamen, with an anise–ozone note
2-Methyl-3-(4-*tert*-butylphenyl)propanal di(2-ethoxyethyl) acetal	Flower, fresh, with a beewax and honey tint, with a light bittery note
2-Methyl-3-(4-methylphenyl)propanal ethylene acetal	Flower-grassy with a tint of parsley, celery, and anise
2-Methyl-3-(4-isopropylphenyl)propanal ethylene acetal	Flower, of cyclamen, with a fresh watermelon note
2-Methyl-3-(4-*tert*-butylphenyl)propanal ethylene acetal	Flower, of cyclamen, with a sweet anise note
2-Methyl-3-(4-methylphenyl)propanal propylene acetal	Grassy, heady, wood, with seaweed note
2-Methyl-3-(4-isopropylphenyl)propanal propylene acetal	Fresh, flower, sweet, with a beewax tint
2-Methyl-3-(4-*tert*-butylphenyl)propanal propylene acetal	Flower, of cyclamen, sweet, powdery

scent changes from green fruit–watermelon through flower-grassy with a bittery note to fresh flower with an ozone note. With diethyl acetals, very gentle heady and wood notes appear. With methoxy and ethoxy groups introduced into the ethyl acetal moiety, the scent changes more significantly: the fresh fruit–watermelon note is enhanced, ozone freshness components disappear, and a sweet wood or honey note appears. These trends are observed with derivatives of all the three aldehydes. Smooth variation of the scent of the initial aldehydes corresponds to smooth variation of the scent in the series of similar acetals with linear alkyl or alkoxy groups.

With compounds containing a cyclic acetal groups (ethylene or propylene acetals), the trend is reverse. In the series of ethylene acetals, the scent varies very sharply with increasing size of the substituent in the phenyl moiety: first a fairly pronounced sweet flower note appears, then it is enhanced, and a fresh watermelon note is added. In the series of propylene acetals, a wood scent gives way to a fresh flower scent subsequently acquiring a warm powdery tint.

The acetals obtained show promise as components of fragrant and perfume formulations, because they produce a fairly wide range of scents of various tints and, in contrast to the initial aldehydes, are stable to oxidation in ready perfumes and cosmetics.

EXPERIMENTAL

The ^{1}H NMR spectra were taken with a Tesla BS-567A spectrometer ($CDCl_3$, internal reference HMDS). The IR spectra were recorded on a Specord 75-IR spectrometer (thin films). The GLC analysis of reaction mixtures was performed with a Chrom-5 chromatograph [flame-ionization detector, 2000 × 3-mm column, Chromaton N-AW-DMCS support (0.125–

0.160 mm), Reoplex-400 stationary phase, programmed heating from 100 to 180°C (4 deg min^{-1}), nitrogen carrier gas].

To prepare acetals, the catalyst (2 wt % relative to aldehyde) was added to a solution of 0.10 mol of aldehyde **I**–**III** and 0.11 mol of dihydric alcohol in 70 ml of benzene. The mixture was refluxed until the release of water ceased and the reaction was complete (monitored by GLC). The catalyst was separated by decanting, washed with benzene (2 × 5 ml), and reused; the wash solutions were combined with the reaction solutions. The solvent was distilled off. When necessary (if the acetal purity was less than 98%), the product was purified by chromatography (alumina, eluent hexane–diethyl ether with gradually increasing content of ether).

Monohydric alcohols were taken in a double amount. With dimethyl acetals, the released water was bound with a stoichiometric amount of triethyl orthoformate.

CONCLUSIONS

(1) A series of 2-methyl-3-(4-R-phenyl)propanal (R = Me, *i*-Pr, *t*-Bu) acetals was prepared; these compounds have pleasant scent and can be used as perfumes.

(2) In the series of acetals with the same monohydric alcohols, the scent changes smoothly depending on the substituent in the phenyl ring. In the series of diols, the scent changes more sharply.

Abstract—Quaternary [1-(1-adamantyl)ethyl]- and (1-adamantyl)trimethylammonium, and also 3-(1-adamantyl)-3-chloro-2-propenylammonium salts were prepared, and their surface activity was studied.

Quaternary ammonium salts, owing to their specific features as cationic surfactants and to colloid-chemical properties, are widely used in various branches of industry as effective antistatics [1], as reagents imparting hydrophobicity to clay impurities in their flotation separation from potassium ores [2], in production of modified starch for multilayered and crimped cardboard [3], and in preparation of bitumen emulsions.

Major researchers' attention is given to adamantane derivatives as compounds with a high biological activity [4, 5]. Amines of the adamantane series—midantane (1-adamantylamine hydrochloride), remantadine {[1-(1-adamantyl)ethyl]amine hydrochloride}, and urotropin (1,3,5,7-tetraazaadamantane)—are effective antiviral agents [6]. 1-Adamantylammonium carboxylates (acetate, salicylate, propionate, etc.) show a high therapeutic activity and are used for treating influenza [7]. However, there are no data on adamantane derivatives containing [1-(1-adamantyl)ethyl]trimethylammonium, (1-adamantyl)trimethylammonium, or 3-(1-adamantyl)-3-chloro-2-propenylammonium cation in combination with an anion of an organic or inorganic acid.

The goal of this work was to prepare new quaternary [1-(1-adamantyl)ethyl]- and (1-adamantyl)trimethylammonium salts and also 3-(1-adamantyl)-3-chloro-2-propenylamine hydrochloride and to study their surface activity and flotation properties. As starting compounds we used (1-adamantylethyl)amine **I** prepared by hydroamination of 1-acetyladamantane **II** and 1-adamantylamine **III** prepared by treatment of aqueous solution of amine **IV** with NaOH (Schemes 1, 2).

By reactions of amines **I** and **III** with formaldehyde [8] in the presence of formic acid (reductant), we prepared (1-adamantylethyl)dimethylamine **V** and (1-adamantyl)dimethylamine **VI**. In the optimal procedure, the reagents are added over a period of 4.5–5 h at 50°C, after which the mixture is heated to 80°C to bring the reaction to completion. The ratio of the amine, formic acid, and formalin is 1 : 5 : 4. The reaction is complete in 21–22 h; the product yield is as high as 94–95%.

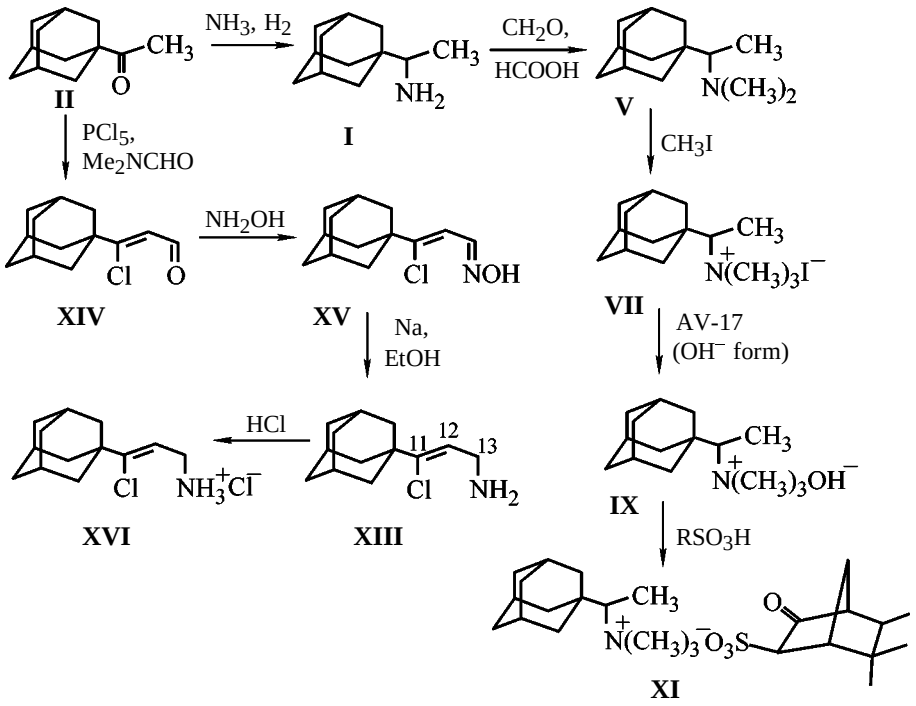
Quaternizzation of amines **V** and **VI** with methyl iodide [9] gave [1-(1-adamantyl)ethyl]trimethylammonium iodide **VII** and (1-adamantyl)trimethylammonium iodide **VIII**. Iodides **VII** and **VIII**, when treated with strongly basic AV-17 anion exchanger in the OH^- form [10], give (1-adamantylethyl)trimethylammonium hydroxide **IX** and (1-adamantyl)trimethylammonium hydroxide **X**. When the reaction was performed at 50–55°C and the equivalent ratio iodide : anion exchanger = 1 : 3, with addition of the resin in two portions, the reaction was complete in 18 h, with the yield of **IX** and **X** being as high as 98–99%.

(1-Adamantylethyl)trimethylammonium (**XI**) and (1-adamantyl)trimethylammonium (**XII**) salts were prepared by neutralization of solutions of hydroxides **IX** and **X** with a solution of isocamphanone-3-*exo*-sulfonic acid [11, 12]. Previous studies showed that the ammonium salt of this acid shows surface activity and is effective collector of potassium chloride in flotation of sylvinite ores [11]. Therefore, it was appropriate to study the surface activity of quaternary ammonium salts with the anion of isocamphanonesulfonic acid.

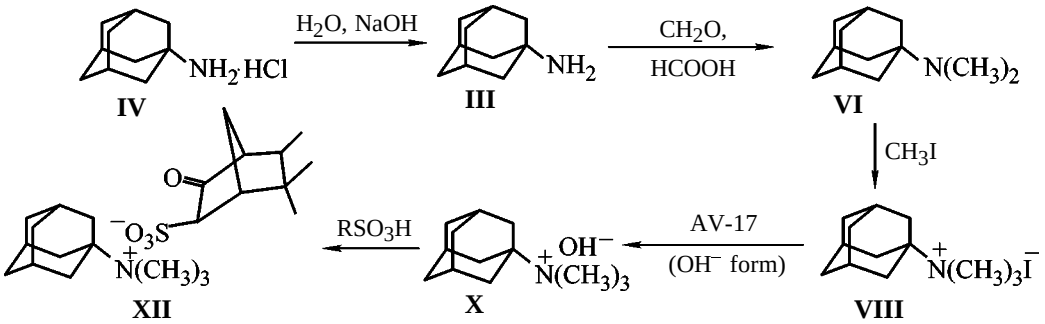
The structure of the compounds was proved by ^1H NMR and IR spectroscopy, and also by mass spectrometry. The ^1H NMR spectra of **VII**, **VIII**, **XI**, and **XII** contain signals at δ 1.6, 1.9, and 2.0 ppm, corresponding to 15 protons of the adamantane core. The signal at δ 3.2 ppm belongs to the $N(CH_3)_3$ moiety. The IR spectra of **XI** and **XII** contain absorption

1070-4272/01/7411-1892$25.00

Scheme 1.

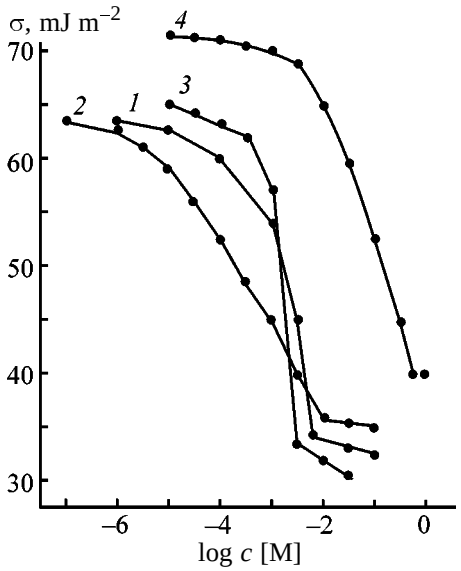


Scheme 2.



bands at 1740 [ν(C=O)], 1180 [ν(SO_2)], and 1070–1040 cm^{-1} [ν(C–O–S)]. In the mass spectra of **VII**, **VIII**, **XI**, and **XII** we identified the molecular peaks of the cation (without acid anion), with the relative intensity of 15%; the base peak was that at *m/z* 135, $[Ad]^+$.

Aliphatic amine salts are used in flotation of sylvinite ores. The flotation properties of amines containing the adamantane cores were not studied previously. To examine the behavior of such substances in flotation of potassium ores, we prepared 3-(1-adamantyl)-3-chloro-2-propenylamine (**XIII**) hydrochloride. The synthesis was performed as follows. First, by reaction of ketone **II** with PCl_5 and dimethylformamide (Vilsmeier–Haack complex [13]), we prepared in 60% yield *s-cis*-3-(adamantyl)-3-chloro-2-propenal **XIV**. In its ^1H NMR spectrum, the adamantane core protons give three broadened singlets at δ 1.8 (6H), 1.9 (6H), and 2.1 ppm (3H). The protons at C^{12} and C^{13} give doublets (δ 6.1 and 10.1 ppm, respectively), with the coupling constant ^3J 6 Hz, which corresponds to the *s-cis* arrangement [14]. The IR spectrum of **XIV** contains bands at 1680 [ν(C=O)], 1610 [ν(C=C)], and 875 cm^{-1} [ν(C–Cl)], and in the mass spectrum there are peaks of the molecular ion at *m/z* 224 and 226; their intensity ratio (100 : 33) corresponds to the presence of one chlorine atom. Treatment of **XIV** with hydroxylamine have *s-cis*-3-(adamantyl)-3-chloro-2-propenal oxime **XV** [15] in a quantitative yield. In its ^1H NMR spectrum, we identified characteristic signals of the tricyclic core in the form of three broadened singlets at δ 1.8 (6H), 1.9 (6H), and 2.1 ppm (3H), and also doublets of the C^{12} and C^{13} protons at δ 6.2 and 8.2 ppm, respectively (^3J 6 Hz). The absorption



Surface tension isotherms of aqueous solutions of (*1*) **XI**, (*2*) **XVI**, (*3*) **XVII**, and (*4*) $RSO_3^-NH_4^+$. (σ) Surface tension and (*c*) concentration.

bands of the C=C, C=N, and C–Cl bonds are observed in the IR spectrum at 1610, 1640, and 850 cm^{-1}, respectively. The mass spectrum of oxime **XV** contains the peak of the molecular ion (I = 43%) and the fragment peaks corresponding to the loss of H_2O (100%), chlorine atom (86%), and adamantane core (31%).

Reduction of oxime **XV** with sodium in absolute ethanol gives 3-(1-adamantyl)-3-chloro-2-propenylamine **XIII** in 40% yield; by treatment with dry HCl it was converted to hydrochloride **XVI** in 90% yield.

Taking into account an important role of surfactants in various industrial processes, in particular, in flotation concentration of ores, we studied the surface activity and flotation properties of **XI**, **XII**, and **XVI**. The collector presently used for recovery of potassium chloride is octadecylamine hydrochloride. Until recently, it was believed that flotation separation of soluble salts occurs only under the action of aliphatic compounds with a hydrophilic group at a primary carbon atom. The longer the hydrocarbon chain of the collector, the higher the energy of dispersion interactions and hence the higher the stability and density of the adsorption layer on the KCl surface and the stronger the hydrophobization effect. Surfactants with radicals containing double bonds or with branched radicals show weaker collecting power. Secondary, tertiary, and quaternary ammonium salts are practically incapable of KCl flotation.

The synthesized compounds differ from sodium alkyl sulfates and aliphatic amines in that the hydrophilic groups in their molecules are linked not to a simple alkyl radical but to a bulky tricyclic fragment with a complex steric structrue. Compounds **XI** and **XII** and the ammonium salt $RSO_3^-NH_4^+$ contain a common surface-active anion with a polar sulfo group. However, in contrast to the ammonium salt, in **XI** and **XII** the cation is also surface-active. This fact can give rise to differences in the surface and volume properties and in the hydrophobizing effect of these surfactants.

The degree of adsorption of surfactants on the phase boundary, characterizing interchange of the molecules on the surface and in the bulk, is determined by the length of the hydrocarbon radical, the nature of polar groups (for straight-chain surfactants with the vertical orientation of the molecules in the surface layer), and by the surfactant solubility.

According to the surface tension isotherms (see figure), the compounds prepared behave in solution as typical lyophilic surfactants, markedly decreasing the surface tension of aqueous solutions (to 30–40 mJ m^{-2}) and showing clearly defined ranges of micelle formation. It should be noted that compounds **XI** and **XII** are less soluble in water (1.1×10^{-1} and 1.2×10^{-1} M, respectively) than the ammonium salt $RSO_3^-NH_4^+$ (0.68 M); therefore, the surface tension of their solutions decreases to a greater extent. As the solubility is decreased, the tendency of surfactant molecules to pass from the bulk of solution to the phase boundary becomes more pronounced. The minimal values of the surface tension give only a qualitative characteristic of the effect of the substance structure on the surface properties. To reveal a correlation between the surface and volume properties, we calculated from the experimental isotherms the parameters of the surface activity of the synthesized surfactants (Table 1). As compared to the ammonium salt $RSO_3^-NH_4^+$, the synthesized compounds show higher activity at the solution–air interface. As seen from Table 1, the surface activiy of **XI** and **XII** considerably exceeds that of $RSO_3^-NH_4^+$.

Thus, the presence in a molecule of a complex organic counterion capable of adsorption, together with a surface-active ion, on the liquid–gas interface and of association in the bulk to form micelles determines certain specific features of such compounds as **XI** and **XII**. Solutions of such surfactants exhibit a pronounced synergism manifested in high surface

Table 1. Colloid-chemical characteristics of surfactant solutions*

XVI	0.0001	1.6	35	0.01	3.7
$RSO_3^-NH_4^+$	0.18	3.1	40	0.56	0.057

* (c_m) Saturation concentration of adsorption layer, determined as the point in which the σ–ln c plot starts to deviate from the straight line; (A_{max}) maximal adsorption calculated according to Gibbs; (σ_{min}) minimal surface tension; (CMC) critical micelle concentration determined from the break point in the σ–ln c isotherm; (G) surface activity determined from CMC according to Rebinder.

activity and low critical micelle concentration, as compared to salts of the surface-active ions with simple counterions. A close-packed adsorption layer is formed on the interface, which considerably decreases the surface tension on the liquid–gas interface (to 30 mJ m^{-2}), and association in solution starts at lower concentrations (10^{-3} M). Such a behavior of the surfactants under consideration is due to enhancement of hydrophobic interactions owing to formation (both on the surface and in the bulk) of electrically neutral complexes as a result of specific (electrostatic) interactions with charge compensation.

We have studied the flotation properties of the compounds. We found that adamantane derivatives **XI**, **XII**, and **XVI** can be used as collectors of KCl in flotation concentration of sylvinite ores. As seen from Table 2, agent **XII** ensures 93% recovery of KCl with the KCl content in the concentrate as high as 86%.

The surfactants synthesized are nontoxic, readily degradable biologically, and well compatible with the traditional surfactants, which makes them promising for industrial use.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded with a Tesla BS-567A spectrometer (100 MHz, $CDCl_3$, internal reference TMS). The IR spectra were taken with a Protege-460 Fourier spectrometer, and the mass spectra, with an MKh-1320 mass spectrometer (electron impact, 50 eV).

The surface tension of the synthesized compounds in aqueous solutions was determined by the ring detachment method allowing measurement of the equilibrium surface tension [16]. The method is based on measuring the force required for detachment of a wire ring from a horizontal liquid surface. The detachment force was measured with a torsion balance calibrated using a reference liquid (hexane) with a known surface tension.

The flotation activity of the new compounds was studied with a laboratory machine (chamber volume 150 cm^3) using natural sylvinite ore of the Starobinskoe deposit (KCl content 27.4%, insoluble residue 3.4%). As the liquid phase we used a saturated solution of KCl and NaCl (d 1.235 g cm^{-3}), and as the agent depressing clay and carbonate impurities, sodium salt of carboxymethyl cellulose (Na-CMC). The agents were introduced in the following order: Na-CMC, stirring for 3 min; collector, stirring for 1 min; flotation. The solid flotation products were separated from the liquid phase on a Büchner funnel, dried, weighed, and analyzed for the KCl content. Flotation tails were analyzed by flame photometry, and concentrates, by precipitation of perchlorate or tetraphenylborate [17].

1-Adamantylamine III. A solution of 20 g of **IV** in 50 ml of water was heated to 45°C, and 4.25 g of solid NaOH was added in small portions with stirring over a period of 5 h. Then the mixture was heated to 60–65°C and kept at this temperature for 6 h. After cooling to room temperature, the precipitate of **III** was filtered off, washed with water (2 × 50 ml), and dried; yield 96%, colorless crystalline substance, mp 210–212°C.

[1-(1-Adamantyl)ethyl]dimethylamine V. A solution of 17.9 g of **I** in 100 ml of isopropyl alcohol was

heated with stirring to 50–53°C, and 27 g of 85% aqueous formic acid was added over a period of 40 min. In the process, the mixture warmed up to 60°C. After cooling to 50°C, 40 g of 30% formalin was added dropwise with vigorous stirring over a period of 4.5 h. Then the mixture was heated to 80°C and kept at this temperature for 21 h. After cooling, the mixture was alkalized (with phenolphthalein indicator) with 25% aqueous NaOH. The mixture was transferred into a dropping funnel, and the upper layer was separated, washed with water, and dried over $MgSO_4$. The solvent was distilled off, and the residue was vacuum-distilled. Compound **V** was obtained, yield 94%, bp 88–90°C (3 mm Hg), n_D^{20} 1.5064. IR spectrum, ν, cm^{-1}: 2950, 2860, 2780, 1460, 1170, 1090, 1050. ^1H NMR spectrum, δ, ppm: 1.47 d (3H, CH_3), 1.80 br.s (6H, $3CH_2$), 1.95 br.s (6H, $3CH_2$), 2.05 br.s (3H, 3CH), 3.22 s (6H, $2CH_3$), 3.30 q (1H, CH). [1-(1-Adamantyl)ethyl]trimethylammonium hydroxide IX. To a solution of 13.96 g of **VII** in 170 ml of isopropyl alcohol, we added 15.4 g (dry weight; 0.06 mol) of AV-17 anion exchanger in the OH^- form and stirred at 55°C for 5 h. Then an additional 15.4-g portion of the resin was added, and the mixture was stirred at 55°C for an additional 5 h. After cooling to room temperature, the resin was filtered off. A 6.45% aqueous-alcoholic solution of hydroxide **IX** was obtained; pH 10, yield 99% (the concentration of hydroxide depends on the moisture content of the anion exchanger).

(1-Adamantyl)trimethylammonium hydroxide X was prepared similarly from salt **VIII**; yield 98%.

[1-(1-Adamantyl)ethyl]trimethylammonium isocamphanone-3-*exo*-sulfonate XI. An equivalent amount of aqueous-alcoholic solution of isocamphanone-3-*exo*-sulfonic acid was added to an aqueous-alcoholic solution of hydroxide **IX** with vigorous stirring. The solvents were removed, and the product was recrystallized from ethanol and vacuum-dried to constant weight; yield 85%, colorless powder, mp 229–230°C. IR spectrum, ν, cm^{-1}: 2910, 2850, 1740, 1176, 1060. ^1H NMR spectrum, δ, ppm: 0.90 d (3H, CH_3), 1.05 s (6H, $2CH_3$), 1.45 d (3H, CH_3), 1.7 br.s (6H, $3CH_2$), 1.80 br.s (6H, $3CH_2$), 2.05 br.s (3H, 3CH), 2.10–2.80 m (5H), 3.30 s (9H, $3CH_3$), 3.40 q (1H, CH), 3.70 d (1H, $HCSO_3$). Mass spectrum, *m*/*z*: 230 (M^+ – $C_{15}H_{28}N$, 12%), 214, 177, 163, 135 (100%), 119.

Found, %: C 66.12, H 9.15, N 2.99, S 7.01.
$C_{25}H_{42}NO_4S$.
Calculated, %: C 66.37, H 9.29, N 3.09, S 7.08.

(1-Adamantyl)trimethylammonium isocamphanone-3-*exo*-sulfonate XII was prepared similarly, by

neutralization of hydroxide **X**; yield 70%, colorless powder, mp 255–256°C. IR spectrum, ν, cm^{-1}: 3050, 2960, 2910, 2850, 1710, 1180, 1040. ^1H NMR spectrum, δ, ppm: 0.90 d (3H, CH_3), 1.00 s (6H, $2CH_3$), 1.50 m (1H, CH), 1.70 br.s (6H, $3CH_2$), 1.90 m (2H, 2CH), 2.00 br.s (6H, $3CH_2$), 2.10 m (1H, CH), 2.30 br.s (3H, 3CH), 2.60 m (1H, CH), 3.10 s (9H, $3CH_3$), 3.70 d (1H, CH). Mass spectrum, *m*/*z*: 328 ($M^+ - SO_4$, 10%), 253, 215, 179, 152, 136, 135 (100%), 122, 108, 93.

Found, %: C 65.03, H 8.90, N 3.25, S 7.60.
$C_{23}H_{38}NO_4S$.

3-(1-Adamantyl)-3-chloro-2-propenylamine XIII. Sodium (10 g) was added with stirring to 4 g of oxime **XV** in 185 ml of absolute ethanol. After complete dissolution of sodium, the mixture was refluxed for 35 min, poured onto ice, and acidified with 15% HCl. The alcohol was distilled off, and the aqueous solution was washed with diethyl ether and alkalized by adding anhydrous KOH with stirring and cooling. Then the mixture was extracted with diethyl ether, and the extract was dried over KOH. After removal of the solvent, 1.5 g of amine **XIII** was obtained; yield 40%. IR spectrum, ν, cm^{-1}: 2920, 2855, 1630, 1580, 1320, 870. ^1H NMR spectrum, δ, ppm: 1.8 br.s (6H, $3CH_2$); 1.9 br.s (6H, $3CH_2$); 2.1 br.s (3H, 3CH); 6.2 d, ^3J 6 Hz (1H, $C^{12}H$); 8.2 d (1H, $C^{13}H$).

Found, %: C 69.22, H 9.04, Cl 15.55, N 6.34. M^+ 225 (15%).
$C_{13}H_{20}N$.
Calculated, %: C 69.16, H 8.93, Cl 15.70, N 6.20. *M* 225.8.

3-(1-Adamantyl)-3-chloro-2-propenal XIV. To 134 ml of dimethylformamide at 25–30°C, 50.2 g of PCl_5 was added in portions over a period of 30 min. The mixture was stirred at 20–25°C for 3 h and then kept at this temperature for 12 h. To the resulting suspension of the Vilsmeier–Haack complex, a solution of 33 g of ketone **II** in 82.5 ml of dimethylformamide was added at 25–30°C over a period of 30 min. The mixture was stirred at 35–55°C for 67 h, after which 200 ml of water was added with cooling, and the mixture was allowed to stand at 20–25°C for a day. The crystalline precipitate of **XIV** was filtered off, washed with water, and vacuum-dried. Yield 24 g (60%), mp 57–59°C (from methanol). IR spectrum, ν, cm^{-1}: 2930, 2855, 1620, 1680, 1460, 1360, 875. ^1H NMR spectrum, δ, ppm: 1.8 br.s (6H, $3CH_2$); 1.9 br.s (6H, $3CH_2$); 2.1 br.s (3H, 3CH); 6.1 d, ^3J 6 Hz (1H, $C^{12}H$); 10.1 d (1H, $C^{13}H$).

Found, %: C 70.04, H 7.96, Cl 15.65. M^+ 224 (100%).
$C_{13}H_{17}ClO$.
Calculated, %: C 69.48, H 7.62, Cl 15.78. *M* 224.7.

3-(1-Adamantyl)-3-chloro-2-propenal oxime XV. A solution of 12 g of sodium acetate in 60 ml of water was added at room temperature with stirring to a mixture of 8 g of aldehyde **XIV** in 30 ml of ethanol and 10 g of hydroxylamine hydrochloride in 10 ml of water. The mixture was made homogeneous by adding 60 ml of ethanol and stirred for 10 h at 55–60°C. Then the mixture was diluted with water, and the precipitate of oxime **XV** was filtered off, washed with water, and vacuum-dried. Yield 6.5 g (76%), mp 158–160°C (from 2-propanol). IR spectrum, ν, cm^{-1}: 2925, 2850, 1640, 1610, 1320, 930, 850. ^1H NMR spectrum, δ, ppm: 1.8 br.s (6H, $3CH_2$); 1.9 br.s (6H, $3CH_2$); 2.1 br.s (3H, 3CH); 6.2 d, ^3J 6 Hz (1H, $C^{12}H$); 8.2 d (1H, $C^{13}H$).

Found, %: C 65.34, H 7.66, Cl 14.51, N 5.73. M^+ 239 (43%).
$C_{13}H_{18}ClN$.
Calculated, %: C 65.13, H 7.57, Cl 14.78, N 5.84. *M* 239.0.

3-Chloro-3-(1-adamantyl)-2-propenylamine hydrochloride XVI. A stream of dry HCl was passed for 2 h through an ether solution of 1.5 g of amine **XIII**. The precipitate of hydrochloride **XVI** was filtered off, washed with diethyl ether, and vacuum-dried. Yield 1.56 g (90%); mp 245°C. IR spectrum, ν, cm^{-1}: 2930, 2860, 1630, 1480, 1450, 1325, 980. ^1H NMR spectrum, δ, ppm: 1.7 br.s (6H, $3CH_2$); 1.8 br.s (6H, $3CH_2$); 2.1 br.s (3H, 3CH); 6.2 d, ^3J 6 Hz (1H, $C^{12}H$); 8.2 d (1H, $C^{13}H$).

Found, %: C 59.28, H 8.15, Cl 26.99, N 5.35. M^+ 262 (40%).
$C_{13}H_{21}Cl_2N$.
Calculated, %: C 59.54, H 8.07, Cl 27.04, N 5.34. *M* 262.2.

CONCLUSIONS

(1) Adamantane derivatives containing (1-adamantyl)trimethylammonium or [1-(1-adamantyl)ethyl]trimethylammonium cation in combination with an organic or inorganic acid anion were prepared.

(2) (1-Adamantyl)trimethylammonium isocamphanone-3-*exo*-sulfonate exhibits a high surface activity, and 3-(1-adamantyl)-3-chloro-2-propenylamine hydro-

chloride actively collects KCl in flotation concentration of sylvinite ores.

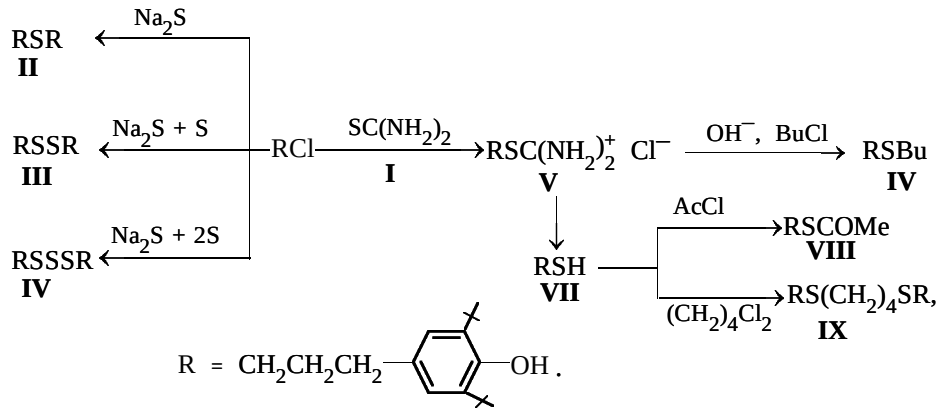
Abstract—3-(3,5-Di-*tert*-butyl-4-hydroxyphenyl)-1-chloropropane was converted into derivatives containing S(II) in various functional groups. The inhibiting power of the compounds with respect to thermal autooxidation of animal fat was evaluated.

Among inhibitors of free-radical oxidation of hydrocarbon substrates, a particular place is occupied by sulfur-containing derivatives of sterically hindered phenols, whose high antioxidative activity is due to the bifunctional mechanism of the antioxidative effect [1] and to internal synergism [2, 3]. Among such antioxidants is bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)-propyl] sulfide (SO-3), which shows a high performance as thermal stabilizer of polymer compounds based on polyethylene and polypropylene [4, 5]. As SO-3 is nontoxic, it can be used in production of household goods [6, 7]; also, the possibility was examined of its use as an antioxidant for fat-containing foodstuffs and fat-soluble drugs [8–10]. With the aim of searching for new high-performance inhibitors, we prepared in this work a series of structural analogs of SO-3 containing S(II) atoms in various functional groups and compared the antioxidative properties of these compounds with respect to thermal autooxidation of animal fat.

From 3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)-1-chloropropane **I**, we prepared sulfur-containing derivatives **II**–**IX** by the following scheme:



The compositions and structures of **II**–**IX** were proved by elemental analysis and spectroscopy.

The antioxidative properties of **II**–**IX** were studied with respect to thermal autooxidation of animal fat. The reference compound was 2,6-di-*tert*-butyl-4-methylphenol (Ionol), a commercial product used in food industry as an antioxidant for fat-containing foodstuffs [11]. As oxidation substrate we used lard; its oxidation was monitored by accumulation of hydroperoxides. The concentration of peroxides in a sample was

1070-4272/01/7411-1899$25.00

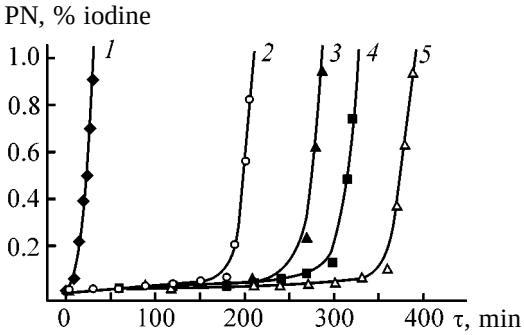


Fig. 1. Kinetic curves of lard oxidation in the presence of phenolic antioxidants. Antioxidant: (*1*) none, (*2*) Ionol, (*3*) **III**, (*4*) SO-3, and (*5*) **IX**. (PN) Peroxide number and (τ) time.

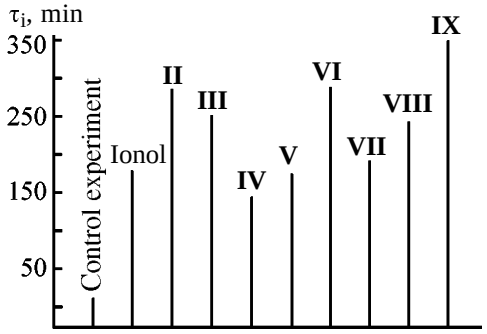

Fig. 2. Diagram of induction periods τ_i of lard oxidation inhibited with phenolic antioxidants (2.5 μmol g^{-1} fat, 130°C).

determined by Zinov'ev's version of the iodometric procedure [12]. The kinetic curves were plotted; they had similar shape for oxidation of the straight fat and the fat containing inhibitors (Fig. 1). The antioxidative activity (AOA) of inhibitors was judged from the duration of the induction period, defined as the time in which the peroxide number reaches 0.1 (the initial peroxide number was 0.003). The results are shown in Fig. 2.

Our results show that compounds **II**–**IX** exhibit pronounced AOA: the induction period of lard oxidation increases by a factor of 12–30. All the compounds except trisulfide **IV** and isothiuronium chloride **V** surpass Ionol in performance, which suggests their bifunctional activity. The AOA decreases in the order **II** (SO-3) > **III** > **IV**, which may be due to thermal oxidative cleavage of the S–S bonds with generation of thiyl radicals [13], which can participate not only in chain termination, but also in chain propagation [14]:

$$RSSR \rightarrow 2RS^{\bullet},$$

$$RS^{\bullet} + {}^{\bullet}OH \rightarrow RSOH,$$

$$RS^{\bullet} + XH \rightarrow RSH + X^{\bullet}.$$

Apparently, the possible formation of thiyl radicals is responsible for the relatively low inhibiting power of thiol **VII**:

$$RSH + {}^{\bullet}OH \rightarrow RS^{\bullet} + H_2O,$$

$$RSH + X^{\bullet} \rightarrow RS^{\bullet} + XH.$$

Among the new compounds, the most effective antioxidants are sulfide analogs of SO-3: unsymmetrical sulfide **VI** and bissulfide **IX**, with the latter appreciably surpassing SO-3 in the antioxidative effect under the experimental conditions. Our results show that compounds **II**, **III**, **VI**, **VIII**, and **IX** deserve further study as antioxidants for fat-containing foodstuffs.

EXPERIMENTAL

The ^1H NMR spectra were recorded with a Bruker spectrometer (500 MHz, external reference TMS). The IR spectra were taken with a Vektor-22 Fourier spectrometer (CCl_4 solutions or KBr pellets, 150 : 1). The melting points were determined with a PTP device.

Bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl] sulfide **II** and bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl disulfide **III** were prepared according to [15, 16].

Bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl] trisulfide IV. A mixture of 3.51 g (45 mmol) of sodium sulfide, 2.88 g (90 mmol) of sulfur, and 80 ml of 2-propanol was refluxed for 2 h. After cooling to 50–60°C, 20 g (69 mmol) of **I** was added, and the mixture was refluxed for 4 h. The reaction mass was cooled and treated with toluene (80 ml). The extract was washed with water and dried over Na_2SO_4; the solvent was distilled off. The reaction product was purified by chromatography on silica gel, eluent hexane–diethyl ether (5 : 1). Yield of **IV** 17.3 g (84%); resinous yellow substance. ^1H NMR spectrum ($CDCl_3$), δ, ppm: 1.430 s (36H, *t*-Bu), 1.970–2.000 m (4H, $ArCH_2CH_2$), 2.612–2.642 t (4H, $ArCH_2$), 2.715–2.742 t (4H, CH_2S), 5.034 s (2H, OH), 6.971 s (4H, H_{arom}). IR spectrum (CCl_4), ν, cm^{-1}: 3640 (OH). UV spectrum (EtOH), λ_{max}, nm (log ε): 220 (4.20), 278 (3.57).

Found, %: C 69.11, H 9.13, S 17.44.
$C_{34}H_{54}O_2S_3$.
Calculated, %: C 69.09, H 9.21, S 16.27.

***S*-[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl]-thiuronium chloride V.** A mixture of 4.24 g (15 mmol) of **I**, 0.95 g (12.5 mmol) of thiourea, and

30 ml of 1-butanol was refluxed for 5 h, after which the solvent was distilled off, and the product was washed with warm pentane, filtered off, and dried. Yield of **V** 4.13 g (92%); colorless crystalline substance, mp 165°C. ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 1.430 s (18H, *t*-Bu), 2.048 m (2H, $ArCH_2CH_2$), 2.726 t (2H, $ArCH_2$), 3.123 t (2H, CH_2S), 7.146 s (2H, H_{arom}). IR spectrum (KBr), ν, cm^{-1}: 3644 (OH), 3263 and 3062 (NH_2^+), 1650 (NH_2^+). UV spectrum (EtOH), λ_{max}, nm (log ε): 209 (1.84), 276 (0.16).

Found, %: C 59.89, H 8.92, Cl 9.74, N 7.52, S 8.71.
$C_{18}H_{31}ClN_2OS$.
Calculated, %: C 60.22, H 8.70, Cl 9.88, N 7.80, S 8.93.

Butyl 3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl sulfide VI. A mixture of 7 g (19.5 mmol) of isothiuronium chloride **V**, 1.72 g (43 mmol) of NaOH, 3.04 ml (29.3 mmol) of 1-chlorobutane, and 20 ml of ethanol was stirred for 1 h at 20°C under argon and then heated at 50–60°C for 2 h. The mixture was treated with toluene. The extract was washed with water and dried over Na_2SO_4, the solvent was distilled off, and the product was vacuum-distilled. Yield of **VI** 4.59 g (70%); bp 165°C (1 mm Hg). ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 0.892–0.921 t (3H, CH_2Me), 1.380–1.416 m (2H, CH_2Me), 1.430 s (18H, *t*-Bu), 1.532–1.591 m (2H, CH_2Et), 1.862–1.908 m (2H, $ArCH_2CH_2$), 2.498–2.524 t (2H, SCH_2Pr), 2.528–2.553 t (2H, CH_2SBu), 2.610–2.641 t (2H, $ArCH_2$), 5.030 s (1H, OH), 6.977 s (2H, H_{arom}). IR spectrum (CCl_4), ν, cm^{-1}: 3646 (OH). UV spectrum (EtOH), λ_{max}, nm (log ε): 208 (1.56), 277 (0.19).

Found, %: C 75.13, H 10.62, S 9.50.
$C_{21}H_{36}OS$.
Calculated, %: C 74.94, H 10.78, S 9.53.

3-(3,5-Di-*tert*-butyl-4-hydroxyphenyl)-1-propanethiol VII. A mixture of 30 g (106 mmol) of **I**, 9.7 g (127 mmol) of thiourea, and 100 ml of DMF was heated at 130°C for 2 h. After cooling to 50°C, a solution of 0.92 g (23 mmol) of NaOH in 3 ml of water was added, and the mixture was stirred for 2 h at 50°C, acidified with HCl, and treated with toluene. The extract was washed with water and dried over Na_2SO_4, the solvent was distilled off, and the reaction product was vacuum-distilled. Yield of **VII** 25.3 g (85%); mp 48, bp 138–145°C (1–2 mm Hg). ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 1.132 s (1H, SH), 1.430 s (18H, *t*-Bu), 1.912 m (2H, $ArCH_2CH_2$); 2.257–2.756 m (4H, $ArCH_2$, CH_2S), 4.852 s (1H, OH), 6.871 s (2H, H_{arom}). IR spectrum (KBr), ν, cm^{-1}: 3650 (OH). UV spectrum (EtOH), λ_{max}, nm (log ε): 207 (3.88), 278 (3.28).

Found, %: C 73.09, H 10.13, S 11.20.
$C_{17}H_{28}OS$.
Calculated, %: C 72.80, H 10.06, S 11.43.

***S*-[3-(3,5-Di-*tert*-butyl-4-hydroxyphenyl)propyl] ethanethioate VIII.** To a mixture of 5 g (17.8 mmol) of **I**, 5 ml (35.6 mmol) of triethylamine, and 20 ml of benzene, we added dropwise 1.3 ml (18.2 mmol) of acetyl chloride. The mixture was refluxed for 2 h, cooled, and treated with toluene. The extract was washed with water and dried over Na_2SO_4, the solvent was distilled off, and the reaction product was recrystallized from ethanol. Yield of **VIII** 5.12 g (89%), mp 57–58°C. ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 1.428–1.446 s (18H, *t*-Bu), 1.851–1.881 m (2H, $ArCH_2CH_2$), 2.328 s (3H, COMe), 2.580–2.611 t (2H, $ArCH_2$), 2.893–2.921 t (2H, CH_2S), 5.040 s (1H, OH), 6.952 s (2H, H_{arom}). IR spectrum (CCl_4), ν, cm^{-1}: 3647 (OH), 1695 (C=O). UV spectrum (EtOH), λ_{max}, nm (log ε): 206 (2.18), 229 (0.94), 221 (0.92), 277 (0.18).

Found, %: C 70.82, H 9.36, S 9.77.
$C_{19}H_{30}O_2S$.
Calculated, %: C 70.76, H 9.38, S 9.94.

1,4-Bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl) propylthio]butane IX. A mixture of 5.05 g (18 mmol) od **I** and 1.3 g (19.7 mmol) of KOH was dissolved in 30 ml of ethanol, and 1.14 g (9 mmol) of 1,4-dichlorobutane was added. The mixture was refluxed for 2.5 h, cooled, and treated with toluene. The extract was washed with water and dried over Na_2SO_4, the solvent was distilled off, and the product was recrystallized from ethanol. Yield of **IX** 4.0 g (72%), mp 64–65°C. ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 1.430 s (36H, *t*-Bu), 1.691 m [4H, $SCH_2(CH_2)_2CH_2S$], 1.871 m (4H, $ArCH_2CH_2$), 2.526–2.556 m (8H, SCH_2), 2.603–2.635 t (4H, $ArCH_2$), 5.030 s (2H, OH), 6.970 s (4H, H_{arom}). IR spectrum (KBr), ν, cm^{-1}: 3643 (OH). UV spectrum (EtOH), λ_{max}, nm (log ε): 210 (1.84), 277 (0.36).

Found, %: C 74.47, H 10.31, S 10.65.
$C_{38}H_{62}O_2S_2$.
Calculated, %: C 74.21, H 10.16, S 10.43.

Oxidation of lard (50 g, Novosibirsk Meat Packing and Canning Plant) was performed at 130°C in an oxygen flow in an oxidation cell similar to that described in [17]. In the course of oxidation, 1-g sam-

ples were taken. The concentration of antioxidants (main substance content no less than 98–99%) was 2.5 μmol g^{-1} fat.

CONCLUSIONS

(1) The synthesized derivatives of 3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)-1-chloropropane containing sulfur atoms in various functional groups (sulfide, disulfide, thiol, thio ester) are effective inhibitors of animal fat oxidation.

(2) Symmetrical and unsymmetrical 3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl sulfides considerably surpass in the antioxidative properties the commercial antioxidant Ionol used in food industry and deserve further study as promising antioxidants for fat-containing foodstuffs.

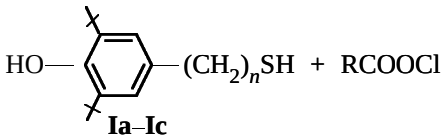
Abstract—ω-(3,5-Di-*tert*-butyl-4-hydroxyphenyl)alkanethiols were converted into thio esters by reactions with aliphatic and aromatic carboxylic acid chlorides. The antioxidative activity of these compounds, evaluated with respect to thermal autooxidation of lard, was studied in relation to their structure.

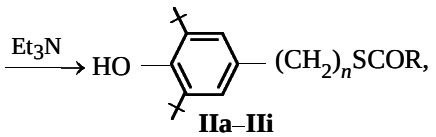
Polyfunctional phenolic antioxidants (PPAOs) exhibiting simultaneously antiradical and antiperoxide activity and showing internal synergism are known as effective inhibitors of free-radical oxidation of organic and bioorganic substrates. For example, bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl sulfide (SO-3 stabilizer) is used to stabilize polymer compounds based on polyethylene and polypropylene [1, 2] and also fat-containing foodstuffs [3–5]. Synthesis of related sulfur-, phosphorus-, and nitrogen-containing derivatives and screening of their antioxidative activity in relation to the structure is a promising line in searching for PPAOs of a new generation.

Thio esters derived from ω-(3,5-di-*tert*-butyl-4-hydroxyphenyl)alkanethiols show a high inhibiting activity with respect to polyethylene and acrylonitrile–butadiene–styrene copolymers [6, 7]. In this work we prepared thio esters derived from ω-(3,5-di-*tert*-butyl-4-hydroxyphenyl)alkanethiols **I** and studied how their antioxidative properties with respect to thermal oxidation of animal fat correlate with their structure.

Reactions of thiols **I** with aliphatic and aromatic carboxylic acid chlorides yielded the corresponding thio esters **II**:

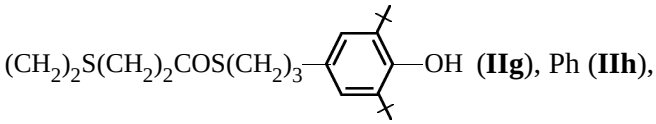


Ia–**Ic**

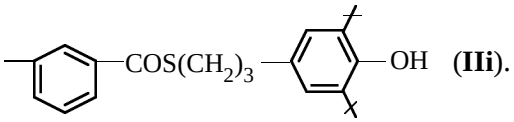


IIa–**IIi**

where n = 2 (**Ia**), 3 (**Ib**), 4 (**Ic**); n = 2, R = Me (**IIa**); n = 3, R = Me (**IIb**); n = 4, R = Me (**IIc**); n = 3, R = Bu (**IId**), C_5H_{11} (**IIe**), $C_{15}H_{31}$ (**IIf**),



(**IIg**), Ph (**IIh**),



(**IIi**).

Syntheses were performed in benzene in the presence of triethylamine (to bind the released HCl) at approximately stoichiometric molar ratio of the reactants. The yields of the target thio esters were 75–89%. The composition and structure of the synthesized compounds were confirmed by elemental analysis and spectral characteristics.

Using thermal autooxidation of lard as model reaction, we studied the antioxidative activity (AOA) of **IIa**–**IIi** in relation to their structure and compared it with that of the known stabilizers: 2,6-di-*tert*-butyl-4-methylphenol (Ionol) and SO-3 stabilizer. The lard oxidation rate was monitored by accumulation of the primary oxidation products, hydroperoxides; the AOA was evaluated by the duration of the induction period τ, defined as the time in which the peroxide number of 0.1 is attained. The results are listed in the table.

Our results show that all the compounds studied exhibit a pronounced antioxidative activity and increase the induction period of lard oxidation by a factor of 5–8. Thio esters **IIa**–**IIi** surpass in AOA

1070-4272/01/7411-1903$25.00

Induction periods τ of lard oxidation inhibited by phenolic antioxidants ([PhOH] = 1 μmol g^{-1} fat, 130°C)

* R = 3,5-di-*tert*-butyl-4-hydroxyphenyl; in the control experiment (no antioxidant added), the induction period was 34 min.

Ionol and its synergistic mixture with dodecyl ethanethioate, which suggests the bifunctional mechanism of their antioxidative effect and internal synergism. We found that under the experimental conditions the AOA is significantly influenced by the length of the hydrocarbon chain between the phenol and thio ester moieties. For example, the inhibiting activity grows in the order **IIa** < **IIb** < **IIc**, as the distance between the sulfur atom and phenol ring increases. The substituent at the carbonyl carbon atom affects AOA to a lesser extent: the inhibiting activity of aliphatic and aromatic thio esters **IIb** and **IId**–**IIi** is similar.

The synergistic mixtures of Ionol with dodecyl sulfide and dodecyl ethanethioate showed a similar inhibiting activity, whereas SO-3 surpassed in the inhibiting effect its thio ester analogs, including thiodipropionic acid derivative **IIg**. The latter fact suggests that the internal synergism is the decisive factor responsible for the high performance of sulfur-containing derivatives of the ω-(3,5-di-*tert*-butyl-4-hydroxyphenyl)alkyl series; the extent of internal synergism depends on the nature of the sulfur-containing fragment and its localization in the *p*-alkyl substituent. In SO-3 the internal synergism is more pronounced than in the corresponding thio esters. The sulfide fragment in thiodipropionic acid derivative **IIg** is remote from the phenol ring; it is not involved in synergistic interactions and therefore does not affect the antioxidative activity.

Among the tested sulfur-containing derivatives of sterically hindered phenols, thiol **Ib** shows the lowest AOA. The weak inhibiting activity of this compound is probably due to the possibility of formation of thiyl radicals $RS^{\bullet}$, which can particilate in both chain termination and chain propagation [8]:

$$RSH + {}^{\bullet}OH \rightarrow RS^{\bullet} + H_2O,$$

$$RSH + R'^{\bullet} \rightarrow RS^{\bullet} + R'H,$$

$$RS^{\bullet} + {}^{\bullet}OH \rightarrow RSOH,$$

$$RS^{\bullet} + XH \rightarrow RSH + X^{\bullet}.$$

On the whole, thio esters **IIa**–**IIi** can be regarded as effective polyfunctional antioxidants.

EXPERIMENTAL

The ^1H NMR spectra were recorded on a Bruker spectrometer (500 MHz, $CDCl_3$, internal reference TMS). The IR spectra were taken on a Vektor 22 Fourier spectrometer from neat samples, CCl_4 solutions, or KBr pellets (150 : 1). The melting points were determined with a PTP device.

The initial thiols **I** were prepared according to [9].

***S*-[2-(3,5-Di-*tert*-butyl-4-hydroxyphenyl)ethyl] ethanethioate IIa**. To a mixture of 5.0 g (18.7 mmol) of thiol **Ia**, 5 ml (25.6 mmol) of triethylamine, and 20 ml of benzene, we added dropwise 1.35 ml (18.9 mmol) of acetyl chloride. The mixture was refluxed for 2 h, cooled, and treated with toluene. The extract was washed with water and dried over Na_2SO_4, the solvent was distilled off, and the residue was crystallized from ethanol. Yield of **IIa** 4.68 g (81%), mp 108°C. ^1H NMR spectrum, δ, ppm: 1.430 s (18H, *t*-Bu), 2.334 s (3H, $COCH_3$), 2.755–2.796 t (2H, $ArCH_2$), 3.070–3.150 t (2H, CH_2S), 5.098 s (1H, OH), 7.000 s (2H, H_{arom}). Oxidation of lard (Novosibirsk Meat Packing and Canning Plant) was performed in an oxidation cell described in [10], by oxygen bubbling at 130°C. The amount of lard in each experiment was 50 g, and the

Kinetic curves of lard oxidation in the presence of inhibitors. Inhibitor: (*1*) none, (*2*) Ionol, (*3*) **IIa**, (*4*) **IIb**, and (*5*) **IIc**. (PN) Peroxide number and (τ) time.

concentration of antioxidants, 1 μmol g^{-1} fat. The progress of lard oxidation was monitored by accumulation of peroxy compounds. Their concentration was determined iodometrically [11] and expressed in peroxide numbers. The initial peroxide number was 0.002% I. The kinetic curves were plotted (see figure), and the induction periods were determined graphically.

CONCLUSIONS

(1) Thio esters derived from ω-(3,5-di-*tert*-butyl-4-hydroxyphenyl)alkanethiols show high inhibiting activity due to the bifunctional mechanism of the antioxidative effect and to internal synergism.

(2) Under the experimental conditions, the antioxidative activity of thio esters is largely influenced by the length of the hydrocarbon chain between the phenolic and thio ester moieties; substituents at the carbonyl carbon atoms affect the antioxidative activity to a lesser extent.

(3) Thio esters derived from ω-(3,5-di-*tert*-butyl-4-hydroxyphenyl)alkanethiols show promise as antioxidants preventing oxidation of fats.

Abstract—A procedure was developed for synthesis of a new monomer from monoethanolamine vinyl ether and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone. The kinetics of its radical polymerization was studied polarographically. The optimal polymerization conditions and properties of the resulting redox resin were studied.

It is known that quinones are capable of reversible reduction–oxidation [1]. Their use in synthesis of macromolecular compounds allows preparation of resins exhibiting redox properties, which are widely used in various branches of science and engineering as reductants, oxidants, enterosorbents, hemosorbents, etc. [2–5]. However, available redox resins do not always exhibit the necessary properties; therefore, search for new available and cheap monomers and development of selective ion-exchange and redox resins thereof remains an urgent problem.

To extend the range of redox resins and simplify their preparation, we have developed a single-stage procedure for synthesis of a new unsaturated monomer exhibiting redox properties. The starting compound, monoethanolamine vinyl ether **I**, is readily available and cheap; therefore, the cost of the resulting redox polymers can be reduced. Furthermore, the possibility of repeatedly using and regenerating the redox resins will help to pay off them faster.

Previously reported procedures for preparing the required monomers include 5–7 stages, with the yields of the target compounds being relatively low [2, 3].

In this work we prepared a new monomer from ether **I** and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone **II**. The kinetics of its radical polymerization was studied polarographically, the optimal polymerization conditions were determined, and some properties of the resulting redox resin were studied.

EXPERIMENTAL

Monoethanolamine vinyl ether was dried over freshly calcined K_2CO_3 and distilled from calcium hydride; bp 114°C, n_D^{20} 1.4382. 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone (Aldrich) was used without preliminary purification; mp 213–216°C. Azobis(isobutyronitrile) **III** was recrystallized from absolute methanol, mp 102–103°C. The solvents were purified by known procedures [6].

2-(2-Vinyloxy)ethyl]amino-3-chloro-5,6-dicyano-1,4-benzoquinone IV. Amine **I** was added slowly with continuous stirring to a solution of quinone **II** in 3 ml of dimethylformamide (DMF) at room temperature, until the molar ratio of amine to quinone of 4 : 1 was reached. After 15 min, distilled water was added. The precipitate was filtered off, repeatedly washed with water, and dried, first in air and then in a vacuum oven at 25°C to constant weight. Compound **IV** was obtained in 90% yield; bright cherry-colored powder, mp 136°C.

Found, %: C 52.25, H 2.93, Cl 12.33, N 14.80. $C_{12}H_8ClN_3O_3$.
Calculated, %: C 51.90, H 2.91, Cl 12.77, N 15.13.

Polymer V. The monomer was placed in an ampule, and the solvent (DMF, to a concentration C 0–250 g l^{-1}) and initiator (**III**, 1–8 wt % relative to **IV**) were added. The ampule was sealed, thoroughly shaken, and placed in a thermostat preheated to 55–72°C. After reaction completion, the ampule was opened, and polymer **V** was precipitated with diethyl ether. The precipitate was filtered off and dried, first in air at 20–25°C and then in a vacuum at 40–50°C. Yield of the polymer 45–62%. Under the optimal conditions (DMF, 4 wt % **III**, 360 min), the yield of the polymer is 62%, $[\eta] = 0.25$.

Kinetic runs were performed similarly except that

1070-4272/01/7411-1907$25.00

a set of ampules was prepared, and after prescribed periods the ampules were successively withdrawn, quickly cooled with water and ice, and opened; samples for polarographic analysis were taken and diluted with ethanol to stop the reaction.

Polarographic measurements were performed in the following supporting electrolytes: phosphate buffer solution (pH 7.4) in 50% ethanol (reduction of C=O groups) and 0.2 M LiCl solution in 50% ethanol (reduction of the C=C bond).

The polarograms were taken in a temperature-controlled cell at 25±0.5°C with a PU-1 polarograph, using a mercury dropping electrode with the open-circuit characteristic of the capillary $m^{2/3}t^{1/6}$ = 4.38 $min^{2/3}\,s^{-1/2}$ and a saturated calomel reference electrode. Prior to polarographic measurements, the solutions were deoxygenated by argon bubbling for 5 min.

The IR spectra were recorded on a Specord M-80 spectrometer using KBr pellets. The ^1H NMR spectra were taken on a Varian Mercury-300 spectrometer (300 MHz, $CDCl_3$, internal reference HMDS), and the mass spectra, and a Hewlett–Packard HPGC-5890 device equipped with an HP MSD 5972 mass-selective detector.

The melting points were determined with a PTP unit.

The structure of **IV** was proved by mass spectrometry and IR and ^1H NMR spectroscopy.

Found M^+ 277 (by mass spectrometry).
$C_{12}H_8ClN_3O_3$.
Calculated M 277.

The IR spectrum of **IV** contains bands characteristic of C=O groups in quinones (about 1660 cm^{-1}), stretching (3228 cm^{-1}) and bending (1576 cm^{-1}) vibration bands of amino groups, and also =C–N (1340 cm^{-1}), =C–O–C (1196 cm^{-1}), C–Cl (756 cm^{-1}), and C≡N (2216 cm^{-1}) absorption bands.

In the ^1H NMR spectrum of **IV**, the signals of vinyl protons (*gem*, *cis*, and *trans*; δ 3.86, 4.18, and 6.48 ppm in $CDCl_3$) are essentially similar to those in the spectrum of **I**. The same is true for the CH_2O protons (δ 3.96 ppm). The signals of the NH_2 protons which are in direct contact with the electron-withdrawing substituent in quinone **II** are shifted downfield (δ 1.47 and 2.19 ppm), and the proton signals of the methylene group adjacent to NH_2, upfield (δ 2.94 and 2.20 ppm).

One of sensitive, quick, adequate, and reliable methods for studying and analyzing macromolecular compounds is polarography. This method is often used in kinetic studies of vinyl polymerizations [7–10]. The main criterion of the monomer reactivity is the polymerization rate constant; however, it was determined polarographically only in a few papers [10–15]. In some studies, a correlation was revealed between the rate constants of radical polymerization of monomers and their half-wave reduction potentials on a mercury dropping electrode [10]. We studied polarographically the polymerization kinetics of **IV**. The conversion was judged from the amount of unchanged monomer **IV**. We found that the height of the polarographic wave is a linear function of the concentration of **IV** in solution. The monomer content was determined from the calibration plot.

To calculate the overall polymerization rate constants, we determined the reaction order. The linear dependence of $\log c_{\mathbf{IV}}$ on the reaction time shows that under these conditions the reaction is first-order with respect to **IV**.

The rate constants of polymerization of **IV** calculated by the first-order kinetic equation [16, 17] are given below:

$k \times 10^4$, min^{-1}	T, K
12.70	335
18.74	341
24.34	345

The activation energy E_a is 47.34 kJ mol^{-1}.

In contrast to ether **I** which does not form homopolymers in the presence of radical initiators [18–20], monomer **IV** is capable of polymerization. Its activity is close to that of *N*-substituted methacrylamides [10]. The decisive factor affecting the homopolymerization rate is, apparently, the reactivity of the arising radical. The higher the electron density on the double bond, the higher the reactivity of the monomer [10]. Polarographic characterisrtics are also determined by the electron density on the double bond: The higher the density, the more negative is the half-wave reduction potential. That is, the more negative the reduction potential, the more readily the monomer polymerizes. This relationship is confirmed by our polarographic data: The half-wave reduction potential of the C=C bond is –1.80 V in the initial ether **I** and –1.85 V in **IV** (supporting electrolyte 0.2 M LiCl in 50% ethanol).

In the IR spectrum of **V**, the quinoid ring bands are broadened, which is typical of polymeric quinones

[21], and shifted to higher frequencies (1680 cm^{-1}, compared to 1660 cm^{-1} in **IV**).

The polymers show a high oxidative power, as evaluated by the yield of naphthalene in dehydrogenation of tetralin. The redox capacity of the samples, determined by potentiometric titration with 0.1 N $Fe_2(SO_4)_3$, is 2.6–4.8 mg-equiv g^{-1}.

CONCLUSIONS

(1) A single-stage procedure was developed for preparing a new redox monomer, 2-[2-(vinyloxy)ethyl]amino-3-chloro-5,6-dicyano-1,4-benzoquinone, from monoethanolamine vinyl ether and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone. The monomer is fairly reactive in radical homopolymerization, with the polymer preserving the redox function.

(2) Radical polymerization of the synthesized monomer in solution was studied, and optimal conditions for preparing the polymeric redox resin were determined. The polymer shows a high oxidative power with respect to organic compounds and can be used as a dehydrogenating agent.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Kinetic Features of the Synthesis of an Acid Corrosion Inhibitor, 5-Methyl-1,2,3,3a,4,8b-hexahydrocyclopent[*b*]indole

Abstract—Kinetic features of thermal cyclization of 2-methyl-6-(cyclopent-2-enyl)aniline hydrochloride at 200–220°C were studied. The cyclization product shows a high performance as acid corrosion inhibitor.

Indoline compounds inhibit oxidation processes and acid corrosion [1, 2]; the highest performance is shown by 2-alkyl- and 2,2-dialkyl-substituted indolines [3]. With the aim of searching for new effective acid corrosion inhibitors, we studied in [4] formation of perhydrocyclopent[*b*]indolines by heterocyclization of hydrochlorides of *o*-(cyclopent-2-enyl)anilines [5] and their *N*-precursors which can be readily prepared from commercially available dicyclopentadiene. Heterocycles of this series, which are potential inhibitors of acid corrosion, are well known, but the kinetic features of their synthesis and the effect of reaction conditions on the product yield are studied insufficiently. In this work we studied some kinetic features of cyclization of 2-methyl-6-(cyclopent-2-enyl)aniline hydrochloride **I** (MCPA) and the inhibiting activity of the reaction product, 5-methyl-1,2,3,3a,4,8b-hexahydrocyclopent[*b*]indole **II**.

EXPERIMENTAL

Tests for protection of structural steels with inhibitor **II** were performed under laboratory conditions in 15% HCl and 20% H_2SO_4. Samples of St.3 steel [GOST (State Standard) 380–87], pretreated for corrosion tests, were placed in a corrosive medium for a prescribed time τ at 20°C. After that, the samples were worked up by an appropriate procedure and weighed with an accuracy of 0.0002 g. The corrosion rate ρ and degree z (%) of metal corrosion protection with the given inhibitor were determined by the formulas

$$\rho = (\Delta m)/S\tau,$$

$$z = (\rho_1 - \rho_2)/\rho_1 \times 100,$$

where Δm is the weight loss (g), S is the sample surface area (m^2), τ is the test time (h), ρ_1 is the corrosion rate without inhibitor (g m^{-2} h^{-1}), and ρ_2 is the corrosion rate in the presence of inhibitor (g m^{-2} h^{-1}).

The kinetic features of intramolecular cyclization of aniline **I** to indoline **II** were studied by the one experiment–one point procedure. The mixture was heated in sealed ampules in a thermostat at a definite temperature for a definite time. The concentrations of reaction products were determined by gas chromatography.

Data on the inhibiting activity of **II** are listed in Table 1. Thus, compound **II** can be regarded as a new inhibitor of acid corrosion of carbon steels.

When developing a synthesis process, it is necessary to elucidate how the reaction conditions (temperature, component ratio, reaction time, etc.) affect the yield of the target product. It was shown previously

Table 1. Performance of indoline **II** as inhibitor of acid corrosion of steel

Inhibitor, wt %	Acid, wt %	ρ, g m^{-2} h^{-1}	z, %
–	HCl, 15	5.0	–
0.4	HCl, 15	0.225	95.5
0.2	HCl, 15	0.585	88.3
0.1	HCl, 15	1.685	66.3
–	H_2SO_4, 20	21.0	–
0.4	H_2SO_4, 20	3.318	84.2
0.2	H_2SO_4, 20	6.279	70.1

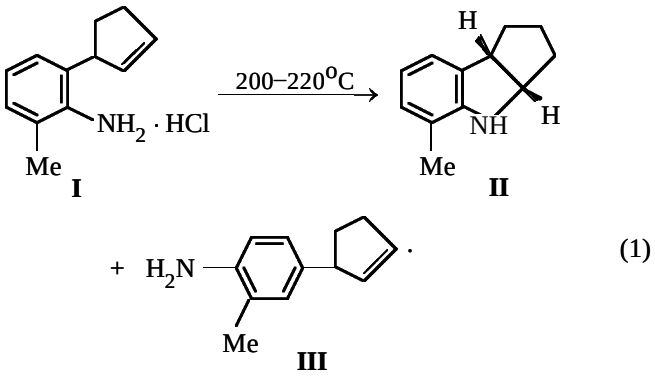
[4] that heating of hydrochloride **I** at 200–220°C in excess *o*-toluidine yields indoline **II** and minor (up to 10%) amounts of 2-methyl-4-(cyclopent-2-enyl)aniline **III**:



(1)

To find how the yield of the target product depends on the initial conditions and heating time, we studied the kinetic features of MCPA **I** consumption and indoline **II** accumulation. As seen from the kinetic curves shown in Fig. 1, the rate of MCPA consumption is the highest in the initial stages, and at 90% MCPA conversion the indoline concentration reaches a certain limit, C_i^∞. The yield of the target product was determined as the ratio of the limiting concentration of indoline **II** to the initial concentration C^0_{MCPA} (Table 2).

The kinetic curves of MCPA consumption are linear in the coordinates of the first-order reaction equation (Fig. 2):

$$\ln C_{MCPA} = \ln C^0_{MCPA} - kt, \qquad (2)$$

where C^0_{MCPA} and C_{MCPA} are the initial and current concentrations of MCPA, respectively; k is the apparent rate constant of consumption of **I**.

From the semilog kinetic plots, we determined the rate constants at various temperatures (Table 2) and obtained the Arrhenius equation

$$\ln k = -(20.1 \pm 5.2) - (98.1 \pm 2.2) \times 10^3/RT,$$

where $R = 8.31$ J mol^{-1} K^{-1}.

The activation energy of MCPA transformation, $E_a = 98.1 \pm 2.2$ kJ mol^{-1}, is consistent with published data. It should be noted that this is an apparent quantity, describing transformation of MCPA not only by scheme (1), but also into by-products.

For example, in the experiment performed at 200°C (Table 2) the yield of the target product was low. This may be due to the fact that the runs at 200°C

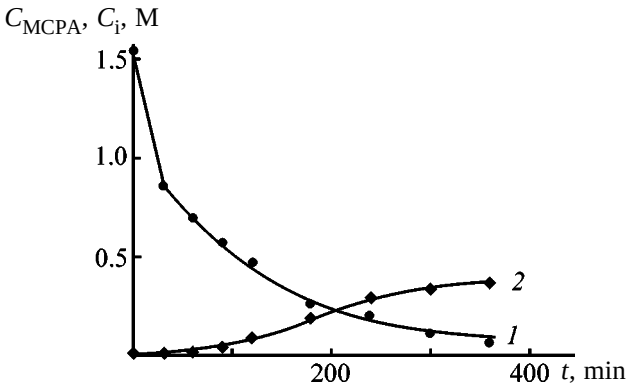


Fig. 1. Kinetic curves of (*1*) MCPA consumption and (*2*) indoline accumulation in intramolecular cyclization of 2-methyl-6-(cyclopent-2-enyl)aniline at 200°C. (C_{MCPA}, C_i) Concentrations of MCPA and indoline, respectively; (τ) time; the same for Fig. 2.

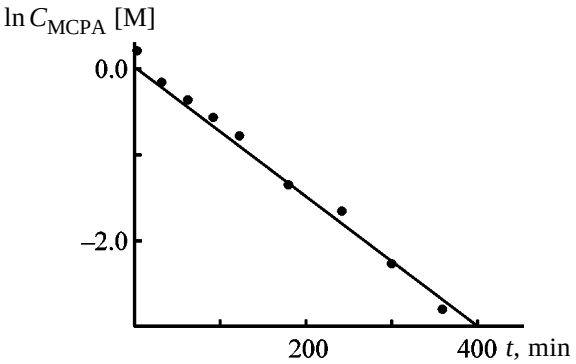

Fig. 2. Kinetic curve of MCPA consumption at 200°C, plotted in semilog coordinates.

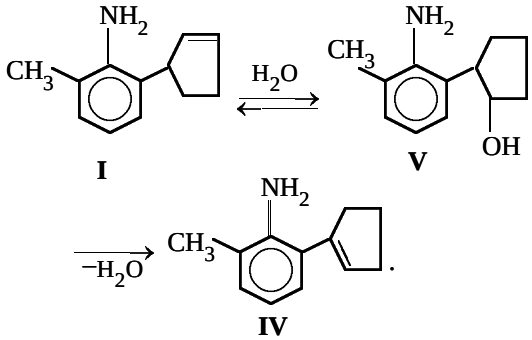
were performed with an MCPA sample that had been stored for a month and had taken up moisture. At relatively high temperatures, traces of moisture could initiate the following side reactions:



It was found previously [6] that, indeed, MCPA can transform into 2-methyl-6-(cyclopent-1-enyl)aniline **IV** in both alkaline and acid solutions. At high temperatures in the presence of HCl, this compound undergoes extensive tarring. An intermolecular reaction of 2-(2-hydroxycyclopentyl)aniline with MCPA, decreasing the yield of the target product, cannot be

Table 2. Yield of indoline **II** and apparent rate constant k as influenced by reaction temperature T (C^0_{MCPA} = 1.53 M)

T, °C	C_i^∞, M	C_i^∞/C^0_{MCPA}	$k \times 10^2$, min^{-1}
190	1.16	0.75	0.84
200	0.36	0.24	0.90
210	0.85	0.55	1.38
220	0.77	0.50	2.18
230	0.69	0.45	3.95

Table 3. Apparent rate constant and yield of indoline in isomerization of aniline **I** at 200°C, as influenced by the initial concentration of **I**

C^0_{MCPA}, M	$k \times 10^2$, min^{-1}	C_i^∞, M	C_i^∞/C^0_{MCPA}
1.53	0.9	0.36	0.24
1.15	0.6	0.18	0.16
0.76	0.8	0.05	0.07

ruled out either. Under the experimental conditions (sealed ampules), moisture is not evaporated; therefore, this pathway of MCPA transformation strongly affects the yield of the target product as a function of temperature (Table 2) and initial MCPA concentration (Table 3).

As seen from Table 3, the yield of **II** drastically decreases as the initial MCPA concentration is decreased.

CONCLUSIONS

(1) 5-Methyl-1,2,3,3a,4,8b-hexahydrocyclopent[*b*]-indole inhibits acid corrosion of carbon steels.

(2) The kinetic features of intramolecular cyclization of 2-methyl-6-(cyclopent-2-enyl)aniline were studied. The yield of the target product, indoline, decreases with decreasing initial concentration of the starting compound.

(3) Increase in temperature in the range 190–230°C is accompanied by a decrease in the yield of indoline.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Polymerization/Depolymerization Mechanism for "Living" Sodium Poly-α-Methylstyryl and Sodium Polystyryl

K. K. Kalnin'sh

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received June 29, 2001

Abstract—The equilibrium polymerization of sodium poly-α-methylstyryl in tetrahydrofuran was studied in the temperature range from –60 to 15°C. For the first time, the reversible process of formation/cleavage of the chemical bond was theoretically analyzed in terms of the electronic excitation views. On this basis, a new mechanism of the "living" polymer depolymerization was proposed. The geometry and electronic structure of the model fragments of "living" polymers comprised of two units were calculated *ab initio* by the 6-31G* method. The energies of the triplet excited states belonging to the complex of the reactants, on the one hand, and to the reaction product, on the other, proved to be close. The theoretical activation energies for depolymerization of sodium poly-α-methylstyryl reasonably agree with the experiment.

As known [1, 2], living sodium poly-α-methylstyryl (NaPMS) undergoes reversible polymerization/depolymerization in accordance with the equation

$$M_i^* + M \underset{K_{-1}}{\overset{K_1}{\rightarrow}} M_{i+1}^*, \quad (1)$$

Here, M_i^* and M_{i+1}^* denote the living polymer chains, and K_1 and K_{-1} are the growth and depolymerization rate constants, respectively [1, 2].

The thermodynamic and kinetic characteristics of depolymerization are given in [1–3], but published data on the elementary stages are lacking. Studies of reaction (1) were focused, for the most part, on determining the equilibrium constants K_{eq}, heats of polymerization, and equilibrium concentrations of the monomer M_{eq} [1, 4–8].

The depolymerziation (degradation) mechanisms for "dead" and living polymer chains, obviously, differ significantly. In the former case, free monomer is yielded by a chain radical process [9, 10] with a high activation energy (~209.0 kJ mol^{-1} [11]). Depolymerization of the living chains is a reversible process, yielding the monomer, which suggests that the structure of the active end of the living polymer is not deteriorated by the process.

The most extensively studied was the living polymer + α-methylstyrene (α-MST) system in tetrahydrofuran (THF) [1, 4–6] with a high equilibrium concentration of the monomer M_{eq}, for which holds

$$K_{eq} = K_1/K_{-1} \rightarrow 1/M_{eq} \quad (2)$$

at $M_0/M_i^* > 10$, where M_0 is the initial monomer concentration [1].

For this system, the growth activation energy was estimated at 20.9–29.3 kJ mol^{-1} [1], and the heat of polymerization and the entropy change, at $-\Delta H$ = 29.3 kJ mol^{-1} and $-\Delta S$ = 103.7 J mol^{-1} deg^{-1}, respectively [1, 3].

By contrast to α-methylstyrene, the equilibrium concentration of styrene in living sodium polystyryl NaPS is negligible (10^{-7} M at 0°C [7]), which points to the stability of this polymer under ordinary conditions. Polymerization/depolymerization of other living polymers was studied much less extensively.

In [12–14], we analyzed addition of styrene to the anionic end of the living polymer in terms of electronic excitation (transfer), with the reaction complex treated as the ion pair separated by the monomer. The back process of monomer detachment in the elementary stage is, evidently, similar to the forward, addition, process and can be treated in terms of the general concept of thermal electronic excitation in chemical reactions [14]. In [15], we analyzed the monomolecular thermochromic reactions in terms of electronic excitation, taking spiropyrans as an example. We showed that the calculated (by PM3 method) triplet energies of spiropyrans are close to the experimental activation energies of the six-membered pyran ring opening.

In this work, we attempted to explain the difference in the depolymerization character for NaPMS and

1070-4272/01/7411-1913$25.00

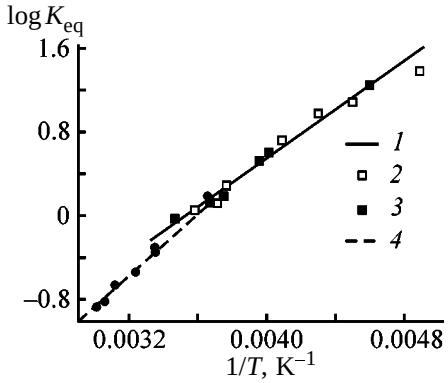

Fig. 1. Variation of the equilibrium constant K_{eq} with the temperature T. (*1*) Data of this work (NaPMS + α-MST, THF; M_0 = 1.1 M); (*2*) polymerization; (*3*) depolymerization; and (*4*) data from [5] (NaNaphth + α-MST, THF, M^0 = 0.75–7.5 M).

NaPS based on the views on thermal electronic excitation in chemical reactions. To this end, we performed quantum-chemical *ab initio* calculations for the NaPMS and NaPS fragments and their anionic forms comprised of two monomer units. The forward (polymerization) and back (depolymerization) reactions were studied theoretically, with the complexes formed by styrene and the end units of living polymers as an example. Also, we studied experimentally the equilibrium polymerization of NaPMS.

EXPERIMENTAL

Polymerization of α-MST was carried out in an IR cell with 0.15-cm-thick NaCl windows under conditions preventing the access of impurities able of deactivating the living polymer. The cell was cooled with liquid nitrogen vapor; the temperature was controlled accurately to within 2°C and varied at a rate of 1 deg min^{-1}. The α-MST concentration was determined from the absorption band at 1652 cm^{-1}. The methods of preparation and purification of the reactants were taken from [16].

Quantum-chemical calculations were carried out with PC GAMESS program, version 5.4, in the 6-31G* basis. The chosen molecular modules required significant PC resources, namely, over 3 Gb of disk memory and a no less than 1 GHz processor. Semiempirical calculations were carried out with HyperChem program, issue 6.0. The molecular geometry optimized by AM1 method served as initial approximation for *ab initio* calculations. The energies of the triplet states were calculated in the spin-unrestricted Hartree–Fock approximation as the differences between the total energies (*ab initio*) or heats of formation (semiempirical methods) of molecules in the triplet and singlet configurations. Because there is no parametrization for the Na atom in the semiempirical AM1 method, instead of sodium derivatives of living polymers we took the corresponding lithium analogs.

Polymerization/depolymerization. Equilibrium polymerization of α-MST was studied over a wide temperature range (from –60 to 15°C) in the NaPMS + α-MST system in THF. Figure 1 shows that the measured K_{eq} values reasonably agree with the published data [1, 4]. Also close are the heats of polymerization calculated with the use of these dependences and those from [4], namely, 23.4 against 29.3 kJ mol^{-1}. Our results and published data suggest that the equilibrium constants and thermodynamic characteristics of the NaPMS + α-MST + THF system do not depend significantly on the initial monomer concentration.

Semiempirical calculations. There exist two configurations of the calculated dimer model, namely, those with aromatic rings in *trans* and in *cis* positions. The *trans* structure is stable in the form of the anion (heat of formation H^{trans} 69.8, H^{cis} 88.2 kJ mol^{-1}), and *cis* structure is stable in the form of the ion pair (H^{cis} 209.8, H^{trans} 214.4 kJ mol^{-1}). For both structures we performed semiempirical calculations of the geometry and electronic states. Also, we considered oligomers $M_n^-Li^+$ and M_n^- with a chain comprised of 2–5 units (M is the monomer).

As known, the chemical activity is exhibited by intra- and intermolecular electronic states with charge transfer. Thus, our task consisted in taking the models chosen as an example and in finding such states with a low energy that can be thermally populated under ordinary conditions. Semiempirical calculations showed that there exist two centers of Li^+ cation localization, at the α-carbon atom in the anionic moiety carrying the maximal negative charge (structure I) and that above the neighboring noncharged aromatic ring (structure II). These two centers are separated by 5 Å in the case of the *trans* configuration of the dimer dim-α^{trans}, but they virtually coincide for the *cis* structure dim-α^{cis}–Li^+.

Structure I which is usually depicted for the ion pair of living polystyrene exhibits the highest stability in the ground electronic state. It is also stable chemically and is characterized by a small dipole moment of 5.7 D (AM1 method) in the case of the dim-α^{cis}–Li^+ model. The polar excited triplet state (μ = 8.5 D) is essentially a state with charge transfer from the anionic unit to the neighboring noncharged ring, but because of high energy (150.5 kJ mol^{-1}) it cannot be

populated at ordinary temperature and thus is chemically inactive.

Optimization of dim-α^{cis}–Lu^+ in the triplet excited state showed that the Li^+ cation occupies position II, above the center of the neighboring noncharged aromatic ring, to which the entire negative charge is transferred. The triplet energies $E(T_1) - E(S_0)$ for the model molecules of dim-α^{cis}–Li^+ and dim^{cis}–Li^+ were estimated at 8.4 and 73.6 kJ mol^{-1}, respectively. These values are, evidently, somewhat underestimated in the case of semiempirical AM1 calculations.

Thus, semiempirical quantum-chemical calculations showed that the lowest electronic transition in anionic systems $M_n^-Li^+$ or M_n^- involves, essentially, a charge (electron) transfer between the last (charged) and last but one (neutral) monomer units. In the case of trimer M_3^-, electronic excitation leads to electron transfer to the last but one monomer unit. By contrast to dimer and trimer, the triplet excitation for free anions of tetramer M_4^- and pentamer M_5^- are localized on the terminal unit. For free M_n^- anions, the lowest triplet state can be of two types: excitation in the terminal unit and charge-transfer excitation. Chemical activity with respect to depolymerization is exhibited by the latter excitation type, but its energy is fairly large for free anions. For example, the optimized (AM1) values of the energy gap $E(T_1) - E(S_0)$ for the dim-α^{trans}– model molecule is equal to 77.7 kJ mol^{-1}. This suggests a low chemical activity of free anions in the dark.

***Ab initio* calculations and structure of triplet states.** *Ab initio* calculations of dim-α^{cis}–Na^+, dim^{cis}–Na^+, and the corresponding anionic forms with full geometry optimization confirmed, on the whole, the relationships established by semiempirical AM1 calculations. For example, a lower energy and, hence, a greater stability of dim-α^{trans}– relative to dim-α^{cis}– [$\Delta(H^{trans} - H^{cis}) = -18.4$ kJ mol^{-1}], as determined by the AM1 method, is confirmed by the 6-31G* *ab initio* calculation: $\Delta(E^{trans} - E^{cis}) = -30.1$ kJ mol^{-1}. The 6-31G* basis satisfactorily describes the major features of the excited triplet states of the molecular models considered, that is, transfer of a negative charge and of the cation between the terminal and penultimate monomer units. Figure 2 illustrates the charge transfer in the triplet state T_1 from the negatively charged terminal unit to the last but one noncharged aromatic ring.

In the case of vertical (without geometry modification) transition, electron transfer to the neighboring monomer unit causes the dipole moment of the molecule to increase relative to the ground state (see table), as the cation retains its position. By contrast, in the equilibrium, optimized triplet state, where the Na^+ cation follows the electron in the transfer to the neighboring monomer unit, the dipole moment even tends to slightly decrease (see table), evidently, owing to closer arrangement of the charged particles.

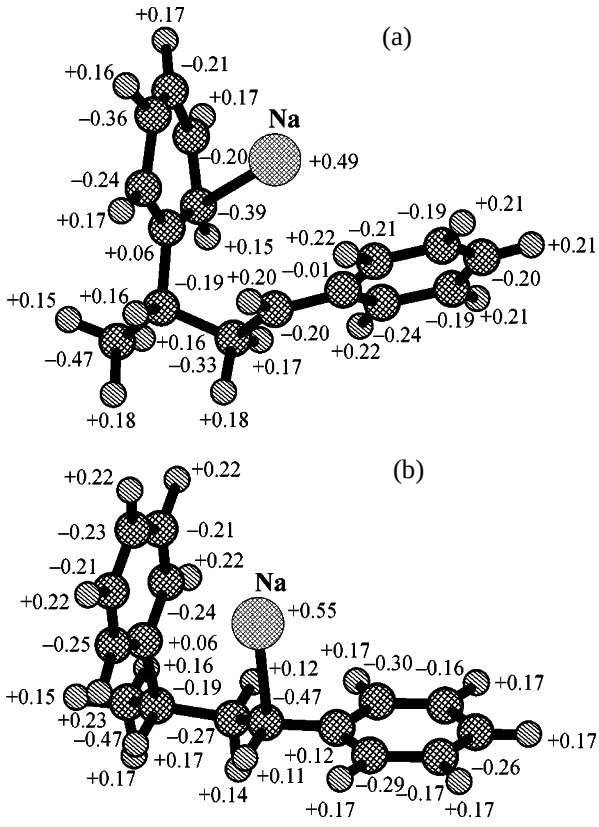

Fig. 2. Charge distribution on dim^{cis}–Na^+ atoms in the (a) ground singlet and (b) excited triplet states.

The energies of the vertical electronic transitions $T_1 \leftarrow S_0$ for the *cis* configuration of the dimer (see table) calculated as the $E(T_1) - E(S_0)$ differences are of the same order of magnitude as the triplet energy (189.8 kJ mol^{-1}), which is to be expected for the experimentally observed lowest singlet–singlet transition in the absorption spectrum of NaPMS at 29400 cm^{-1} (352.4 kJ mol^{-1}). The corresponding triplet energies for the *trans* configuration have higher energies (>334.4 kJ mol^{-1}). The table compares the energies of the vertical electronic transitions with those of "indirect", thermal transitions $T_1 \leftarrow\sim\sim S_0$ between the relaxed (optimized) states.

As already mentioned, the two living polymers, NaPMS and NaPS, which are close in chemical composition, differ significantly in thermodynamic charac-

teristics. The structural differences, evidently, should be manifested in the heats of reactions which determine equilibrium (1), as well as in the energies of the triplet states characterizing the reaction activation energy.

Let us consider the reversible model polymerization/depolymerization reactions:

$$\text{α-mst + mon-α}^-\text{Na}^+ \rightleftarrows {}^3(\text{charge-transfer complex}) \rightleftarrows {}^3(\text{dim-α}^{cis-}\text{Na}^+) \rightleftarrows {}^1(\text{dim-α}^{cis-}\text{Na}^+), \quad (3)$$

$$\text{st + mon}^-\text{Na}^+ \rightleftarrows {}^3(\text{charge-transfer complex}) \rightleftarrows {}^3(\text{dim}^{cis-}\text{Na}^+) \rightleftarrows {}^1(\text{dim}^{cis-}\text{Na}^+), \quad (4)$$

$$\text{st + mon}^- \rightleftarrows {}^3(\text{charge-transfer complex}) \rightleftarrows {}^3(\text{dim}^{trans-}) \rightleftarrows {}^1(\text{dim}^{trans-}), \quad (5)$$

where mon-α$^-$Na$^+$ is the monomer unit of sodium poly(α-methylstyryl), ^{3}(dim-α^{cis}Na$^+$) and ^{1}(dim-α^{cis}Na$^+$) are the triplet excited and singlet ground states of NaPMS dimer, respectively, st is styrene, and mon$^-$ is poly(styryl anion) monomer.

The results of 6-31D* *ab initio* calculations for all the stages of reactions (3)–(5) are shown schematically in Figs. 3a–3c.

The *cis* configuration of the dimer is of special importance for understanding the depolymerization mechanism. This configuration was experimentally confirmed by ^{1}H and ^{13}C NMR studies [17] of isomerization of living polymers during chain growth.

An essential result of *ab initio* calculations is the low energy of the optimized triplet state of the model dim-α^{cis-}Na$^+$ molecule (Fig. 3a), namely, 29.7 kJ mol^{-1}. High population of this state under ordinary conditions should afford rapid depolymerization, which is actually observed experimentally. The steric structure of the triplet differs from that of the singlet by a minor (~0.5 Å) shift of the Na$^+$ cation towards the neighboring unit. Also, two aromatic rings, which are located virtually perpendicularly in the singlet state, markedly approach each other during triplet optimization (Fig. 3b). The electronic singlet–triplet transitions of this kind are indirect transitions involving both electron transfer and heavy particle shift.

The number of methyl groups in the model molecule of dim^{cis-}Na$^+$ is by 2 less than in dim-α^{cis-}Na$^+$ (Figs. 3a, 3b), and no significant effect of structural features on the electronic characteristics could be expected. However, *ab initio* calculations show that the triplet energy markedly increases: $E(T_1) - E(S_0)$ = 61.4 kJ mol^{-1}. Tentative estimates show that the population of the triplet level of the dim^{cis-}Na$^+$ molecule should decrease relative to that of dim-α^{cis-}Na$^+$ by 5 orders of magnitude, with a similar difference in in the depolymerization rates [14].

A sharp difference in the chemical behavior of the two structurally related polymers, PMSNa and PSNa, is, evidently, due to the nature of the excited states. According to *ab initio* calculations, specific low-lying excited states are formed in the terminal units of living polymers through interaction of the last and the last but one aromatic rings via the common Na atom. This interaction, which is similar to chemical conjugation, is most strongly manifested in the dim-α^{cis-}Na$^+$ molecule with the maximally close rings (Fig. 3a). In the dim-α^{cis-}Na$^+$ molecule simulating poly(sodium styryl) the conjugation is manifested to a significantly smaller extent because of the large distance separating the aromatic rings (Figs. 3a, 3b). In our opinion, this is specifically responsible for the large difference in the energies of the lowest triplet states of the dim-α^{cis-}Na$^+$ and dim^{cis-}Na$^+$ molecules. It should be

noted that such interactions are not characteristic of the triplet states of dim-α^{cis-} and dim^{cis-} or dim-α^{trans-} and dim^{trans-} anions which do not contain a Na^+ cation.

The highest triplet energies were found for dim-α^{trans-} and dim^{trans-} anions, namely, 112.9 and 112.4 kJ mol^{-1}, respectively (Fig. 3c). Evidently, in these cases high activation barriers fully retard depolymerization. This is consistent with the results of semiempirical AM1 calculations predicting low chemical activity of free anions. Forward addition (polymerization) reactions characterized by low triplet energies of the complexes between the molecules of the reactants (Figs. 3a–3c) should have high rates in all the cases. It should be expected that the rate of forward reactions decreases in the series dim-$\alpha^{cis-}Na^+$ > $dim^{cis-}Na^+$ ≫ dim^{trans-}.

Based on the principle of reversibility of chemical processes, it can be qualitatively concluded that the electronic state responsible for cleavage of the chemical bond in depolymerization should be similar to that participating in bonding during polymerization. This, not evident, statement can be verified by comparing two stages in each of Eqs. (3)–(5): (1) conversion of the complex of the reactants (styrene + living polymer comprised of one unit) to the end product and (2) the back conversion of the dimer as the stable product to the initial reactants. The calculations revealed the following essential feature of the systems described by Eqs. (3)–(5): the energy of the triplet excited state of the end product is close to that of the triplet complex of the reactants (Figs. 3a–3c). This theoretical result was obtained for the first time; it is consistent with the general concept [14] stating that the forward (polymerization) and back (depolymerization) reactions proceed via the same electronically excited triplet state.

The chemical activity of the triplet states T_1 with respect to depolymerization events is determined by their biradical nature. The radical centers are localized on the last and last but one monomer units, as evidenced by the spin-density distribution pattern (Fig. 4). Similar pattern is characteristic of the vertical transition, when the cation is localized at the α-carbon atom of the terminal unit. This suggests the identity of the electronic states in these two cases differing in the cation position. Both states, vertical and relaxed (optimized), are able of dissociation of the bond linking the last and last but one monomer units. However, the vertical state is inactive in the depolymerization reaction because of high energy.

The $E(T_1) - E(S_0)$ parameters characterize the thermal degradation activation energy E_a^{depol} and, as follows from Table 1, differ significantly for the two cases of interest, dim-$\alpha^{cis-}Na^+$ and $dim^{cis-}Na^+$. The experimental value of E_a^{depol} for NaPMS can

(*E*) Energy.

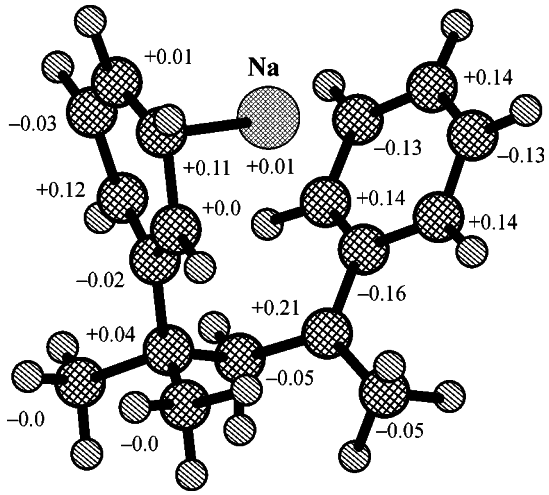

Fig. 4. Spin density distribution for heavy atoms of dim-α^{cis}–Na^+ in the triplet state.

be tentatively estimated as the sum of the growth activation energies E_a^{pol} (20.5 kJ mol^{-1}) and the heat of reaction $-\Delta H_r$ (23.4 kJ mol^{-1}): $E_a^{depol} = E_a^{pol} + |\Delta H_r| = 43.9$ kJ mol^{-1}. The same parameter was estimated theoretically by 6-31G* *ab initio* method at 29.7 kJ mol^{-1}, and the activation energy is taken equal to the triplet energy. For NaPS one can expect greater E_a^{depol} because of high polymerization heat: $-\Delta H_r = 72.7$ kJ mol^{-1} [1]. The calculated triplet energy for the model system dim$^-Na^+$ is also much greater than that for dim-α^-Na^+ of 61.4 kJ mol^{-1}.

Depolymerization of "dead" polymers. A well-known example of radical-chain depolymerization is thermal degradation of poly-α-methylstyrene (PMS) [9, 10] during which radical species are recorded. The latter are generated by heating the polymer to a high temperature (~250°C), and this is followed by rapid depolymerization releasing free monomer. Significant thermal activation is required for the initial cleavage of the C–C bond between the monomer units, which is, evidently, followed by fairly facile detachment of further monomer molecules.

The experimental activation energy of PMS thermal degradation is equal to 209.0 kJ mol^{-1} [11]. AM1 optimization of the "dead" PMS fragment comprised of three units yields $E(T_1) = 197.7$ kJ mol^{-1} for the triplet state, which is in satisfactory agreement with the experimental E_a value. The spin density in this state is concentrated on the central moiety of the "dead" trimer and the neighboring C–C bonds. In the elementary process, the chemical bond is cleaved in the low-lying electronically excited triplet state of the molecule [14].

CONCLUSION

Theoretical analysis of the depolymerization reaction of living polymers, by contrast to "dead" polymers, showed that the electronic state responsible for cleavage of the C–C bond between the terminal and the penultimate monomeric units is the triplet excited state of the terminal moiety of the polymer. First, this state is generated by electron transfer from the terminal unit to the neighboring aromatic ring. Second, simultaneously with electron transfer the cation is shifted in the same direction, yielding a biradical structure active in chemical bond cleavage events. Third, such states are characterized by low energy, which affords high reaction rate. Finally, after detachment of the monomer the initial ground state of the end of living polymer is regenerated, which is able of either chain growth or further depolymerization. Forward depolymerization reactions proceed via low-energy triplet states of the reactants. The 6-31G* *ab initio* calculations provided satisfactory explanation to the experimental kinetics of depolymerization reaction.

Abstract—The acidity parameters of metal and polymeric surfaces were determined as influenced by the extent of surface oxidation of metals and by the modifier content in the polymer.

Acid–base interphase bonds, including hydrogen bonds, are considered at present as factors largely responsible for adhesion [1].

To evaluate the interaction of solids with a wetting liquid and of polymer layers with supports, data on the acidity and basicity of compounds involved are required. In this connection, procedures for measuring surface properties by gas chromatography, flow microcalorimetry, ellipsometry, and NMR and IR spectroscopy are actively developed [1–3].

Berger [4] proposed a simple and convenient procedure for determining the surface acidity of polymers and metals by measuring the contact angle between the surface and reference liquids.

Estimation of the adhesive properties of a material from its surface acidity is of special interest. The correlation between the strength of adhesion joints and the acid–base properties of adhesives and adherents was observed in many works [5].

Correct determination of the acidity of any smooth solid surfaces, increase in adhesion of a polymer to the metal surface by variation of this parameter, and prediction of the interface interactions in actual systems are urgent problems.

The aim of this work was to study the nature of interface interactions in corrosion-protective coatings of various polyethylenes (PEs) modified with various additives and to determine the main relationships of the acid–base interactions occurring in modified PEs during formation of their coatings.

EXPERIMENTAL

In this work we used the following materials: powdered (particle diameter less than 315 μm) nonstabilized high-density polyethylene (HDPE) prepared by the gas-phase procedure [for pipe production, GOST (State Standard) 16338–85]; powdered (particle diameter less than 315 μm) nonstabilized low-density polyethylene (LDPE) of 16803–070 trade mark [GOST (State Standard) 16337–77]; primary aromatic amines (PAAs) [4,4'-diamino-3,3'-dichlorodiphenylmethane (DC), polyamine T, and *o*-phenylenediamine (*o*-PDA)] and phenols [diphenylolpropane (DPP) and pyrocatechol] as modifiers; *N*,*N*'-*m*-phenylendimaleinimide (PDMI) and dithiodiphenylenedimaleinimide (TPDMI) as cross-linking agents. The supports were made of steels of various types, copper, aluminum, titanium, zinc, brass, etc.

The procedure for preparing PE–modifier composites and PE coatings on metal supports are described in our previous works [6–8].

The surface acidity was estimated by the Berger's procedure [4]. Cosines of the contact angles of six reference liquids with the tested surface were determined with a KM-8 cathetometer. The thermodynamic work of adhesion for each liquid W_a was calculated by the equation

$$W_a = \gamma_{lv}(1 + \cos\theta),$$

where γ_{lv} is the total free surface energy of the reference liquid.

The values of γ_{lv} are presented in Table 1. W_a was calculated from the measured cosines of angles between the reference liquids and the surface. The geometric mean of the total free surface energy of the support γ_s was determined by graphic solution of the Owens–Wendt equation

$$\gamma_{lv}(1 + \cos\theta)/2 = (\gamma_{lv}^d \gamma_s^d)^{1/2} + (\gamma_s^p \gamma_{lv}^p)^{1/2}$$

1070-4272/01/7411-1920$25.00

(γ_s^p and γ_s^d are polar and dispersion components of the free energy of the solid surface, $\gamma_s = \gamma_s^p + \gamma_s^d$), which can be transformed as follows:

$$W_a/2(\gamma_{lv}^d)^{1/2} = (\gamma_s^d)^{1/2} + (\gamma_s^p\gamma_{lv}^p)^{1/2}(\gamma_{lv}^d)^{-1/2}.$$

To determine γ_s, a straight line in the $W_a/2(\gamma_{lv}^d)^{1/2}$ (ordinate) and $(\gamma_{lv}^p/\gamma_{lv}^d)^{1/2}$ (abscissa) coordinates was plotted. This line intersects the ordinate at point $(\gamma_s^d)^{1/2}$ and angle $(\gamma_s^p)^{1/2}$. The dispersion and polar components of the free surface energy were calculated by raising $(\gamma_s^d)^{1/2}$ and $(\gamma_s^p)^{1/2}$ to the second power. The geometric mean total surface energy of the tested material is the sum of the resulting parameters.

The dispersion component of W_a for each of two Lewis acids and two Lewis bases was calculated as $W_a^d = 2(\gamma_{lv}^d\gamma_s^d)^{1/2}$ from γ_s^d. Then the acid–base component of W_a, W_a^{ab}, for the same liquids was calculated as $W_a^{ab} = W_a - W_a^d$.

Division of each W_a^{ab} by $(\gamma_{lv}^p)^{1/2}$ gives $W_a^{ab} \times (\gamma_{lv}^p)^{-1/2} = 2(\gamma_s^p)^{1/2}$. The surface acidity was quantitatively estimated from the equation

$$D = 2\{[\gamma_s^p(\text{aniline})]^{1/2} + [\gamma_s^p(\text{formamide})]^{1/2}\} - 2\{[\gamma_s^p(\text{phenol})]^{1/2} + [\gamma_s^p(\text{glycerol})]^{1/2}\}.$$

The free surface energy and its components were calculated from the experimental results for 10 drops of each liquid on each support. The determination error was 5%.

The surface acidity D was calculated from the base and height of the reference liquid drops by the specially developed program.

The adhesion of the coatings was estimated from their resistance to cathodic exfoliation by the procedure in [6]. The tested coating with a 3-mm initial defect was kept for 8 h in 0.1 N sodium chloride at the potential of 6 V and room temperature. The resistance to the cathodic exfoliation was estimated from the diameter of the defect (exfoliated coating) after experiment completion.

Correct assignment of the acid–base properties, i.e., whether compound is acidic, basic, neutral, or amphoteric, is important problem. We measured the acidity D of a series of smooth solid polymeric and metallic surfaces. The results are summarized in Table 2.

As seen from Table 2, the modifiers containing primary amino group decrease D of the polyethylene coatings to the negative values, i.e., the coatings modified with PAA exhibit pronounced basic properties. This is the reasonable conclusion since primary amines are Lewis bases.

Modification of PE with phenols, which are acids, increases the acidity of PE coatings. It should be noted that D slightly increases with increasing temperature and time of coating formation, which is due to oxidation of PE.

Relative acidity $\Delta D = D(\text{coating}) - D(\text{support})$ is used to estimate the adhesion of the coatings and to adequately evaluate the acidity of the coatings and supports. As ΔD increases, the difference in the acid–

base properties of the polymer and support increases, and the interphase interaction should become stronger.

The concentration depedences of Δ*D* of modified PE coatings (Figs. 1, 2) show that the acidity strongly depends on the modifier concentration. The relative acidity of coatings of HDPE modified with DC and of LDPE modified with PDMI correlates with their resistance to cathodic exfoliation and hence with their adhesion. These results confirm the correlation of the acid–base properties of adhesives and adherents with the strength of the adhesive joints. Certain decrease in the resistance of the coatings of HDPE modified with DC to the cathodic exfoliation with increase in Δ*D* is due to concentration of unreacted DC at the interface with formation of weakly bonded intermediate layer [6, 7].

Table 3. Effect of the heat treatment on the acidity of metal supports

Metal	*D*, $(mJ\ m^{-2})^{1/2}$	
	initial	after heat treatment
Titanium	4.30	1.31
Brass	8.44	7.82
G-65 steel	4.54	4.21
St.20 steel	4.70	3.31
ChZh-1 sheet iron	6.45	5.50
Copper	3.25	4.95
Aluminum	–1.93	3.95
Zinc-plated sheet iron	5.05	8.50
Duralumin	–2.15	1.24

Heat treatment of a series of metal supports has ambiguous effect on their surface acidity. The acidity of copper, aluminum, and zinc-plated sheet iron increases after their heating at 150°C for 10–15 min, whereas *D* of titanium, brass, and steel decreases after this treatment.

This is probably caused by the different properties of the oxides formed during the heat treatment of the metal surface, which, in their turn, depend on the chemical state of the surface.

Previously we found [7] that the adhesion of DC-modified HDPE coating correlates with the acidity of their supports (Fig. 3). This experiment was performed as follows. An HDPE + 2% DC composition was applied to various metal supports under identical conditions. Then the resistance of these coatings to cathodic exfoliation was studied. It was found that, the higher *D* of the metal support, the smaller is the minimal diameter of the defect of this coating.

To confirm the theoretical correlation between the adhesion and acidity of adhesives and adherents, we examined the adhesive joints prepared from the components maximally differing in the acidity. Coatings with high adhesion (the diameter of the initial mechanical defect did not change after cathodic exfoliation) were prepared under appropriate conditions in the following systems: heat-treated titanium–LDPE + 1% PDMI, heat-treated titanium–HDPE + 2% DPP, brass–HDPE + 2% DC, and ChZh-1–HDPE + 2% DC.

Thus, adhesion of polyethylene to a metal support can be appreciably increased by varying the acid–base properties of these materials.

CONCLUSION

The acidity of a series of smooth solid metal and polymeric surfaces were measured. The dependence of these parameters on the extent of metal surface oxi-

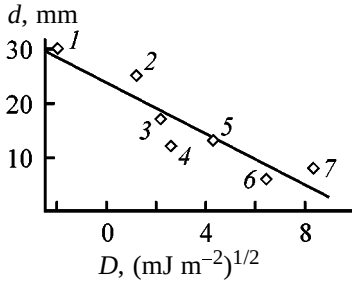

Fig. 3. Diameter of defect *d* formed at cathodic exfoliation of HDPE + 2% DC coating as a function of the acidity *D* of the metal support. Support: (*1*) aluminum, (*2*) duralumin, (*3*) St.3 steel, (*4*) St.20 steel, (*5*) G-65 steel, (*6*) ChZh-1 sheet iron, and (*7*) brass.

dation and on the modifier content in polyethylene was determined. A correlation was revealed between the acidity of these surfaces and the adhesion of the polyethylene coating to the metal support.

Abstract—The solubility of flax fibers differing in the degree of purity in triethylamine *N*-oxide monohydrate was studied. The size and amount of the associates in equiconcentrated solutions were estimated from the turbidity spectra. Rheological properties of solutions of cotton and flax cellulose were compared. Hydrated cellulose films were obtained from solutions, and their physicomechanical properties were studied. The films were characterized by IR spectroscopy.

In recent years production of flax-fiber-based textile materials increased. Simultaneously increased the amount of flax waste, namely, shive (flax stalks) and short fibers. The latter can be utilized in production of hydrated cellulose fibers. Modern processes utilize *N*-methylmorphopline *N*-oxide as cellulose solvent [1, 2].

It is of interest to study the dissolution of flax cellulose fibers, differing in the degrees of purity, in a mixture of triethylamine *N*-oxide monohydrate (mTEAO) with dimethyl sulfoxide (DMSO) as diluent. Utilization of short fibers in preparing cellulose solutions will extend the application field for flax fibers. In this work, we compared the properties of dilute and moderately concentrated solutions of flax cellulose in the mTEAO–DMSO system and showed their suitability for obtaining hydrated cellulose films.

EXPERIMENTAL

We utilized cotton cellulose with PD_η = 1500 and flax cellulose with PD_η = 1000 (PD_η is the polymerization degree determined viscometrically from the viscosity of cellulose in cadoxene). We used mTEAO as solvent. The water content of the latter was determined by Fischer titration [3]. Flax fibers were treated to remove fats, waxes, and pectins to various degrees of purity [4].

We studied the solubility in the mTEAO–DMSO system of flax fibers against cotton linter. Fiber samples were dissolved at T = 338 K for 60 min. Dilute solutions of flax cellulose and cotton linter samples (c = 0.5 wt %) were studied by the turbidity spectrum method [5, 6]. We calculated the average radius of the associates r, nm, and their amount in a unit volume N (number of associates per cm^3) by the equations

$$r = \alpha\lambda_{mid}/(2\pi n_D^{20}), \quad (1)$$

$$N = 1.26 \times 10^{17}\tau/[\lambda^2 k(\alpha, m)\alpha^2], \quad (2)$$

$$\lambda' = \lambda_{mid}/n_D^{20},$$

where r is the average radius of the associates, nm; α is the relative particle size; λ_{mid} is the wavelength corresponding to the middle of the range measured; n_D^{20} is the refractive index of the solvent at 293 K; τ is the turbidity of solvents, cm^{-1}; λ' is the light wavelength in the medium studied, nm; and $K(\alpha, m)$ is the scattering function tabulated for specific α and m [5].

The optical density and the turbidity were measured on a KFK-2 photoelectric colorimeter in a temperature-controlled cell in the wavelength range 490–750 nm. Moderately concentrated solutions were studied on a Rheotest 2.1 rheoviscometer. To this end we prepared 3% solutions of flax cellulose treated with benzene, hydrochloric acid, and a surfactant solution and those of cotton linter. The samples were dissolved on an oil bath with stirring for 2 h. The resulting solutions were filtered under pressure through 5 layers of glass fabric, and then kept for 1 h at room temperature to remove air bubbles (deaeration).

Hydrated cellulose films were cast onto Teflon plates through a laboratory spinneret with a controlled

slit. The solutions were applied to the plates, kept for 30 s in air, and immersed in a precipitation bath filled with distilled water. The resulting films were separated from the plates, kept for 1 h in the precipitation bath, and washed with several portions of distilled water for 4 h. Then films were fixed in rectangular frames and dried at room temperature for 12 h. This afforded 15–20-μm-thick hydrated cellulose films.

The mechanical characteristics of the films were determined in the uniaxial stretching mode on a UTS 10 setup at the stretching rate of 30 mm min^{-1}. The results were averaged over 5 measurements. The scatter was within 10%.

The IR spectra of the samples were measured on a Specord M80 spectrometer (KBr).

As known, dissolution of cellulose in tertiary amine *N*-oxides involves degradation of its macromolecules. This is explained by the stepwise dissolution of cellulose (swelling, degradation into individual crystallites or stacks of macromolecules, involving degradation of tie macrochains and their dissolution to molecular dispersion) and by oxidative degradation caused by oxygen that is released from amine oxide at elevated temperatures, yielding the initial amine [6, 7]. The solubility of the polymer is affected by concomitant substances. Flax fibers include lignin, fatty acids, waxy substances, pectins, pentosans, and dyes [8]. These substances modify the surface tension of fiber solutions [8], thereby affecting the flax cellulose solubility and self-association of solvated macromolecules in solution. We began our work with studying the solubility of cellulose from flax bast fibers differing in the degree of purity. Treatment of flax fibers with benzene removes, above all, fats and waxes, and then dilute solution of hydrochloric acid removes pectins, as well as pentosans (partially) [4]. Therefore, by dissolving in mTEAO flax fiber samples differing in the degree of purity it is possible to elucidate how the concomitant impurities affect the solubility of fibers in the mTEAO–DMSO system.

The initial fiber samples contain, along with cellulose, 10–15 wt % of other substances, while bleached cotton linter which served as the reference contains 99.8 wt % cellulose. Therefore, for cotton and flax fiber solutions with identical weight concentrations in nonaqueous mixed solvent the content of flax cellulose is lower than that of cotton cellulose. Flax fiber solutions can contain dissolved cellulose and other concomitant components. Fatty acids and waxes decrease the surface tension of fiber solutions and modify the conditions of sample dissolution. The greatest surface tension forces are exhibited by solutions of refined cellulose [8]. The concomitant substances passing into solution modify the properties of polymer solutions as well.

It should be noted that fats and pectins are removed at elevated temperatures (treatment with benzene, hydrochloric acid solution, boiling with a surfactant), which results in additional degradation of cellulose and modifies the solution viscosity. Therefore, comparison of the viscosity of solutions of cotton linter with those of flax fibers differing in the degree of purity reveals a combined effect of the molecular weight of cellulose proper and of various amounts of the impurities on the viscosity of solutions of a certain concentration.

Table 1 shows that the viscosities of solutions of cotton linter and raw flax fiber are comparable. Removal of fats and pectins (experiment nos. 6–8) causes the viscosity to increase. This can be explained by increase in the cellulose concentration and self-association of its solvated macromolecules. The sizes of the associates and their content per unit volume were estimated from the turbidity spectra [5]. In view

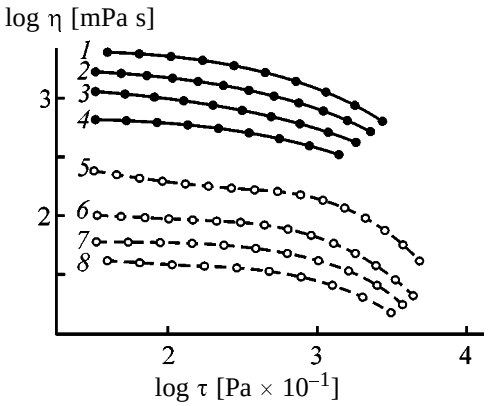

Fig. 1. Flow curves for 3% solutions of (*1–4*) cotton linter and (*5–8*) flax cellulose in the mTEAO–DMSO system. (η) Viscosity and (τ) shear stress. Temperature, °C: (*1, 5*) 20, (*2, 6*) 30, (*3, 7*) 40, and (*4, 8*) 50.

of the fact that the solutions were prepared under identical conditions and filtered through glass filters with identical pore sizes, we can make conclusions on the size of fluctuation associates that appear in solutions owing to intermolecular interactions of solvated macromolecules.

Our results show that removal of waxes and pectins causes the associates to grow in size (Table 1, experiment nos. 5–8). This can be explained by increase in the fraction of cellulose and by changes in the hydrogen bond system in solutions. It should be noted that flax fiber solutions in the mTEAO–DMSO system also contain hemicelluloses (pentosans, hexosans, mannan, etc.) whose removal from the initial material requires more severe conditions of flax fiber purification [4], which is beyond the scope of this work. Treatment with aqueous surfactant solution causes the viscosity of the solution and the size of the associates to grow (Table 1, experiment no. 6). Thus, comparative analysis of the viscosity and turbidity spectra of 0.5% solutions of flax and cotton linter fibers shows that mTEAO can dissolve flax fibers of various degrees of purity.

The rheological properties of the solutions were studied for a sample treated with benzene (removal of fats and waxes), hydrochloric acid (removal of pectins), and a surfactant solution. This choice was governed by the need in minimizing the influence of the impurities on the properties of moderately concentrated flax cellulose solutions. It is assumed that after the treatment runs listed above, the flax fiber contains the residual lignin, hemicellulose, and a mineral component. Figure 1 presents the flow curves of 3% solutions of cotton linter and refined flax cellulose. The solutions exhibit non-Newtonian flow patterns. The viscosity sharply decreases in the shear stress range $\log\tau = 2.6–2.8$. Substantial difference in the solution viscosity can be explained by the fact that flax fiber refining yields flax cellulose with DP_η 1000, whereas DP_η of cotton linter is 1500.

Table 2. Physicomechanical properties of hydrated cellulose films

Solution	*E*, GPa	σ_f, MPa	σ_t, MPa	ε_b, %
Cotton linter	8.7 ± 0.30	101 ± 2	112 ± 2	3.5 ± 0.2
Flax cellulose	7.9 ± 0.31	95 ± 2	109 ± 2	4.0 ± 1.0

* *E* is the elasticity modulus, σ_f is the forced elasticity limit, σ_t is strength, and ε_b is the elongation at break.

Using the temperature dependences, we calculated the viscous flow activation heats E_a which proved to be 43.4 and 38.2 kJ mol^{-1} for solutions of cotton linter in the mTEAO–DMSO system and flax cellulose solutions, respectively. The difference in these parameters may be due to different molecular weights of cotton linter cellulose and flax cellulose, as well as to the occurrence in the flax cellulose solution of hemicelluloses which can also affect structurization of solutions.

Thus, studies of the rheological properties of moderately concentrated solutions of cotton and flax cellulose show that these are non-Newtonian liquids with similarly shaped flow curves and similar viscous flow activation heats. This allows hydrated cellulose films to be prepared from the systems studied under identical conditions.

The composition of the precipitation bath affects the structure and the morphology of hydrated cellulose films. Therefore, by choosing appropriate composition of the precipitation bath it is possible to obtain films suitable as membranes [9, 10]. We formed hydrated cellulose films from two solutions by room-temperature precipitation of the polymer. The physicomechanical properties of these films are presented in Table 2. The resulting hydrated cellulose films differ in their physicomechanical properties insignificantly.

The composition of the films was studied by IR spectroscopy (Fig. 2). In the case of raw flax fibers the spectra contain absorption bands characteristic for lignin and pectins. The absorption bands characteristic for lignin are those at 1600, 1500, and 850 cm^{-1} [10]. The IR spectra of pectins contain the bands at 1740, 1615, and 1410 cm^{-1} [10, 11]. The absorption band at 1740 cm^{-1} belongs to free COOH groups of pectins.

The bands at 1615 and 1410 cm^{-1} are assigned to

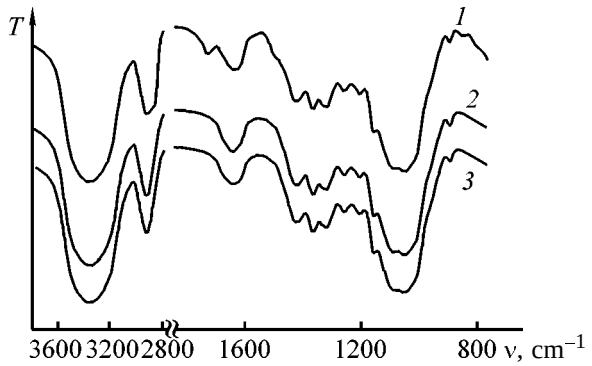

Fig. 2. IR spectra of (*1*) raw flax fibers and (*2*, *3*) hydrated cellulose films obtained from cotton linter and flax cellulose, respectively, in the mTEAO–DMSO system. (*T*) Transmission and (ν) wave number.

asymmetric and symmetric vibrations of ionized COO^- groups of pectins. A band characteristic of cellulose was observed at 2900 cm^{-1}; it is assigned to symmetric and asymmetric vibrations of CH_2 and CH groups of the polymer. The spectrum of pectin exhibits two absorption bands in the 2890–2925 cm^{-1} range [11]. The shoulder near 2900 cm^{-1} and the bands at 1740 cm^{-1} in the IR spectrum of raw flax cellulose suggest the presence of pectin. The presence of lignin is indicated by broadening of the band at 1650 cm^{-1} towards 1600 cm^{-1}, as well as by the appearance of a shoulder at 1500 and a band at 850 cm^{-1} [10].

The lack of characteristic absorption bands of lignin and pectin in the IR spectrum of hydrated cellulose film obtained from solution of refined flax cellulose in the system mTEAO–DMSO suggests that treatment of flax fibers followed by their dissolution and filtration of solutions removes lignins and pectins. The differences in the physicomechanical properties of hydrated cellulose films based on flax cellulose and cotton linter are due to different molecular characteristics of the polymer and to the presence of hemicelluloses in the films obtained from flax cellulose solutions.

CONCLUSIONS

(1) Comparative analysis of the solubility of flax fibers, differing in the degree of purity, in mixtures of triethylamine *N*-oxide monohydrate with dimethyl sulfoxide shows that the impurities in fibers modify the viscosity properties and the association structure of solutions. Removal of fats and pectins results in degradation of cellulose macromolecules.

(2) The size and amount of associates in solutions of identical concentrations depend on the degree of purity of the flax fibers. Moderately concentrated solutions of cotton linter and flax cellulose do not markedly differ in the mechanisms of their viscous flow.

(3) Physicomechanical properties and structural organization of the films obtained from cotton linter and flax fiber solutions differ insignificantly.

Abstract—To develop procedures for producing graphite from polyacetylene, the effect of crystalline regions in the structure of homo- and copolymers of acetylene with vinyl chloride on the structure and properties of the products of their profound carbonization was studied.

Due to unique properties of graphitic carbon materials (high chemical, electrochemical, and thermal stability and significant thermal and electrical conductivity), they are widely used in various branches of industry.

These materials are mainly prepared from petroleum, pitch, and shale cokes by heat treatment at 2300–3000°C [1]. Graphitic carbon can also be produced by high-temperature (2000–3000°C) pyrolysis of macromolecular compounds, e.g., polyvinyl chloride (PVC) [2] and polyacrylonitrile [3], but their graphitization is low even at high temperatures.

With the aim of finding new precursors of graphitic carbon materials, it was of particular interest to study high-temperature pyrolysis of the simplest carbon-chain polymer with a system of conjugated double carbon–carbon bonds, polyacetylene (PAc), and copolymers of acetylene with vinyl chloride prepared by phase-transfer PVC dehydrochlorination.

EXPERIMENTAL

In our work we used polyacetylene prepared by complete dehydrochlorination of PVC and copolymers of acetylene with vinyl chloride, which are the products of incomplete conversion of PVC into PAc. For this purpose S-65 polyvinyl chloride (degree of polymerization 1950) was dehydrochlorinated with potassium hydroxide in the presence of tertiary ammonium salts [4]. The conversion was controlled by varying the concentration of the dehydrochlorinating agent in the reaction mixture.

The polymer was heated in the 100–1200°C range in a quartz ampule in a vacuum (10^{-3} mm Hg); at temperatures above 1200°C, a ceramic ampule was used. The heating rate was 1.5 deg min^{-1}; then the samples were kept at chosen temperature for 6 h. At the polymer graphitization the heating rate was 2.5 deg min^{-1}, the product was kept at 1100–1200°C and higher temperatures for 24 h. All manipulations were performed in an inert atmosphere (argon). The degrees of dehydrochlorination α and dehydrogenation C/H were determined by elemental analysis.

The TGA was performed on a Perkin–Elmer du Pont 900 thermal analyzer at a 3 deg min^{-1} heating rate in a helium flow (40 ml min^{-1}).

The concentration of paramagnetic species in the polymer was evaluated with an RE-1306 radiospectrometer.

The structure and morphology of the carbonized products were studied with an REM-100 scanning electron microscope and an EMMA-4 transmitting electron microscope. The reflections in the electron diffraction pattern were indexed with standard natural graphite references. The content of graphite C_{gr} in the pyrolysis products was determined using a DRON-2 diffractometer according to the procedure given elsewhere [5].

The specific electrical resistivity ρ of the pelletized samples (300 μm thick) was registered by the four-probe method using cells equipped with stainless steel electrodes and an E-7-8 ac bridge potentiometer (1 kHz).

1070-4272/01/7411-1928$25.00

The common feature of polymers with conjugated bonds is their high thermal stability, which is due to the decrease in the internal energy at polyconjugation. In study of the PAc thermal stability we found that the thermal degradation of this polymer begins at 300–320°C and is accompanied by significant weight loss and formation of volatile (predominantly benzene) and oily aromatic products. At higher temperatures formation of benzene is terminated. The polymers break down stepwise with maximal rates at 300–320 and 440–450°C, and the process is terminated at 600–650°C with formation of the coke residue (25–40% yield).

The mechanism of thermal degradation of PAc prepared by phase-transfer dehydrochlorination of PVC probably involves cleavage of the chain caused by the electron–proton exchange and in some cases by the ring closure [6]. The intermolecular electron migration and ring closure result in formation of benzene and other aromatic hydrocarbons.

The supramolecular structure affects the degradation processes in the polymer. In the case of crystalline PAc the degradation rate of macromolecules is lower and the yield of the carbonized residue is higher than in the amorphous sample: weight loss curve *1*' lies higher than curve *2*' (Fig. 1). The rigid crystal structure of PAc hinders elimination of macromolecular fragments, but facilitates carbonization of the polymer at heat treatment. Dehydrogenation of this polymer begins at 250–300°C and via several intermediate structures yields completely carbonized samples at 1100–1200°C. As seen from the dependences of the C/H ratio characterizing the hydrogen loss (Fig. 1), the dehydrogenation rate of crystalline PAc is higher compared to the amorphous polymer. The amorphous polymer is carbonized completely only at 2000°C. At certain temperature the dehydrogenation–hydrogenation equilibrium is attained, which is confirmed by appearance of the saturation plateau on the kinetic curve of hydrogen loss at fixed temperature (Fig. 2). This equilibrium is shifted toward dehydrogenation with increasing temperature.

These experimental results can be explained by features of macromolecular packing in the crystalline polymer. Electron diffraction and structural studies show that the distance between the macromolecules is 3.40 Å. This is significantly smaller than the sum of the van der Waals radii, which suggests interchain interaction. The distance between the hydrogen atoms in the neighboring macrochains of 1.40 Å was evaluated using model structures. This is probably responsible for facile hydrogen elimination with formation of two radical centers in the neighboring macromolecules.

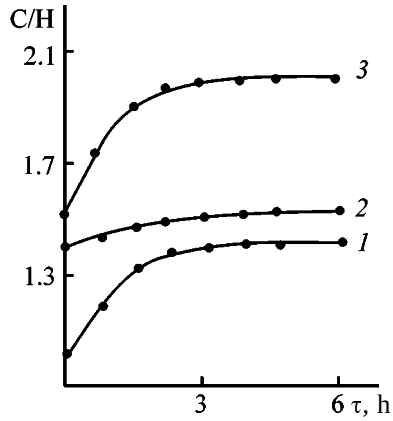

Fig. 2. Kinetic curves of thermolysis of crystalline PAc at (*1*) 300, (*2*) 350, and (*3*) 400°C. (C/H) Atomic ratio and (τ) time. Samples were preliminarily annealed at (*1*) 100, (*2*) 300, and (*3*) 350°C.

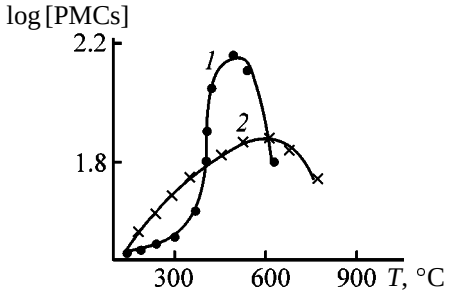

Fig. 3. Concentration of PMCs as a function of the temperature of thermal treatment *T* of (*1*) crystalline and (*2*) amorphous PAc polymers.

Dehydrogenation is accompanied by variation of the number of paramagnetic centers (PMCs) in the samples. The curves of PMC accumulation pass through maxima (Fig. 3) at 400–500 (crystalline polymer) and 500–600°C (amorphous polymer), when

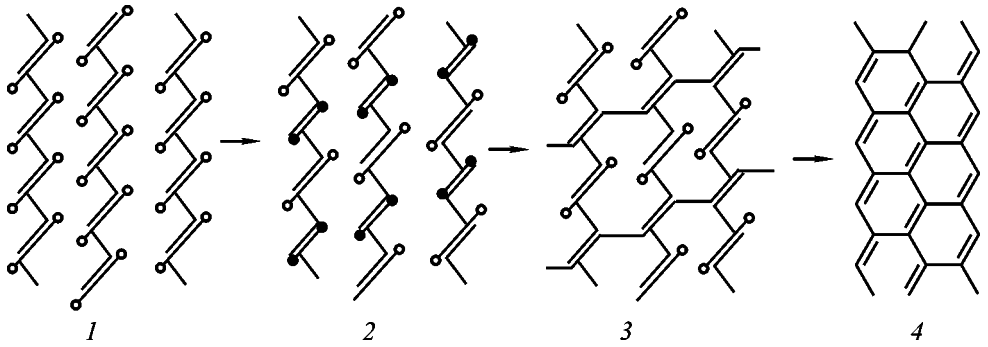

Fig. 4. Transformations of crystalline PAc in the course of thermal treatment in a vacuum: (*1*) initial PAc, (*2*, *3*) $-(C_2H)_n-$ product, and (*4*) condensed aromatics.

the $-(C_2H)_n-$ products are formed. These products are rather stable systems containing up to 10^{22} PMCs (i.e., one paramagnetic center per two carbon atoms). Enrichment with paramagnetic centers affects the magnetic and electrophysical properties of these products, which differ from those of the less and more carbonized products. As shown in [7, 8], the $-(C_2H)_n-$ products exhibit high paramagnetism and high tension sensitivity. The structure of the $-(C_2H)_n$ products can be presented by pattern *2* (Fig. 4). The rigid crystal structure hinders cross-linking and formation of the –C≡C– bonds, as these processes involve the contraction of the chains or their straightening, respectively. Further temperature rise increases the chain flexibility and promotes cross-linking, which decreases the number of PMCs. In this case the IR spectra exhibit the absorption bands at 1330 and 740 cm^{-1}, lacking in the spectrum of the initial polymer and characterizing the in-plane and out-of-plane bending vibrations of the =C–H group in the *cis* configuration.

The IR spectra of PAc prepared by phase-transfer dehydrochlorination of PVC contain bands belonging to the in-plane and out-of-plane bending vibrations of the =C–H group in the *trans* configuration: 1292 and 1015 cm^{-1}, respectively. The fact that the IR spectrum of the carbonized polymer contains the bands belonging to the *cis* structure with simultaneous decrease in the intensity of the bands of the =C–H group in the *trans* configuration can be explained by formation of structure *3* (Fig. 4) by cross-linking.

Further carbonization of the sample results in formation of compact planar layers of six-membered carbon rings (Fig. 4, structure *4*). These layers can be considered as a macromolecule consisting of condensed aromatic rings.

The products of incomplete carbonization of PAc polymer are intermediate between the linear polymers with a system of conjugated double bonds and the products of complete carbonization (carbon, graphite) involving two- and three-dimensionally ordered networks of six-membered rings. In nongraphitic carbon the layers are arranged in small stacks without mutual (azimuthal) ordering between the planes. In graphite there is a three-dimensional order of the carbon networks due to weak van der Waals attraction.

The thermal treatment at 1100–1200°C of both amorphous and crystalline PAc polymer yields nongraphitic carbon (Table 1). As known [1], mutually parallel orientation of the crystallites and the absence of strong cross-links between the aromatic layers at the crystallite edges are necessary conditions for good graphitization of cokes. In the case of PAc this condition is not met. The amorphous polymer contains no crystallites, whereas in the crystalline polymer interchain cross-links hinder graphitization.

Thermolysis of the products of incomplete dehydrochlorination of PVC (block copolymer of acetylene and vinyl chloride) is a gross process involving successive reactions of thermal dehydrochlorination and thermal dehydrogenation. The elimination of HCl is complete at about 300°C, and elimination of hydrogen from the macromolecule starts simultaneously. In this case the structure of the final products is determined by the conditions of the polymer synthesis, namely, the concentration of potassium hydroxide used as dehydroclorinating agent. As seen from Table 1, pyrolysis of copolymers prepared at high concentrations of KOH both in the initial solution and reaction mixture yields products with a disordered structure. With decreasing KOH concentrations in solution or in the reaction mixture the copolymer of vinyl chloride and acetylene is formed, whose thermolysis yields the product with an ordered structure, polycrystalline graphite, i.e., graphitic material with cross-linked small crystalline areas.

As shown previously [4], the concentration of

* Concentration of KOH in solution.

** Amount of KOH in the reaction mixture, gram of dry compound per milliliter of the organic phase (solution of PVC in nitrobenzene).

KOH solutions affects the density of the samples obtained by complete dehydrochlorination of the polymer. At a low concentration of potassium hydroxide the crystal packing is denser (d 1.35 g cm^{-3}) than at high hydroxide concentrations (1.25 g cm^{-3}). Obviously, the presence of compact crystallites in the products of incomplete dehydrochlorination of PVC is a prerequisite for high ordering in the pyrolysis products. The PAc crystallites in the copolymer of vinyl chloride and acetylene exhibit a three-dimensional ordering. The carbon networks formed during pyrolysis of this copolymer are ordered in all three dimensions, i.e., graphite crystals are formed. The topochemical transformations of the products of incomplete conversion of PVC proceed at relatively low temperatures of about 1200°C.

Three-dimensional ordering of the carbon networks (graphitization) starts at 900–1000°C. The samples studied involve both crystalline and amorphous fractions. The XRD patterns of the samples obtained in these stages of graphitization exhibit the reflections at 3.40 (crystalline PAc) and 3.35 Å (graphite), and a broad reflection at 3.60–3.80 Å (amorphous product). With increasing temperature the graphite structure is progressively formed (Table 2). At pyrolysis of this copolymer at 1100–1200°C the interlayer spacing sharply decreases from 3.40 to 3.35–3.38 Å, typical of graphite [9]. The electron diffraction patterns of PAc and polycrystalline graphite are shown in Figs. 5a and 5b, respectively. The crystallite size in graphite is 10^4–10^5 Å, whereas the size of two-dimensional island structures appearing in carbonization of amorphous polymer (Fig. 5d) does not exceed 50–60 Å.

The density and electrical conductivity of commercial synthetic graphite depend on the properties of the raw material (coke) and vary within 1.4–2.2 g cm^{-3} and 7–30 Ω cm [9], respectively. The pycnometric density and specific electrical conductivity of graphite prepared by pyrolysis of acetylene–vinyl chloride copolymer are 2.03–2.06 g cm^{-3} and 10 Ω cm, respectively.

Thus, the properties of graphite prepared by pyrolysis of acetylene–vinyl chloride copolymer are similar to those of graphite produced by coke pyrolysis. This product belongs to the class of filled graphites used, for example, in the diamond synthesis.

Along with polycrystalline graphite, in the course of pyrolysis at 1100–1200°C, a bright compact film

of pyrolytic carbon (20–100 μm thick) is formed at the boundary between the polymer and reaction vessel wall. This film consists of azimuth-disordered graphite-like layers packed in parallel to each other with the interlayer spacing d_{002} 3.49 Å and can be identified as quasi-two-dimensional graphite. Heating of the film to temperatures higher than 2000°C improves the structure and packing of the graphite-like areas; the interlayer spacing decreases and at 2200°C it reaches 3.43 Å. This two-dimensional graphite with a high anisotropy of electrical and optical properties was described in [10].

Carbonization of acetylene–vinyl chloride copolymer in the presence of quartz and ceramic plates results in coating of their surface with pyrolytic carbon and formation of graphite. In the case of stainless steel supports, products with a random structure are formed.

CONCLUSIONS

(1) Crystalline amorphous polyacetylene prepared by phase-transfer dehydrochlorination of polyvinyl chloride to complete polymer conversion is not graphitized at heating to 1100–1200°C.

(2) The products of incomplete conversion of polyvinyl chloride, which are the block copolymers of acetylene and vinyl chloride involving crystalline regions, are converted into graphite at 1100–1200°C.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Reactions of Polysaccharide Aldehydes with Aromatic Hydroxy Compounds

O. B. Suvorova, A. A. Iozep, and B. V. Passet

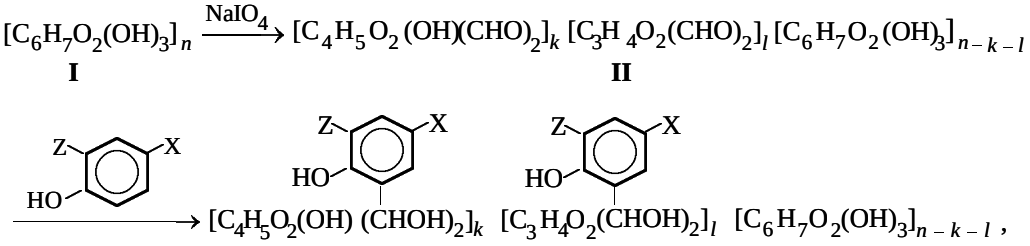
St. Petersburg State Academy of Pharmaceutical Chemistry, St. Petersburg, Russia

Received October 16, 2000; in final form, May, 2001

Abstract—Reaction of dextran polyaldehyde with phenol or its derivatives was suggested as a way to modify polysaccharides with aromatic hydroxy compounds.

Phenols readily enter into electrophilic substitution, even with such weak electrophiles as aldehydes. Reaction of polysaccharide aldehyde (PA) with phenols was not studied previously; therefore, it was appropriate to study this reaction with the aim to develop a new procedure for modifying polysaccharides.

Chemical modification of PA was performed as follows:



IIIa–**IIIf**

where Z, X = H (**IIIa**); X = CH_3, Z = H (**IIIb**); X = NO_2, X = H (**IIIc**); X = Cl, Z = H (**IIId**); X = COOH, Z = H (**IIIe**); X = H, Z = COOH (**IIIf**).

In our study we used extracellular microbial polysaccharides: aubasidan (branched β-1,3-β-1,6-α-1,4-glucan produced by yeast-like fungus *Aureobasidium pullulans*), rhodexman (β-1,3-β-1,4-mannan produced by *Rhodotorula rudra*), rhonasan (sulfated rhodexman), and also dextran commercially produced in Russia.

Polysaccharides **I** were activated by periodate oxidation [1] in acetate buffer solution (pH 4.1). The consumption of sodium periodate was checked spectrophotometrically at 222.5 nm [1]; the amount of the released formic acid was determined by volumetric titration. To prepare water-soluble polyaldehydes **II** derived from dextran (DPA), rhodexman, and rhonasan, the low-molecular substances were removed by dialysis, the solutions were concentrated in a vacuum at 60°C, and the polyaldehydes were precipitated with ethanol. Water-insoluble aubasidan polyaldehyde was filtered off and washed successively with distilled water, alcohol, and ether.

To determine the optimal conditions for reactions of aromatic hydroxy compounds with PA, we studied the reaction of DPA with phenol.

The reaction was performed in water at 20–90°C for 2–10 h. To prepare monohydroxyalkylation products, 1–5 mol of phenol was added per mole of aldehyde groups in the polysaccharide. After reaction completion, the product was precipitated with alcohol and reprecipitated from water to remove excess phenol. The absence of free phenol in the target product was checked by thin-layer chromatography.

The synthesized phenol–polysaccharide compounds are light yellow amorphous powders readily soluble in water and aqueous alkali but insoluble in alcohol, ether, and the majority of other organic solvents.

1070-4272/01/7411-1933$25.00

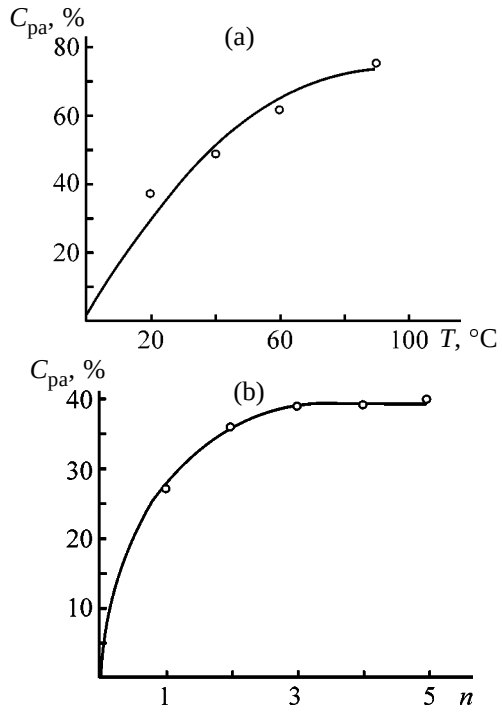


Fig. 1. Conversion of aldehyde groups C_{pa} in reaction of DPA with phenol as a function of (a) reaction temperature T and (b) molar ratio of the reactants n. Reaction time 2 h, pH 10; (a) 2 mol of phenol per mole of aldehyde groups; (b) 20°C.

The products of reaction of PA with phenols were studied by UV and IR spectroscopy, conductometric titration, and viscometry and characterized by the degree of substitution C_{sp} (number of phenolic fragments per polysaccharide monomeric unit) and degree of conversion $C_{ca} = (C_{sp}/C_{sa}) \times 100\%$, where C_{sa} is the content of aldehyde groups in the polymer.

The IR spectra of the products contain bands at 1500 cm^{-1}, assignable to the stretching vibrations of the C=C bonds in aromatic compounds, and at 695 and 770 cm^{-1}, corresponding to the out-of-plane bending vibrations of the C–H bond in 1,2-disubstituted benzene derivatives. The absorption band of 1,4-substituted benzene derivatives at 800–830 cm^{-1} is lacking, which suggests that under experimental conditions the electrophilic substitution in the benzene ring mainly occurs at the *o*-position relative to phenolic hydroxyl, yielding the 1,2 derivative as the major product.

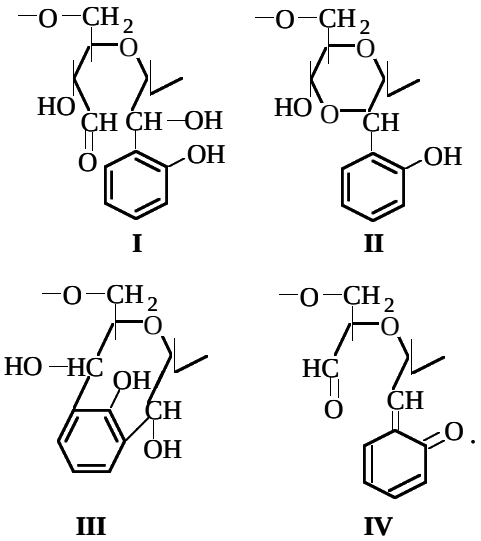
The position of the UV absorption maxima of aqueous solutions of phenol–polysaccharide samples depends on pH (275 nm at pH < 7 and 290 nm at pH > 7) and differs from that characteristic of free phenol under similar conditions (λ_{max} 265 nm). Polysaccharides exhibit no absorption in this range.

Reactions of aldehydes with phenols can yield polymerization products by reaction of one phenolic fragment with several aldehyde groups. This should result in cross-linking of the polysaccharide chains, with a considerable increase in the molecular weight of the polymer and hence in the relative viscosity of polysaccharide solutions. However, the relative viscosity of aqueous solutions of the polyaldehyde does not increase after reaction with phenol. This fact suggests that phenols react with aldehyde groups of only one polymer chain, with no cross-linking.

It is known that polyaldehydes are unstable in alkaline solutions and are readily oxidized with atmospheric oxygen to carboxylic acids [2]. We found that in the presence of phenols under the synthesis conditions (20°C, pH 10, 2 mol of phenol per mole of aldehyde groups) PA is not oxidized. Carboxy groups were not detected in the samples.

To prove the absence of quinoid structures, PA–phenol samples were treated with hydroxylamine after reduction of aldehyde groups with sodium borohydride. The elemental analysis and IR spectra of the resulting samples showed the absence of nitrogen atoms and of absorption bands at 1640 cm^{-1} typical of oximes. Hence, the polysaccharide samples contain no quinoid structures. Therefore, the content of the residual aldehyde groups in phenol–polysaccharide samples was determined by the oxime method. It was found that approximately 2 mol of aldehyde groups are converted per mole of phenol.

The molecular-mechanics (MM+) simulation of the reaction products showed that structures obtained by reaction of phenol with two aldehyde groups of the same PA fragment (**III**) are the least stable. Quinoid structures **IV** are also poorly stable.



Our results suggest that the samples have lactol structures **II**. Such structures are fairly stable in neutral and alkaline solutions.

Thus, the most probable pathway of reaction of PA with phenol is monohydroxylation of phenol followed by closure of a six-membered lactol ring.

To find the conditions allowing incorporation of a preset amount of phenol into a polysaccharide, we studied how C_{sp} is influenced by temperature, time, reactant ratio, and pH, using as example the reaction of DPA with phenol (Figs. 1a, 1b).

We found that DPA readily reacts with phenol even at 15–20°C, with conversion of approximately 40% of aldehyde groups. Therefore, subsequent experiments were performed at room temperature.

At increased content of phenols in the reaction mixture, the content of phenolic fragments in the polysaccharide samples decreases. However, at the phenol-to-aldehyde ratio higher than 3 : 1, C_{sp} does not increase further.

To attain the desired conversion of DPA aldehyde groups in reaction with phenol at room temperature, we varied the reaction time and found that C_{pa} does not further increase after the 4-h reaction.

Finally, as seen from Table 1, the highest conversion is attained in alkaline solutions. When the reaction is performed at pH ≤ 7, C_{pa} drastically decreases.

Having determined, by the example of DPA, the optimal conditions for the reaction of PA with phenol, we studied the reactivity of the other polyaldehydes under the conditions allowing incorporation of the maximal amount of phenolic fragments.

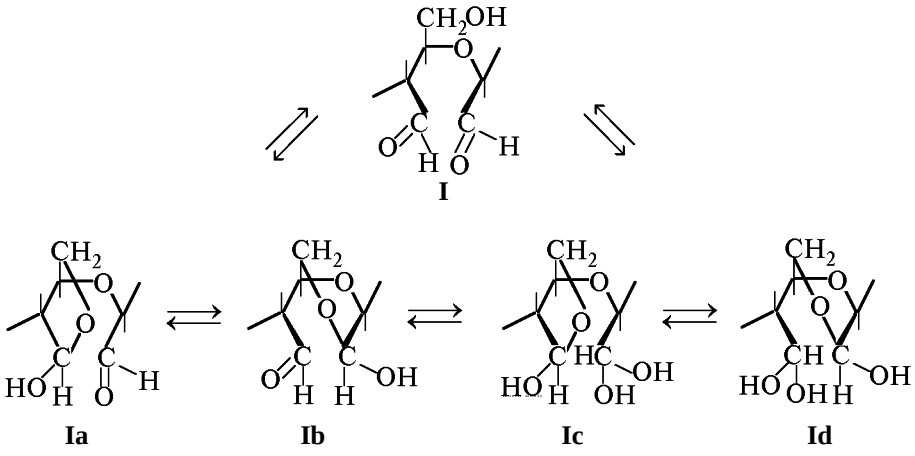
Table 1. Conversion of aldehyde groups C_{pa} of the polymer in reaction of DPA with phenol as influenced by pH. 20°C, 4 h, 2 mol of phenol per mole of aldehyde groups, C_{sa} 1.32

pH	C_{sp}	C_{pa}, %
5	0.31	24
6	0.36	27
7	0.33	25
9.3 (0.25)*	0.44	41
9.85 (0.5)	0.8	74
10.2 (0.75)	0.91	84
10.65 (1.0)	0.92	85

* In parentheses is the amount of NaOH (moles per mole of phenol).

As expected, the structural features of polyaldehydes affect the reaction course and the product quality (Table 2).

The least active in the reaction with phenols is water-insoluble aubasidan polyaldehyde. Somewhat lower reactivity of rhodexman and rhonasan is probably due to the prevalence in their molecules of 2,3-oxidized fragments capable of forming three types of structures: dialdehyde **II**, is hemiacetal forms **IIa** and **IIb**, and hemiacetal–hydrate forms **IIc** and **IId** occurring in equilibrium [3]. In alkaline solutions, the equilibrium is shifted toward less reactive hemiacetal–hydrate structures:



I

Ia **Ib** **Ic** **Id**

Table 2. Results of the reaction of PAs with phenol. 90°C, 4 h, 3 mol of phenol per mole of aldehyde groups, 0.5 mol of NaOH per mole of phenol

Compound	C_{sa}	C_{sp}	C_{pa}, %
Polyaldehyde of:			
dextran	1.09	0.8	74
aubasidan	0.62	0.36	58
rhodexman	0.78	0.51	65
rhonasan	0.5	0.32	64

As expected, electron-withdrawing substituents in the benzene ring appreciably hinder the reaction of DPA with phenolic compounds. On the contrary, introduction of an electron-donating substituent increases C_{pa}. The substituent effect on the reactivity of a compound can be quantitatively evaluated using the Hammett equation. In this contextm it was interesting to find a correlation between C_{pa} and the σ constants of substituents. We obtained a linear correlation: $C_{pa} = -46.032\sigma_p + 43.234$, $r = 0.9984$.

CONCLUSION

Reaction of polysaccharide aldehydes with phenol is a convenient route of polysaccharide modification. It is performed in aqueous solution at 20–40°C for 4 h at the molar ratio of phenol to aldehyde groups of 2–3. Up to 0.6–0.9 mol of phenolic fragments is introduced per mole of the monosaccharide unit. The highest conversion of aldehyde groups in attained in alkaline solutions (0.75–1.0 mol of alkali per mole of phenol). The reaction is not accompanied by oxidation of aldehyde groups with atmospheric oxygen or by gelation due to cross-linking.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Physicochemical Modification of Siloxane Compounds for Electrical Engineering in the Course of Mixing

D. N. Lazarev, V. P. Britov, and V. V. Bogdanov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received December 20, 2000

Abstract—The effect of silica fillers, used separately or in combination, on the rheological properties of siloxane compounds based on low- and high-molecular-weight rubbers was studied. A model was suggested for formation of the structure of filled compounds during mixing under conditions of shear stresses, and a procedure was proposed for preparing compounds for shells of high-voltage insulators produced by pressure casting.

Wide use of polymeric insulators in contact wiring systems and high-voltage installations is due to their advantages over porcelain and glass insulators, such as high electrical parameters (low dielectric permittivity, high breakdown voltage, etc.), good service properties (high hydrophobicity, resulting in self-cleaning, so that it becomes unnecessary to wash insulators; resistance to vandalism), and also very favorable characteristics from the viewpoint of transportation and mounting (no damage at transportation because of the lack of friability; lower, by a factor of 2, weight as compared to the porcelain articles) [1].

At present, three classes of polymeric materials are used as protective coatings for insulators: epoxy resins highly filled with ground quartz or aluminum hydroxide, ethylene–vinyl acetate copolymers (with the same fillers), and silicone elastomers [2]. The latter compounds are the most promising materials. This is due to their high weather resistance, capability for long operation in a wide temperature range (from –60 to 60°C), and elasticity. In contrast to the majority of insulating materials, silicone elastomers are capable to preserve a low surface energy, which prevents formation of a continuous water film on the insulator surface and appearance of leakage arcs. Furthermore, silicone polymers are environmentally clean.

Development of procedures for fabrication of polymeric insulators is based on attempts to pass from successive coating with separate components to continuous pressure casting of protective shells of various shapes and sizes. The developed procedures for fabrication of insulator shells by casting mainly utilize thermoplastic materials or some types of thermosetting plastics (epoxy compounds) [3].

Protective siloxane shells for insulators can be made of compounds based on low- and high-molecular-weight rubbers. The advantages of one or anoter class of materials are not fully understood, despite a clear trend toward the use of liquid rubbers with the aim to perform casting efficiently. Certain drawbacks are inherent in compounds based on both high- (high viscosity) and low-molecular-weight (low strength, problems with introduction of reinforcing fillers) rubbers. The common drawback of both high- and low-molecular-weight siloxane compounds is the long vulcanization time, which significantly complicates casting.

To develop a casting process for preparing protective coatings for insulators, it is necessary to modify some properties of siloxane compounds (ensure high flowability, shorten vulcanization time); it seems more expedient to perform physicochemical modification in the course of compounding, rather than to adjust the formulation.

The goal of this study was to find procedures for physicomechanical modification of polysiloxane compounds for electrical engineering with the aim to develop an efficient process for pressure casting of protective insulator shells.

As the major investigation objects we chose compounds based on SKTV-1-NT high-molecular-weight siloxane rubber (hereinafter, SKTV), differing in the

content of Aerosil A-175, BS-50 white black, titanium dioxide, and aluminum hydroxide. To evaluate the physicomechanical and service properties, the compounds modified in the course of mixing were compared with traditional materials for electrical engineering based on SKTV-1 rubber (Lebedev Research Institute of Synthetic Rubber, St. Petersburg) and with the compounds produced by Wakker. In view of the existing predictions that low-molecular-weight rubbers will find growing use in production of siloxane articles, we also studied the behavior of compounds based on materials that are commercially produced in Russia (SKTN-A) and Germany (Bayer).

The compounds were prepared on different apparatus: laboratory rollers, a laboratory mixer with Z-shaped blades, and a closed rotary measuring mixer, with the aim to evaluate how apparatus features affect the compounding process.

Evaluation of the process characteristics of siloxane compounds and description of their behavior were based on the results of rheological tests performed by capillary and rotary viscometry.

Determination of the service properties of compounds (frost resistance coefficient, resistance to thermal aging, specific volume electrical resistivity, tangent of the dielectric loss angle, electrical strength, dielectric permittivity, tracking erosion resistance, arc resistance) were performed according to GOST (State Standard).

In the first stage of our studies, we performed a comparative analysis of the rheological behavior of model compounds based on high- and low-molecular-weight rubbers with the same degree of filling with white black. The viscosities of these compounds differ by a factor of 10 and more, and such a difference is preserved in the entire range of the actual shear rates used in the process equipment (Fig. 1). At the same time, by varying the processing conditions, it is possible to decrease the viscosity of high-molecular-weight compounds to the level characteristic of low-molecular-weight compounds [the viscosity of low-molecular-weight compounds at a shear rate of 10 s^{-1} corresponds to that of high-molecular-weight compounds at a shear rate of $(1–1.5) \times 10^2$ s^{-1}], which allows their processing by pressure casting.

The most important feature of the actual organosilicon compositions used for protective coatings of electrical insulators, from the viewpoint of their process behavior, is the presence of various fillers: aluminum hydroxide, titanium dioxide, and silica (Aerosil). Their total effect increases the viscosity of the system and does not allow production of articles by high-performance pressure casting.

The typical formulations of the compounds are as follows (wt parts): SKTV high-molecular-weight rubber 100, Aerosil A-175 20–30, anti-cross-linking additive 9–10, aluminum hydroxide 90–130, and titanium dioxide 5–7.

Among the ways to control the rheological behavior of the compounds (variation of the formulation, proper order of adding components, use of special methods of strain action), only the latter approach appeared to be feasible.

We have studied the effect of fillers, used separately or in combination, on the rheological behavior of the system. With both active (Aerosil) and inert (aluminum hydroxide) fillers, irrespective of the degree of filling, the viscosity decreased considerably in the range of shear rates 30–120 s^{-1}; at the shear rates of 180–240 s^{-1} the structures formed by the fillers degrade, and the compounds acquire flowability similar to that of Newtonian liquids. We suggested that this effect would be preserved in a compound filled with both types of fillers simultaneously, although the range of shear rates corresponding to the transition to the Newtonian flow would naturally be shifted to higher values. The experimental results (Fig. 2) confirm this suggestion.

The curves in Fig. 2 show that on introducing both types of fillers the increase in the viscosity is not additive. This fact can be accounted for as follows.

An inert filler prevents formation of a thixotropic skeleton formed of Aerosil elements (with the rubber adsorbed on the surface); the higher the content of an inert filler, the larger the deviation from the additivity.

When considering the mechanism of formation of the structure and properties of the compounds, we see that the strain action plays a decisive role. The behavior of a filled compound can be clearly demonstrated by a three-dimensional pattern characterizing the dependence of the viscosity on two parameters: degree of filling and shear rate (Fig. 3). Each section of this pattern can be described analytically by

$$\eta = \eta_0 \exp\left(\frac{\Phi}{1 - \Phi/\Phi_m} \frac{K}{\dot\gamma^x}\right), \quad (1)$$

where K is the form factor characteristic of a given type of filler; $\dot\gamma$ is the shear rate (s^{-1}); Φ is the true volume filling; Φ_m is the volume fraction of the filler at the closest packing of its particles (for randomly packed spheres, 0.61); and x is the coefficient accounting for physicochemical interactions in the system.

The second term inside the exponent characterizes the form factor, which is a function of the shear rate and is related to the strength of the reversible three-dimensional structures polymer–filler.

The calculations show that, e.g., for Aerosil A-175 $K = 50$, $x = 0.07$. The viscosities calculated by the suggested relationship are nicely consistent with the experimental data in a wide range of filler concentrations and shear rates.

It should be noted that, as the shear rate is increased and the degree of filling is decreased, $K/\dot\gamma^x$ tends to 2.5, i.e., the classical Einshtein equation is a particular case of the equation suggested by us.

Equation (1) sufficiently reliably describes the dependence of the viscosity on the degree of filling and shear rate. With several fillers, it can be represented as

$$\eta = \eta_0 \exp\left(\frac{\Phi_1}{1 - \Phi_1/\Phi_m} \frac{K_1}{\dot\gamma^{x_1}} + \frac{\Phi_2}{1 - \Phi_2/\Phi_m} \frac{K_2}{\dot\gamma^{x_2}} + \ldots + \frac{\Phi_n}{1 - \Phi_n/\Phi_m} \frac{K_n}{\dot\gamma^{x_n}}\right). \quad (2)$$

At the same time, in analysis of the effect of external actions on the physicomechanical and service

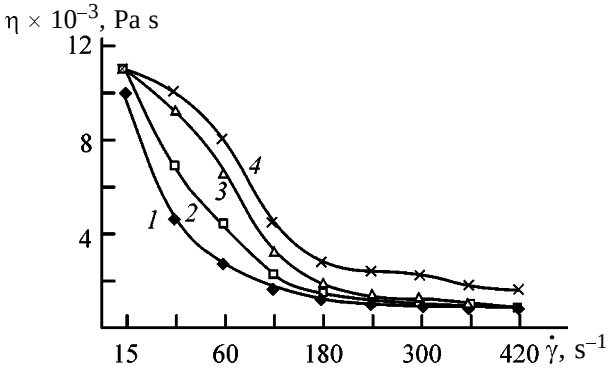

Fig. 2. Viscosity η of compounds with different fillers as a function of the shear rate $\dot\gamma$. Filler (wt parts): (*1*) Aerosil A-175, 30; (*2*) aluminum hydroxide, 130; (*3*) Aerosil A-175, 30 + $Al(OH)_3$, 130; and (*4*) theoretical viscosity of a compound with a complex filler.

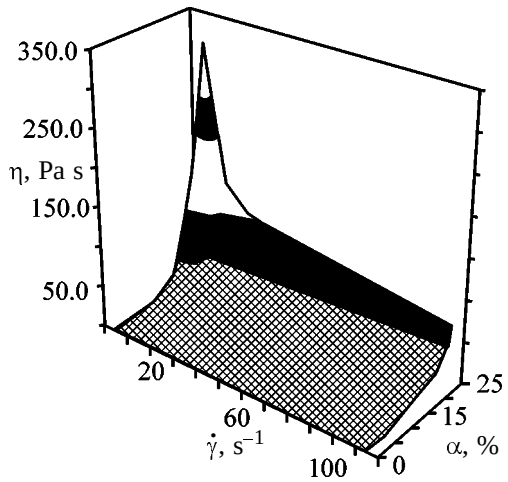

Fig. 3. Combined effect of the degree of filling α and shear rate $\dot\gamma$ on the viscosity η of compounds based on SKTN-A rubber and BS-50 white black.

characteristics of the compounds and process calculations, it is appropriate to use not the shear rate, shear strain, or its dispersion, but a generalized criterion whose physical sense is the strain energy density τΓ [where τ is the shear stress (Pa), and Γ is the shear strain].

The experimental dependences obtained by us allowed us to suggest a generalized model for structure formation in compounds based on both high- and low-molecular-weight rubbers and filled with various fillers. The model suggests the only possible order of introducing the components: first Aerosil with anti-cross-linking additive and then aluminum hydroxide.

Initially, at the instant of introducing the filler, the system is practically unmixed and consists of

Aerosil agglomerates and rubber matrix. Bulk interaction of the active filler with the rubber in this stage is insignificant, because it is aggregated, and the surface of the filler contacting with the polymeric matrix is shielded by the occluded air.

In the course of strain, aggregates and agglomerates of the filler are gradually broken down, and the polymer is adsorbed on the filler surface. The initial stage of adsorption involves "unrolling" of the polymer molecule on the filler surface. This process occurs in time, with its rate depending on the relaxation time of the polymer, and enhances the adsorption. With high-molecular-weight rubbers, the relaxation time is considerably longer, and in this case compounding should involve intermediate keeping as a special operation. When the filler content is sufficiently high, its particles link with each other directly or via adsorbed polymer to form chains and ultimately a three-dimensional network, i.e., a rigid skeleton. As a result, the compound becomes thixotropic (if the shear does not exceed a definite level). The shear stress in the course of compounding can increase even without changing the processing conditions. This is due to the fact that in the course of mixing the system becomes more homogeneous, the surface area of the boundary between the components increases, and hence the interactions in the system as a whole are enhanced. In the second stage of compounding, aluminum hydroxide is added. Its effect on the rheological properties of the system are dual. On the one hand, it increases the viscosity of the compound owing to intrinsic hydrodynamic resistance; on the other hand, it increases the shear stress in mixing and promotes further dispersion of Aerosil. When the required shear stress is attained, Aerosil chains are broken down, and separate particles are isolated from each other with the adsorbed polymer. In the limiting case, each particle can be enclosed in an envelope of the adsorbed polymer. Such a structure exhibits the properties of a Newtonian liquid and is suitable for processing by pressure casting.

It is well known that siloxane compounds, when allowed to stand, acquire thioxotropic properties. This case differs from the case of compounds subjected to strain in that the thioxotropic structure is restored by the other mechanism. After lifting the shear stress, the polymer layer on the surface of an active filler will grow owing to adsorption forces, increasing the apparent volume filling. As a result, the viscosity will increase, and at a certain degree of filling and keeping time the compound can lose flowability and become thixotropic. However, such a thixotropic structure is mainly formed via polymer layers, and it will be broken down reversibly, with the compound becoming fluid.

The results of testing the compounds showed that the vulcanization time largely depends on the strain treatment, which is due to the following facts.

(1) In the absence of strain, the silicone molecule as a constituent of a thioxotropic film on the surface of an active filler is largely unrolled in the adsorption field of the Aerosil particle. In this case it is highly probably that the terminal group is accessible for interaction with the cross-linking agent.

(2) The subsequent strain disturbs the adsorption equilibrium, with the molecule partially rolling up to form a globule; as a result, the number of freely interacting radical groups decreases, and hence the vulcanization time increases.

(3) Further increase in the strain results in significant unrolling of the molecule; as a result, the radical groups get free and become readily accessible for the peroxide, and the vulcanization time considerably decreases.

The combined consideration of the effect of strain on the viscosity, vulcanization time of compounds, and physicomechanical properties of the vulcanized products allows evaluation of appropriate conditions for strain treatment of the material. Figures 4a and 4b show that, as the criterion $\tau\Gamma$ is increased, the strength of the compound first increases and then slightly decreases. The hardness monotonically decreases with time, and the elasticity increases.

Thus, there are three different parameters affected by strain treatment of a material: (1) rheological characteristics (improving the processability of a compound); (2) vulcanization time (shortening the article fabrication time); and (3) physicomechanical characteristics (operation suitability). Simultaneous optimization of these parameters, which are all dependent on $\tau\Gamma$, will give the range of favorable values of $\tau\Gamma$ and allow the choice of the processing procedure, equipment, and process conditions.

Silicone compounds exhibiting required physicomechanical characteristics and ensuring the high service properties of insulators, as a rule, are highly viscous and do not pass to the viscous-flow state at elevated temperatures; therefore, their processing by casting is difficult.

The previously used procedures were unsuitable for efficiently fabricating articles from filled organosilicon rubbers by pressure casting, because of the high viscosity of the compound. At the same time, studies showed that such systems exhibit pronounced thixotropic properties, and their structure can be formed so that strain treatment will make the system fluid.

It was suggested to additionally subject the compounds to shear strain, ensuring $\tau\Gamma$ in the range $(8–16) \times 10^5$ kJ m^{-3} [4].

The procedure can be performed as follows. A standard compound is subjected to strain treatment in a mixer of any type (rotary, roller, screw), so as to ensure $\tau\Gamma$ in the range $(8–16) \times 10^5$.

The quantity Γ for a given mixer type is known (or can be calculated). The procedures for calculating Γ for different types of mixers are comprehensively described in the literature. The viscosity of a compound at a given shear rate is determined from rheological tests.

Based on our studies, a process was developed and put into operation[1] for fabricating polymeric insulators by pressure casting (Fig. 5). The main operations in fabrication of insulators from siloxane compounds are preparation of reinforcement (cutting of rod ends; drying and pressing of end tips); dosing of rubber stock ingredients; mixing of main ingredients; additional treatment of the compound, mixing with a curing agent, sheeting, molding of the article, and first stage of vulcanization; removal of the article from the mold and second stage of vulcanization in an oven; checkout and packaging.

By the developed process, batch production of trolley bus insulators [tension rod polymeric insulator NSK 36/800-7, TU (Technical Specifications) 3494-001-7 825 684 185–98] has been mastered. The article was certified. Also, a pilot batch of linear hanging rod insulators for a 20 kV voltage was produced.

CONCLUSIONS

(1) The viscosity of compounds based on low- and high-molecular-weight rubbers with a complex filler is not an additive function of the content of the fillers; the higher the content of an inert filler, the larger the deviation from the additivity. These systems can also be converted to a fluid state for subsequent pressure casting.

(2) To characterize the external strain action

[1] Izolyator Research and Production Association, St. Petersburg.

on the system, it is appropriate to use a generalized criterion, the strain energy density in the physical sense, rather than traditional concepts of the shear strain.

(3) For the compounds under consideration, the optimal ranges of the strain action values ensuring the required flowability, minimal vulcanization time, and the required physicomechanical properties of insulator shells prepared by pressure casting are in are in the range $(8–16) \times 10^5$ kJ m^{-3}.

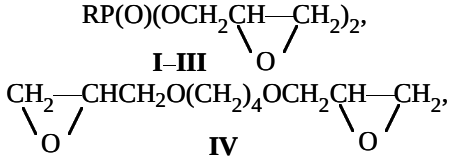
Abstract—The process parameters of production of epoxy binders modified with glycidyl esters of phosphorus acids were studied, and the performance characteristics of glass- and basalt-reinforced plastics on their basis were determined.

Composites based on epoxy oligomers (EOs) and various fibers often have defective structure because of the low ability of the binder to impregnate the filler. This is due to the high viscosity and low wetting power of the binder. As a result, the strength properties of the fiber and matrix are not realized in full measure. Most often the viscosity of binders, in particular epoxy compounds, is decreased by adding appropriate solvents [1]. However, evaporation of the solvent during molding causes large shrinkage, significant internal stresses, and formation of defects, and thus the strength of the resulting composite decreases. All these disadvantages are not typical for active diluents [2, 3] containing one and more epoxy groups, which are incorporated into the polymer network. In this case the most preferable are various glycidyl esters of phosphorus acids (GEPs), whose preparation and properties were described previously in [4]. Epoxy polymers modified with GEP exhibit high levels of strength [5] and heat and fire resistance [6]. In this work we studied the preparation of glass- and basalt-reinforced plastics using binders based on epoxy resins modified with GEPs.

EXPERIMENTAL

In our work we used ED-20 epoxy-4,4'-isopropylidenediphenol oligomer [GOST (State Standard) 10587–84], 4,4'-diaminodiphenylmethane hardener (DADPM), glycidyl esters of phosphorus acids **I**–**III**, and butandiol diglycidyl ether **IV**:



I–III

IV

where R = $OCH_2CH(O)CH_2$ (**I**), OCH_3 (**II**), CH_3 (**III**).

The matrices for the glass- and basalt-reinforced plastics were the T-11 glass fabric (GOST 19170–73) and BT-8 basalt fabric [TU (Technical Specifications) 5952-031-002004949–95].

The viscosity of the mixture of epoxy oligomers and GEPs was determined according to the GOST 10587–84 by the discharge time of the corresponding volume of the mixture through the capillary of a VPZh-1 viscometer (the capillary diameter varied from 0.54 to 5.1 mm). The angle of wetting θ of the surface of various materials by epoxy compounds was measured directly from the drop profile using a microscope equipped with a goniometer. The surface tension of the liquids at the liquid–air interface γ_{lg} was measured by the ring detachment method and by the method of a drop on a low-energy surface (Teflon). The impregnation rate v was determined on a KM-6 cathetometer using the dependence of the lifting height of the binder h in the fabric. In each time t for modified (m) and unmodified (um) binders we measured $(h_m)_t$ and $(h_{um})_t$ and calculated v_m and v_{um}, respectively. The effect of the modifying agent on the impregnating power of the binder was characterized by the relative rate of impregnation (v_m/v_{um}) and the ratio of the ultimate lifting heights of the binder in the fabric h_m/h_{um}.

The standard mechanical tests were performed on an FPZ tensile-testing machine: the tensile strength, according to GOST 25601–80, the bending strength, according to GOST 25604–82, the plane shear stress, according to GOST 24778–81, and the interlaminar

shear stress, by tension of a strip with a transverse notch [7].

The adhesion of the fiber to the matrix was studied by the procedure presented elsewhere [8]. The porosity and volume content of the binder and filler in the plastics were evaluated microscopically. The thermal and moisture aging were studied by the procedure presented in [9].

As seen from Fig. 1, the effect of the modifying agents studied on the viscosity of the epoxy binder is most pronounced at their concentration of up to 15 wt %. All glycidyl esters and ethers, with respect to their effect on the decrease of the binder viscosity, can be ranked in the following order: **I** > **II** > **III** > **IV**. As seen, the effect of widely used active diluent **IV** is the weakest. Thus, our data suggest high impregnating power of the binder compositions based on GEPs.

Data on the impregnation of glass and basalt fabrics with epoxy binders with various GEP content are listed in Table 1. These data show that with addition of GEP into the binder the impregnation rate considerably increases and reaches constant values at the content of modifying agents ≥20 wt %. Further increase in the GEP content decreases the impregnation rate, but it remains higher than that for the unmodified binder. The accelerating effect of GEPs on impregnation of the glass and basalt fabrics varies in the order **I** > **II** > **III**, which agrees with the above data on the effect of GEPs on the EO viscosity. As seen, in the case of basalt fabrics the relative rate of impregnation with all GEPs is greater than that in the fiber glass fabrics. This is probably due to higher wettability of the basalt fiber surface as compared to glass fibers. The angles of wetting of the glass and basalt fibers with the epoxy oligomer modified with ester **I** are given in Table 2.

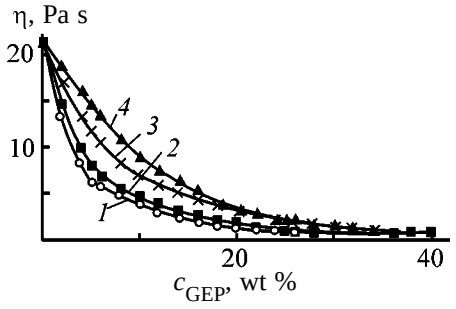

Fig. 1. Viscosity η of modified EP-20 epoxy oligomer as a function of the content c of the active diluent. Diluent: (*1*) **I**, (*2*) **II**, (*3*) **III**, and (*4*) **IV**.

Table 2 shows that with the same fabric the relative lifting height h_m/h_{um} of the binder in the fabric increases by factor of nearly two even at low content of GEP in the binder. At a further increase in the GEP content to 30 wt %, only slightly pronounced maximum in the h_m/h_{um} ratio is observed at a 15–20 wt % content of the modifying agent.

Impregnation of a fabric can be considered as the height of the binder lifting in a capillary (e.g., in the interfiber space). According to the Young–Laplace equation, the lifting height is directly proportional to the surface tension γ_{lg} and cosine of the wetting angle θ and inversely proportional to the liquid density ρ and capillary radius r.

For the same filler, i.e., at constant r, we calculated the relative lifting heights of the binders, which agree with the experimental h_m/h_{um} values (Table 2). These data show that, with respect to the decrease in the viscosity and increase in the relative lifting height and impregnation rate of the glass and basalt fabrics, the

30	450	401	466	413	393	377	420	391

optimal GEP content in the binder is about 15 wt %. Based on the experimental data, the low-viscosity binders for reinforced plastics were developed and patented [10].

The strength properties of the composites prepared using the above binders were also studied. The experimental strength parameters for plastics (70 wt % filler content) modified with esters **I** and **III** (for **II** the intermediate values were obtained) are listed in Table 3. At equal strength (1.9 GPa) of the glass and basalt fibers the higher strength of the basalt-reinforced plastics is probably due to better wettability and impregnability of the basalt fabrics. As seen from Table 3, even insignificant amounts of GEPs improve the strength properties of epoxy composites. The highest strength of the plastics modified with ester **I** may be due to smaller number of defects thanks to its lower viscosity and higher wetting and impregnating power, to higher strength of the polymer matrix in the presence of **I** [5], and to stronger adhesion to the fiber. Data on the adhesion of modified matrices to the glass and basalt fibers are given in Table 1.

The increase of the adhesion strength with modification of the binder can be illustrated by the data on the plane shear stress τ_{xy} and interlaminar shear stress τ_{xz} of the plastics modified with ester **I** (Table 2). Modification of the binder with glycidyl esters of phosphorus acids does not noticeably affect the thermal and moisture aging of the resulting glass- and basalt-reinforced plastics (Fig. 2).

CONCLUSIONS

Modification of epoxy binders for reinforced plastics with glycidyl esters of phosphorus acids improves

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Photoetching of Copper Surface with Photosensitive Polymeric Coatings

V. A. Anfinogenov, E. E. Sirotkina, N. G. Domina, and A. I. Khlebnikov

Polzunov State Engineering University, Barnaul, Russia
Institute of Petrochemistry, Siberian Division, Russian Academy of Sciences, Tomsk, Russia

Received November 14, 2000; in final form, August 2001

Abstract—Solid-phase photoetching of copper surface with photosensitive polyvinyl chloride compositions was studied. The depth of the relief was determined as influenced by the nature of photosensitizers present in the composition and by the exposure time of the photosensitive layer.

The main principles of photoetching were proposed in 1967 [1]. Preparation of a relief image consists of three steps: (1) application of a polymeric film containing photosensitive C–Hlg bonds on the metal surface (2) activating irradiation through a phototemplate, and (3) dissolution of the polymeric film.

The advantages of this procedure over, e.g., the photoresist process is smaller number of steps owing to etching of the surface during its irradiation and the absence of aggressive media.

The photoetching mechanism involves formation of active products in the polymeric matrix during photolysis of polyhalogenated organic compounds and reaction of these products with the metal surface [2].

The feasibility of etching is determined by the ability of the metal to form stable halides upon irradiation [3].

The necessary conditions for all photosensitive systems are photolysis of the etching agent with a high quantum yield, high thermal stability under these conditions, and compatibility of the components.

Solid-phase photoetching of the copper surface finished to the 14th grade was studied with the aim of producing reflecting diffraction grating with the line depth no less than 0.1 μm. Photosensitive compositions containing polyvinyl chloride resin and various photosensitizing agents were developed. The samples thermostated at 25±2°C were irradiated with a DRSh-250 lamp through a quartz phototemplate. The line depth on the copper surface was measured with an MII-4 microinterferometer after removal of the polymeric film and photoetching products.

Solid-phase etching strongly depends on the thickness of the polymeric film. The thicker the film, the faster the process but worse the resolution. Therefore, we studied how the polyvinyl chloride concentration in the casting solution C_{PVC} affects the thickness of photosensitive films l:

C, g ml^{-1}	l, μm
0.10	18.5
0.09	15.0
0.08	12.0
0.07	9.0
0.06	7.5
0.05	6.5
0.04	5.5

The films with the optimal thickness (8–15 μm), allowing formation of a sharp image without side etching, were prepared at the polymer concentration ranging from 0.07 to 0.09 g ml^{-1}.

Most of photosensitive polymers contain C–C, C–O, C–N, and C–Hlg bonds whose energy does not exceed 420 kJ mol^{-1} [4]. Since the energy of UV quanta is enough for homolytic rupture of these bonds, photolysis of these polymers almost always involves generation of radicals. Various organic and inorganic halogen-containing compounds used as photosensitive components are presented un Table 1. Inorganic additives have virtually no effect on the solid phase photoetching, probably because of poor compatibility with the polymeric matrix of the photosensitive layer. Bromoform, tetrachloro-9-octylcarbazole (TCOC) [5], and phenothiazine with *p*-toluenesulfonyl chloride are the most effective organic additives.

Etching of the inorganic surface depends also on the nature of solvent used for photosensitive film cast-

* (τ) Etching time.

ing. We found that 1,1,2,2-tetrachloroethane (TCE) and bromoform increase the line depth during photoetching, whereas dioxane and toluene have no effect on it (Table 1, 2). This fact can be explained as follows. A small amount of the solvent is retained in the polymeric film dried at 70±2°C for 4 h. The C–Hlg bonds in 1,1,2,2-tetrachloroethane and bromoform are cleaved on exposure to UV radiation with generation of free radicals. Reactions of these radicals with each other or with the photolysis products of polyvinyl chloride yield Hlg_2 and HHlg which, in their turn, react with the copper surface:

$$\text{—CH}_2\text{—CH(Cl)—CH}_2\text{—CH(Cl)—} \xrightarrow{h\nu} \text{—CH}_2\text{—}\dot{\text{C}}\text{(Cl)—CH}_2\text{—CH(Cl)—} + \text{H}^\bullet,$$

$$C_2H_2Cl_4 \xrightarrow{h\nu} Cl^\bullet + C_2H_2Cl_3^\bullet,$$

$$Cl^\bullet + Cl^\bullet \rightarrow Cl_2,$$

$$H^\bullet + Cl^\bullet \rightarrow HCl,$$

Table 2. Solvent effect on the line depth on the copper surface*

Solvent	PVC, g	Line depth, μm
TCE	0.9	0.07
	0.7	0.06
Dioxane	0.9	0.05
	0.7	0.05
Toluene	0.9	0.05
	0.7	0.05
Bromoform	0.9	0.08
	0.7	0.06

* Exposure time 240 min, irradiation with a DRSh-250 lamp, solvent volume 10 ml.

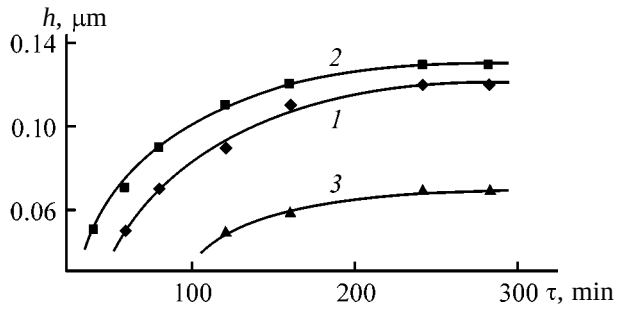
$$Cu + HCl \rightarrow CuCl + 1/2H_2,$$

$$Cu + Cl_2 \rightarrow CuCl_2.$$

The line depth on the copper surface depends on the exposure time. This dependence for samples **XVII**, **XXI**, and **XXIX** (Table 1) is shown in the figure. The exposure time should be no shorter than 240 min irrespective of the composition of the photosensitive mask. On longer irradiation the line depth does not increase owing to degradation of the polymeric film and decrease in the concentration of the etching agent on the copper surface.

The products of copper photoetching were removed from the copper surface with a mixture of *N*,*N*-dimethylacetamide and acetoacetic ester (1 : 1 volume ratio) and analyzed by reactions with diethyldithiocarbamate and potassium hexacyanoferrate [6]. We found that the main products of copper photoetching are copper(I) chloride and copper(II) chloride. This is confirmed by the fact that the absorption bands of these products appear in the range (780–800 nm) similar to that in the spectra of a mixture of copper(I) and copper(II) chloride in these solvents (800–820 nm).

Thus, we propose the following scheme for solid-phase photoetching of the copper surface with photosensitive polymer coatings.



Line depth on the copper surface *h* as a function of the exposure time τ: (*1*) **XVII**, (*1*) **XXI**, and (*3*) **XXIX** (for compositions, see Table 1).

$$D \xrightarrow{h\nu} D^*,$$

$$D^* + PVC \rightarrow PVC^* + D,$$

$$PVC^* \rightarrow Cl^\bullet + PVC,$$

$$PVC + Cl^\bullet \rightarrow HCl + PVC,$$

$$Cu + HCl \rightarrow CuCl + 1/2H_2,$$

$$Cl^\bullet + Cl^\bullet \rightarrow Cl_2,$$

$$Cu + Cl_2 \rightarrow CuCl_2,$$

where D and PVC denote photosensitizer and polyvinyl chloride, respectively.

CONCLUSIONS

(1) Solid-phase photoetching of copper surface with photosensitive compositions based on polyvinyl chloride was studied. Solvents for polyvinyl chloride were found that, being partially retained in the polymeric matrix after evaporation, increase the etching depth owing to an increase in the concentration of etching agents on the copper surface.

(2) The dependence of the etching depth of the copper surface on the time of irradiation of the photosensitive layer was revealed.

(3) Photosensitizing additives to the polyvinyl chloride matrix, allowing photoetching of the copper surface at a depth of no less than 0.1 μm, were chosen.

(4) The composition of photoetching products was determined. The mechanism of photoetching of the copper surface with photosensitive polymeric coatings was proposed.

CHEMISTRY OF FOSSIL FUEL

Molecular Oxygen and Oxygen- and Nitrogen-Containing Compounds in Diesel Fractions of West-Siberian Oil

Received July 30, 2001

Abstract—Heteroatomic compounds in middle-cut (200–360°C) distillates of West-Siberian oil were identified by gas chromatography–mass spectrometry.

The composition of diesel frtactions boiling in the range from 160–200 to 360°C is complex, and the existing analytical procedures do not allow complete identification of the components, especially of heteroorganic (N-, S-, and O-containing) compounds. The most studied components of diesel fractions are alkanes, isoalkanes, isoprenoids, and naphthene and aromatic hydrocarbons [1].

In this work we showed that in fractions boiling at higher temperatures than benzine the content of methane hydrocarbons (oils of grades A and B) decreases, the content of branched hydrocarbons increases, and isoprenoids appear in significant amounts. As for naphthenic hydrocarbons, their structure becomes more complex in going from benzine to diesel fractions; in particular, the number of rings in the molecule increases to 2–3.

Aromatic hydrocarbons of the diesel fraction consist of homologs of benzene, naphthalene, and, in part, phenanthrene and anthracene. Also, hybrid compounds are present, containing, along with one or two aromatic rings, also one or several naphthene rings. Primarily these are indane and tetralin derivatives. In going from the benzine to diesel fractions, the number and length of alkyl substituents in aromatic compounds increase, as well as the number of rings in the molecule; in particular, tricyclic condensed aromatic hydrocarbons (phenanthrene derivatives) appear.

Heteroorganic compounds of the diesel fraction are oxygen-, sulfur-, and nitrogen-containing derivatives of the above-mentioned hydrocarbons.

The oxygen-containing compounds are mainly mono- and dibasic petroleum acids and phenols (dimethyl-, trimethyl-, and methylethylphenols) [2].

Sulfur-containing compounds of the diesel fraction are sulfides (thiacyclanes) and thiophene derivatives. The content of thiols and disulfides in the diesel fractions is low.

Nitrogen-containing compounds of the diesel fraction are mainly derivatives of pyridine, quinoline, and, to a lesser extent, aniline. Very small amounts of porphyrins can be present. On the whole, it is desirable to obtain more detailed information on the composition of oxygen- and nitrogen-containing compounds of the diesel fraction in various stages of commercial refining of a mixture of West-Siberian crude oils at the Kirishinefteorgsintez Production Association, Limited Liability Company.

EXPERIMENTAL

Molecular oxygen dissolved in diesel fractions (sample nos. 1–5[1]) was determined chromatographically.

Hydroperoxide in diesel fractions were determined iodometrically [3].

Heteroorganic compounds were concentrated with a Diapak silica gel cartridge (BiokhimMak, Moscow).

[1] Diesel fractions (five samples) were taken March 28, 2001, from L-24/6 and L-24/2000 installations of the Kirishinefteorgsintez Production Association. Sample nos. 1–3 were supplied from the Parex installation (200–300°C fraction) to the L-24/6 installation and were taken from the 225 reservoir in the feed pumping line (sample no. 1), at the outlet of the TsN-2 feed pump (sample no. 2), and at the outlet of the TsN-4 feed pump (sample no. 3). Sample nos. 4 and 5 (200–360°C fraction) were taken from the L-24/2000 installation at the inlet of the N-201 feed pump (sample no. 4) and at the line of pumping into reservoir 261 (sample no. 5).

1070-4272/01/7411-1950$25.00

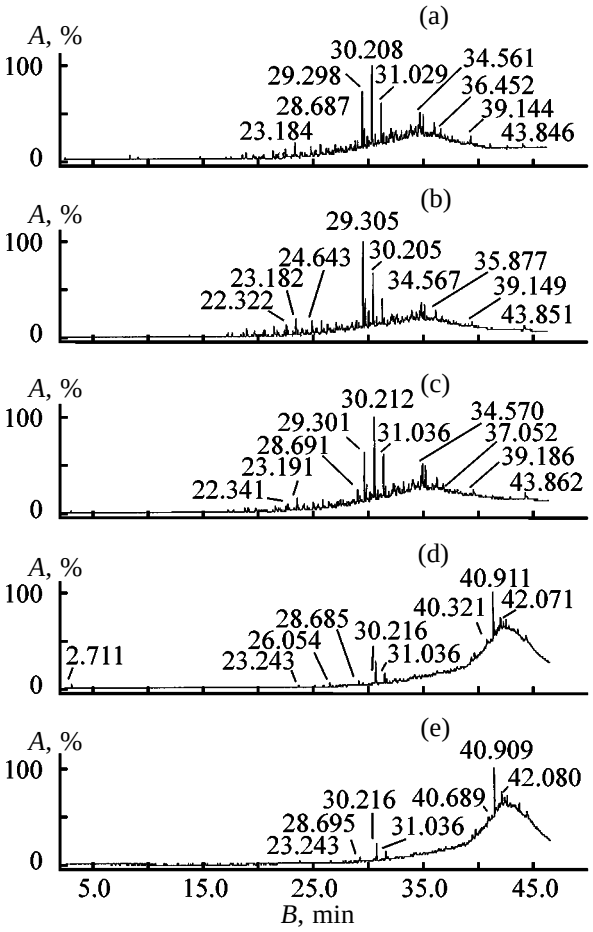

Fig. 1. Chromatograms of extracts of diesel fractions. (*A*) peak intensity and (*B*) retention time; the same for Fig. 2. Sample no.: (a) 1, (b) 2, (c) 3, (d) 4, and (e) 5.

The cartridge was washed with *n*-hexane, and 100 ml of a diesel fraction sample was passed. Then the cartridge was repeatedly washed with *n*-hexane and dried in a nitrogen flow. The extracted O- and N-containing compounds were eluted from the cartridge with 5 ml of methanol. The methanol extract was evaporated in a nitrogen flow to 1 ml and analyzed by GC–MS.

Mass-spectrometric analysis of diesel fuel extracts was performed with an MD 800 device (Fisons, the United States). The components of the diesel fuel extracts (five samples) that gave separate or partially overlapping chromatographic peaks were identified using MassLab and AMDIS software with an electronic library of the mass spectra. The programs provided for calculation of the direct and inverse similarity parameters of the experimental and reference mass spectra. When identifying individual compounds, we took into account the general parameters characterizing the similarity between the mass spectra of the discovered compounds and reference mass spectra from the library, the identity of the molecular ions in the mass spectra being compared, the similarity between the relative intensities of the major peaks in the mass spectra being compared (difference by no more than 20–30%), and the results obtained by running the expert block of the AMDIS program. These criteria allow identification of individual compounds or group identification.

The content of dissolved molecular oxygen in the analyzed samples varied from 0.7×10^{-3} to 1.8×10^{-3} M, namely: sample no. 1, 1.8×10^{-3}; no. 2, 1.1×10^{-3}; no. 3, 1.4×10^{-3}; no. 4, 0.76×10^{-3}; and no. 5, 0.72×10^{-3} M). Samples are not saturated with oxygen; the oxygen solubility in them is 2×10^{-3} M.

The concentration of hydroperoxides is low: sample nos. 1 and 2, below detection limit (5×10^{-5} M); no. 3, 1.3×10^{-4}; and nos. 4 and 5, 7×10^{-5} M. That is, the diesel fractions are not appreciably oxidized. The extent of oxidation increases in the course of storage and use of the diesel fuel.

The chromatograms of the extracts of the heteroatomic compounds from the diesel fractions (sample nos. 1–5) are shown in Fig. 1.

The identified heteroorganic compounds corresponding to the major peaks in the chromatograms are listed in the table. The corresponding peak numbers are indicated in the chromatograms (Fig. 2).

Thus, in diesel fractions we detected diverse oxygen- and nitrogen-containing organic compounds C_6–C_{18}: alcohols and ketones of the paraffin and naphthenic series, alkylphenols, pyridines, quinolines, and possibly other nitrogen-containing heterocyclic compounds.

In the mass spectra we detected no peaks, even on the trace level, characteristic of carboxylic acids; these compounds, apparently, appear in diesel fuel on storage, at higher extents of oxidation.

The total content of oxygen-containing compounds in various samples of diesel fuels, as estimated from data in the table and peak areas in the chromatograms of the extracts, is very low: $(0.5–6.1) \times 10^{-4}$%. This value is considerably lower than their content in gasolines in the course of production (0.002–0.004%) [3–5] and in A-76 gasoline "in the initial state before storage" (an equivalent parameter, content of acetone-soluble resins, is 1.9 mg ml^{-1}, or 0.003% [6]). Thus, data on the quantitative content of oxygen-containing organic compounds and on their qualitative composi-

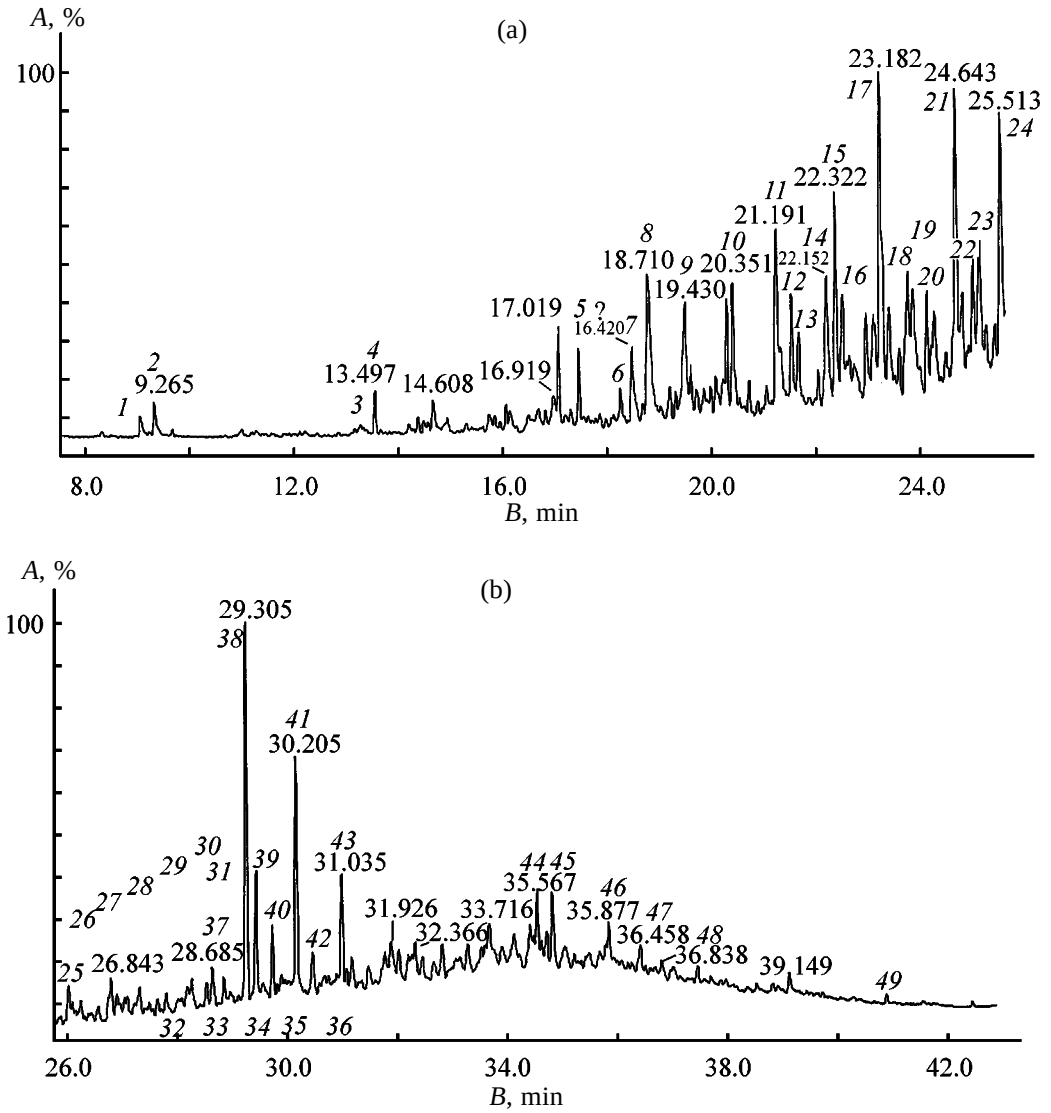

Fig. 2. (a) Initial and (b) final sections of the chromatogram of the diesel fraction extract (sample no. 2). For peak identification, see table.

tion (lack of acids), in combination with the results of determination of molecular oxygen and hydroperoxides, correspond to a certain, very low ("natural") extent of oxidation of hydrocarbon components of oil. It is notable that in diesel fuels the content of phenols relative to nonaromatic oxygen compounds is higher than in gasolines, which can considered as a stabilizing factor.

Diesel fuel sample nos. 1–3 are similar in composition and contain practically all the oxygen compounds mentioned in the table. Sample nos. 4 and 5 are wider-cut fractions, the total weight fraction of oxygen compounds in them is lower by a factor of 4–12; in these samples, the lowest-boiling compounds of those mentioned in the table are absent. Also, these samples contain no cyclohexylidenecyclohexanone (or isomeric naphthenic ketone), which is the major component in sample nos. 1–3 and is presumably formed by condensation of cyclohexanone.

At the same time, the identified nitrogen-containing compounds are present in all the samples in approximately equal amounts [$(1.5–3.6) \times 10^{-4}$% in total], comparable wtih the content of oxygen compounds in sample nos. 1–3 (see table). The composition of nitrogen-containing compounds in sample nos. 1–3 somewhat differs from that in sample nos. 4 in 5. In the first three samples the major components are those with the molecular weight of approximately

230, most probably, pyridine and/or quinoline derivatives (see table and Figs. 2a, 2b, peaks *41*, *43*; the compound corresponding to peak *41* may also contain oxygen). These two compounds are present in approximately the same amounts in the wider-cut fractions (sample nos. 4, 5), but in this case the major component is that corresponding to peak *49* (see table and Fig. 2b), most probably C_8-alkylquinoline (molecular weight 241).

It should be noted that the presence of pyridine and quinoline derivatives in the samples agrees with published data on the composition of middle-cut oil distillates.

CONCLUSIONS

(1) Diesel fuel samples from installations L-24/8 and L-24/2000 of the Kirishinefteorgsintez Production Association in the course of their processing are not saturated with molecular oxygen. Their oxygen content is lower than that of samples of the main gasoline components (reformer naphthas) and in commercial gasoline.

(2) A total of 43 heteroatomic compounds (O- and N-containing) present in diesel fractions of a commercial mixture of West-Siberian crude oil were identified. These are paraffinic and cycloparaffinic alcohols and ketones, alkylphenols with one or two alkyl (C_1–C_5) substituents, pyridine and quinoline derivatives, and probably some other nitrogen-containing heterocyclic compounds.

(3) The total content of oxygen-containing compounds in the examined diesel fuel samples is lower than in commercial gasoline.

BRIEF COMMUNICATIONS

Study of Co–Mn–O- and Li–Co–Mn–O-Containing Layers Synthesized by Successive Ionic Layer Deposition on Silica Surface

L. B. Gulina, V. P. Tolstoi, and I. V. Murin

St. Petersburg State University, St. Petersburg, Russia

Received December 7, 2000; in final form, March 2001

Abstract—The possibility for preparing $Co_3MnO_x \cdot nH_2O$ and $LiCo_3MnO_x \cdot nH_2O$ nanolayers by successive ionic layer deposition was examined. The resulting layers were studied by X-ray photoelectron spectroscopy, UV–Vis diffuse reflection spectroscopy, Fourier transmission IR spectroscopy, atomic absorption spectroscopy, ellipsometry, and X-ray powder diffraction.

The aim of this work was to synthesize nanolayers of double cobalt and manganese oxide, doped with Li^+ ions, by successive ionic layer deposition. This compound is known to be used in lithium batteries as cathode material [1].

EXPERIMENTAL

The synthesis was carried out by the ionic layer deposition described in [2] using cobalt and manganese salts. The Li^+ ions were introduced by impregnation from 0.1 M $LiNO_3$ solutions in alcohol. An excess of the lithium salt was washed out with the solvent from the surface. The supports were silica gel (Merck-60, specific surface area 360 $m^2\ g^{-1}$) and wafers of single-crystal silicon ⟨100⟩. Before the synthesis all the supports were subjected to the standard treatment [3].

The resulting layers were studied by X-ray photoelectron spectroscopy, UV-Vis diffuse reflectance spectroscopy, Fourier transmission IR spectroscopy, and powder X-ray diffraction. The X-ray photoelectron spectra were obtained on a Perkin–Elmer-5400 spectrometer using MgK_α exciting radiation. The quantitative content of each element in a layer was evaluated by the standard technique [4] accurate to within 10%. The diffuse reflectance spectra were recorded on a Perkin–Elmer Lambda-9 spectrophotometer at a scanning rate of 50 nm min^{-1} and a 2 nm slit program. The Fourier transmission IR spectra were recorded on a Perkin–Elmer-1760 IR spectrometer by means of 50 scans at 4 cm^{-1} resolution. The lithium and manganese content in a layer synthesized was determined by atomic absorption spectroscopy. For this purpose a weighed sample of silica gel with the layer synthesized was treated with concentrated sulfuric acid and thoroughly washed with distilled water. Proportions of elements in the filtrate were determined by atomic absorption technique on an AAS-1 spectrometer in propane–air flame. A hollow cathode lamp (wavelength 279.48 nm) was used to determine manganese contents. Lithium was determined in the emission mode at a wavelength of 640.78 nm. The error of these determinations did not exceed 5%. The layer thickness was measured on an ellipsometer with an incidence angle of 45° and light wavelength of 632.8 nm. The X-ray patterns of silica gel samples with the layers synthesized were obtained on a DRON-3.0 diffractometer using CuK_α radiation (recorder tape velocity 2400 cm h^{-1}, rate of sample rotation 2 rpm, current 18 mA, and voltage 36 kV).

The diffuse reflection spectra of Co–Mn–O-containing nanolayers formed on the silica surface by the layer deposition reactions are given in Fig. 1, which shows that the intensity of the absorption band in the range of 300–700 nm, and hence the layer thickness, increases as the number of deposition cycles is increased.

The thickness of synthesized layers on the surface of single-crystal silicon was monitored by ellipsometry. The layer thickness was found to increase linearly with the number of successive ionic layer deposition cycles, a layer with a thickness of 0.49 nm being formed in each successive cycle.

The X-ray photoelectron spectrum of the layer syn-

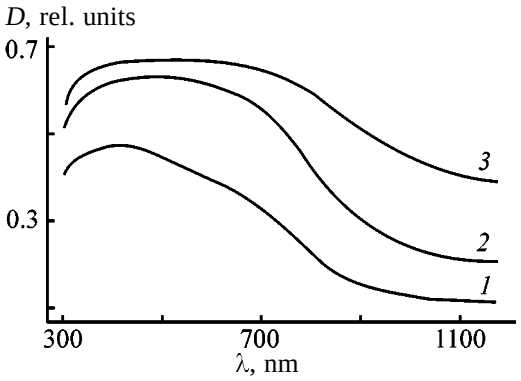

Fig. 1. Differential (against the initial silica gel) UV–Vis diffuse reflection spectra of Co–Mn–O-containing layers synthesized on the silica gel surface. (*D*) Optical density and (λ) wavelength. Number of successive ionic layer deposition cycles: (*1*) 1, (*2*) 3, and (*3*) 5.

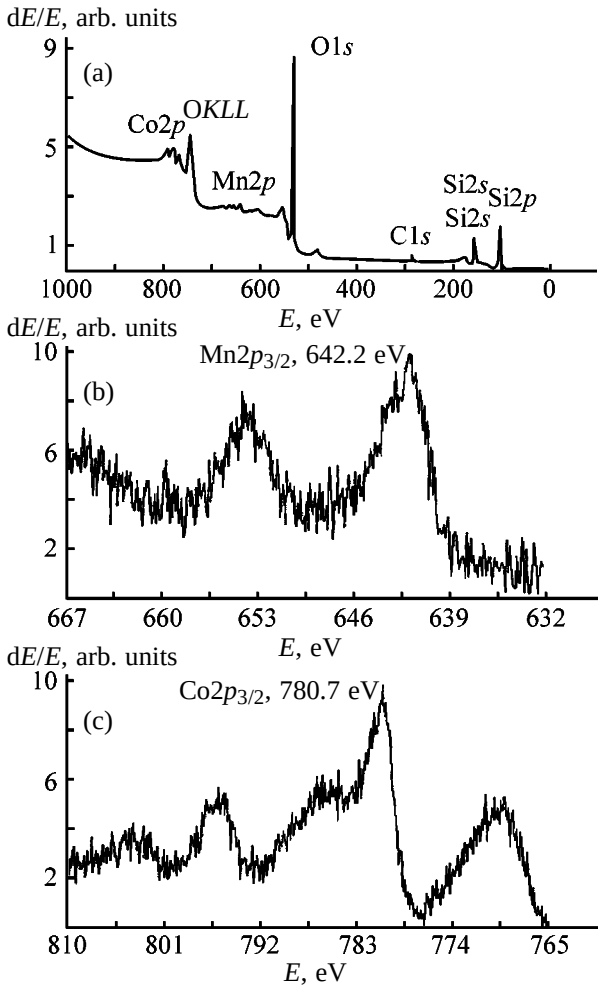

Fig. 2. X-ray photoelectron spectrum of a Co–Mn–O-containing layer synthesized on the silicon surface by 30 successive ionic layer deposition cycles: (a) total spectrum, (b) cobalt range, and (c) manganese range. (d*E*/*E*) Peak intensity and (*E*) binding energy.

thesized on the silica gel surface by 30 successive ionic layer deposition cycles (Fig. 2) contains bands with the maximal binding energies of 780.7 and 642.2 eV related to 2*p* electrons of Co and Mn, respectively [4]. According to the X-ray photoelectron spectra, the oxidation state of manganese in the compound is +4. As for the oxidation state of cobalt, examination of the relevant reference data shows that the band maxima of Co^{2+} and Co^{3+} ions are close to each other. However, the ratio of the intensities in the X-ray photoelectron spectrum indicates that the Co : Mn ratio in the layer is 3 : 1. This is an indirect evidence for the existence of Co^{3+} ions, as, according to the synthesis procedure [2], the layer is formed as a result of a redox reaction in the layer of Mn^{7+} and Co^{2+} ions adsorbed on the surface. In this case manganese is reduced from the oxidation state +7 to the state +4, which means that three electrons from three Co^{2+} ions participate in the reduction.

By the data of X-ray powder analysis, the layer synthesized was amorphous; however, its X-ray pattern contains a weak peak at $2\theta = 22.56°$ corresponding to CoOOH [5].

The data of X-ray photoelectron spectroscopy and X-ray powder analysis are in good agreement with the data of Fourier transmission IR spectroscopy (Fig. 3). Thus, in the range 1500–1400 cm^{-1} of the spectrum there are absorption bands of the bending vibrations of O–H bonds in a metal hydroxide, most likely in CoOOH, and the band with a maximum at 605 cm^{-1} corresponding to β-MnO_2 [6]. The spectrum also contains a broad band in the range 4000–3000 cm^{-1} (not shown in Fig. 3), corresponding to the O–H stretching vibrations in OH groups and water molecules transferred from solution into the layer.

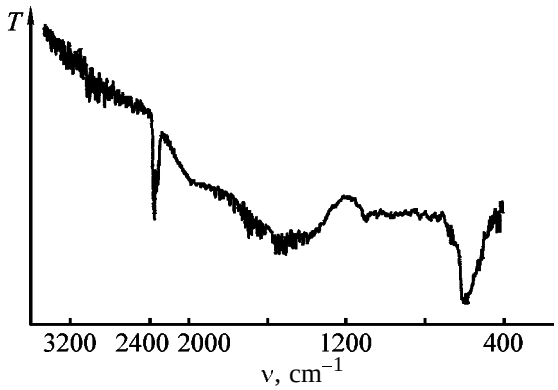

Fig. 3. Fourier transmission IR spectrum of a Co–Mn–O-containing layer synthesized on the surface of single-crystal silicon by 30 successive ionic layer deposition cycles. (*T*) Transmission and (ν) wave number.

Analysis of the synthesized layer containing hydrated manganese oxide $MnO_2 \cdot nH_2O$ and cobalt hydroxide CoOOH reveals incorporation of Li^+ ions [7]. The lithium content was determined by atomic absorption spectroscopy, which showed that the Li : Mn ratios after one, five, or ten cycles are the same (1 : 1). According to the X-ray powder analysis, the resulting layer is amorphous.

CONCLUSION

The composition of Co–Mn–O- and Li–Co–Mn–O-containing nanolayers can be described as $Co_3MnO_x \cdot nH_2O$ and $LiCo_3MnO_x \cdot nH_2O$, respectively, and the thickness of the layers can be precisely specified by the number of layer deposition cycles.

Electrodeposition of Palladium–Zinc Alloy from the Ammonium Chloride–Na_2EDTA Electrolyte

S. V. Kabanov and Yu. P. Perelygin

Penza State University, Penza, Russia

Received April 26, 2001

Abstract—The influence of the electrolysis regime and electrolyte composition on the cathodic current efficiency by the palladium–zinc alloy and on the alloy composition was studied.

Coatings with alloys of palladium and a number of metals have found application owing to lower consumption of noble metal and enhanced physicomechanical and chemical properties [1]. A metallurgical palladium–zinc alloy is a complex system consisting of a solid solution at a zinc content of up to 6% and of a few chemical compounds at higher zinc contents [2]. In this work wee examined electrodeposition of the palladium–zinc alloy, which was not studied previously.

Electrodeposition was performed from the ammonium chloride–Na_2EDTA solution in a 100-ml glassy rectangular bath using permanent graphite anodes. Zinc in the alloy was determined by complexometric titration after separating palladium in the form of palladium dimethylglyoximate [3].

The influence of the electrolysis conditions and electrolyte composition on the cathodic current efficiency (CE) by the alloy and the alloy composition were studied in a solution containing (g l^{-1}) palladium chloride 20 (in terms of metal), zinc oxide 5 (in terms of metal), ammonium chloride 20, and Na_2EDTA 40. The temperature was 20°C, current density, 0.5 A dm^{-2}, and pH 9.

As the zinc concentration in the electrolyte is increased, its content in the coating increases and the CE by the alloy decreases.

Zn concentration in solution, g l^{-1}	2	3	4	5
Zn content of the alloy, %	2.7	4.1	5.5	7.8
Cathodic CE by the alloy, %	98	98	98	96

The dependence of the relative content of the alloy metals on the relative concentration of their ions in the electrolyte is described by the equation [4]

$$\log\frac{[Pd]}{[Zn]} = 0.4 + 1.16\log\frac{[Pd^{2+}]}{[Zn^{2+}]}.$$

The correlation coefficient of the equation is 0.993.

At the zinc concentration in the electrolyte increased to 10 g l^{-1}, the CE by the alloy decreases from 96 to 33% and the zinc content in the alloy increases from 7.8 to 31%. Decreasing palladium concentration in the electrolyte under the similar conditions results in the deterioration of the deposit quality.

The influence of the current density, temperature, and pH was studied in an electrolyte with a zinc concentration of 5 g l^{-1}. At the current density increased from 0.25 to 1.25 A dm^{-2}, the CE by the alloy decreases from 96 to 83% and the zinc content in the alloy, from 18 to 4.5% (Fig. 1, curves *1* and *2*, respectively). At higher current densities the coating quality gets worse. As the temperature is increased from 10 to 40°C, the CE by the alloy grows from 74 to 98%

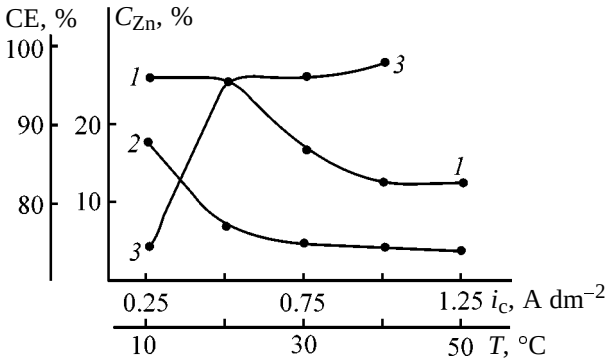

Fig. 1. (*1, 3*) Current efficiency CE by the alloy and (*2*) zinc content of the alloy C_{Zn} vs. (*1, 2*) cathodic current density i_c and (*3*) temperature T.

1070-4272/01/7411-1958$25.00

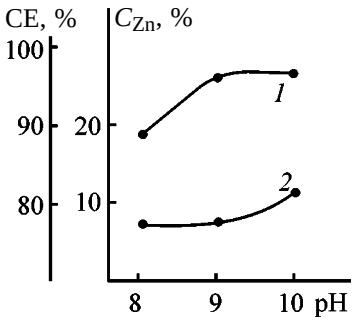

Fig. 2. (*1*) Current efficiency CE by the alloy and (*2*) zinc content of the alloy C_{Zn} vs. pH.

(curve *3*), with the alloy composition virtually unaffected and the coating quality improved. With solution pH varied from 8 to 10 the CE increases from 88 to 96% (Fig. 2, curve *1*) and the zinc content in the alloy, from 7.5 to 11% (curve *2*). In this case, the deposit quality is unaffected.

Stirring of the electrolyte with a magnetic stirrer decreases the CE by the alloy from 96 to 88%, with the zinc content in the alloy slightly increased (from 7.8 to 8.5%).

Increasing the ammonium chloride concentration in the electrolyte from 20 to 80 g l^{-1} does not affect the alloy composition. The increase in the Na_2EDTA concentration from 30 to 40 g l^{-1} inconsiderably increases the cathodic CE by the alloy (from 92 to 96%) and does not affect the alloy composition. At lower Na_2EDTA concentrations the deposit quality gets worse.

Thus, for the deposition of semilustrous alloy coatings with the zinc content from 3 to 8%, we can recommend an electrolyte containing (g l^{-1}) palladium oxide 20 (in terms of metal), zinc oxide 2–5 (in terms of metal), ammonium chloride 20, and Na_2EDTA 30–40, with pH 9. The optimal conditions of deposition are 20°C and the current density, 0.5 A dm^{-2}. Under these conditions the CE by the alloy is 92–96%. In the course of the process, to compensate for exhaustion of the components, the electrolyte composition should be adjusted with palladium chloride and zinc oxide and its pH, with an ammonia solution.

The study by method [5] of the transient electrical resistance of the alloy coatings with a zinc content of 7.8% showed that, with the load on the contact increased from 0.5 to 3 N, the transient resistance decreases from 0.044 to 0.026 Ω. Apparently, this is due to the depression of a passivation film and increase in the contact area. At a 1 N contact load the transient electrical resistance surpasses that of pure palladium coating (0.028 and 0.015 Ω, respectively). This result is ascribed to the growth of the alloy electrical resistance and to a greater tendency to passivation of the alloy-coated surface.

As the coating thickness is increased from 10 to 20 μm, the microhardness of the alloy coating containing 7.8% zinc increases from 258 to 321 kg m^{-2}, i.e., to a value exceeding 1.2–1.5 times that for pure palladium coating.

Effect of Methods Used to Fabricate the Combined Matrix of Air Electrode on Its Electrical Characteristics

M. O. Danilov and N. V. V'yunova

Vernadsky Institute of General and Inorganic Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received July 3, 2001

Abstract—Electrochemical characteristics of electrodes based on a combined matrix obtained in two ways: by successive electrochemical deposition of polyaniline and electrolytic manganese dioxide and by mechanical mixing of these components, were studied.

Electrically conducting polymer polyaniline (PAN), obtained by electrochemical synthesis from aniline, is used as cathode material for chemical power cells with salt electrolyte [1–4]. Its synthesis and electrochemical properties were described in [1, 5]. Previously, it has been shown that the working voltage can be raised by addition of electrochemical manganese dioxide (EMD) to the combined matrix of the air electrode [6].

The aim of the present study was to analyze the effect of methods of EMD introduction into a comined PAN-based matrix on the electrochemical characeristics of air electrodes in prototype zinc–air chemical power cells.

The air electrode comprised a hydrophobic and an active layer. The active layer is a combined matrix based on PAN, EMD, and carbon fiber. Two ways to introduce EMD were studied: mechanical mixing and electrochemical deposition of manganese dioxide onto a finished electrode, with or without preliminary deposition of PAN. The electrochemical deposition of EMD was done using a standard solution based on manganese(II) sulfate and sulfuric acid. PAN was deposited from sulfuric acid solutions of aniline. The current used in anodic synthesis of manganese dioxide and PAN was 5 mA cm^{-2} per apparent surface area of the electrode. The electrolysis duration was chosen depending on the amount of substance to be deposited. When the EMD layer was electrochemically deposited onto a preliminarily formed PAN layer, the deposit was uniform and homogeneous. If first EMD and then PAN were deposited, the obtained PAN coating was nonuniform and contained groups of clusters. The clusters were removed and ground after washing and drying. If the mass of PAN was insufficient after this procedure, then the ground powder was pressed onto the electrode. The amount of deposited substance was determined gravimetrically after washing and drying at 110°C before and after substance deposition.

Electrodes were fabricated by pressing in the form of pellets 3 cm in diameter. The hydrophobic layer of mass 0.4 g was the same in all electrodes. It was composed of 75% acetylene black and 25% FD-4D fluoroplastic emulsion in terms of dry substance. The active layer compositions are presented in the table. The compositions differ in the methods by which EMD and PAN are introduced into the combined matrix and in the order in which their layers are deposited in the case of electrochemical introduction

Compositions of the active layer of the combined matrix in the air electrode

Composition no.	Component	Mass, g	Method of EMD and PAN introduction
1	PAN	0.46	Mechanical mixture
	CF*	0.14	
2	PAN	0.32	
	EMD	0.14	
	CF	0.14	
3	PAN	0.32	Electrochemical deposition
	EMD	0.14	of EMD on a layer of PAN
	CF	0.14	on CF
4	PAN	0.32	Electrochemical deposition
	EMD	0.14	of PAN on a layer of EMD
	CF	0.14	on CF

Current–voltage characteristics of air electrodes based on combined matrices obtained by (*1*) depositing PAN onto carbon fiber, (*2*) mechanical mixing of components, (*3*) depositing EMD onto PAN layer on carbon fiber, and (*4*) depositing PAN onto EMD layer on carbon fiber. (*U*) Voltage and (*I*) current density. Digits at curves correspond to matrix composition numbers in the table.

of the components. The procedure used for electrochemical tests was described in [6].

The figure shows dependences of the voltage on the working current density for air electrodes in a prototype chemical power cell based on their combined matrices. The compositions of these matrices are presented in the table. Analysis of the obtained characteristics shows that the highest current densities can be achieved with a combined matrix obtained by mechanical mixing of PAN deposited onto carbon fiber with EMD (see figure, curve *2*). The electrode matrix obtained by depositing EMD on a PAN layer on carbon fiber gives better characteristics (curve *3*) than that prepared by depositing PAN onto an EMD layer preliminarily deposited on the carbon fiber (curve *4*). This difference in characteristics is due to the fact that the coating obtained by depositing PAN onto EMD is nonuniform and cluster-like because of the low electrical conductivity of the EMD layer. In depositing EMD onto a PAN layer, the electrical conductivity of the latter is high and uniform over the surface, with the result that the coating quality is high in this case. The electrical characteristics of such an air electrode are better than those of an electrode fabricated by depositing PAN onto EMD, but worse than the characteristics of an electrode formed by mechanical mixing of the components. This is presumably due to PAN surface blocking by EMD in deposition of EMD onto PAN, resulting in that not all EMD and PAN particles interact with one another. Mechanical mixing of the components results in more uniform intermixing of EMD and PAN particles, with nearly all particles interacting with one another and the electrical characteristics improved.

Thus, it is shown that the electrical characteristics can be improved through interaction between PAN and EMD only by creating a homogeneous matrix of PAN and EMD with uniform particle distribution. Electrochemical deposition of PAN and EMD layers fails to ensure their uniform distribution at any succession of the layers. This goal can be obtained by mechanical mixing.

Electrochemical Regeneration of Polishing Electrolytes of Chromium-Containing Steels

V. V. Bakaev, E. A. Fedorov, and V. N. Flerov

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received August 2, 2001

Abstract—A diaphragm-separated electrolysis method was used for regeneration of spent phosphoric–sulfuric acid solutions for electropolishing of chromium-containing steels (12Cr18Ni10Ti, 40Cr13, and others). The process regime and the cathode materials were optimized.

In a number of processes [1, 2], electrochemical polishing (ECP) is an irreplaceable method for treatment of the surface of metallic parts, but its applicability is impeded by the lack of practically acceptable methods for regeneration of spent ECP solutions. The previous sorption method [3] using activated carbons for regeneration of spent polishing electrolytes is relatively cheap and simple, but sometimes it is accompanied by considerable loss of concentrated solutions (from 20 to 40 vol %).

In the course of ECP of chromium-containing steels there occurs anodic dissolution of their components. The strongest negative effect on the polishing properties of phosphoric–sulfuric acid (PS) electrolyte of ECP is produced by the iron(III) ions [3]. When more than 25 g l^{-1} of these ions is present, the degree of polishing decreases by 20%, and at Fe^{tot} > 70–72 g l^{-1} (Fe^{tot} is the total concentration of Fe ions), the solution performance is lost completely [3]. The Cr(III) and Cr(VI) ions present in ECP electrolyte did not deteriorate the polishing quality.

In this work, we studied electrochemical regeneration of spent ECP electrolytes of chromium-containing steels including cathodic reduction of Fe^{3+} ions followed by removal of iron compounds from the catholyte by freezing the latter in the form of iron(II) sulfate monohydrate sparingly soluble in the PS electrolyte [4].

EXPERIMENTAL

Spent PS electrolyte for ECP of chomium-containing steels (12Cr18Ni10Ti and 40Cr13) was regenerated electrochemically in an organic glass electrolyzer with its anode and cathode spaces separated by an acid-resistant microporous plastic diaphragm of lead batteries. The ratio of anolyte to catholyte volumes was maintained at 1 : 5 [5]. The anode was made of lead, and the cathode, of lead [5] or (and) fibrous carbon material (FCM) with a specific surface area of up to 500 – 600 cm^2 cm^{-3} and a ratio of anode to cathode areas $S_a : S_c = 1 : 10$ [6]. Regenerated (or model) solution fed into the cathode space of the electrolyzer had the folloring initial composition: H_3PO_4 10 M, H_2SO_4 4 M, Fe^{tot} 50 g l^{-1}, $Fe^{3+} : Fe^{2+} = 4 : 1$, and Cr^{tot} 7–9 g l^{-1}. Into the anode space, a 20% solution of H_2SO_4 was fed.

The cathodic current density (per geometric surface) was varied within 1–10 A dm^{-2}. At each current density the similar quantity of electricity (22 A h per 1 l catholyte) was passed through the solution. After purification, the solution was analyzed photocolorimetrically for the content of Fe^{2+} and Fe^{3+} ions [7]. The degree of metal ion extraction from the electrolyte (%) was determined by the formula

$$\eta = (C^i_{init} - C^i_{fin})/C^i_{init} \times 100,$$

where C^i_{init} and C^i_{fin} are concentrations of the ith metal ion in the solution before and after regeneration, respectively.

The current efficiency (CE, %) of the cathodic reduction of Fe^{3+} to Fe^{2+} and the specific power consumption W (W h) were calculated by the equations

$$CE = (C^{Fe}_{init} - C^{Fe}_{fin})V_{cath}/Q q^{Fe} \times 100,$$

$$W = QU_{av}/(C^{Fe}_{init} - C^{Fe}_{fin})V_{cath},$$

where Q is the passed quantity of electricity (A h), q^{Fe} is the electrochemical equivalent of Fe^{3+} ion re-

1070-4272/01/7411-1962$25.00

duction (g A^{-1} h^{-1}), C_{init}^{Fe} and C_{fin}^{Fe} are the Fe^{3+} ion concentrations in the solution before and after regeneration, respectively, and V_{cath} is the catholyte volume (l).

During electrochemical regeneration of solutions for ECP of chromium-containing steels, the following reactions can occur on the cathode:

$$Fe^{3+} + e \rightarrow Fe^{2+}, \quad E_0 = 0.771 \text{ V}, \qquad (1)$$

$$Cr_2O_7^{2-} + 14H^+ + 6e \rightarrow 2Cr^{3+} + 7H_2O, \quad E_0 = 1.36 \text{ V}, \qquad (2)$$

$$2H^+ + 2e \rightarrow H_2. \qquad (3)$$

In the solution bulk (mainly in the near-cathode space), the Cr^{6+} ions are reduced to Cr^{3+}:

$$Cr_2O_7^{2-} + 6Fe^{2+} + 14H^+ \rightarrow 2Cr^{3+} + 6Fe^{3+} + 7H_2O, \qquad (4)$$

Reactions (2)–(4) lead to undesirable power consumption for the conversion of Fe^{3+} ions in the catholyte.

Reactions (2) and (3) are electrocatalytic, with their rate dependent on the cathode material, electrolyte composition, and electrolysis conditions (the observed trends can strongly vary in such concentrated solutions as polishing electrolytes). At the same time, reactions (1) and (4) are mainly diffusion-controlled. When two redox systems (Cr^{6+}/Cr^{3+} and Fe^{3+}/Fe^{2+}) are present in a solution, their redox potentials become closer. This may be due to the differently controlled processes and to reaction (4) occurring in the near-cathode space of the solution.

It was unreasonable from the economical standpoint to use monolithic lead cathodes because of prolonged regeneration. If the operation time of the chromium-plating solutions is 280–300 A h l^{-1}, then at bulk and cathodic current densities of 1.1 A l^{-1} and 0.5 A dm^{-2}, respectively, the time of cyclic operation of a regeneration bath with monolithic Pb cathodes reaches 14 h, i.e., a 124 A h l^{-1} charge must be passed to decrease by 32% the Fe^{tot} concentration in a solution.

A considerable intensification of the electrochemical regeneration was attained using FCM cathode instead of monolithic lead cathode. A strong increase in the actual working surface area of such cathodes allowed the bulk regeneration current density to be increased considerably without marked decrease in the cathodic current efficiency by the Fe^{3+} reaction.

The dependences of the regeneration parameters

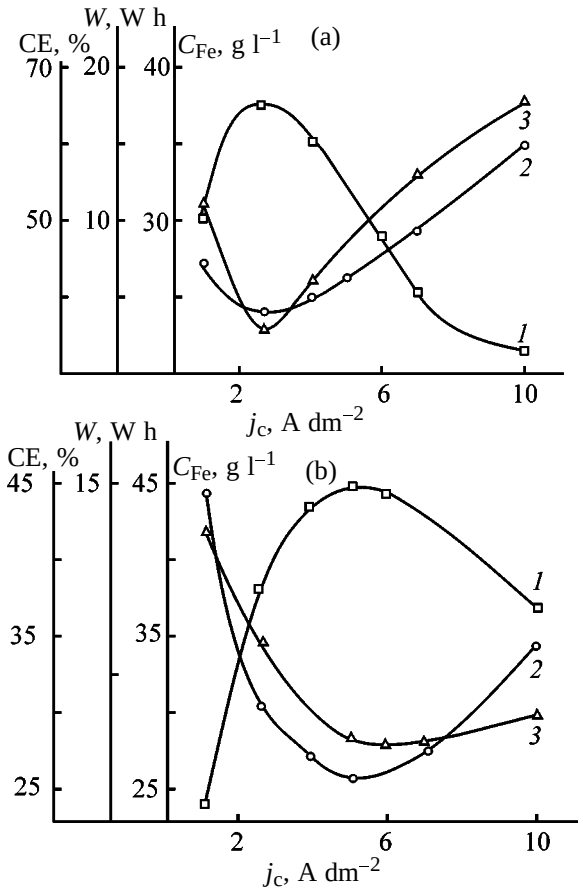

Fig. 1. (*1*) Current efficiency CE, (*2*) power consumption *W*, and (*3*) iron concentration C_{Fe} vs. cathodic current density j_c. Initial solution: H_3PO_4 10 M, H_2SO_4 4 M; Fe^{tot} 50 g l^{-1}, and Cr^{tot} 7–9 g l^{-1}. Steel: (a) 40Cr13 and (b) 12Cr18Ni10Ti.

were taken for actual spent PS solutions of ECP of 40Cr13 and 12Cr18Ni10Ti steels with the initial concentration of Fe^{tot} ions of 50 g l^{-1} (Fig. 1). For steels of the first brand, the final concentration of Fe^{tot} ions decreases with increasing cathodic regeneration current to j_c = 2–3 A dm^{-2}, when the current efficiency by the target reaction is maximal (Fig. 1a). A more marked effect with CFM cathodes was observed in regeneration of spent solutions of ECP of 12Cr18Ni10Ti steels. In this case, the optimal regeneration current density was about 5 A dm^{-2} (Fig. 1b). The effect was higher by approximately one order of magnitude than with monolithic Pb cathodes at virtually the similar specific power consumption.

The measured dependences of the total iron concentration on the quantity of electricity per liter of electrolyte at optimal regeneration cathodic current densities of ECP of 40Cr13 and 12Cr18Ni10Ti steels (Fig. 1) showed that at the low quantity of the passed electricity (up to 10–20 A h l^{-1}) the efficiency of

current utilization for exhaustive purification of ECP solution to remove noxious impurities (iron salts) is determined by the amount of the $FeSO_4 \cdot H_2O$ solid phase separated from the solution in a crystallizer cooled to 277–270 K. Crystallization of the solid iron(II) salt was accelerated by dosed addition into the solution of 0.05–0.25 M of finely crystalline potassium sulfate (seed). The degree of Fe^{tot} recovery from the solution with FCM cathodes was 45–54% at a power consumption of 5.2–7.5 W h per gram of extracted iron(II) salt. After separation, iron(II) salt can be used for technical purposes.

In the course of regeneration, the anolyte composition of the regenerator varied slightly owing to the high acidity of the solutions (large transport numbers of H^+ cations) and slow anion migration, which did not noticeably affect the overall regeneration process during a few cycles. After regeneration, the ECP solution added with a new portion of adamantane (1 g l^{-1}) [3] acquired additional polishing power corresponding to the passage of 240–260 A h l^{-1} of electricity.

CONCLUSIONS

(1) Solutions for ECP of chromium-containing steels can be regenerated electrochemically by cathodic reduction of noxious impurity [iron(III) salts] in a diaphragm-separated regenerator. As a cathode, we recommend to use fibrous carbon material, allowing regeneration of the solutions to be accelerated 5–10-fold.

(2) The contributions of the main reaction of cathodic reduction of Fe^{3+} ions and the side reactions of Cr(VI) reduction and H_2 evolution were studied. The stage of freezing of the $FeSO_4 \cdot H_2O$ solid phase from the catholyte of the regenerator was considered.

Abstract—A method for recovery of heavy metals (Fe, Zn, Cu, Cr, Ni, Pb, Co) from excess activated sludge is proposed, based on substitution of heavy metals in the cells of microorganisms by calcium after introducing poorly soluble calcium salts into the system at 6–37°C.

Industrial wastewater generally contains high concentration of heavy metals. Occasionally, this concentration approaches tens milligrams per liter. In biological treatment of such wastewater or its mixtures with residential wastewater at a treatment plant heavy metals are accumulated by microorganisms of activated sludge [1].

Utilization of excess activated sludge, contaminated with heavy metals, as an organic fertilizer for farming or raw material for biosynthesis of various useful products becomes impractical. Disposal by incineration is rather expensive, requiring thorough cleaning of waste gases. By virtue of these factors excess activated sludge is often simply stored in sludge sites. With time the amount of excess sludge increases, which requires steadily growing areas for its storage. Correspondingly increases the heavy-metal contamination hazard for the environment. According to the estimates of some German companies, the cost needed for utilization of excess activated sludge by drying with subsequent disposal approaches 450–800 DM per ton dry substance; by warehousing, 600 DM; and by incineration, 800–1200 DM. If the utilization method provides the use of excess sludge in farming, the cost may be reduced to 250–300 DM per ton dry substance. Therefore, the problem of treatment of excess sludge to remove heavy metals is an issue of the day.

According to the existing regulations, the maximal permissible concentrations of heavy metals in excess sludge for use as a fertilizer in farming are as follows (mg kg^{-1} dry substance): Ni 100, Pb 100, Cr 300, Cu 600, and Zn 1500 [2]. In excess activated sludge of a municipal treatment plant before filter presses (moisture content 96%), i.e., before sludge thickening to a 91% moisture content, the concentrations of heavy metals were as follows (mg kg^{-1} dry substance): Co 57, Pb 95, Ni 120, Cr 250, Cu 810, and Zn 1710 (data obtained in 1997). The metal concentrations in the aqueous phase (mg dm^{-3}) are as follows: Co 0.6, Pb 1.7, Ni 3.5, Cr 3.3, Cu 5.4, and Zn 1.8. After the filter presses the heavy metal concentrations in excess activated sludge increased to the following values (mg kg^{-1} dry substance): Co 66, Pb 160, Ni 220, Cr 320, Cu 1010, and Zn 2300; the concentrations in the aqueous phase increased also. Unconditionally, such a sludge is unsuitable as a fertilizer. The existing methods for recovery of heavy metals from sludge [3, 4] find no wide application, and by now the utilization of excess activated sludge is at a level of about 1.5% of the total all over the world.

We developed a method for recovery of heavy metals from excess activated sludge, based on substitution of heavy metals in the cells of microorganisms by calcium after introducing poorly soluble calcium material in the system at 6–37°C. Activated sludge was dried at 106°C to constant weight and analyzed for heavy metals on a Saturn atomic absorption spectrophotometer and a Perkin–Elmer spectrophotometer. Excess activated sludge before thickening (moisture content 96%) or after thickening (moisture content 90–92%) was mechanically mixed with poorly soluble calcium salts, $CaCO_3$ and $CaSO_4 \cdot 2H_2O$ (both of chemically pure grade), in the proportion 15 parts per 100 parts of sludge in open vessels for 3–6 h. The pH 6–8 of the aqueous phase remained unchanged throughout the experiment. The results obtained with various ratios of salt to sludge a and mixing times τ are given in the table.

The results show that heavy metals can be effec-

tively recovered from activated sludge using poorly soluble Ca salts (Figs. 1, 2). In some experiments the degree of recovery of Pb, Co, and Ni was over 90%.

The possible mechanism of recovery of heavy metals from sludge is as follows. The introduced poorly soluble calcium salts serve as a mineral support for immobilization of cells of the microorganisms and of enzymes produced by them, which activates and stabilizes all processes with participation of the enzymes, including biodegradation of the sludge organic matter, particularly that complexing heavy metals. Metals transferred to the aqueous phase, for example, in the form of hydroxo compounds, can be sorbed on the porous surface of the support. Calcium salts provide an increased concentration of Ca ions in the extracellular space, resulting in opening of the potential-dependent Ca^{2+} channels. Calcium ions penetrate into the intracellular space by these channels and also with the help of carrier proteins; the Ca concentration increases there, initiating opening of Ca-dependent K^+ and Na^+ channels, by which heavy metals can be discharged from the cells [6]. Furthermore, heavy metals can be replaced by calcium by ion exchange on the cell surface.

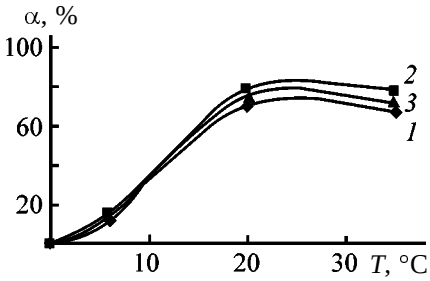

Fig. 1. Degree of recovery α of heavy metals from activated sludge before thickening with $CaSO_4 \cdot 2H_2O$ as a function of the temperature *T*: (*1*) Zn, (*2*) Cu, and (*3*) Ni; the same for Fig. 2.

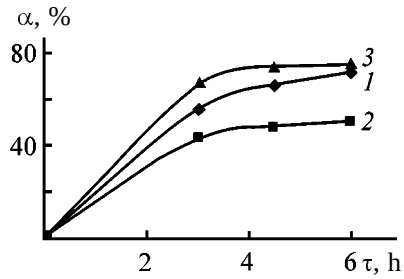

Fig. 2. Degree of recovery α of heavy metals from activated sludge before thickening with $CaSO_4 \cdot 2H_2O$ as a function of the process time τ.

One part of heavy metals, recovered from activated sludge in the form of sols, is sorbed on the solid material surface and the other part passes to the aqueous phase in soluble and colloidal forms. After phase separation by settling sludge goes to further processing into an organomineral fertilizer, as now meeting the requirements on the heavy metal concentrations. The calcium material can be recycled after washing with water or even without washing. Heavy metals,

concentrated in the aqueous phase to tens or even hundreds milligrams per liter, can be recovered by precipitation or sorption.

CONCLUSIONS

(1) Treatment of excess activated sludge to remove heavy metals is proved to be a pressing problem in the context of utilization of sludge as a fertilizer for farming needs.

(2) A method for recovery of heavy metals from excess activated sludge is proposed, based on substitution of heavy metals in the cells of microorganisms by calcium after introducing a poorly soluble calcium salt in the system.

(3) The results obtained demonstrate that heavy metals can be sufficiently effectively recovered from activated sludge using poorly soluble Ca salts. The resulting sludge meets the requirements on the residual heavy metal content for sludge suitable for use as a fertilizer for farming.

Abstract—Quaternary ammonium salts containing a 4-penten-2-ynyl group in addition to the alkoxycarbonylmethyl group are synthesized. The surface activity and antimicrobial action of the resulting compounds are studied.

The practical significance of surface-active quaternary ammonium salts (QASs) is caused by the possibility of their use as emulsion stabilizers [1–3] and antimicrobial agents [4, 5]. Quaternary ammonium salts containing acryloyl, acetylene, diene, and vynyl groups as polymerizable fragments are of interest as monomers for preparation of the corresponding polyelectrolytes [6].

Previously we synthesized micelle-forming QAS surfactants containing 5-methyl-2,4-hexadienyl group in addition to a hydrophobic radical [7] and demonstrated the antimicrobial activity of these compounds with respect to Gram-positive and Gram-negative microorganisms [8].

In this work we synthesized new surface-active ionic complex monomers and characterized their antimicrobial activity. Quaternary ammonium salts **I**–**IV** containing 4-penten-2-ynyl group (see table) were synthesized by the reaction

$$(CH_3)_2NCH_2C{\equiv}CCH{=}CH_2 + ROCOCH_2Cl \longrightarrow ROCOCH_2N(CH_3)_2CH_2C{\equiv}CCH{=}CH_2]^+Cl^-,$$

I–**IV**

where R = C_7H_{15} (**I**), C_8H_{17} (**II**), $C_{10}H_{21}$ (**III**), and $C_{12}H_{25}$ (**IV**).

The critical micelle concentration (CMC) of compounds **I**–**IV** was determined from the surface tension isotherms [9]. The foaming power was estimated from data on the foam stability *h* in aqueous QAS solutions as the ratio of the height of the foam column 5 min after its formation to the initial height [10]. It follows from the table that CMC and σ_{CMC} decrease and the foam stability increases with increasing length of the alkyl radical in the QAS molecules.

The antimicrobial activity of compounds **I**–**IV** was studied by the method of disinfection of cambric test objects [11] seeded with standard strains of *Staphylococcus aurous* (strain 906) and *Escherichia coli* (strain 1257). Cambric test objects were infected with a suspension of the indicated microorganisms, containing 2 billions cells per ml. The exposure was 5–30 min at 20°C.

The results obtained show that compounds **I**–**IV** possess the bactericidal action (see table), which depends on the length of the alkyl radical R. The maximal bactericidal action is shown by compound **IV**. A 0.2% aqueous solution of this compound kills *Escherichia coli* and *Staphylococcus aurous* in 5 min.

EXPERIMENTAL

Infrared spectra were registered on UR-20 and Specord 75-IR spectrometers in liquid paraffin or KBr, and the ^1H NMR spectra, on a Mercury-300 Varian spectrometer (300 MHz) in CD_3OD or $(CD_3)_2SO$ using TMS an internal reference.

Ammonium salts **I**–**IV** were synthesized as follows. An equimolar mixture of dimethyl(4-penten-2-ynyl)amine and the corresponding alkyl chloroace-

tate was allowed to stand for 5–6 days at room temperature. Th resulting waxy mass was washed several times with absolute diethyl ether and dried; mp of salt **IV** 33–34°C.

Along with complex multiplets typical of the alkyl groups of an ester, in the ^1H NMR spectra of compounds **I**–**IV** we found the following signals, δ (ppm): 3.41 s (6H, NCH_3), 3.90–4.10 s (2H, CH_2COO), 4.30–4.45 s (2H, $CH_2C{\equiv}$), and 5.93–6.00 m (3H, $CH{=}CH_2$).

The infrared spectra of compounds **I**–**IV** show the adsorption bands typical of the pentenyne and ester groups at 1645 ($CH{=}CH_2$), 2260 (C≡C), 1180, and 1740 cm^{-1} (COO).

CONCLUSIONS

(1) Surface-active ammonium salts containing a 4-penten-2-ynyl group in addition to the alkoxycarbonylmethyl group are synthesized. With increasing length of the alkyl radical the critical micelle concentration and σ_{CMC} decrease and the foam stability increases.

(2) The ammonium compounds obtained demonstrate a bactericidal action; their bactericidal activity depends on the length of the alkyl radical R in the ester group. The maximal bactericidal activity is shown by dodecylcarbonylmethyldimethyl(4-penten-2-ynyl)ammonium chloride.

BRIEF COMMUNICATIONS

Phosphorylation of 4-Oxo-2-thioxo-1,3-thiazolidine with $POCl_3$ in the Solid Phase

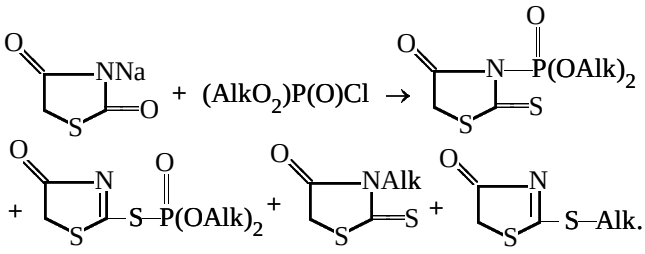
E. B. Aronova and A. I. Ginak

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received October 2, 2000; in final form, July 2001

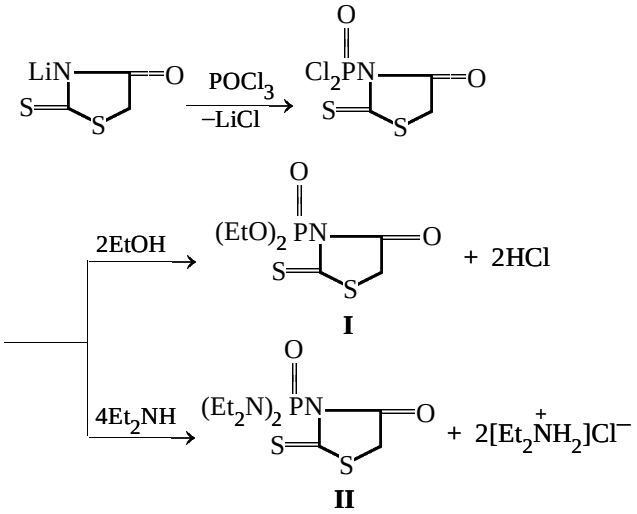
Abstract—Lithium salt of 4-oxo-2-thioxo-1,3-thiazolidine was phosphorylated with $POCl_3$.

Phosphorylation of heterocyclic compounds is of great interest as a route to valuable substances: curing agents, vulcanization rate regulators [1], herbicides, plant and microorganism growth regulators [2]. However, in most cases heterocyclic compounds are ambifunctional and in reactions with phosphorylating agents (phosphoric chlorides, $POCl_3$, phosphoramidic chlorides) yield difficultly separable isomer mixtures [3, 4], often contaminated with side alkylation products [5]:



Synthesis of phosphorylated heterocycles by cyclization of phosphorylated fragments also yields complex reaction mixtures from which the pure product can be isolated difficultly and with a low yield [6].

By varying the factors that affect the reaction pathways of ambident compounds (solvent, counterion, nature of substrate and reagent) [7], it is possible to increase somewhat the yield of the target product, but the impurities remain the same. At the same time, it is known [8] that nucleophilic substitution reactions of crystalline ambident substrates with gaseous electrophiles occur more selectively, often yielding only one of the isomers. We attempted phosphorylation of ambident thiazolidones in the system gas–solid. As substrate we took crystalline lithium salt of 4-oxo-2-thioxo-1,3-thiazolidine, and as phosphorylating agent, $POCl_3$. The reaction was performed in an electrically heated tubular reactor (1 cm diameter, 10 cm height) in which the temperature could be adjusted in the range 25–250°C. A mixture of $POCl_3$ vapor with an inert gas (nitrogen, argon) was passed through a fixed bed of the substrate. The reaction progress was monitored by thin-layer chromatography (TLC). After reaction completion, excess $POCl_3$ was blown off, and ethanol or diethylamine vapor was fed to replace the chlorine atom and obtain, respectively, diethyl 4-oxo-2-thioxo-1,3-thiazolidine-3-phosphonate **I** and tetraethyl 4-oxo-2-thioxo-1,3-thiazolidine-3-phosphonic diamide **II**:



The phosphorylation pathway was judged by the hydrolysis products of **I** and **II**. Phosphorylation of the nitrogen atom of the heteroring is confirmed by formation of 4-oxo-2-thioxo-1,3-thiazolidine. Hydrolysis of the hypothetical product formed by phosphorylation of the exocyclic sulfur atom would yield 1,3-thiazolidine-2,4-dione, but it was not detected.

4-Oxo-2-thioxo-1,3-thiazolidine was identified by TLC (Silufol UV-254, eluent acetone–hexane–acetic acid, 1 : 2 : 0.01) [7] and by comparison of its IR

ANNIVERSARIES

Andrei Georgievich Morachevskii (to 75th Birthday Anniversary)

On October 1, 2001, Andrei Georgievich Morachevskii, a known scientist working in the field of physical chemistry of metals and alloys and high-temperature electrochemistry, doctor of technical science, professor, honored scientist and technologist of the Russian Federation, head of Chair of Physical Chemistry at St. Petersburg Technical University, and deputy Editor-in-Chief of *Zhurnal Prikladnoi Khimii* was 75. He also accomplished 50 years of engineering, scientific, and pedagogical activities.

In 1950, A.G. Morachevskii graduated from Lensovet Technological Institute in Leningrad as a specialist in physical chemistry. In 1951–1953, he worked at enterprises of the Ministry of Interior. At the Krasnoyarsk plant of nonferrous metals he took direct part, under supervision of profs. Ya.I. Bashilov and R.L. Myller, in the development of a technology for electrolytic manufacture of rhodium.

He became a postgraduate student at Kalinin Polytechnic Institute in Leningrad (now St. Petersburg State Technical University) in December 1953; an assistant at the chair of physical chemistry at the same institute, in 1956; a docent at the same chair, in 1961; a professor, in 1970; and headed the chair of physical chemistry in 1973. He backed his candidate dissertation in 1957 and doctoral dissertation in 1969.

Andrei Georgievich has performed extensive investigations of thermodynamic and other properties of binary, ternary, and more complex metal systems in liquid and solid states. He studied in detail the thermodynamic properties of liquid alloys with strong interatomic interaction and revealed characteristic features of the concentration dependence of thermodynamic functions in these alloys. Morachevskii and co-workers were the first to study the thermodynamic properties of dilute solutions of alkali and alkaline-earth metals in various liquid–metal solvents and gave detailed recommendations on how to calculate the thermodynamic properties of ternary and more complex metal systems from data on binary subsystems. Morachevskii paid much attention in his works to computer simulation of thermodynamic properties of liquid metal systems with varied nature of component interaction and gave recommendations on compiling an appropriate database.

Morachevskii and co-workers studied the thermodynamic properties of a great number of chalcogenides and metal–chalcogen systems, developed new investigation techniques, studied equilibria between the chalcogenide and salt phases, and analyzed the interaction of sulfur and sulfides with molten salts. The thermodynamics and kinetics of alloying on liquid and solid electrodes and processes of joint discharge of impurities at liquid cathodes were studied in detail on various objects.

In cooperation with a number of institutions, Morachevskii took part in large-scale investigations in the field of manufacture of high-purity metals, production of alkali metals and their alloys, and development of new chemical power sources for various purposes. In recent years, the scientist has been paying much attention to creating an environmentally safe technology for processing of secondary lead and to new methods for refining of black lead.

In 1986, Morachevskii was awarded, as a member of a group of researchers, a State Prize of the Ukraine in science and technology for the study *"Physicochemical Foundations, Technology, and Industrial*

Implementation of Manufacture of Ultra-High-Purity Metals (Mercury, Cadmium, Zinc, Lead, Bismuth, Gallium, Indium, Thallium, Tellurium)."

The results of his studies have been reported in quite a number of monographs, including: *Elektrody sravneniya dlya rasplavlennykh solei* (Reference Electrodes for Molten Salts, Moscow: Metallurgiya, 1965, translated in the United States); *Zhidkie katody* (Liquid Cathodes, Tbilisi, 1978); *Fizikokhimiya i metallurgiya vysokochistogo svintsa* (Physical Chemistry and Metallurgy of High-Purity Lead, Moscow: Metallurgiya, 1991); *Natrii: Svoistva, proizvodstvo, primenenie* (Sodium: Properties, Manufacture, and Use, St. Petersburg: Khimiya, 1992); *Pererabotka vtorichnogo svintsovogo syr'ya* (Processing of Secondary Lead, St. Petersburg: Khimiya, 1993); *Elektrokhimiya svintsa v ionnykh rasplavakh* (Electrochemistry of Lead in Ionic Melts, St. Petersburg: Khimiya, 1994); and *Kalii: Svoistva, proizvodstvo, primenenie* (Potassium: Properties, Manufacture, and Use, Moscow: Ruda i Metally, 2000). Morachevskii wrote a large number of spacious reviews.

Together with staff member of his chair and specialists from other institutions, Morachevskii received more than 60 Inventor's Certificates; he was awarded a breastplate "Inventor of the USSR."

During his entire scientific career, professor Morachevskii has been paying much attention to preparation and publication of reference literature and to problems of scientific information. Under his editorship and with his supplements were published in translation three volumes of the Reference Book of Molten Salts (Leningrad: Khimiya, 1971, 1974). Also published were (together with I.B. Sladkov) reference books *Termodinamicheskie raschety v metallurgii* (Thermodynamic Calculations in Metallurgy, Moscow, 1985; supplemented edition 1993), *Fiziko-khimicheskie svoistva molekulyarnykh neorganicheskikh soedinenii* (Physicochemical Properties of Molecular Inorganic Compounds, Leningrad: Khimiya, 1987; translated into Japanese; supplemented edition 1996). Morachevskii took part in compilation of *Spravochnik po elektrokhimii* (Handbook of Electrochemistry, Leningrad: Khimiya, 1981, translated into Japanese). In 1957–1967 Morachevskii annually published reviews on electrochemistry of molten salts, which attracted much interest of specialists in russia and other countries. Morachevskii published in scientific journals more than 100 reviews of monographs, reference books, and textbooks of domestic and foreign authors.

During the years of his pedagogical activities, Andrei Georgievich wrote a great number of tutorials and developed a number of special courses. The book *Termodinamika rasplavlennykh metallicheskikh i solevykh sistem* (Thermodynamics of Molten Metal and Salt Systems, Moscow: Metallurgiya, 1987; translated into Polish) was highly appreciated by specialists and recommended for students specializing in physicochemical investigations of metallurgical processes. For students of the same specialty were written tutorials *Fizikokhimicheskie svoistva zhidkikh metallov i splavov* (Physicochemical Properties of Liquid Metals and Alloys, Leningrad: Leningr. Politekh. Inst., 1986), *Vysokotemperaturnaya elektrokhimiya* (High-Temperature Electrochemistry, Leningrad: Leningr. Politekh. Inst., 1986), etc.

Under Morachevskii's supervision, 47 candidate dissertations have been prepared and successfully backed, and this work is being continued now. Graduates from higher school institutions from all over the country were Morachevskii's postgraduate students, and they are teaching now in Vologda and Cherepovets, Volgograd and Vladikavkaz, Krasnoyarsk, Irkutsk, Ulan-Ude. Four lecturers of the chair backed their doctoral dissertation. Specialists from Poland, Germany, Czechoslovakia, Italy, and China have been trained at the chair. Morachevskii is a scientifically broad-minded person possessing deep knowledge in physical chemistry of metallurgical systems and processes, inorganic materials science, and applied electrochemistry. For a long time he was a member of specialized councils entitled to award the doctor-of-science degree at Leningrad State University and Mining Institute. More than 30 times he was an official opponent at presentations of doctoral dissertations in Moscow and St. Petersburg, Kiev and Sverdlovsk, Tbilisi and Alma-Ata.

Morachevskii carries out extensive scientific-organization work. Since 1980 he has been a member of the Editorial Board of *Zhurnal Prikladnoi Khimii* (deputy Editor-in-Chief since 1986) and a member of the Editorial Board of *Rasplavy* (Melts) journal. During many years he was a member of the editorial boards of *Izvestiya Vysshikh Uchebnykh Zavedenii: Tsvetnaya Metallurgiya* (Bulletin of Higher School Institutions: Nonferrous Metallurgy) journal and *Fiziko-khimicheskie issledovaniya metallurgicheskikh protsessov* (Physicochemical Studies of Metallurgical Processes) intercollegiate collection. Morachevskii took active part in the work of the Scientific Council of the Academy of Sciences of the USSR for physical chemistry of ionic melts and solid electrolytes, and headed a section of the Council. Also, he was a member of Scientific Councils of the Academy of Sciences of the USSR for chemical thermodynamics and ther-

mochemistry and for electrochemistry and corrosion. Morachevskii took part, as a member of the Organizing Committee, in preparing and holding All-Union Symposia on physical chemistry of ionic melts and solid electrolytes and on thermodynamics of metal systems; he is one of organizers of the regularly held Kola symposia on electrochemistry of less-common metals.

In recent years, Morachevskii has been paying much attention to the history of chemistry and chemical technology and published quite a number of works concerned with this subject matter.

Andrei Georgievich originates from a St. Petersburg professor's family, he is distinguished by high working capacity, sense of duty, and readiness to help colleagues, postgraduate students, and students.

The Editorial Board and Editorial Staff of *Zhurnal Prikladnoi Khimii* congratulate Andrei Georgievich Morachevskii on the jubilee and wish him sound health and further creative success.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Andrei Egorovich Pereverzev (to Centennial Birthday Anniversary)

In November 2001, Andrei Egorovich Pereverzev, a prominent scientist, excellent pedagogue, talented organizer and top manager, doctor of technical science, professor, honored scientist and technologist of the Russian Soviet Federative Republic and Tartar Autonomous Soviet Socialist Republic, founder and head of the chair of ammunition charging (1939–1972), and rector of the Technological Institute (1945–1946), would be 100.

Andrei Egorovich Pereverzev was born on November 29, 1901, into a poor peasant family. In 1918, when being 17, he joined Red Army as a volunteer.

Pereverzev created a scientific school that predetermined the development in the field of ammunition charging for many years and developed safe methods of formation and use of charges of various-purpose explosives. Many leading specialists and top industry managers were, and still are, his pupils.

In his work, Andrei Egorovich always strove for close relation of scientific research to the practical needs of the industry. He was a prominent scientist possessing a creative mind of researcher and combined pedagogic talent with organization abilities.

In the severe years of the World War II, Andrei Egorovich was appointed director of the Kazan Institute of Chemical Engineering (KKhTI) and simultaneously supervised important scientific research of great military value. By Andrei Egorovich's initiative, large workshop for charging of varied-purpose ammunition was organized.

After the war, Pereverzev, then director of LTI im. Lensoveta (Leningrad Technological Institute), much contributed to the reconstruction and consolidation of the Institute as a scientific and pedagogical center of Leningrad. Simultaneously, Andrei Egorovich continued his scientific activities. In 1947, he successfully backed his doctoral dissertation.

In 1926, Andrei Egorovich entered Leningrad Technological Institute and graduated as engineer in 1934. Then he worked as deputy director of the Institute, was a post-graduate student, backed his candidate dissertation, and, finally, organized in 1939 a chair of

technology of ammunition charging and headed it for 32 years. During this time, the chair became one of the leading chairs of LTI im. Lensoveta. The scientific interests of Andrei Egorovich started to take shape under the influence of Semen Petrovich Vukolov, professor of the Technological Institute and D.I. Mendeleev's pupil.

Under Pereversev's supervision, blend formulations based on high-power explosives and thermoplastic (thermoreactive) polymers were developed and introduced into practice. The formulations were used to create charges with controllable energy and performance characteristics. In particular, charges of unique design and power, formed by casting under pressure, were used for explosive pumping of chemical lasers. The same formulations were used to create thin-walled spherical charges and cumulative charges of various purposes.

Andrei Egorovich possessed unique creative intuition and was one of the first in the country to appreciate the potentialities of computers, which were widely used at his chair for calculating processes of article fabrication and thermodynamic processes occurring in explosion of explosive charges.

A particular place in this group of works is oc-

1070-4272/01/7411-1975$25.00

cupied by investigations aimed at the development of a continuous process for pressing of elongated charges from elastic and plastic explosives.

A prominent contribution to the technology of ammunition charging was made by Pereverzev's works concerned with the development of vibrational and pneumatic methods for mixing of explosives and blended solid propellants. These works laid foundations of the theory and gave methods for calculation of component mixing processes and demonstrated advantages of the vibrational and pneumatic methods for manufacture of explosive mixtures and solid propellants.

Being one of the leading scientists in the field of ammunition charging technology, Andrei Egorovich developed theoretical foundations of a number of processes and reported on this issue in his lectures and in the manual *Tekhnologiya snaryazheniya boepripasov* (Technology of Ammunition Charging).

Preverzev was the author of numerous scientific papers and recipient of Inventor's Certificates and patents in chemical technology. Under Andrei Egorovich's supervision, more than 70 candidate and several doctoral dissertations were prepared and backed. Andrei Egorovich trained numerous cadre of engineers, specialists in ammunition charging technology.

In 1999, St. Petersburg Technical Institute celebrated 60th anniversary of the foundation by professor Pereverzev of the chair of chemical power engineering. The main results of the research and pedagogical activities of the chair during this period of time were generalized. Particular emphasis was placed on the outstanding role played by Pereverzev in the creation of a scientific school.

During the time of its existence, the chair trained 1700 specialists, of whom 10 became doctors of technical science, and 175, candidates of science.

The history of the chair includes periods of varied significance; but its staff members always honestly and skillfully performed its main task: trained students, carried out research, and preserved and developed traditions of the institute, faculty, and chair, founded by Pereverzev.

Andrei Egorovich Pereverzev did everything in his power and gave all his knowledge for the welfare of the domestic science in order to improve the defensive capacity of the Motherland and train specialists in ammunition charging.

Russian Journal of Applied Chemistry, Vol. 74, No. 11, 2001, pp. 1977–1979. Translated from Zhurnal Prikladnoi Khimii, Vol. 74, No. 11, 2001, pp. 1913–1915.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Scientific, Pedagogical, and Public Activities of Professor N.N. Sokolov (to 175th Birthday Anniversary)

One of honorable places in the history of the domestic chemical science of the XIX century belongs to Nikolai Nikolaevich Sokolov, a talented scientist and pedagogue, organizer of scientific investigations, founder of the first Russian chemical journal.

N.N. Sokolov was born on December 13, 1826, in Yaroslavl province into a merchant's family. Having entered, when being very young, St. Petersburg University, he graduated from the then existing cameral department of the faculty of law, and later, in 1847, from the natural department with a candidate degree. At that time, chemistry was taught at the University by a known scientist and excellent pedagogue, A.A. Voskresenskii (1809–1880), who graduated in 1836 from the Central Pedagogical Institute in St. Petersburg and worked in 1836–1837 at the laboratory of J. Liebig (1803–1873) at Giessen University (Germany).

In 1848, to complete his education, Sokolov went abroad and, at first, also worked at Liebig's laboratory and carried out quite a number of investigations there. He, in particular, studied the behavior of creatinine in products of vital activity of herbivorous animals and birds. Together with A. Strecker (1822–1871), Liebig's co-worker, he synthesized hippuric acid, converted it into benzoglycolic acid, and for the first time obtained glycolic acid by its hydrolysis (*Ann. Chim.*, 1851). At the same place, at Giessen University, Sokolov studied crystallography and mineralogy under supervision of Prof. H.F. Kopp (1817–1892). Sokolov retained interest in crystals and minerals for his whole life. In 1852, Nikolai Nikolaevich moved to Paris and began investigations at the laboratory of Prof. C.-F. Gerhardt (1816–1856) who in his time (1836–1837) was taught by J. Liebig in Giessen. Charles Gerhardt and another French chemist, Auguste Laurent (1807–1853), made an outstanding contribution to the development of the atomic-molecular theory. In his book Introduction to Study of Chemistry by the Unitary System (1848), Gerhardt substantiated a novel concept of the molecule as an indivisible integrated system of atoms, "unitary system," and

clearly distinguished the concepts of atom, molecule, and equivalent. He established that radicals do not exist independently, being rather groups of atoms, whose combination forms molecules. Sokolov completely adopted these and other new, by that time, concepts of French scientists and, owing to him, chemistry was taught in Russia in the framework of the new scheme already in the late 1850s, earlier than in other countries, including France [1].

In Paris, Sokolov also worked at the chemical laboratory of Henri Regnault (1810–1878), an organic chemist, also a representative of Liebig's school, and a foreign corresponding member of the St. Petersburg Academy of Sciences (since 1848).

In 1854, Sokolov returned to Russia and started to work at the Mining School (Mining Institute since 1866; founded in 1773) in St. Petersburg as teacher of mineralogy and curator of the mineralogical museum. In 1855, on the instructions of the Mining Department he traveled across the Urals and exhibited much interest in minerals formed in metallurgical processes.

Н. СОКОЛОВА и А. ЭНГЕЛЬГАРДТА.

Augustin Thierry.

ТОМЪ I.

САНКТПЕТЕРБУРГЪ.

1859.

In 1857, he defended master of chemistry's dissertation in this field.

In 1857, Sokolov organized, together with A.N. Engel'gardt (1832–1893), the Russia's first private public chemical laboratory, at which all comers could perform investigations for a relatively small fee. Engel'gardt graduated from Mikhail Artillery College; in 1853–1865, he headed the chemical and foundry laboratories of the St. Petersburg Arsenal; in 1866–1870, he was a professor of chemistry at the St. Petersburg Agricultural Institute (transformed into Forestry Institute in 1877; later, Forestry Academy).

Sokolov and Engel'gardt's chemical laboratory existed for three years and was closed in 1860; the laboratory equipment was passed, without compensation, to St. Petersburg University, where Sokolov himself started to work, too.

In May 1859, Nikolai Nikolaevich successfully backed at St. Petersburg University his doctoral (Chem.) dissertation "Treatise of Hydrogen in Organic Compounds." The dissertation contained a vast experimental material and was a major contribution to the development of organic chemistry of fatty compounds. The author described for the first time synthesis of glyceric acid by glycerol oxidation, considered alcohol oxidation processes in general, and pointed to different functional features of hydrogen in organic compounds. As mentioned in memoirs of N.A. Menshutkin (1842–1907) [2], the concept of difference between hydrogen atoms is especially important. It was shown for the example of four acids: glycolic, β-hydroxypriopionic, lactic, and glyceric, that part of hydrogen atoms in hydroxy acids has acidic, and another part, alcoholic nature, with the relative amounts of these parts in the mentioned acids correctly determined.

In 1859, Sokolov and Engel'gardt started to publish Russia's first periodical in the field of chemistry: *Khimicheskii zhurnal N.N. Sokolova i A.N. Engel'gardta* (Chemical Journal by N.N. Sokolov and A.N. Engel'gardt). During the two years of its existence, 4 volumes containing 6 issues each were published. The journal published both original articles and abstracts in Russian of the most interesting works of foreign authors, reports on dissertation presentations, and other information of value for chemists. The journal, in particular, published Sokolov's extensive fundamental paper "On Modern Directions in Chemistry," the full text of his doctoral dissertation, experimental works of the leading Russian chemists D.I. Mendeleev (1834–1907), N.N. Beketov (1827–1911), A.M. Butlerov (1828–1886), and N.N. Zinin (1812–1880). To the first Russian journal was devoted Yu.S. Musabekov's work [3].

In September 1860, as a member of the Russian delegation together with Mendeleev, Zinin, A.P. Borodin (1833–1887), and other scientists, Sokolov took part in the First International Chemical Congress in Karlsruhe (Germany). The Congress clearly distinguished the fundamental notions of chemistry (those of molecule, atom, equivalent, and valence). Sokolov and Engel'gardt were members of the initiative group which organized the Congress.

In view of Mendeleev's going to a business trip abroad in 1860, Nikolai Nikolaevich was invited to St. Petersburg University as privatdocent, and then extraordinary professor, to deliver lectures in organic chemistry. Warm recollections of these lectures were written by Menshutkin [2], who studied at the university at that time. Sokolov managed to do much to expand the experimental facilities of the chemical laboratory at the university, but, unfortunately, because of deteriorated health, he had to go to southern Europe for treatment already in 1862.

The scientist continued his pedagogical and scientific activities at the end of 1864 in Odessa, where

Novorossiya University was opened at the beginning of 1865. In May of the same year, a chair of chemistry was organized at the university, and Sokolov was invited there as its first professor [4–6]. The chair conducted courses in inorganic, organic, and analytical chemistry. During his relatively short stay in Odessa (1864–1871), Sokolov, with gusto characteristic of him, created and provided with equipment the chemical laboratory at the university, making it the best in Russia, so that a new center of domestic chemical science emerged in Russia. The closest Sokolov's associate was A.A. Verigo (1837–1905), who became a docent in 1866, extraordinary professor in 1871, and head of the chemical laboratory at Novorossiya University in 1873. A known chemical school formed in Odessa, to which belonged, in particular, V.M. Petriashvili (1845–1908), S.M. Tanatar (1849–1917), P.G. Melikishvili (1850–1927), N.D. Zelinskii (1861–1953), and P.I. Petrenko-Kritchenko (1866–1944).

In Odessa, Sokolov performed a number of experimental studies. In particular, he continued studies of lactic acid, commenced in St. Petersburg. In 1871, Nikolai Nikolaevich left the chair of chemistry at Novorossiya University and returned, on completing his treatment, to St. Petersburg, where he started teaching at the Agricultural Institute in 1872, having replaced Engel'gardt at the chair of chemistry. This period of scientist's life was described in recollections of his closest associates P.A. Lachinov (1837–1891) and M.G. Kucherov (1850–1911) [7, 8].

Nikolai Nikolaevich Sokolov died on July 13, 1877, at the age of 51. The Russian Physicochemical Society, whose member Sokolov was from the time of its foundation, set up in 1880 the N.N Sokolov Prize to be awarded to Russian scientists for outstanding works in the field of chemistry. The prizes wee awarded till 1888. The first of these was awarded in 1882 to Menshutkin for his work in the field of chemical kinetics: "Effect of Isomerization of Alcohols and Acids on Formation of Esters." In 1883, the Sokolov Prize was awarded to G.G. Gustavson (1843–1908), professor of Peter's Agricultural and Forestry Academy in Moscow for studies of reactions involving organic compounds in the presence of aluminum halides. In 1885, the prize was awarded to M.G. Kucherov for the discovery and investigation of reactions between acetylene hydrocarbons and mercury compounds. In 1888, the prize was awarded for the last time to A.E. Favorskii (1860–1945) for the discovery and investigation of isomerization of acetylene hydrocarbons.

Detailed evidence concerning Sokolov's life and activities can be found in works by Musabekov [3, 9] and N.S. Kozlov [10]. His role in the development of domestic chemistry was discussed in a monograph by Yu.I. Solov'ev [11].

In a paper devoted to the history of the chair of chemistry at Leningrad University (1819–1939) [12], Academician V.E. Tishchenko (1861–1941) named Sokolov "one of the most talented Russian chemists, with his pupils having the warmest recollections of him." Sokolov's activities were highly appreciated by K.A. Timiryazev (1843–1920): "Hardly any other teacher... has been equipped with such a full knowledge of modern science, had such broad views, and demonstrated such exuberant versatile activities as N.N. Sokolov. Brilliant, ingenious, with a somewhat skeptical mind and implacable logic, he was a professor in the finest sense of the word" [10]. Nikolai Nikolaevich Sokolov can be rightfully regarded as one of the most prominent chemists of the second half of the XIX century.

BOOK REVIEWS

Utkin, N.I., *Proizvodstvo tsvetnykh metallov* (Manufacture of Nonferrous Metals),

Moscow: Intermet Inzhiniring, 2000, 442 pp.

The book published in the framework of the Federal Special-Purpose Program of book publishing in Russia is intended for specialists of widely varied professional skills, working at nonferrous metallurgical plants. The author covered a wide variety of problems concerning the theory and technology of manufacture of the most important nonferrous metals. The presented material is grouped into five sections. The first of these (pp. 9–112) contains general evidence, including description of the main methods and operations for dressing of ores of nonferrous metals, characterization of products and intermediates of metallurgical plants, preparation of raw materials for metallurgical processing, and problems of environment protection.

The second section (pp. 112–294) is devoted to metallurgy of heavy nonferrous metals: copper, nickel, lead, zinc, and gold. The third section (pp. 294–382) discusses processes used in manufacture of aluminum, magnesium, and titanium. The fourth section (pp. 382–417) presents evidence concerning the metallurgy of two less-common metals: tungsten and molybdenum. A small concluding fifth section (pp. 417–441) gives notion of the manufacture of a number of nonferrous metals (copper, aluminum, lead, and tin) and their alloys from secondary raw materials. The recommended bibliographic list (p. 442) includes the most important domestic publications in the field of nonferrous metallurgy, which have mainly appeared in the last 15–20 years.

With the publication assessed, on the whole, positively and account taken of the fact that this book is far from being the first concerned with manufacture of nonferrous metals, it seems appropriate to express some wishes. The presented material could be markedly enlivened by data on the scale of production of various nonferrous metals in Russia as a whole and at separate largest plants. In contrast to the recent times, such evidence is accessible now, being regularly published in our country and abroad. The book gives virtually no data of economical nature. Some materials presented by the author are markedly out-of-date and fail to reflect the present state of affairs. As a characteristic example can be mentioned data on lead consumption. In our opinion, the book contains insufficient amount of specific data concerning the largest plants of different branches of nonferrous metallurgy, such as, e.g., Norilsk combine or Bratsk aluminum plant.

Of noble metals, the author considered only gold, making absolutely no mention of platinum metals whose manufacture is most closely associated with processing of copper–nickel ores of the Norilsk deposit. The presented characteristics of the domestic ore raw materials are insufficient.

Admittedly, the quality of much of the illustrative material presented in the book is not too high. The book of such a level needs clear schemes not burdened with abundant minor details. Instead of, e.g., a general scheme illustrating the operation principle of the shaft furnace, the book presents its design with all details and dimensions (Fig. 98). The same refers to many other figures. It is hardly appropriate to use in material presentation such out-of-date terms as “vapor tension” or “dissociation tension.” The remarks made are, naturally, debatable and do not cast doubt upon the usefulness and high scientific level of the publication.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of Calcium Nitrate Purification

A. A. Fakeev and A. I. Sukhanovskaya

State Research Institute of Chemical Reagents and Ultrapure Chemical Substances, Moscow, Russia

Received September 25, 2000; in final form, March 2001

Abstract—Two methods of calcium nitrate purification were studied: crystallization from aqueous solutions and joint precipitation of impurities from aqueous solutions onto inorganic collectors (calcium hydroxide or carbonate and hydrated aluminum or zirconium oxides). The efficiency of purification of calcium nitrate solutions was studied and the purification coefficients were calculated for hydrated aluminum or zirconium oxides as collectors.

Calcium nitrate is widely used in metallurgical, chemical, and food industries, glass manufacture, agriculture, etc. [1].

In chemical industry, calcium nitrate is a key compound for preparing the most practically significant calcium products (carbonate, hydroxide, phosphate, chromate, oxalate, etc.) [2, 3].

In recent years, ultrapure calcium compounds (carbonate, phosphate, and fluoride) have found application in fabrication of optical fibers, optical glass, single crystals, and phosphors. This required the development of a method for deep purification of calcium nitrate, which is the most accessible raw material [2]. The great number of publications devoted to calcium nitrate purification stems from the necessity for preparing pure and ultrapure calcium salts.

The efficiency of crystallization purification of calcium nitrate can be estimated from data on phase equilibria in water–salt systems. Analysis of the solubility diagrams in the systems $Ca(NO_3)_2$–$M^{n+}(NO_3)_n$–H_2O, where M^{n+} is Sr, Ba [4], Be [5], Ni [6, 7], Ag [8], Cu(II) [9], Fe(III) [10], Co [11, 12], or Mn(II) [12], at 25°C indicates the lack of isomorphism (i.e., the systems are of simple eutonic type), and the apparent possibility of separating calcium nitrate and nitrates of the above metals. However, joint crystallization of nonisomorphous impurities is a much more complex process, since the quantitative characteristics of the component distribution at low concentrations of one of the components cannot be, as a rule, predicted solely on the basis of solubility diagrams [13]. It is this fact that made necessary prolonged and rather complex experimental studies.

Crystallization from aqueous solutions as a method for purification of calcium nitrate was proposed in [3, 14]. It was shown that double crystallization results in the removal of iron salts and makes the lead concentration 15–20 times lower.

The impurity distribution upon crystallization of calcium nitrate from nitric acid solutions has not been studied. However, by analogy with strontium and barium nitrates, this process seems to be efficient for calcium nitrate purification, with, however, the solubility of the compound being rather high (29.8 wt % in 40% HNO_3 at 25°C [4]). This necessitates treatment of large volumes of mother liquors and makes the technology more complex.

A way to purify 20% calcium nitrate solutions by precipitation of sparingly soluble metal sulfides at pH 4.5–5.0, addition of H_2O_2 at pH 7.6, and subsequent adsorption of impurities onto glass wool has been described [15]. The thus obtained product contains 5×10^{-6}–5×10^{-5} iron ions and 1×10^{-5} wt % manganese and heavy metal ions each.

Use of complexing reagents (sodium diethyldithiocarbamate [16], sodium salt EDTA [17], lumogallion IREA, and rubeanic acid [18]), with subsequent adsorption of the formed complexes, excess amount of complexing reagents, and products of their partial decomposition onto ion-exchange resins or activated carbon, is an efficient method for purification of calcium nitrate solutions. However, the described methods involve introduction of complexing agents, which makes necessary their thorough removal from the purified solutions and special pretreatment of sorbents (resin, carbon).

* K_{pur} is the purification factor for $Ca(NO_3)_2 \cdot 4H_2O$ crystals.

The high efficiency, especially at low component concentrations, and the feasibility of simultaneous removal of a great number of impurities make joint precipitation onto collectors a rather promising method for salt purification [19]. The joint precipitation of impurities from solutions of calcium nitrate has been studied with $CaCO_3$ [15, 16, 18, 20], $CaHPO_4$ [18], hydrated titanium dioxide [21], and other collectors. However, the technological aspect of these processes has been studied insufficiently, and data on the impurity distribution are lacking.

Extraction of 8-oxyquinolinate of heavy metals with chloroform [22] or with its mixture with isoamyl alcohol [23] from calcium nitrate solutions is an efficient method. However, this technique is complex and encounters considerable difficulties in removal of the residual amounts of organic substances from a purified solution.

Barium, strontium, iron, copper, and manganese ions can be removed from $Ca(NO_3)_2 \cdot 4H_2O$ by zone smelting (at ~42°C) [24].

The analysis of the presented data on calcium nitrate purification shows that the crystallization from aqueous solutions and joint precipitation of impurities onto inorganic collectors are the most promising methods.

The aim of the present study was to analyze the process of calcium nitrate purification.

EXPERIMENTAL

We studied two methods of calcium nitrate purification: crystallization from aqueous solutions and joint precipitation of impurities onto inorganic collectors.

The distribution of iron and cobalt (typical triply and doubly charged ion impurities) upon crystallization of calcium nitrate from aqueous solutions was studied using radioactive tracers. Into 75 ml of 40% aqueous solution of calcium nitrate [chemically pure grade, GOST (State Standard) 4142–77] was introduced ^{59}Fe iron or ^{60}Co cobalt isotope, and the mixture was thoroughly stirred for 2–3 h. The solution was evaporated on a water bath to obtain solid phase in varied yield and cooled under continuous agitation. The precipitated $Ca(NO_3)_2 \cdot 4H_2O$ crystals were carefully squeezed between two sheets of filtering paper to remove mother liquor. The specific activities were determined for the initial solution and squeezed crystals (upon dissolution in water).

The gamma radiation was recorded using a BDIS-3-05 sensor with a detector (thallium-activated sodium iodide) and a PS-2 counter unit. The accuracy of the radiometric measurements of activity was 2–3 rel.%. The purification factors for the crystals (the ratio of the crystal activities before and after crystallization) and the degree α of precipitation of the main substance into the solid phase during crystallization were calculated from the results of radiometric analysis [19].

Analysis of the obtained results shows that, with the yield of the $Ca(NO_3)_2 \cdot 4H_2O$ crystals increasing from 0.35 to 0.55, the purification factors for iron and cobalt impurity ions remain virtually unchanged (Table 1). Unfortunately, experiments on crystal washing could not be carried out owing to the considerable solubility of the salt in water and nitric acid [4]. The use of saturated aqueous calcium hydrate solution or organic solvents miscible with water used as washing liquid led to changes in the crystal mass even upon minor temperature fluctuations.

Apparently, the low degree of purification of $Ca(NO_3)_2 \cdot 4H_2O$ crystals to remove iron and cobalt impurities (Table 1) is due to occlusion of the mother liquor by crystals [14], which is confirmed by published data [10, 11].

The results obtained (Table 1) are accounted for by the high stability of the metastable supersaturated solutions, characteristic of calcium nitrate, and by changes in the crystal habitus, depending on the cooling rate [25]. This leads to changes in the crystal growth mechanism, facilitates formation of closed cavities and capillaries, and causes surface damage, which results in pronounced entrapment of mother liquor (purification factors are about the same at 55–60% yield).

Presently, the efficiency of solution purification onto collectors cannot be calculated theoretically. Therefore, the purification of calcium nitrate solutions

was studied experimentally. As inorganic collectors served calcium hydroxide, calcium carbonate, and hydrated oxides of aluminum or zirconium, which were precipitated in a solution being purified by addition of calculated amounts of aqueous solutions of sodium hydroxide, ammonia, or ammonium carbonate. The study was performed with use of radioactive tracers for the example of iron and cobalt impurities (^{59}Fe and ^{60}Co). To 50 ml of a 20% solution of calcium nitrate (chemically pure grade) were added solutions containing radioactive isotopes of the elements studied, the mixture was stirred, and a sample was taken for the radiometric measurements. Then, calculated amounts of a 20% aluminum nitrate solution (17-3 special-purity grade, [TU (Technical Specification) 6-09-3657–74] or a 20% solution of oxodichlorozirconium (chemically pure grade, TU 6-09-3677–74) were introduced into the solution to precipitate, respectively, hydrated oxide of aluminum or zirconium, and the solution pH, monitored by a pH262 pH-meter, was adjusted to 7–8 by gradual addition of 25% aqueous ammonia (17-4 special-purity grade, TU 6-09-3282–7) under agitation, and the mixture was stirred for 0.5–1.0 h. Calcium hydroxide and calcium carbonate were precipitated from the initial calcium nitrate solution by calculated amounts of 25% solution of NaOH [18-3 ultrapure grade; OST (All-Union Standard) 6-01-302–74] or 20% solution of ammonium carbonate (chemically pure grade, GOST 3770–75). The precipitated collectors were separated on a TsLN-2 centrifuge, and the purified solution was sampled for radiometric analysis. The methods for measuring the activity before and after purification and the procedures for calculating the purification factors are described above.

The preliminary estimates of the efficiency of inorganic collectors for purification of calcium nitrate solutions for the example of iron(III) and cobalt(II) impurities show (Table 2) that hydrated oxides of aluminum and zirconium are the most promising materials. Calcium carbonate is efficient as collector solely for purification to remove iron(III) impurity, in satisfactory agreement with published data [15, 16, 18, 20].

Comparison of the obtained results (Table 2) and published data, with account taken of accessibility and cost of collector-forming materials, shows the practicability of using aluminum hydroxide as collector for deep purification of aqueous calcium nitrate solution.

The obtained results show that heteronuclear hydroxo complexes of complex composition are formed in the nitrate systems Al(III)–M^{n+}–NO_3^-–H_2O [M^{n+} = Fe(III), Cr(III), Co(II), Ni(II), or Cu(II)] [26–28]. ESR spectroscopy revealed formation of three paramagnetic complexes in the system Al(III)–Fe(III)–NO_3^-–H_2O at low iron(III) concentrations and pH 7–10 [29]. Apparently, the forming heteronuclear hydroxo complexes of iron(III) and aluminum(III) of complex composition have a chain-like structure [28–30].

The processes of coprecipitation of impurities onto aluminum hydroxide as a result of heteronuclear complexation are of great practical importance and require further investigation.

2.0, pH 7–8	Co(II)	22750	650	35 ± 4

* Concentration (wt %): solution 20, impurities (1–5) × 10^{-4}; time of contact between solution and collector 0.5 h; temperature 25 ± 1°C.

Table 3. Quality of initial and purified calcium nitrate samples and the best foreign products (according to catalogues)

Sample	Content, $C \times 10^6$, wt %					
	Fe	Mn	Cu	Cr	Ni	Co
Laboratory:						
initial	200	50	70	50	20	5
purified	30	<5	6	4	<1	<1
Chemically pure grade, GOST 4142–77, Russia	100					
Aldrich, USA	40		10			
RPE, C. Erba, Italy	300		200			
Suprapur, E. Merck, Germany	5	1	1		1	1

were performed in laboratory. The conditions of the experiment are described above. The quality of the obtained samples was analyzed chemically and spectroscopically [31].

Comparison of the quality of the initial calcium nitrate samples and those purified by crystallization from aqueous solutions (Table 3) confirmed that this method is promising for preparing rather pure samples of the product.

CONCLUSIONS

(1) Purification of calcium nitrate by crystallization from aqueous solutions was studied using radioactive tracers. The purification factors were calculated. It was shown for the example of iron(III) and cobalt(II) impurity ions that the moderate values of the purification factors are due to occlusion of the mother liquor.

(2) The purification of aqueous calcium nitrate solutions by the coprecipitation of impurities onto inorganic collectors (calcium hydroxide, calcium carbonate, and hydrated oxides of aluminum or zirconium) was studied by the method of radioisotope tracers. The high efficiency of hydrated oxides of aluminum and zirconium was demonstrated.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

New Colloid Silicate Solutions for Restoration and Conservation of Stone Facades

V. I. Tarasov

Institute of Silicate Chemistry, Russian Academy of Sciences, St. Petersburg, Russia

Received March 12, 2001

Abstract—The kinetics of water absorption by samples taken from facades of buildings (marbled footing limestone, bricks, plaster), both in initial state and those treated with solutions of classical water repellents and new hydrophilic and hydrophobic colloid silicates, was studied, and the state of the initial material was assessed. Recommendations on how to stabilize stone and protect it from the destructive influence of the humid atmosphere are given.

The mechanism of disintegration of stone materials is well known [1–3]. Hydrophilic pores of the stone surface take up excess atmospheric moisture, favorable for life activity of bacteria promoting the dissolution of minerals constituting stone. The dissolved components may migrate and be deposited in pores as new formations when water evaporates or freezes as a result of atmospheric changes in the environment. The presence of alkaline or acid components in the liquid phase on the porous surface accelerates dissolution of minerals and structural disintegration of stone. For example, limestone building materials are carbonized in the course of time under the action of carbon dioxide contained in air. In addition, the carbonate-containing surface of stone used to build city monuments of architecture is continuously subject to the action of sulfur dioxide; the stone destruction is especially intensive in the presence of nitrogen oxides contained in industrial and exhaust gases [4].

An effective way to protect stone materials from the aggressive action of the atmosphere is to treat their surface with solutions of water-repellent organosilicon liquids [5, 6]. Silicone molecules penetrating into pores interact with minerals constituting the surface, imparting to it water-repellent (hydrophobic) properties. Water can penetrate into such pores only under pressure. The excess moisture is easily removed from stone pores. As a result, the frost resistance of the stone is improved, its heat conductivity decreases, and life activities of bacteria are terminated.

In the 1950s, a technique was developed [7] for modifying the facade surface of the Marble Palace and other historical monuments of St. Petersburg by treatment with a nonaqueous solution of trimethylchlorosilane:

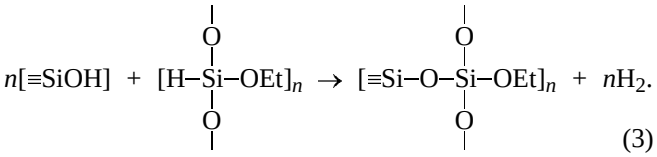
$$2CaCO_3 + 2(CH_3)_3SiCl \rightarrow Ca[OSi(CH_3)_3]_2 + CaCl_2 + 2CO_2. \quad (1)$$

The treated facades have retained up to now fresher appearance (natural color) as compared with other, untreated objects. However, organochlorosilane solutions have limited applicability because of their being toxic. Sodium alkyl siliconates (SAS), which are well soluble in water and low-toxic, are used for hydrophobization of building materials (including calcareous, silicate, carbonate, and sulfate materials) [6, 8]. The reaction of carbonate surface modification with SAS solution occurs to give sodium carbonate in solution:

$$CaCO_3 + 2NaOSi(OH)_2(C_2H_5) \rightarrow Ca[OSi(OH)_2(C_2H_5)]_2 + Na_2CO_3. \quad (2)$$

The longevity of the hydrophobic effect of such a surface layer does not exceed 2–4 years [9], since the alkali metal cation makes higher the solubility of components and favors their transport, which leads to development of a porous structure in the stone and its disintegration [10]. Poly(ethoxyhydrosiloxane) (PEHS) is used in the form of aqueous emulsions or nonaqueous solutions [5] for hydrophobization of concrete, roofing slate, and lime-sand and ceramic brick:

1070-4272/01/7412-1985 $25.00 © 2001 MAIK "Nauka/Interperiodica"



$$n[\equiv SiOH] + [H-Si(O)(O)-OEt]_n \rightarrow [\equiv Si-O-Si(O)(O)-OEt]_n + nH_2. \quad (3)$$

For calcium carbonates (marble, limestone), and especially for calcium sulfate (gypsum), PEHS solutions are inefficient as water repellents for the surface layer, compared with SAS solutions [6].

These circumstances stimulate a search for more effective silicate solutions for obtaining protective coatings on stone materials [11, 12].

The aim of the present study was to perform comparison tests of classical (SAS, PEHS) and new colloid silicate solutions in desulfurization and hydrophobization of stone materials in some buildings of the historical center of St. Petersburg.

EXPERIMENTAL

Experiments were done with typical stone material samples (footing materials, red brick and its binder, plaster), taken from facades of buildings in St. Petersburg along the Nevsky Avenue and Fontanka River embankment. These buildings had been in use under St. Petersburg conditions for more than 100 years and were not heated for several recent years in expectation of reconstruction. Samples of stone material were taken in the form of pieces with weight ranging from 20 to 100 g into plastic sachets, weighed in laboratory, and left to dry indoors (commonly for 3 days at 20°C and 50% relative humidity) to constant weight. A sample of each representative of a stone facade material included no less than 4–5 pieces for tests, treatment, and characterization. The phase composition of facade samples (and presence of calcium sulfate dihydrate) was determined by comparing X-ray patterns obtained on a DRON-2 instrument and reference data from the ASTM file.

To treat the stone material, the following solutions were prepared: (1) aqueous solution of 10 wt % SAS (GKZh-10; Khimprom AO, Novocherkassk); (2) isopropanol solution of 5 wt % PEHS (GKZh-136-41; Silan ZAO, Dankov); (3) aqueous colloid solution of 10 wt % sodium polysilicate $Na_2O \cdot 4SiO_2$ (Goltar OOO, St. Petersburg); and (4) aqueous-alcoholic sol of hydrophobic silica (10 wt %), prepared by the sol–gel technology [13, 14]. Dried samples were treated with solutions nos. 1 and 2 by full submersion for 15–20 min at 20°C. The samples were weighed before and after submersion. Drying of the samples was done under room conditions (20°C, 50% relative humidity) to constant weight. Samples were treated with sols nos. 3 and 4 as follows. The samples were submerged in an aqueous weakly alkaline silicate sol no. 3 for 15–20 min and then dried under room conditions for 1 day, submerged in water for 15–20 min, again dried under room temperature conditions for 1 day, and submerged in water for 15–20 min. Then the samples were again dried for 3 days and submerged in water for 15–20 min. After that the samples were dried under room temperature conditions for 7 days and impregnated with aqueous–alcoholic sol of hydrophobic silica (no. 4), dried under room temperature conditions for 1 day, and placed on an atmospheric stand. After 7 days and 3 and 12 months, the kinetics of water absorption by samples (preliminarily kept under room temperature conditions for 1 day) was determined.

The samples were weighed in air and in water (at a depth of 15 mm at 20°C). The difference of weights of dry sample in air, m_1, and that saturated with water (having density ρ of 1 g cm^{-3}), m_2, allows evaluation of the sample volume V and calculation of its density m_1/V: $m_1 = m_2 - V\rho$. The technique enables recording of the course of sample saturation with water. At the initial instant of complete submersion in water a sample has mass m_0 and contains a certain volume of pores, V_0, filled with air (and giving rise to buoyancy force). This volume is filled, during a certain period of time, with water, and the mass of the submerged sample increases to m_2. The pore volume is equal to the difference between masses of submerged samples in the initial and final stages of the process of saturation with water, divided by the density of water: $V_0 = (m_2 - m_0)/\rho$. The ratio of water volume absorbed by a sample to its dry mass is shown as a function of time elapsed upon sample submersion into water in Fig. 1. The total time of sample submersion was no less than 1 day. The increase in the mass of absorbed water with time can also be followed by weighing a sample in air and its periodic submersion for a certain time.

Table 1 presents the results of determining the moisture content in initial samples, those saturated with water, and those treated with various solutions. The content of moisture in the initial samples of footing limestone from different parts of a building was in the range 0.6–1.8 wt %, and increased, 5 min after full submersion in water, to 1.5–4.5 wt % and then remained virtually unchanged for 24 h. The sample density was 2.8 g cm^{-3}. The phase composition of the samples is mainly represented by calcite, wollastonite, and admixture of quartz and gypsum. The

Table 1. Moisture content in various samples of facade materials

Sample	Moisture content (wt %) in indicated samples

* (F) Samples from a building facade and (W_n) samples submerged in water for 24 h after *n* months of additional keeping under atmospheric conditions.

density and the phase composition of the samples indicate that the footing material is composed of partly marbled limestone (sedimentary limestone subjected to high temperature and pressure). The difference between the saturating amounts of water for samples taken from different parts of a building presumably indicates different conditions of stone weathering. Red brick samples were humid (12–17 wt %) and porous (saturating amount of moisture 17–20 wt % upon 24 h of full submersion in water) near building drains. In moisture-protected parts of the building, samples were less humid (3–7 wt % water), stronger, and less porous (saturating amount of water 13–16 wt %). The mineral phase composition of brick mainly included quartz and kaolin. Brickwork binder samples contained 8–10 wt % moisture in the initial state and up to 17 wt % upon saturation. The phase composition of the binder mainly includes

Note: Superscripts: (1) gypsum, (2) calcite, and (3) quartz.

quartz and calcite. Samples of facade plaster contained 1.5–8 wt % moisture in the initial state and up to 13–18 wt % upon saturation. The phase composition of the plaster mainly includes quartz, calcite, and gypsum (Table 2).

Figure 1 shows the kinetics of water absorption by selected samples of limestone, brick, binder, and plaster on their submersion in water. Pores in the initial samples are virtually completely filled with water during the first 5 min. The amount of moisture absorbed by samples upon submersion in water both during the first 5 min and in 24 h can be reduced by treating the initial samples of the stone material both with conventional solutions nos. 1 and 2 and with new sols nos. 3 and 4 (see Fig. 1, Table 1). A comparison of how treatment with the conventional solutions affects the moisture-protective properties of samples demonstrated that solution no. 1 has advantage for the binder and plaster, and solution no. 2 for marbled limestone and, especially, brick. The amount of absorbed moisture is reduced to the maximum extent for all samples after their technological treatment with silicate sols nos. 3 and 4. The reason for such a difference in efficiency between the hydrophobizing solutions is that the plaster and binder contain calcium carbonates and sulfates. These minerals react with SAS in solution no. 1 by reaction (2), whereas PEHS in solution no. 2 mainly reacts with surface hydroxy groups [reaction (3)] of minerals, e.g., kaolin, quartz (brick), and wollastonite (limestone). Impregnation of sulfated samples with an aqueous sol of sodium silicate $Na_2O \cdot 4SiO_2 \cdot nH_2O$ leads to an exchange reaction between the sulfate on the stone surface and hydroxylated silicate of the aqueous-alkaline liquid phase of sol in the stone pores:

$$CaSO_4 \cdot 2H_2O + 2Na^+ + SiO_2(OH)_2^{2-} + 3SiO_2 \rightarrow CaSiO_2(OH)_2 \cdot 3SiO_2 \cdot 2H_2O + 2Na^+ + SO_4^{2-}. \quad (4)$$

Subsequent washing of the surface with water removes sodium sulfate from the poorly soluble gel of calcium hydrosilicate and silica formed in the stone pores. Pores in the surface layer of the stone decrease in size, but remain hydrophilic, i.e., covered with hydroxy groups. To hydrophobize the surface, the pores in the surface layer were dried and impregnated with active sol no. 4 of hydrophobic silica [13]. This procedure leads to reaction of the hydroxy groups in the surface layer with active radicals of hydrophobic particles of sol in colloid solution no. 4

$$\equiv SiOH + C_2H_5OSi(O)_3[SiO_2]_nO_3SiC_2H_5 \rightarrow \equiv SiOSiO_3[SiO_2]_nO_3SiC_2H_5 + C_2H_5OH, \quad (5)$$

pore filling with hydrophobic silica, and the corresponding decrease in pore radius. In this case, in accordance with the Jurene formula [15], a much higher pressure is necessary for water to penetrate into hydrophobic pores of smaller diameter.

The durability of moisture-protective properties of the surface layer of various samples can be illustrated by the data in Table 1. The moisture-protective properties of the surface layer of samples treated with solution no. 1 deteriorate by 40–50% after 1 year of keeping under atmospheric conditions. Apparently, introduction of the alkali metal cation into the surface layer of stone with solution no. 1 makes higher the solubility of its components and favors their transport, development of a porous structure in the stone, and stone decomposition. For example, calcium silicate decomposes under the action of sodium hydrocarbonate solution to give calcite and soluble sodium silicate:

$$2CaO \cdot SiO_2 + 2NaHCO_3 \rightarrow 2CaCO_3 + Na_2[SiO_2(OH)_2]. \quad (6)$$

The presence of an alkaline component favors origination and development of cracks and disintegration of concrete constructions [10].

The moisture-protective properties of the surface layer of samples treated with colloid solutions nos. 3 and 4 remained unchanged after a year of keeping under atmospheric conditions.

It should be noted that, under the atmospheric conditions, the stone surface is continuously subjected to abrasive action of specks of dust and grains of sand driven by wind, which impairs the hydrophobic effect of the surface. Moreover, mutual diffusion of the components of the surface layer will also impair its moisture-protective properties in the course of time. Therefore, treatment of the surface layer of stone should be repeated every 10–20 years.

CONCLUSIONS

(1) It was found, with the historical center of St. Petersburg serving as an example, that plaster over brickwork and binder in brick walls of buildings are subject to deep sulfation and fail to accomplish their moisture-protective functions. In spring, pores in brick walls of buildings are filled with moisture to no less than 50%.

(2) It is recommended that, prior to impregnation with a sol of hydrophobic silicate, the sulfated and carbonized surface layer of stone materials should be treated with a weakly alkaline aqueous silicate sol and dried under atmospheric conditions in summer.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Specific Features of Preparation of Liquid Glass-Based Colloid Solutions for Synthesis of Glass Coatings

Received March 28, 2000; in final form, June, 2001

Abstract—Conditions for obtaining stable colloid solutions for synthesis of alkali-silicate glass coatings based on lithium, sodium, and potassium liquid glass were studied. The influence of the solution pH and the nature and concentration of liquid glass on the gel formation was established.

The sol-gel method is one of the most promising and universal among a number methods for obtaining glass coatings. In many cases, sols [1, 2], colloid solutions [3, 4], gels, or their dried powders [5, 6] are used. The choice of a specific solution state or solution-based products for the formation of glass coatings depends on a support material and its final destination. In each case, the technological process starts from solution preparation. The preparation of a highly homogeneous and stable solution with required composition and concentration is an important and complicated task.

The main problem in obtaining homogeneous colloid solutions based on liquid glass arises from the fact that addition of even insignificant amounts of solutions of IIA and IIIA group elements to silicate solutions breaks the homogeneity of the corresponding systems due to the formation of difficulty soluble silicates of most of metals. Obviously, addition of boron-containing compounds gives rise to precipitation of amorphous silicic acid.

It is known [1, 7] that the ability of colloid solutions to be in fluid state for a long time determines their stability and depends on a number of factors, in particular, on their composition, concentration, pH, and the order of component mixing. Therefore, the conditions of solution preparation are of paramount significance.

The aim of this work was to find optimal component concentrations and technological parameters for obtaining high-quality colloid solutions for synthesis of coatings of various technical destinations.

EXPERIMENTAL

Boron aluminosilicate glasses and, in some cases, silicophosphate glasses form the base of the majority of glass coatings. Thus, the main problem is to obtain a colloid solution containing liquid glass, aluminum salts, and also salts of boric and phosphoric acids.

A specific character of silicates of alkali metals requires use of an unconventional approach to the choice of aluminum-, boron-, and phosphorus-containing compounds for obtaining stable colloid solutions. These compounds must satisfy a number of requirements: 1) absence of reactions with alkali metal silicates resulting in the formation of heterogeneous systems; 2) high water-solubility and low decomposition or melting point; 3) high content of a required oxide (Al_2O_3, B_2O_3, P_2O_5, etc.) in solution.

A glass formed in the system $Na_2O(K_2O)$–Al_2O_3–B_2O_3–SiO_2 is used for obtaining protective corrosion-resistant coatings. Sodium and potassium liquid glasses with a modulus of M = 2–4 were used as bases for preparation of colloid solutions. The concentration of alkali metal silicates was 5.5–10 wt %.

Hydroxoaluminates are appropriate for use as aluminum-containing compounds. It is the hydroxo complex $R[Al(OH)_4(H_2O)_2]$ or similar compounds that are alkali metal aluminates obtained in solutions. Therefore, we further use the general formula $R_n[Al(OH)_m]$ for alkali metal aluminates. The composition of a resulting compound depends on pH and the concentration of reacting solutions.

As shown in [8], among boron-containing reagents, only boric acid meets the above-mentioned requirements.

1070-4272/01/7412-1990 $25.00 © 2001 MAIK "Nauka/Interperiodica"

Presently, it is agreed that monoborate ions and polymeric forms of boric acid are present in its solutions with concentrations greater than 0.1–0.2 M. Therefore, silicic acids are very likely to precipitate upon pouring together liquid glass and H_3BO_3 solutions under the action of both H_3BO_3 and polyboric acids.

To obtain high-concentrated (5–12 wt %) colloid solutions, we used a sodium aluminate solution with concentrations of aluminum ions and boric acid of 0.6 and 0.1 M, respectively. Depending on a modulus, the pH of liquid glass solution was 12.0–13.4, and the pH of sodium aluminate solution was fixed at 13.1.

Addition of an even insignificant amount of an aluminate solution (0.5–1.0 ml) to 10 ml of liquid glass results in the formation of a gelatinous substance at the boundary between these liquids, whereas dropwise introduction of this solution does not give rise to this phenomenon. Taking this fact into account, we prepared colloid solutions by adding small portions of the sodium aluminate solution under vigorous stirring to liquid glass. However, it is worth noting that the solution homogeneity was retained only up to a certain critical aluminate concentration, which, in turn, depends on the nature of an alkali metal cation and on the liquid glass modulus. For the same modulus (M = 3), gelatination is observed upon addition of 10.6 and 8.0 ml of the aluminate solution to potassium and sodium liquid glass solutions, respectively. The liquid glass modulus has the most pronounced effect on this process: an increase in the modulus to four leads to gel formation on addition of only 3.2 ml of the aluminate solution.

Thus we have determined the critical content of alkali metal aluminate in terms of Al_2O_3 which can be introduced in the liquid glass composition before gelatination occurs:

x in $Na_2O \cdot xSiO_2$	3	3.5	4
Al_2O_3(critical), wt %	8.0	6.3	3.2
x in $K_2O \cdot xSiO_2$	2	2.5	3
Al_2O_3(critical), wt %	14.1	12.3	10.6

The resulting critical content of Al_2O_3 is sufficient for obtaining glass coatings with high service characteristics [9].

As already mentioned, the system $K_2O \cdot nSiO_2$–$Na_n[Al(OH)_m]$ is more stable toward gelatination than the system $Na_2O \cdot nSiO_2$–$Na_n[Al(OH)_m]$. At the same modulus (M = 3) and concentration, the critical content of Al_2O_3 in the potassium system is significantly higher. This trend is likely to be first of all related to the nature of cation and to the structure of solutions of alkali metal silicates. It should be noted that the difference in coagulation action of various single-charged ions was observed also in [10]. An increase in stability of systems based on liquid glass with low modulus results from a decrease in the amount of high-polymeric SiO_2 forms.

The oxide B_2O_3 was introduced into the system in the form of boric acid solution. A white jelly-like precipitate was formed upon addition of H_3BO_3 as a result of the pH decrease from 12–13.4 to 10.

An examination of the data obtained suggests that the addition of aluminate to alkali metal silicates gives rise to an interaction between the system components in solution. Along with an increase in size of SiO_2 colloid particles in such a solution, a three-dimensional gel skeleton is formed from these particles, $Si(OH)_4$ groups, and negatively charged $Al(OH)_4^-$ particles. Addition of an H_3BO_3 solution to the system results in the formation of a precipitate owing to decreasing pH of the $R_2O \cdot nSiO_2$–$Na_n[Al(OH)_m]$–H_3BO_3 system. It is evident that $Al(OH)_3$ is first precipitated due to decreasing aluminate stability at low pH values. It is necessary to note that the "coagulation threshold" (pH value at which a precipitate starts to form) for potassium systems is 11.6, whereas for sodium it is 12. This fact once more confirms the greater stability of the system based on potassium liquid glass.

The stability of such solutions strongly depends on the order in which the components are poured together when preparing colloid solutions. It is necessary to note that we added to the solutions soluble salts that do not react with solution components in order to obtain coatings with specified technological parameters (low melting point, adhesion, and color). The optimal order of pouring together component of the colloid solutions, as found experimentally, is: $Na_2O \cdot 2SiO_2$ + $Na_nK[Al(OH)_m]$ + H_3BO_3 + adhesion promoters + pigments.

The system Li_2O–K_2O–BaO–Al_2O_3–B_2O_3–SiO_2 is of great importance for the production of electrically insulating glass materials. Aluminum oxide was introduced into the solution in the form of potassium aluminate. In addition, we studied the behavior of aluminum and barium nitrates.

A mixture of lithium (M = 10) and potassium (M = 3.5) liquid glasses was prepared in a preliminary stage. The total mixture concentration was 13 wt % and pH was 11.8. It should be noted that suspended particles were present in lithium liquid glass. Mixing these components does not break the solution homogeneity, and no precipitate is formed. However, an additional

pouring of both the aluminate and aluminum or barium nitrate (c = 0.3 M) results in the immediate formation of a precipitate, and a little later the entire solution is transformed to a gel. An increase in pH to 11.6 does not improve its stability.

One of effective means for stabilization of colloid solutions is variation of their concentration [11]; therefore, the prepared lithium-potassium liquid glass was gradually diluted with water to a concentration of 6.5 wt %. In this case, further addition of required components (aluminum and barium salts) does not give rise to gel formation. In so doing an insignificant precipitate is formed, which dissolves in the course of time.

Our experiments have proved that the probability of gelatination grows with increasing concentrations of silicate ions SiO_3^{2-} and also of SiO_2 colloid particles. In order to avoid formation of precipitates in the colloid solutions, liquid glass must contain no more than 6.5 wt % of salts.

The general sequence of component pouring together and solution preparation is the following: $K_2O \cdot 3.5SiO_2 + Li_2O \cdot 10SiO_2 + LiOH + Al(NO_3)_2 + H_3BO_3 + Ba(NO_3)_2$.

Using X-ray diffraction analysis, we found that the powder obtained on drying the solution contains aluminum and barium nitrates. Thus, the data obtained prove the absence of chemical reactions between the solution components.

A glass of the system K_2O–Al_2O_3–B_2O_3–SiO_2–P_2O_5 is used in production of low-melting decorative coatings. To prepare the solutions, we used potassium liquid glass (M = 3.5, c = 14.47 wt %) and the following solutions (M): KOH 9, $(NH_4)_2HPO_4$ 1.5, and H_3BO_3 0.7. The total concentration of the colloid solution was 17.7 wt %, pH 9.1.

Solutions of this system show strong tendency toward gelatinization. This tendency is rather sensitive to the concentration of hydrogen ions. We found experimentally that a drastic change in the solution behavior takes place at pH close to 10. Therefore, it was of importance to find conditions for obtaining solutions of this system at various pH values. We established specific features of preparation of each particular solution. For the case of solution with pH < 10, the order of pouring together components is as follows: $(NH_4)_2HPO_4 + H_3BO_3 + KOH + K_2O \cdot 3.5SiO_2 + K_n[Al(OH)_m]$.

When liquid glass is added in the course of solution preparation, a gel of orthosilicic acid H_4SiO_4 is precipitated, and, upon addition of an aluminate solution, $Al(OH)_3$ flakes also appear.

We found by X-ray diffraction analysis that a crystalline phase of $0.73NH_4H_2PO_4 \cdot 0.27KH_2PO_4$ composition is formed during drying of the gel at 50°C [12].

The time during which the solution is in the fluid state depends on concentration and may be as long as 20 days.

To obtain a colloid solution of the system under study with pH > 10, we added aqueous ammonia solution to the $(NH_4)_2HPO_4 + H_3BO_3$ mixture, which resulted in the formation of a precipitate. Therefore, we changed the order of pouring together the components and found the following appropriate sequence: $K_n[Al(OH)_m] + KOH + K_2O \cdot 3.5SiO_2 + [H_3BO_3 + (NH_4)_2HPO_4]$.

With increasing pH, the lifetime of the solutions grows up to 40 days.

CONCLUSIONS

(1) The procedure for obtaining glass coatings includes high-temperature treatment of finely dispersed raw powder mixtures. Mostly the quality of the coatings depends on the homogeneity of colloid solutions.

(2) The preparation of colloid homogeneous solutions based on liquid glass differs fundamentally from the preparation involving tetraethoxysilane. As the solution composition becomes more complex, the probability of formation of an insoluble precipitate or of instantaneous gelatination appears. The stability of the solutions depends on their composition, concentration, and pH. This problem should be specifically solved in each particular case. The order of pouring together the components depends on their composition and pH value.

(3) To avoid precipitate formation, it is necessary to add aluminum ions to solution in an anionic form. If aluminum and barium ions are added in the form of nitrates, the resulting solution must be diluted as much as possible. Solutions based on liquid potassium glass are more stable than sodium-based solutions. Their stability increases with decreasing silicate modulus.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Analysis of Component Interaction in the System Lithium–Sulfur

A. G. Morachevskii

St. Petersburg State Technical University, St. Petersburg, Russia

Received September 11, 2001

Abstract—Data on the thermodynamic properties of liquid and solid phases in the system lithium–sulfur are compared and discussed.

Only one congruently melting compound Li_2S is formed in the system lithium–sulfur. The sulfur-rich part of the system has a stratification region. Several, virtually simultaneous studies [1, 2] of the phase diagram of this system gave rather close results. The phase diagram of the system, taken from Janz and Tomkins' handbook [3], is presented in Fig. 1. The melting point of the compound Li_2S lies in the range from 1367 to 1382°C, and the monotectic horizontal, at 362 ± 3°C. At this temperature, the liquid phase, containing 34.5 mol % Li, is in equilibrium with a phase of virtually pure sulfur (containing less than 0.035 mol % Li). The upper critical temperature of separation is estimated to be within 838–860°C. No lithium polysulfides were found in the system. No essential differences in the main parameters of the phase diagram of the Li–S system have been found in later studies [4, 5].

The emf value of a Li–S cell in the separation region ($0.026 \le x_{Li} \le 0.346$, 11 compositions, 400–445°C, x_{Li} is the molar fraction of lithium in the system) was determined using a solid glassy electrolyte with lithium-ion conductivity [6, 7]. The average emf at 420°C is 2.215 ± 0.007 V. Correspondingly, the lithium activity in this region of compositions is $(7.95 \pm 0.97) \times 10^{-17}$. The partial molar Gibbs energy of lithium ΔG_{Li} is -213.7 ± 0.7 kJ mol^{-1}.

In [8], the cathode potential of a sulfur electrode in the $LiNO_3$–$LiNO_2$–LiOH melt was determined by measuring polarization curves in pulsed galvanostatic mode. At 150°C, below the monotectic horizontal, the potential of the sulfur electrode relative to lithium reference is constant (2.216 ± 0.002 V at a confidence probability of 0.95) over the entire polarization range. In this case, the electrochemical reaction reduces to the formation of lithium sulfide from pure components:

$$2Li(s) + S(l) = Li_2S(s). \quad (1)$$

The change in the Gibbs energy, corresponding to reaction (1), is -427.6 ± 0.6 kJ, and that corresponding to the formation of one mole of $Li_{0.667}S_{0.333}$ equals -142.5 ± 0.2 kJ (423 K). Only a single potential plateau (2.215 ± 0.003 V relative to lithium reference electrode) is clearly observed in the switch-off curves recorded upon cathodic polarization of the electrode in the above electrolyte (at 150°C).

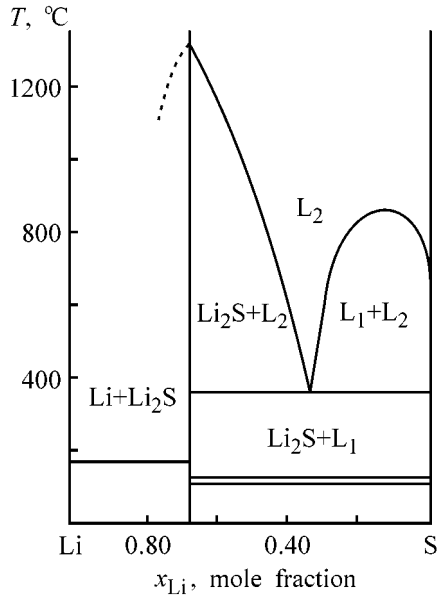

Fig. 1. Phase diagram of the lithium–sulfur system. (T) temperature, (x_{Li}) lithium content in the system, and (L_1 and L_2) liquid phases.

1070-4272/01/7412-1994 $25.00 © 2001 MAIK "Nauka/Interperiodica"

At higher temperatures (377°C, above the monotectic horizontal) the polarization curve of the halide melt LiF–LiCl–LiI also shows a potential plateau (2.195 ± 0.009 V relative to lithium reference). In the given case, the potential is associated with the occurrence of the reaction:

$$2Li(l) + S(l) = Li_2S(s), \quad (2)$$

with a change in the Gibbs energy of -423.6 ± 1.7 kJ (650 K). Correspondingly, for one mole of $Li_{0.667}S_{0.333}$, $\Delta G = -141.2 \pm 0.6$ kJ.

A reference book [9] contains evidence concerning the thermodynamic properties of the compound Li_2S. The authors are mainly based on the results of calorimetric measurements of the enthalpy of formation of the compound [10] and on estimates of the standard entropy and heat capacity of Li_2S in terms of different models [11]. As noted in [9], the presented data need refinement.

In [10], the enthalpy of formation of the compound Li_2S was determined by means of dissolution calorimetry to be ($\Delta H^0_{298} = -445.6$ kJ mol^{-1}). The enthalpy of formation of not only Li_2S, but also a hypothetical compound Li_2S_2 was determined by dissolution calorimetry in a later study [12]. The following results were obtained: $\Delta H^0_{298} = -427.4 \pm 4.6$ kJ mol^{-1} for Li_2S and $\Delta H^0_{298} = -432.6 \pm 5.4$ kJ mol^{-1} for Li_2S_2.

The thermodynamic properties of lithium sulfide have been analyzed in detail by Khachkuruzov [13]. The author used experimental data and approximate methods to determine the thermodynamic functions of Li_2S in crystalline and liquid state in the range 298–3000 K with a step of 200 K. The following values were obtained for Li_2S under the standard conditions:

$$H^0_{298} - H^0_0 = 10.1 \pm 0.2 \text{ kJ mol}^{-1},$$

$$S^0_{298} = 62 \pm 2 \text{ J mol}^{-1} \text{ K}^{-1},$$

$$C^0_{p,298} = 61 \pm 3 \text{ J mol}^{-1} \text{ K}^{-1}.$$

The above value of the standard entropy is in good agreement with $S^0_{298} = 60.67$ J mol^{-1} K^{-1} from reference book [9]. However, according to [13], the heat capacity of crystalline Li_2S varies with increasing temperature more strongly than it is accepted in [9]. In the temperature range 298–1450 K, the $C_p = f(T)$ dependence is expressed by the equation (J mol^{-1} K^{-1}) [13]:

$$C_p(T) = 24.48 + 0.1157T + 2.269 \times 10^{-5}T^2.$$

Thermodynamic functions for lithium sulfide Li_2S

Function	Data of [9]		Data of [13]	
	400 K	600 K	400 K	600 K
H, kJ mol^{-1}	–438.96	–423.68	–440.41	–422.79
S, J mol^{-1} K^{-1}	82.21	113.13	81.785	117.119
G, kJ mol^{-1}	–471.85	–491.56	–473.12	–493.06
ΔG^0_T, kJ mol^{-1}	–434.56	–424.60	–435.83	–426.10

At the relatively low temperatures of interest (up to 700°C) the data of [13] give the following heat capacities (J mol^{-1} K^{-1}): 74.39 (400 K), 88.00 (500 K), 102.07 (600 K), and 116.59 (700 K). In reference book [9], the following C_p values are given: 74.38 (400 K), 76.40 (500 K), 78.48 (600 K), 80.43 J mol^{-1} K^{-1} (700 K).

The difference in heat capacities tells upon the standard entropies of crystalline Li_2S. According to [13], S^0_T (J mol^{-1} K^{-1}) is 81.785 (at 400 K), 117.119 (600 K), and 150.478 (800 K). At the same time, the following values were reported in [9]: 82.21 (at 400 K), 113.13 (600 K), and 136.24 J mol^{-1} K^{-1} (800 K).

The reference book [14] gives the following thermodynamic characteristics for Li_2S in the standard state: $\Delta H^0_{298} = -447.3 \pm 1.3$ kJ mol^{-1}, $S^0_{298} = 62.8 \pm 8.4$ J mol^{-1} K^{-1}, and $\Delta G^0_{298} = -439.1 \pm 2.8$ kJ mol^{-1}. The melting point of Li_2S is reported to be 1370 ± 10°C.

Taking into account the scarcity of data on the temperature dependence of the lithium sulfide thermodynamic properties and the fact that the thermodynamic functions reported in [9, 13] are to a certain extent based on different approaches, let us consider in more detail the feasibility of using data [9, 13] for estimating the standard Gibbs energy of Li_2S formation from pure components. The H, S, and G functions for chemical compounds and individual substances at various temperatures with a step of 100°K are presented in the tabulated form in a reference book [9].

$$H = \Delta H^0_{298} + (H_T - H_{298}),$$

$$S = S^0_T, \; G = H - TS.$$

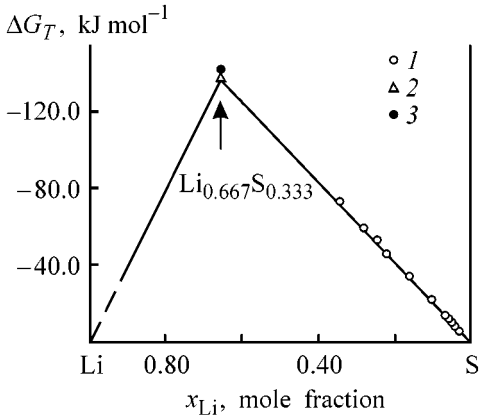

Fig 2. Integral molar Gibbs energy ΔG_T vs. composition. (*1*) Data of [6], 420°C; (*2*) calculated from data of [9], 420°C; (*3*) data of [8], 377°C.

The ΔG_T^0 value for reactions (1) or (2) is obtained by algebraic summation of the functions *G* for Li_2S and pure components (lithium and sulfur) in the corresponding aggregate state. The *H*, *S*, and *G* functions at 400 and 600 K [9, 13] are given in the table. The discrepancy between the ΔG_T^0 values is very small.

Calculation of ΔG_{423}^0 for reaction (1) from the data of [9] yields −433.66 kJ, i.e., the deviation from the experimental value (−427.6 kJ) [8] does not exceed 1.4%. Correspondingly, the calculated ΔG_{650}^0 for reaction (2) is −421.75 kJ, i.e., the deviation from the experimental value (−423.6 kJ) [8] is less than 0.5%. Thus, determining the standard Gibbs energy of Li_2S formation from pure components by means of polarization measurements gives reasonably reliable results. Also, these measurements indirectly confirm the absence of an intermediate phase (Li_2S_2) at the experimental temperatures (423–650 K).

The activity of sulfur in the system Li–S was determined in [5] by the emf method with solid electrolyte for a number of compositions both in the homogeneity region, which is very narrow at 400°C, and in the separation region. Unfortunately, no numerical data were given, but, as follows from the presented plots, the activity of sulfur in the separation region is 0.90. Since pure sulfur is taken as the standard state, and one of equilibrium phases is virtually pure sulfur, the above value of its activity is probably somewhat underestimated. According to [6], the activity of sulfur in the separation region at 420°C is 0.947 ± 0.011.

At 420°C the plot of the molar Gibbs energy of the Li–S system against composition shows no homogeneity region (Fig. 2).

The emf of the cell (–) Li | Li^+ | Li, S (+), observed in the separation region (2.215 V at 420°C), differs only slightly from the emf established at the corresponding temperature in the two-phase region Li_2S(s) + liquid. The results of the performed thermodynamic analysis of the Li–S system are not in quite good agreement with the emf of a lithium–sulfur circuit, reported in [5].

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Liquid–Liquid and Liquid–Vapor Phase Equilibria in Stratifying Binary System *n*-Hexane–Water

A. R. Rasulov and S. M. Rasulov

Institute of Physics, Daghestan Scientific Center, Russian Academy of Sciences, Makhachkala, Daghestan, Russia

Received October 5, 2000; in final form, April 2001

Abstract—Thermal properties of a binary system *n*-hexane–water were studied by the constant-volume-piezometer method for seven concentrations of water on the basis of isochores at temperatures of 372.75–620.55 K, homogeneous phase densities in the range 66.87–834.30 kg m^{-3}, and pressures of up to 65 MPa.

Studying the thermal properties on *n*-alkane–water mixtures is of not only theoretical, but also practical interest, since natural hydrocarbon mixtures are, as a rule, in contact with water. In addition, stratifying water–hydrocarbon systems are widely used in chemical technology, petroleum and petrochemical industries, and power engineering.

The properties (*PVT*) of the *n*-hexane–water binary system, which can be considered a simple model of a stratal mixture, were studied in a number of works [1–7]. However, data on phase liquid–liquid and liquid–vapor equilibria are scarce.

In this work, thermal properties of the *n*-hexane–water binary system was studied by the constant-volume piezometer method at temperatures of 372.75–620.55 K, homogeneous phase densities ρ of 66.87–834.30 kg m^{-3}, and pressures of up to 65.34 MPa for seven concentrations *x* of water (mol fraction): 0.166, 0.257, 0.347, 0.615, 0.827, 0.935, and 0.964. The measurements cover a parameter range between the liquid–liquid and liquid–vapor phase equilibria.

The temperature of the system was maintained automatically within ±0.01 K by means of three heat controllers. The pressure was controlled using a membrane transducer with sensitivity of 0.005 MPa and measured with standard pressure-gage at pressures below 1 MPa and MP-600 deadweight gage with accuracy of 0.05% at pressures exceeding 1 MPa. The piezometer volume (21.160 ± 0.025 cm^3) was determined by calibration against water. The piezometer was filled under vacuum through a valve at the piezometer edge. Mixtures were prepared using degassed twice-distilled water and *n*-hexane of 99.94% purity. The mixture components were weighed on analytical balance with an error not exceeding 0.5 mg. The error in density measurements was 0.12–0.15%. The setup was described in detail in [8].

The measurements were made using isochores. For each composition, 7–9 isochores were obtained, which covered a wide range of densities. The dependences of pressure *P* on temperature *T* along the isochores exhibit inflections corresponding to liquid–liquid and liquid–vapor phase transitions. A typical *P*–*T* dependence along different isochores for a composition with $x = 0.935$ is given in Fig. 1. Lines connecting the inflection points are phase equilibrium

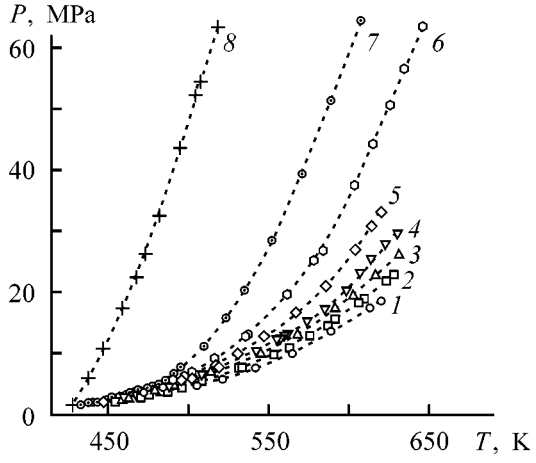

Fig. 1. Dependence of *P* on temperature *T* for *n*-hexane–water binary system of composition $x = 0.935$ along isochores. ρ (kg m^{-3}): (*1*) 205.1, (*2*) 273.4, (*3*) 341.7, (*4*) 410.1, (*5*) 478.4, (*6*) 546.8, (*7*) 615.1, and (*8*) 649.3.

* Indices "r" and "l" refer to, respectively, right and left branches of the liquid–liquid coexistence curve.

lines separating the triple-phase region from the double-phase region, and the latter from the single-phase one. An isochore without inflection passes through the point of maximum temperature—cricondentherm of the phase equilibrium line. The thus obtained temperatures and pressures, corresponding to liquid–liquid (T_{ll}, P_{ll}) and liquid–vapor (T_{lg}, P_{lg}) phase transitions along different isochores for all of the measured compositions of the *n*-hexane–water binary system, are given in Table 1.

Figure 2 presents critical point lines in the *T*–*x* coordinates for the *n*-hexane–water binary mixture. According to van Koninenburg and Scott's classification [9], the phase diagram of the *n*-hexane–water binary system belongs to type III. This means that the liquid–vapor critical state does not exist in the concentration range 0.257–0.882 mol fraction of water. The lower locus of the liquid–vapor critical line *1* begins at the critical point of *n*-hexane CP1 and ends in the upper terminal critical point (UTCP) corresponding to $x = 0.257$ mol fraction of water. The upper part begins at the critical point of water, CP2, passes through the double critical point (DCP; $x = 0.935$), and, with decreasing concentration of water, goes to the region of higher values. The dashed line represents the line of discontinuity of liquid–vapor critical points. This line is so designated because the *P*–*T* line shows an inflection despite the absence of a critical state. The same is indicated by investigations of the caloric properties [6] in which an abrupt change in isochoric heat capacity is observed in intersecting line *3*.

The curve of liquid–liquid phase equilibrium was approximated by the expression [10, 11]

$$\frac{\rho - \rho_c}{\rho_c} = \pm B_0 |t|^{\beta} \pm B_1 |t|^{\beta + \Delta} + B_2 |t|^{1-\alpha} + B_3 t, \quad (1)$$

where β, Δ, and α are the critical indices, with Δ and α fixed [9] (Δ = 0.50, α = 0.11); B_0, B_1, B_2, and B_3 are the critical amplitudes; $t \equiv (T_c - T)/T_c$ is the reduced temperature; ρ_c and T_c are, respectively, the critical density and temperature; the signs plus and minus refer to, respectively, the right- and left-hand branches of the liquid–liquid coexistence curve (Fig. 3).

Table 2 presents calculated values of the critical index β, critical amplitudes B_0, B_1, B_2, and B_3, and the region of approximation by Eq. (1) for the liquid–liquid equilibrium curves for the *n*-hexane–water mixture of various compositions. The results of calculations indicate that for the liquid–liquid phase transition the critical indices β are close (within calculation error) to 0.325. This confirms the validity of the conclusion that, near the liquid–liquid phase transition point, the liquids belong to universal three-dimensional Ising systems.

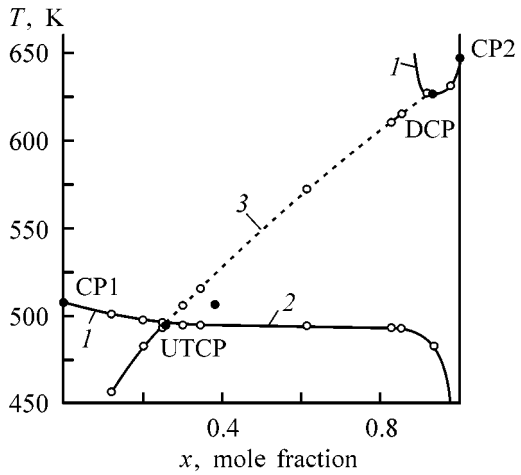

Fig. 2. Lines of critical points in the *n*-hexane–water binary system. (*T*) Temperature and (*x*) water content. (*1*) Liquid–vapor, (*2*) liquid–liquid, (*3*) "pseudocritical" curve; CP1 and CP2 are the critical points of, respectively, straight *n*-hexane and water; UTCP is the upper terminal critical point, and DCP is the double critical point.

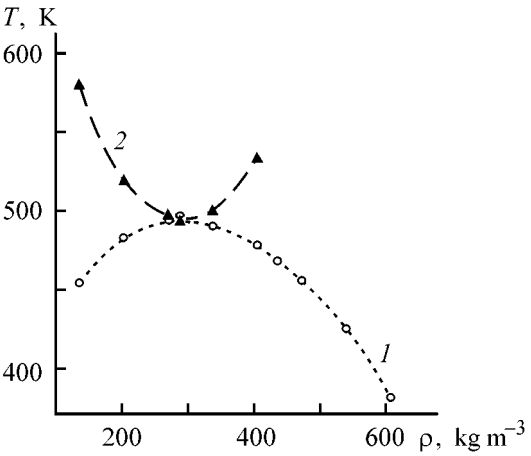

Fig. 3. Phase diagram *T*–ρ of the *n*-hexane–water binary mixture of composition $x = 0.257$. (*1*) Liquid–liquid and (*2*) liquid–vapor.

The liquid–vapor coexistence curve was described in accordance with the equation [10, 12]

$$\frac{\rho_l - \rho_g}{2\rho_c} = B |t|^{\beta}, \quad (2)$$

where ρ_1 and ρ_2 are, respectively, the liquid and vapor phase densities; and *B* is the critical amplitude.

The results of calculations for four compositions (for which the liquid–vapor critical point exists) of

Table 3. Calculated values of the critical index β, amplitude *B*, and the region of approximation with respect to *t* by Eq. (2) for the liquid–vapor coexistence curve for the *n*-hexane–water binary mixture

x, mole fraction H_2O	β	*B*	Approximation region
0.166	0.478 ± 0.012	2.638 ± 0.024	1×10^{-2}–9×10^{-4}
0.257	0.317 ± 0.030	0.620 ± 0.030	1×10^{-2}–1×10^{-3}
0.935	0.556 ± 0.083	5.421 ± 0.346	8×10^{-3}–8×10^{-4}
0.964	0.331 ± 0.047	1.060 ± 0.045	5×10^{-3}–8×10^{-4}

the *n*-hexane–water binary mixture are presented in Table 3. It can be seen that the critical index β obtained for compositions with $x = 0.257$ and 0.964 is close to 0.325, a value characteristic of three-dimensional Ising systems. The value $\beta = 0.556$ for $x = 0.964$ corresponds (within calculation error) to the assumption of [13] that critical indices are doubled in the double critical point.

The thermodynamic properties of the *n*-hexane–water binary system near the liquid–vapor critical line were described using the crossover equation of state [14, 15]. This method consists in obtaining crossover functions transforming the six-term Landau expansion into Wegner expansion for the Helmholtz free energy of liquid in the near-critical region.

The specific Helmholtz energy $A(\tau, \rho, \zeta)$ is written as [14]

$$A(\tau, \rho, \zeta) = \frac{P_c(\zeta)}{RT_c(\zeta)}[\Delta A(\tau, \rho, \zeta) + A_0(\tau, \zeta) + \rho h_0(\tau, \zeta)], \quad (3)$$

where ζ is the field variable corresponding to the concentration *x*, *R* the molar gas constant, P_c the critical pressure, $\tau = [T - T_c(\zeta)]/T$, $\Delta A(\tau, \rho, \zeta)$ the singular part of the free Helmholtz energy, $h_0(\tau, \zeta)$ and $A(\tau, \zeta)$ regular functions represented as truncated Taylor series.

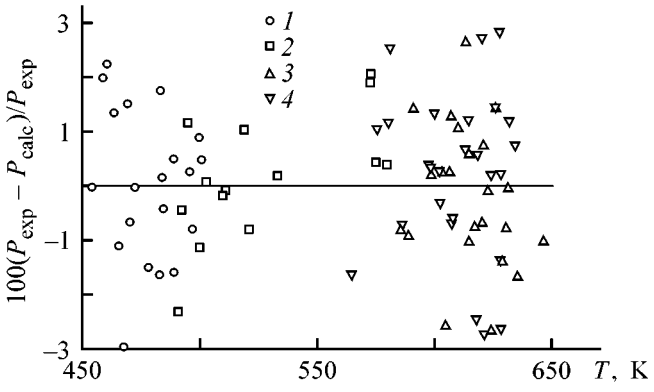

Fig. 4. Deviation of the calculated pressures P_{calc} from the experimental values P_{exp} for the *n*-hexane–water binary mixture. *x* (mole fraction): (*1*) 0.166, (*2*) 0.257, (*3*) 0.935, and (*4*) 0.964.

The quantity $\Delta A(\tau, \rho, \zeta)$ depends on the so-called crossover function *Y*; according to the value of this function, the singular part of the Helmholtz free energy transforms into a Wegner expansion (in close vicinity of the critical point) or into classical Landau series (far from the critical point). To identify the dependences of the critical parameters on the variable ζ as dependences on *x*, a condition that $x = \zeta$ along the critical line is imposed.

The asymmetry of the real liquid is taken into account on passing from model to physical variables. Nonuniversal constants of substance, characterizing the individual properties of the system, were calculated on the basis of published data and authors' *PVTx* experimental investigations [16].

The critical parameters for *n*-hexane were taken from [17]: $T_c = 507.20$ K, $P_c = 3.025$ MPa, $\rho_c = 233.5$ kg m^{-3}; and for water, from [18]: $T_c = 647.047$ K, $P_c = 22.046$ MPa, $\rho_c = 322.788$ kg m^{-3}. The concentration dependences of the critical parameters, necessary for calculations, were approximated by polynomials and splines.

Figure 4 shows deviations of the calculated pressures P_{calc} from the experimental values P_{exp}. The crossover equation of state makes it possible to describe the pressure of the *n*-hexane–water binary mixture with an error not exceeding 3% for densities in the range $0.50\rho_c \le \rho \le 1.7\rho_c$ (at $T = T_c$) and temperatures in the range $0.95T_c \le T \le 1.7T_c$ (at $\rho = \rho_c$).

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Determination of Internal Rotation Barrier

V. M. Yanborisov, M. Yu. Zaitsev, and Yu. B. Monakov

Bashkortostan State University, Ufa, Bashkortostan, Russia

Received June 14, 2001

Abstract—The interrelation between the experimental heights of the potential barrier to internal rotation about the C–C bond and those calculated by the semiempirical and nonempirical quantum-chemical methods for 25 compounds was studied. The height of the potential barrier to internal rotation about the C–C bond can be determined by the AM1 semiempirical method with correction introduced according to the correlation dependence established.

Studies of thermomechanical characteristics and deformation of polymers have long been utilizing the rotamer theory [1]. To determine the statistical weights of rotamers, it is necessary to know the difference in the free energies ΔG for these conformers. In the case that the entropy difference for the rotamers is negligible, it is possible to use for rotamers the energy difference ΔE instead of ΔG. The internal rotation barrier U for polymers is typically determined from the ΔG or ΔE values for low-molecular-weight analogs, found experimentally or by quantum-chemical calculations. However, in the latter case the results obtained by semiempirical methods strongly differ from experimental data, and nonempirical calculations require elucidating how the basis affects the results, which consumes much computer time.

In this work, we propose a technique for promptly calculating the parameter U. This technique is based on the correlation between U_{exp} and U_{calc}, established for 25 low-molecular-weight compounds (see figure and Tables 1, 2).

The figure presents the correlation dependences

$$U_{calc} = cU_{exp} + d. \quad (1)$$

Here, c and d are coefficients yielded by calculations for low-molecular-weight compounds listed in Table 2 by various quantum-chemical methods: semiempirical methods AM1, MNDO, and PM3 and nonempirical methods in the 3-21G* basis which affords adequate results for the problem and the class of compounds under consideration [12, 13].

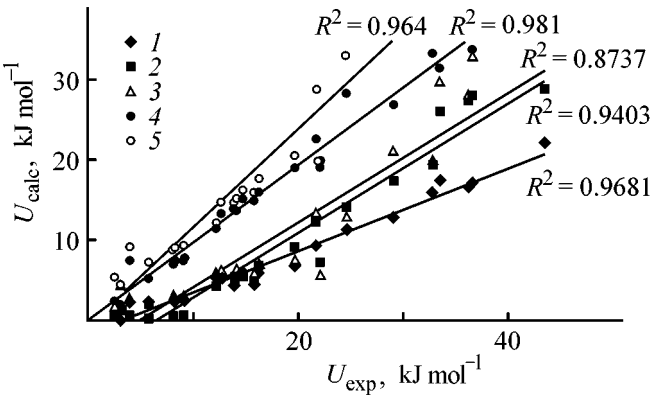
For a compound for which the experimental value U_{exp} is unknown, we propose to determine the height of internal rotation barrier by the inverse relationship

$$U = aU_{calc} + b. \quad (2)$$

The coefficients a and b are listed in Table 3. In expressions (1) and (2) for semiempirical methods AM1, MNDO, and PM3, we used the relation

$$U_{calc} = \Delta_f H^0_{max} - \Delta_f H^0_{min}.$$

Here, $\Delta_f H^0_{min}$ is the enthalpy of formation calculated from the optimal geometry of the molecule, $\Delta_f H^0_{max}$ is the enthalpy of formation calculated for the maximum in the dependence of the enthalpy on the internal rotation angle $\Delta_f H^0(\varphi)$.



Correlation between the experimental (U_{exp}) and calculated, by various quantum-chemical methods, (U_{calc}) heights of potential barrier to internal rotation about the C–C bond in molecules (Table 2). (*1*) AM1, (*2*) MNDO, (*3*) PM3, (*4*) 3-21G* (*E*), and (*5*) 3-21G* (*G*).

* ΔU calculated by formula (5) for ethane, ** U_{calc} calculated by formula (3), *** U_{calc} calculated by formula (4).

In the case of nonempirical calculation in the 3-21G* basis, the barrier height was determined either as difference of total energies

$$U_{calc} = E_{total}^{max} - E_{total}^{min}, \quad (3)$$

or that of free energies

$$U_{calc} = G_{max} - G_{min}. \quad (4)$$

The criterion of the transition state was the occurrence of a single negative value of the force constant of the chemical bond. The parameters of dependence (2) for the quantum-chemical methods utilized are given in Table 3.

The choice of quantum-chemical method for calculating U_{calc} is dictated by the following criteria (Table 3): correlation factor R^2, coefficients a and b (ideally, $a = 1$, $b = 0$), inaccuracy ΔU, and the computer time spent.

As regards the first criterion, namely, the correlation factor, the most suitable are AM1 method among semiempirical methods and, certainly, nonempirical method in the 3-21G* basis. It should be noted that from the viewpoint of all the criteria, calculation of the height of the internal rotation barrier as difference of total energies yields better results than calculation as difference of free energies (Table 3). The reason can be that in certain experimental works, especially those utilizing NMR method, specifically the height of the potential barrier was determined rather than the difference free of energies for conformers.

As regards the second criterion, namely, the coeffiicents a and b, the first place is, naturally, occupied by the nonempiirical method ($a = 1.01$, $b = 0.26$).

As to the third criterion, namely, inaccuracy in U, we calculated the standard inaccuracy ΔU by the formula

$$\Delta U = \sqrt{U_{calc}^2 \Delta a^2 + \Delta b^2}. \quad (5)$$

Hence, ΔU depends not only on the inaccuracies Δa and Δb, which are close for all the quantum-chemical methods applied (Table 3), but also on the calculated U_{calc} parameter, which is at a minimum for the AM1 method. The drawback of the AM1 method, namely, major underestimation of U_{calc}, compared with the experimental values, turns to advantage in the given case, as the accuracy in determining U increases.

Lastly, nonempirical calculations consume an order of magnitude longer computer time than semiempirical calculations.

CONCLUSION

The height of the potential barrier to internal rotation about the C–C bond can be calculated by semiempirical (AM1, MNDO, and PM3) or nonempirical methods with correction introduced according to the correlation dependences established. Among the methods considered the most suitable from the viewpoint of both accuracy and required computer time is AM1. This technique determines the height of the internal rotation barreir to within 1 kJ mol^{-1}, which is comparable with the accuracy of experimental methods.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Steady-State Concentration of Trace Amounts of Aromatic Hydrocarbons from Gas–Vapor Mixtures on Sorbent Surface

A. N. Marinichev, E. D. Makarov, and B. V. Stolyarov

St. Petersburg State University, St. Petersburg, Russia

Received July 12, 2001

Abstract—Features of sorption–desorption in solid-phase microextraction of aromatic hydrocarbons are considered in terms of the model with two consecutive steps. The data processing method proposed is based on determination of the steady-state microextraction parameters from experimental data obtained in the initial stage of the process.

Sorbent trapping of ecotoxicants from the atmosphere or air of production areas finds a wide practical use. It is realized with either total absorption of analytes on a sorbing material or establishment of steady-state mode of the gas flow as a result of sorption–desorption [1]. Finding out this mode may require full calibration of the peak area of a sorbed component against the gas–vapor mixture volume contacted with the sorbent. Competition between individual components for sorption sites may result in appearance of maxima in the calibration curves [2]. It is evident also that determination of the steady-state mode of sorption becomes complicated with increasing number of analytes.

In this study, we analyzed the possibility of predicting the solid-phase microextraction on the basis of experimental data obtained only in the initial stages of the process in terms of the second-order autoregressive model. Previously, this model has been successfully used in studying slow chemical and mass-exchange processes by interrupted or flow perturbation GC [3, 4].

EXPERIMENTAL

Gas-vapor mixtures of aromatic hydrocarbons C_6–C_8 (benzene, toluene, ethylbenzene, and *p*-xylene) in high-purity nitrogen with concentrations of 40–50 and 4–5 mg m^{-3} were prepared using a certified vapor generator (Monitoring Research and Production Association) or the original laboratory setup operating on the principle of phase distribution of volatiles between the coexisting gas and condensed phases [5, 6]. As a sorbing material we used domestically produced sorbent PDF-1 [poly(diphenylphthalide), S_{sp} ~250 m^2 g^{-1}, grain size 0.20–0.25 mm, sorbent bed 1 cm)] packed in a steel capillary (internal diameter about 0.5 mm).

Solid-phase microextraction of aromatic hydrocarbons was performed by passing the gas–vapor mixture through the sorbent bed at a rate of 5 to 20 ml min^{-1}. The flow rate was monitored and kept constant with an IRG-10 electronic flow meter/controller (Tsvet Public Corporation). The sorption time was measured with a stopwatch.

The amounts of individual hydrocarbons in the sorbent phase were estimated from data on their exhaustive desorption in a vaporizer of a gas chromatograph (nitrogen carrier gas, temperature 300°C). The response of the flame-ionization detector was measured with a Multichrom automatic chromatographic system. To separate the analytes, we used a quartz capillary column (20 m × 0.2 mm) with DB-1 stationary phase (analog of SE-30). The column temperature was 65°C, and the carrier gas (high-purity nitrogen) flow rate, 0.9 ml min^{-1}. The readings were taken at equal 100-ml intervals of the gas–vapor mixture passed through the sorbent. The calibration curve represented the dependence of the volume of the gas–vapor mixture passed through the sorbent on the peak area in the strippant chromatogram.

The table presents the results as a set of equidistant chromatographic peak areas A (equispaced by ΔV_g, where V_g is the volume of the gas–vapor mixture). Such data files are often treated in the frame-

1070-4272/01/7412-2005 $25.00 © 2001 MAIK "Nauka/Interperiodica"

work of the second-order autoregressive model (AR-2) correlating any three neighboring readings $A(V_g + 2\Delta V_g)$, $A(V_g + \Delta V_g)$, and $A(V_g)$:

$$A(V_g) + 2\Delta V_g) = pA(V_g + \Delta V_g) + qA(V_g) + r, \quad (1)$$

where p and q are the so-called slopes and r is the absolute term of the AR-2 model.

The difference equation (1) has a general solution

$$A(V_g) = A(0) + C_1\exp(-k_1V_g) + C_2\exp(-k_2V_g), \quad (2)$$

if the roots of the characteristic equation

$$z^2 + pz + q = 0 \quad (3)$$

are real numbers (z_1 and z_2). Modeling of sampled data as a linear combination of exponentials is known in the literature as Prony's method [7]. Note that in the chemical kinetics [8, 9], when considering consecutive two-step reactions of the type ($B_1 \xrightarrow{k_1} B_2 \xrightarrow{k_2} B_3$), the current concentration of compound B_3 [B_3] as a function of time t is described by a similar expression:

$$[B_3](t) = b_0[1 - \frac{k_2}{k_2 - k_1}\exp(-k_1t) + \frac{k_1}{k_2 - k_1}\exp(-k_2t)], \quad (4)$$

where b_0 is the initial concentration of B_1 ($t = 0$) and k_1 and k_2 are the rate constants of the corresponding stages.

The similarity of Eqs. (2) and (4) is evident, which will be used in the subsequent analysis of experimental data. In the case of complex roots ($z_{1,2} = m \pm n\sqrt{-1}$), the difference equation (2) has a general solution (5).

$$A(V_g) = A(0) + \exp(-kV_g)[C_1\cos(\varphi V_g) + C_2\sin(\varphi V_g)]. \quad (5)$$

The constants k_1 and k_2 in Eq. (2) are estimated as

$$k_i = -\frac{\ln z_i}{\Delta V_g} \quad (i = 1, 2).$$

The constants in Eq. (5) can be expressed as

$$k = -\frac{\ln(\sqrt{m^2 + n^2})}{\Delta V_g}, \quad \varphi = \frac{\arctan(n/m)}{\Delta V_g}.$$

The linear coefficients $A(0)$, C_1, and C_2 in Eqs. (1) and (2) can be easily estimated by the least-squares method {$A(0)$ can be also estimated as $A(0) = r/(1 + p + q)$ [10]}.

It should be noted that, just in processing equidistant data with AR-2 model, it becomes possible to obtain unique solutions for all target values (of course, if the model is adequate, i.e., has high coefficients of variation or determination), despite that Eqs. (2) and (5) are nonlinear in some of them.

Below are given equations similar to Eqs. (2) or (5), obtained by processing the $\bar{A}(V_g)$ data taken from the table according to the proposed procedure. In the parentheses are presented the mean (σ) and standard deviations (S) of the absolute values of the differences between the experimental [$\bar{A}(V_g)$] and estimated values [$\hat{A}(V_g)$].

For gas–vapor mixture I (see table) the expressions are as follows (coefficients of determination >0.95): for benzene (σ 0.2, S 0.2)

$$\hat{A}(V_g) = 31.5 + \exp(-0.0014V_g)[-13.1\cos(0.0090V_g) + 14.0\sin(0.0090V_g)],$$

for toluene (σ 1.1, S 1.5)

$$\hat{A}(V_g) = 171.3 + \exp(-0.0086V_g)[105.7\cos(0.011V_g) - 341.4\sin(0.011V_g)],$$

for *p*-xylene (σ 9, S 6)

$$\hat{A}(V_g) = 1458 - 1477\exp(-0.0006V_g) + 20\exp(-0.005V_g),$$

and for ethylbenzene (σ 6, S 6)

$$\hat{A}(V_g) = 727 - 751\exp(-0.00088V_g) + 28\exp(-0.0058V_g).$$

For mixture II (see table) the expressions are as follows: for benzene (σ 0.6, S 0.8)

$$\hat{A}(V_g) = 51.9 + \exp(-0.015V_g)[-247.1\cos(0.0088V_g) + 836.6\sin(0.0088V_g)],$$

for toluene (σ 1.3, S 1.4)

$$\hat{A}(V_g) = 391.4 + \exp(-0.0092V_g)[-1657\cos(0.0086V_g) + 1405\sin(0.0086V_g)],$$

and for *p*-xylene (σ 16, S 14)

$$\hat{A}(V_g) = 1892 - 4331\exp(-0.0084V_g) + 3858\exp(-0.020V_g).$$

The results demonstrate a satisfactory agreement of the theoretical $\hat{A}(V_g)$ and experimental peak areas $\bar{A}(V_g)$ (see table). Note also that for *p*-xylene and eth-

* Sorbent bed about 1 cm; gas–vapor mixture feed rate 20 ml min^{-1}.

ylbenzene the dependences of the peak area on V_g are described by expressions like Eq. (2) and for benzene and toluene, by expressions like Eq. (4).

Let us consider the features of sorption of *p*-xylene and ethylbenzene. A process described by the AR-2 model may be stationary or nonstationary [11]. Mathematically, the stationary condition is that roots of the characteristic equation should be within a unit disk, i.e., $|z_i| < 1$. Starting from certain V_g^*, $\hat{A}(V_g \geq V_g^*)$ remains practically constant and equal to the absolute term of the regression equation (in other words, steady-state mode is established). Just such a mode is realized for both *p*-xylene and ethylbenzene. Drawing an analogy with a consecutive two-step process, one may accept that these steps are sorption of a hydrocarbon on, and its desorption from the sorbent, and the instrumental signal $A(V_g)$ reflects here the concentration of the hydrocarbon that participated in sorption–desorption in the carrier gas that passed through the sorbent bed. Assuming that the sorption stage is reflected in the equations as the exponential term with the minus sign, one can recognize that the exponential indices (sorption rate constants) in the equations for *p*-xylene and ethylbenzene are different, whereas those in the terms with the plus sign appear to be close for these components (they can be regarded as the characteristics of desorption).

By virtue of complex roots of the characteristic equations, the regression equations obtained for benzene and toluene describe an oscillating (occasionally called pseudoperiodic) process [11].

To conclude, the model with two consecutive steps for sorption–desorption processes allows thorough characterization of the sorption behavior of each analyte of a complex gas–vapor mixture, making it possible to determine what volume of the gas–vapor mixture should be passed through the sorbent bed for the process to become stationary.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Kinetics of Water Desorption from Wheat Cereals

B. L. Korsunskii, N. V. Chukanov, V. P. Tarasov, and O. V. Anan'ina

Institute for Problems of Chemical Physics, Russian Academy of Sciences, Chernogolovka, Moscow oblast, Russia

Received February 15, 2001

Abstract—Water desorption from wheat cereals was studied by thermogravimetry, IR spectroscopy, and NMR relaxation in the temperature range 94–220°C. The process kinetics were described in terms of polychromic reactions. The kinetic parameters of the process were determined.

Sorption of water vapor by wheat cereals and other plant products and reverse desorption are of scientific and practical importance. The most commonly used method for determining the moisture content of cereals is based on measurements of water desorption and involves measurement of weight loss under thermostatic control (in the case of wheat cereals) at 130°C for 40 min [GOST (State Standard) 13586.5–93]. Moisture is desorbed in the course of drying of cereals. Water contained in cereals is actively involved in various physiological processes, and the features of sorption and desorption are closely related to these processes. From the purely chemical standpoint, sorption and desorption of water in cereals is a special case of hydration and dehydration of solids. These reactions are extremely widespread (in particular, for crystal hydrates [1]); in the case of cereals, the specific feature of hydration and dehydration consists in that these processes occur in essentially heterogeneous solids.

Here we report the kinetic features of water desorption from wheat[1] that was not subjected to premilling.

EXPERIMENTAL

The main characteristics of wheat were as follows: type IV, subtype 4, class 5, nature 760, passing through a sieve 1.7 × 20, the gluten amount corresponds to the second group; content of impurities (%): weedy, 0.8 and cereal, 1.2.

The drying kinetic were monitored by the variation of the wheat weight, using ATV-13R automatic thermal balance designed and manufactured at the Institute for Problems of Chemical Physics. The experiments were carried out in the temperature range 94–220°C. At a temperature of 110°C and above, the typical weighed portion of wheat was 40–50 mg, i.e., a single wheat cereal was studied. At lower temperatures, when the reaction proceeds extremely slowly, larger weighed portions, up to 1 g, were used.

When the samples were heated to high temperature, irreversible chemical transformations occurred in wheat in addition to water desorption. The composition of gaseous products formed in these transformations was determined by IR spectroscopy. For this purpose, the gaseous products were condensed in a glass trap cooled to –196°C. After defrosting, the products were extracted with ether, the ether solution was applied on a KBr window, and ether was allowed to evaporate. Then, the window was placed in a Specord M82 spectrometer and a spectrum was recorded.

The NMR spectra were recorded on an RI-23-03 pulse spectrometer operating at 60 MHz for protons. The spin–spin relaxation time T_2 was measured. The pulse length was 1.5–2 ms. The time interval of signal strobbing was 1 μs. The measurements were carried out in the temperature range from –150 to 150°C.

The typical kinetic curves of water desorption from wheat are shown in Fig. 1. It is seen that the process includes two clearly pronounced macroscopic stages: the first stage is very fast and then the process substantially self-decelerates. For example, at 110°C (curve *1*) the desorption rate at a 67% degree of desorption is a factor of 32 lower than the initial rate.

The kinetic curve of desorption is complicated and cannot be described by a simple kinetic equation (e.g.,

[1] Wheat from Tula oblast (harvest 1998, Mironovskii-88 sort) was used.

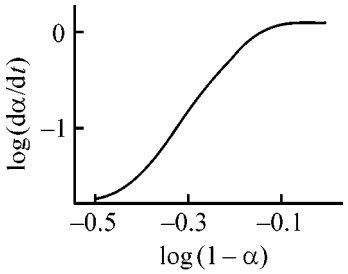

Fig. 2. Rate of water desorption from wheat cereals vs. the current water content in cereals. Temperature 130°C.

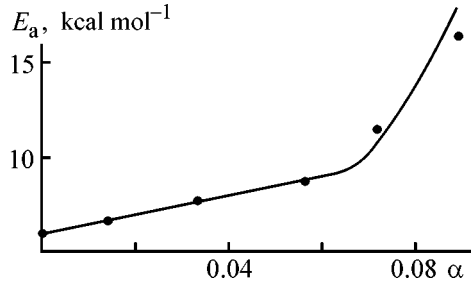

Fig. 3. Apparent activation energy E_a of water desorption from wheat cereals with initial moisture content of 11.25% vs. the amount of the released moisture.

equation of an *n*th-order reaction). Actually, when the reaction is described by an *n*th-order kinetic equation

$$\log(1 - \alpha) = f[\log(d\alpha/dt)], \quad (1)$$

where $\alpha = (m_0 - m)/m_0$ is the degree of conversion, m_0 is the initial weighed portion of the substance, and m is the current weight of the sample, a straight line with a slope equal to n should be obtained. It is seen from Fig. 2 that the actual plot is essentially nonlinear. That is, the reaction order n determined as the slope in the coordinates of Eq. (1) is not constant but varies in the course of the reaction. In the initial stage, n is close to 0, and then it passes through a maximum ($n_{max} \approx 7$) and tends to 1 at high degrees of dehydration.

This complicated kinetic behavior of the system does not allow determination of the activation energies with the standard procedures. Therefore, the activation energy of the process was found as follows. At a given temperature T_1 and degree of desorption α (corresponding to the reaction rate w_1) the system was heated to a higher temperature T_2, and the process rate w_2 was measured. Since the system was heated up rapidly (in approximately 3 min), we assumed that w_1 and w_2 values correspond to the same value of α. Then, the activation energy was determined from the expression

$$(E_a/R)[(1/T_1) - (1/T_2)] = \ln(w_2/w_1). \quad (2)$$

This method was detailed and substantiated in [2].

It was found that the apparent activation energy of desorption is not constant but varies during the process. For example, for wheat cereals with moisture content of 8.45% (determined from the weight loss at 130°C in 40 min), the activation energy increases from 5.9 in the initial stage of the process to 9.4 kcal mol^{-1} at a degree of dehydration of 80.5% (Fig. 3). At higher α, attempts to measure the activation energy failed, since under these conditions the reaction is extremely slow. In this case, an increase in temperature (which can noticeably accelerate dehydration at these values of α) is impossible, since this requires a heating that results in irreversible chemical transformations. In the special series of experiments, we studied the dependence of the activation energy at given α on temperature at which this α value was reached. For this purpose, the reaction was brought to $\alpha = 0.04$ at 91, 110, and 130°C and then the temperature was abruptly raised by 20°C. It was found that the activation energy was practically constant within the limits of experimental error; at the above temperatures it was 8.2, 7.9, and 7.1 kcal mol^{-1}.

As seen from Fig. 1, water is completely removed from wheat cereals within several hours only at approximately 160°C. At a higher temperature the reaction also proceeds in two stages (Fig. 1, curve *4*). However, in this case, the second slower stage of the reaction involves not dehydration but irreversible

chemical transformations. Actually, in this run the cereals were carbonized and various organic compounds were present in gaseous reaction products. In the IR spectrum of these products, absorption bands at 3620 (weak hydrogen bonds), 3300–3400 (water and alcohols), 3220 (OH or NH), 2930 (methyl groups), 2860 (methylene and methyl groups), 2500 (carboxy groups), and 1710 cm^{-1} (C=O stretching modes) were found. It should be noted that, according to IR data, dehydration of cereals at 160°C for 1 h is accompanied by transition of only water to the gas phase. The stage corresponding to chemical transformations in cereals has higher activation energy, which is close to 25 kcal mol^{-1} for the temperature range 180–220°C.

The results of NMR relaxation studies of wheat cereals are presented in Fig. 4. Curve *1* was obtained for the initial cereals, and curve *2*, for cereals subjected to heating at 130°C for 100 min. In both curves, there are two portions corresponding to fast and slow proton relaxation (*A* is fraction of oriented spins). The fast decay corresponds to the low-mobile protons of starch, and slow decay, to mobile protons of water molecules. Computer simulation showed that the slow decay in curve *2* is exponential and the decay in curve *1* is two-exponential. A computer extrapolation of the two-exponential portion to the initial instant of time showed that the amount of water protons in the initial cereals is about 30% of the total amount of protons in cereals. At the same time, for curve *2* (i.e., after heat treatment) this fraction decreases to 8–10%. The kinetic curve describing the decrease in the amount of mobile protons β (%) during heating of wheat cereals at 130°C is presented in Fig. 5.

The kinetic curve of water desorption from wheat cereals at 130°C, obtained from NMR data, is shown in Fig. 1 in the form of experimental points. Comparison of this curve with curve *2* (Fig. 1) shows that the results of gravimetric and NMR measurements are in reasonable agreement.

In discussing the results obtained, it is appropriate to consider only the processes related to water desorption and not to irreversible chemical transformations accompanied by formation of various organic products. The above data suggest that in wheat cereals there are at least two types of water molecules, relatively weakly and relatively strongly bonded. As seen from Fig. 3, the boundary between these two types corresponds to $\alpha = 6.6\%$ and activation energy of 9.4 kcal mol^{-1}. It is interesting that the latter value is close to the heat of water vaporization, 9.7 kcal mol^{-1} [3]. In the initial stages of dehydration, the apparent activation energy is noticeably lower than the heat of

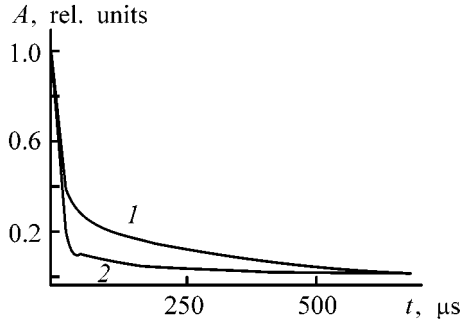

Fig. 4. Free induction decay *A* of (*1*) the initial wheat cereals and (*2*) cereals preliminarily heated at 130°C for 100 min. (*t*) Time.

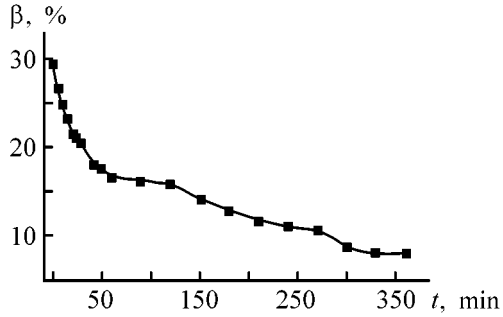

Fig. 5. Fraction of mobile protons in wheat cereals β vs. time *t* at 130°C.

water vaporization. Hence, water desorption from wheat is controlled in these stages not by vaporization (i.e., rupture of several hydrogen bonds is not limiting stage), but, evidently, by diffusion. By contrast, when $\alpha > 6.6\%$, the activation energy is higher than the heat of water vaporization, i.e., in this case, dehydration is controlled not only by water diffusion but also involves overcoming of the difficulties produced by the material of wheat cereals.

Thus, it is reasonable to speak about distribution of water molecules with respect to their reactivity during dehydration of wheat. Similar phenomena, namely, different reactivities of molecules of the same substance in different sites of the reaction mixture, are common in chemistry of solids and are termed "polychromic processes" [4]. The kinetic curves presented in Fig. 1 are typical of such reactions [5].

As already mentioned, the right branch of curve *4* (Fig. 1) corresponds to chemical degradation of cereals, rather than to water desorption. Therefore, extrapolation of this curve to zero time must correspond to weight loss due to dehydration only. In Fig. 1, the corresponding weight loss is shown by dashed line; it characterizes the true moisture content of cereals, equal to 11.25% for this specific case. It is of interest that the same line is the asymptote for kinetic curve *3* obtained at 160°C. In other words,

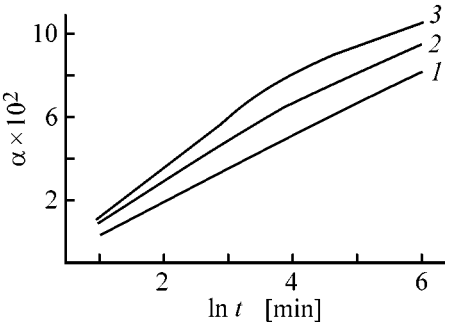

Fig. 6. Kinetic curves of water desorption from wheat cereals in the coordinates of the Elovich equation. (*t*) Time. Temperature (°C): (*1*) 110, (*2*) 130, and (*3*) 150.

this curve describes only dehydration (without chemical destruction); in this case, virtually complete removal of water is attained within several hours. Thus, the kinetic approach to water desorption from wheat cereals allows determination of the total content of water in cereals with high accuracy without grinding required by GOST 13586.5–93.

It was already noted that there is a qualitative agreement between the gravimetric and NMR relaxation data. However, there is no close similarity. As seen from Fig. 1, the process described by the NMR relaxation is somewhat faster and is finished earlier than it follows from gravimetric measurements. In addition, this process is very complex: at high degrees of desorption the process becomes multistage (Fig. 5). This disagreement with data of gravimetric measurements suggests that during heating water molecules not only leave cereals but are also subjected to transformations involving, in particular, the loss of their mobility.

Considering two types of water molecules in wheat cereals (weakly and strongly bonded), we somewhat simplified the situation. The point is that water molecules differ in activation energy even within each type (Fig. 3). In the simplest case, polychromic kinetics can be described by the Elovich equation [6], in which it is assumed that the activation energy depends linearly on the degree of conversion. In the case in hand, it would be expected that two straight portions corresponding to one or another type of water molecules can be obtained in the coordinates of this equation. The data obtained in the temperature range 110–150°C are presented in Fig. 6. As seen, the linear dependence is actually obeyed up to $\alpha \approx 7\%$, i.e., practically to the degree of conversion corresponding, according to Fig. 3, to the boundary between different types of water molecules. It should be noted that this degree of conversion, up to which the Elovich equation is obeyed, is temperature-independent within experimental error. Then, there is a bend in the curve, and, after short transition portion, the Elovich equation is obeyed again, but with another slope corresponding to the other type of water molecules (strongly bound water).

CONCLUSIONS

(1) Water desorption from wheat cereals not subjected to grinding was studied by gravimetry, IR spectroscopy, and NMR relaxation in the temperature range 94–220°C. At temperatures below 160°C and heating time of about several hours, water desorption from wheat cereals is the only process; at higher temperatures, along with water desorption, irreversible chemical transformations occur, accompanied by release of various organic substances.

(2) The kinetic data suggest that water is present in wheat cereals in two forms: weakly and strongly bound. The kinetics of desorption of both weakly and strongly bound water were described in terms of the model of polychromic reactions, according to which the activation energy is a function of the degree of desorption. The kinetic parameters of the process were determined.

(3) Kinetic data on water desorption can be effectively used for determination of the moisture content of wheat cereals.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Removal of Heavy Metal from Solutions of Their Complexes with a Sorbent Prepared from Shells of *Musca Domestica* Larvas

O. Gyliene and A. Pigaga

Institute of Chemistry, Vilnius, Lithuania

Received November 23, 2000; in final form, March 2001

Abstract—Sorption of Cu(II) and Ni(II) complexes with ammonia, aminoacetic acid, and EDTA and sorption of chromium(VI) by shells of *Musca Domestica* larvas was studied.

Metal complexes are widely used in various branches of industry (electroplating, textile industry, production of dyes and drugs, radioelectronics, etc.). The presence of ligands forming strong complexes with these metals prevents precipitation of the metals from solutions. In this case, to remove metal ions from solutions, these ligands are decomposed. In solutions containing carboxylate anions, coprecipitation of metal hydroxides and carboxylates provides almost complete removal of the metal from solutions [1]. To precipitate bivalent metal ions in the form of oxalates from solutions of their amino complexes, the solutions are acidified to pH 0–1. The degree of removal of metals from these solutions is 95–98% [2]. Removal of metals from solutions by their reduction or electrodeposition is also incomplete. In this case, additional purification is required after removal of the major portion.

Natural sorbents or industrial wastes, such as peat and wood sawdust, are widely used to remove heavy metals from dilute solutions [3, 4]. Among these sorbents is the material of Shells of *Musca Domestica* larvas (SMDL) which is produced by biological treatment of protein raw materials.[1] These shells contain 40% of natural polysaccharide [(1→4)-2-acetamido-2-deoxy-β-*D*-glucan] exhibiting good sorption properties with respect to heavy metal ions [5–7]. It should be noted that sorption of metal complexes on both synthetic and natural sorbents has been poorly studied. Previously, we have studied [8] the sorption properties of chitin prepared by conventional treatment of SMDL with HCl and NaOH solutions [8]. It was found that this chitin sorbs only free heavy metal cations, whereas degreased SMDL do not sorb free ions of most of heavy metals at all [9]. Relatively good sorption of metal complexes form solutions on SMDL was surprising.

In this work, sorption of metal complexes from solutions on SMDL was studied in detail.

EXPERIMENTAL

To make SMDL wettable, they were degreased by treatment with a 40 g l^{-1} NaOH solution at room temperature for 24 h. During this treatment, proteins partially dissolved, as indicated by a decrease in the nitrogen content from 7.8 to 6.2 wt %. The study of the sorption kinetics showed that, with stirring, the equilibrium between the solid and liquid phases was attained within 2–3 h, although an insignificant decrease in metal concentration was observed throughout the experiment (up to 20 days). A metal complex solution containing washed and dried shells was stirred at room temperature for 4 h. When sorption isotherms were studied, the shells were additionally kept in the solution for 5 days with intermittent stirring to attain the true equilibrium. The pH was adjusted with NaOH or H_2SO_4 solutions. The sorption of metal ions and glycine was estimated from the difference of their concentrations before and after the experiment, which, in their turn, were determined by complexometric titration and, at trace level, by colorimetry.

Since the metal sorption is almost independent of the degree of SMDL grinding, we used partially ground shells in the form of 0.5–2.0 mm^2 flakes, which are

[1] About 20 kg of SMDL is formed daily during processing of food wastes with *Musca Domestica* at Chitinas Joint Stock Company (Vilnius).

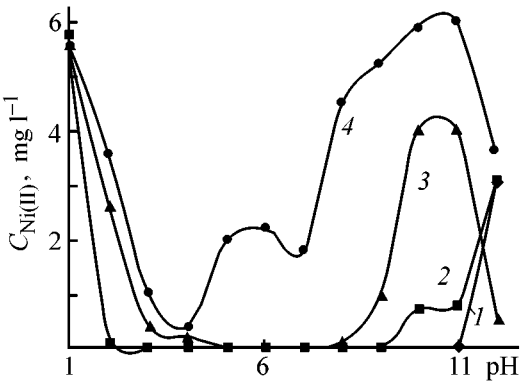

Fig. 1. Residual concentration of nickel ions after sorption $C_{Ni(II)}$ vs. solution pH. Amount of SMDL 10 g l^{-1}, initial Ni(II) concentration 0.1 mM Glycine concentration (mM): (*1*) 0.4, (*2*) 4.0, (*3*) 40, and (*4*) 400.

readily stirrable, filterable and washable. The shells were repeatedly used after regenration with 3–6 M acetic acid. After this treatment, their sorption capacity even slightly increased.

We studied sorption of metal complexes widely used in electroplating and production of printed-circuit boats. The results presented in Table 1 show that SMDL, to a greater or lesser extent, sorb metal complexes from solutions. The metal sorption depends on both pH and the ligand concentration in the solution. In acidic solutions, the shells probably reduce Cr(VI) to Cr(III), which is not the case at higher pH.

A study of the sorption of Ni(II) glycine (aminoacetate) complexes widely used in nickel plating showed a rather complex dependence of the residual

N(II) concentration on the solution pH. The sorption is maximal at pH 3–6 and ~12 (Fig. 1). This may be due to the pH dependence of the composition of Ni glycinate complexes [10]. In acidic solutions, $[Ni(gly)]^+$ is formed. At higher pH, $[Ni(gly)_2]$ exists in solution. At pH > 10, $[Ni(gly)_3]^-$ is detected. The ligand concentration also affects the metal sorption (Fig. 1, Table 2). The sorption of nickel ions decreases with increasing ligand concentration in the solution. Strong effect of glycine on the sorption properties of SMDL suggests cosorption of nickel ions with the ligand. Determination of the glycine content in the solutions showed that the sorption of glycine on SMDL is even higher than that of nickel ions (Fig. 2).

Sorption on SMDL of Cu(II)–EDTA complexes used for electroless copper plating of perforations in printed-circuit boards differs somewhat (Fig. 3, 4). When the EDTA concentration in the solution is lower than the Cu(II) concentration, SMDL sorb copper ions only from alkaline solutions (pH ≈ 12). In this case, $[Cu(EDTA)(OH)]^{3-}$, rather than $[Cu(EDTA)]^{2-}$, is probably sorbed [11].

As the EDTA-to-Cu(II) ratio increases, the copper sorption grows. When this ratio is in the range 100–1000, copper is readily sorbed at pH 3–12. In more acidic solutions (pH 0–2), EDTA exists in the form of difficulty soluble acid H_4EDTA, which decreases the copper sorption.

Since EDTA enhances copper sorption, SMDL can be used for additional removal of copper ions from electroless copper plating solutions. These solutions contain, after preliminary copper removal by precipitation with oxalate or reduction on active CuO, 10–250 and 0.1–0.5 mM ligand and copper, respectively.

Our previous experimental results [9] suggest that metal complexes are not sorbed by chitin, which is the main component of the shells. The sorption involves formation of complexes with other compounds present in the shell, such as keratins, melanins, inorganic compounds, etc. [6]. This agrees with the fact that sorption of heavy metals on Khizit (waste of processing of crab armors) is about 8 times higher [4] than on chitin.

CONCLUSIONS

(1) Shells of *Musca Domestica* larvas sorb ammonia, citrate, tartrate, glycinate, and EDTA complexes of nickel and copper, which are difficultly removed from solutions.

(2) The sorption capacity and degree of metal removal depend in the complex manner on the ligand concentration in the solution and on pH. An increase in the ligand fraction suppresses nickel sorption from glycine solutions and enhances copper sorption from EDTA solutions.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Modification of Fine Silica with Polyvinylpyrrolidone

N. V. Guzenko, E. M. Pakhlov, N. A. Lipkovskaya, and E. F. Voronin

Institute of Surface Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received July 19, 2000; in final form, December 2000

Abstract—The interaction of fine silica with polyvinylpyrrolidone in aqueous medium was studied by IR spectroscopy.

Due to its specific properties, fine amorphous silica is widely used in biotechnology, agriculture, medicine, and pharmaceutics [1, 2]. Silica sorbents with required properties can be prepared by their chemical modification. Modification involves substitution of the initial functional surface groups of silica by other groups or coating of the surface by a monomolecular layer of the corresponding polymer. Modification of the surface of fine silica with polyvinylpyrrolidone (PVP) allows preparation of silica sorbents with new properties [3].

Polyvinylpyrrolidone is used in medicine, pharmacy, and cosmetics. This hydrophilic polymer is soluble in water and other solvents and can participate in complex formation. Such PVP properties as stabilization of emulsions and suspensions, prolongation of the effect of some drugs, and nontoxicity [2] are important in the pharmaceutical industry.

In our study, we used A-300 brand Aerosil with specific surface area of 287 $m^2 g^{-1}$, containing spherical primary particles (9–10 nm in diameter). The surface of these particle contains isolated hydroxy groups ≡Si–OH (silanol groups), hydroxy groups linked by hydrogen bonds in various combinations, and molecular water in various forms, from coordination-bound to physically sorbed. The concentration of silanol groups, which are the main sorption centers, on the surface of the silica studied was 0.65 mmol g^{-1}, and the total water content, 4–5 wt %. Owing to hydrogen bonds, these primary Aerosil particles form secondary particles or aggregates 200–500 nm in diameter [1, 4].

As modifying agent we used a 5% aqueous solution of pharmacopeia grade PVP (molecular weight about 12000). Since PVP is rather hygroscopic, PVP solutions are more convenient for experimental work than powders. Aqueous PVP solutions are stable for a long time after their sterilization for 15–20 min.

In this work, we studied the interaction of fine silica with PVP and the effect of sorption modification of the surface on some sorbent properties.

EXPERIMENTAL

The PVP sorption was performed under static conditions at room temperature. Solutions of PVP (initial concentration 0.1–0.6 wt %) were mixed with a 5% silica suspension so that the solution : sorbent ratio was constant, 10 ml : 100 mg. After 1-h contact the mixture was centrifuged for 30 min at 8000 rpm. The amount of sorbed PVP was determined photocolorimetrically with iodine [5] from the difference in the PVP concentrations in solution before and after interaction with silica.

The curve of PVP sorption on the fine silica surface is described by the Langmuir isotherm (Fig. 1). In the C_e/A–C_e coordinates, where C_e is the equilib-

rium concentration of a dissolved compound and A is the PVP sorption, this isotherm is a straight line. This allows evaluation of the maximal sorption of the PVP polymer A_{max} [6], equal to 200 mg g^{-1}. According to the Langmuir theory, A_{max} corresponds to the monolayer capacity.

In amounts of up to 100 mg g^{-1}, PVP is irreversibly sorbed on the Aerosil surface and is not removed from the sample upon contact with pure water. At higher PVP content the polymer is partially desorbed. It was found that, with increasing initial PVP content, the degree of its desorption increases, simultaneously the absolute amount of the irreversibly sorbed polymer increases also (Fig. 2). Since the stability of composition and properties of sorbents in the course of their operation is an important requirement [7], we should distinguish, for more correct characterization of the sorbents in question, two parameters. These are the PVP sorption A_{PVP} (total content of polymer in the surface layer) and the degree of surface modification θ_{mod}, namely, the ratio of the amount of irreversibly sorbed PVP to a value of 100 mg g^{-1}, which, taking into account the above data (Figs. 1, 2), can be considered 100% modification (θ_{mod} = 100%).

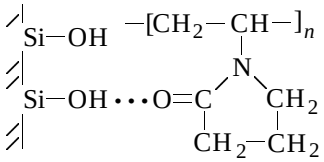
To analyze the structure of the adsorption layers and conformation of macromolecules in them, we must know the fraction of fragments of the polymeric chains directly interacting with the silica surface, because, in contrast to the sorption of low-molecular-weight compounds, simultaneous interaction of all the fragments of macromolecular chain with the sorbent surface is impossible. In this case, the parameter p is used, namely, the ratio of the number of fragments directly interacting with the sorbent surface to the total number of fragments in the polymer sorbed.

The number of fragments in the macromolecular chains directly interacting with silica surface can be effectively determined by IR spectroscopy [6]. As seen from Fig. 3, the intensity of the absorption band at 3750 cm^{-1}, belonging to free silanol groups ≡Si–OH, decreases with increasing coverage of the silica surface with PVP, and a new absorption band appears at 3350 cm^{-1}, which belongs to the silanol groups linked by hydrogen bonds. The absorption bands at 1350–1550 and 2800–3000 cm^{-1} belong, respectively, to the bending and stretching vibrations of the C–H bonds in the polymer, whereas the absorption in the 1600–1750 cm^{-1} range is typical of the C=O carbonyl groups [8].

The degree of participation of the surface OH groups in the interaction with PVP can be determined from the ratio of the optical densities of the band at 3750 cm^{-1} before and after sorption (D_0 and D, respectively) using the following expression:

$$\theta = 1 - D/D_0.$$

Analysis of the structures of the silica surface and PVP molecule and the experimental IR data suggest that the polymer adsorption proceeds predominantly through formation of hydrogen bonds between the oxygen atom of the carbonyl group in the PVP molecule and hydrogen of the silanol group:



It is often assumed that strong sorption of PVP on silica is also due to the formation of an additional hy-

drogen bond between the hydrogen atom of the silanol surface group and nitrogen atom of the pyrrolidone ring ≡Si–OH···N(PVP) [9]. However, we found no characteristic absorption bands in the IR spectra attributable to the interaction of the PVP nitrogen atom with the silica surface (Fig. 3). Analysis of the chemical properties of lactams (such as PVP) suggests that nitrogen atom in the pyrrolidone ring loses its electron-donor power and thus cannot form hydrogen bonds [10].

To determine the quantitative ratio between the sorbent and sorbate, we regard the polymer macromolecule as a sum of vinylpyrrolidone (VP) units. Then, using the data on the PVP sorption A_{PVP} for each sample, we can determine the total concentration of the carbonyl groups α_{CO} in the polymer layer, which is obviously equal to the content of VP units on the surface:

$$\alpha_{CO} = \alpha_{VP} = A_{PVP}/M_{VP},$$

where α_{CO} is the total content of the carbonyl groups (mmol g^{-1}), α_{VP} the content of the VP fragments (mmol g^{-1}), A_{PVP} the PVP sorption (mg g^{-1}), and M_{VP} the molecular weight of the VP unit (111 mg $mmol^{-1}$).

Since a single VP unit forms bond with a single silanol group on the silica surface, the number of the carbonyl groups, α'_{CO}, participating in the linking is equal to the number of the hydroxy groups, α'_{OH}, and can be determined from the following equation:

$$\alpha'_{CO} = \alpha'_{OH} = \alpha_{OH}\theta,$$

where α'_{CO} is the concentration of the carbonyl groups interacting with the silica surface (mmol g^{-1}), α'_{OH} the concentration of the excited silanol groups (mmol g^{-1}), α_{OH} the initial concentration of the surface silanol groups (0.65 mmol g^{-1}), and θ the degree of involvement of the silanol groups in hydrogen bonding with VP units.

Thus, the criterion p describing the conformation of the adsorbed macromolecules can be calculated by the following expression:

$$p = \alpha'_{CO}/\alpha_{CO} = \alpha_{OH}\theta/(A_{PVP}/M_{VP})$$
$$0.65\theta/(A_{PVP}/111) = 72.15\theta/A_{PVP}.$$

As seen from our calculations (Fig. 4), p depends on the PVP content at the silica surface. At low polymer sorption, p = 0.8, which corresponds to a highly compact sorption layer [6]. At higher degrees of coverage, p decreases, which suggests formation of looser structure of the adsorption layer with saturation of the sorbent surface. At higher coverage of the surface the sorption layer undergoes certain rearrangement.

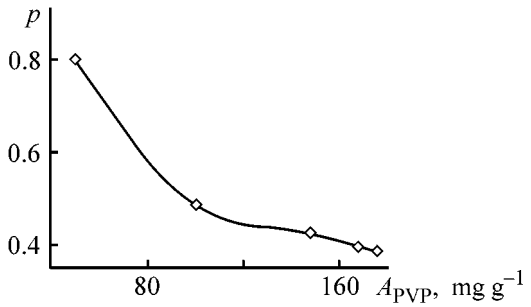


Fig. 4. Fraction of bound carbonyl groups p vs. PVP sorption A_{PVP}.

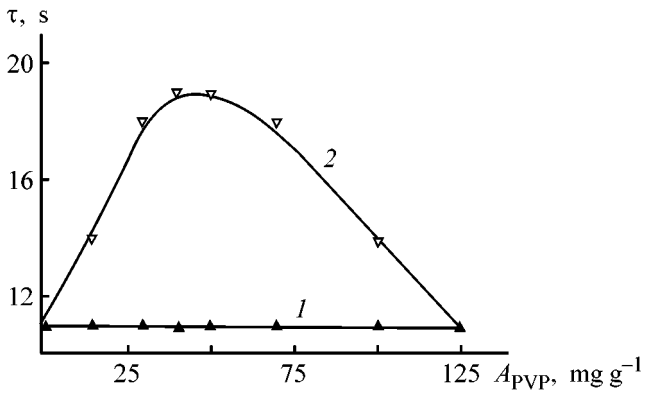

Fig. 5. Efflux time of 5% suspension τ vs. PVP sorption A_{PVP}. Solvent: (*1*) distilled water and (*2*) 0.9% NaCl solution.

The appearance of free carbonyl groups on the surface would obviously cause certain changes in the sorption and other properties of the modified silica sorbents.

We studied the rheological properties of the silica suspensions in relation to the degree of their surface modification. The viscosity of suspensions was determined using a VZ-4 viscometer designed as a 100-ml plastic beaker in which the conical bottom had a calibrated 4-mm outlet.

The measurements were performed as follows. The viscometer was filled with a suspension and the efflux time, which is inversely proportional to the viscosity of the sample, was determined at 20°C. It was found that the viscosity of our suspensions is almost independent of the PVP content and is only slightly higher than that of water. However, when the suspensions were prepared using normal saline (0.9% NaCl solution), the dependence of the suspension viscosity on the degree of modification passes through a maximum (Fig. 5). With increasing degree of Aerosil modifica-

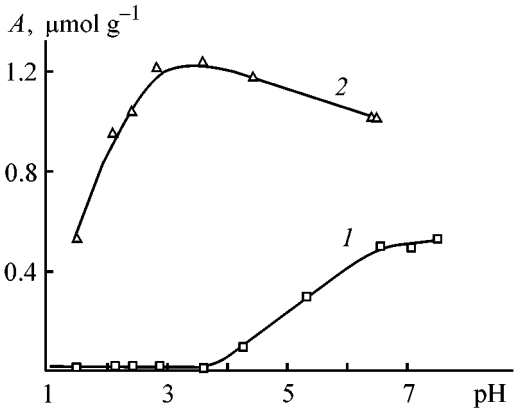

Fig. 6. Sorption of quercetin *A* on the (*1*) initial and (*2*) PVP-modified (θ_{mod} = 100%) sorbents vs. the suspension pH.

tion with PVP, the suspension viscosity first increases, reaching a maximum at θ_{mod} = 50%, and then gradually decreases. We assume that such a dependence is due to the interaction of free carbonyl groups appearing at the surface of a silanol particle with the silanol groups still preserved on the surface of another silica particle. Apparently, the strongest interaction is observed when the number of the silanol and carbonyl groups on the silica particles is close. At complete filling of the sorbent surface with PVP the interaction between the Aerosil particles would rather be similar to contacts between polymer macromolecules.

A question arises as to why such a significant increase in the interparticle interaction is observed only in the presence of NaCl. We assume that the effective interaction between partially modified Aerosil aggregates is hindered by certain, most probably steric factors. However, according to [1], cations occurring in silica colloids or suspensions can act as linking agents forming bridges between particles. Hence, appearance of hydrated sodium cations in the suspensions in question promotes linking of the particles and leads to formation of three-dimensional networks, which, in turn, increases the suspension viscosity.

Since PVP easily forms complexes with various (including aromatic) compounds, we suggested that modification of the silica surface with PVP would affect the sorption properties of modified sorbents with respect to phenols, which are not noticeably sorbed on the initial silica. We studied sorption of natural polyphenol quercetin from aqueous alcohol on Aerosil containing 100 mg g^{-1} of PVP (θ_{mod} = 100%).

The sorption was performed under static conditions: the solution : sorbent ratio was 10 ml : 100 mg, the initial quercetin concentration was $C_0 = 3.2 \times 10^{-5}$ M, the suspension pH was adjusted using HNO_3 and NaOH. After 1-h contact the mixture was centrifuged for 30 min at 8000 rpm. The sorption capacity was evaluated from the difference of the quercetin concentrations in solution before and after interaction with silica by spectrophotometry (λ = 367 nm [11]).

The isotherms of the quercetin sorption (Fig. 6) show that modification of the silica surface with PVP strongly affects its sorption properties, especially in weakly acidic solutions. No quercetin is sorbed on the initial silica at pH < 4, whereas in the case of the modified sorbent the highest sorption capacity is observed at pH 3–4.

CONCLUSION

Our experimental results show that sorption modification with polyvinylpyrrolidone allows control of the properties of fine silica and composites based on it.

CATALYSIS

Oxidation of *D*-Glucose to *D*-Gluconic and *D*-Glucaric Acids Catalyzed by Sodium Nitrite

I. A. Grigor'eva, S. S. Chernaya, and S. R. Trusov

Riga Technical University, Riga, Latvia

Received January 30, 2001

Abstract—Kinetics of catalytic oxidation of *D*-glucose in the $HClO_4$–H_2O–sulfolane system containing $NaNO_2$ was studied. Kinetic equations of the process were derived. A scheme for oxidation of *D*-glucose with oxygen in the presence of $NaNO_2$ was proposed.

Conventional oxidation of organic compounds with oxygen in the presence of metal complexes is not always selective. Recently, alternative catalytic procedures have been proposed, involving, in particular, oxygen-containing nitrogen compounds [1, 2].

Previously, we showed that alcohols are selectively oxidized by oxygen in stronly acidic solutions containing catalytic amounts of $NaNO_2$ [3]. The reaction rate and yield of the products increase in the presence of organic sulfones [4].

In this study, we used this procedure for oxidation of monosaccharides, with *D*-glucose as an example, since the products of its selective oxidation are widely used in pharmaceutics.

EXPERIMENTAL

The kinetics of the process was studied by the gasometric procedure described in [5]. The concentrations of *D*-glucose, *D*-gluconic acid, $NaNO_2$, and $HClO_4$ were varied in the following ranges (M): 0.5–1.5, 0.5–1.5, 0.01–0.25, and 4.0–6.0, respectively. The partial oxygen pressure in the gas phase, p_{O_2}, was varied from 0.2×10^5 to 1.0×10^5 Pa, and temperature, from 313 to 343 K. A mixture of $HClO_4$, water, and sulfolane was used as solvent. The total pressure in the system was kept constant at 1×10^5 Pa. The volume of the liquid V_l and gas phase V_g was 5 and 80 ml, respectively. The fact that the rate of oxygen uptake is independent of the hydrodynamic parameters (reactor volume, shape of its walls, frequency and amplitude of rocking) indicates that the rate-determining step of the process in the chemical reaction.

The quantitative and qualitative composition of the oxidation products was determined by GLC [6]. The structure of the products was confirmed by elemental analysis, ^{1}H NMR, and chromato-mass spectrometry. The total equilibrium concentration of N(III) compounds in the liquid phase {[N(III)], M} was determined by spectrophotometry [7] and chromato-mass spectrometry.

We found that oxidation of *D*-glucose under these conditions is described by the equation

$$\underset{D\text{-glucose}}{RCHO} + \frac{1}{2}O_2 \xrightarrow[H^+]{NaNO_2} \underset{\substack{D\text{-gluconic}\\ \text{acid}}}{RCOOH} + O_2 \xrightarrow[H^+]{NaNO_2} \underset{\substack{D\text{-glucaric}\\ \text{acid}}}{R_1(COOH)_2} + H_2O. \quad (I)$$

The results of GLC and gasometry showed that the volume of oxygen taken up and the concentration of the oxidation products correspond to the stoichiometry of Eq. (I). Therefore, in further studies, the volume of oxygen taken up was recalculated to the concentration of the reactants by Eq. (I).

In the absence of sodium nitrite, all other conditions being the same, *D*-glucose is not noticeably oxidized. At $NaNO_2$ concentration from 0.075 to 0.25 M, *D*-glucose is almost quantitatively converted within 2 min into *D*-gluconic acid, which is slowly oxidized to *D*-glucaric acid (Fig. 1a). This makes impossible a kinetic study of oxidation of *D*-glucose to *D*-gluconic acid (the first step) under these conditions. At catalyst concentration of 0.01–0.05 M, reaction (I) is appreciably slower (Fig. 1b), with the rate of the second step (oxidation of *D*-gluconic acid to *D*-glucaric acid) being negligible as compared with that of the first step up to 60% conversion of *D*-glucose. This allowed kinetic study of the first step of reaction (I) at the initial $NaNO_2$ concentration from 0.01 to 0.05 M.

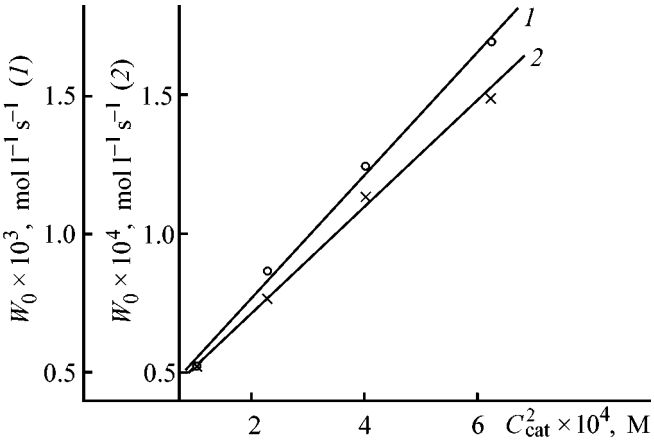

Fig. 5. Initial rate of oxidation W_0 of (*1*) *D*-glucose and (*2*) *D*-gluconic acid as a function of the $NaNO_2$ concentration C_{cat}. Initial concentration of (*1*) RCHO, (*2*) RCOOH, $HClO_4$, and sulfolane 1.0, 1.0, 6, and 2.6 M, respectively. $T = 333.2$ K, $p_{O_2} = 1 \times 10^5$ Pa; the same for Fig. 6.

The experimental kinetic curves of *D*-glucose oxidation to *D*-gluconic acid are shown in Figs. 2, 3. The following dependences of the initial rate of *D*-glucose oxidation W_0 (mol l^{-1} s^{-1}) on the reaction conditions was derived by mathematical processing of these results:

$$\frac{\partial W_0}{\partial C_g} = 0,\ \frac{\partial W_0}{\partial T} = 0,\ \frac{\partial W_0}{\partial C_a} = 0,\ \frac{\partial W_0}{\partial C_{cat}} > 0,\ \frac{\partial W_0}{\partial p_{O_2}} > 0, \quad (1)$$

where C_g, C_a, and C_{cat} are the initial concentrations (M) of glucose, perchloric acid, and sodium nitrite, respectively.

Processing of the data presented in Figs. 4, 5 gives

$$W_0 = k_{exp} C_{cat}^2 p_{O_2}, \quad (2)$$

where $k_{exp} = (0.42 \pm 0.08) \times 10^{-4}$ mol^{-1} l s^{-1} Pa^{-1}.

To explain these kinetic dependences, let us consider the composition of the catalytic sustem and possible reactions of its compounds. Chemical transformations of sodium nitrite in 4–9 M aqueous solutions of perchloric acid can be described by the following scheme [8]:

$$NO_2^- + H^+ \rightleftarrows HNO_2, \quad (II)$$

$$HNO_2 + H^+ \overset{K_{NO^+}}{\rightleftarrows} NO^+ + H_2O, \quad (III)$$

$$NO_2^- + NO^+ \rightleftarrows NO + NO_2. \quad (IV)$$

Bayliss and Watts found [8] that equilibrium (III) is almost completely shifted to the right. Thus, we suggest that, in the liquid phase of the catalytic system, the catalyst occurs partially in the form of HNO_2 and NO^+. The gas phase probably contains nitrogen oxides NO and NO_2. Since the system is closed, the mass balance must be fulfilled:

$$n(NaNO_2) = n(HNO_2) + n(NO^+) + n(NO) + n(NO_2), \quad (3)$$

where $n(NaNO_2)$ is the initial amount of sodium nitrite (mole); $n(HNO_2)$, $n(NO^+)$, $n(NO)$, and $n(NO_2)$ are the amounts (mole) of the respective components of the catalytic system in the course of oxidation.

Then

$$C_{cat} = [HNO_2] + [NO^+] + \frac{V_g(p_{NO} + p_{NO_2})}{V_l \times 10^3 RT}, \quad (4)$$

$$[N(III)] = [HNO_2] + [NO^+], \quad (5)$$

where p_{NO} and p_{NO_2} are the partial vapor pressures (Pa) of the nitrogen oxides, and $[HNO_2]$ and $[NO^+]$ are the equilibrium concentrations (M) of nitrous acid and nitrosonium cation, respectively.

It is known [3, 4, 8–13] that, in aqueous solutions of nitric and nitrous acids, the nitrosonium cation NO^+ is an oxidizing agent with respect to a wide range of organic compounds. Based on analysis of published data and kinetic relationships obtained in this work, we propose the following scheme of catalytic oxidation of *D*-glucose by oxygen in the presence of sodium nitrite in a strongly acidic solution: reactions (II)–(IV), then

Table 1. Rate of *D*-glucose oxidation to *D*-gluconic acid at different $NaNO_2$ amounts

$$RCHO + NO^+ \xrightarrow{k_2} [^-R–HC^+–O–N=O] \rightarrow NO + [R–CHO]^{+\cdot}, \quad (V)$$

$$NO_{(l)} \rightleftarrows NO_{(g)}, \quad (VI)$$

$$2NO_{(g)} + O_2 \xrightarrow{k_1} 2NO_{2(g)}, \quad (VII)$$

$$NO_{2(g)} \rightleftarrows NO_{2(l)}, \quad (VIII)$$

$$[RCHO]^{+\cdot} + NO_2 \xrightarrow{k_3} HNO_2 + [R–C=O]^+, \quad (IX)$$

$$[R–C=O]^+ + H_2O \xrightarrow{k_4} RCOOH + H^+. \quad (X)$$

The experimental dependence (2) obtained at a constant volume of the liquid phase in the system, V_l = 5 ml, and unusual dependence of the oxygen uptake rate W_{O_2} on the volume of the liquid phase at constant initial concentration of $NaNO_2$ (Table 1) indicate that the rate-determining step of the process is gas–phase reaction (VII). As seen from Table 1, at a constant volume of the liquid phase, W_{O_2} depends on the initial $NaNO_2$ concentration, which, in its turn, determines $n(NaNO_2)$ and the partial vapor pressures of the gaseous components (e.g., p_{NO}). Variation of V_l at constant initial concentration of $NaNO_2$ also affects $n(NaNO_2)$ and p_{NO} in the system, with W_{O_2} changing significantly. At simultaneous variation of V_l and the initial $NaNO_2$ concentration, it was possible to keep $n(NaNO_2)$ constant. In this case W_{O_2} did not change noticeably. Thus, W_{O_2} is determined by the absolute amount of sodium nitrite introduced into the reactor, rather than by its initial concentration. The experiments with different V_l were performed with V_g varying by no more than 19%, which had virtually no effect on the partial pressure of the gaseous components. The p_{NO} depends mainly on $n(NaNO_2)$.

0.02	7.5	1.0	313.2	1.21	1.09

* Initial concentration of RCHO and $HClO_4$ 1.0 and 6.0 M, respectively; V_l = 5, V_g = 80 ml.

These data suggest that the rate–determining step of *D*-glucose oxidation under the examined conditions is step (VII). The kinetic equation of gas-phase reaction (VII) is as follows [14]:

$$W_{O_2} = k_1 p_{O_2} p_{NO}^2 \ (\text{Pa s}^{-1}), \qquad (6)$$

where $k_1 = 2.62 \times 10^{-10}\exp(644/T)$ $(\text{Pa}^{-2}\,\text{s}^{-1})$.

It is known [13] that reactions of NO_2 with organic radical cations are considerably faster than reaction (VII). We assume that

$$\partial p_{NO_2}/\partial\tau = 0, \text{ hence, } p_{NO} \gg p_{NO_2}. \qquad (7)$$

Taking into account Eqs. (4), (5), and (7)

$$p_{NO} = \frac{10^3 V_l RT}{V_g}(C_{cat} - [\text{N(III)}]). \qquad (8)$$

Recalculation of the oxygen uptake rate W_{O_2} [Eq. (6)] to the rate of *D*-glucose oxidation in the liquid phase, *W* (mol l^{-1} s^{-1}), gives

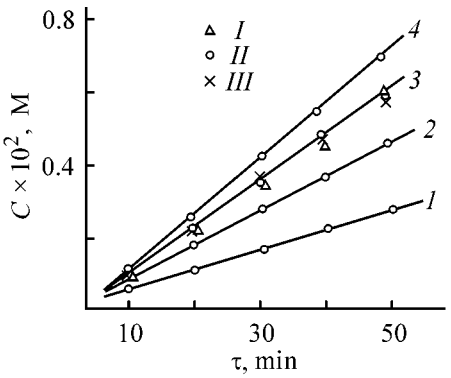

Fig. 6. Kinetic curves of *D*-gluconic acid oxidation at (*1–4*) different $NaNO_2$ concentrations. Initial concentration of *D*-gluconic acid, M: (*3*) (*I*) 1.2, (*II*) 1.0, and (*III*) 0.5 M; (*1, 2, 4*) 1.0. (*C*) Concentration of glucaric acid; (τ) time. Initial concentrations of $HClO_4$ and sulfolane 6.0 and 2.6 M, respectively.

$$W = 2k_1 p_{O_2}(C_{cat} - [\text{N(III)}])^2 \frac{10^3 V_l RT}{V_g}. \qquad (9)$$

The initial rate of glucose oxidation W_0 was calculated by Eq. (9) from the N(III) concentration in the liquid phase, determined spectrophotometrically. The N(III) concentrations in the first oxidation steps (τ = 2–3 min) are presented in Table 2. The initial rates of *D*-glucose oxidation, calculated by Eq. (9) at various initial $NaNO_2$ concentrations, p_{O_2}, and *T*, are close to the experimental values (Table 2). This confirms our conclusion about the rate-determining step and assumption (7). According to [14], reaction (VII) decelerates with increasing temperature. However, as seen from Eq. (1), W_0 is almost independent of temperature. This discrepancy is due to the fact that the solubility of N(III) in the liquid phase decreases with temperature (Table 2), and hence p_{NO} increases. The decrease in k_1 is compensated for by an increase in p_{NO}.

The nonlinearity of the kinetic curves (Fig. 2, 3) of the first step of reaction (I) suggests that the oxidation product, *D*-gluconic acid, reacts with the catalyst and removes it from the catalytic cycle. In addition, oxidation of *D*-gluconic acid to *D*-glucaric acid (second step of *D*-glucose oxidation) can also affect the shape of the kinetic curves. To understand these phenomena, we studied the kinetics of oxidation of *D*-gluconic acid to *D*-glucaric acid under conditions similar to those of oxidation of *D*-glucose to *D*-gluconic acid.

The kinetic curves of *D*-gluconic acid oxidation are shown in Fig. 6. In all cases, the oxidation rate is independent of the *D*-gluconic acid concentration and coincides, all reaction conditions being the same, with that of the second step or reaction (I), when *D*-glucose is completely spent and the *D*-gluconic acid accumulated is oxidized (Fig. 1b). Thus, reaction (I) involves consecutive oxidation of *D*-glucose to *D*-gluconic acid and of *D*-gluconic acid to *D*-glucaric

Table 3. Kinetic parameters of *D*-gluconic acid oxidation with oxygen under different reaction conditions*

* Initial concentration of $HClO_4$ 6.0 M; T = 333.2 K; V_l = 5, V_g = 80 ml.

** C_{ga} is the initial concentration of *D*-gluconic acid.

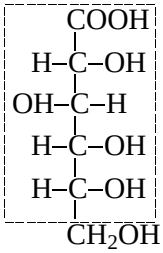
acid. The dependence of the initial rate of *D*-gluconic acid oxidation W_0 on the initial concentration of the catalyst is shown in Fig. 5 (curve *2*).

The rate of *D*-gluconic acid oxidation is also described by Eqs. (1) and (2); however, $k_{exp} = (0.25 \pm 0.05) \times 10^{-5}$ mol^{-1} l s^{-1} Pa^{-1}, i.e., k_{exp} is lower by an order of magnitude than that of *D*-glucose oxidation to *D*-gluconic acid.

A nitrite derivative of *D*-gluconic acid was detected among the oxidation products by chromato-mass specmetry. Since its amount is approximately 0.5% of the initial content of *D*-gluconic acid, about 30 ± 8% of the catalysts is converted into the nitrite derivative of *D*-gluconic acid, i.e., is removed from the catalytic cycle by the reaction

$$R_2CH_2OH + NO^+ \rightleftarrows R_2CH_2ONO + H^+, \quad (XI)$$

where R_2CH_2OH is *D*-gluconic acid, RCOOH and



The kinetics of *D*-gluconic acid oxidation can be described by the scheme proposed for *D*-glucose oxidation [reactions (II)–(X)] with additional step (XI). Taking into account the stoichiometry of reaction (I) and assumption (7), the rate of *D*-gluconic acid oxidation in the liquid phase (mol l^{-1} s^{-1}) is described by the equation

$$W = k_1 p_{O_2} (C_{cat} - [N(III)])^2 \frac{10^3 V_g RT}{V_l}, \quad (10)$$

$$[N(III)] = [HNO_2] + [NO^+] + [R_2CH_2ONO]. \quad (11)$$

The total concentration [N(III)] in the liquid phase was calculated by Eq. (10), using the kinetic data obtained (Table 3). This concentration was also measured over the course of the whole process of *D*-gluconic acid oxidation. The concentrations $[N(III)]_{sp} = [HNO_2] + [NO^+]$ and $[R_2CH_2ONO]$ were determined by spectrophotometry and chromato-mass spectrometry, respectively. The concentration $[N(III)]_{exp}$ remains constant up to ~60% conversion of *D*-gluconic acid. As seen from Table 3, the $[N(III)]_{calc}$ values are close to $[N(III)]_{exp}$. In addition, the N(III) concentration in the case of *D*-gluconic acid oxidation is considerably higher than that in the initial steps of *D*-glucose oxidation (Table 2, 3), p_{O_2}, and T, being the same. Hence, p_{NO} is higher in the course of *D*-glucose oxidation than that in the course of *D*-gluconic acid oxidation [Eq. (8)]. In the course of *D*-glucose oxidation, the N(III) concentration increases owing to accumulation of the nitrite derivative of *D*-gluconic acid, and p_{NO} decreases, thus decelerating the rate-determining step (VII). The decrease in p_{NO} may be due to the fact that the rate constant of reaction (V) is higher than that of the reaction

$$\underset{\text{acid}}{\underset{D\text{-gluconic}}{R_2CH_2OH}} + NO^+ \xrightarrow{k_2'} [R_2CH_2OH]^+ + NO. \quad (XII)$$

Hence, the initial rate of *D*-glucose oxidation is higher than that of *D*-gluconic acid oxidation to *D*-glucaric acid, with the rate-determining step being the same. The nonlinearity of the kinetic curves

of the first step of reaction (I) is due to a decrease in p_{NO} and *D*-glucose concentration.

CONCLUSION

Sodium nitrite catalyzes oxidation of *D*-glucose by oxygen in strongly acidic $HClO_4$–H_2O–sulfolane solution. Under these conditions, *D*-glucose is successively oxidized to *D*-gluconic and then to *D*-glucaric acid. The rate-determining step of the process is oxidation of nitrogen monoxide to nitrogen dioxide in the gas phase. A scheme of catalytic oxidation was proposed. The kinetic equation of the process was derived.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Mathematical Modeling of Corrosive Alloy Cracking on the Basis of Generalized Dimensionless Electrochemical Factor

V. V. Maslov, N. V. Adamova, and N. V. Makarova

St. Petersburg State Technical University, St. Petersburg, Russia

Received April 17, 2001

Abstract—A new generalized dimensionless electrochemical factor of corrosive alloy cracking was developed and a quantitative theory of corrosive-mechanical destruction was constructed on its base. The existence of a threshold value of the proposed factor, above which there is no corrosion cracking, was revealed.

One of the most dangerous and frequently occurring kinds of corrosion, leading to severe emergency damage to machine and metalwork parts, is corrosion cracking (CC) [1–4]. In view of the complexity of physicochemical phenomena associated with CC (local anodic dissolution, hydrogen embrittlement, adsorption-induced deterioration of the surface strength) [5–8] and specificity of the process (not all materials are subject to CC, not at any tensile stresses, and not in any media [9]), no unified theoretical concept of CC has been constructed and the main cause of CC has not been revealed. As a result, there is no satisfactory mathematical description of corrosive-mechanical destruction, despite numerous theoretical and experimental investigations.

The aim of the present study was to develop a generalized dimensionless electrochemical factor of CC of metallic materials and construct on its base a mathematical model of CC. For this purpose, account was taken of the recommendations of [10–13] concerning the most important role of the electrochemical aspects of CC. In particular, the conditions of, and processes occurring in CC are closely associated with the conditions of, and processes in other kinds of local corrosion: crevice, pitting, etc. Therefore, in developing the mechanism of local anodic dissolution (LAD) of materials on the basis of the known mechanisms [13–15], we assume that the main cause of CC is the nonuniform electric field distribution over the surface of metal, affecting not only the rate of LAD, but also the amount of surfactant adsorption and the rate of possible hydrogen pickup. The development and experimental verification of the generalized electrochemical factor of CC were done with the use of the basic electrochemical characteristic of a material—its anodic polarization curve.

It was shown in [15] that the electrochemical length X (cm), corresponding to nonuniformity of electric field distribution in crevice corrosion, depends on metal nature [slope of the anodic polarization curve, k (A cm^{-2} V^{-1}), near the steady-state potential], nature of electrolyte [conductivity æ (Ohm^{-1} cm^{-1})], and geometric size of the system [crevice width a (cm)] and is defined by

$$X = [æa/(4k)]^{1/2}. \quad (1)$$

It is known [16] that the most important geometric factor of CC of metallic materials is the ratio of the cross-section area to the perimeter, S/Per (cm). Replacing in (1) the quantity a with the ratio S/Per, characterizing geometric changes in the system in the case of CC, we obtain an expression for the current electrochemical length γ (cm) corresponding to nonuniformity of the electric field distribution in CC at an arbitrary instant of time:

$$\gamma = [æ(S/\mathrm{per})/(4k)]^{1/2}, \quad (2)$$

where æ and k are current values of the electrochemical characteristics of the system.

Beginning with the instant of time when strained metal is brought in contact with a medium, not only k and æ, but also the geometric size of the system, S/Per, may change as a result of, e.g., formation of protective films on the surface and their possible local

1070-4272/01/7412-2027 $25.00

destruction under the action of tensile stresses under conditions of CC. Therefore, let us consider now the initial period of the process and take kinetic features into account later. Denoting the fraction of the surface area covered with a protective film by θ and introducing notions of the base system (θ = 0) and that under study (0 < θ ≤ 1), we obtain respective expressions for the electrochemical lengths corresponding to nonuniformity of electric field distribution under the conditions of CC at the initial instant of time:

$$\gamma_0 = [æ_0(S/\mathrm{Per})_0/(4k_0)]^{1/2}, \quad (3)$$

$$\gamma'_0 = [æ'_0(S/\mathrm{Per})_0(1 - \theta)/(4k'_0)]^{1/2}, \quad (4)$$

where $æ_0$, k_0, $(S/\mathrm{Per})_0$, $æ'_0$, k'_0, and $(S/\mathrm{Per})'_0(1 - \theta)$ are the initial values of the electrochemical characteristics and geometric sizes of the base system and that under study, respectively; $(1 - \theta)$ is the fraction of the surface not occupied by the protective film.

Under the general corrosion conditions, the fraction of the surface area not occupied by the protective film can be described by [17]

$$1 - \theta = j'_{a,0}/j_{a,0}, \quad (5)$$

where $j_{a,0}$ and $j'_{a,0}$ are the anode current densities at the steady-state potential E_s without and with an inhibitor present in the medium, respectively.

With account taken of the possible changes in potential, ΔE, in the case of local kinds of corrosion [18], including that by 0.2 V in corrosion cracking [19], it seems appropriate to replace the ratio of current densities in (5) with the ratio of areas under anodic polarization curves, N'_0/N_0, at potentials in the range 0–0.2 V, i.e.,

$$1 - \theta = N'_0/N_0, \quad (6)$$

where N_0 and N'_0 are the areas under the anodic polarization curve at potentials of 0–0.2 V without and with inhibitor.

Substituting (6) into Eq. (4), we obtain an expression for the initial electrochemical length in any system studied:

$$\gamma'_0 = \{[æ'_0(S/\mathrm{Per})_0(N'_0/N_0)]/(4k'_0)\}^{1/2}. \quad (7)$$

Let us assume that the ratio of left-hand sides of expressions (7) and (3) can be used to describe the corrosion-mechanical behavior of any system studied not only at the initial stage of the process, but also at any arbitrary instant of time. Let us denote by z this quantity, which is a generalized dimensionless electrochemical factor simultaneously taking into account the nature of metal, corrosive medium, and, in part, the role played by tensile stresses (via changes in the geometric size of the system). For the initial instant of time, we can write

$$z = \gamma'_0/\gamma_0 = (\bar{æ}\bar{N}/\bar{k})^{1/2}, \quad 0 < z \le 1, \quad (8)$$

$$æ = \bar{æ}'_0/æ_0, \quad (9)$$

$$\bar{k} = k'_0/k_0, \quad \bar{k} \in \bar{k}(\Delta E = 25\text{–}75 \text{ mV}), \quad (10)$$

$$\bar{N} = N'_0/N_0, \quad \bar{N} \in \bar{N}(\Delta E = 0\text{–}200 \text{ mV}). \quad (11)$$

It can be seen from formulas (8)–(11) that the numerical values of the dimensionless factor corresponding to condition (8) can be found from a set of three dimensionless electrochemical characteristics calculated using expressions (9)–(11).

To verify experimentally the above assumptions, we carried out a set of corrosion-mechanical and electrochemical measurements under the conditions of natural aeration of solutions at room temperature. We passed from one system to another by changing the composition of a medium by introducing into the base solution various CC-inhibiting additives (see table, systems nos. 4–10, 12, 13) or by diluting the base solution with distilled water (systems nos. 2, 3, 11). As material was used St.70 high-strength carbon steel [GOST (State Standard) 9389–60]. The choice of the base system was governed by the high sensitivity of St.70 to CC in acid sulfide-containing media [20].

The electrical conductivity æ of the solutions was measured with R5058 high-frequency ac bridge and an Arrhenius vessel with platinum-plated electrodes under conditions of thermostating at 25°C [21]. The obtained æ values are presented in the table.

Polarization measurements were done with a P-5827M potentiostat with separated cathode and anode spaces in the potentiodynamic mode with potential sweep rate of 2 mV s^{-1}. The inoperative surfaces of the unstrained electrodes under study were insulated with a 1 : 1 mixture of wax and rosin. Platinum was used as auxiliary electrode, and silver chloride electrode, as reference. The potentials are given relative to a standard hydrogen electrode. Prior to measuring anodic polarization curves, samples were subjected to cathodic activation at E = –1.2 V for 10 min. The anodic polarization curves obtained on St.70 in the media under study are presented in Fig. 1, and the table lists the results of their processing (values of k and N) and, in descending order, the

numerical values of the factor z, calculated using formulas (8)–(11) for the systems studied.

The corrosion-mechanical tests of St.70 wire samples 0.09 cm in diameter were carried out under constant strain conditions [20, 22] without polarization and with a waterline at stresses exceeding the elastic limit and corresponding to approximately 74% of the ultimate strength. For this purpose, a sample 110 mm long without stress concentrator was bent, after standard pretreatment, in its middle part, fixed in apertures of the support plank, thoroughly degreased, and submerged in a solution under study (50 ml), and the time to cracking, τ (h), was determined at the chosen test duration of 7000 h, exceeding the average τ in the base system St.70–H_2SO_4 (0.25 M)–Na_2S (6×10^{-4} M (see table, E_s = –0.32 V, z = 1) more than 5×10^4-fold. Cells with samples were covered with a special glass case to prevent changes in solution composition in the course of the tests. The distance between the apertures of the support plank, h, and the sample curvature radius R_w were, respectively, 32 and 16 mm, which ensured a tensile stress in the lower, U-shaped, part of a sample in solution, corresponding to metal deformation in the case of metal corrosion under strain. The occurrence of plastic de-

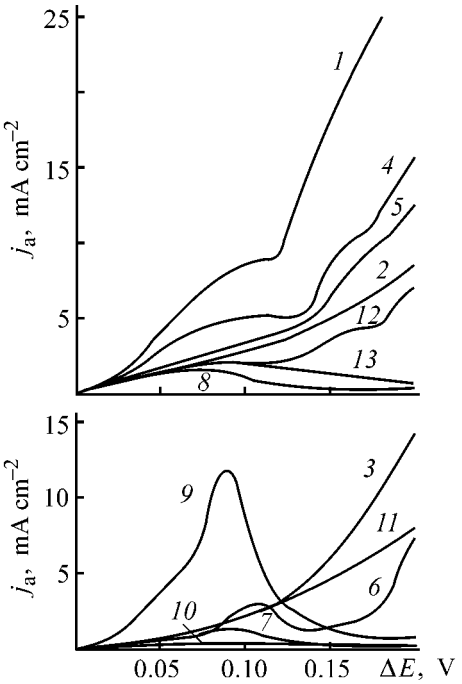

Fig. 1. Anode current density j_a vs. potential shift ΔE reckoned from the steady-state value E_s for St.70 in solutions of various compositions. *Digits at curves* correspond to system numbers in the table.

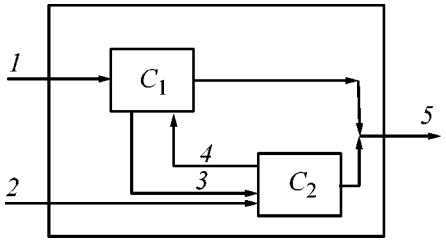

Fig. 2. Schematic of the process of corrosion cracking as a complex system. C_1 and C_2, elements of the system: C_1 electrochemical process; C_2, mechanical process; (*1*, *2*) external couplings of the system: (*1*) *z*, (*2*) σ; (*3*, *4*) internal couplings between the elements of the system; (*5*) output (result of functioning) of the system (τ_{in}, $\tau_{c.g.}$, τ, α).

formation was confirmed in a blank run: on removing the sample from the support plank it retained a U-bent shape ($R > R_w$). The numerical value of the tensile stress under the conditions of constant strain (~$0.74\sigma_u$) was found on performing an additional set of experiments (under conditions of constant, as measured with dynamometer, axial tension in the base system, $z = 1$) ensuring close values of the time to cracking, τ. The effect α of protection against CC upon introduction of an inhibiting additive into the base solution was calculated using the formula

$$\alpha = \tau/\tau_0, \qquad (12)$$

where τ_0 and τ are the times to cracking of, respectively, the base system ($z = 1$) and that under study ($0 < z < 1$).

The results of corrosion-mechanical tests are presented in the table. It can be seen that a correlation is clearly traced between the generalized factor *z* and susceptibility of St.70 to CC: with decreasing *z*, the time τ to cracking becomes longer. It should be noted that no other separately taken characteristic of the system (æ, *k*, *N*) exerts such an influence. Also, the factor *z* has a threshold value z_{th}, which accounts for the specific course of the CC process: at $z \le z_{th}$ (systems nos. 11–13) there is no cracking and the material can be assessed under these conditions (at the same level of tensile stress) as stable against CC. For example, high susceptibility of St.70 to CC in acid sulfide-containing media (system no. 1) is completely suppressed by introduction of MEA into solutions, in concentrations ensuring a generalized factor value $z < z_{th}$ (systems nos. 12, 13). Low concentration of MEA (system no. 6), not ensuring a threshold value of the factor *z*, fails to rule out CC, even though producing a substantial protective inhibiting effect (see table). It should be emphasized that the error of experimental determination of z_{th} does not exceed 0.5% since the z_{th} value corresponds to a rather narrow interval $0.406 \le z < 0.408$.

To develop a quantitative theory of the CC process, based on the nonuniformity of electric field distribution over the surface of strained metal in a corrosive medium and on the general principles of systems analysis [23–25], we proceed from the assumption that the total time to destruction is a sum of two times [5]:

$$\tau = \tau_{in} + \tau_{c.g}, \qquad (13)$$

where τ_{in} is the incubation time in which a stress concentrator of the type of a crack is formed under conditions of a corrosive-mechanical process, and $\tau_{c.g}$ is the time of crack growth in strained metal to a critical value corresponding to its destruction in a corrosive medium.

The corrosion-mechanical process will be regarded as a complex deterministic dynamic system with distributed parameters (factors), comprising an electrochemical and a mechanical processes (Fig. 2) with inequiprobable couplings in different stages of CC. In the stage of crack formation, the electrochemical process exerts strong influence on the mechanical process, whereas the reverse influence is less significant and can be neglected. By contrast, in the crack growth stage, only the mechanical process affects the CC substantially. Let us assume that the dimensionless factors of these elementary processes are, respectively, the mean dimensionless electrochemical length corresponding to nonuniformity of the electric field distribution in the system ($z = \gamma'/\gamma_0$, where $0 < z \le 1$), and the mean dimensionless externally applied (or internal residual) tensile stress ($\sigma = \sigma/\sigma_u$, where σ_u is the ultimate strength of the metal). Applying the systems principle of kinetic hierarchy [24, 25] to CC, we reduce the problem of a kinetic description of the system to a study of the behavior of the slowest stage. We assume, with account of the data of [26], that under the CC conditions

$$\tau_{in} >> \tau_{c.g}, \qquad (14)$$

i.e., the rate *V* of the corrosive-mechanical process is determined by the stage of stress concentrator formation, V_{in}. Then, taking as a measure of the rate of stress concentrator formation under the CC conditions the rate of change (increase) in the dimensionless electrochemical length, V_{in}, we obtain the following kinetic equation for the incubation period of CC:

$$\pm\partial z/\partial\tau = (1/T)f(z, \bar{\sigma}), \qquad (15)$$

where $1/T$ is a positive variable factor accounting for the possible low CC rates ($0 < 1/T << 1$), and $\pm$ is the sign of the partial derivative $\partial z/\partial\tau$, depending on the chosen initial condition [(+) if $z(0) = z_{min}$, and (–) if $z(0) = z_{max} = 1$].

Applying another systems principle—decomposition [24], and the known Fourier method, we can represent the rate of the incubation period of CC as a product of three functions, two of which are mutually independent, and the third, $F(z, \bar{\sigma})$, accounts for the interaction of elementary processes:

$$-\partial z/\partial\tau = F(z, \bar{\sigma})f(z)f(\bar{\sigma}), \quad (16)$$

$$z \in \varphi(z), \quad \varphi(z) = z - z_{th} > 0, \quad (17)$$

$$\bar{\sigma} \in \Psi(\bar{\sigma}), \quad \Psi(\bar{\sigma}) = \bar{\sigma} - \bar{\sigma}_{th} > 0, \quad (18)$$

$$z(0) = z_{max} = 1, \quad (19)$$

where $f(z)$ is the nonstationarity function of the z field; $f(\bar{\sigma})$ is the nonstationarity function of the $\bar{\sigma}$ field [$f(\bar{\sigma}) = f(z, \bar{\sigma})/f(z)$]; $F(z, (\bar{\sigma}))$ is the nonuniformity function of the z and σ fields [$F(z, (\bar{\sigma})) = 1/T$]; and z_{th} and $\bar{\sigma}_{th}$ are the mean threshold values of dimensionless factors, beginning with which there is no CC.

Assuming a relationship between the electrochemical and mechanical processes in the form

$$z_{th} = F(\bar{\sigma}), \quad (20)$$

$$\bar{\sigma}_{th} = \Psi(z, z_{th}), \quad (21)$$

we have

$$F(z, \bar{\sigma}) = F(z, z_{th}). \quad (22)$$

If we take that the nonuniformity function $F(z, z_{th})$ contains graddiv z (or grad z), the mathematical construction (16)–(19) can be solved for a system with distributed parameters only numerically, on a computer. To obtain an analytical solution to (16)–(19), we assume [with account of the experimentally revealed strong influence of z on the rate of CC (see table)] that the mathematical expectation of the distribution function of the dimensionless factors with respect to their mean values (22) is described by the exponential Poisson distribution, which is widely used in practice [28]:

$$F(z, z_{th}) = [F(z_{th})/z]\exp\{-[F(z_{th})/z]\}, \quad (23)$$

where $F(z_{th})/z$ is the parameter of the distribution, assuming at any particular instant of time a unique value, with $F(z_{th})/z >> 1$; $F(z_{th})$ is a dimensionless function accounting for tensile stresses.

Combination of conditions (20) and (23) makes it possible to replace $f(\sigma)$ in (16) with a new function $\Psi(z_{th})$ taking into account tensile stresses:

$$\Psi(z_{th}) = f(\bar{\sigma})F(z_{th}). \quad (24)$$

Further, taking $f(z) = z^3$, i.e., assuming that the effect of z on the CC rate is similar, with account of (23), to the effect of temperature on the rate of chemical processes [29] and passing from a partial to total derivative with the use of the initial condition (19), we obtain a kinetic equation of CC

$$-dz/d\tau = \Psi(z_{th})z^2\exp\{-[F(z_{th})/z]\}, \quad (25)$$

whose boundary and initial conditions are, respectively, expressions (17) and (19).

Provided that the tensile stresses are constant (or strain is constant, which is the case in the experimental part of this study), the functions $\Psi(z_{th})$ and $F(z_{th})$ in expression (25) remain invariable. Denoting these functions by the constants

$$c = \Psi(z_{th}) = \varphi(\bar{\sigma}), \quad (26)$$

$$B = F(z_{th}) = \Phi(\bar{\sigma}), \quad (27)$$

we pass to a particular case of a kinetic equation describing the incubation period of CC

$$-dz/d\tau = cz^2\exp(-B/z), \quad (28)$$

where c has the meaning of the rate constant of the incubation period (h^{-1}).

Separating the variables, we obtain

$$(-1/z^2)\exp(B/z)dz = cd\tau, \quad (29)$$

$$\exp(B/z)d(1/z) = cd\tau. \quad (30)$$

Upon integration with the initial condition (19) we have the following expression for the duration of the incubation period of CC:

$$\tau_{in} = [1/(cB)]\exp(B/z) - [1/(cB)]\exp B, \quad (31)$$

where $z_{th} < z < 1$.

Introducing the following designation

$$A = 1/(cB) = \gamma(z_{th}) = \beta(\bar{\sigma}) \quad (32)$$

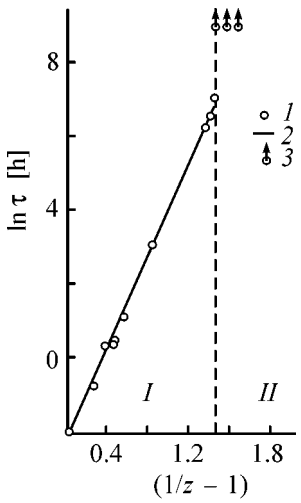

Fig. 3. Dependence of the time to cracking, τ, on the generalized parameter (1/*z* – 1) for the systems studied. (*1*) Experiment, (*2*) calculations using model (33), and (*3*) no sample destruction during the chosen testing time. (*I*, *II*) Regions of model applicability and absence of CC, respectively.

and comparing (31) and (13), we find expressions for calculating the time of crack growth and the total time to destruction under CC conditions:

$$\tau_{c.g} = A\exp B, \quad (33)$$

$$\tau = A\exp(B/z), \quad (34)$$

where $z_{th} < z \leq 1$.

The data obtained in our corrosion-mechanical investigations (see table) made it possible to find particular values of the applicability threshold of model (34) and its parameters:

$$z_{th}(\bar{\sigma} = 0.74) = 0.407, \quad (35)$$

$$B(\bar{\sigma} = 0.74) = 6.036, \quad (36)$$

$$A(\bar{\sigma} = 0.74) = 3.11 \times 10^{-4} \text{ h}, \quad (37)$$

and then establish general expressions for functions (27) and (32), describing the relationship between the model parameters and the threshold value of the proposed factor:

$$B = 1/z_{th}^2, \quad (38)$$

$$A = \tau_0/\exp B = \tau_0/\exp(1/z_{th}^2), \quad (39)$$

where τ_0 is the total time to metal destruction in the base system with $z_{max} = 1$ [see table, $\tau_0(\bar{\sigma} = 0.74) = 0.13$ h].

In this connection, the mathematical model (34) describing the total time to destruction under the conditions of plastic deformation of a metal in a corrosive medium ($\bar{\sigma}$ = const) assumes, on substitution of expression (39), with account of the clear physical meaning of the pre-exponential factor τ_0, a more convenient form

$$\tau = \tau_0\exp[B(1/z - 1)], \quad (40)$$

where z is the proposed generalized factor ($z_{th} < z \leq 1$); B and τ_0 are the obtained parameters of the model.

The results of a calculation relying upon the linearized model (40) (Fig. 3) are in satisfactory agreement with the obtained experimental data. A verification by means of Fisher's test [23–25] demonstrated the adequacy of the constructed model [$F^{calc}(9, 10) = 0.19$], with mean calculation error not exceeding 17% at average experimental error in determining the time to destruction equal to 34%. Therefore, the obtained mathematical model (40) of the CC process and its variety (34) can be used to prognosticate CC, provided that all the conditions specified in the study are satisfied.

The adequacy of the model described by expression (40) for evaluating the durability of a metallic material under the CC conditions also makes it possible to analyze a number of dependences and parameters obtained in its derivation. For example, it follows from a comparison of (33) and (39) that the duration of the crack growth period in a metal at arbitrary value of the factor z ($z_{th} < z < 1$) can be evaluated using the total time to metal destruction under the conditions corresponding to $z_{max} = 1$ and the same fixed tensile stress $\bar{\sigma}$. The exponential in (40) is the factor by which the total time to destruction exceeds the crack growth time at a given stress $\bar{\sigma}$. Another meaning of the exponential follows from a comparison of expressions (12) and (40). It reflects the protective (CC-inhibiting) effect, α, and can be used to evaluate this characteristic:

$$\alpha = \exp[B(1/z - 1)] = \exp[(1/z_{th}^2)(1/z - 1)]. \quad (41)$$

In addition, comparison of dependences (32), (38), and (39) gives a general expression for the function (26) describing the rate constant of CC:

$$c = 1/(\tau_0 B)\exp B = (z_{th}^2/\tau_0)\exp(1/z_{th}^2). \quad (42)$$

It should be noted that the adequacy of the mathematical model described by expression (40) apparent-

ly confirms the validity of the hypotheses put forward and assumptions made in this study for developing not only the generalized electrochemical factor of CC, z, but also a quantitative theory of CC in metallic materials in electrolyte solutions in general. The last circumstance requires additional experimental verification, which, in particular, refers to the quantitative condition (2).

CONCLUSIONS

(1) A new generalized dimensionless electrochemical factor of corrosion cracking, which takes into account the metal nature and the type of corrosive medium simultaneously, was developed and experimentally verified under conditions of constant plastic strain and test duration of 7000 h.

(2) A correlation between the generalized factor and the susceptibility of a material to corrosion cracking and the existence of the threshold value of this factor, above which there is no cracking, were established.

(3) A quantitative theory of corrosion cracking of alloys in electrolyte solutions was proposed, and mathematical models for evaluating the durability of a metallic material and the effect of inhibition of the corrosion cracking, adequately describing experimental data, were developed on its base.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Composite Copper-Based Coatings with Ultradispersed Phase

Received April 10, 2001

Abstract—The electrolytic deposition of composite copper-based coatings with an ultradispersed phase (TiN or Al_2O_3) was studied. Conditions for obtaining coatings with the maximum microhardness were determined.

To improve the chemical and mechanical properties of electrolytic coatings, composite deposition of metallic layers with powdered high-melting compounds (nitrides, carbides, oxides, etc.) is commonly used [1–6]. However, with commercial coarse-grained (1–30 μm) powders, formation of composite electrolytic coatings with particles uniformly distributed on the microscopic level over the surface and across the thickness cannot be achieved, and the mechanical and chemical resistance of the coatings is improved only slightly.

It is known that formation of composite electrolytic coatings is essentially affected by particle size [1]. With crystalline ultradispersed powders (UDPs) having particle size in the range from tens to hundreds of nanometers, composite materials and coatings with improved physicochemical and mechanical properties can be obtained.

Ultradispersed powders are characterized by physicochemical properties different from those of macropowders (high surface energy, enhanced energy excitation of the crystal lattice, etc.). Studies are known, in which composite electrolytic coatings were obtained on the basis of nickel and chromium with the use of using UDPs. Analysis of published data shows that that the use of UDPs of niobium or titanium nitride [7, 8], tantalum nitride [9, 10], silicon carbide [11], or silicon nitride [12] as components of a composite electrolyte gives coatings with uniform finely grained structure and improved corrosion and mechanical properties (wear resistance, hardness, etc.).

In the present study, we analyzed the effect of UDP on the microhardness of copper coatings and pressed powder crystalline precipitates obtained from electrolytes widely used in industry.

Ultradispersed powders of titanium nitride and aluminum oxide with particle size of about 60 and 80 nm, respectively, were used in the study. Titanium nitride was obtained by decomposition of TiH_2 in arc-discharge nitrogen plasma, and Al_2O_3, by oxidation of ASD-4 aluminum powder in arc-discharge air plasma [13, 14].

EXPERIMENTAL

The coatings were deposited from simple copper-plating acid electrolytes containing (g l^{-1}): $Cu(BF_4)_2$ 400 ± 50, HBF_4 30, H_3BO_3 15 [fluoroborate electrolyte (I)]; $CuSO_4 \cdot 5H_2O$ 220, H_2SO_4 60, ethanol 8 [sulfate electrolyte (II)].

An ultradispersed powder was poured in an electrolyte prepared with distilled water, and the mixture was stirred. The electrolysis was carried out at room temperature with constant stirring of the electrolyte in a 2-l electrolytic bath (Fig. 1). Anodes were made of copper, as a cathode served a copper plate $15 \times 15 \times 1$ mm in size, on which a coating was

deposited. Prior to electrolysis, the copper plates were treated as described in [15] to remove an oxide layer and various impurities. The treatment involved: (1) etching in a 10% solution of H_2SO_4 at 60–70°C to remove oxides, (2) etching at room temperature in a mixture of equal volumes of concentrated HNO_3 and H_2SO_4 with addition of 5–10 g l^{-1} of NaCl to obtain a glossy, to the point of being lustrous, surface. Before etching, the copper plates were ground to luster with a micropowder.

The microhardness of the coatings was determined by the method of static indentation of a diamond pyramid under a load of 50 g on a Neophot device with measured diagonal values averaged over 10–12 indentations for each sample. The coating thickness was 100–200 μm.

The elemental compositions of the electrolyte and coatings were determined by means of chemical analysis. The high reactivity of UDPs and, in particular, TiN could result in their reaction with the electrolyte, and, therefore, we determined the content of dissolved titanium species in the composite electrolyte. The content of titanium and aluminum was determined in coatings and crystalline deposits. The content of the dispersed phase in composite coatings was calculated from the chemical analysis data. It is known that coarse powder of titanium nitride is sparingly soluble in acids. In particular, the solubility of TiN in dilute and concentrated sulfuric acid is 2%. To estimate the electrolyte stability, we determined the solubility of TiN UDPs in electrolyte (II) at varied content of the nitride:

TiN content in the electrolyte, g l^{-1}	2	10	100
Concentration of Ti(IV) ions in the electrolyte, mg ml^{-1}	0.27	0.43	1.13

The enhanced UDP solubility, compared with that of coarse-grained powders, seems to be associated with the large specific surface area of UDPs, with dissolution involving the oxidized surface layer covering the particles. It should be noted that the oxidation proceeds slowly and has a continuous nature, which was confirmed by X-ray phase analysis. X-ray diffraction patterns of the deposits taken from the bottom of the electrolytic bath within several months show that the deposits consist of TiN. Within three years, TiN in the deposit is almost completely converted into TiO_2 (all TiO_2 reflections and a single, the highest-intensity TiN reflection with *hkl* [200] were present in the diffraction pattern). This circumstance should be taken into consideration when working with the electrolyte.

Table 1 presents data on the content of titanium (mg per 1 g of coating) in coatings obtained in both electrolytes in relation to powder content in an electrolyte. The content of titanium is greater in the coatings, although the deposition rate in electrolyte (I) exceeds that in electrolyte (II). For the coatings obtained in electrolyte (I) at TiN content of 2.5 g l^{-1}, the content of the second phase in terms of TiN is 0.15 wt %, which is the highest value, since, according to X-ray phase analysis, a coating contains inclusions of the Cu_2O phase at greater TiN content in the electrolyte.

Despite the considerable increase in Ti content (0.19–0.98 wt % of TiN) in coatings obtained in electrolyte (II) at powder content of 100 g l^{-1}, this mode was not used further, as outgrowths are formed in large quantities on the edges of coatings. These outgrowths are easily chopped off, and the coating flakes away in places.

We optimized the current density for each electrolyte in obtaining composite electrolytic coatings. For this purpose, we determined the current density ranges, in which the titanium content in coatings is the highest and high-quality coatings are formed. In the range 7.4–11.0 A dm^{-2}, the average content of titanium nitride in coating (I) is 0.23 wt %. Beyond this range, the content of the second phase decreases, and, in addition, coatings with a rough crystalline surface are formed at current densities exceeding 11 A dm^{-2}.

In the same range of current densities, the titanium nitride content of 0.10–0.11 wt % in coatings remains unchanged in the case of electrolyte (II) with titanium nitride content of 10 g l^{-1}.

The microhardness of coatings H_μ was measured at various concentrations of titanium nitride in electrolytes and at current densities of 7.4 and 11.0 A dm^{-2} (Table 1). The microhardness of coatings obtained in electrolyte (I) varies between 0.93 (simple electrolyte) and 1.11 (i = 7.4 A dm^{-2}) and between 1.08 and 1.27 HPa (i = 11.0 A dm^{-2}), i.e., it is 1.3–1.5 times that of pure copper (0.85 HPa).

The microhardness of coatings obtained in electrolyte (II) has a maximum value of 1.06 HPa at TiN content of 100 g l^{-1}, which is 1.2 times the microhardness of pure copper. However, poorquality coatings were obtained in this case.

Coatings with Al_2O_3 UDPs were obtained in electrolyte (II) at powder content of 12.5 g l^{-1} and current densities of 7.4, 11.0, and 14.8 A dm^{-2}. The maximum current density was determined by the outward appearance of coatings (finely crystalline surface). Above the indicated current density, a rough surface and, according to X-ray diffraction patterns, the Cu_2O phase are formed. According to chemical analysis, the aluminum content in the coating is 0.22 wt % (or 0.41 wt % in terms of Al_2O_3; Table 2), irrespective of the current density. However, in contrast to coatings containing titanium nitride, the microhardness increases twofold, compared with that in pure copper (Table 2), being equal to 1.77 HPa at i = 14.8 A dm^{-2}.

Apart from deposition of strengthened coatings, it was of interest to obtain three-dimensional samples modified with an ultradispersed phase. For this purpose, we obtained powder crystalline precipitates, pressed to obtain compact samples.

Composite copper plating was carried out on six copper wire electrodes of diameter 0.18 mm and length 10 mm in electrolyte (II) containing 12.5 g l^{-1} of the Al_2O_3 UDP. The current strength was varied between 1 and 4 A, which provided the formation of easily removed deposits.

The resulting crystals were washed with distilled water and dried. To measure the microhardness, the crystals were pressed in a mold (cold pressing) under a pressure of 1.7 HPa. The fillets obtained were 8 mm in diameter, 3 mm in height and had porosity of 1.8%.

With the current strength raised from 1 to 4 A, the content of aluminum in crystalline copper precipitates increases from 0.21 to 0.84 wt % (or from 0.41 to 1.6 wt % in terms of Al_2O_3; Fig. 2, curve *1*). Correspondingly, the microhardness of pressed crystals grows from 1.37 to 1.75 HPa (Fig. 3, curve *1*).

Table 2. Effect of current density on the composition and microhardness of coatings

i, A dm^{-2}	Content in a coating, %		H_μ, HPa
	Al	Al_2O_3	
7.4	0.22	0.41	1.31
11.0	0.17	0.32	1.68
14.8	0.21	0.40	1.77

Thus, the microhardness of coatings and compact (pressed) finely crystalline precipitates containing Al_2O_3 UDP as the second phase increases twofold as compared with the microhardness of pure copper.

To reveal the possibility to vary the microhardness of cast copper by its modification with Al_2O_3 UDP, a sample was subjected to vacuum melting (1100°C). The sample was pressed from crystalline precipitates obtained at current strength of 1 A. Measurements of the microhardness of pressed and cast samples demonstrated that the microhardness of a cast sample is lower by 40%. The microhardness of the cold-pressed sample is 1.42, and that of the cast sample, 0.85 HPa,

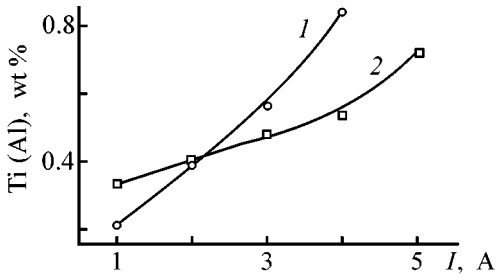

Fig. 2. Effect of current strength I on the Ti (Al) content in crystalline powder precipitates obtained in electrolyte (II). Content of UDP in electrolyte (g l^{-1}): Al_2O_3 12.5, TiN 10. Metal: (*1*) Al, (*2*) Ti; the same for Fig. 3.

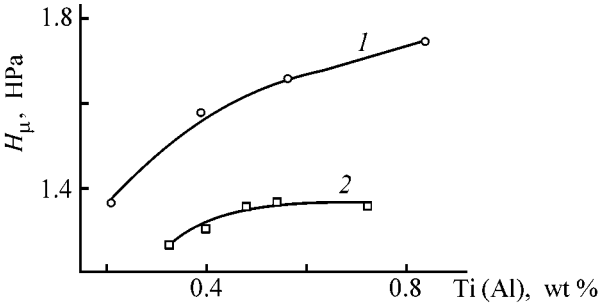

Fig. 3. Microhardness H_μ of pressed crystalline precipitates vs. the Ti (Al) content.

Table 3. Calculated contents of particles of the second phase in a unit volume of coating

Condition	Phase	d, μm	$V_p \times 10^{12}$, cm^3	N_c		$N_c / V_c \times 10^{-10}$
				wt %	vol %	
1	TiN	0.06	1.1×10^{-4}	0.15	0.88	10^4
	Al_2O_3	0.08	2.4×10^{-4}	0.41	1.6	10^4
2	TiN	1–5	0.52–65.4	0.15	0.88	$2–10^{-2}$
	Al_2O_3	1–5	0.52–65.4	0.41	1.6	$3–12 \times 10^{-2}$
3	TiN	1–5	0.52–65.4	10	63	$1.2 \times 10^2–1$
	Al_2O_3	1–5	0.52–65.4	10	40	$0.8 \times 10^2–0.6$

which corresponds to the microhardness of pure copper.

After vacuum melting, a gray powder in amount of 0.47 wt % relative to the weight of the initial sample was present in an ampule alongside with the sample. According to chemical analysis, the content of aluminum in crystals obtained as a result of electrolytic copper plating at a current strength of 1 A was 0.21 wt % (0.41 wt % in terms of Al_2O_3). Thus, the decrease in the microhardness of the cast sample is related to the removal of Al_2O_3 from it. Upon melting, Al_2O_3 was isolated from the bulk sample owing to the low wettability of Al_2O_3.

The titanium content of crystalline deposits obtained from electrolyte (II) with 10 g l^{-1} of TiN grows from 0.33 to 0.70 wt % (from 0.42 to 0.93 wt % in terms of TiN) with the current strength increasing in the range 1–5 A (Fig. 2, curve *2*). In this case, the microhardness of pressed compacts increases from 1.26 to 1.37 HPa (Fig. 3, curve *2*), i.e., by a factor of 1.6 as compared with the microhardness of pure copper, being somewhat greater than that in coatings.

It is known that the content of Al_2O_3 in coatings obtained from a sulfate composite electrolyte with coarse powders is 0.2–0.5 wt % at powder concentrations in the electrolyte of 50–200 g l^{-1} [1]. In practice, the microhardness of Cu–Al_2O_3 coatings obtained from a sulfate composite electrolyte can be raised to 2.4–2.9 HPa by introducing special additives into the electrolyte [1], with the Al_2O_3 content increasing up to 5.5–7.3 wt %.

To find the content of the second phase in the coating, we calculated the content N_c of particles in the formulation bulk at a known percentage X_p and average particle volume V_p [3]:

$$N_c = V_c X_p / 100 \times V_p.$$

The calculation was performed under the following conditions: (1) size of TiN particles 0.06 μm, that of Al_2O_3 particles – 0.08 μm; content of TiN and Al_2O_3 0.15 and 0.41 wt %, respectively (experimental data); (2) content of the second phase the same, but with particle size assumed to be 1–5 μm; (3) particle size 1–5 μm, content of the second phase 10 wt % (assumption).

The calculation demonstrated (Table 3) that the use of UDPs without special additives at small content of the second phase (0.15–0.41 wt %) gives the content of particles in a coating of about 10^{14}, whereas the content of 1–5-μm particles is 10^{10}–10^8, i.e., the content of ultradisperse particles is greater by 4–6 orders of magnitude. When the content of the second phase is 10 wt %, the content of 1–5-μm particles is 10^{10}–10^{12}, i.e., under the same conditions the content of ultradisperse particles is greater by 2–4 orders of magnitude. In this case, the microhardness is 1.5–2 times higher.

The mechanism of strengthening of the electroplated metal by dispersed particles was considered in [3]. The dispersed particles, being incorporated in a metal being deposited, distort its crystal structure and form defects (dislocations), which results in coating strengthening, since the action of force on the metal causes a shear deformation of the crystal, which propagates along the least distorted directions of the crystal lattice. The dispersed particles incorporated into coatings take up the shear stress and also hinder displacement of microlayers. The presence in the electrolyte of particles in direct contact with the cathode also results in coating strengthening, since at the instance of impact a particle screens the cathode, thereby disrupting the original sequence of atomic layers.

The use of UDPs at low content of the second phase in coatings and deposits gives rise to a signif-

icant number of dislocations hindering the propagation of the shear deformation and making the electrolytic deposits stronger, which results in higher microhardness of coatings and powder crystalline deposits. We can assume that the electrical conductivity of copper coatings remains unchanged at the indicated content of the second phase in the coatings.

CONCLUSIONS

(1) Introduction of ultradispersed powder of titanium nitride and aluminum oxide with particle size of 0.06–0.08 μm in a composite electrolyte, instead of the commonly used coarse powders (1–5 μm), allows the microhardness of copper coatings and precipitates to be raised by a factor of 1.5 (with TiN) and 2 (with Al_2O_3), compared with pure copper coatings.

(2) The increase in microhardness was achieved: (a) at lower content of the ultradispersed phase in electrolytes (TiN 2.5 and Al_2O_3 12.5 g l^{-1}), compared with the content of coarse powders (50–200 g l^{-1}); and (b) at lower content of the second phase in coatings and deposits (0.15–1.6 wt %), compared with the case of coarse powders (2–10 wt %). This makes it possible to largely retain in a coating the properties inherent in the copper substrates.

(3) The calculation demonstrated that the number of ultradispersed particles in unit coating volume is 4–6 orders of magnitude greater than that of particles 1–5 μm in size. As a consequence, a significant amount of dislocations is formed, which hinders propagation of shear deformation and makes electrolytic deposits stronger.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

A Study of Charge Preservation with Coulometer Based on Solid Copper-Ion-Conducting Electrolyte

I. E. Shpak and A. M. Mikhailova

Saratov State Technical University, Saratov, Russia

Received February 2, 2001

Abstract—The influence of the material of an inert electrode on the coulometric reversibility of electrodeposition and dissolution of copper in a cell with $Rb_4Cu_{16}C_{13}I_7$ solid electrolyte was studied. The reasons for time instability of the electrolyte and coulometric reversibility were analyzed.

Compared with analogous liquid-phase systems, solid-electrolyte (SE) electrochemical cells have a number of advantages: they are manufactured by simpler technology, are more suitable for miniaturization, have high resistance to mechanical action, can operate in a wide temperature range (–60–200°C), possess long service and storage life (up to 10 years), and can be manufactured in a single run with fabrication of an electronic unit. As a rule, the known coulometers are based on silver systems [1]. A study of copper-conducting electrochemical systems is necessitated by their possible application to exclude use of precious metals. In this case, the ability of a coulometer to preserve coulometric reversibility in the course of time is a key issue.

EXPERIMENTAL

Coulometer samples were prepared in a box in dry argon. The copper electrode was a mixture of powdered copper and copper-ion-conducting electrolyte of composition $Rb_4Cu_{16}Cl_{13}I_7$ (mass ratio 1 : 1). As inert electrodes were used platinum, carbon black–graphite mixture with polyacrylonitrile (PAN) binder, and glassy carbon. As current lead served titanium wire. The internal ac resistance of the samples was within 8–12 Ω.

The nonequivalence of the quantities of electricity passed during the cathodic and anodic processes for all the three inert electrodes is illustrated in the table. The presented data show that, except in the case of

Nonequivalence of the quantities of electricity passed in deposition and dissolution of copper on various electrodes at 25°C

the graphite electrode, the nonequivalence is high during several first cycles and decreases approximately linearly with cycling and increasing current density. The best reversibility of cathodic and anodic processes is characteristic of the inert glassy carbon electrode.

If copper is deposited onto a mixture of graphite with PAN binder and the deposit is anodically dissolved after 1 h, then the nonequivalence of the cathodic and anodic quantities of electricity will be 35%. This value decreases somewhat in further cycling of the electrode. When copper deposit is dissolved 2 h after its preparation, the coulometric nonequivalence becomes as high as 50%. The same was observed on the platinum electrode. For a deposit stored for 1 day after preparation, the nonequivalence increases to 80% and remains large till the 10th cycle.

The cells cycled continuously for a long time (~1 month) degraded, which was manifested in an increase in their internal resistance and impossibility to pass high current densities through the cells.

The stationary potentials of the inert electrodes were 0.545–0.550, 0.53–0.538, and 0.519–0.525 V for graphite, platinum, and glassy carbon, respectively. The closeness of these potentials to the potential of the iodine electrode suggests that the solid electrolyte decomposes at the interface with inert electrodes or, at least, the concentration of free iodine in the near-electrode layer of the electrolyte is noticeable. This assumption is corroborated by the fact that, when the potential of the inert electrode of an assembled cell is shifted from the stationary value toward positive potentials, high currents are observed in the current–voltage characteristic (Fig. 1). The polarization resistances, calculated using the initial parts of the curves, were 640, 1660, and 133 $\Omega\,cm^2$, on the average, for graphite, platinum, and glassy carbon electrodes, respectively, at 25°C.

The cyclic polarization curves of solid electrolyte oxidation and reduction of electrolyte oxidation products at the interface between the solid electrolyte and the platinum electrode are presented in Fig. 2. The character of these curves reflects the stage-by-stage nature of oxidation–reduction processes in the solid electrolyte.

The observed dependence of the oxidation and reduction current peak potentials on the potential sweep rate indicates the irreversibility of these processes.

The whole set of the presented data shows that the electrolyte decomposes at some rate even at potentials close to 0.5 V. This instability of the electrolyte was also manifested in that, despite the termination of

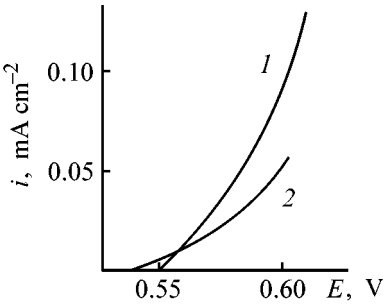

Fig. 1. Initial portions of cyclic potentiodynamic curves in the first cycle for various inert electrodes. Electrode: (*1*) Carbon black–graphite + PAN and (*2*) Pt.

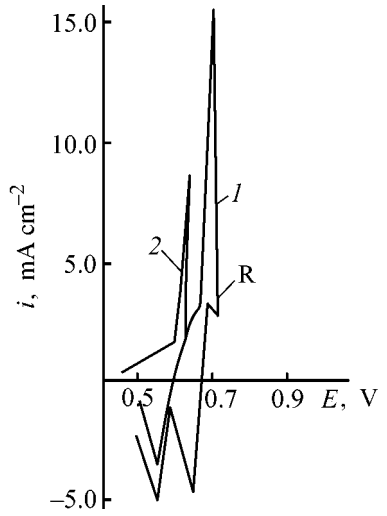

Fig. 2. Cyclic potentiodynamic curves of the $SE(Cu^+)\,|\,Pt$ interface at different potentials of potential sweep direction switching, E_R. $V_s = 8 \times 10^{-4}$ V s^{-1}, T = 25°C; the same for Fig. 3. E_R (V): (*1*) 0.72 and (*2*) 0.65.

cell cycling each time after the cathodic semi-cycle, ensuring reduction of the oxidation products, and even after deposition and subsequent dissolution of copper on an inert electrode, prolonged storage of the cell (~1 month) led to complete degradation of the solid electrolyte. This is manifested, in the first place, in a drastic decrease in currents in electrode polarization. The change in the phase composition of SE was confirmed by X-ray phase analysis.

Noteworthy is the presence near E = 0.6 V of a weakly pronounced peak of current of electrolyte oxidation on the platinum electrode in the initial portion of curve *2*, possibly associated with copper dissolution occurring independently of electrolyte oxidation. With account taken of the small capacity (5–6 mC cm^{-2}) under the peak, it may be suggested that this current peak corresponds to dissolution of a copper microphase layer from the surface of platinum

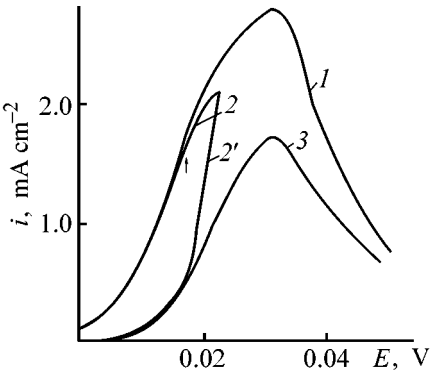

Fig. 3. Potentiodynamic curves of copper deposit dissolution from glassy carbon. Curve numbers: (*1*) taken to a potential of 0.055 V; (*2*, *2*′) anodic semi-cycle to 0.022 V; and (*3*) obtained immediately after measuring curve *2*.

(adsorption layer). The difference ΔE_d of the peak potentials of macro- and microphase dissolution is linearly related to the difference of the electron work functions, $\Delta\Phi$, of deposited metal and material of the inert electrode by the equation [2]

$$\Delta E_d = \alpha\Delta\Phi, \quad (1)$$

where $\alpha = 0.5$ V eV^{-1}.

Estimation of ΔE_d by means of Eq. (1) at $\Delta\Phi$ = 0.85 eV gives 0.425 V, a value rather close to the experimental ΔE_d = 0.576 V.

The coulometric reversibility of copper deposition onto, and dissolution from an inert glassy carbon electrode was studied by chronovoltammetry at copper amounts deposited onto electrode, ensuring the microphase formation. In this case, the amount of the deposit, expressed in charge units, varied between 37.5 and 750 mC cm^{-2}. The minimum thickness of the layer formed by the reaction

$$Cu^+ + e = Cu^0,$$

was 200–300 monolayers. It was found that copper dissolution from the glassy carbon surface occurs in two stages, which is indicated by the presence of two current peaks in the potentiodynamic curves of copper dissolution (Fig. 3). These two processes occur in parallel to a +0.022 V potential. The transfer coefficients β, calculated from the dependences $\ln\{-i/\exp(-nF\eta/RT) - 1\}-\eta$ plotted for the initial portions of curves *1* and *2* at n = 1 and 2, are considerably higher than unity (1.22–3.87). Such large coefficients, and also the nonlinearity of the dependences at low overvoltages, can be accounted for by the control exerted over the process by the rate of dissolution of two-dimensional nuclei. In the overvoltage range in question, this mechanism of control is not replaced yet by the charge-transfer-controlled mechanism. Analysis of the dependences of the dissolution current peak potentials on ln V_s allowed calculation of the number of electrons involved in the reaction, which was found to be approximately 2, i.e., two electrons are transferred in the second, reversible stage of copper dissolution.

Storage of an electrode with copper deposit for several days leads to a decrease in the intensity of the current peaks and to a nonlinear dependence of the peak potential on the logarithm of the potential sweep rate, which may be due to electrolyte degradation.

Owing to the large amount of deposit on the inert electrode, it is difficult to account for the presence of two peaks in the potentiodynamic curves of copper dissolution by the existence of two energy states of copper on the glassy carbon surface. It is reasonable to assume that the second peak corresponds to the reaction

$$Cu^0 - 2e = Cu^{2+}. \quad (2)$$

The assumption that the first peak is attributable to the reaction

$$Cu^0 - e = Cu^+, \quad (3)$$

is at variance with the data of Fig. 3. Since only a minor portion of the deposit dissolves during the anodic semi-cycle at potentials of up to 0.022 V, the activity of the copper electrode and the phase composition at the metall–electrolyte interface do not alter. Then, two peaks should have also been observed in subsequent anodic semi-cycle, which is not the case in the experiment. Apparently, it is more reasonable to assume that the first peak corresponds to oxidation of Cu^+ to Cu^{2+}.

The proposed interpretation of the potentiodynamic curves of copper dissolution in a solid electrolyte with conduction by copper cations is in agreement with the mechanism of the well-known instability of copper-conducting solid electrolytes [3]. This mechanism is based on the possibility of electrochemical or chemical oxidation of the conducting ions of the solid electrolyte from Cu^+ to Cu^{2+}. The concomitant increase in the hole concentration makes higher the hole conductivity of SE. As a result, copper cations can be reduced not only at the electrode surface, but also in the near-electrode layer of ES. This results in the formation of a thin electrolyte layer with high electron-hole conductivity. The copper atoms in this layer are uniformly distributed in the bulk. Evidently,

the current peaks in copper dissolution in such a layer will be dependent on the amount of preliminarily deposited copper.

Apparently, the patterns of anodic dissolution from such a layer must be similar to those observed in dissolution of metals from thin films of their amalgams, characterized by a proportional dependence of the peak current on V_s^{λ}, where λ may assume, depending on film thickness, values ranging from 0.5 to 1.0 (for thick and thin films, respectively). In accordance with this assumption, the dependence of $\ln i_d$ on $\ln V_s$ must be linear with a slope equal to λ. The constructed plots are well described by a linear dependence (Fig. 4). A calculation of λ by the least-squares method yielded a value of 0.83 ± 0.03, 0.95 for Q_0 = 75 mC cm^{-2} and 0.712 ± 0.025, 0.95 for Q_0 = 150 mC cm^{-2} at correlation coefficients of 0.9988 and 0.9996, respectively. The presented data show that λ increases with decreasing Q_0, and, therefore, with decreasing layer thickness, in line with the behavior of amalgam films.

It follows from the proposed model that, if the anodic dissolution of copper yields Cu^{2+} ions and the main conducting ions of ES are oxidized (from Cu^+ to Cu^{2+}), degradation of the solid electrolyte (i.e., a decrease in its ionic conductivity and increase in hole conductivity) is inevitable. This degradation is inherent, to some extent, to all solid electrolytes with conduction by Cu^+ ions. It may be assumed that, owing to the weak binding of Cu^+ cations to the SE anion sublattice, the rates of these processes will depend only slightly on the composition of the sublattice.

It is difficult to account for the comparatively high peak current densities of copper dissolution by the large diffusion coefficient of doubly charged cations in SE. More likely, they can be accounted for by the high hole diffusion rate in the electrolyte, with hole motion accompanied by transfer of unit charge from Cu^{2+} to a neighboring Cu^+ cation. Macroscopically, this is perceived as diffusion of doubly charged cations.

If the electrolyte were free from Cu^{2+} cations, then, owing to the conversion of a copper atom into a doubly charged cation, capacities markedly larger than Q_0 would be observed during anodic semicycles in deposit dissolution from the surface of the inert electrode. At the same time, the experimental coulometric reversibility was usually less than, and close to unity. This suggests that either a high concentration (comparable with that of Cu^+) of doubly charged copper cations discharging in deposition is present in the electrolyte, or the $Cu^+ \rightarrow Cu^{2+}$ and $Cu \rightarrow Cu^{2+}$

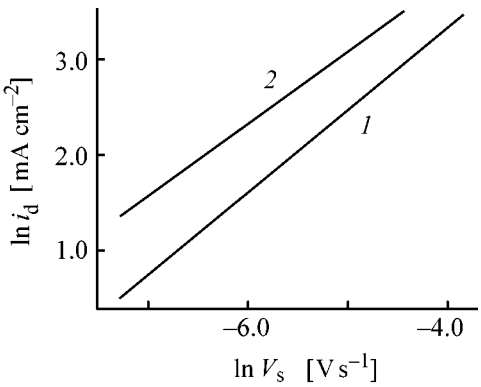

Fig. 4. Current density i_d at peaks of the potentiodynamic polarization curves of copper dissolution from the surface of glassy carbon vs. potential sweep rate V_s. Deposition current density 2.5 mA cm^{-2}, T = 25°C. Q_0 (mC cm^{-2}): (*1*) 75 and (*2*) 150.

transitions make small (as regards the current and capacity) contribution to the potentiodynamic curves of deposit dissolution, and the peak shape is mainly determined by the $Cu \rightarrow Cu^+$ process. As shown by the presented data, the last process is irreversible, i.e., is controlled by charge transfer, and $\beta n \approx 0.5$, which gives $\beta = 0.5$ at $n = 1$.

The presence of an amalgam-like layer inevitably leads to the loss of capacity in dissolution, which occurs, at least, owing to deterioration of the electrical contact between the grains of the layer and between grains and electrode, or owing to a decrease in the copper concentration in the layer in the course of dissolution, which makes lower its electronic conductivity. This fact can account for, in particular, the existence of noticeable currents in the potentiodynamic curves at potentials much exceeding the current peak potentials, just at which the residual copper in the layer is oxidized. This range of potentials is directly responsible for the abrupt change in potential in galvanostatic curves of copper dissolution from the surface of the inert electrode.

Evidently, such a layer will undergo recrystallization when in storage. As a result, the electrical contact between copper in the layer and the electrode may be deteriorated, and the area of contact between copper in the layer and the solid electrolyte, may decrease.

The given near-electrode layer of electrolyte may be formed not only by the above mechanism, but also as a result of the difference in energies of binding between metal and inert electrode and between atoms of deposited metal [4].

Probably, a similar electrochemical behavior will be also observed in other copper-conducting solid electrolytes, which impairs the feasibility of preparing

systems with high coulometric reversibility on their basis.

CONCLUSION

The model of anodic oxidation and cathodic reduction of copper on the surface of an inert electrode was proposed. The model is based on the assumption that redox processes may occur not only on the electrode surface but also in the near-electrode layer of solid electrolyte owing to its comparatively high hole conductivity. This assumption furnishes a qualitative explanation for specific features of processes occurring at the interface between the inert electrode and copper-conducting solid electrolyte.

Abstract—The reaction of nickel(II) and copper(II) sulfate solutions with carbonate flour prepared from carbonatite was simulated thermodynamically and studied experimentally. The conditions under which open systems and those isolated from the atmosphere attain stationary state (carbonatite consumption and grain size, pH of the medium) were determined. The ionic and mineral composition of new formations and the theoretically possible degree of purification were found.

In the affected zones by mining-and-smelting plants in natural basins, a substantial increase in the content of acid oxides and ions of a number of heavy metals exerting negative influence on living organisms is observed in some cases [1]. These contaminants may adversely affect the human health if such water basins are sources of drinking water.

The contamination is caused by acid rains and uncontrollable discharges from tailing dumps and waste piles, containing sulfides of nonferrous metals and iron.

A liter of acid rain with pH in the range from 3.6 to 4.7 contains from 0.002 to 1.15 mg l^{-1} of nickel(II), 0.003 to 2.36 mg l^{-1} of copper(II), and a number of other ions of toxic metals, and also 2.1 to 52.7 mg l^{-1} of the sulfate ion. In winter, the contaminants are accumulated in the snow cover and are discharged to water basins during snow thawing. During this period of time, the content of acid oxides and heavy metal ions in water much exceeds the maximum permissible concentration (MPC) [1, 2].

During storage of mining wastes, the constituent sulfides are oxidized and nonferrous metals pass into readily soluble sulfates. This process is particularly intensive in the case of alternating moistening and drying [3–5]. The MPC may be exceeded 18-fold for cobalt(II) ions, 180-fold for copper(II), and 880-fold for nickel(II) [6].

Water basins can be decontaminated to remove metal ions and inorganic acids with the use of carbonate flour prepared from carbonatite [7]. Use of more active reagents, e.g., suspended $Ca(OH)_2$ is inadmissible for open water basins because of the impossibility of stirring, with the result that the local concentration of the reagent may exceed the MPC and, therefore, adversely affect the ecosystem of a water basin. The optimal acidity (for fish) is within $6.5 < pH < 8.5$, with relatively safe conditions achieved at $5.5 < pH < 9.0$ [8].

It has also been found that the carbonate flour can be used to remove such contaminants as ions of some heavy metals and nickel(II) and copper(II), in particular. However, the purification methods are somewhat different in this case.

In the case of near-surface water contamination with only sulfur oxides (SO_2, SO_3), it is recommended to use for purification a finely dispersed carbonate flour having large specific surface area [4–6, 9]. This ensures a high rate of the reaction and the minimum consumption of the reagent. The use of finely dispersed reagents for purification to remove nickel(II) and copper(II) ions leads to formation of even more finely dispersed secondary products, which stay suspended for a long time. Therefore, it is appropriate to use a reagent with coarser grain and raise its expenditure, to achieve incomplete dissolution of carbonate particles and their settling out together with hydroxides

and basic sulfates and carbonates of heavy metals, formed on their surface. A certain excess of carbonates will hinder reverse reactions in both settled and stirred sludge.

To optimize the purification of natural and wastewater to remove nickel and copper ions, computer simulation of the reaction of dilute solutions with carbonate flour prepared from carbonatite, whose active component is calcite $CaCO_3$, was performed and a set of laboratory experiments was carried out. The computer simulation was done with Selektor PC [10]. The method of physicochemical simulation of natural mineral formation processes is based on finding the minimum Gibbs energy. The reaction of the solid phase with a solution may give a new secondary product compatible with the solution. In this case, despite the established equilibrium between the secondary products and the solution, the primary rock continues to react with the liquid phase and the process goes on [11]. The process of irreversible dissolution can be represented as a sequence of elementary stages, which yields eventually the chronological or spatial succession of changes occurring in the system on its way to equilibrium. The thermodynamic data were taken from [12–15].

The computer simulation was used to study the nature of the reaction of nickel-containing solutions with calcite in open and closed (isolated from the atmosphere) systems at different salt concentrations. The conditions of nickel(II) precipitation from solutions with varied concentration of nickel(II) sulfate were modeled by the thermodynamic system N–C–Ca–Ni–S–O–H–e, containing 32 components in the aqueous phase, including Ni^{2+}, $Ni(OH)^+$, NiO, $HNiO_2^-$; 10 components in the gas phase; and 14 solid phases. The system included nickel and calcium carbonates, oxides, sulfides, and sulfates, and nickel hydroxide $Ni(OH)_2$. According to the results of calculation, precipitation of nickel hydroxide starts in an open system at an initial $NiSO_4$ concentration of 5×10^{-5} M (2.9 mg l^{-1} Ni^{2+}) at pH 8.14 (Table 1), with pH tending to 8.3, and the degree of purification is 24%. Raising the reagent concentration in the system leads to its precipitation, with neither the amount of $Ni(OH)_2$, nor residual concentrations of nickel ions in solution changed. A study of this system in isolation from the atmosphere at the same concentration of nickel(II) ions in solution demonstrated that nickel hydroxide is formed at lower reagent expenditure of 1.78×10^{-4} g l^{-1} at pH 8.059.

Raising the calcite content in the system further leads to a rise in pH, increase in the $Ni(OH)_2$ concentration, decrease in the residual concentration of nickel ions in solution, and transition of the system to a steady state.

In a solution with initial Ni(II) concentration of 1×10^{-5}, no $Ni(OH)_2$ precipitation occurs. The theoretically possible minimum nickel(II) concentration in an open system is 3.8×10^{-5} M (2.23 mg l^{-1}), which corresponds to pH 8.32 of a solution saturated with $CaCO_3$.

In a closed system (Table 1), the maximum pH value in $CaCO_3$-containing solutions (9.85) is higher than that in the open system. The nickel ion concentration in the pH range 8–9.5 is 1–2 orders of magnitude lower than that in the open system, and virtually the entire amount of nickel passes into the solid phase at pH 9.75 and 9.58, and initial nickel concentrations of 1×10^{-5} and 5×10^{-5} M (0.6 and 2.9 mg l^{-1}), respectively. Water purification to remove nickel with calcium carbonate in a closed system is much more efficient as compared with that in the open system. The maximum degree of purification of a $NiSO_4$ solution with initial concentration of 5×10^{-5} M is 25 and 99.8% in open and closed systems, respectively. At an initial Ni(II) concentration of 1×10^{-5} M, no nickel precipitation occurs in the open system, with the degree of purification being as high as 99.7% in the closed system.

The kinetics of reagent reaction with solutions was studied experimentally under laboratory conditions. To avoid reverse reactions, the reagent with products should be precipitated as soon as possible. At the same time, the residence of each grain in the bulk of water being purified must be long enough for the forward reaction to occur. Figure 1 presents a kinetic curve of carbonatite dissolution in distilled water (consumption 0.5 g l^{-1}, fraction 0.4 mm), and Fig. 2, that of carbonatite reaction with a nickel sulfate solution [Ni(II) concentration 2.91 mg l^{-1}]. It can be seen from Fig. 2 that the reaction is virtually complete in 20 min, when the maximum degree of solution purification to remove nickel ions is reached. This approximately corresponds to the time of attainment of the maximum pH value in carbonatite dissolution. Further reaction of the solution with calcium carbonate leads to a slight increase in Ni(II) concentration, which is possibly due to partial dissolution of the newly formed phase.

The number of newly formed phases is small, since the reagent is taken in gross excess. Their precise identification is impossible, since they are characterized by high dispersity and low ordering of the crystal lattice. However, comprehensive studies, including optical and X-ray determinations, revealed that the newly formed phases are close to zaratite $Ni_3[(OH)_4CO_3] \cdot 4H_2O$.

As seen in Figs. 3 and 4, at initial Ni(II) concentrations of 0.3 mg l^{-1}, corresponding to contamination in the immediate vicinity of a source, adding even a minor amount of carbonate flour leads to a dramatic decrease in the content of nickel(II). The degree of purification at reagent consumption of 2 g l^{-1} is 76.67%. With the reagent expenditure raised to 10 g l^{-1}, the degree of purification can be made as high as 83.3%. However, further increase in reagent expenditure is inefficient. The MPC values adopted for fishing basins (0.01 mg l^{-1}) could not be achieved even at reagent consumption of 20 g l^{-1}. Presumably, the residual concentration of nickel(II) ions in water being purified is comparable in this case with the solubility limit of the newly formed phases.

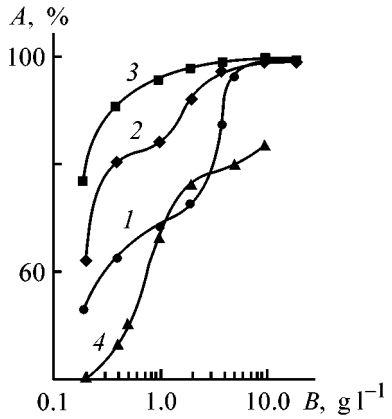

Fig. 4. Degree of solution purification, A, vs. carbonate flour consumption B at different initial metal ion concentrations.

A comparison of the experimental data with results of computer simulation demonstrated that equilibrium is not attained in the system as a whole in reaction of nickel(II) with calcite in real solutions. Local equilibria are created near the surface of grains, simulating conditions that are intermediate between those for the open and closed systems. As a result, the measured residual concentrations of nickel(II) were found to be lower than the calculated values for the corresponding pH values in the open system.

The conditions of copper(II) precipitation from sulfate solutions were found on studying the thermodynamic system N–C–Ca–Cu–S–O–H–e, containing 34 components in the aqueous phase, including Cu^{2+}, Cu^{+}, $Cu(OH)^{+}$, $HCuO_2^{-}$, CuO_2^{2-}, and $Cu(CO_3)_2^{2-}$; 10 components in the gas phase; and 18 solid phases. As also in the case of nickel sulfate solutions, the nature of reaction of copper sulfate solutions with calcite in open and closed systems at Cu(II) concentrations of 1.4 and 5.1 mg l^{-1} was studied by means of computer simulation. At initial Cu(II) concentra-

tion of 5.1 mg l^{-1} in a system open to the action of atmosphere, brochantite $Cu_4SO_4(OH)_6$ is formed at 5.97 < pH < 7.24 (Table 2). Raising the calcite content in the system further does not change the amount of brochantite, with the pH of the system becoming 8.3. Under the conditions when a system is isolated from the atmosphere, brochantite is formed at the same calcite consumption (Table 2). Its concentration grows gradually with increasing reagent consumption and tends to a constant value. The residual concentrations of copper-containing ions are much lower than in the case of an open system. At initial salt concentration of 1.4 mg l^{-1} in an open system, brochantite is formed at pH 6.47 and calcite consumption of 0.001 g l^{-1}, and, additionally, malachite $Cu_2(OH)_2CO_3$, at pH 8.1 and calcite consumption of approximately 0.03 g l^{-1}. The concentrations of copper-containing ions decrease by 2–3 orders of magnitude.

Figure 2 presents a kinetic curve of calcium carbonate reaction with copper sulfate solution [Cu(II) concentration 1.90 mg l^{-1}]. It can be seen that the reaction is virtually complete in 30 min. In contrast to the similar curve for nickel sulfate, no rise in the Cu(II) concentration with increasing reaction time is observed.

As in the preceding case, the number of newly formed phases is small, and their structure is exceedingly imperfect. As a result, they could not be identified precisely. However, comprehensive studies, including optical and X-ray determinations, established that the newly formed phases are close to the natural pozdnyakite and langite [16, 17], with composition $Cu_4SO_4(OH)_6 \cdot H_2O$. The newly formed phase has finely crystalline structure, and, therefore, only averaged refractive index could be evaluated, which gave no way of performing a more precise identification. The X-ray pattern shows only the strongest lines, having close positions in both minerals. Interestingly, pozdnyakite and langite are insoluble in water in contrast to copper sulfates. At the same time, artificial analogs of pozdnyakite or langite could not be synthesized in the system $CuO–SO_3–H_2O$ [18]. Presumably, minerals of this kind can only be formed in strongly diluted solutions.

As it can be seen from Figs. 3 and 4, at initial Cu(II) concentrations of 1.4–5.1 mg l^{-1}, addition of even minor amounts of carbonate flour leads to a dramatic decrease in the content of copper ions. The degree of purification at reagent consumption of 2 g l^{-1} is 75–95%. With the reagent expenditure raised to 10 g l^{-1}, the degree of purification can be made as high as 95–99%. However, at lower contaminant concentrations, the efficiency of the reagent decreases drastically. The MPC values adopted for fishing basins (0.001 mg l^{-1}) could be achieved even at reagent consumption of 20 g l^{-1}. Presumably, the residual concentration of copper ions in water being purified is comparable in this case with the solubility limit of the newly formed phases. As shown by investigations on natural objects, the solubility of basic copper sulfates depends on the pH value: the sulfates are virtually insoluble at pH > 7, but their solubility increases dramatically at lower pH values.

CONCLUSIONS

(1) A comparison of the results of a thermodynamic simulation with experimental data on the reaction of dilute nickel and copper sulfate solutions with carbonate flour demonstrated that the nature of the process is determined by kinetic factors and local equilibria between solution and newly formed phases on the surface of carbonate grains, and between these phases and carbonates, which are established 20–30 min after the beginning of the reaction. In this case, the maximum degree of purification is achieved. The grain size of the carbonate flour must ensure settling out, during this time, of the excess amount of the reagent together with newly formed phases.

(2) The thermodynamic computer simulation was used to find the conditions (carbonatite consumption, pH of the medium) for transition of an open or isolated (from the atmosphere) system to a steady state, establish the ionic and newly formed mineral composition, and determine the theoretically possible degree of purification. The obtained theoretical and experimental data are compared. It is shown that, even though local pH values may be as high as 9.6, the value of this parameter in the water basin bulk does not exceed 8.3, which is safe for living organisms.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Effect of Some Ion Impurities on Accuracy of Fluorometric Determination of Aluminum(III) Concentration in Natural Water

V. L. Krasikov and V. P. Belokurov

St. Petersburg University of Electrical Engineering, St. Petersburg, Russia

Received December 29, 2000

Abstract—The possibility of determining the aluminum(III) concentration in aqueous solutions in the form of a complex compound with lumogallion by means of fluorometry with a portable analyzer and the effect of impurities on the accuracy of determining this concentration were studied.

The fluorometric analytical technique, based on measuring the intensity of fluorescence of a complex compound of aluminum with lumogallion [1] under the action of short-wavelength visible or UV light, is widely used to find the content of aluminum(III) in various media. Owing to its high sensitivity and selectivity, this method is frequently employed to analyze water, eatables, various biological media, etc. [2–8].

Devices for fluorometric analysis frequently use as light sources gas-discharge lamps, halogen incandescent lamps, or lasers [9], with the result that these devices are bulky, power-consuming, and electric mains–dependent. However, it is desirable in many cases to have a precise portable instrument with low power consumption, weight, and size. Such a device could be designed owing to the fact that the fluorescence peak of the aluminum(III) complex with lumogallion is observed at 576 nm, and the wavelength of exciting light must be 450–500 nm [1]. This allowed use of a blue LED with emission peak at 473 nm and brightness of 1 cd at nominal current of 20 mA, instead of power-consuming sources of excitation light. The device is based on a double-beam scheme with the illuminance of a glass measuring cell monitored and maintained constant and account taken of the fluorescence decay with increasing temperature and the possibility of working under scattered daylight.

The aim of this study was to determine the intensity of fluorescence in relation to the aluminum concentration in solution and also to analyze the effect of impurities present in natural water on the accuracy of determining the aluminum concentration.

In view of the high sensitivity of the fluorometric analytical technique, particular attention was given to the purity of laboratory vessels and reagents. State standard aluminum(III) samples of precisely known concentration, reagents of special-purity and chemically pure grades, and lumogallion of pure grade were used.

Working solutions were prepared by pouring approximately 10 ml of distilled water in a clean 50-ml flask and adding by means of a calibrated pipette a calculated amount of a solution containing an aluminum compound. Further, a second pipette was used to introduce 6 ml of a solution containing lumogallion and acetate buffer, with a prescribed amount of a solution of impurity compound introduced when necessary, and the volume of the solution in flask was brought to the mark with distilled water.

Measuring vessels with the solutions were heated. For this purpose, they were placed in a vessel with boiling water for 5 min and then cooled in cold water to room temperature. This procedure was necessary since the fluorescent complex compound is formed at room temperature in several hours (and, correspondingly, the intensity of fluorescence gradually grows during this time), but this process is markedly accelerated at elevated temperatures. Heating for 5 min was sufficient for converting all forms of aluminum(III) into an analytical form.

The main components of the auxiliary solution were as follows (M): lumogallion (0.00012, acetic acid 1.1, and sodium acetate 0.167. Prior to measurements, glass cuvettes were thrice rinsed, with all

necessary precautions, with a solution to be analyzed and then charged with this same solution, by always pouring-in one and the same volume of 5 ml with a pipette. The total volume of the measuring cuvette was about 7 ml. The cuvette with a solution to be analyzed was inserted into the optical compartment of the measuring cell and the intensity of fluorescence was measured. To assess more precisely the reproducibility of the results, three vessels with solution of the same composition were prepared and each solution was analyzed two or three times. On the whole, the experimental procedure had no fundamental differences from that described in [1].

EXPERIMENTAL

In order to use the device for measuring the aluminum(III) concentration, it was necessary to find the dependence of the fluorescence intensity on the concentration of aluminum(III) in a solution being analyzed and determine the concentration range in which this dependence is linear, i.e., to plot the calibration curve. For this purpose, a set of solutions with varied aluminum(III) concentration and the same constant concentration of lumogallion were prepared and then the dependence of the output signal (in volts) on the aluminum(III) concentration in solution was plotted. The data obtained are presented in Fig. 1.

It can be seen that a linear rise in fluorescence signal is observed at aluminum(III) concentrations in the range 0–0.22 mg l^{-1}. At higher concentrations of aluminum(III) this dependence exhibits deviation from linear behavior, and then the fluorescence intensity starts to decrease gradually. In a blank sample without aluminum(III) in solution, the output signal intensity was as low as 0.06 ± 0.02 V, on the average, which may be due to the presence of trace amounts of aluminum(III) in the sample and also to luminescence of glass in the measuring cuvettes etc.

In the linear portion of the calibration curve (Fig. 1), the dependence of the fluorescence signal on the concentration of aluminum(III) in solution is expressed by a straight line with a slope of 23.32 V mg^{-1} aluminum(III) per liter. The scatter of the results of parallel runs did not exceed ±(0.03–0.04) V, i.e., the accuracy of determining the aluminum(III) concentration in the upper linear portion of the calibration curve was ±0.6%. The detection limit of aluminum(III) was about 0.004 mg l^{-1}.

It is known that fluoride ions hinder photometric determination of the aluminum(II) concentration with aluminon [10]. As shown by preliminary experiments, the presence of fluoride ions in solution also leads to a pronounced distortion of results obtained in fluorometric determination of aluminum(III) concentration, and, therefore, the effect of fluoride ions was studied in more detail. For this purpose, solutions were prepared containing 0.11 mg l^{-1} of aluminum(III), which corresponds to the middle of the linear portion of the calibration curve (Fig. 1), with addition of 0.05, 0.1, 0.15, 0.3, 0.6, and 1.5 mg l^{-1} of fluoride ions.

The results obtained in determining the aluminum(III) concentration in the presence of fluoride ions are presented in Fig. 2. As seen from the figure, curve *1*, the measured aluminum(III) concentrations become significantly underestimated with increasing content of fluoride ions. In particular, at a fluoride concentration of fluorides of 1.5 mg l^{-1} in a sample being analyzed (which corresponds to maximum permissible concentration in drinking water [11]) the actual concentration of aluminum(III) is underestimated approximately 60-fold. This is probably due to decomposition of the colored fluorescent complex compound of aluminum with lumogallion to give more stable colorless nonluminescing fluoride complex compound of aluminum $[AlF_6]^{3-}$. Therefore, if a solution being analyzed contains fluoride ions, the results of aluminum(III) concentration measurements may be distorted.

In a similar way was studied the influence of other anions that are frequently present in natural water. It was found that the accuracy of aluminum(III) determination in water is not affected by the following ions in the concentration ranges (mg l^{-1}): chloride ions 0–500, sulfate ions up to 2000, phosphate ions up to 10, hydrocarbonate ions up to 1000, and nitrate ions up to 100 (in the form of sodium salts).

The accuracy of aluminum(III) determination in water is not affected, either, by the following cations in the concentration ranges (mg l^{-1}): sodium 0–1000, potassium up to 500, calcium up to 1000, ammonium up to 500, and magnesium up to 500 (in the form of acetates or sulfates). However, a strong influence is exerted by the presence in water of ions of iron—one of the most widely occurring impurities.

To study the effect of iron(III) concentration, solutions containing 0.11 mg l^{-1} of aluminum(III) and 0.01, 0.02, 0.06, 0.1, 0.3, 0.5, 0.7, and 1.0 mg l^{-1} of iron(III) were prepared. The results of determining the concentration of aluminum(III) in the presence of iron(III) ions are presented in Fig. 2, curve *2*.

It can be seen that the output signal decreases with increasing concentration of iron(III); however, the nature of the influence exerted by iron(III) on the accuracy of aluminum(III) determination is fundamentally different from that of fluoride ions. In a solution being analyzed at pH 8, iron(III) is present mainly in colloid form as brown hydroxide $Fe(OH)_3$, which absorbs the exciting blue light, thereby leading to an underestimated measured concentration of aluminum(III).

Thus, fluorometric analysis for the content of aluminum(III) in natural water is not hindered by phosphate, chloride, sulfate, hydrocarbonate, and nitrate ions in concentrations as high as their maximum permissible concentrations in drinking water, and by high water hardness caused by presence of calcium and magnesium compounds.

At the same time, presence of fluoride ions or iron(III) leads to underestimated measurement results, which requires that appropriate methods to mask the hindering ions should be used.

The use of a miniature LED as light source allowed the development of a portable and sufficiently accurate instrument for fluorometric analysis of solutions in field conditions.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Effect of Polydisperse Drop Composition on Hydrodynamics of Gas-Fluid Jet

O. I. Protod'yakonova, S. V. Aniskin, and Yu. I. Kadashevich

St. Petersburg State Technical University of Plant Polymers, St. Petersburg, Russia

Received July 12, 2001

Abstract—A model is constructed describing the hydrodynamics of a polydisperse gas-fluid jet outflowing from a single-plume atomizer in a spray scrubber. Results of a calculation of hydrodynamic characteristics of a polydisperse plume, obtained using the proposed model, are presented and assessed.

Description of flowing gas-fluid jets in spray mass-exchange apparatus is an essential component of models of adsorption processes carried out in these apparatus. In a number of studies [1, 2], models of such jets were constructed, assuming that drops in the gas-fluid jet are monodisperse. However, it is known that the amount of a component sorbed by absorber drop strongly depends on the size of a drop and time of its contact with the gas flow. Therefore, a model of a mass-exchange process in the gas-fluid jet must take into account the polydisperse drop-size composition. Correspondingly, a model of a flowing gas-fluid jet, which is an important component of the model of a mass-exchange process, must take account of the effect of the polydisperse drop composition on specific features of the flow of a gas-fluid jet.

The aim of this study was to construct a model of a flowing gas-fluid jet that would take into account the effect of the polydisperse drop composition on the jet dynamics. To solve this problem, we use as a basis the previously developed hydrodynamic model of a free plume of atomized fluid [2] whose main advantages over the known models consist in that there is no necessity for determining preliminarily the gas jet boundaries in calculating the flow and in the possibility of taking into account the nonuniform gas velocity distribution in the jet.

In this study, the model taking into account the drop polidispersity is constructed for that region of the gas-fluid jet in which the process of fluid flow breakup into drops may be considered complete. In constructing the model, we make the following assumptions. There is no drop breakup or coagulation. The jet flow is stationary. The distribution of all parameters of the gas-fluid jet is axially symmetric. There is no heat exchange in the dispersed system. The stress in the gas jet developing within the plume of dispersed fluid is negligible as compared with the stresses created in this jet by the drop flow. The drops are polydisperse and have spherical shape. The gas-fluid jet is directed vertically downwards.

Equations describing the flow of a polydisperse gas-fluid jet are derived using the following considerations. We assume that the jet plume can be represented as a certain combination of m interpenetrating plumes, each constituted by drops of the same size. Let us introduce in the space a cylindrical system of coordinates φ, Y, Z. In accordance with the assumption that the plume is axially symmetric, we consider in what follows that all flow parameters are independent of the angle φ.

Let us divide each of the above m plumes into n cone jets in such a way that the fluid flow rate G_{kj} within each of these jets is constant. We also assume that the fluid is uniformly distributed over the cross-section of each so-defined jet. Thus, the following conditions are satisfied:

$$G_{kj} = \text{const}, \quad k = 1, 2, \ldots, n; \quad j = 1, 2, \ldots, m; \quad (1)$$

$$\frac{dG}{dS} = \text{const}, \text{ if } dG \in G_{kj},$$

where indices k and j are, respectively, the number of fluid jet in spatial partitioning of the plume and the number of fraction of drops with certain size; S is the cross-sectional area of the jet.

The total number of jet in such partitioning of the gas-fluid plume is given by the product mn. Appar-

1070-4272/01/7412-2054 $25.00 © 2001 MAIK "Nauka/Interperiodica"

ently, the trajectories of drops of different sizes are dissimilar, which gives rise to a shift of jets composed of drops of one size with respect to jets constituted by drops of other sizes. We assume that such a shift begins at a distance L from the atomizer nozzle exit, where breakup of the fluid flow into drops is complete.

Figure 1 shows a cross-section of a polydisperse plume with a plane passing through the Z axis. The scheme shown in Fig. 1 illustrates the above-described partitioning of a polydisperse axially symmetric plume of a gas-fluid flow by monodisperse jets and their relative shift. The scheme shows streamlines delimiting jets with constant flow rate. The index belonging to jet is assigned to a streamline delimiting the corresponding jet from its outer side. Let us derive the equation of momentum conservation in a gas-fluid jet for the coordinates z and y. For this purpose, let us single out at an arbitrary distance z from the jet cross-section L (Fig. 1) an elementary layer of height dz. Let us consider a part of this layer, delimited by lateral surfaces ac and bd, chosen in such a way that they coincide with the streamlines delimiting the jet k,m. In what follows, we name the volume $abcd$ the ith part of the distinguished layer of height Δz (Fig. 1).

Let us determine the flow rate Q_i of fluid passing through the cross-section of the elementary volume $abcd$. We represent this flow rate as a sum of components defined by fluid jets passing through ab either entirely (as, e.g., jet k,m composed of drops of the largest size, forming the fraction denoted by m) or partially (as, e.g., jet k,j and jet $k+1,j$ composed of drops belonging to the fraction denoted by j).

With account of of the previously made assumption that the distribution of spraying density is uniform within each jet k,j, it may be considered that the flow rate of fluid in jet k,j through section ab is given by

$$G_{ikj} = G_{kj}\frac{(b')^2 - a^2}{(b')^2 - (a')^2}, \qquad (2)$$

where G_{ikj} is part of fluid in jet k,j passing through section ab.

For convenience of further transformation, we replace the quantities, a, b, a', b' by the corresponding values of the radial coordinate y. The relation (2) takes the form

$$G_{ikj} = G_{kj}\frac{y_{kj}^2 - y_{k-1,m}^2}{y_{km}^2 - y_{k-1,m}^2}. \qquad (3)$$

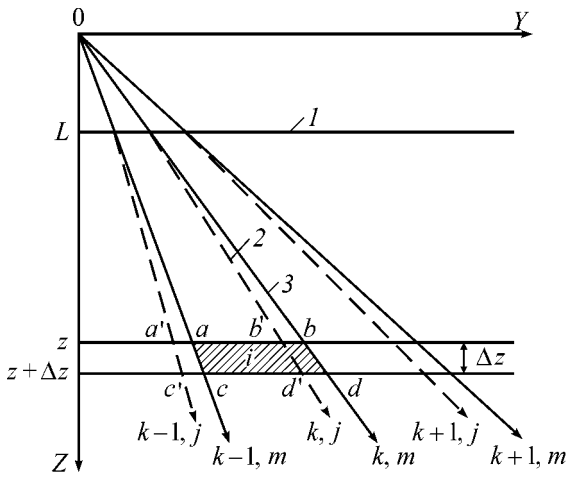

Fig. 1. Scheme of partitioning of a polydisperse plume of a gas-fluid flow into monodisperse jets. (*1*) Line drawn at a distance L from the atomizer nozzle exit—that boundary of the gas-fluid jet flow, at which the fluid flow breakup into drops is considered to be complete; (*2*) streamline of fluid jet k,j, where k = 1, 2, ..., n, j = 1, 2, ..., m are indices denoting, respectively, the number of fluid jet and that of some drop fraction; m is the index denoting the fraction number of drops having the maximum size; (*3*) streamline of fluid jet at $j = m$, distinguishing i-th element of the plume space in a layer.

In a similar way can be written an expression for that part of the fluid flow rate which belongs to jet $k+1,j$ and passes through section ab

$$G_{i,k+1,j} = G_{k+1,j}\frac{y_{km}^2 - y_{kj}^2}{y_{k+1,j}^2 - y_{k,j}^2}. \qquad (4)$$

Let us introduce coefficient θ_{ij} defined by

$$\theta_{ijk} = G_{ijk}/G_{kj}. \qquad (5)$$

This coefficient defines that part of the flow rate of fluid in jet k,j which passed through ith part of the plume layer. Then the total flow rate G_i of fluid passing through section ab can be written as

$$G_i = \sum_{k=1}^{n}\sum_{j=1}^{m}\theta_{ikj}G_{kj}. \qquad (6)$$

Apparently, the coefficient θ_{ikj}, defined as the ratio of flow rates G_{ikj} and G_{kj}, generally depends on the y value. In this case, four ways to calculate the θ_{ikj} are possible, chosen depending on how a particular jet passes through ith layer of the plume, e.g., with its left- or right-hand side coinciding with, or passing within, or by-passing this layer. To these cases correspond the following formulas for calculating θ_{ikj}:

$$y_i > y_{ki} > y_{i-1} \text{ and } y_{k-1,j} \le y_{i-1},$$

$$\theta_{ikj} = \frac{y_{kj}^2 - y_{i-1}^2}{y_{kj}^2 - y_{k-1,j}^2}; \quad (7)$$

$$y_i \ge y_{kj} > y_{i-1} \text{ and } y_{k-1,j} \ge y_{i-1},$$

$$\theta_{ikj} = 1; \quad (8)$$

$$y_i > y_{k-1,j} \ge y_{i-1} \text{ and } y_{kj} > y_i,$$

$$\theta_{ikj} = \frac{y_i^2 - y_{k-1,j}^2}{y_{kj}^2 - y_{k-1,j}^2}; \quad (9)$$

$$y_{kj} \le y_{i-1} \text{ or } y_{k-1,j} \ge y_i,$$

$$\theta_{ikj} = 0. \quad (10)$$

We assume that the variation of the coefficient θ across the layer Δz is negligible. Then the change in the fluid momentum W_i in ith part of the elementary layer of the plume will depend only on a change in fluid velocity, du_{kj}, which occurs as a result of drop deceleration in the gas-fluid jet and can be described as follows:

$$\frac{d}{dz} W_{zi} \sum_{k=1}^{n} \sum_{j=1}^{m} \theta_{ikj} G_{kj} \frac{du_{zkj}}{dz}, \quad (11)$$

$$\frac{d}{dz} W_{yi} \sum_{k=1}^{n} \sum_{j=1}^{m} \theta_{ikj} G_{kj} \frac{du_{ykj}}{dz}, \quad (12)$$

It should be noted that the components u_{zkj} and u_{ykj} of the fluid velocity u_{kj} in jet k, j, appearing in expressions (11) and (12), are defined as quantities averaged over the entire section z of the elementary layer in jet k, j. These can be found from the expressions

$$\frac{du_{zkj}}{dz} = \sum_{i=1}^{n} \theta_{ikj} \frac{du_{zikj}}{dz}, \quad (13)$$

$$\frac{du_{ykj}}{dz} = \sum_{i=1}^{n} \theta_{ikj} \frac{du_{yikj}}{dz}, \quad (14)$$

where du_{zikj} and du_{yikj} are the components of changes in the velocity u_{kj} of jet k, j in elementary layer i in the directions of the Z and Y axes, respectively.

The sought-for equations for describing the changes in momentum in a layer dz of the gas-fluid jet in the case of a polydisperse drop composition, written for the coordinates z and y, will differ from similar equations derived in [2] for monodisperse drops only in the term W_i expressing the momentum flux of ith fluid jet. Therefore, they can be written as

$$\frac{d}{dz} \sum_{i=1}^{i} (\rho_g Q_{gi} v_{zi}) - \rho_g v_{z\,i+1} \sum_{i=1}^{i} \frac{d}{dz} Q_g + \sum_{i=1}^{i} \frac{d}{dz} W_{zi} + \sum_{i=1}^{i} S_i \frac{dP_i}{dz} = 0, \quad (15)$$

$$2\pi(P_{i+1} - P_i) y_i + \frac{d}{dz} W_{yi} = 0, \quad (16)$$

where ρ_g is the gas density (kg m^{-3}), Q_{gi} the volumetric flow rate of gas (m^3 s^{-1}), v_i the gas velocity (m s^{-1}), P_i pressure (kg m^{-2}), and S_i the cross-sectional area of ith layer (m^2).

In developing a model of gas-fluid jet flow, which would take into account the polydisperse drop composition, Eqs. (13) and (14) must be supplemented with gas flow continuity equations, equations describing fluid drop motion, and fluid streamline equations, and also with closing relations derived in [2]. Let us write these additional equations and closing relations with the use of indexation introduced in the present study.

The gas flow continuity equation has the form

$$\sum_{i=1}^{i} \frac{d}{dz} Q_{gi} = -2\pi y_{i+1} v_{y,\,i+1}. \quad (17)$$

Equation describing the fluid drop motion

$$\frac{du_{zikj}}{dz} = -\xi_{ikj} \frac{3\rho_g (u_{ikj}^{rel})^2}{4 d_{kj} u_{zkj} \rho_l} \cos\alpha_{ikj} + \frac{g}{u_{zkj}}, \quad (18)$$

$$\frac{du_{yikj}}{dz} = -\xi_{ikj} \frac{3\rho_g (u_{ikj}^{rel})^2}{4 d_{kj} u_{zkj} \rho_l} \cos\alpha_{ikj}, \quad (19)$$

where ξ_{ikj} is the coefficient of resistance to drop motion in the gas medium, α_{ikj} the angle between the z axis and the direction of the resistance force, and u_{ikj}^{rel} the relative velocity of motion of drops belonging to jet k, j in the gas flow of layer i.

The equations of fluid streamlines coinciding with the trajectories of drop motion have the form

$$\frac{dy_{kj}}{dz} = \frac{u_{ykj}}{u_{zkj}} \quad (20)$$

The obtained system of equations, describing the hydrodynamics of a polydisperse gas-fluid jet, can be supplemented with closing relations

$$Q_{gi} = S_i v_{zi}, \quad (21)$$

$$S_i = \pi(y_i^2 - y_{i-1}^2), \quad (22)$$

$$v_{ikj}^{\text{rel}} = \sqrt{(u_{ykj} - v_{yj})^2 + (u_{zkj} - v_{zi})^2}, \quad (23)$$

$$\alpha_{ikj} = \text{arctg}\left(\frac{u_{ykj} - v_{yi}}{u_{zkj} - v_{zi}}\right), \quad (24)$$

$$\xi_{ikj} = \frac{24}{\text{Re}_{ikj}}(1 + 0.125\text{Re}_{ikj}^{0.72}). \quad (25)$$

Relation (25) is valid for the region $0.1 < \text{Re} < 1000$. The boundary conditions for the closed system of equations of the model, obtained here, have the form

$$\text{at } z = L,\ G_{kj} = G_{kj}^{(L)},\ u_{zkj} = u_{zkj}^{(L)},\ u_{ykj} = u_{ykj}^{(L)},$$
$$v_{zi} = v_{zi}^{(L)},\ v_{yi} = v_{yi}^{(L)},\ y_i = y_i^{(L)} \quad y_{kj} = y_i^{(L)},$$
$$d_j = d_j^{(L)},\ k = i; \quad (26)$$

$$\text{at } y = 0\ v_{yi} = 0. \quad (27)$$

At the outer boundary of the jet, at $y = y_{n+1}$

$$v_{z,\,n+1} = 0, \quad P_{n+1} = P_a, \quad (28)$$

where P_a is the atmospheric pressure (Pa).

To calculate the quantities appearing in relations (26), it is necessary to use the distribution functions of spraying density and disperse composition. The experimentally observed spraying density distributions over the cross-section of a gas-fluid jet outflowing from a single-plume atomizer can be described using the distribution function

$$I = \frac{a_0}{1 + b_0 r^{h_0}} - \frac{c_0}{1 + d_0 r^{h_0}} \quad (29)$$

(I is the dimensionless spraying density; r the dimensionless radius; a_0, b_0, c_0, d_0, and h_0 constants),

$$I = J/\bar{J},\ r = y/y_R,\ \bar{J} = 0.95G_n/(\pi y_R^2), \quad (30)$$

where J is the spraying density (m s^{-1}), $\bar{J}$ the average spraying density in a cross-section of a plume with radius y_R, and y_R the radius of a plume within which passes 95% of fluid, G_n, outflowing in unit time from the nozzle.

Using function (29), we obtain an expression for determining the fluid flow rate in ith jet at a distance L from the atomizer nozzle exit:

$$G_i = \sum_{j=1}^{m} G_{kj} = 1.9\, G_n \int_{r_{i-1}}^{r_i} I r dr, \quad (31)$$

where r_i are the initial values of the dimensionless radius.

These values make it possible to find the initial coordinates y_{kj} of the jets distinguished, using the formula

$$y_{kj} = y_i = r_i Y_R. \quad (32)$$

the y_R value is determined from the maximum spraying density $I_{\max}$ in accordance with the relation

$$y_R = R_n \sqrt{T_{\max}/\beta}, \quad (33)$$

where R_n is the atomizer nozzle radius and β is the volume content of fluid, taken to be 0.02.

The L value can be found, with account of (33), using the formula

$$L = \frac{y_R - R_n}{\text{tg}\,\alpha}, \quad (34)$$

which enables calculation of the initial values of the gas and fluid velocities. The angle α determines the boundary of that part of the gas-fluid jet, which contains 95% of the fluid.

If we neglect the deceleration of fluid in the first zone, the velocity distribution can be set as follows

$$v_{zi} = u_{zkj} = \frac{Lu}{\sqrt{L^2 + y_i^2}}, \quad (35)$$

$$v_{yi} = u_{ykj} = \frac{y_i u}{\sqrt{L^2 + y_i^2}}, \quad (36)$$

where u is the velocity of fluid outflow from the atomizer nozzle, determined using the Bernoulli formula

$$u = \mu\sqrt{2P_f/\rho_f}, \quad (37)$$

where P_f is the fluid pressure before the atomizer, and μ is the coefficient of fluid outflow velocity.

The initial values of the fluid flow rate G_{kj} can be conveniently found using the integral drop volume distribution S with respect to drop size. It is known that the best fit to the real distribution in fluid spraying by atomizers is given by the Rosin–Rammler distribution

$$S^{\text{RR}} = 1 - e^{-(d/a)^l}, \quad (38)$$

where a and l are the characteristic constants of the given distribution.

Formula (38) can be used to determine the part of fluid volume, S_j, constituted by drops having diameter less than d_j.

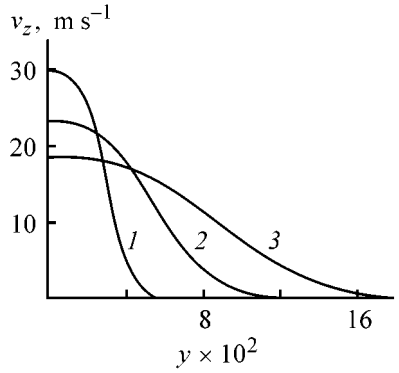

Fig. 2. Distribution of gas velocities v_z across the plume. Distance z (m) from section L: (*1*) 0.2, (*2*) 0.5, and (*3*) 1.0.

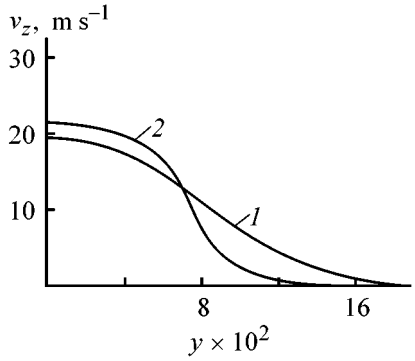

Fig. 3. Comparison of distributions of gas velocity v_z for (*1*) polydisperse and (*2*) monodisperse gas-fluid flows at $z = 1$ m.

With account of (38), the flow rate G_{kj} of fluid in jet kj can be expressed as

$$G_{kj} = G_i(S_j - S_{j-1}). \quad (39)$$

The constant a in the formula describing the Rosin–Rammler distribution (38) is found from the average volume-surface diameter (Sauter diameter)

$$a = 1.3542 d_{32}. \quad (40)$$

If the sprayed fluid is water, then the d_{32} value can be found by the formula [3]

$$d_{32} = 0.154 P_l^{-0.44} (2R_n)^{0.23}, \quad (41)$$

where the quantities d_{32} and R_n are expressed in millimeters, and P_l, in megapascals.

We define the quantities $d_j^{(L)}$ as average volume-surface diameters of drops of each fraction, necessary for calculating the hydrodynamic parameters:

$$d_j^{(L)} = \frac{S_j - S_{j-1}}{\int_{x_{j-1}}^{x_j} \frac{dS}{dx} \frac{1}{x} dx}, \quad (42)$$

where d_j is the Sauter diameter for drops of jth fraction, x the drop diameter, and x_j the boundary value of the diameter of drops belonging to jth fraction.

The constructed closed system of Eqs. (1), (6)–(29) with boundary conditions (26), describing the hydrodynamics of a polydisperse plume of the gas-fluid jet, can be solved only numerically. To find the solution, this system of first-order differential equations was preliminarily reduced to the canonical form and then solved by the Adams–Bashfort method. The solution was obtained for the following values of the parameters determining the fluid spraying mode: P_l = 0.6 MPa, R_n = 1.5 mm, $\alpha = 12.5°$, $a_\perp = 3.0$, $b = 49.0$, $c = 1.06$, $d = 32\,544$, $h = 6.4$, $I_{max} = 2.87$, $\mu = 0.96$, $l = 3$, $\rho_g = 1.2$ kg m^{-3}, $\nu_g = 1.51 \times 10^{-5}$ m^2 s^{-1}, where ν_g is the kinematic viscosity of air, necessary for determining the Reynolds number Re.

The curves plotted using the result of numerical solution of the equations of the model are presented in Figs. 2–5. Figure 2 shows gas velocity distribution across the plume. It is similar to the known distribution of this parameter across the gas jet. A distribution of the same kind was obtained in an experimental study of a gas-fluid jet [4]. This means that the theoretical results obtained in the present study are sound. The calculation results presented in Fig. 2 confirm the possibility of finding gas velocity fields without setting boundaries of the gas jet inside the fluid flow.

Figures 3–5 present calculated dependences which reveal the influence of taking the flow polydispersity into account on the results obtained in calculating the hydrodynamic parameters. Figure 3 shows gas velocity distribution curves obtained for a polydisperse flow of drops, and also those for a monodisperse flow. These latter were calculated at a volume-surface Sauter diameter d_{32} = 0.248 mm. Comparison of these curves suggests that taking the polydisperse nature of the drop flow into account markedly affects the results obtained in calculating the gas velocity. For example, in the near-axis region of the flow, the gas velocity calculated using the model taking into account the polydispersity of the drop flow is higher than that calculated in terms of the model based on the assumption that this flow is monodisperse.

In the region close to plume boundaries, the calculated gas velocity in a monodisperse flow is lower than that in a polydisperse flow. The differences in

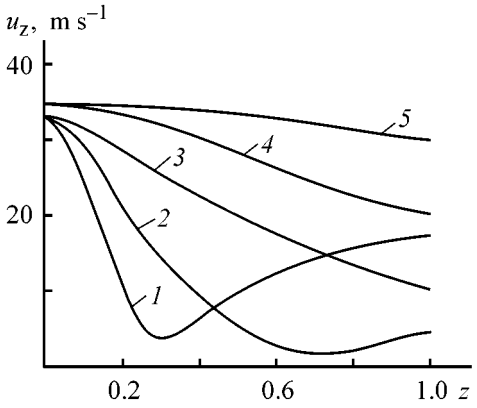

Fig. 4. Variation of drop velocity u_z along the plume length. Drop motion: (*1–3*) along the plume boundary and (*4, 5*) along the plume axis. Drop diameter d_j (mm): (*1, 4*) 0.117, (*2*) 0.202, and (*3, 5*) 0.453.

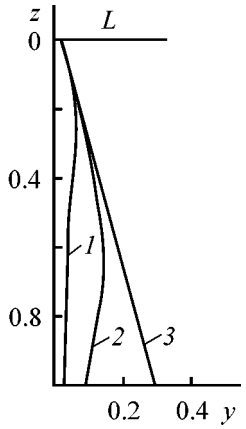

Fig. 5. Trajectory of drops starting their motion at the plume boundary. Drop diameter d_j (mm): (*1*) 0.117, (*2*) 0.202, and (*3*) 0.453.

the nature of curves presented in Fig. 3 indicate that the calculated width of the gas jet is smaller for the monodisperse plume, compared with the polydisperse one.

Figure 4 presents calculated curves characterizing changes in the velocity of drops with different diameters, which started their motion in the second zone from two different points in the section L of the plume. One of these points lies on the plume axis, and the other, on its boundary.

According to formula (35) the velocity u_z at points lying on the plume axis is higher than that at points on its boundary. This boundary was found from the condition that the amount of fluid flowing in unit time within the region delimited by this boundary constitutes 99% of the total rate of fluid outflow from the atomizer.

The specificity of drop motion in a polydisperse plume consists, as follows from Fig. 4, in that, irrespective of how the above points in the section L are chosen, the motion velocities of drops having different sizes rapidly become markedly different in the initial stage of the deceleration process. Fine drops are decelerated in their motion faster than large drops. In the case illustrated by Fig. 4, this feature is characteristic of all particles in the zone delimited by distance z = 0.3 m along the Z axis.

Another hydrodynamic feature of the polydisperse plume, which is illustrated in Fig. 4, consists in that fine drops beginning their motion at points lying on plume boundaries start to increase their velocity at $z > 0.3$ m (Fig. 4, curves *1* and *2*). This phenomenon occurs because of the displacement of fine drops in their motion toward the middle of the plume, where the gas velocity is higher, which leads to acceleration of just fine drops.

The calculated trajectories of drops whose motion is characterized by curves *1–3* in Fig. 4 are presented in Fig. 5. It can be seen that trajectories of fine drops do show a significant displacement toward the plume axis at distances $z > 0.3$ from section L. In the process, the drops shift from the near-boundary region with low gas velocities to a flow region with higher gas velocity. It is this circumstance that is the reason why fine drops starting to move from the near-boundary region of the plume exhibit the above specific feature of motion.

The results obtained in this study suggest that, compared with the model of monodisperse gas-fluid jet, the model constructed here yields significantly different calculated values of such highly important hydrodynamic characteristics of the system in question as the relative velocity and time of drop motion, and their spatial coordinates in relation to their initial position in the plume cross-section, drop size, and initial velocity of drop motion. Thus, taking into account the polydisperse nature of the drop flow in constructing a hydrodynamic model of the dispersed system in question exerts strong influence on the quantitative description of mass-exchange process occurring in systems of this kind and, in particular, absorption process.

For example, in the case when the absorption rate is limited by resistance in the fluid phase, the calculation of this velocity is strongly affected by the results of calculation of the drop motion time and coordinates. The time of drop motion is determined

by the time of absorption, and drop coordinates yield information about the filed of concentration of a component being absorbed around a drop. In those cases when the absorption rate is limited by resistance in the gas phase, the procedure for calculation of the absorption process is, in addition, markedly affected by the result of calculation of the relative velocity of phase motion. The last hydrodynamic characteristic determines, through the Reynolds number entering into the Sherwood number, the calculated intensity of mass transfer.

CONCLUSIONS

(1) The results of the study enable calculation of hydrodynamic characteristics of both poly- and monodisperse gas-fluid jets, without a preliminary setting of the gas jet boundaries, on the basis of the real shape of the spraying density distribution across the plume.

(2) The size distribution of drops strongly affects the results of calculation of the most important hydrodynamic characteristics of a gas-fluid jet outflowing from a single-plume atomizer.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Breakup Mechanism of Drops of Viscous Fluid in Spraying Apparatus

Yu. G. Chesnokov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received April 25, 2001

Abstract—Wave development on the drop surface in the course of fluid dispersion in a spray apparatus is analyzed theoretically. The equation derived allows calculation of the process of drop breakup in relation to wavelength.

Solution drying frequently poses the problem of obtaining grains uniform in size, which can be solved if drops of solution outflowing from atomizer have approximately equal sizes. The problem of creating a flow of drops having the same size in dispersion of a fluid in apparatus of chemical technology invites a theoretical analysis of drop breakup in a gas flow under the action of surface tension forces. In performing the analysis, account should be taken of the fact that a solution drop moving in a gas flow can be deformed by this same flow, with waves of different lengths and amplitudes formed on its surface. Breakup of a drop is associated with the appearance on its surface of waves having length at which the rate of wave amplitude rise will be the highest. Hence the necessity for employing in calculations of the hydrodynamic modes of the apparatus in question of an equation relating the mentioned wavelength to the amplitude of the wave, Reynolds number, and Weber number. Deriving an equation of this kind by means of a theoretical analysis of wave development on the drop surface is the aim of this study.

It is assumed that a fluid drop acquires an initial, nonuniform along its length, velocity distribution and is deformed under the action of inertia forces. As a result of elongation, the drop loses stability with respect to capillary forces, so that secondary drop breakup can be observed. This process can be described using a theory based on investigations of capillary waves on the surface of a cylindrical fluid jet [1]. The problem of stability of a viscous fluid jet subjected to uniaxial tension and flowing into another viscous fluid, immiscible with the former, was first considered by Tomotika [2]. In [3], the problem of the stability of an elongate cylindrical drop in an external shear flow was considered. In both these studies [2, 3], it was assumed that inertia forces are negligible as compared with viscous friction and surface tension forces, so that the fluid flow, both inside and outside the jet, can be described using linear Stokes equations. Another important case of flows of this kind, when the inertia and surface tension forces are the most important and viscous friction forces can be neglected, was considered in [1, 4].

In the case when both inertia and surface tension forces and viscous friction forces are to be taken into account, the problem of perturbation development on the surface of a fluid jet is more complicated. Even when the perturbation amplitude is small and linearized equations can be used, it is difficult to construct an analytical solution to the problem. Therefore, of particular importance is the question as to whether or not it is possible to construct such an approximate solution that would describe the most essential features of the phenomenon under study.

As shown in [1], the behavior of a sinusoidal perturbation of the surface of a cylindrical jet of ideal fluid depends on the initial perturbation wave-length. Long-wavelength perturbations, whose wave-length exceeds the circumference of the jet cross-section at the initial instant of time, start to build-up immediately; however the rate of their build-up is relatively low because of the comparatively strong influence of fluid inertia on the development of perturbations. If a perturbation is short-wavelength, the jet surface executes oscillatory motion during

1070-4272/01/7412-2061 $25.00 © 2001 MAIK "Nauka/Interperiodica"

the initial period of time, with the amplitude of oscillations changing only slightly and their period increasing.

The aim of this study was to analyze long-wavelength perturbations on the surface of a cylindrical viscous fluid jet. In the course of time the radius of the cylindrical jet decreases, and the perturbation wavelength, contrariwise, increases. Therefore, whatever the initial perturbation wavelength, any perturbation can be considered longwavelength after a certain interval of time. Consequently, the results obtained in this study are valid not only for perturbations with large initial wavelength, but also for any other perturbations. However, the results become applicable to short-wavelength perturbations only after the current wavelength exceeds the current jet radius.

Long-wavelength perturbations can be described in terms of an approximate theory based on application of approximate one-dimensional (1D) equations of jet dynamics. These 1D equations are derived on the assumption that the transverse scale of variation of hydromechanical quantities is small as compared with the scale of variation along the jet axis. Approximate 1D equations of this kind have been considered in numerous studies. For example, approximate 1D equations describing the dynamics of a capillary jet of ideal fluid were proposed in [5, 6]. More exact 1D equations (so-called Kosser equations) were used in [7–9] to describe capillary waves on the surface of a semi-bounded jet. In [10], equations were constructed in a next approximation in small parameter for ideal fluid jet. One-dimensional equations were also used to describe the development of perturbations in viscous fluid jets. For example, such equations were used in [11] to numerically simulate the dynamics of a capillary jet. In [12], 1D equations were applied to study nonlinear development of capillary waves in a viscous fluid jet by expanding the solution to the problem in a small parameter (perturbation amplitude). Various kinds of approximate 1D equations were compared in [13]. A method for constructing approximate equations, which can, in principle, be used to obtain approximate equations in any approximation in small parameter (transverse to longitudinal flow scale ratio), was developed in [14].

Let us assume that the fluid jet has cylindrical shape, with the shape preserved in the course of time and the jet radius possibly changing. The surface area of the jet decreases as a result of development of axially symmetric perturbations on its surface. Therefore, jet breakup into drops may occur as a result of evolution of just these perturbations, and the present study is concerned with perturbations of this kind. In the case when the fluid velocity in the jet is sufficiently high, the effect of the gravity force on the process of jet breakup into drops can be neglected. This condition will be considered satisfied. Let us introduce dimensionless variables. We denote the jet radius at the initial instant of time by r_0, time by t, and the derivative of the jet radius with respect to time at the initial instant of time by $r_t(0)$. The quantity r_0 can be used as characteristic linear scale of the problem, and $t_0 = -r_0[2r_t(0)]$, as time scale. The quantity r_0/t_0 can be used as velocity scale, and the quantity $p_0 = \sigma/r_0$, where σ is the surface tension at the interface between the jet and its environment (gas), as the pressure scale. Let us introduce a cylindrical system of coordinates (r, ϑ, z) whose z axis coincides with the jet axis. Let us denote the axial and radial components of the fluid velocity vector by, respectively, u and v; and pressure by p. Then equations describing fluid motion in a jet, which are the continuity equation and projections of the Navier–Stokes equation onto the axes z and r of the cylindrical system of coordinates, can be written as

$$v_r + \frac{v}{r} + u_z = 0,$$

$$u_t + vu_r + uu_z = -\frac{1}{\mathrm{We}} p_z + \frac{1}{\mathrm{Re}}\left[\frac{1}{r}(ru_r)_r + u_{zz}\right],$$

$$v_t + vv_r + uv_z = -\frac{1}{\mathrm{We}} p_r + \frac{1}{\mathrm{Re}}\left[\frac{1}{r}(rv_r)_r - \frac{v}{r^2} + v_{zz}\right].$$

In writing the equations, the symbol subscripts of the variables denote differentiation with respect to the corresponding variable, e.g., $u_t = \partial u/\partial t$ etc. The Reynolds and Weber numbers Re and We in these equations are introduced as follows

$$\mathrm{Re} = \frac{\rho h_0^2}{\mu t_0^2}, \quad \mathrm{We} = \frac{\rho h_0^3}{\sigma t_0^2},$$

where μ is fluid viscosity.

The jet surface can be defined by the following relation

$$r = \eta(z, t).$$

Three boundary conditions are to be set on this surface. The kinematic boundary condition is as follows:

$$\eta_t + u\eta_z = v \text{ at } r = \eta.$$

The existence of surface tension forces results in that the normal stresses at the jet surface on the sides of liquid and gas differ by $\sigma(1/R_1 + 1/R_2)$, where R_1 and R_2 are the principal radii of surface curvature in the longitudinal and transverse directions. Therefore,

one of the boundary conditions on the jet surface has the form

$$p - \frac{We}{Re}[2v_r - (u_r + v_z)\eta_z] = p_e + \frac{1}{R_1} + \frac{1}{R_2},$$

where p_e is the environment pressure.

This quantity is assumed to be constant. In the cylindrical system of coordinates, the principal radii of curvature are calculated as follows:

$$\frac{1}{R_1} = \frac{1}{\eta(1+\eta_z^2)^{1/2}}, \quad \frac{1}{R_2} = -\frac{\eta_{zz}}{\eta(1+\eta_z^2)^{3/2}}.$$

The third boundary condition means that the tangential (to the jet surface) component of the viscous strain vanishes on this surface:

$$2v_r\eta_z + (u_r + v_z)(1 - \eta_z^2) - 2u_z\eta_z = 0 \text{ at } r = \eta.$$

Let us assume that the jet radius changes, but the jet retains its cylindrical shape, i.e., $\eta_z = 0$ at any t. The above-formulated problem has a solution of the following kind

$$u = u^{(0)} = \frac{z}{\tau}, \quad v = v^{(0)} = -\frac{r}{2\tau}, \quad \eta = \eta^{(0)} = \tau^{-1/2},$$

$$p = p^0 = p_e + \tau^{1/2} + \frac{3We}{8\tau^3}(1 - \tau r^2) - \frac{We}{Re\,\tau},$$

where $\tau = 1 + t$.

This solution describes the uniaxial tension of the jet. The solution differs from that considered in [1] only in the additional term in the expression for pressure.

The development of small perturbations in the given flow can be described using linearized equations and boundary conditions. However, in the case of a viscous fluid, solutions to these equations are difficult to obtain. The present study is concerned with long-wavelength perturbations. Such perturbations can be described using approximate 1D equations. Here, we use the following equations [13]:

$$\eta_t + w\eta_z = -\frac{1}{2}\eta w_z, \tag{1}$$

$$w_t + ww_z - \frac{1}{8\eta^2}\left[\eta^4\left(w_{zt} + ww_{zz} - \frac{1}{2}w_z\right)\right]_z = \frac{1}{We}\left(\frac{\eta_z}{\eta^2} + \frac{\eta_z\eta_{zz}}{\eta} - \frac{\eta_z^3}{2\eta^2} + \eta_{zzz}\right) + \frac{1}{Re\,\eta^2}\left[3\eta^2 w_z + \frac{3}{4}\eta^3\eta_{zz}w_z - \frac{9}{4}\eta^2\eta_z^2 w_z\right]_z, \tag{2}$$

where w is the cross-section-averaged axial component of the fluid velocity.

The written equations have a solution describing the uniaxial tension of the jet

$$\eta^{(0)} = \tau^{1/2}, \quad w^{(0)} = z/\tau.$$

Let us assume that at the initial instant of time there exists a small-amplitude perturbation of the mentioned flow. Solution to Eqs. (1) and (2) will be sought in the form

$$\eta = \eta^{(0)} + \delta\eta, \quad w = w^{(0)} + \delta w. \tag{3}$$

The quantities $\delta\eta$ and δw are assumed to be small. Substituting (3) into Eqs. (1) and (2) and neglecting products of small quantities, we obtain equations for small perturbations of the main flow

$$\delta\eta_t + \frac{z}{\tau}\delta\eta_z + \frac{1}{2}\tau^{-1/2}\delta w_z + \frac{1}{2}\tau^{-1}\delta\eta = 0, \tag{4}$$

$$\delta w_t + \frac{z}{\tau}\delta w_z - \frac{1}{8}\left[\frac{1}{\tau}\left(\delta w_{tz} + \frac{z}{\tau}\delta w_{zz} - \frac{1}{\tau}\delta w_z\right) - \frac{6}{\tau^{5/2}}\delta\eta\right]_z = \frac{1}{We}\left(\tau\delta\eta_z + \delta\eta_{zzz}\right) + \frac{3}{Re}\left[\delta w_z + \frac{2}{\tau^{1/2}}\delta\eta + \frac{1}{4}\tau^{-3/2}\delta\eta_{zz}\right]_z. \tag{5}$$

Let us consider a sinusoidal perturbation. A solution to equations for small perturbations will be sought in the form

$$\delta\eta = \tau^{-1/2}h(\tau)\exp(ikz), \quad \delta w = \tau^{-1}s(\tau)\exp(ikz), \tag{6}$$

where $k(\tau)$ is the wave number, i is imaginary unit, and multipliers $\tau^{-1/2}$ and τ^{-1} are introduced for convenience. The variable z is eliminated from the equations if the wave number varies with time following the law

$$k = k_0/\tau,$$

where k_0 is the initial wave number.

Substituting (6) into Eqs. (4) and (5), we obtain two ordinary differential equations for $h(\tau)$ and $s(\tau)$:

$$h_t = -\frac{iks}{2\tau}, \tag{7}$$

$$s_t + \frac{k^2}{8}\left(\frac{s_t}{\tau} - \frac{2s}{\tau^2}\right) + \frac{3ikh}{4\tau^2} = \frac{ik\tau^{3/2}h}{We}\left(1 - \frac{k^2}{\tau}\right) + \frac{3}{Re}\left(-k^2 s + 2ikh - \frac{ik^3 h}{4\tau}\right). \tag{8}$$

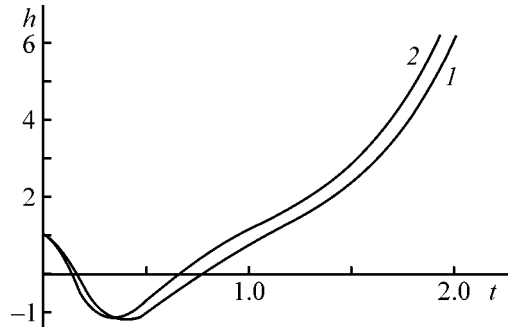

Fig. 1. Development of perturbations on the surface of ideal fluid jet, calculated using (*1*) exact and (*2*) approximate theories. Weber number 0.1, initial wave number 2.7. (*h*) Amplitude of jet radius perturbation and (*t*) time; the same for Fig. 2.

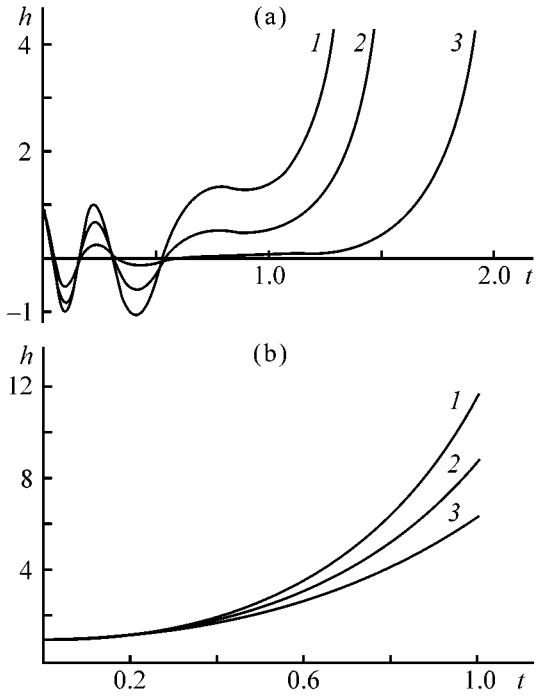

Fig. 2. Effect of Reynolds number on the rate of build-up of the amplitude of jet radius perturbation at small Weber number (We = 0.01) and comparatively (a) large and (b) small initial wave number k_0. Wave number k_0: (a) 2.5 and (b) 0.8. Reynolds number: (a): (*1*) 20, (*2*) 3, and (*3*) 1; (b): (*1*) 20, (*2*) 0.5, and (*3*) 0.2.

Eliminating the variable $s(\tau)$ from Eq. (8) with the use of Eq. (7), we obtain a second-order ordinary differential equation for $h(\tau)$

$$\left(1 + \frac{k^2}{8\tau}\right)h_{tt} + \left(\frac{2}{\tau} + \frac{3k^2}{\mathrm{Re}}\right)h_t + \left[\frac{3k^2}{8\tau^2} - \frac{3k^2}{\mathrm{Re}\,\tau}\left(1 - \frac{k^2}{8\tau}\right) - \frac{k^2\tau^{1/2}}{2\mathrm{We}}\left(1 - \frac{k^2}{\tau}\right)\right]h = 0. \quad (9)$$

Equation (9) is applicable to describing the evolution of jet radius perturbations for which the initial wave number is sufficiently small. For an ideal fluid, a comparison can be made with the exact solution obtained in [1]. As it can be seen from Fig. 1, the exact and approximate solutions are in good agreement even at comparatively large k_0. The solution was constructed using the following initial conditions:

$$h = 1,\ h_t = 0 \text{ at } t = 0.$$

In the case when the initial wave number is not small, the obtained equation for the amplitude of jet radius perturbation remains applicable, but only beginning with that instant of time when the current wavelength becomes larger than the current jet radius.

The type of solution is determined by values of the following three parameters: Weber and Reynolds numbers and initial wave number. The effect of viscosity forces on the development of perturbations is manifested in different ways, depending on the Weber number. If the Weber number is small, i.e., surface tension forces are important, the following pattern is observed. At relatively large initial wave numbers in the initial period of time, the solution has oscillatory nature (Fig. 2a). In the course of time, the current perturbation wavelength increases (in inverse proportion to τ). Simultaneously, the current jet radius decreases in proportion to $\tau^{-1/2}$. Therefore, after a certain time elapses, the fluid flow in the jet loses stability and the amplitude of the jet radius perturbation starts to grow fast. The effect of viscosity is manifested in that, in the initial period of time, the oscillation amplitude decreases in the course of time with decreasing Reynolds number. Simultaneously, with decreasing Reynolds number, the instant of time when the perturbation amplitude starts to grow steadily comes later. At small Weber numbers and relatively small wave numbers, the amplitude of jet radius perturbation starts to grow immediately (Fig. 2b). Here too, the effect of viscosity is manifested in that the development of perturbations is slower at smaller Reynolds numbers. However, the situation changes with increasing Weber number. Initially, the amplitude of jet radius perturbation is larger for those perturbations, which are characterized by smaller Reynolds numbers (Fig. 3a). In the course of time, the amplitude of those perturbations for which the Reynolds number is larger starts to grow faster and their amplitude becomes higher than that of perturbations characterized by smaller Reynolds numbers (Fig. 3b). Thus, at comparatively small Weber numbers, the viscosity exerts stabilizing influence on the development of perturba-

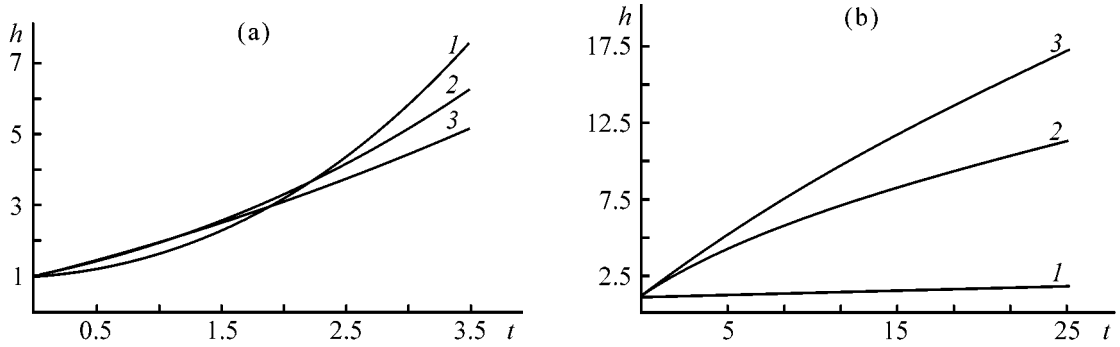

Fig. 3. Amplitude of jet radius perturbation, h, vs. time t at $k_0 = 0.8$. Weber number: (a) 0.08 and (b) 2.0. Reynolds number: (*1*) 50, (*2*) 0.1, and (*3*) 0.03.

tions. However, with increasing Weber number, the presence of viscous strain in a jet leads to its instability.

It should be noted that the derived equation describing the mechanism of fluid jet breakup in a spray apparatus can be used not only for describing the disintegration of this jet in the case of long-wavelength perturbations of the jet radius, but also for perturbations with arbitrary initial wave number.

CONCLUSIONS

(1) An equation is derived on the basis of a theoretical analysis of how a drop disintegrates as an element of a dispersed system in a spray apparatus. This equation relates the amplitude of the fluid jet radius perturbation, wave number, and Weber and Reynolds numbers.

(2) The equation obtained allows calculation of the time necessary for a fluid jet to breakup into drops in a spray apparatus.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

A Study of Convective Mass Exchange between Dispersed Flows in a Valve-Pulsatory Apparatus with Permeable Partition

Abstract—A mathematical model of convective mass exchange between dispersed flows in a valve-pulsatory apparatus with permeable partition for carrying out processes with finely dispersed solid phase is proposed. The mass exchange between flows of aqueous Na_2CO_3 solution and distilled water, or pearlite suspension in water and aqueous solution of NaCl was studied on a pilot apparatus.

Interaction of different phases in technological apparatus commonly yields hydro- or aerodispersed heterogeneous systems composed of a continuous and a dispersed phases. The output capacity of a unit volume of the reaction space depends on parameters of the intercomponent interaction, interfacial contact area per unit volume, and rates of transfer within phases and exchange between phases. The interfacial area per unit volume is determined by the concentration and dispersity of phases; and the rates of transfer within phases and between phases are governed by, among other things, the particle size in the dispersed phase and hydrodynamics of the flow of the continuous phase about the particles. All other conditions being the same, the smaller the particle size and the higher the velocity of the flow about them, the higher the intensity of a process. However, the known scheme of technological processes—counterflow of the dispersed and continuous phases—has limitations imposed by the laws of particle motion in a medium. The maximum achievable velocity of flow about particles in counterflow of phases depends on the particle size, difference in density between the particles and the medium, and viscosity of the medium, being small for fine particles of the dispersed phase. At high flow rate of the continuous phase the dispersed phase is carried away from the reaction space and the counterflow of phases is disrupted. This is the reason why, e.g., washing or extraction of a component from a finely dispersed solid phase is commonly carried out by mixing it with an extracting agent and subsequent multistage counterflow mixing–separation of solid and liquid phases in apparatus comprising several mixers, decanters, pumps, and transporters.

The essence of the previously proposed methods for carrying out extraction in the solid–liquid system [1], chemical reactions yielding a dispersed solid phase [2], sorption and ion exchange in the solid–liquid system [3], and heat exchange between media [4] consists in the use of convective mass and heat exchange between dispersed flows separated by a permeable partition (permeable to continuous, and impermeable to dispersed phases in the flows). In the course of extraction, convective mass exchange occurs between the flow of a suspended dispersed solid material and that of an extracting agent; in carrying out chemical reactions, between the flow of a sediment suspension, catalyst, or reagent and the flow of a medium to be treated; and in performing sorption or ion exchange, between the flow of suspended sorbent or ion exchanger and that of a medium to be treated. In the proposed technique, convective heat exchange is carried out between dispersed flows through a permeable partition without mixing of their dispersed phases. The above-mentioned convective mass exchange is also carried out with a combination of extraction and sorption, when suspended sorbent or ion exchanger is used as extracting agent, in performing chemical reactions, sorption, or ion exchange, with hydro- or aerodispersed media.

For example, it is proposed to carry out extraction as follows (Fig. 1). The solid phase containing a soluble component is mixed in reactor R with a part of

1070-4272/01/7412-2066 $25.00 © 2001 MAIK "Nauka/Interperiodica"

extracting agent to form a suspension. During the time of suspension residence in reactor R, the component is extracted from dispersed particles into the liquid phase. Further, continuous counterflow convective mass exchange between the flows of this suspension and the main part of the extracting agent is carried out through a permeable partition in a valve-pulsatory mass-exchange apparatus (VPMEA). By the convective mass exchange between flows through a permeable partition is meant, in the given case, exchange of components dissolved in liquid phases without mixing of the dispersed phases of the flows. This process replaces several stages of phase mixing–separation. Component-depleted washed suspension is obtained at the output of channel *2* of VPMEA, and component-enriched extract, at the output of channel *1*. Compared with multiple mixing–separation of phases, the proposed process has technological advantages: possibility of working with finely dispersed kinetically favorable phases at high counterflow velocities, smaller number of technological procedures and employed equipment units, compactness, and high specific volume output capacity [1–4].

The outcome of the process is defined by the achieved degree of component extraction from particles of the solid phase into the liquid continuous phase of suspension in reactor R and also by the degree of convective transfer of the component from the suspension flow in channel *2* into the flow of a liquid extracting agent in channel *1* of VPMEA. The processes of phase interaction in stirred displacement reactor have been studied in sufficient detail.

The task to be accomplished consists in establishing the fundamental aspects of convective mass exchange between dispersed flows, in developing calculation procedures, and in designing efficient VPMEAs. Previously, a procedure for calculating the mass-transfer coefficient and a mathematical model of mass-transfer in a shell-and-tube extractor of the "tube-in-tube" type with permeable inner tube and piston pulsator have been reported [5, 6]. The present communication is concerned with the case when the exchange between flows separated by a permeable partition in VPMEA is achieved by creating sign-alternating pressure differential between the flows with the use of more advanced, computer-controlled valve-pulsatory system.

The operation of VPMEA (Fig. 1) consists in alternating stages defined by positions of valves *4–7*. The duration of each stage is t_s. In the first stage, valves *4* and *7* are open, and valves *5* and *6*, closed. In this case, the first suspension (the general case of convective mass exchange between flows of two suspensions is considered) with initial concentration

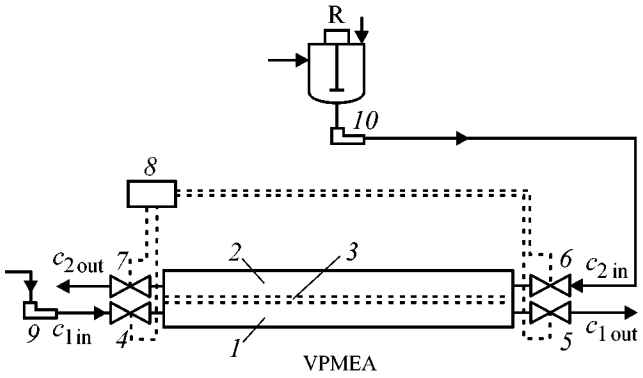

Fig. 1. Schematic of the unit. R is reactor; VPMEA, valvepulsatory mass-exchange apparatus; (*1*, *2*) VPMEA channels; (*3*) permeable partition; (*4–7*) valves; (*8*) valve control unit; and (*9*, *10*) pumps.

of the component $c_{1\,in} = c_1(0, t)$ is delivered by pump *9* through valve *4* into channel *1* and filtered through permeable partition *3*, creating a flow in channel *2*, discharged with concentration $c_{2\,out} = c_2(0, t)$ through valve *7*. In the second stage, valves *4* and *7* are closed, and valves *5* and *6*, opened. In this case, the second suspension with initial concentration $c_{2\,in} = c_2(l, t)$ is delivered from the reactor through valve *6* into channel *2* and filtered through partition *3*, creating a flow in channel *1*, discharged with outlet concentration $c_{1\,out} = c_1(l, t)$ through valve *5*. Here, c is the mass of the component in unit volume of the liquid phase, l is the channel length, and t is time. Thus, sign-alternating pressure differentials between the channels are created. In the course of such a pulsatory motion, the first and second suspensions repeatedly exchange portions of liquid phases, without mixing of their dispersed phases. As a result of this counterflow (Π scheme of flow) convective mass exchange, the concentration $c_{2\,out}$ is close to $c_{1\,in}$, and $c_{1\,out}$, to $c_{2\,in}$.

The aim of the present study was to study convective mass exchange between flows of suspension and liquid (both Newtonian) in the VPMEA. In doing so, mass-transfer or any other interaction between the solid and liquid phases within VPMEA was disregarded. Let us write a system of equations of convective mass exchange in the form

$$\oiint_s w\,ds = 0, \quad \oiint_s \rho w(w\,ds) + \oiint_s p\,ds - \oiint_s \sigma\,ds = 0,$$
$$\iiint_\omega \frac{\partial \varepsilon}{\partial t}\,d\omega + \oiint_s \varepsilon w\,ds = 0, \qquad (1)$$
$$\iiint_\omega \frac{\partial (\varepsilon c)}{\partial t}\,d\omega + \oiint_s \varepsilon c w\,ds = 0,$$

where w, ρ, and ε are the velocity, density, and porosity of the suspension; ω and s are an arbitrary vol-

ume and closed surface delimiting it; σ is the friction stress tensor, and p is pressure.

It is assumed that the density ρ_l and viscosity μ_l of the liquid phase are independent of concentration c, and the volume of the dissolved component can be neglected, compared with the volume of the liquid phase. We also neglect the time of hydrodynamic relaxation in passing from one stage to another, compared with the stage duration t_s.

Let us apply system (1) to a suspension flow along a permeable channel [7]. We direct the x axis along the channel and choose a closed surface s formed by two sections f of the channel and part of lateral surface between the sections. We then perform integration in system (1) and find projections onto the x axis, divide the equations by the distance dx between the section, and make dx approach zero. The layer of deposit formed on the partition will be considered thin as compared with the equivalent channel diameter d_{equiv}. Therefore, the section f is considered constant along the entire channel. Let us assume that the longitudinal velocity w_x is zero at channel walls [8, 9]. Let, also, the pressure p be constant over the section f [10]. We assume that the concentration c and porosity ε are also constant over the section f. This assumption is, in part, justified by the fact that transverse sign-alternating flows are created in VPMEA. Using the coefficients of friction, ξ, and momentum flux, β [11–13], we write

$$\begin{gathered}\frac{du}{dx} + \frac{\pi_v}{f}v = 0,\\ \frac{dp}{dx} + \rho\frac{d}{dx}(\beta u^2) + e_u\frac{\pi_f}{f}\frac{\xi}{8}\rho u^2 = 0,\\ \frac{\partial\varepsilon}{\partial t} + \frac{\partial}{\partial x}(\varepsilon u) + \frac{\pi_v}{f}v = 0,\\ \frac{\partial}{\partial t}(\varepsilon c) + \frac{\partial}{\partial x}(\varepsilon c u) + \frac{\pi_v}{f}c_\delta v = 0,\end{gathered} \tag{2}$$

where π_f and π_v are the perimeter of the channel cross-section and its permeable part, u is the cross-section-average longitudinal velocity, and v is the filtration rate averaged over the permeable part of the perimeter, $e_u = u/|u|$.

The c_δ value depends on the sign of the filtration rate v. At $v > 0$ (filtration from the channel) $c_\delta = c$, at $v < 0$ (filtration into the channel) c_δ is equal to the component concentration in the liquid phase in the partition pores at the boundary of the channel under consideration. If the partition thickness can be neglected, then, at $v < 0$, c_δ is equal to the component concentration in the liquid phase outside the channel and, in particular, in an adjacent channel.

The pressure in the channel can be related to the filtration rate by the Darcy law:

$$v(x) = \frac{p(x) - p_0}{\mu_l r_{ef}}, \quad r_{ef} = r_p\delta_p + r_d\delta_d, \tag{3}$$

where p_0 is the pressure outside the channel, e.g., in an adjacent channel; r_{ef} is the filtration resistance (m^{-1}); r_p, r_d, δ_p, and δ_d are the resistances (m^{-2}) and thicknesses (m) of the partition and deposit. The expression for r_{ef} in (3) is valid for the case of a planar wall. Passing to dimensionless variables in Eqs. (2), we obtain

$$\begin{gathered}\frac{dU}{dX} + \frac{l}{d_{equiv}}\frac{Re_0}{R_{ef}}Eu = 0,\\ \frac{dEu}{dX} + \rho_{rel}\frac{d}{dX}(\beta U^2) + e_u\frac{l}{d_{equiv}}\frac{\xi}{2}\rho_{rel}U^2 = 0,\\ \frac{\partial\varepsilon}{\partial Ho} + U\frac{\partial\varepsilon}{\partial X} - \frac{dU}{dX}(1-\varepsilon) = 0,\\ \frac{\partial C}{\partial Ho} + U\frac{\partial C}{\partial X} - \frac{1}{\varepsilon}\frac{dU}{dX}(C_\delta - C) = 0,\end{gathered} \tag{4}$$

where $X = x/l$, $U = u/u_0$, $V = v/u_0$, $C(X, Ho) = [c(x, t) - c']/(c'' - c')$, c' and c'' are arbitrary constants, $Ho = tu_0/l$ is the homochronicity number, $Eu(X) = [p(x) - p_0]/(\rho_l u_0^2)$ is the Euler number, $\rho_{rel} = \rho/\rho_l$, $u_0 = u(0)$, $R_{ef} = fr_{ef}/\pi_v$, and $C_\delta = (c - c')/(c'' - c')$.

Let us consider two adjacent channels separated by a permeable wall. For each channel we write Eqs. (4) and take into account that the liquid cross-flow occurs because of the pressure difference between the channels. Then we have

$$\begin{gathered}\frac{dU_1}{dX} + \frac{f_2}{f_1}\frac{dU_2}{dX} = 0, \quad \frac{dU_1}{dX} + \frac{l}{d_{equiv\,1}}\frac{Re_{01}}{R_{ef\,1}}Eu_v = 0,\\ \frac{dEu_v}{dX} + \frac{d}{dX}(\rho_{rel\,1}\beta_1 U_1^2 - \rho_{rel\,2}\beta_2 U_2^2)\\ + \frac{e_{u1}l}{2d_{equiv1}}\rho_{rel\,1}\xi_1 U_1^2 - \frac{e_{u2}l}{2d_{equiv2}}\rho_{rel\,2}\xi_2 U_2^2 = 0,\\ \frac{\partial\varepsilon_1}{\partial Ho} + U_1\frac{\partial\varepsilon_1}{\partial X} - \frac{dU_1}{dX}(1-\varepsilon_1) = 0,\\ \frac{\partial C_1}{\partial Ho} + U_1\frac{\partial C_1}{\partial X} - \frac{1}{\varepsilon_1}\frac{dU_1}{dX}(C_{\delta1} - C_1) = 0,\\ \frac{\partial\varepsilon_2}{\partial Ho} + U_2\frac{\partial\varepsilon_2}{\partial X} - \frac{dU_2}{dX}(1-\varepsilon_2) = 0,\\ \frac{\partial C_2}{\partial Ho} + U_2\frac{\partial C_1}{\partial X} - \frac{1}{\varepsilon_2}\frac{dU_2}{dX}(C_{\delta2} - C_2) = 0,\end{gathered} \tag{5}$$

where index denotes the channel number, and $Eu_v(X) = [p_1(x) - p_2(x)]/(\rho_l u_0^2)$.

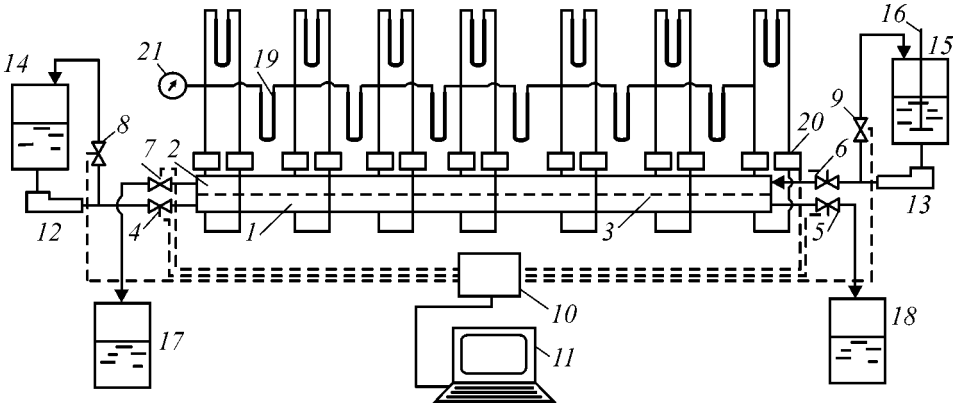

Fig. 2. Schematic of experimental setup for studying convective mass exchange in VPMEA: (*1, 2*) first and second channels of VPMEA, (*3*) permeable partition, (*4–9*) controlled valves, (*10*) computer interface, (*11*) microcomputer, (*12, 13*) pumps, (*14, 15, 17, 18*) vessels, (*16*) stirrer, (*19*) differential pressure gages, (*20*) expansion vessels, and (*21*) standard pressure gage.

So, we obtained the system of equations (5) for $U_1(X)$, $U_2(X)$, $\mathrm{Eu}_v(X)$, $C_1(X, \mathrm{Ho})$, $C_2(X, \mathrm{Ho})$, $\varepsilon_1(X, \mathrm{Ho})$, $\varepsilon_2(X, \mathrm{Ho})$. Setting the boundary $[U_1(0), U_2(0), U_1(1), \mathrm{U}_2(1), C_1(0, \mathrm{Ho}), C_2(1, \mathrm{Ho}), \varepsilon_1(0, \mathrm{Ho}), \varepsilon_2(1, \mathrm{Ho})]$ and initial $[C_1(X, 0), C_2(X, 0), \varepsilon_1(X, 0), \varepsilon_2(X, 0)]$ conditions defines the boundary-value problem for mass exchange between the flows.

The given model can be used, with the assumptions made, also for describing heat exchange between flows with temperature-inactive particles.

In practice, $c_1(0, t) = c_{1\,\mathrm{in}} = \mathrm{const}$ during the first stage and $c_2(l, t) = c_{2\,\mathrm{in}} = \mathrm{const}$ during the second stage. In this case, the maximum concentration in the VPMEA will be, e.g., $c_{1\,\mathrm{in}}$, and the minimum concentration $c_{2\,\mathrm{in}}$. Let us choose $c' = c_{2\,\mathrm{in}}$, $c'' = c_{1\,\mathrm{in}}$. Then the dimensionless concentration $C(X, \mathrm{Ho}) = [c(x, t) - c_{2\,\mathrm{in}}]/(c_{1\,\mathrm{in}} - c_{2\,\mathrm{in}})$, and the boundary conditions become universal: in the first stage $C_1(0, \mathrm{Ho}) = C_{1\,\mathrm{in}} = 1$, and in the second, $C_2(1, \mathrm{Ho}) = C_{2\,\mathrm{in}} = 0$. This means that the dimensionless output concentrations $C_1(1, \mathrm{Ho}) = C_{1\,\mathrm{out}}(\mathrm{Ho})$ and $C_2(1, \mathrm{Ho}) = C_{2\,\mathrm{out}}(\mathrm{Ho})$ are independent of the input concentrations $c_{1\,\mathrm{in}}$ and $c_{2\,\mathrm{in}}$, being universal in this sense. Therefore, the degree of mass exchange [14]

$$E = \lim_{\mathrm{Ho}\to\infty} C_{2\,\mathrm{out}}(\mathrm{Ho}) = \lim_{t\to\infty} \frac{c_{2\,\mathrm{out}}(t) - c_{2\,\mathrm{in}}}{c_{1\,\mathrm{in}} - c_{2\,\mathrm{out}}} \qquad (6)$$

is a characteristic of VPMEA. It is independent of input concentrations and characterizes component transfer between the flows.

For experimental studies, we fabricated a planar model of VPMEA (Fig. 2). The model is made of two organic glass plates with 7.5-m-long grooves with 6×6 mm square cross-section. The permeable partition—capron filter fabric is placed in stretched state between the plates, after which the latter are firmly pressed to one another by means of bolted clamps. In doing so, the plates are in such a position that their grooves are opposite one another. This gives adjacent channels *1* and *2* separated by permeable partition *3*. The flows are fed-in and discharged by means of pipes. The programmed control of electromagnetic sphincter valves *4–9* is done by a microcomputer *11* with interface *10*. Hose-type pumps *12* and *13* are operated by the same drive, HShR-15M, to make equal their volumetric flow rates.

Liquid is fed from vessel *14* into channel *1* by pump *12* through valve *4* and discharged through valve *5* into vessel *18*. The suspension is fed by pump *13* in the counterflow mode from vessel *15* with stirrer *16* into channel *2* through valve 6 and discharged from the channel through valve *7* into vessel *17*. Valves *4–7* are program-controlled by a microcomputer *11*. To prevent blocking by valves *4* and *6* of flows delivered by pumps *12* and *13*, the pumps are equipped with bypass lines with valves *8* and *9*. Valve *8* is opened when valve *4* is closed, and valve *9* is opened when valve *6* is closed. The pressure distributions in the channels are measured with differential pressure gages *19* with expansion vessels *20*. Prior to experiments, air bubbles were removed from the VPMEA by switching-on pumps *12* and *13* with open valves *4–7* and closed valves *8* and *9*.

An experimental study of the convective mass exchange between flows of two liquids—distilled water and Na_2CO_3 solution was performed as follows. A solution was prepared in vessel *15*, and vessel *14* was filled with water. To remove air and ensure specified initial conditions, the solution from vessel *15* was fed into both channels at open valves *4–7*, with the solution from the channel outlets directed into the

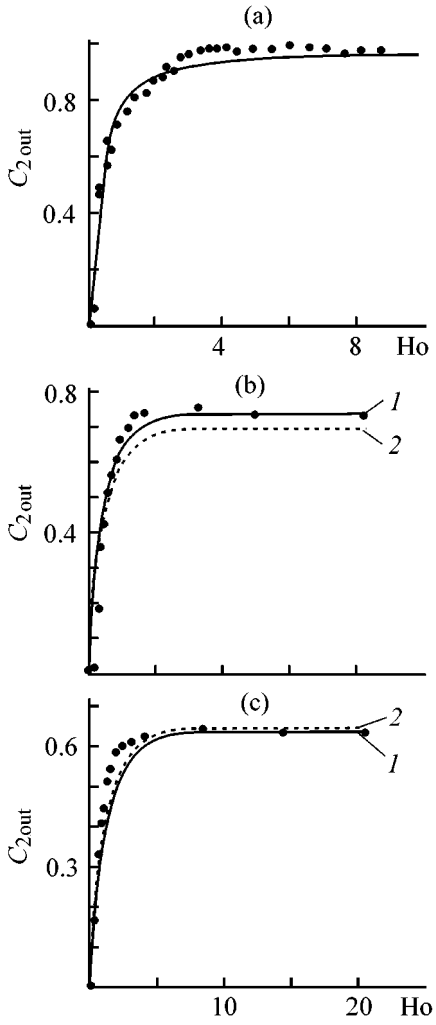

Fig. 3. Time dependence of $C_{2\,out}$(Ho). (a) Re_0 = 1892, l/d_{equiv} = 1250, ε_{in} = 1.0, Sr = 0.137, $R_{ef} = 1.4 \times 10^6$, Δ_p = 0.03; (b) Re_0 = 2754, l/d_{equiv} = 1250, ε_{in} = 0.99, Sr = 0.11; Δ_p = 0.025; R_{ef} = (*1*) 8.8×10^6, (*2*) 11.4×10^6; (c) Re_0 = 2754, l/d_{equiv} = 1250, ε_{in} = 0.97, Sr = 0.11, Δ_p = 0.025; R_{ef} = (*1*) 18.8×10^6, (*2*) 17.6×10^6. *Curves*, calculation; *points*, experiment; the same for Fig. 4.

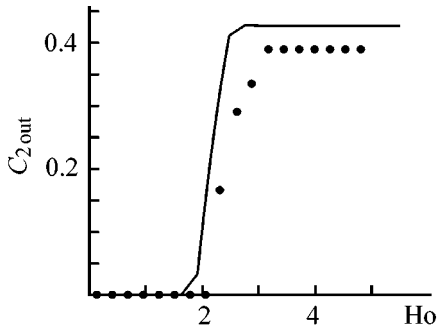

Fig. 4. Time dependence of $C_{2\,out}$(Ho) = C_2(1, Ho) at direct-flow delivery of flows. Re_0 = 1892, l/d_{equiv} = 1250, ε_{in} = 1.0, Sr = 0.137, $R_{ef} = 1.4 \times 10^6$, Δ_p = 0.03.

same vessel *15*. After that the lines of solution feed and discharge were put in the state corresponding to Fig. 2, the program controlling the valves was initiated, and pumps *12*, *13* switched on. Simultaneously, sampling was commenced at the outlet of channel *2*. In the steady state, samples were taken at the outlets of both channels. The Na_2CO_3 concentration in the samples was determined by means of refractometry. The experiments were carried out repeatedly. The results obtained are presented in Fig. 3a.

A set of experiments was carried out on studying the convective mass exchange between liquid and suspension flows. An aqueous solution of NaCl was taken as liquid, and suspension of ground pearlite in distilled water, as model suspension. The choice of pearlite as model dispersed material was governed by its inertness toward the transported component—NaCl. The inertness of pearlite was judged from the results of refractometric measurements of the NaCl solution concentration before and after introducing a weighed portion of pearlite into the solution. The pearlite fraction with particle size in the range 10–100 μm was selected by sieving. The apparent density of pearlite was 300 kg m^{-3} [15]. The porosity of pearlite was determined pycnometrically to be 0.75.

The experimental study was carried out as follows. First, suspension was fed into channel *1* of the VPMEA, and distilled water, into channel *2*, at open valves *4–7*. After the channels were filled and air removed from them, the program of valve control was started and the input line of the liquid delivery pump *12* was connected to the vessel with solution. Simultaneously, sampling was commenced at the outlet of channel *1*. The experiments were conducted at ε = 0.97 and ε = 0.99 for two partitions with different R_{ef} values an suspension–liquid counterflow velocity of 0.5 m s^{-1} (Figs. 3b and 3c).

Also, the convective mass exchange between flows of distilled water and Na_2CO_3 solution was studied with a *Z*-scheme of flow delivery. In this case, flows are delivered in the direct-flow mode into channel *1* through valve *4* and into channel *2* through valve *7* (Fig. 2). In the first stage, valves *4* and *6* are open, and valves *5* and *7*, closed. In the second stage, the situation is the opposite. The experiments were carried out in the following sequence. First, the channels were filled with the solution through open valves *4–7*. Then water was delivered to channel *2* and samples were taken at the outlet of channel *1*. The results obtained are shown in Fig. 4.

As seen from Fig. 4, the residence time of the liquid in the VPMEA is $2l/u_0$ (Ho = 2). Virtually sta-

tionary concentrations are attained at the apparatus outlets at homochronicity number Ho ≈ 3. For the counterflow Π scheme, the degree of mass exchange between the flows reaches values of 0.64–0.99 at Ho = 3 (Figs. 3a–3c). This indicates the possibility of creating a high-efficiency VPMEA for dispersed flows on the basis of the proposed principle.

Figures 3 and 4 show, in addition to experimental points, curves calculated for the experimental conditions with $l/d_{\text{equiv}1} = l/d_{\text{equiv}2} = l/d_{\text{equiv}}$, $f_1 = f_2$. The rates of flow delivery into the first and second channels are the same. The flow characteristics are as follows: $\varepsilon_1 = 1$, $\rho_1 = \rho_l$, $\mu_{\text{rel}1} = 1$, $\mu_1 = \mu_l$, $\varepsilon_2 = \varepsilon$, $\rho_2 = \varepsilon\rho_l + (1 - \varepsilon)\rho_s$, $\rho_{\text{rel}2} = \rho_{\text{rel}}$, $\mu_2 = 0.59\ \mu_l(\varepsilon - 0.23)^{-2}$ [16], where ρ_s is the density of the solid phase, μ_1 and μ_2 are the viscosities of the first and second suspensions, and $\text{Sr} = t_s u_0/l$ is the Struchal number. It was assumed in the calculations that R_{ef} is constant along the longitudinal coordinate X.

The coefficients ξ and β were determined for the given channel in relation to the Reynolds number in this channel [14, 17].

For the Π scheme, we have the following boundary and initial conditions:

$$U_1(0) = 1,\ U_2(0) = -1,\ U_1(1) = 0,\ U_2(1) = 0,$$
$$C_1(0,\ \text{Ho}) = 1, \qquad (7)$$

$$U_1(0) = 0,\ U_2(0) = 0,\ U_1(1) = 1,\ U_2(1) = -1,$$
$$C_2(1,\ \text{Ho}) = 0,\ \varepsilon(1,\ \text{Ho}) = \varepsilon_{\text{in}}, \qquad (8)$$

$$C_1(X,\ 0) = 1,\ C_2(X,\ 0) = 0,\ \varepsilon(X,\ 0) = \varepsilon_{\text{in}}. \qquad (9)$$

For the Z scheme, the boundary and initial conditions have the form

$$U_1(0) = 1,\ U_2(0) = 0,\ U_1(1) = 0,\ U_2(1) = 1,$$
$$C_1(0,\ \text{Ho}) = 1, \qquad (10)$$

$$U_1(0) = 0,\ U_2(0) = 1,\ U_1(1) = 1,\ U_2(1) = 0,$$
$$C_2(0,\ \text{Ho}) = 0,\ \varepsilon(1,\ \text{Ho}) = 1, \qquad (11)$$

$$C_1(X,\ 0) = 1,\ C_2(X,\ 0) = 1,\ \varepsilon(X,\ 0) = 1, \qquad (12)$$

where (7), (10) and (8), (11) are the boundary conditions for the first and second stages, respectively; (9) and (12) are the initial conditions.

With account of the boundary conditions (7), (8) for the Π scheme or (10), (11) for the Z scheme, the hydrodynamic part of system (5) was solved by the method of iterations with respect to U_1, U_2, and Eu_v. Each iteration was calculated by the method of orthogonal matrix run [18]. The obtained functions $U_1(X)$, $U_2(X)$, and $\text{Eu}_v(X)$ were used to calculate concentrations and porosities by means of equations of system (5).

In the course of calculations, account was taken of the change in the position of the interface between liquids with concentrations $C_1(X, \text{Ho})$ and $C_2(X, \text{Ho})$ inside the permeable partition for any point of the apparatus. The displacement of the interface in a time ΔHo related to the partition thickness δ_p is equal to $V\Delta\text{Ho}/(\Delta_p D_{\text{equiv}})$, where $\Delta_p = \delta_p/d_{\text{equiv}}$.

The calculation was started using the equations for the first stage with initial conditions (9) and (12). Then the calculation was continued using the equations of the second stage. For the initial distribution of concentrations and porosities for each subsequent stage was taken the final distribution for the preceding stage.

All parameters of the model, except for the dimensionless resistance R_{ef}, can be determined exactly. To find the real R_{ef} values of permeable partitions, we performed an experiment on measuring the pressure difference $\text{Eu}_v(X)$ between the channel with distilled water flowing in accordance with the Π scheme [17]. The experimental data were processed using the second equation of system (5). Let us integrate this equation over X from 0 to 1 with account of condition (7):

$$R_{\text{ef}} = \frac{l}{d_{\text{equiv}}}\,\text{Re}_0 \int_0^1 \text{Eu}_v(X)\,dX. \qquad (13)$$

The experimentally found $\text{Eu}_v(X)$ were integrated using the method of trapezoids. In processing the results of hydraulic experiments [17], the filtration resistance of the partition was found to be $r_{\text{ef}} = (9.3 \pm 2.1) \times 10^6$. The r_{ef} measurement error was 22%. Therefore, the dimensionless resistance R_{ef} was chosen as the model identification parameter.

The values of this parameter were selected so as to achieve the best fit of calculation to the experiment. In the experiment on mass exchange between flows of two liquids (Fig. 3a), the selected R_{ef} value and that measured by the technique described above coincided (1.4×10^6). In experiments on mass exchange between liquid and suspension flows at $\varepsilon_{\text{in}} = 0.99$ (Fig. 3b) the selected (solid line) and measured (dashed line) R_{ef} values are 8.8×10^6 and 11.4×10^6, respectively; for $\varepsilon_{\text{in}} = 0.97$ (Fig. 3c), the respective values are 18.8×10^6 and 17.6×10^6.

In the modes studied, the average resistance of deposit accumulated during a stage is small, compared with the partition resistance. Estimation of the average dimensionless resistance of the deposit at specific resistance of pearlite $r_d = 10^{12}$ m^{-2} [19] and suspension porosity of 0.97 gives a value of 5.4×10^4, which is two orders of magnitude less than the R_{ef} of the partition. Therefore, we used in calculations for the first and second stages the R_{ef} value for the partition. This circumstance also justifies the assumption that R_{ef} is independent of X, made in calculations.

The maximum deviation of the degrees of mass exchange, calculated for the selected values of the parameter R_{ef}, from those calculated for the measured R_{ef} is 6.2%. Therefore, R_{ef} can be regarded with satisfactory accuracy in calculating VPMEA as a real dimensionless resistance, rather than the identification parameter of the mathematical model. In filtration from the liquid channel, the parameter R_{ef} can be considered equal to the dimensionless resistance of the partition, found from experiment or from the literature. In filtration from the suspension channel, the parameter R_{ef} is defined as a sum of dimensionless resistances of the partition and the deposit layer.

The operation principle of the mass-exchange apparatus VPMEA, the mathematical model, the developed software for design calculations, and the obtained experimental results may serve as a basis of effective apparatus and technological schemes for carrying out combined and involving a small number of operations processes with finely dispersed solid phase: extraction, sorption, ion exchange, chemical reactions, and heat exchange.

CONCLUSIONS

(1) A mathematical model of convective mass exchange between dispersed flows in a two-channel apparatus with permeable partition and controlled valve-pulsatory system is proposed.

(2) The results of an experimental study demonstrate that numerical solutions obtained using the model are in satisfactory agreement with the measured dependences of concentration variation at the flow outlets on the homochronicity number and that the model is adequate to the experiment at the following parameters: Re_0 = 1892–2754, l/d_{equiv} = 1250, Sr = 0.11–0.137, ε_{in} = 0.97–1.0, $R_{ef} = (1.4–18.8) \times 10^6$, Δ_p = 0.025–0.03.

(3) The stationary concentrations at the apparatus outlet are attained at homochronicity number Ho $\approx$ 3.

(4) The possibility is established of creating apparatus with degree of mass exchange between flows of up to 0.9, and software is developed for their design calculations to achieve a prescribed degree of mass exchange.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Combined Processes of Polymerization and Drying of Prepolymer Grains in Double-Section Apparatus with Fluidized Bed

Abstract—The possibility of combining polymerization and drying in obtaining polymers from derivatives of methacrylic acid was revealed experimentally. A mathematical model of combined polymerization and solvent removal under conditions of a fluidized bed of the material was developed.

Water-soluble polymers based on derivatives of acrylic and methacrylic acids are used in various fields of technology as flocculants, thickeners, water-retaining agents, and substances reducing the hydraulic resistance [1].

Highly promising for manufacture of water-soluble acrylic polymers are continuous methods in which the process is carried out in a set of apparatus, e.g., reactor–extruder–granulator–drying chamber, combined in a single installation.

One of the possible ways to make the technological cycle shorter consists in combining the process of polymerization with high conversion and solvent removal from the reaction mass [2]. In addition, this reduces the power consumption, since moisture is partly evaporated by the heat of the chemical reaction. In synthesizing water-soluble polymers, water is the reaction medium. Therefore, the process of drying must not occur in advance of the polymerization. Otherwise, the reaction terminates at low conversions [3].

To reveal the possibility of combining the processes of polymerization and drying, special-purpose experiments were carried out. The initial stage of synthesis was performed in concentrated aqueous solutions. For example, in copolymerization of sodium methacrylate (SMA) with methacrylamide (MAA), the concentration of the solution of the starting monomers was 66 wt %. The copolymerization was done in the course of 1200 s at 65°C. During this time, the conversion was as high as 67%. Further, the prepolymer was ground and dried.

Selected results of the experiments are presented in Fig. 1 as dependences of the conversion and the humidity of the product on the process time. During the first 1800 s of drying, the conversion became as high as 93, 96, and 98%, and the humidity as low as 25, 23, and 20%, at temperatures of, respectively, 70, 90, and 105°C. Further drying during 13 500 s raises the conversion only slightly. In all experiments, the conversion was 99.5%. The product humidity decreased to 10, 4, and 1%.

The results of the experiments demonstrated that, in the course of prepolymer drying, the rate of the chemical process much exceeds that of solvent (water) removal. Under these conditions, the polymerization

process goes till virtually complete exhaustion of the starting monomers. Rather effective is performing combined processes in apparatus with fluidized bed.

The performed investigations of the process of copolymerization of SMA with MAA in its final stage allowed development of a mathematical description of drying and additional polymerization of the granulated prepolymer. The description includes units related to chemical kinetics, kinetics of heat-and-mass exchange for isolated particle, and material and heat balances for the apparatus as a whole.

In developing a mathematical model of processes occurring in an isolated inclusion of the dispersed phase, the following assumptions were made: stirring of the material in the fluidized bed is intensive, heat-transfer coefficients are high, small particle size leads to absence of temperature fields, each grain is a microreactor operating in the quasistationary mode. The particles are spherical.

In describing the kinetics of SMA copolymerization with MAA, account is taken of the reactions of chain initiation, growth, and termination. The system of kinetic equations for the concentrations of the initiator and monomers and initial moments of the molecular weight distribution has the form [4]

$$dI/d\tau = -k_d I, \quad (1)$$

$$dC_A/d\tau = -k_{pAA}R_A C_A - k_{pBA}R_B C_A, \quad (2)$$

$$dC_B/d\tau = -k_{pAB}R_A C_B - k_{pBB}R_B C_B, \quad (3)$$

$$dR_A/d\tau = fk_d I + k_{pBA}R_B C_A - k_{pAB}R_A C_B - k_{tAA}R_A^2 - k_{tAB}R_A R_B, \quad (4)$$

$$dR_B/d\tau = fk_d I + k_{pAB}R_A C_B - k_{pBA}R_B C_A - k_{tBB}R_B^2 - k_{tBA}R_B R_A, \quad (5)$$

$$dP/d\tau = k_{tAA}R_A^2 + k_{tAB}R_A R_B + k_{tBA}R_B R_A + k_{tBB}R_B^2, \quad (6)$$

where I, C_A, C_B, R_A, R_B, and P are the concentrations of initiator, SMA, MAA, growing radicals with SMA and MAA end units, and inactive chains (M); τ time (s); f the efficiency of initiation; k_d the rate constant of initiator decomposition (s^{-1}); k_p, k_t the rate constants of chain growth and termination ($M^{-1}\ s^{-1}$).

The efficiency of initiation and the rate constants of elementary reactions, which vary in the course of the process, are calculated using the formulas reported in [4]. The grain temperature is found from the heat balance equation

$$\rho_m(c_m + \bar{U}c_w)\frac{dT}{d\tau} = 6\frac{\alpha}{d_{equiv}}(T_g - T) - \left(\frac{dC_A}{d\tau} + \frac{dC_B}{d\tau}\right)\Delta H + \frac{d\bar{U}}{d\tau}r^*\rho_m, \quad (7)$$

where d_{equiv} is the equivalent particle diameter (m); ρ_m the material density ($kg\ m^{-3}$); α the heat-transfer coefficient ($W\ m^{-2}\ K^{-1}$); ΔH the heat effect of polymerization ($J\ mol^{-1}$); T the particle temperature (°C); T_g the temperature of the drying agent (°C); r^* the latent heat of vaporization ($J\ kg^{-1}$); $\bar{U}$ the absolute humidity of the material ($kg\ kg^{-1}$); c_m, c_w the specific heats of dry material and water, respectively ($J\ kg^{-1}\ K^{-1}$).

The last term in the right-hand side of Eq. (7) accounts for the relationship between heat and moisture transfer processes. The mathematical description is supplemented with an equation characterizing the kinetics of variation of the moisture content of a prepolymer grain. As is known, in drying of materials with high diffusion resistance to moisture transfer, to which also belongs the copolymer of SMA with MAA, the equilibrium humidity is virtually instantaneously attained on the body surface [5]. In this case, the variation of the moisture-content field in a material being dried is described by a differential mass-transfer equation with a boundary condition of the first kind with variable coefficient of moisture transfer. For a spherical particle we have

$$\frac{\partial U(r,\tau)}{\partial \tau} = k_m(\bar{U}, T)\left[\frac{1}{r}\frac{\partial^2 (rU)}{\partial r^2}\right], \quad 0 \le r \le R,\ \tau > 0, \quad (8)$$

$$\frac{\partial U(0,\tau)}{\partial r} = 0, \quad U(0,\tau) \ne \infty, \quad (9)$$

$$U(R,\tau) = U_p, \quad (10)$$

$$U(r,0) = U_{in}. \quad (11)$$

The moisture-transfer coefficient $k_m(\bar{U}, T)$ is a complex function of the moisture content and temperature of a particle. Exact analytical solution of the problem (8)–(11) is impossible. An approximate solution to this problem will be sought for in the classical form [5] at finite number of expansion elements:

$$U(x,\tau) = U_p + (U_0 - U_p)\frac{R}{r}\sum_{j=1}^{n} A_j(\tau)\sin\left(j\pi\frac{r}{R}\right). \quad (12)$$

Let us use the Petrov–Galerkin method [6]. We substitute a trial solution (12) into Eq. (8) and require

that the residual should be orthogonal to the calibration functions of the type

$$\Psi_k(r) = \frac{r}{R}\sin\left(k\pi\frac{r}{R}\right), \quad (13)$$

$$\sum_{j=1}^{n}\frac{\partial A_j(\tau)}{\partial\tau}\int_0^R (U_0 - U_\mathrm{p})\frac{R}{r}\sin\left(j\pi\frac{r}{R}\right)\frac{r}{R}\sin\left(k\pi\frac{r}{R}\right)$$

$$= k_\mathrm{m}(\bar{U}, \tau)\sum_{j=1}^{n}A_j(\tau)\int_0^R \frac{1}{r}\frac{\partial^2}{\partial r^2}\left\{r\left[U_\mathrm{p} + \left(U_0 - U_\mathrm{p}\right)\frac{R}{r}\sin\left(j\pi\frac{r}{R}\right)\right]\right\}$$

$$\times \frac{r}{R}\sin\left(k\pi\frac{r}{R}\right), \quad k = 1, ..., n. \quad (14)$$

We come to a system of explicit ordinary differential equations in unknown coefficients $A_j(\tau)$:

$$\frac{\mathrm{d}A_j(\tau)}{\mathrm{d}\tau} = -\frac{k_\mathrm{m}(\bar{U}, \tau)}{R^2}(j\pi)^2 A_j(\tau), \quad j = 1, ..., n. \quad (15)$$

We find the coefficients A_j at $\tau = 0$, applying the Petrov–Galerkin method to the initial condition (11):

$$\int_0^R [U_\mathrm{p} + (U_0 - U_\mathrm{p})\frac{R}{r}\sum_{j=1}^{n}A_j^0\sin\left(j\pi\frac{r}{R}\right) - U_0]\frac{r}{R}\sin\left(k\pi\frac{r}{R}\right)\mathrm{d}r = 0,$$
$$k = 1, ..., n, \quad (16)$$

$$A_j^0 = 2(-1)^{j+1}/(j\pi), \quad j = 1, ..., n. \quad (17)$$

Now, we determine the average moisture content of a particle:

$$\bar{U} = \frac{3}{R^3}\int_0^R r^2 U(r, \tau)\,\mathrm{d}r$$

$$= U_\mathrm{p} + (U_0 - U_\mathrm{p})\frac{3}{\pi}\sum_{j=1}^{n}A_j(\tau)(-1)^{j-1}/j. \quad (18)$$

Differentiating expression (18), we obtain a relation for the rate of drying $\mathrm{d}\bar{U}/\mathrm{d}\tau$, appearing in formula (7):

$$\frac{\mathrm{d}\bar{U}}{\mathrm{d}\tau} = (U_0 - U_\mathrm{p})\frac{3}{\pi}\sum_{j=1}^{n}\frac{(-1)^{j-1}}{j}\frac{\mathrm{d}A_j(\tau)}{\mathrm{d}\tau}. \quad (19)$$

The system of equations (1)–(7), (15), (18), and (19) gives a mathematical description of combined polymerization and drying for an isolated particle. The coefficient k_m, appearing in Eq. (8), was found using the Rudobashta method [7]. For this purpose, special experiments were carried out on drying and additional polymerization of granulated prepolymer with initial humidity of 0.42 kg moisture/kg absolutely dry material and monomer conversion of 75–80%. The prepolymer was obtained by copolymerization of SMA with MAA in aqueous medium

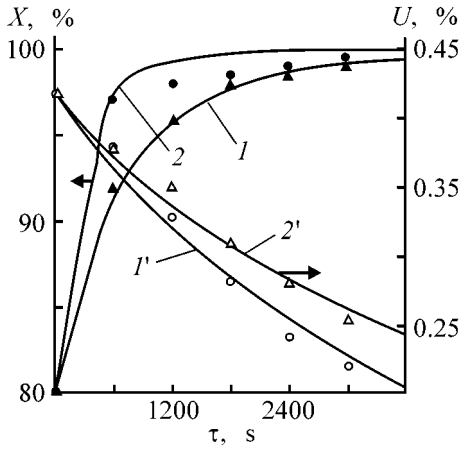

Fig. 2. Variation of the conversion X and humidity U in the course of additional polymerization and drying in an apparatus with fluidized bed. Equivalent particle diameter d_equiv = 0.004 m, air flow velocity 2.5 m s^{-1}. Bed temperature (°C): (*1*, *1*') 70 and (*2*, *2*') 90.

at total concentration of monomers of 6.75 M and monomer ratio of 1 : 1 (mol : mol). The kinetics of drying was studied in the temperature range 60–105°C under conditions ruling out any outer-diffusion resistance. Experimental data processing yielded the following relation for calculating the mass-conductivity coefficient for humidities in the range $0.03 < U < 0.42$:

$$k_\mathrm{m} = 10^{-10}[1.854 + 7.35\times10^{-5}\exp(0.086T)]/(1 + 15.1\bar{U}^2). \quad (20)$$

To confirm the adequacy of the mathematical model of the process of drying and additional polymerization, experiments were carried out in batch mode in an apparatus with gas-distributing grate area of 0.013 m^2. Prepolymer grains poured in the apparatus were there in fluidized state. Samples were taken at regular intervals. The results of analysis of these samples are given in Fig. 2. The solid lines in the figure represent the results of calculations in terms of the mathematical model, the points show the results of analysis. Comparison of the data in Fig. 2 shows that discrepancy of the experimental and calculated values does not exceed 5% for conversion and 10% for material humidity. This allows the given mathematical description to be used for practical purposes.

In the case of a continuous process of manufacture of a water-soluble polymer, the combined installation employs a double-section fluidized-bed dryer with vertical arrangement of sections [2]. The diagram of material flows in the dryer is presented in Fig. 3. The apparatus operates on the counterflow principle.

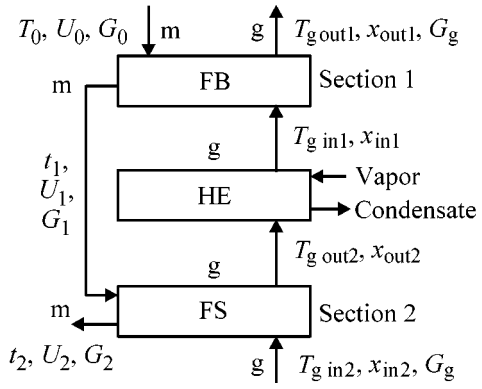

Fig. 3. Diagram of material flows in a double-section dryer. BB, fluidized bed; FB, filter section; HE, heat exchanger; g, gas; and m, material.

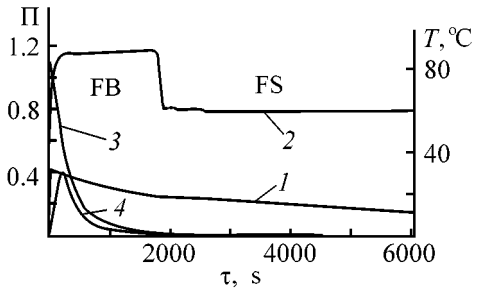

Fig. 4. Basic parameters Π of the combined processes vs. residence time τ in a fluidized bed. (*1*) Polymer humidity, (*2*) grain temperature *T*, (*3*) monomer concentration, and (*4*) Q_p/Q_c ratio.

Grained prepolymer is fed into the top section (FB) where the main part of moisture is removed. The fluidization number K_w = 2–3. From the first section, the material comes through a downpipe to the bottom section and is additionally dried there under the filter section conditions (K_w = 1.2–1.3). The drying agent (air) passes successively the bottom and top sections, with its heat potential increasing, in going from the filter section to the fluidized bed, in the heat exchanger mounted between the sections.

The continuous process of drying of prepolymer grains is considered on the assumption of complete displacement for the drying agent flow. The parameters of the drying agent at the inlet and outlet of each section are found from the system of heat (21) and material balance (22) equations and additional relations

$$G_g(c_g + c_v x_{in\,i})(T_{g\,in\,i} - T_{g\,out\,i}) + G_{ad}(c_m + c_w U_{i-1})T_{i-1} + Q_{pi} = G_{ad}(r^* + c_v T_{g\,out\,i})(U_{i-1} - U_i) + G_{ad}(c_m + c_w U_i)T_i, \quad (21)$$

$$x_{out\,i} = x_{in\,i} + G_{ad}(U_{i-1} - U_i)/G_g, \quad (22)$$

$$\frac{T_{g\,in\,i} - T_{g\,out\,i}}{T_{g\,in\,i} - T_{gi}} = [1 - \exp(-B_i H_i)]\left[1 - \frac{1 - \exp(-B_i H_i)}{-B_i H_i}\right], \quad (23)$$

$$B_i = 6\alpha_i(1 - \varepsilon_i)S_i/(c_g G_g d), \quad (24)$$

$$Q_{pi} = G_{ad}(1 + U_{i-1})C_m^0(X_i - X_{i-1})\Delta H/\rho_f, \quad (25)$$

$$G_g(c_g + c_v x_{out\,2})(T_{g\,in\,1} - T_{g\,out\,2}) = \frac{K_t F_t(T_{g\,in\,1} - T_{g\,out\,2})}{\ln[(T_{gv} - T_{g\,in\,1})/(T_{gv} - T_{g\,out\,2})]}, \quad i = 1, 2, \quad (26)$$

where G_g, G_{ad} are mass flow rates of gas and absolutely dry material (kg s^{-1}); c_g, c_v, c_m, c_w the specific heats of gas, water vapor, dry material, and water, respectively (J kg^{-1} K^{-1}); *T* the material temperature (°C); *i* the section number; $T_{g\,in}$, $T_{g\,out}$ the gas temperatures at the inlet and outlet of *i*th section (°C); Q_{ri} the heat flow released as a result of the polymerization reaction (W); ε_i, H_i the porosity and height of fluidized bed in *i*th section (%, m); S_i the cross-sectional area of *i*th section (m^2); X_i monomer conversion at the outlet of *i*th section (fraction units); ρ_{pp} prepolymer density (kg m^{-3}); C_m^0 the initial total concentration of monomers (mol m^{-3}); K_t the heat-transfer coefficient (W m^{-2}); F_t the heat-exchange surface area (m^2); and T_{hs} the temperature of heating steam (°C).

Expression (22) relates the average $\overline{T}_{gi}$ and final T_{gfi} temperatures of the drying agent in the fluidized bed [8]. The relationship between the temperature of the drying agent at the outlet of the second section and after the heat exchanger is defined by formula (26).

The system of Eqs. (1)–(7), (12), (15), and (17)–(26) is a mathematical description of the processes of additional polymerization and drying of prepolymer grains in a double-section apparatus with material fluidization in terms of the adopted simplifying assumptions.

Calculation of a double-section dryer, through which continuously passes a flow of prepolymer grains, consists in a search for such a combination of process parameters to be determined that would ensure prescribed characteristics of the technological process and, in particular, the moisture content of the material and conversion of starting monomers.

The above organization of the process in the apparatus leads to certain specific features of the kinetics and dynamics of drying. The combined processes of additional polymerization and drying in a prepolymer grain were simulated using the proposed mathematical model.

Figure 4 shows the temperature, grain humidity, total concentration of monomers, and ratio of the polymerization heat to heat supplied by convection as functions of the residence time of the material in the double-section dryer.

In the fluidized bed (top section), a prepolymer particle with equivalent diameter of 4 mm is heated from 50 to 90°C in about 200 s. The increase in temperature leads to weaker diffusion limitations on the reactions of chain initiation and growth, which makes higher the polymerization rate. By the end of the heating period the rate of the chemical process reaches its maximum value. A characteristic peak appears in the plot characterizing the ratio of the reaction heat to the heat delivered by convection. Further, the rate of polymerization decreases. Nevertheless, under the created conditions (temperature of about 90°C, sufficient content of water in the prepolymer), the process goes during the residence time of the material in the top section of the apparatus to virtually complete exhaustion of the monomers.

Figure 5a illustrates the variation of the moisture-content field in a prepolymer grain in relation to its residence time in the fluidized bed. The moisture distribution within the grain is highly nonuniform. After 1800 s, the content of water in the surface layer of thickness 0.07*R* (20% of the grain weight) is less than 0.1 kg moisture/kg absolutely dry material. The moisture content at the grain center remains virtually equal to the initial content.

It was established experimentally that the product with humidity less than 0.1 kg moisture/kg absolutely dry material poorly dissolves in water. This undesirable phenomenon can be eliminated by changing the drying mode in the bottom section of the apparatus. The air flow velocity in this section is 1.25 m s^{-1}, and the average air temperature, 60°C.

The process in the filter bed occurs in two stages. In the first stage, the moisture content of a particle remains unchanged. Arriving in the second section, the particle is cooled (Fig. 4) and the moisture is redistributed in the material. The moisture content decreases at the particle center and increases on the surface from the equilibrium humidity $U_{eq1} = 0.048$ in the first section to $U_{eq2} = 0.123$ in the second, which is illustrated in Fig. 5b. To describe this stage, the mathematical model was supplemented. By differentiating the expression

$$\overline{U} = U_s + (U_0 - U_s)\frac{3}{\pi}\sum_{j=1}^{n} A_j(\tau)(-1)^{j-1}/j = \text{const}, \quad (27)$$

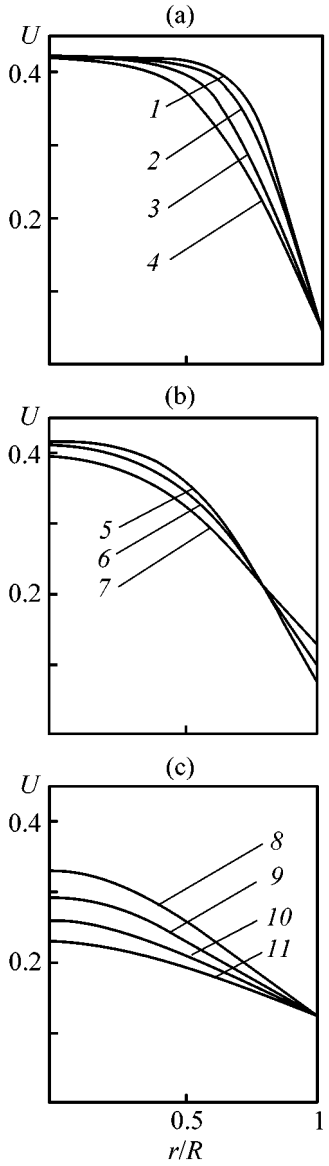

Fig. 5. Distribution of moisture content *U* along the grain radius. Time (s): (*1*) 792, (*2*) 1080, (*3*) 1440, (*4*) 1800, (*5*) 1932, (*6*) 2130, (*7*) 2440, (*8*) 3880, (*9*) 4600, (*10*) 5320, and (*11*) 6040.

which defines the average moisture content in a particle, an equation was derived for calculating the humidity at the grain surface

$$\frac{dU_s}{d\tau} = \frac{(U_s - U_0)\frac{3}{\pi}\sum_{j=1}^{n}\frac{dA_j(\tau)}{d\tau}(-1)^{j-1}/j}{1 - \frac{3}{\pi}\sum_{j=1}^{n}\frac{dA_j(\tau)}{d\tau}(-1)^{j-1}/j}. \quad (28)$$

The moisture content profile is calculated by

$$U(r, \tau) = U_s + (U_0 - U_s)\frac{R}{r}\sum_{j=1}^{n} A_j(\tau)\sin\left(j\pi\frac{r}{R}\right). \quad (29)$$

The second stage of the process in the filter section is characterized by constant particle temperature and particle humidity. The moisture content at the grain center and moisture content gradients decrease gradually, as seen from Fig. 5c.

CONCLUSIONS

(1) The possibility of combining the processes of polymerization and drying in the final stage of synthesis of water-soluble acrylic polymers was established experimentally. Thermal treatment of the prepolymer leads to weakening of the diffusion limitations on the reactions of initiation and growth of the polymeric chain, which favors reaction till virtually complete exhaustion of the monomer and makes it possible to combine the final polymerization with moisture removal from the obtained product.

(2) The moisture-transfer coefficient was determined experimentally for the prepolymer, and a functional dependence of this coefficient on temperature and moisture content was obtained.

(3) A mathematical description of combined processes of polymerization and drying in an isolated particle and a mathematical model of a double-section dryer were developed.

(4) It was shown that, for obtaining a water-soluble polymer with required quality characteristics and preventing the undesirable phenomenon of crust formation, the prepolymer should be dried in a double-section apparatus with fluidized bed under conditions of variable thermal and hydrodynamic modes.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Oxidizing Alkoxylation of Phosphine in Alcoholic Solutions of Iodine

G. S. Polimbetova and A. K. Borangazieva

Received May 23, 2000; in final form, July 2001

Abstract—Oxidizing alkoxylation of PH_3 to trialkyl phosphates was performed in pyridine-alcoholic solutions of iodine. The optimal conditions of the reaction were found.

The reaction of PH_3 with I_2 was studied in detail in [1, 2]. Iodine solutions are widely used for gas treatment to remove PH_3 [3] and for phosphine analysis [4]. Hypophosphorous, phosphorous, or phosphoric acids are formed depending on I_2/PH_3 ratio [1–3].

Reaction of PH_3 with I_2 in alcohols has not been studied [5]. We found that alcoholic solutions of I_2 rapidly oxidize PH_3 at 25–70°C into phosphoric acid:

$$4I_2 + PH_3 + 4ROH \rightarrow (HO)_3PO + 4RI + 4HI, \quad (1)$$

where R is Me, Et, Bu, Am, and Oct.

In pyridine-alcoholic solutions, I_2 oxidizes PH_3 into trialkyl phosphate:

$$4I_2 + PH_3 + 4ROH + 7PyH \rightarrow (RO)_3PO + RI + 7PyH \cdot HI \quad (2)$$

with the formation of a white precipitate of pyridine hydroiodide. Reaction (2) quantitatively yields trialkyl phosphates, which are widely used in extraction of rare earth elements and preparation of polymers [6]. Due to the high rate and high selectivity, the new reaction (2) can be used for utilization of PH_3 contained in exhaust gases from phosphorus plants [3]. In this work, we studied reactions (1) and (2) by IR and ^{31}P and ^{13}C NMR spectroscopy, gas chromatography, potentiometry, and the differential kinetic method.

EXPERIMENTAL

Oxidizing alkoxylation of PH_3 in alcoholic solutions of iodine was studied in a flow-type installation equipped with a vigorously shaken isothermal reactor, a unit for redox potential measurement, and supply and sampling of gaseous, solid and liquid reagents and products, a gasometer with an Ar–PH_3 mixture, and a rheometer for measuring the gas flow rate. The reactor volume was 150 ml, and that of supplied liquid, 10 ml. The relative error of measurements of the uptake rate and the volume of the converted PH_3 was within 8–10%. The reactor was charged with alcohol (or alcohol–pyridine mixture) and iodine, purged with Ar, the shaker was switched on, the redox potential measurement was started, and then the Ar–PH_3 gas mixture was supplied into the reactor. The rate of the gas mixture supply was controlled so as to obtain the constant PH_3 concentration at the outlet (~1 Pa). During the experiment, the redox potential, the rate of PH_3 uptake w (mol l^{-1} min^{-1}), and the amount of PH_3 taken up Q (M) were continuously measured, and the compositions of the liquid and gas phases were analyzed at regular intervals. The experiment was continued until the PH_3 uptake ceased. The rate of oxidizing alkoxylation of phosphine (2) was determined from the consumption of PH_3 and alcohol and the accumulation of trialkyl phosphate and alkyl iodide. The concentrations of the reaction components were varied depending on particular alcohol as follows (M): 0.4–1.2 (I_2), 0.0–22.2 (ROH), 0.0–12.4 (PyH), and p_{PH_3} (1.6–4.0) $\times 10^{-3}$ Pa. The temperature T was 25–70°C.

Phosphine was prepared by acid decomposition of Zn_3P_2. Gases (PH_3 and Ar) were dried over granulated NaOH. Alcohols were purified by distillation from CaO, and pyridine by distillation from Na metal. Analytically pure iodine was used without additional purification. The I_2 concentration was determined titrimetrically [8].

The chromatographic analysis of PH_3 in the initial gas mixture was performed on an LKhM-8 MD chromatograph equipped with a heat conductivity detector and a steel column packed with Porapak *Q* at 100°C at a helium flow rate of 12 ml min^{-1}. Unreacted phosphine was determined colorimetrically [9]. The stationary redox potential of alcoholic solutions of I_2 was continuously measured with a pH-121 millivoltmeter, using calomel and platinum electrodes, with a ground-glass stopper wetted with KCl solution as an electrolytic junction [10].

The chromatographic analysis of alcohols, pyridine, alkyl iodides, and organic products was performed on a 3700 chromatograph with a flame-ionization detector and a 3.0 m × 3.0 mm steel column packed with Chromaton-N-AW-DMCS impregnated with PEG-20M (10%). The column temperature was programmed from 100 to 200°C at a carrier gas (argon) flow rate of 30 ml min^{-1}.

Inorganic phosphates were determined colorimetrically in the form of vanadomolybdophosphate on an FEK-56 PM in 4-cm cells relative to water at 370 nm [8].

Trialkyl phosphates were recovered by vacuum distillation at 1–10 mm Hg after separation of the PyH · HI precipitate by decanting. The products obtained were identified by the boiling point, refractive index, and IR and ^{31}P and ^{13}C NMR spectra.

The IR spectra in the 400–4000 cm^{-1} range were recorded on a Specord IR-75 spectrometer with KBr windows. The ^{31}P and ^{13}C NMR spectra were registered on a Bruker WP-80 spectrometer [31.44 MHz (^{31}P) and 20.55 MHz (^{13}C)]. The main physicochemical constants of the isolated products agreed well with reference data [11]. In the ^{31}P NMR spectra, the signal at δ from –0.3 to –0.9 ppm relative to 85% H_3PO_4 corresponds to the chemical shift of trialkyl phos-

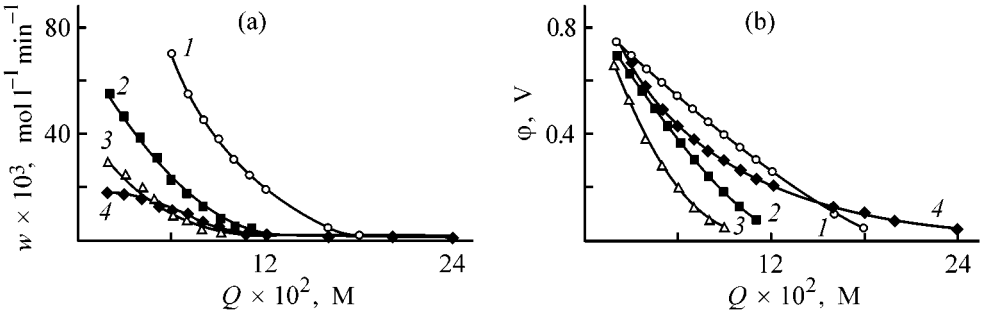

Fig. 1. (a) Conversion and (b) potentiometric curves of phosphine uptake by iodine solution. (*w*) Rate of phosphine uptake, (φ) potential, and (*Q*) amount of phosphine taken up. c_{I_2} (M): (*1*, *4*) 0.8; and (*2*, *3*) 0.4. c_{Py} (M): (*1*) 0, (*2*, *3*) 1.2, and (*4*) 12.4. c_{BuOH} (M): (*1*) 10.9, and (*2*) 9.8; (*3*) c_{OctOH} 5.7; (*4*) No alcohol. $p_{PH_3} \times 10^{-3}$ (Pa): (*1*) 1.6, (*2*, *4*) 3.3, and (*3*) 4.0. *T* (°C): (*1*) 70, (*2*, *3*) 50, and (*4*) 25.

phates [12]. The IR spectra of the trialkyl phosphates obtained coincided with those of the reference samples and contained characteristic bands of P=O (ν = 1260–1285 cm^{-1}) and P–O–C (ν = 1020–1045 cm^{-1}) groups [13]. The ^{13}C NMR spectra of the products contained signals with chemical shifts $\delta(CH_3) = 19.5 \pm 0.5$, $\delta(CH) = 29.5 \pm 0.5$, and $\delta(CH_2) = 73.6 \pm 0.5$ ppm, characteristic of trialkyl phosphates.

The PH_3–I_2–ROH system. The alcoholic solution of I_2 is fairly stable at 20–70°C. The I_2/I^- redox potential was constant for a long time (30 min). The I_2 concentration did not change, and no products of alcohol oxidation with iodine were detected [14]. Introduction of PH_3 into this solution is accompanied by a cathodic shift of the redox potential φ from 0.8 to 0.1 V because of the decrease in the I_2 concentration due to reaction (1). In the course of PH_3 uptake by iodine alcoholic solution, I_2 is reduced to RI and HI, and PH_3 is oxidized to phosphoric acid by Eq. (1). The yield of organic phosphates is 1–2% (see the table). The *W*–*Q* conversion and φ–*Q* potentiometric curves are descending (Figs 1a, 1b, curves *1*). The alcoholic solution of iodine eliminates from Ar–PH_3 mixtures even trace amounts of PH_3 (< 10 Pa). The PH_3 uptake stops only when I_2 is completely reduced and, correspondingly, the reddish brown alcoholic solution of I_2 is decolorized.

The PH_3–I_2–ROH–PyH system. The pyridine-alcoholic solution of I_2 is fairly stable at 20–70°C. The redox potential of the I_2/I^- couple remains constant for 30–40 min. During this time, the I_2 concentration is also unchanged, and products of alcohol and pyridine oxidation by iodine do not appear. Introduction of PH_3 into the pyridine-alcoholic solution of I_2 is accompanied by uptake of PH_3, decrease in the I_2 concentration, and cathodic shift of the redox potential from 0.7 to 0.05 V (Fig. 1). During the experiment, the initial reddish brown solution of I_2 is decolorized, and a white precipitate of PyH · HI is formed. The uptake of PH_3 by the pyridine-alcoholic solution is accompanied by the oxidizing alkoxylation of PH_3 (2) with the formation of trialkyl phosphates in high yields (see table). The table illustrates the effect of the temperature and concentration of iodine, phosphine, pyridine, and alcohol on the trialkyl phosphate yield. Under the optimal conditions, the yield is 100%. The increase in PyH concentration in the alcoholic solution of I_2 from 1.2 to 7.4 M does not affect the tributyl phosphate (TBP) yield. At the pyridine concentration of 9.9 M, the TBP yield decreases to 64%. The pyridine solution of I_2 takes up PH_3, and a yellow precipitate of, probably, P_2I_4 is formed [15], with no organophosphorus compounds detected in the solution. The effect of alcohol on reaction (2) was studied at the optimal $[PyH]/[I_2]$ ratio close to the stoichiometric ratio. The character of conversion and potentiometric curves of PH_3 uptake by pyridine-alcoholic solutions of I_2 are similar to those for alcoholic solutions of I_2. The rate of reaction (2) grows with increasing concentration of I_2 and PH_3, temperature, and alcohol acidity and decreases with accumulation of PyH · HI (Fig. 1).

CONCLUSION

At 20–70°C, pyridine-alcoholic solutions of I_2 rapidly take up PH_3 from gas mixtures with selective formation of trialkyl phosphates. The optimal conditions of this reaction are *T* = 25–50°C, p_{PH_3} = $(1.4–2.3) \times 10^{-3}$ Pa, and $c_{I_2} = c_{PyH}$ = 10–30 wt% (the remainder is ROH).

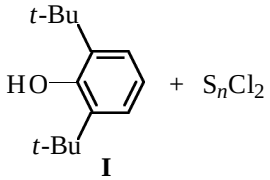
Abstract—Bis(4-hydroxy-3,5-di-*tert*-butylphenyl) sulfide and polysulfides were prepared, and their inhibiting power was studied in relation to the number of sulfur atoms.

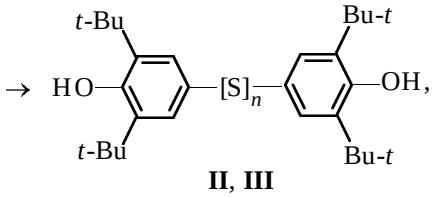
Studies concerned with synthesis of oxidation inhibitors and the mechanism of their antioxidative effect showed that hydroxyaryl sulfides and polysulfides [1, 2] containing simultaneously a phenolic moiety and sulfur atom(s) are oxidation inhibitors with a complex effect.

Proceeding with studies in this field [3–10], we prepared new compounds of this group and examined their inhibiting effect on cumene oxidation in relation to the number of sulfur atoms.

As the initial compound we chose commercially available 2,6-di-*tert*-butylphenol (**I**).



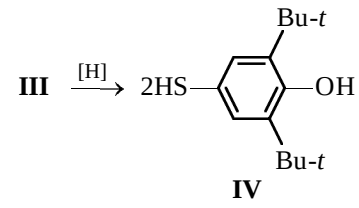
I



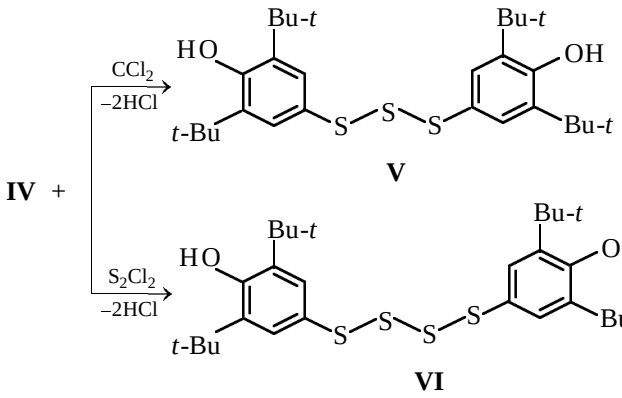
II, **III**

where n = 1 (**II**), 2 (**III**).

Reduction of bis(4-hydroxy-3,5-di-*tert*-butylphenyl) disulfide (**III**) with hydrogen yielded 4-hydroxy-3,5-di-*tert*-butylthiophenol (**IV**), which is a precursor of the corresponding trisulfide (**V**) and tetrasulfide (**VI**).



IV



V

VI

To evaluate the antioxidative power of **II**–**VI** in elementary stages of cumene oxidation, we studied the reactions of these compounds with cumylperoxy radicals and cumyl hydroperoxide (CHP). The capability of mono- and polysulfides **II**–**VI** to terminate oxidation chains by reaction with peroxy radicals was studied for the example of cumene oxidation at 60°C, intiated with azobis(isobutyronitrile) (AIBN). As seen from Fig. 1, sulfides **II**–**VI** suppress initiated oxidation of cumene.

From the duration of the induction period τ we calculated the stoichiometric coefficient of inhibition f, equal to the number of oxidation chains terminated on

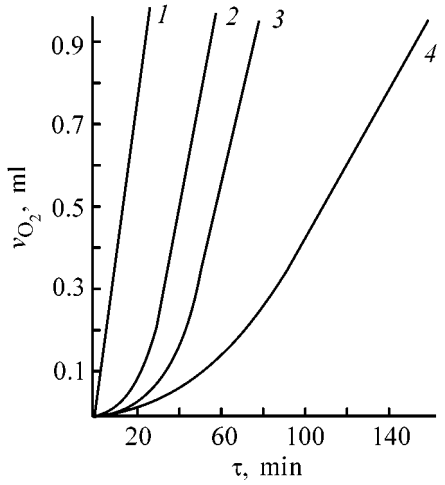

Fig. 1. Initiated oxidation of cumene in the presence of **IV**. (V_{O_2}) Oxygen volume and (τ) time; the same for Fig. 2. $c_{\mathbf{IV}}$, M: (*1*) 0, (*2*) 3×10^{-4}, (*3*) 4×10^{-4}, and (*4*) 5×10^{-4}.

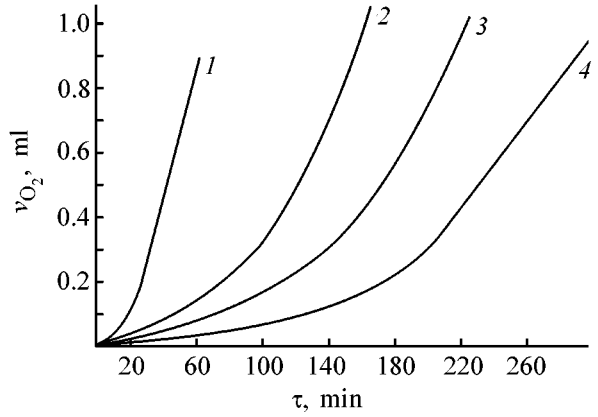

Fig. 2. Autooxidation of cumene in the presence of **III**–**V** at 60°C. Inhibitor (10^{-5} M): (*1*) none, (*2*) **III**, (*3*) **IV**, and (*4*) **V**.

one molecule of the inhibitor and its transformation products:

$$f = \tau v_i / [\mathrm{InH}]_0,$$

where τ is the induction period (s), v_i is the initiation rate (under our conditions, $v_i = 2 \times 10^{-7}$ mol l^{-1} s^{-1}), and $[\mathrm{InH}]_0$ is the initial inhibitor concentration.

Table 1. Kinetic parameters of reactions of sulfides **II**–**VI** with cumylperoxy radicals

Compound	f	k_7, l mol^{-1} s^{-1}
II	1.96	2.69
III	1.08	2.24
IV	2.80	4.18
V	2.30	5.82
VI	2.80	6.43

Note: 60°C, [AIBN] = 2×10^{-2} M, $v_i = 2 \times 10^{-7}$ mol l^{-1} s^{-1}.

From the kinetics of oxygen uptake, we calculated the rate constants of the reactions of **II**–**VI** with peroxy radicals k_7 [11, 12]. To do this, we plotted the oxygen uptake curves in the coordinates $[O_2]^{-1}$–τ^{-1} and determined k_7 from the slope of the straight line [11]:

$$\tan\alpha = \frac{fk_7[\mathrm{InH}]_0}{k_2[\mathrm{RH}]_{v_i}},$$

$$k_7 = \frac{\tan\alpha\, k_2 [\mathrm{RH}]_{v_i}}{f[\mathrm{InH}]_0},$$

where $k_2 = 1.51$ l mol^{-1} s^{-1} is the rate constant of chain initiation [11, 12]; [RH] = 6.9 M.

The high antioxidative activity of **II**–**VI** is also manifested in autooxidation of cumene at 110°C (Fig. 2).

The kinetic parameters of the reactions of **II**–**VI** with cumylperoxy radicals are listed in Table 1. It is seen that the stoichiometric coefficient f for **II**–**VI** varies from 1.08 to 2.80. The inhibition rate constant k_7 varies from 2.24×10^{-4} to 6.4×10^{-4} l mol^{-1} s^{-1}. Inhibitors with $f \le 1$ usually terminate a single oxidation change. Since the molecules under consideration contain two functional groups, sulfide and hydroxy, the coefficient f is somewhat higher than unity. The products formed in reactions of **II**–**VI** with cumylperoxy radicals also show certain inhibiting power: The oxidation rate after the induction period is somewhat lower than in the case of noninhibited oxidation.

In initiated oxidation of cumene in the presence of sulfides **II**–**VI**, in which the sulfur atom is directly bonded to the benzene ring, the stoichiometric coefficient of inhibition f is close to unity (Table 1). In compounds in which the sulfur atom is linked to the benzene ring via methylene bridge, $f = 2$ [13].

It is known that for alkylphenols $f = 2$ [12, 14], i.e., they terminate two oxidation chains:

$$\mathrm{InH} \xrightarrow{\mathrm{RO_2^{\cdot}}} \mathrm{In}^{\cdot} \xrightarrow{\mathrm{RO_2^{\cdot}}} \text{Inactive products.}$$

Presumably, termination of only one oxidation chain by monosulfides in which the sulfur atom is directly bonded to the benzene ring is due to stabilization of the arising phenoxy radical by resonance with electron delocalization involving the unpaired electron of oxygen and the vacant 3*d* orbital of sulfur. In hydroxyaryl sulfides containing a methylene group between the benzene ring and sulfur atom, the πp–$d\pi$ conjugation is impossible, and the arising phenoxy radical is capable of reacting with the second peroxy radical.

In the case of disulfides, thiyl radicals [7] formed by homolysis of the S–S bond can participate along with OH groups in reaction with peroxy radicals. This fact probably accounts for the high inhibiting power of disulfides.

Our studies showed that all the compounds **II**–**VI** actively decompose CHP. The kinetic curve of CHP decomposition in the presence of the examined compounds has a shape typical of autocatalytic reactions (Fig. 3). The autocatalytic character of the kinetic curves shows that CHP decomposition is effected by products formed in the first, slow stage of the reaction, rather than by inhibitors **II**–**VI** proper.

To determine the reaction order, we studied how the initial rate of catalytic decomposition of CHP depends on the reactant concentrations. We found that the reaction is first-order with respect to both inhibitor (InH) and CHP:

$$v = k[\mathrm{InH}][\mathrm{CHP}].$$

To determine the reaction stoichiometry, CHP was taken in excess. The stoichiometric coefficient γ was calculated by the formula

$$\gamma = \frac{[\mathrm{ROOH}]_0 - [\mathrm{ROOH}]_\infty}{[\mathrm{InH}]_0},$$

where $[\mathrm{ROOH}]_0$ and $[\mathrm{ROOH}]_\infty$ are, respectively, the initial and final concentrations of CHP and $[\mathrm{InH}]_0$ is the initial concentration of the inhibitor.

Our data show that transformation products of a single inhibitor molecule decompose from several hundreds to several tens of thousands of CHP molecules.

The kinetic parameters of catalytic decomposition of CHP under the action of **II**–**VI** are listed in Table 2. Similarly to the reaction with cumylperoxy radicals, the catalytic activity of **II**–**VI** in decomposition of CHP depends on the number of sulfur atoms. The greater the number of sulfur atoms in the molecule, the higher *k*, and tetrasulfide **VI** is the most active.

EXPERIMENTAL

The IR spectra were recorded on a Specord IR-75 spectrophotometer (mulls in mineral oil), and the ^{1}H NMR spectra, on Varian-60 and Tesla (80 MHz) spectrometers; the chemical shifts δ (ppm) are given relative to TMS as internal reference.

Thin-layer chromatography was performed on Silufol UV-254 plates, with ethanol–hexane (1 : 5) as eluent.

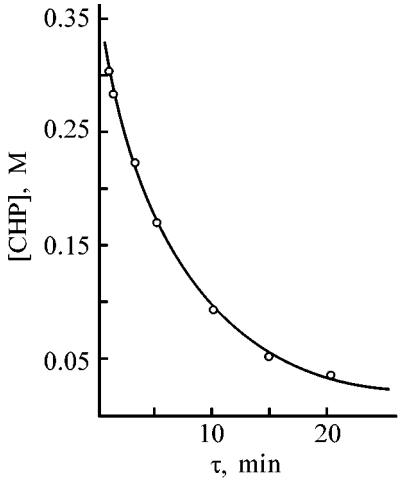

Fig. 3. Catalytic decomposition of CHP under the action of **V** (4×10^{-5} M) at 110°C. [CHP] CHP concentration and (τ) time.

Cumyl hydroperoxide was purified according to [15] with subsequent distillation; chlorobenzene and cumene were purified by a conventional procedure based on sulfonation of impurities with concentrated sulfuric acid [16, 17]. The CHP concentration was determined by iodometric titration [15] of samples taken at regular intervals. Experiments on decomposition of CHP were performed in chlorobenzene at 110°C in a glass bubbler in an inert atmosphere; the CHP concentration was varied within 0.16–0.64 M, and the concentration of the inhibitors, from 10^{-4} to 5×10^{-4} M.

Experiments on initiated oxidation of cumene were performed on a manometric installation [17]. The initiator was AIBN; at 60°C, its initiation rate constant is 10^{-6} s^{-1} [18]. The initiator concentration was 2×10^{-2} M in all the experiments, and the concentration of the inhibitors, 10^{-5} M.

Bis(4-hydroxy-3,5-di-*tert*-butylphenyl) sulfide II, mp 139°C, was prepared by reaction of SCl_2 with phenol **I** in acetonitrile at a temperature from –15 to –30°C.

Table 2. Kinetic parameters of catalytic decomposition of CHP under the action of **II**–**VI** at 110°C

Compound	k, l mol^{-1} s^{-1}	γ
II	9.5	6900
III	18.6	12500
IV	29.8	32600

VI	46.0	60800

Bis(4-hydroxy-3,5-di-*tert*-butylphenyl) disulfide III was prepared similarly by reaction of S_2Cl_2 with phenol **I**; mp 145–146°C [19, 20].

4-Hydroxy-2,5-di-*tert*-butylthiophenol was prepared according to [21].

Bis(4-hydroxy-3,5-di-*tert*-butylphenyl) trisulfide V. A mixture of 12 g of thiophenol **IV** and 50 ml of acetonitrile was cooled to a temperature from –15 to –30°C, and a solution of 2.5 g of SCl_2 in 20 ml of acetonitrile was added. The mixture was stirred at the same temperature for 1 h, washed with water, and treated with diethyl ether. After distillation of the solvent, the product was recrystallized from hexane. Yield of **V** 10.7 g (85%), mp 129–130°C, R_f 0.52. ^{1}H NMR spectrum, δ, ppm: 1.45 s (36H), 4.75 s (2H), 6.85 s (2H). IR spectrum, ν, cm^{-1}: 3625, 1805, 685, 465.

Found, %: C 66.51, H 8.51, S 18.31.
$C_{28}H_{42}O_2S_3$.
Calculated, %: C 66.35, H 8.35, S 18.98.

Bis(4-hydroxy-3,5-di-*tert*-butylphenyl) tetrasulfide VI was prepared similarly from 12 g of thiophenol **IV** and 3.4 g of S_2Cl_2; yield 12 g (90%), R_f 0.46. ^{1}H NMR spectrum, δ, ppm: 1.41 s (36H), 4.83 s (2H), 6.73 s (2H). IR spectrum, ν, cm^{-1}: 3620, 1810, 690, 475.

Found, %: C 64.62, H 8.01, S 23.17.
$C_{28}H_{42}O_2S_4$.
Calculated, %: C 62.41, H 7.86, S 23.80.

CONCLUSIONS

(1) Bis(4-hydroxy-3,5-di-*tert*-butylphenyl) sulfide and polysulfides were prepared and characterized.

(2) These compounds effectively reduce the rate of cumene oxidation by catalyzing decomposition of the hydroperoxide and terminating the oxidation chains via reaction with peroxy radicals generated from cumene. The inhibiting activity of the compounds grows with the increasing number of sulfur atoms in the molecule.

Abstract—The structure and composition of polyheterosiloxanes formed in hydrolytic polycondensation of ethyl silicate in the presence of copper salts under the conditions of base catalysis (NH_4OH) were studied as influenced by the nature of acid anion (SO_4^{2-}, Cl^-, NO_3^-, CH_3COO^-).

Sol-gel process is widely used to prepare high-tech materials for modern engineering thanks to the high versatility of sol-gel methods, their low power consumption, and large assortment of the resulting three-dimensional macromolecular structures. The possibility of controlling the topological features of amorphous and crystalline polyheterosiloxane fractal structures of the products of sol-gel synthesis using metal ions [1] is of particular importance.

The most important mode of the sol-gel synthesis of polyheterosiloxane is based on hydrolysis and polycondensation of tetraalkoxysilanes in nonaqueous solutions in the presence of metal salts [2]. Rather difficult control of these reactions complicates obtaining the reaction products with reproducible composition, structure, and properties.

EXPERIMENTAL

In our study, we used commercial ethyl silicate-40 (partially hydrolyzed tetraethoxysilane), 2-propanol (solvent), and copper salts [$CuCl_2 \cdot 2H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$, $CuSO_4 \cdot 5H_2O$, and $Cu(CH_3COO)_2 \cdot 2H_2O$]. These salts were chosen taking into account their ability to form hydrate and ammine complexes playing an important role in sol-gel synthesis of polyheterosiloxane [3]. The ethyl silicate : water : 2-propanol molar ratio was 1 : 8 : 4; the temperature and time of synthesis were 25, 35, and 45°C and 1, 3, and 5 h, respectively. After that, gelation was induced by adding 25% aqueous ammonia to pH 11.0.

The products of hydrolytic polycondensation were thoroughly washed by decantation and dried to xerogel for 16 h at 120 ± 0.5°C. Then the reaction products were studied by thermography in air (MOM derivatograph, heating rate 10 deg min^{-1}) and IR spectroscopy (Specord IR-75 device, KBr pellets).

Polycondensation of ethyl silicate with copper salts under the conditions of basic catalysis yields polymeric structures containing Si–O–Cu–O fragments and residual ethoxy and isopropoxy groups formed in the course of ester interchange. This is confirmed by a shift of the characteristic absorption band ν(Si–O) in the IR spectra of copper-containing polyalkoxysiloxane xerogels as compared with silica xerogels [ν(Si–O) = 1093 cm^{-1}]. This shift is determined by the nature of the anion in the initial copper salt (Table 1). As seen, for copper-containing polyalkoxysi-

* Weight loss for silica xerogel is 1.50 wt %.

loxanes prepared using $CuSO_4$ the ν(Si–O) band is shifted by 6–33 cm^{-1} toward lower frequencies, whereas in the case of $Cu(NO_3)_2$ this band moves toward both lower and higher frequencies by 0–27 and 0–13 cm^{-1}, respectively. We found no regular trends in the value and direction of the band shift. Similar phenomenon was observed in the case of $CuCl_2$.

The IR data show that inorganic copper salts promote formation of thermodynamically unstable structures characterized by random redistribution of the mobile fragments in the siloxane matrix. This is typical of copper-containing siloxanes prepared using copper salts of inorganic acids and is inevitable in common procedures of their drying [4].

In the case of $Cu(CH_3COO)_2$, a different pattern is observed. In the IR spectra of copper-containing polyalkoxysiloxanes prepared using copper acetate, the ν(Si–O) band is shifted to lower frequencies by 10–26 cm^{-1}. This shift decreases steadily with increasing process time at a given temperature. A similar trend was found for the half-width of this band, characterizing the number of siloxane and metal–siloxane bonds, i.e., the degree of three-dimensional cross-linking (Table 2).

It should be noted that copper acetate sharply decreases the gel time and the process is complete at 35 and 45°C in, respectively, 2.5 and 1 h. This is probably due to the fact that, compared with copper chloride, nitrate, and sulfate, copper acetate is more reactive in heterofunctional polycondensation proceeding by the following reaction:

$$CuX_2 + 2ROSi{\equiv} \rightarrow {\equiv}Si–O–Cu–O–Si{\equiv} + 2RX, \quad (1)$$

where R is H or alkyl and X is the acid anion (CH_3COO^-) [4].

Using copper acetate, more thermodynamically stable copper-containing polyalkoxysiloxane structures are prepared. Moreover, in contrast to $CuCl_2$, $CuSO_4$ and $Cu(NO_3)_2$, the gel obtained in the case of $Cu(CH_3COO)_2$ contains no residual metal salt or its ammine complexes. In thermal formation of xerogel, the former salts cause cleavage and redistribution of the siloxane groups according to the scheme given in [4]:

$$CuX_2 + 2{\equiv}Si–O–Si{\equiv} \rightarrow {\equiv}Si–O–Cu–O–Si{\equiv} + 2XSi{\equiv}, \quad (2)$$

$$\equiv SiX + ROSi{\equiv} \rightarrow {\equiv}Si–O–Si{\equiv} + RX, \quad (3)$$

where X = Cl, NO_3, $0.5SO_4$ and R–H, alkyl.

The insignificant amount of the organic component in the resulting products is confirmed by the weight loss in the range of thermal degradation of the ethoxy groups (Table 3, 200–450°C).

Depending on the anion in the initial copper salt, the exothermic peaks in the DTA curves of copper-containing polyalkoxysiloxane xerogels have different intensities and widths, with maxima in the 295–350°C range. The shift of the exothermic maximum toward higher temperatures as compared with silica xerogel (250°C) is due to the shielding of the ethoxy groups by new Si–O–Cu–O–Si fragments (Table 4).

The results of thermal analysis also confirm the effect of the copper salt anion on the product nature. In copper-containing polyalkoxysiloxanes prepared

using copper salts of strong mineral acids, the content of alkoxy groups decreases with the synthesis time increasing from 1 to 5 h, which is confirmed by the DTA and DTG data. This fact can be accounted for by further hydrolysis and heterofunctional condensation (1). At synthesis time of 3 h at 45°C, the relative weight loss is 25, 38, and 23 wt % for copper-containing polyalkoxysiloxanes prepared using copper sulfate, chloride, and nitrate, respectively.

The resulting heteropolyalkoxysiloxanes retain 1.50–2.25 wt % water and hydroxy groups upon heating even to 1000°C. As seen from the DTA and DTG data, the composition and structure of the resulting copper-containing polyalkoxysiloxanes depends on the copper salt anion and on the time and temperature of synthesis. On the whole, the yield of the product of hydrolytic polycondensation grows with increasing temperature, whereas the relative content of copper-containing siloxane slightly decreases owing to the significant amount of sorbed water.

In the case of copper sulfate and temperatures of 35 and 45°C, the increase in the synthesis time does not affect noticeably the composition and structure of the resulting heterosiloxane; in the 200–450°C range, the weight loss only slightly decreases, whereas the temperature maximum remains almost constant. In the presence of copper nitrate at 45°C, the temperature of the maximal weight loss sharply grows (from 270 to 340°C) with the synthesis time increasing from 1 to 5 h, T_{max} in the DTA curve grows by 15°C, and the range of the exothermic peak extends from 260 to 390°C. This is probably due to the side reactions of nitration and oxidation of the alkoxy groups by copper nitrate, which causes formation of a more random structure of the heterosiloxane.

In the presence of copper acetate, the structure and composition of the resulting heterosiloxanes strongly depend on the preparation conditions. The yield of heterosiloxane decreases with increasing synthesis temperature; this is typical of 25 and 35°C. In contrast to copper sulfate, nitrate, and chloride, in the case of copper acetate, the content of sorbed water, organic fraction, and hydroxy groups grow by 67.5 and 25 wt %, respectively with increasing synthesis time. As the synthesis time increases to 2.5 h at 35°C, the content of sorbed water and organic component in the resulting copper-containing polyalkoxysiloxane grows by 15 and 30 wt %, whereas the content of hydroxy groups remains almost constant. This process is accompanied by a sharp increase in the intensity and by a certain change in the shape of the exothermic peak in the DTA curves (see Fig. 1). All these data suggest that more uniform but less condensed heterosiloxanes are formed with increasing temperature and time of the synthesis in the case of copper acetate.

Table 4. Temperature of the exothermic peak T_{max} of copper-containing polyalkoxysiloxane xerogels

Preparation conditions		T_{max}, °C			
T, °C	τ, h	$Cu(NO_3)_2$	$CuSO_4$	$CuCl_2$	$Cu(OCOCH_3)_2$

	5	340 390	340 190	–	–

* Exothermic peak is given in the numerator.

** Exothermic effect range is given in the denominator.

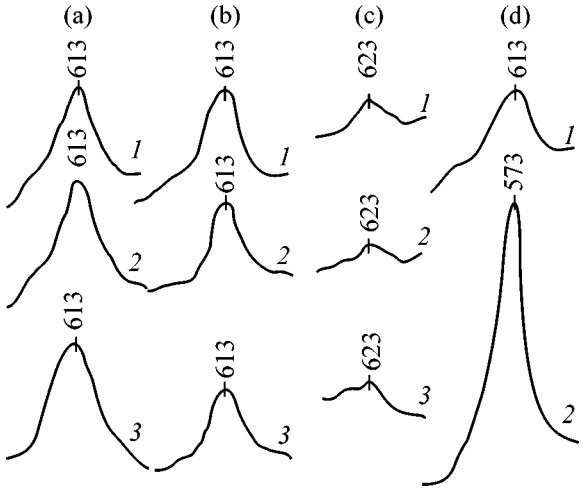

Fig. 1. DTA curves of copper-containing polyalkoxysiloxane xerogels based on (a) $CuSO_4$, (b) $Cu(NO_3)_2$, (c) $CuCl_2$, and (d) $Cu(CH_3COO)_2$ at 35°C. Synthesis time, h: (*1*) 1, (*2*) 3, and (*3*) 5.

On the whole, the sol–gel synthesis from ethyl silicate and copper salts in 2-propanol solutions under the conditions of base catalysis (NH_4OH) yields highly uniform cross-linked copper-containing polyalkoxysiloxanes.

The conditions of copper salt hydrolysis are also of particular importance. Due to hydrolysis, solutions of copper sulfate, chloride, and nitrate are weakly acidic (pH 4). As a result, they decrease the total basicity of the reaction mixture, decelerating the hydrolytic polycondensation. Moreover, these salts form strong ammine complexes. As a result, when the amount of ammonia in the reaction mixture is insufficient, the time of hydrolytic polycondensation increases to 3–5 h. In the case of copper acetate solution (pH 7), the process is complete in 2.5 h at 35°C and in 1 h at 45°C.

Thus, the rate and yield of hydrolytic polycondensation and the structure and properties of copper-containing polyalkoxysiloxanes and the resulting copper-containing siloxane xerogels (copper polysilicates) strongly depend on the anion.

The anion of the copper salts studied also affects the water sorption capacity of the copper-containing polyalkoxysiloxanes (wt %): 39.8 for $CuCl_2$, 15.6 for $Cu(NO_3)_2$, 16.3 for $CuSO_4$, and 37.5 wt % for $Cu(CH_3COO)_2$.

CONCLUSIONS

(1) The anion in copper salts [$CuCl_2$, $Cu(NO_3)_2$, $CuSO_4$, $Cu(CH_3COO)_2$] affects the rate and yield of their hydrolytic polycondensation with ethyl silicate, and also the composition, structure, and properties of the resulting copper-containing polyalkoxysiloxanes.

(2) In the case of copper salts of mineral acids, thermally unstable copper-containing polyalkoxysiloxanes with random distribution of the mobile fragments in the siloxane matrix are formed, whereas in the presence of copper acetate, the resulting structure is thermodynamically stable and has predictable properties.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Recovery of Trimethylchlorosilane from Its Azeotropic Mixture with $SiCl_4$

M. G. Voronkov, V. P. Baryshok, and G. A. Kuznetsova

Favorskii Institute of Chemistry, Siberian Division, Russian Academy of Sciences, Irkutsk, Russia

Received July 30, 2001

Abstract—Reaction of tetraethoxysilane with the azeotropic mixture Me_3SiCl–$SiCl_4$ in the presence of certain cyclic (tetrahydrofuran, dioxane) and acyclic (diethyl ether) ethers, ethanol, or dimethylformamide was studied with the aim of $SiMe_3Cl$ recovery.

Trimethylchlorosilane is one of the most important organosilicon monomers. It is used to incorporate inert terminal groups into oligoorganosiloxanes to be applied as heat- and frost-resistant oils, lubricants, liquid dielectrics, heat carriers, hydrophobizing components, lacquers, and enamels; also, it is widely used as trimethylsilylating agent in organic and organometallic chemistry [1].

Direct synthesis of methylchlorosilane by reaction of CH_3Cl with the Si–Cu contact mass yields up to 10% of the azeotropic mixture Me_3SiCl–$SiCl_4$ [2]. The majority of methods proposed for its separation [azeotropic distillation with acetonitrile; partial hydrolysis or alcoholysis; chemical binding of $SiCl_4$ in the form of solid complexes with tertiary aliphatic and aromatic amines, formamide, and dimethylformamide (DMF), insoluble in the reaction medium; fluorination in aqueous solution] have a number of drawbacks: low yield of Me_3SiCl, strongly corrosive medium, gelation, and formation of abundant by-products whose utilization requires sophisticated procedures [3–5].

Simple procedures for Me_3SiCl recovery from the azeotropic mixture Me_3SiCl–$SiCl_4$ have been developed only recently. They are based on binding of $SiCl_4$ with organylalkoxysilanes, ethyl silicate, and bottoms from its synthesis in the presence of alcohols, traces of moisture, metal salts, and acid catalysts [6, 7].

The reaction between alkoxy- and chlorosilanes occurs either as exchange of an alkoxy group for a halogen atom [scheme (1), *a*] or as heterofunctional condensation [scheme (1), *b*] [1]:

$$X{-}Si^{*} + RO{-}Si{-} \overset{a}{\rightleftarrows} {-}Si{-}X + {-}Si^{*}{-}OR \xrightarrow{b} RX + {-}Si{-}O{-}Si^{*}{-}. \quad (1)$$

Both pathways, *a* and *b*, are accelerated in the presence of HCl. As a rule, the contribution of pathway *b* becomes appreciable at elevated temperatures.

Reaction of $SiCl_4$ with $Si(OEt)_4$ at 150–160°C yields a mixture of OEt–Cl exchange products [8–10]. In the presence of 0.24 wt % ethanol, this reaction is 76–97% complete in 20–70 h at molar ratio $SiCl_4$: $Si(OEt)_4$ = 1 : 3 and 20–22°C [11].

A procedure has been developed for separation of a technical azeotropic mixture Me_3SiCl–$SiCl_4$ containing $MeSiHCl_2$ and $HSiCl_3$ impurities by binding $SiCl_4$ with tetraethoxysilane to form ethoxychlorosilanes in a selective reaction in the presence of initiators, with subsequent fractionation of the reaction mixture [12, 13].

To this end, a technical azeotropic mixture was brought into reaction with $Si(OEt)_4$ in the presence of 0.2–10 wt % DMF, tetrahydrofuran (THF), dioxane, diethyl ether, or ethanol. The reaction was performed at 20–25°C or at refluxing (60–65°C) for 2–72 h until conversion of $SiCl_4$ into ethoxychlorosilanes and -siloxanes was complete:

$$SiCl_4 + (EtO)_4Si \rightarrow Cl_{4-n}Si(OEt)_n + [Cl_mSi(OEt)_{3-m}O]_kSiCl_p(OEt)_{3-k-p}, \quad (2)$$

where n, m, k, p = 1–3.

With the above initiators, it was possible to recover 6–88% of Me_3SiCl from the reaction mixture. In the presence of DMF, the mixture undergoes partial tarring due to low thermal stability of DMF–$SiCl_4$ complexes [14].

Reaction (2) performed in the presence of 0.2 wt % ethanol, 1 wt % THF or dioxane, or 2 wt % diethyl ether mainly yields triethoxychlorosilanes, with relatively low content of siloxanes originating from heterofunctional condensation (see table). Raising the concentration of THF or dioxane to 2 wt % noticeably decreases the yield of ethoxychlorosilanes and favors formation of oligosiloxanes even at 20–25°C (see table). At THF content as high as 10 wt %, Me_3SiCl is also involved in the heterofunctional condensation.

Initiation of exchange between alkoxy groups and chlorine atoms in reactions of chlorosilanes with alkoxysilanes under the action of HCl (usually present in chlorosilanes because of their partial hydrolysis by atmospheric moisture) is believed to occur in two stages [1]:

$$-\overset{|}{\underset{|}{Si}}-OEt + HCl \rightleftarrows -\overset{|}{\underset{|}{Si}}-Cl + HOEt, \quad (3a)$$

$$-\overset{|}{\underset{|}{Si^*}}-Cl + HOEt \rightleftarrows -\overset{|}{\underset{|}{Si^*}}-OEt + HCl. \quad (3b)$$

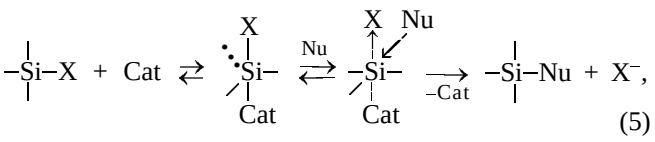
The initial rate of the reaction between trimethylmethoxysilane and $SiCl_4$ in the presence of HCl or hydroxyl-containing compounds ROH (R = H, MeO, PhCO, Et_3Si) releasing HCl in the reaction with $SiCl_4$, is proportional to squared HCl concentration [15]. In this connection, formation of intermediate associates like $Me_3SiOMe \cdot 2HCl$, decomposing with cleavage of the Si–O bond, was suggested:

$$Me_3SiOMe \cdot 2HCl \rightleftarrows Me_3SiCl + HOMe + HCl. \quad (4)$$

In a solvent forming associates with HCl, the equilibrium of reaction (4) is significantly shifted to the left. This fact is nicely consistent with the previously found [13] catalytic activity of ethanol in reaction (3). However, addition of acyclic (Et_2O) and cyclic (THF, dioxane) ethers, capable of forming oxonium complexes with HCl [16], must enhance the catalytic effect of HCl. In the case of THF, the oxonium complex can transform into 4-chloro-1-butanol whose capability for etherification of type (3b) is considerably lower than that of ethanol. This fact could decrease the content of HCl in the reaction mixture and hinder reaction (3). However, when THF is added in an amount as large as 10 wt %, the reaction is not inhibited; moreover, more inert Me_3SiCl is involved in the process.

Nucleophilic substitution at the silicon atom is accelerated in the presence of strong nucleophiles (DMF, HMPA, F^-, $RCOO^-$, Cl^-) and is a first-order reaction with respect to the initial silane, alcohol, and activating nucleophile [17, 18]. The suggested reaction mechanism involves formation of an intermediate

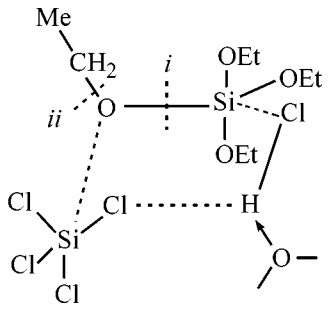
with a five-coordinate Si atom and its subsequent attack by a nucleophile (Nu):



(5)

where X = H, OR, NR_2, Cl.

Presumably, DMF in reaction (2), forming a complex with $SiCl_4$, enhances the nucleophilicity of the Cl atoms. However, THF, dioxane, and diethyl ether are quite inert relative to $SiCl_4$ and $Si(OEt)_4$ [19, 20]. A common property of ethers (and alcohols) is their capability to form oxonium complexes with hydrogen halides. In such complexes, the nucleophilicity of chloride ions is enhanced, and their exchange with ethoxy groups is activated. Presumably, reaction (2) involves formation of a six-membered cyclic transition state in which cleavage of the Si–O bond (i) yields exchange products, and cleavage of the $O–CH_2Me$ bond (ii), heterofunctional cyclization products:



EXPERIMENTAL

The azeotropic mixture $SiCl_4$–Me_3SiCl obtained from synthesis of chlorosilanes[1] contained 49.07% Me_3SiCl, 37.05% $SiCl_4$, 12.00% $MeSiHCl_2$, 0.77% SiH_2Cl_2, 0.74% $SiHCl_3$, and 0.21% $Me_3SiOSiMe_3$.

Chromatographic analysis was performed with a Hewlett–Packard HP 5890 device (EI, 70 eV, HP 5971 A mass-selective detector, 50-m Ultra-2 column coated with polymethylsilicone containing 5% phenyl groups, vaporizer temperature 250°C, column temperature 50–280°C).

Reaction of $Si(OEt)_4$ with $SiCl_4$ in azeotropic mixture with Me_3SiCl in the presence of initiator. (a) A mixture of 10.15 g of $Me_3SiCl–SiCl_4$ azeotrope, 15.6 g of $Si(OEt)_4$, and 1.0 wt % THF was heated for 10 h at 60–65°C and fractionated. Yield of Me_3SiCl 3.3 g (66%), purity 99%.

(b) A mixture of 25.0 g of $Me_3SiCl–SiCl_4$ azeotrope, 11.5 g of $Si(OEt)_4$, and 1.83 g (5.0 wt %) of DMF was heated to reflux for 18 h and cooled to room temperature; the liquid phase was separated by decanting and fractionated.

(c) A mixture of 17.9 g of $Me_3SiCl–SiCl_4$ azeotrope, 10.7 g of $Si(OEt)_4$, and 6.0 g of the complex $SiCl_4 \cdot 2H(O)CNMe_2$ was heated to reflux for 4 h. After cooling to room temperature, the liquid phase was separated from the precipitate (4.9 g) by decanting and distilled to give 5.9 g (67%) of Me_3SiCl, bp 55–56°C; 4.9 g of $(EtO)SiCl_3$, bp 102–105°C; 3.7 g of $(EtO)_2SiCl_2$, bp 137–139°C; and 5.8 g of $(EtO)_3 \cdot SiCl$, bp 156–158°C.

At other reaction times and temperatures and with other amounts of catalysts, the mixtures were worked up similarly. The experimental conditions and reaction products are listed in the table.

Reaction of $Me_3SiCl–SiCl_4$ azeotrope with $Si(OEt)_4$ in the presence of 10 wt % THF. A mixture of 5.08 g of $Me_3SiCl–SiCl_4$ azeotrope, 7.8 g of $Si(OEt)_4$, and 10 wt % THF was heated at 60–65°C for 10 h. The resulting mixture was analyzed by GC–MS. Component content, wt %: Me_3SiCl 7.7, THF 8.5, $(EtO)_2SiCl_2$ 5.5, $(EtO)_3SiCl$ 58.5, $Si(OEt)_4$ 15.0, $(EtO)_3SiOMe_3$ 3.2, $(EtO)_2Si(OSiMe_3)_2$ 1.5, and $EtOSi(OSiMe_3)_3$ and unidentified products <0.5.

Reaction of $SiCl_4$ with $Si(OEt)_4$ in the presence of Et_2O. (a) A mixture of 4.25 g of $SiCl_4$, 5.2 g of $Si(OEt)_4$, and 2 wt % Et_2O was heated at 60–65°C for 10 h and then analyzed by GC–MS. Component content, wt %: Et_2O 0.2, $EtOSiCl_3$ 1.1, $(EtO)_2SiCl_2$ 14.9, $(EtO)_3SiCl$ 76.7, $Si(OEt)_4$ 5.1, and ethoxychloropolysiloxanes 2.0.

(b) A mixture of 1.7 g of $SiCl_4$, 6.24 g of $Si(OEt)_4$, and 2 wt % Et_2O was heated at 60–65°C for 10 h and then analyzed by GC–MS. Component content, wt %: Et_2O 1.6, $EtOSiCl_3$ 22.4, $(EtO)_2SiCl_2$ 2.5, $Si(OEt)_4$ 69.0, $Cl_3SiOSi(OEt)_3$ 2.7, and unidentified compounds 1.8.

CONCLUSION

Treatment of the azeotropic mixture $Me_3SiCl–SiCl_4$ with $Si(OEt)_4$ at 25–65°C in the presence of 0.2–10 wt % cyclic (THF, dioxane) or acyclic (diethyl ether) ethers, ethanol, or dimethylformamide allows isolation of 99% pure trimethylchlorosilane in up to 88% yield.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Spectrophotometric Study of Interaction in the System Sodium Dodecyl Sulfate–Cetylpyridinium Chloride–Methylene Blue

T. V. Vladimirova and E. E. Morgunova

Institute of Solution Chemistry, Russian Academy of Sciences, Ivanovo, Russia

Received May 7, 2001

Abstract—Complexation of a cationic dye (Methylene Blue) with anionic and cationic surfactants (sodium dodecyl sulfate and cetylpyridinium chloride) was studied spectrophotometrically. The formation constants of complexes formed in the system were estimated. Dispersion of the investigated system was studied as a function of time and cetylpyridinium chloride concentration.

The presence of surfactants in wastewater overburdens the treatment by commonly accepted methods. By virtue of the fact that surfactants are physically and chemically reactive compounds, it is significant to know which components of waste they can interact with and what degree of their decomposition is reached as a result.

Multicomponent systems containing two or more different surfactants are of considerable theoretical interest and practical significance. For example, systems containing a surfactant and a dye are widely used in textile manufacture, making it topical to study interaction between compounds of various classes in solutions.

Previously, we studied the interaction in systems cationic dye–anionic surfactant and cationic dye–anionic surfactant–nonionic surfactant [1].

It is known [2] that cationic surfactants may exist in the presence of anionic surfactants in three forms: (1) monomers (unassociated molecules), (2) mixed micelles (after reaching CMC), and (3) precipitated solid (at concentration above the product solubility).

It has been demonstrated previously [1] that Methylene Blue (MB) and sodium dodecyl sulfate (SDS) form an ionic associate in solution.

EXPERIMENTAL

The concentrations of MB (cationic dye), DDS (anionic surfactant), and cetylpyridinium chloride (CPC) (cationic surfactant) in the system investigated were 10^{-3}, 10^{-2}, and 10^{-3} M, respectively. The quality of SDS and CPC was determined as in [3]. The optical density of the solutions was measured on an SF-46 spectrophotometer over the range 200–700 nm at $l = 1$ cm. The residual concentration of SDS and CPC was determined photometrically after extraction with chloroform [4].

To estimate the scattering factor F_r, we measured the absorption spectra over the range 500–700 nm and then determined the slope of the linear portion of the $\ln A$–$\ln \lambda$ plot. The size of colloid aggregates was determined turbidimetrically [5]. The solution turbidity was estimated as $\tau = 2.3A/l$, where A is the optical density measured at $\lambda = 400$ nm and l is the layer thickness.

We measured absorption spectra of MB over a wide concentration range in the presence of SDS and CPC. In the visible range, we found formation of no associates other than the ionic associate SDS–MB. In the UV range, we observed changes in the shapes and positions of absorption bands in the systems MB–CPC and MB–SDS–CPC as compared with the spectra of the individual compounds (Fig. 1). These evolutions reflect the interaction occurring in the investigated systems, suggesting the formation of new compounds [6]. From the optical density data obtained in solutions with various concentrations of the components, the logarithms of the association constants ($\log K$) for MB–SDS, MB–CPC, and MB–CPC–SDS were estimated by the procedure described in [7] to be 2.50 ± 0.09, 4.66 ± 0.33, and 8.42 ± 0.55, respectively.

Presumably, formation of MB–CPC–SDS is caused by both coulombic and hydrophobic interactions [6].

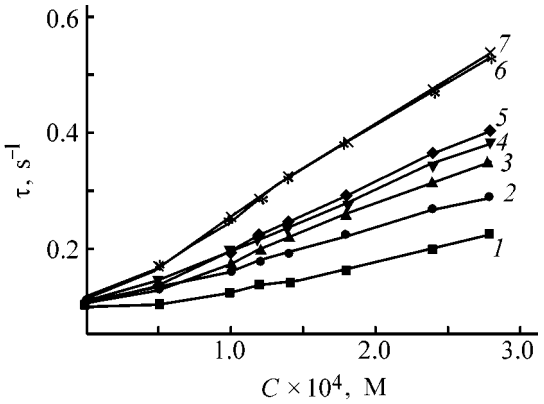

Fig. 2. Solution turbidity τ in the system MG–SDS–CPC vs. the CPC concentration *C*. Time elapsed after solution preparation (h): (*1*) 0, (*2*) 1, (*3*) 2, (*4*) 3, (*5*) 4, (*6*) 22, and (*7*) 24.

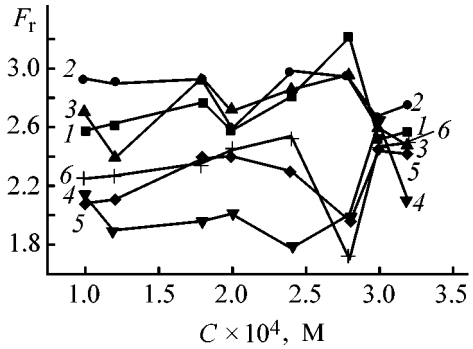

Fig. 4. Effect of the CPC concentration *C* on the scattering factor F_r in the systems (*1–3*) SDS–CPC and (*4–6*) MG–SDS–CPC. Time elapsed after system preparation (h): (*1*, *4*) 0, (*2*, *5*) 1, and (*3*, *6*) 2.

Interaction of the cationic dye, MB, having a delocalized positive charge [8], with the cationic surfactant, CPC, probably proceeds by the mechanism similar to micelle formation. Such interactions have been observed, for example, for merocyanine dyes with surfactants and chrome dyes with lignosulfonic acid [10].

In our experiments, as the CPC concentration in the system increases, the MB and SDS concentrations being unchanged, the initially clear, homogenous solution becomes opalescent. Similar changes (appearance of opalescence) were also observed in aging of initially homogeneous MB–SDS–CPC solutions, suggesting that this system is thermodynamically unstable.

The solution turbidity grows with increasing CPC concentration (Fig. 2) and time (Fig. 3). The turbidity increases more rapidly in the first 4 h after decanting, but continues even a month later.

The size of colloid aggregates of the associates MB–SDS–CPC and SDS–CPC was estimated from the scattering data. It is seen from Fig. 4 that both the associates are aggregatively stable over a broad concentration range and may be classified with colloids by their size ($F_r < 4$). Over the CPC concentration range $(1–2.8) \times 10^{-4}$ M, the colloid aggregates MB–SDS–CPC have larger radius, and their solutions, lower F_r than those of SDS–CPC aggregates. At a CPC concentration above 3×10^{-4} M the threecomponent system becomes more stable with time: during the first 1 h after solution preparation, the size of colloid aggregates MB–SDS–CPC increases and then remains practically unchanged. The system SDS–CPC is more aggregatively stable in time.

We also performed experiments on removal of the dye, SDS, and CPC from the solution by sorption on freshly precipitated aluminum hydroxide, using the procedure described in [1]. The results are given in

Degree of removal of MB, SDS, and CPC at various CPC initial concentrations C^*

$C \times 10^4$, M	Degree of removal, %		
	dye	SDS	CPC
2.0	99	89.2	99.9
2.8	99	88.2	98.8
3.2	99	89.1	99.5

* pH 4.5; $Al_2(SO_4)_3$ concentration 1.9 g l^{-1}; the initial dye concentration 10^{-5}; and SDS concentration 2×10^{-3} M.

the table. As seen, the sorption allows efficient clarification of the solution and removal of up to 90% of the anionic surfactant and up to 99% of the cationic surfactant.

CONCLUSIONS

(1) The logarithms of the formation constants of associates formed in the investigated system are determined to be 2.50 ± 0.09, 4.66 ± 0.33, and 8.42 ± 0.55 for Methylene Blue–sodium dodecyl sulfate, Methylene Blue–cetylpyridinium chloride, and Methylene Blue–cetylpyridinium chloride–sodium dodecyl sulfate, respectively.

(2) The associates Methylene Blue–sodium dodecyl sulfate–cetylpyridinium chloride are aggregatively stable over the CPC concentration range $(1–3.2) \times 10^{-4}$ M and may be classified with colloids by their size ($F_r < 4$).

(3) The possibility of simultaneous recovery of the cationic dye and anionic and cationic surfactants from solutions by coagulation with aluminum hydroxide is demonstrated.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

In memory of distinguished physical chemist and outstanding person Professor Ariel' Abramovich Abramzon

Optimization of the Component Concentrations in Solutions of Synthetic Detergents

A. A. Kotomin, M. B. Petel'skii, A. A. Abramzon,† A. E. Punin, and O. D. Yakimchuk

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received April 25, 2001

Abstract—The detergency of formulations composed of organic and inorganic components that form the basis of synthetic detergents was studied. Mathematical design of experiment—method of orthogonal Latin rectangles, was applied to determine the component concentrations corresponding to the maximal detergency. Thus obtained concentrations of the detergent components in aqueous solutions can be used for optimization of the detergent formulation.

Detergency is of great practical importance both in household and in industrial sectors, but its mechanism is far from comprehensive understanding now. In our previous work [1], we discussed the detergency of individual components of synthetic detergents. In this work, we studied detergency of a formulation as a whole as influenced by its formula. This approach is essential for development and application of detergents.

At the present, detergent formulations are composed empirically, because physicochemical mechanisms of elementary events in detergency have been studied inadequately. Modern methods of mathematical designing of experiments can yield a mathematical model of a chemical process even when its mechanism is unknown. Also, mathematical designing of experiments significantly reduces the number of experiments and minimizes the costs involved [2].

In this work, we determined the optimal concentrations of the components of complex detergent mixtures by the method of orthogonal Latin rectangles. The method consists in assessing the variation of the output parameter (in our case, detergency) by varying to a certain extent the influencing factors, namely, the concentrations of the components. These concentrations were varied at four levels. According to the scheme of orthogonal design, the number of experiments was in the formulation, and $i = 4$ is the number of the concentration variation levels (Table 1). In this scheme, each concentration of one of the eight components is combined with each concentration of any other component the same number of times (two in our case) [3].

$n \times i = 32$, where $n = 8$ is the number of components

More than 50-year practice of using detergents showed what components endow the composition with high efficiency and desired consumer's properties [4–8].

Modern detergents have surfactants (typically, anionic and nonionic ones) as the major components [9]. By combining these two types of surfactants, as well as high-molecular-weight surfactants stabilizing contaminants in solutions and preventing their resorption onto the surface to be cleaned and substances binding the hardness salts, it is possible to gain the optimal effect. The most widely used components are sodium tripolyphosphate; sodium carbonate which imparts alkalinity to solution; silicates, in particular, sodium metasilicate, which are protecting colloidal systems; substances that chemically and biologically degrade contaminants; oxidizing and bleaching agents (e.g., peroxy salts), as well as enzymes; and optical bleaching agents, that is, substances "painting over" contaminants.

Also used are components that virtually do not contribute to removal of contaminants: sodium sulfate (provides friability of the detergent formulation), hydrotrops (facilitate dissolution of organic compounds

† Deceased.

in water), and enzyme stabilizers. Fragrances and dyes make the formulation aesthetically attractive.

In this work, we studied substances that facilitate surface decontamination: linear sodium alkylbenzenesulfonate C_{10-14}–$(C_6H_4)SO_3Na$, Synthanol DS-10 C_{10-18}–$O(C_2H_4O)_{10}H$, anhydrous sodium carbonate Na_2CO_3, sodium tripolyphosphate $Na_5P_3O_{10}$, sodium hydrosilicate $2SiO_2 \cdot Na_2O \cdot 2H_2O$, sodium sulfate Na_2SO_4, sodium percarbonate $Na_2C_2O_6$ and sodium perborate $NaBO_3 \cdot 4H_2O$, and sodium salt of carboxymethyl cellulose $[C_6H_7O_2(OH)_{3-x}$–$(OCH_2COONa)_x]_n$.

Detergency involves a number of successive events ensuring separation of contaminants and their emulsification in aqueous solutions [8]: (1) surface wetting and displacement of contaminants; (2) dispersion of contaminants; (3) stabilization of contaminants in aqueous solution; (4) solid surface protection; (5) solubilization; (6) chemical and biological degradation of contaminants; and (7) foaming.

These elementary events are qualitatively clear, but there is no equation to describe them. Numerous attempts to develop the detergency theory on the basis of a thermodynamic approach have been unsuccessful. In our opinion, the most practically promising way is to establish experimentally a correlation between the detergency, on the one hand, and the detergent formulation and process conditions, on the other. In the first stage, we obtained systematized experimental data concerning the detergency of individual components of detergents depending on their concen-

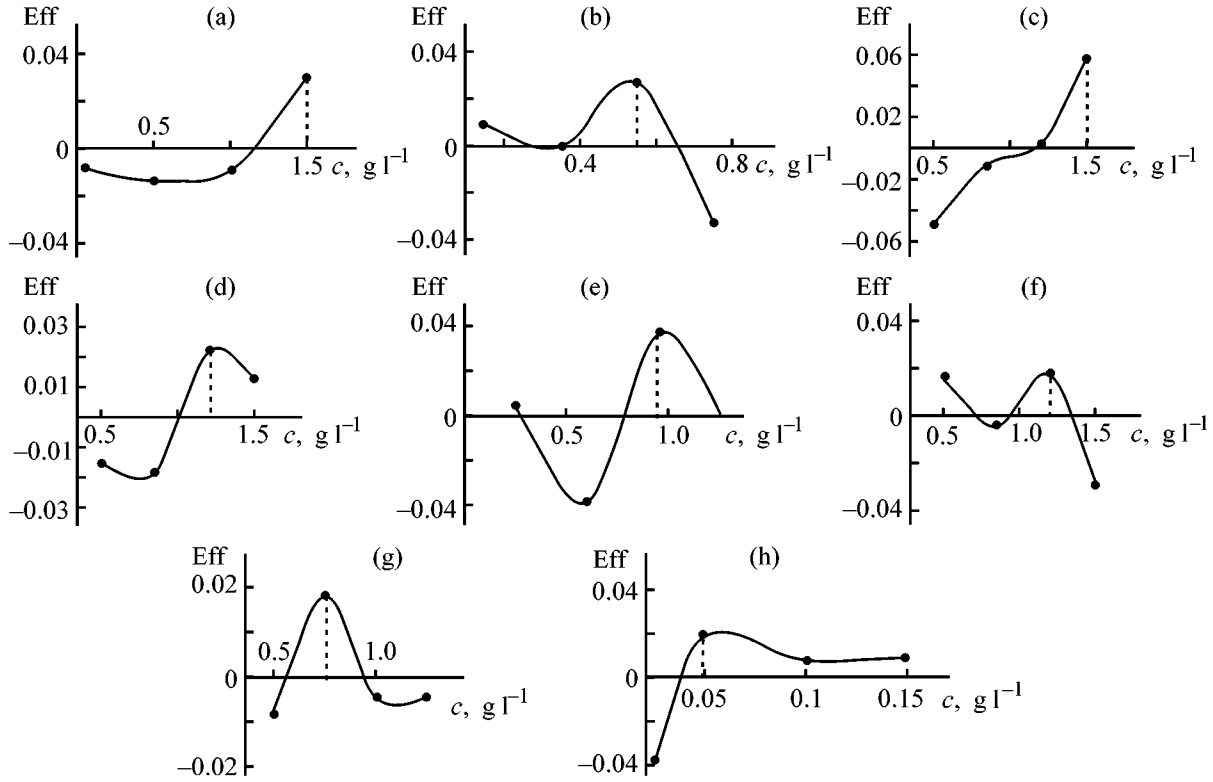

Fig. 1. Component effect Eff vs. component concentration *c*, in solutions. Solution: (a) SABS, (b) Synthanol DS-10, (c) Na_2CO_3, (d) STPP, (e) SHDS, (f) Na_2SO_4, (g) $Na_2C_2O_6$, and (h) NaCMC.

tration in aqueous solutions [1]. In this work, we studied more complex objects—detergent formulations.

We studied aqueous solutions of detergent formulations in two practically important concentration ranges: 1–10 and 15–40 g l^{-1}, characteristic of detergents intended for household and technical application, respectively. A separate study of these two concentration ranges affords a better sensitivity in solving the optimization problems. The variation ranges for concentrations of each component of a detergent formulation were suggested by published data [6–9] and the authors' experience.

Detergency was estimated from variation of the whiteness of a cotton fabric during washing out of the contaminants from the detergent solution under study [1]. The detergencies obtained were compared for all the solutions studied with that of a standard solution M_{st} determined under identical conditions. The standard solution corresponded to OST (Branch Standard) 6-15-1574–87 and contained SABS (1 g l^{-1}) and STPP (2 g l^{-1}). The results obtained were analyzed using the relative detergency of a substance $\overline{M} = M/M_{st.}$

Table 1 presents for the concentration range 1–10 g l^{-1} the experimental $\overline{M}$ values for each of the detergent formulations made up by the orthogonal Latin rectangle scheme.

For all the components at each concentration c_i we estimated the effect of the component on the formulation detergency:

$$\mathrm{Eff}_{c_i} = \frac{\sum_{c_i}\overline{M}}{8} - M_{av}. \quad (1)$$

Here, $\sum_{c_i} \overline{M}/8$ is the average $\overline{M}$ value for all the cases when the component concentration c_i was at the *i*th level, and $\overline{M}_{av}$ is the average relative detergency for the whole experimental series.

For each component we plotted the component effect Eff vs. concentration in solutions *c* (Fig. 1). This made it possible to determine the optimal concentrations of the components corresponding to maximal effects. The plots show that the maximal detergency of solutions should be afforded by the following concentrations of the components, g l^{-1}: SABS 1.5, Synthanol 0.55, Na_2CO_3 1.5, STPP 1.2, SHDS 0.95, Na_2SO_4 1.2, $Na_2C_2O_6$ 0.75, and NaCMC 0.05. The total concentration of components in solution amounts to 7.7 g l^{-1}. It should be noted that none of the 32

experiments involved such concentration ratio for the components.

Next, using the optimal concentrations of the components in solutions, we formulated the corresponding composition OK-1 and studied its detergency in the concentration range 0.5–10 g l^{-1}. The resulting plot of $\overline{M}$ vs. concentration of this formulation in solution is shown in Fig. 2. Combined analysis of the data in Fig. 2 and Table 1 shows that the maximal detergency of the formulation is observed not only at the total concentration of the components of 7.7 g l^{-1}, as yielded by optimization, but also throughout the concentration range covered (0.5–10 g l^{-1}). Thus, the ratio of the chosen components should be considered the optimal for the low-concentration range.

We have shown previously [1] that the relative detergency and the concentrations of individual components, as well as the parameters $1/\overline{M}$ and $1/c$, are related by linear dependences. For the optimal formulation OK-1 prepared by us, the plot of $1/\overline{M}$ vs. $1/c$ is close to a straight line (Fig. 3, straight line *1*), with correlation factor of 0.994. This confirms the validity of the detergency equation derived by us in [1]:

$$\overline{M} = \frac{\overline{M}_{\max} c}{\alpha + c}. \qquad (2)$$

Here, $\overline{M}_{\max}$ is the maximal relative detergency, and α is the coefficient having the dimensionality of the concentration and depending on the energy parameters of the process.

Based on the data presented in Fig. 3, we estimated for the formulation OK-1 the $\overline{M}_{\max}$ and α values to be 1.49 and 1.22, respectively.

Similarly, we optimized the concentrations of the components for the concentration range 15–40 g l^{-1}. The formulations had the same qualitative composition as that at low concentrations, except for the bleaching agent. In this case, sodium perborate $NaBO_3 \cdot 4H_2O$ served as bleaching agent. The optimal concentrations of the components were estimated as follows, g l^{-1}: SABS 1.0, Synthanol 2.0, STPP 4.0, Na_2CO_3 4.0, SHDS 2.5, NaCMC 0.7, sodium perborate 6.0, and Na_2SO_4 1.0. The total concentration of the components in solution was 21.2 g l^{-1}.

The plot of the relative detergency vs. concentration for the optimal component ratio (formulation OK-2) looks similar to that obtained for low concentrations. The detergency is also at a maximum not only for the total component concentration yielded by optimization, 21.2 g l^{-1}, but also throughout the 15–40 g l^{-1} range. In this concentration range, the solutions are saturated, and an extensive factor, i.e., the total concentration of the components, is of less importance, whereas the mutual influence of the components (closeness of their ratio to the optimum) is of greater importance. The plot of inverse relative detergency vs. inverse concentration for the OK-2 formulation, $1/\overline{M}$–$1/c$, is also described by a straight line with correlation factor of 0.992 (Fig. 3, curve *2*). The maximal detergency $\overline{M}_{\max}$ and parameter α were estimated for this optimal formulation to be 1.56 and 1.52.

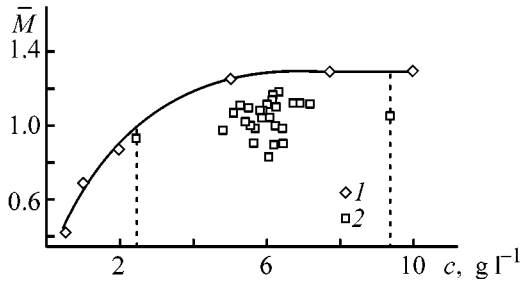

Fig. 2. (*1*) Relative detergency $\overline{M}$ of the optimal formulation OK-1 vs. the concentration c, in aqueous solutions and (*2*) experimental $\overline{M}$ values for formulations derived from the experimental design matrix (Table 1).

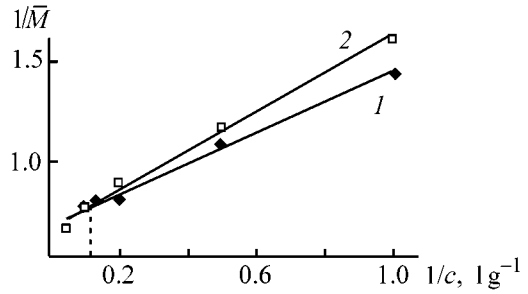

Fig. 3. Inverse relative detergency $\overline{M}$ vs. inverse concentration $1/c$, for the optimal formulations in the range of (*1*) low and (*2*) high concentrations.

The numerical values of the parameters $\overline{M}_{\max}$ and α can serve as convenient characteristics of the detergency of solution. The maximal relative detergency characterizes the maximum attainable detergency at the detergent concentration in solution tending to infinity, and α is related to the rate of the $\overline{M}$ growth with increasing concentration. The greater $\overline{M}_{\max}$ and the smaller α, the more effective is the detergent solution. The parameter α plays especially significant role in the low-concentration range of detergent solutions.

The parameter α has the dimensionality of concentration, and formula (2) shows that it must be numerically equal to the concentration corresponding to the detergency of $1/2\overline{M}_{\max}$. Table 2 compares the experimental c values obtained at $\overline{M} = 1/2\overline{M}_{\max}$ and the α values calculated as the slope of the

Table 2. Experimental values of the concentration c for $\overline{M} = 1/2\overline{M}_{max}$ and of the parameter α

* C_{9-12}–(C_6H_4)–$O(C_2H_4O)_{12}H$.

** C_{10-18}–COONa.

*** OK-1 and OK-2 are the optimal detergent formulations for low- and high-concentration ranges of solutions, respectively.

$1/\overline{M}$–$1/c$ dependence multiplied by $\overline{M}_{max}$ for individual components of detergents [1] and the formulations prepared in this work. Table 2 shows that the calculated and experimental values of α and concentrations agree reasonably at $\overline{M} = 1/2\overline{M}_{max}$.

Figure 3 compares the plots of inverse detergency vs. inverse concentration for the optimal formulations in the range of (1) low and (2) high concentrations. The resulting straight lines actually intersect, and the intersection point corresponds to the concentration of 8.4 g l^{-1}, below which a greater detergency is achieved at the component ratio obtained for the low concentration range (OK-1 formulation) and above which the formulation optimized for high concentrations is more effective (OK-2 formulation).

The method of mathematical designing of experiment allows optimization of detergent formulations not only with respect to one output parameter, detergency (as in this work), but also with respect to several paramaters. As optimization criteria can serve prime cost and environmental, technological, and consumer's attractiveness of a detergent formulation. Other influencing factors are, along with concentration, temperature, time, hydrodynamic parameters of detergents process, etc.

CONCLUSIONS

(1) The synthetic detergent formulations can be optimized by mathematical designing of the experiment, using the orthogonal Latin rectangles method. An experimental-statistical model of detergency was developed; the optimal concentrations of the main organic and inorganic components in solutions of synthetic detergents, affording the maximal detergency, were determined.

(2) The equation derived, which relates the detergency to the concentration in aqueous solutions, is valid for both individual components and complex detergent formulations. The physical meaning of the parameters $\overline{M}_{max}$ and α in the detergency equation was disclosed. These parameters were proposed as quantitative characteristics of detergency of synthetic detergent formulations.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

High-Molecular-Weight Compounds and Related Materials Cross-Linking of Macrochains in Thermal Degradation of Poly(Vinyl Chloride)

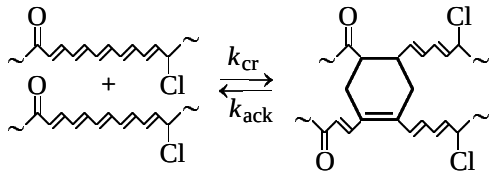
Abstract—Macrochain cross-linking in thermal degradation of PVC was studied. The onset time of gelation was determined as a function of the content of oxoallyl groups in the polymer.

Macrochain cross-linking is thought to be among the reactions leading to breakdown of the conjugated chain in polyene sequences formed in degradation of poly(vinyl chloride) (PVC). In the absence of agents promoting cross-linking by the radical mechanism, this reaction proceeds via the Diels–Alder mechanism [1–3]. This conclusion is supported by the following experimental results: (1) in the presence of reactive dienophiles (maleic anhydride, maleic acid esters or metal salts) reacting with polyene blocks via the Diels–Alder mechanism, the onset time of gelation in degraded PVC increases [1]; (2) in treatment of the cross-linked polymer with maleic anhydride, the gel phase is degraded by virtue of diene recondensation of polyenes with the stronger dienophile [2], suggesting also that the macrochain cross-linking in PVC is a reversible reaction; (3) the closeness of the kinetic parameters of PVC macrochain cross-linking in thermal degradation ($E_a = 50 \pm 8$ kJ mol^{-1}, $\log A = 6.3 \pm 0.5$ [3]) to those of the Diels–Alder reaction (E_a = 40–80 kJ mol^{-1}, $\log A$ = 5–7 [4]); and (4) modification of PVC with conjugated dienes increases the onset time of gelation in thermal degradation as compared with the initial polymer as a result of competition of the cross-linking and the reaction of conjugated dienes with polyenes [5].

It was suggested in [3, 6] that the cross-linking proceeds with participation of polyene sequences (ketopolyenes), such as ~C(O)–(–CH=CH–)$_n$~. In this case, each block of conjugated C=C bonds can serve as both a diene and a dienophile.



If PVC macrochain cross-linking involves polyene sequences whose formation is initiated by the oxoallyl (OA) groups ~C(O)–CH=CH~, as the gel fraction is formed, the sol fraction must be depleted in polyene sequences of the type ~C(O)–(–CH=CH–)$_n$~. The amount γ_0 of such ketopolyenes can be easily determined by the hydrolytic cleavage method as the change in the intrinsic viscosity of the sol fraction after alkaline hydrolysis of PVC [7]:

$$\gamma_0 = \frac{62.5 \times 1.86}{\overline{M}_v^0}\left\{\left(\frac{\eta_0}{\eta}\right)^{1.38} - 1\right\}, \qquad (1)$$

where η_0 and η are the intrinsic viscosities before and after macrochain degradation and $\overline{M}_v^0$ is the initial viscosity-average molecular weight.

Indeed, the experimental results show (Fig. 1) that the amount of ketopolyenes in the sol fraction gradually decreases with increasing PVC degradation time. Therefore, one may suggest that the macrochain cross-linking in PVC degradation directly involves polyene sequences whose formation is promoted by OA groups.

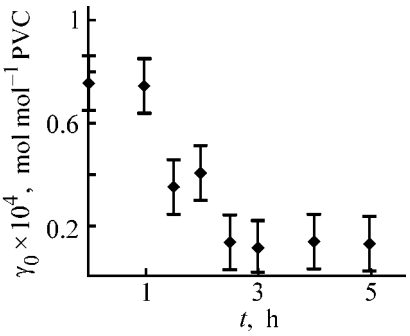

Fig. 1. OA group content γ_0 in the sol fraction of degraded PVC vs. degradation time *t*. Polyvinyl chloride S-70 ($\overline{M}_v$ 110 000).

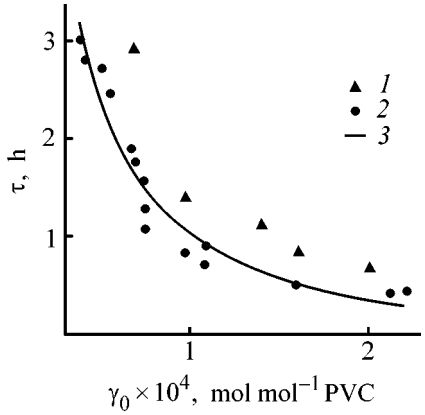

Fig. 2. Gelation time τ vs. the OA group content in PVC. Temperature 448 K; pressure 1×10^{-2} Pa. (*1*) Continuous removal of HCl [6], (*2*) barium stearate added, and (*3*) estimated by Eq. (3) at $n = 1.26$.

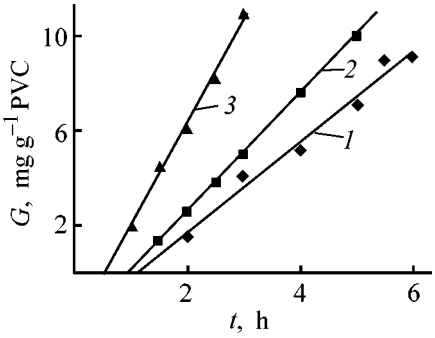

Fig. 3. Amount of gel *G* formed in thermal degradation of PVC. Pressure 1×10^{-2} Pa; $BaSt_2$. (*t*) Time. OA group content $\gamma_0 \times 10^{-4}$: (*1*) 0.76, (*2*) 0.098, and (*3*) 1.60.

However, cross-linking of only ketopolyene sequences cannot produce the observed yield of the gel phase at a degradation time much over the onset time of gelation τ [6, 8], since the fraction of the OA-containing PVC molecules is small (8–10%). Therefore, diene recondensation may occur at later stages of PVC degradation, with polyene blocks formed as a result of activation by β-chloroallyl groups originating from HCl elimination in ordinary VC units and tertiary chloride groups [3]. In performing PVC degradation in the presence of barium stearate, an effective acceptor for HCl, the reverse reaction of HCl addition to polyene sequences is suppressed [9]. In this case, the most probable secondary reactions are macrochain cross-linking [1–5] and polyene cyclization [10]. It has been demonstrated previously [6] that the onset time of gelation depends on the OA group content (Fig. 2, curve *1*). In the study cited, thermal degradation of PVC was performed with continuous removal of HCl from the reaction zone by freezing.

To obtain the best suited equation for τ as a function of γ_0, it is necessary to study experimentally this dependence over a wide range of γ_0. At the same time, γ_0 of the ordinary commercial and laboratory samples of PVC varies within a narrow range $(0.8–1.4) \times 10^{-4}$ mol mol^{-1} PVC. That is why samples with low OA group content were specially prepared in the present study by modification of PVC with maleic anhydride [11]. This reaction provides irreversible decrease in the OA group content in PVC. As a result, the rate of its dehydrochlorination decreases by virtue of decreasing amount of polyene sequences formed. The characteristics of thus modified PVC are given in the table. At low OA group content in PVC the error of γ_0 determination from viscometric data by Eq. (1) is high. Therefore, this parameter for modified PVC (γ_0^m) was occasionally estimated more exactly by Eq. (2).

$$\gamma_0 = (V_{HCl} - V_c)/k_p, \quad (2)$$

where V_{HCl} is the experimental rate of rough dehydrochlorination (see the table), $V_c = 0.8 \times 10^{-7}$ mol mol^{-1} PVC s^{-1} is the rate of HCl elimination from ordinary PVC units, and $k_p = 0.75 \times 10^{-2}$ s^{-1} is the constant of HCl elimination from polyene sequences [3].

Typically, the dependence of the amount of the gel phase formed on the PVC degradation time is linear; the onset time of gelation was determined by linear extrapolation of the plot to the abscissa (Fig. 3).

Performing the reaction in the presence of barium stearate inhibits readdition of HCl to polyenes to a greater extent, as demonstrated by the decrease in the gelation time as compared with the preceding case (Fig. 2, curve *2*).

Generally, the dependence τ–γ_0 can be fitted to Eq. (3).

$$\tau = C\gamma_0^{-n}, \quad (3)$$

where *n* is the order of macrochain cross-linking by the conjugated bond blocks.

* (τ_m) Modification time.

** Estimated by Eq. (3).

Processing of the logarithmic form of Eq. (3) by the least-squares method gives $n = 1.26 \pm 0.17$ (r 0.979) at a 0.95 confidence level.

Thus, the reaction order with respect to ketopolyenes is close to unity. Therefore, it appears more probable that macrochain cross-linking in thermal degradation of PVC is caused not only by interaction of the polyene blocks, as suggested previously [6], but also, and to a greater extent, by the reaction of the polyenes with other unsaturated groups in PVC macrochains. Among such groups can be unsaturated terminal groups whose content in PVC is about 10^{-3} mol mol^{-1} PVC [2], and backbone β-chloroallyl moieties formed in PVC thermal degradation via random elimination of HCl from both the tertiary chloride and ordinary units of the macrochain.

EXPERIMENTAL

PVC was modified according to the procedure described in [11]. Degradation of PVC was performed at 448 K in sealed ampules evacuated to a residual pressure of 10^{-2} Pa. The liberated HCl was absorbed with barium stearate and then determined mercurometrically. The gel fraction of degraded PVC was washed and then separated by centrifugation with fresh portions of cyclohexane in the same ampules. To remove unreacted $BaSt_2$, the precipitate was triply washed with decyl alcohol at 373 K. The resulting gel was triply washed with ether to remove the residual solvent and dried to constant weight at 348 K. The error of determination of the gel amount G was within 10%. The gelation time was determined by linear extrapolation of the G-vs.-t plot to the abscissa axis. Alkaline hydrolysis of PVC and measurement of the intrinsic viscosity to determine the oxoallylgroup content were performed as in [7].

The sol fraction of degraded PVC was prepared by centrifugation for 1 h at 5000 rpm.

CONCLUSION

It was confirmed experimentally that cross-linking of macrochains in thermal degradation of PVC to proceeds by the Diels–Alder mechanism, which involves conjugated bond blocks formed in activation with oxoallyl moieties serving as dienes and with unsaturated terminal and inner β-chloroallyl moieties as dienophiles.

Research Institute for Physicochemical Problems, Belarussian State University, Minsk, Belarus

Received January 30, 2001

Abstract—Kinetics of potato starch oxidation by dinitrogen tetroxide in CCl_4 was studied as influenced by the oxidant concentration, temperature, and starch to N_2O_4 ratio. The starch oxidation products were analyzed by IR spectroscopy.

Starch is a mixture of polysaccharides, amylopectin and amylose, differing in their degree of polymerization, macromolecular packing, and nature of bonding between the α-*D*-anhydroglucopyranose units. Starch is widely used in textile, food, paper, and other branches of industry. In pharmacology, starch and some of its derivatives (carboxymethyl starch, hydroxyethyl starch, etc.), having low toxicity and good assimilability in the organism, serve exclusively as aids in manufacture of pills, pastes, and suspensions.

At the same time, high reactivity of the polysaccharide components of starch allows purposeful synthesis of starch derivatives and introduction of functionalities, imparting required medicobiological properties to the product, on the basis of modern concepts of processes occurring in living bodies. In this case, it is possible to obtain both substances of bioactive compounds and derivatives suitable for immobilization of various drug preparations with the purpose of their durable action on the basis of starch or its polysaccharides.

Starch oxidation products containing carboxy groups show promise for these purposes. Data are available on oxidation of starch with various oxidizing agents ($KMnO_4$, Br_2, NaClO, etc.) aimed at preparation of starch derivatives capable of forming pasters of a preset viscosity [1–3]. However, the abovementioned oxidants are not selective, and the resulting oxidation products are structurally nonuniform. The most selective oxidants for polysaccharides are periodic acid and dinitrogen tetroxide. The former oxidizes primarily the hydroxy groups at the positions C_2 and C_3 of the elementary unit to aldehyde groups, and the latter, the hydroxy groups at the position C_6 to carboxy groups. The product of oxidation with periodic acid, starch dialdehyde, is used in medicine as a sorbent for ammonia and urea in peroral treatment of patient with uremia [4], and Li and Na salts of starch oxidized with dinitrogen tetroxide demonstrate analgesic, antipyretic, and antidysrhythmic effects [5, 6]. However, oxidation of starch and its polysaccharides by dinitrogen tetroxide is not virtually understood yet [7, 8], which hampers targeted synthesis of carboxy derivatives with fixed degree of oxidation and desired physicochemical and medicobiological properties. Therefore, we studied in this work the effects of various factors on the kinetics of starch oxidation by dinitrogen tetroxide in tetrachloromethane. The starch oxidation products were characterized by IR spectra.

EXPERIMENTAL

As starting materials we used potato starch (amylose content 23.8 wt %, degree of polymerization (DP) 1760, ash content 0.31%, moisture content 12.5%, and acid number 15.5 [9]); CCl_4 (analytically pure grade), and N_2O_4 containing <2 wt % of foreign compounds (recalculated to nitric acid).

Starch was oxidized at 0–18°C in CCl_4 with 5, 10, 20, and 60 wt % N_2O_4 at various starch : N_2O_4 molar ratios. A dispersed weighed portion of starch in a fixed volume of the reaction mixture was allowed to stand at a prescribed temperature for a fixed time. Then oxidized starch was separated from the solution on

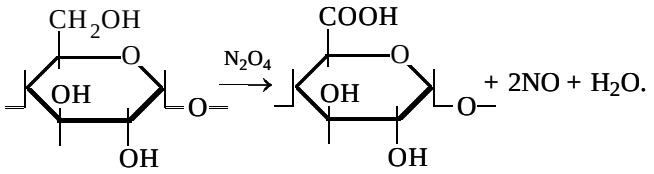
1070-4272/01/7412-2106 $25.00 © 2001 MAIK "Nauka/Interperiodica"

a glass filter no. 1, washed with a water/isopropanol mixture (1 : 1 by volume) to neutral reaction, and air-dried at room temperature. The oxidation kinetics was monitored by increase in the carboxy group content, using the Ba acetate method [10]. The selectivity of oxidation was monitored by means of IR spectra recorded in the range 400 – 4000 cm^{-1} in KBr pellets (Specord IR-75 spectrometer). The carbonyl group content was determined by the modified hydroxylamine method [11]. The degree of substitution (DS) with respect to COOH groups was estimated as

$$DS_{COOH} = \frac{162.15C_{COOH}}{4500 - 14C_{COOH}},$$

where 162.15 is the molecular weight of an anhydroglucopyranose unit and C_{COOH} is the carboxy group content (wt %).

Starch oxidation by dinitrogen tetroxide proceeds essentially by the following scheme:



Depending on the reaction conditions, side reactions may occur, which results in insignificant accumulation of carbonyl and nitro ester groups in the polysaccharide macromolecules. The yield of oxidized starch in all cases approaches 100%, i.e., no soluble low-molecular-weight products are formed.

The effect of the starch : N_2O_4 molar ratio at constant oxidant concentration on the starch oxidation rate is demonstrated in Fig. 1a. Raising the amount of the oxidant, all other conditions being equal, provides an increase in both the carboxylation rate and degree of oxidation over the experimental time interval. Raising the amount of the oxidant further, to above 10 mol per mole starch units, provides no additional gain in the indicated parameters. Therefore, all the subsequent kinetic experiments were carried out at a 10-fold excess of N_2O_4 against the stoichiometric amount needed for total oxidation of the primary hydroxy groups to carboxy groups.

With the N_2O_4 concentration increasing from 5 to 20 wt % at constant reactant ratio (1 : 10), the degree of oxidation and the reaction rate constant k grow (Fig. 1b, Table 1), which can be attributed to the activating effect of the oxidant polar molecules initiating rupture of the intermolecular hydrogen bonds.

droxymethyl groups for the oxidant, have only a slight effect on the reaction, since only the linear polysaccharide of starch, amylose, shows pronounced tendency to crystallize, while the content of the highly branched amorphous amylopectin in starch approaches 80 wt %. As a result, starch grains absorb the oxidizing mixture quite rapidly, which produces their strong swelling, increasing with the N_2O_4 concentration in CCl_4. With the oxidant concentration increasing further, to 60 wt %, the reaction rate constant no longer changes (Table 1), so that the kinetic curves *1* and *2* virtually coincide, and one can say that, under the experimental conditions used, 20 wt % N_2O_4 in CCl_4 provides the maximal rate of reagent diffusion to the active centers.

Note that the moisture content in the initial starch is an important factor influencing the oxidation rate and the maximal content of the COOH groups in 5-carboxy starch (Fig. 1b). The results show that even after a 17-h oxidation of starch dried to constant weight with N_2O_4 in CCl_4, the COOH content is as low as 1.35 wt % (DS_{COOH} = 0.049). Probably, this is due to the fact that hydration water immediately participates in the initial or intermediate oxidation stages and also promotes reagent penetration to active centers of the macromolecules and rapid swelling of the polysaccharide. It is also known [12] that hydration water influences the chain conformation so that even an insignificant decrease in the moisture content initiates a polymorphic transformation of starch B into starch A, in which the linear chains take the place of hydration water stacks, also decreasing the accessibility of the hydroxymethyl groups to the reagent. It was demonstrated in our experiments that dry starch does not swell in the reaction mixture throughout the process, and the observed insignificant formation of carboxy groups is probably due to surface oxidation of the starch grains.

The experimental data (Table 1) were processed using the Erofeev–Kolmogorov topokinetic equation [13].

$$\alpha = 1 - \exp(-K\tau^n),$$

where α is the degree of conversion of starch by a time τ, K is a constant, and n is the kinetic factor.

The reaction order n was determined from the slope of the anamorphoses. The results suggest that the reaction is chemically controlled in most cases (condition $n \geq 1$). Also, the estimated effective activation energy E_a is too high for the diffusion-controlled kinetics to be the case [14].

To obtain the apparent rate constants of starch oxidation, we used the equation proposed by Sakovich [15]:

$$\log k = \frac{1}{n}\log K + \log n,$$

where K and n are the parameters of the Erofeev–Kolmogorov equation, and k is the oxidation rate constant.

Raising the temperature of the reaction mixture from 0 to 18°C results in an abrupt growth in the reaction rate in the correspondence with van't Hoff's law. The estimated n values suggest that, with temperature increasing in the experimental temperature range, the reaction passes from the diffusion to kinetic control. This may be associated to some extent with increasing degree of dissociation of N_2O_4 with the formation of more reactive NO_2.

Formation of carboxy groups can be monitored by the strong band at 1743 cm^{-1} due to C=O stretching vibrations in the IR spectrum of oxidized starch (Fig. 2). Oxidation of the primary hydroxy groups in the position C_6 of the α-*D*-anhydroglucopyranose unit is reflected in decreasing intensity of the band at 1420 cm^{-1} due to CH_2 bending vibrations and also of the band at 928 cm^{-1} due to vibrations of the COH groups at C_6 [16, 17]. Analyzing IR spectra of oxidized cellulose, Ermolenko noted [18] that oxidation is reflected in increasing absorption at 2700–2400 cm^{-1} assigned to stretching vibrations of OH groups of carboxyls strongly associated through hydrogen bonding. Increased absorption in this range is observed in oxidized starch too. The considerable low-frequency shift of this band relative to the band due to vibrations of the hydroxy groups of the anhy-

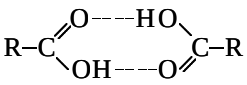
* Starch : N_2O_4 = 1 : 10; T = 18°C.

droglucopyranose ring suggests that the carboxylic hydroxy groups form starch in 5-carboxy new strong hydrogen bonds.



It is not inconceivable that fairly strong intramolecular hydrogen bonds formed by the carboxy and hydroxy groups of the same unit also contribute significantly to the absorption in this range. It should be pointed out that the IR spectra of oxidized starch clearly demonstrate the structure of the complex absorption band at 1200–990 cm^{-1}, including stretching vibrations of C–O and C–C groups and cyclic structures and COH bending vibrations [19]. In the IR spectra of oxidized samples, the intensity of the absorption bands at 1200–1350 cm^{-1} is higher, and that of the bands at 1015 and 1156 cm^{-1}, lower, compared with native starch. With increasing degree of starch oxidation, these differences become more pronounced. It is not improbable that some of the absorption bands in the investigated range can be assigned to vibrations of the secondary and primary hydroxy groups. However, at present thorough interpretation of the spectrum is problematic. One may suggest that the observed evolutions of the spectra can be caused by the fact that, along with the main reaction path (oxidation of primary hydroxy groups at C_6 to carboxy groups), the side reaction also takes place, producing carbonyl and carboxy groups at C_2 and C_3 of the α-*D*-anhydroglucopyranose unit, which is supported by the chemical analysis data (Table 2). In highly oxidized samples, the COOH content was demonstrated to be even higher than the theoretical value of 25.57 wt % corresponding to the case when all the hydroxymethyl groups are oxidized, and the carbonyl group content grows steadily with increasing oxidation time and oxidant concentration.

CONCLUSIONS

(1) It follows from the estimated kinetic factor n and activation energy E_a that the oxidation rate of potato starch in the system N_2O_4–CCl_4 is limited by the chemical stage.

(2) A 20 wt % solution of dinitrogen tetroxide in CCl_4 ensures the maximal rate of starch oxidation, all other conditions being equal. The presence of moisture in starch is the necessary condition for efficient oxidation.

(3) The IR spectra show that the OH groups of the α-*D*-anhydroglucopyranose unit of starch are preferentially oxidized to carboxy groups.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Degradation Treatment of Butadiene–Styrene Copolymer Wastes

S. S. Nikulin and Yu. A. Sergeev

Voronezh State Forestry Engineering Academy, Voronezh, Russia

Received April 16, 2001

Abstract—Degradation of butadiene–styrene rubber production wastes, coagulums, using a catalytic system based on hydroperoxide, variable-valence metal salt, and alcohol was studied.

Industrial progress inevitably involves formation of growing amounts of wastes and by-products, with a hazard of environmental pollution [1–3]. Therefore, development and commercial implementation of new processes should be primarily based on using environmentally safe systems, with utilization of secondary raw materials, rejects, and production wastes.

One of promising procedures for processing rejected and spent polymeric products and polymeric deposits formed on equipment surfaces in the course of polymer synthesis is degradation treatment. Oxidative degradation of polymers yields lower-molecular-weight products containing functional groups: carbonyl, carboxy, and hydroxy. Classical oxidative degradation of polymers is performed by heating in an organic solvent in the presence of air, organic derivatives of variable-valence metals, and/or compounds generating free radicals [4–7].

Degradation processes are very important and promising as ways of treating polymeric wastes from synthetic rubber industry and of cleaning process equipment to remove polymeric deposits (coagulums). Cleaning the equipment to remove polymeric deposits is a difficult and labor-consuming process, often requiring manual labor and much time. Furthermore, mechanical cleaning does not ensure complete removal of polymeric deposits from the surfaces of reactors and other process equipment and, on the other hand, a problem arises of processing the removed wastes.

In this work, we studied degradation of butadiene–styrene rubbers in the presence of a catalytic system consisting of a radical initiator and a variable-valence metal compound.

We chose peroxides widely used in synthetic rubber industry: isopropylbenzene hydroperoxide and cyclohexylisopropylbenzene hydroperoxide as substances decomposing by the radical mechanism, and iron, cobalt, and nickel chlorides as variable-valence metal compounds.

Degradation experiments were performed with samples of polymeric deposits (coagulums) taken from reactor walls and stirrers and from the surfaces of other equipment used in commercial production of emulsion butadiene–styrene rubbers. These coagulums were virtually insoluble or sparingly soluble in hydrocarbon solvents.

Degradation of polymeric deposits was performed as follows. A vessel was charged with 10 g of coagulum and 130 g of a hydrocarbon solvent, stirring was switched on, and 7.0 g of a 4.0% solution of a variable-valence metal salt in 1-butanol and a hydroperoxide were added in succession. The reaction was performed in contact with atmospheric oxygen at a prescribed temperature for a prescribed time. The degradation progress was monitored gravimetrically (by the weight loss of the solid residue in the hydrocarbon phase), by variation of the intrinsic viscosity $[\eta]$, and visually.

In the first stage of our study, we examined the influence of the hydroperoxide concentration on degradation treatment of coagulum of SKS-30 ARK rubber. As seen from Table 1, the optimal concentration of isopropylbenzene hydroperoxide is 0.6–6.0 wt % based on coagulum. At higher hydroperoxide concentrations, the intrinsic viscosity grows, suggesting the occurrence of secondary cross-linking, although dissolution of the coagulum is complete under these conditions too.

The influence of temperature on degradation of SKS-30 ARK rubber in the presence of the chosen catalytic system is illustrated in Fig. 1a. It is seen that the optimal temperature is 50–100°C. At 40°C,

Table 1. Influence of isopropylbenzene hydroperoxide concentration *C* on degradation of the coagulum of SKS-30 ARK rubber*

C, wt %	Dissolution, %	[η], dl g^{-1}
0.1	59.5–62.4	1.91–1.99
0.2	72.2–77.8	1.18–1.23
0.6	100	0.52–0.57
2.0	100	0.43–0.48
6.0	100	0.41–0.45
12.0	100	0.42–0.47
15.0	100	0.49–0.54

* The process was performed in toluene at 60°C for 3 h in the presence of $FeCl_3$.

the degradation rate and the degree of coagulum dissolution decrease. Temperatures above 100°C are also unsuitable, because of the occurrence of secondary cross-linking, decreasing the solubility of the coagulum and increasing the viscosity of the solutions. The intrinsic viscosity is the lowest when the degradation is performed in the range 50–80°C, and this range should be considered the optimal.

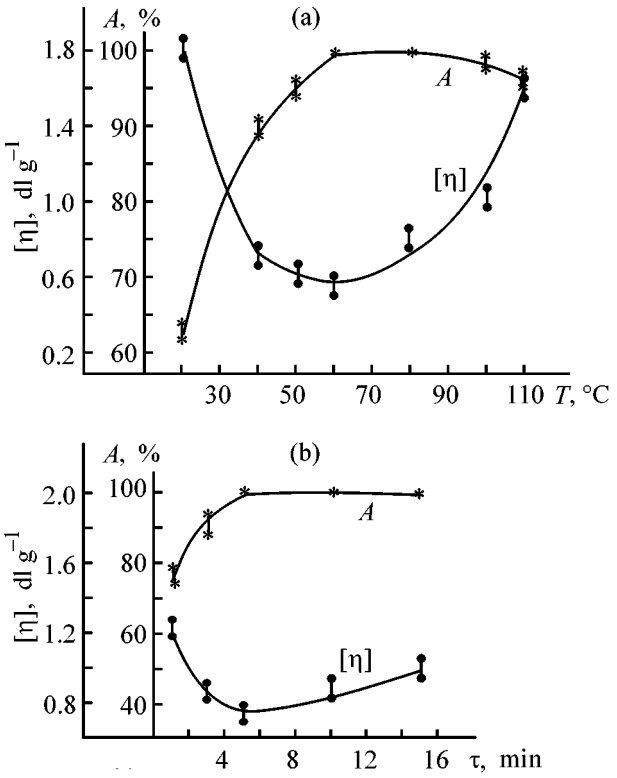

Fig. 1. Effects of (a) temperature *T* and (b) time τ of degradation on the instrinsic viscosity [η] and degree of dissolution *A* of the coagulum of SKS-30 ARK rubber. Solvent toluene; 2.0 wt % isopropylbenzene hydroperoxide based on coagulum; $FeCl_3$; (a) 5 h; (b) 80°C.

One of the most important parameters of degradation is the process time. As seen from Fig. 1b, the optimal time is 5 h. Longer treatment results in higher intrinsic viscosity, which may be due to secondary cross-linking. The viscosity of the resulting polymer solutions is a very important process parameter, because high viscosity prevents transport of the solutions through pipelines after equipment cleaning.

The process of oxidative degradation of polymeric chains can be represented as follows.

Preliminarily dissolution in butanol of a variable-valence metal salt, followed by addition of this solution to the system under treatment, ensures fine dispersion of the salt in the bulk of the system. The first stage of the reaction is, most probably, reduction of Fe(III) ions to Fe(II). The possible reductants are mercaptans, phenol and its derivatives, and also polybutadiene units [4] present in the coagulum of the rubber produced by emulsion (co)polymerization:

$$\sim CH_2{-}CH{=}CH{-}CH_2\sim + Fe^{3+}$$
$$\rightarrow \sim\dot{C}H{-}CH{=}CH{-}CH_2\sim + Fe^{2+}.$$

Oxidative degradation of butadiene–styrene rubber may occur by several pathways, namely, with participation of the redox system in which the variable-valence metal (Fe, Co, Ni, etc.) promotes, on the one hand, oxidative degradation of the polymers in the presence of oxygen and, on the other, decomposition of the hydroperoxide:

$$R{-}OOH + Fe^{2+} \rightarrow RO^{\cdot} + HO^{-} + Fe^{3+}.$$

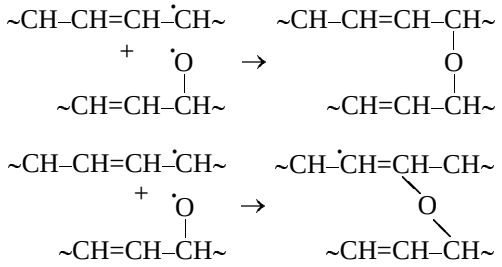
Oxidative degradation of the polymeric chains of the butadiene–styrene coagulum can be represented as oxidative degradation of butadiene blocks:

$$\sim CH_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CH{=}CH{-}CH_2\sim + RO^{\cdot}$$
$$\rightarrow \sim CH_2{-}CH{=}CH{-}\dot{C}H{-}CH_2{-}CH{=}CH{-}CH_2\sim + ROH,$$

$$\sim CH_2{-}CH{=}CH{-}\dot{C}H{-}CH_2{-}CH{=}CH{-}CH_2\sim + O_2 + RH$$
$$\rightarrow \sim CH_2{-}CH{=}CH{-}\underset{\displaystyle OOH}{\underset{|}{CH}}{-}CH_2{-}CH{=}CH{-}CH_2\sim,$$

$$\sim CH_2{-}CH{=}CH{-}\underset{\displaystyle OOH}{\underset{|}{CH}}{-}CH_2{-}CH{=}CH{-}CH_2\sim$$
$$\rightarrow \sim CH_2{-}CH{=}CH{-}CHO + \underset{\displaystyle OH}{\underset{|}{CH_2}}{-}CH{=}CH{-}CH_2\sim.$$

Secondary cross-linking of the resulting low-molecular-weight polymeric chains can occur as follows:



Degradation of the coagulum from production of BS-65 (A) butadiene–styrene latex was studied with catalytic systems containing Fe(III), Co(II) and Ni(II) chlorides (in 1-butanol) as variable-valence metal salts. The influence of the kind of the catalytic system and reaction time on degradation of the BS-65 (A) coagulum is illustrated in Fig. 2. It is seen that a combination of isopropylbenzene hydroperoxide with a butanol solution of iron, cobalt, and nickel chlorides facilitates degradation of coagulums with high content of styrene units. With these catalytic systems, dissolution of the coagulum is virtually complete in 35 h.

Similar results were obtained with other radical initiators, e.g., cyclohexylisopropylbenzene hydroperoxide, and with other solvents [xylene, Nefras S-4-150/200 (petroleum solvent based on butylbenzene), white spirit]. As solvents for variable-valence metal salts, some other alcohols (e.g., ethanol, propanol) can be used along with 1-butanol. However, low-boiling alcohols are removed from the system at elevated temperatures, which results in agglomeration of the metal salts and negatively affects the degradation process.

Thermal oxidative degradation is accompanied by breakdown of gel structures and decrease in the molecular weight of the polymers, so that solutions of low-molecular-weight polymers can be obtained. Such solutions prepared from solid rubber production wastes can be used for modification of bitumens, production of film-forming substances, mastics, and sealants, protective treatment of wood items, etc.

For example, low-molecular-weight copolymers can be used in production of composite drying oil. Its optimal composition is as follows (wt %): polydiene-M (copolymer based on styrene and unsaturated compounds of toluene distillation bottoms from production of butadiene rubber; for synthesis description, see [8–11]; the product is commercially available) 44.0, degraded butadiene–styrene rubber 5.0, siccative 6.0, and solvent (Nefras S-4-150/200) 45. Coatings obtained from this composite drying oil exhibit satisfactory properties (Table 2), and this material can be used in production of paint-and-varnish materials.

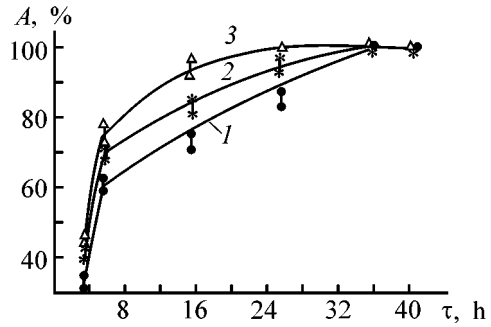


Fig. 2. Degree of dissolution *A* of BS-65 (A) coagulum vs. degradation time τ. 90°C, solvent toluene, 2.0 wt % isopropylbenzene hydroperoxide based on coagulum. (*1*) $FeCl_3$, (*2*) $NiCl_2$, and (*3*) $CoCl_2$.

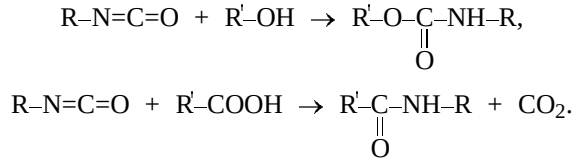
The hydrocarbon solution of degraded SKS-30 ARK rubber can be used for preparing a cold-curable two-component sealant which shows promise for industry and civil engineering, and also for sealing airport pavement seams. To prepare the first component, low-molecular-weight polyethylene and indene–coumarone resin are dissolved at 95–100°C with continuous stirring in a toluene solution of degraded SKS-30 ARK rubber, which is followed by distillation of the solvent to 60–70 wt % content of the nonvolatile fraction and addition of the antioxidant.

As the cross-linking component we used polyisocyanates (3.0–5.0 wt %).

The major advantage of this sealant is the absence of shrinkage, which is due to the chemical reaction of the isocyanate groups with the hydroxy and carbonyl groups:



Carbon dioxide released in the reaction imparts high porosity to the sealant, eliminating any shrinkage.

Table 2. Properties of coatings based on composite drying oil

Parameter	Testing results
Color on iodometric scale (IMS units)	700–800
Viscosity by VZ-246 viscometer, s	25–28
Bending strength, mm	1
Hardness by ME-3	0.1
Time of drying to degree of dryness 3, h	24

The performance characteristics of the sealant are as follows:

Working life after component mixing, h	1.5
Curing time, h	24
Cohesion strength, MPa	0.6–0.7
Relative elongation at cohesion break, %	250–270
Adhesion to concrete, MPa	0.5
Brittle point, °C	–60

CONCLUSIONS

(1) The optimal concentration of the hydroperoxide is 0.6–6.0 wt % based on coagulum, and the optimal temperature, 50–100°C.

(2) The degradation rate depends on the styrene content in the coagulum. The higher the styrene content, the longer the process.

(3) It is appropriate to perform degradation of high-styrene coagulums on catalytic systems containing Co(II) or Ni(II) salts; in this case, the degradation time is shorter.

(4) The resulting hydrocarbon solutions of low-molecular-weight copolymers can find wide use in production of paint-and-varnish materials, mastics, sealants, and also as components of polymeric-concrete and asphalt formulations.

CHEMISTRY OF FOSSIL FUEL

Molecular Oxygen and Oxygen-Containing Compounds in Kerosene Fractions of West-Siberian Oils

Abstract—Oxygen-containing compounds that are present in straight-run kerosenes produced by the Kinef, Ltd. were identified by chromato-mass spectrometry.

The presence of olefins and of oxygen-containing and other heteroatomic compounds in gasolines, kerosenes, and diesel fuels, as a rule, deteriorates their stability in storage and use. At the same time, some oxygen-containing compounds (e.g., phenols) play a positive role, behaving as antioxidants. Some sulfur- and nitrogen-containing compounds present in these fuels (especially in kerosenes and diesel fuels) also play a positive role as polyfunctional additives (antiwear, antiscuff, dispersing, etc.).

By now, no qualitative and quantitative data are available on the content of molecular oxygen and composition of oxygen-containing compounds in jet fuels (kerosenes). Obtaining such data was the goal of this work.

EXPERIMENTAL

Straight-run kerosene (TS-1) samples (nos. 1, 2) were used.[1] Molecular oxygen dissolved in these fractions of TS-1 fuel (sample nos. 1, 2) was determined chromatographically [1]. Hydroperoxides in kerosene fractions were determined by iodometric titration [2, 3]. Oxygen-containing compounds were concentrated with a Diapak silica gel cartridge (BiokhimMak, Moscow).

The cartridge was washed with *n*-hexane, and 100 ml of a kerosene fraction to be analyzed was passed. Then the cartridge was repeatedly washed with *n*-hexane and dried in a nitrogen flow. The extracted oxygen-containing compounds were eluted from the cartridge with 5 ml of methanol. The methanol extract was evaporated in a nitrogen flow to a volume of 1 ml and analyzed by chromato-mass spectrometry.

A mass-spectrometric analysis of the extracts of TS-1 kerosene fractions was performed with an MD 800 device (Fisons, USA). To indetify compounds present in these extracts and giving resolved or partially overlapping peaks in the chromatograms, we used the MassLab and AMDIS software, with the electronic libraries of the mass spectra. The programs provide for calculation of the direct and inverse parameters of similarity of the experimental and reference mass specrta. When identifying individual compounds, we took into account the general similarity parameters of the mass spectra of the detected compounds and the reference mass spectra, the identity of the molecular peaks in the spectra being compared, and the similarity of the relative intensities of the major peaks in the mass spectra being compared (difference of no more than 20–30% was admissible), and also the results of running the expert modulus of the AMDIS program. These criteria allow identification of individual compounds or group identification.

The content of dissolved molecular oxygen was 1.7×10^{-3} M in sample no. 1 and 1.9×10^{-3} M in

[1] Straight-run samples of kerosene (TS-1) produced by the Kirishinefteorgsintez, Ltd. from a commercial mixture of West-Siberian crude oils were taken May 24, 2001, from the AT-6 unit. Sample no. 1 was the process feed before the storage tank of the AT-6 unit, and sample no. 2, the process feed after this tank, at the inlet of the feed pump.

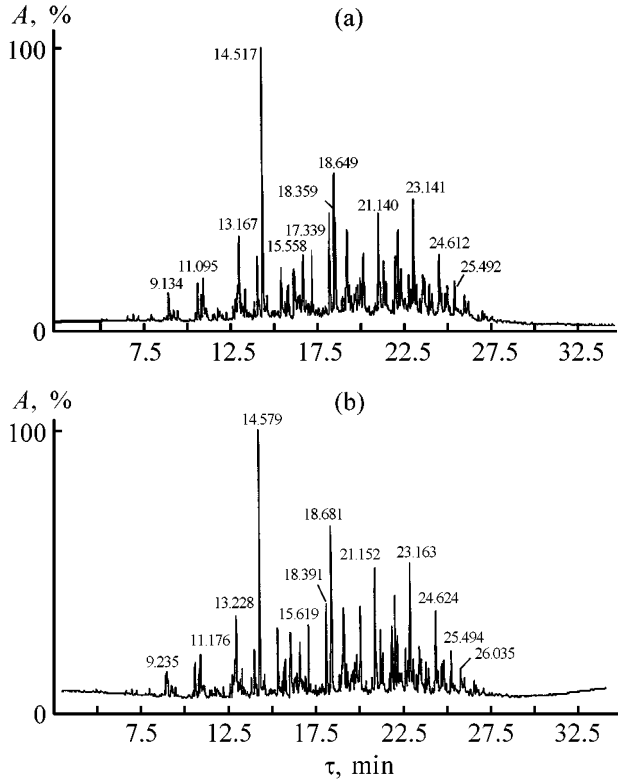

Fig. 1. Comparison of chromatograms of kerosene extracts. Sample nos. (a) 1 and (b) 2. (*A*) Signal intensity and (τ) retention time; the same for Fig. 2.

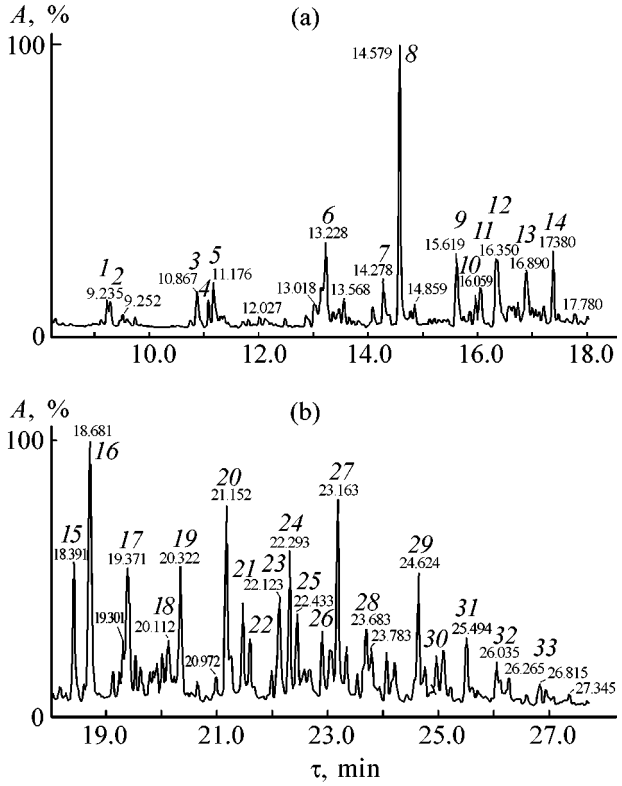

Fig. 2. (a) Initial and (b) final sections of a chromatogram of the kerosene extract. For peak identification, see Table 1.

sample no. 2. This value is well consistent with the volume fraction of oxygen in components of gasolines produced by Kinef (2.3–4.6% [4]) and are somewhat higher than the corresponding values for the diesel fuel (1.6–4.1%). As shown by special experiments, the solubility of oxygen in the samples under consideration was 5.1% (2.3×10^{-3} M) in the case of their saturation with air. Thus, in the course of oil refining on AT-6, the kerosine fractions are not saturated with oxygen. We found that the limiting solubility of molecular oxygen increases in the order diesel fuel (4.4%) < kerosene (5.1%) < benzine (6.5%).

The concentration of hydroperoxides in sample nos. 1 and 2 was as low as 1.3×10^{-4} and 5×10^{-5} M, respectively, i.e., the extent of hydrocarbon oxidation in the examined kerosene fractions is very low.

The total chromatograms of the kerosene extracts are shown in Fig. 1, and the initial and final sections of a chromatogram of the extracts of oxygen-containing and other heteroatomic compounds, in Figs. 2a and 2b.

The identified heteroorganic (mainly oxygen-containing) compounds corresponding to the major peaks in the chromatograms of the extracts of sample nos. 1 and 2 are shown in Fig. 1. It is seen that the kerosene contains a wide variety of organic compounds C_7–C_{12}: paraffinic and naphthenic alcohols and ketones, aromatic alcohols (alkylphenols), and one of dialkylpyridines. Identification of individual compounds is not always possible because of the close similarity of the mass spectra of structurally similar compounds (isomers). Therefore, many peaks are assigned in Table 1 not to a definite compound, but to unknown representative(s) of a certain group of isomers.

It should be noted that carboxylic acids were not detected in noticeable amounts. On the whole, the content of various groups of oxygen-containing compounds in kerosene decreases in the order aromatic > aliphatic > naphthenic compounds.

This relation differs from that observed in benzines and diesel fuels. The content of oxygen-containing derivatives of aliphatic and aromatic hydrocarbons in kerosenes is intermediate between those in benzines and diesel fuels (Table 2).

The total content of oxygen-containing compounds in kerosenes (Table 1) is low and varies within relatively narrow concentration limits: 0.0015–0.003%. This parameter is approximately an order of mag-

* By C_n-phenols are meant phenols containing alkyl substituents with n carbon atoms (in total).

** One of isomeric dimethylphenols.

*** One of isomeric trimethyl-, methylethyl-, propyl-, and isopropylphenols.

**** One of isomeric tetramethyl-, dimethylethyl-, methylpropyl-, etc., phenols.

***** One of isomeric pentamethyl-, trimethylethyl-, dimethylpropyl-, etc., phenols.

****** One of isomeric tetramethylethyl-, trimethylpropyl-, etc., phenols.

Table 2. Content of oxygen-containing compounds of various groups in petroleum products

Group composition	Relative content, wt %			Group composition	Relative content, wt %		
	benzine [1–3]	diesel fuel [4]	kerosene		benzine [1–3]	diesel fuel [4]	kerosene
Aliphatic	50–58	1–3	21–24	Aromatic	28–35	50–98	61–66
Naphthenic	15	0–48	11	Sum	100	100	100

nitude higher than that observed for diesel fuels [$(0.05–6.5) \times 10^{-4}$%] but similar to that observed in gasoline components in the course of their production {$(2–4) \times 10^{-3}$% [4]} and in A-76 gasoline "in the initial state before storage" (the equivalent parameter, content of "acetone-soluble resins," is 1.9 mg ml^{-1}, or 0.003% [5]).

Thus, data on the quantitative content of identified oxygen-containing organic compounds and on their qualitative composition (absence of acids), combined with the results obtained in determining molecular oxygen and peroxides, correspond to certain low ("natural") extent of oxidation of petroleum hydrocarbon components.

CONCLUSIONS

(1) A total of 33 organic oxygen-containing compounds C_7–C_{12} were identified in kerosene by GC–MS, including paraffinic and cycloparaffinic alcohols and ketones, alkylphenols with several alkyl substituents (up to C_6 in total), and one of dialkylpyridines. No carboxylic acids were detected.

(2) The content of oxygen-containing compounds in kerosenes under consideration decreases in the order aromatic > aliphatic > cycloaliphatic (naphthenic) compounds. The total content of these compounds does not exceed 10^{-3}%.

Kinetics of Reaction of Aluminum Hydroxide with Dimethyl Hydrogen Phosphite in Nitrobenzene

S. N. Bondarenko, T. V. Khokhlova, O. I. Tuzhikov, M. P. Lyabin, and S. M. Moskvichev

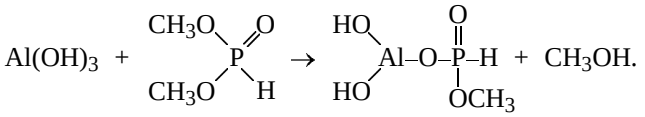
Volgograd State Technical University, Volgograd, Russia

Received May 22, 2001

Abstract—The kinetics of the reaction of aluminum hydroxide with dimethyl hydrogen phosphite in nitrobenzene was studied.

Polymeric composite materials based on epoxy oligomers are widely used in electric devices, TV and radio equipment, building, mechanical engineering, and auto repair. Their substantial disadvantage is high combustibility. It can be decreased by introducing a fireproofing compound, aluminum hydroxide. Its use is preferable, because it forms no toxic products at high temperatures, decreases the toxicity of the products of the polymer thermal decomposition, and reduces smoke formation.

However, introduction of aluminum hydroxide deteriorates physicomechanical characteristics of polymers. We showed in [1] that this disadvantage can be diminished by modification of aluminum hydroxide (**I**) with dimethyl hydrogen phosphite (**II**). Furthermore, the fire-extinguishing properties of the novel fireproofing compound are thus enhanced:



I **II**

In this study the kinetics of this reaction was examined.

EXPERIMENTAL

The reaction was performed in nitrobenzene at temperatures in the range 126–146°C, maintained to within ±0.2°C with UTU-2 ultrathermostat. The mixture was continuously stirred with removal of the methanol formed. The reaction course was monitored potentiometrically by the change of the phosphite concentration. The reaction was stopped by cooling to 2–5°C.

Under experimental conditions, when compound **I** occurs mainly in the solid phase, its concentration in solution is constant and equal to the solubility. Therefore, the actual order of the reaction with respect to **I** cannot be determined. The apparent reaction order with respect to **I** is zero. In the experiments in

* All calculations were performed by the least-squares method; $c^0_{\mathbf{II}}$ is the initial concentration of **II**, V_0 the initial reaction rate, and k_{ap} the apparent reaction rate constant.

which the initial concentrations of **II** and the amount of the diluent were constant and the amount of **I** was varied, the kinetic dependences were virtually the same (deviations were within the experimental error) (Fig. 1a). This confirms the apparent zero order with respect to **I** and shows that the reaction proceeds in the solution bulk, rather than on the surface of aluminum hydroxide. Otherwise, larger amounts of **I** in the reaction mixture and hence the increased contact surface area would accelerate the reaction.

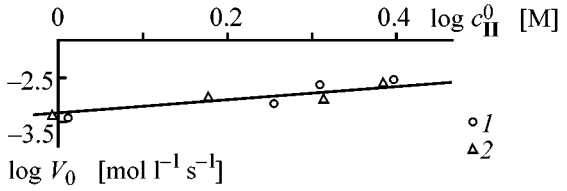

Fig. 2. Dependence $\log V_0$–$\log c^0_{\mathbf{II}}$ plot for the reaction between aluminum hydroxide **I** and dimethyl hydrogen phosphite **II**: (*1*) determination of the reaction order with respect to **II** and (*2*) determination of the total reaction order.

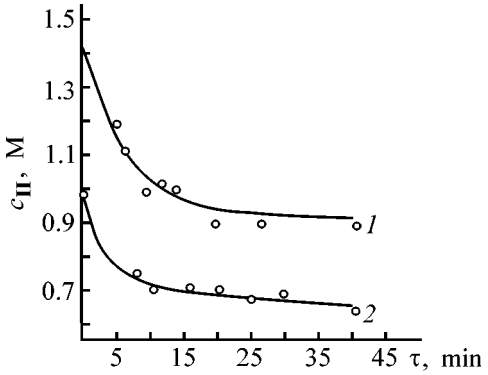

Fig. 3. Variation with time τ of dimethyl hydrogen phosphite **II** concentration $c_{\mathbf{II}}$ in the reaction with aluminum hydroxide **I** in nitrobenzene at the equimolar ratio of reactants (146°C). $c^0_{\mathbf{II}}$ (M): (*1*) 1.4265 and (*2*) 0.988.

To determine the reaction order with respect to **II**, we measured the initial reaction rates at the same amounts of **I** and the initial concentrations of **II** varied in the 1.717–2.31 M range (see table and Fig. 1b).

The partial reaction order with respect to **II** was determined from the $\log V_0 = f(\log c^0_{\mathbf{II}})$ plot (Fig. 2). As seen from Fig. 2, the slope of the straight line is equal to 1, i.e., the reaction is first-order with respect to **II**. Taking into account the pseudo-zero order with respect to **I**, the total reaction order is also close to unity. The linear equation

$$\log V_0 = \log k + n_1 \log c_{\mathbf{I}} + n_2 \log c^0_{\mathbf{II}}$$

[here k is the reaction rate constant and n_1 and n_2 are the orders with respect to **I** and **II**, respectively (under the experimental conditions $n_1 \log c_{\mathbf{I}} = \text{const}$)] takes the form

$$\log V_0 = (-3.1072 \pm 0.03898) + (1.083 \pm 0.124) \log c^0_{\mathbf{II}}.$$

It follows from this equation that more precise value of the apparent reaction order with respect to **II** n_2 is 1.08 ± 0.12.

To confirm the obtained value of the total reaction order, we performed experiments in which the initial concentration of **II** was varied, keeping the equimolar ratio of reactants in the reaction mixture constant (see table and Fig. 3).

For the set of the initial concentrations of **II**, we obtain the dependence

$$\log V_0 = \log k_{ap} + n\log c^0_{\mathbf{II}}$$
$$= (-3.1007 \pm 0.055) + (1.053 \pm 0.28)\log c^0_{\mathbf{II}}$$

characteristic of first-order reactions. From this dependence, the reaction rate constant (which is probably a function of the concentration of **I** in the liquid phase) was determined. The reaction rate is described by the Arrhenius equation: the dependence $\log k_{ap} = f(1/T)$ is linear

$$\log k_{ap} = \log A + \log \alpha \times 10^3 \times 1/T$$
$$= (5.277 \pm 0.878) + (-3.525 \pm 0.561) \times 10^3 \times 1/T.$$

The activation energy E_a found from this equation in the Arrhenius coordinates is 67.7 kJ mol^{-1}. The activation entropy calculated by Eyring's equation $\Delta S^{\neq}$ is –154.6 J mol^{-1}deg^{-1}, the activation free energy $\Delta G^{\neq}$ is 127.2 kJ mol^{-1}, and the enthalpy $\Delta H^{\neq}$ is 64.2 kJ mol^{-1}. The relatively small E_a and $\Delta H^{\neq}$ suggest that the reaction between **I** and **II** involves formation of a highly structurized intermediate.

CONCLUSIONS

(1) The reaction of aluminum hydroxide with dimethyl hydrogen phosphite in nitrobenzene is first-order with respect to dimethyl hydrogen phosphite, and the total reaction order is close to unity.

(2) The reaction proceeds in solution, rather than on the aluminum hydroxide surface.

(3) The calculated activation parameters of the reaction suggest the formation of a highly structurized intermediate.

Preparation of an Ion-Exchange Fiber by Polymer-Analogous Transformations in Polycaproamide–Polyglycidyl Methacrylate Grafted Chains

I. V. Lavnikova and V. F. Zheltobryukhov

Volgograd State Technical University, Volgograd, Russia

Received November 13, 2000; in final form, April 2001

Abstract—The possibility of preparing an ion-exchange fiber based on polycaproamide–polyglycidyl methacrylate graft copolymers was examined. Specific features of phosphorylation of epoxy groups in grafted polycaproamide–polyglycidyl methacrylate chains were revealed.

Natural and synthetic sorbents are widely used in scientific research and engineering, in particular, for treatment of exhaust gases and wastewater, with recovery of valuable substances. Chemisorbents are especially effective for these purposes [1]. Among the procedures developed for preparing ion-exchange fibers, graft polymerization followed by polymer-analogous transformations is one of the most promising [2, 3]. Preparation of ion exchangers by chemical transformations involves certain problems: the processes are multistage; toxic compounds are used; macromolecules of the initial polymers undergo partial degradation; and the chemical transformation is incomplete [4]. However, despite these drawbacks, it is possible to introduce into the side chains new functional groups by using polymer-analogous transformations and thus to prepare new polymeric materials with valuable properties.

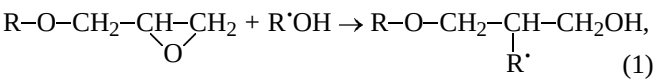
Among a wide variety of monomers used in graft polymerization, mention should be made of glycidyl methacrylate (GMA). Glycidyl methacrylate contains reactive epoxy groups allowing subsequent polymer-analogous transformations in grafted polycaproamide–polyglycidyl methacrylate (PCA–PGMA) chains with the aim to incorporate new functional groups into the side chain of the copolymer [5].

In this study, we developed a procedure for preparing a complexing sorbent containing P–OH groups from the graft copolymer by phosphorylation of grafted PGMA chains.

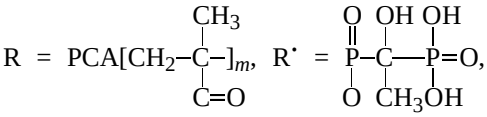
As phosphorylating agent we used 1-hydroxyethylidenediphosphonic acid (HEDP) $C_2H_3(OH)[PO(OH)_2]_2$, a white crystalline powder, mp 198–199°C, readily soluble in water and organic solvents. Owing to a combination in the HEDP molecule of two phosphonic acid groups capable of complexation in strongly acidic solutions and hydroxyethyl group OH–C–CH_3, HEDP is a versatile complexing agent exhibiting complexing power in a wide pH range [6].

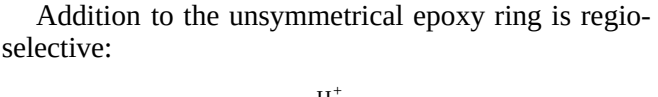
To develop an efficient procedure for preparing an ion-exchange fiber, we studied how the kinetic features of polymer-analogous transformations of PGMA affect the phosphorus content in the graft copolymer, the degree of transformation of epoxy rings, and the static exchange capacity (SEC).

Phosphorylation presumably follows the scheme



(1)





(2)

The RO group stabilizes the positive charge on the β-carbon atom; as a result, normal addition occurs with the formation of β-derivatives [8].

The heterophase reaction of the PCA–PGMA fiber with an aqueous solution of HEDP is influenced by such factors as HEDP concentration in solution, temperature and time of phosphorylation, and use of catalyst; the effect of each factor was studied separately.

The influence of HEDP concentration on the phosphorus content in the graft polycaproamide copolymer (GPC) and conversion of epoxy groups is illustrated by Table 1. As the HEDP concentration is increased from 0.81 to 4.04 M, the phosphorus content in the graft PGMA copolymer grows substantially. Further increase in the HEDP concentration is not appropriate, because the reaction decelerates. Furthermore, at HEDP concentrations higher than 4.86 M the fiber undergoes partial degradation.

The kinetic parameters of phosphorylation are listed in Table 2. These data show that the initial rate of phosphorylation is high in the examined range of HEDP concentrations. For example, the reaction rate is 0.28×10^{-4} mol l^{-1} s^{-1} at [HEDP] = 0.81 M, and 0.83×10^{-4} mol l^{-1} s^{-1} at [HEDP] = 4.04 M, with simultaneous increase in the phosphorus content in GPC to 2.7%. From the data obtained for the HEDP concentration range 0.81–4.04 M, we calculated using the procedure described in [7] the reaction order: $n = 1.92$.

Data on the effect of phosphorylation temperature on the content of phosphorus in graft PGMA copolymer are listed in Table 3. These data show that phosphorylation occurs at a high rate. It should be noted that, as the temperature is raised by 20°C, the reaction rate increases by a factor of 1.8. From the temperature dependence of the reaction rate constant, determined from the kinetic curves, we calculated the activation energy of the process: $E_a = 51.74$ kJ mol^{-1}. This value is nicely consistent with published data [8].

The amount of incorporated phosphorus strongly depends on the reaction time. The phosphorus content in GPC increases during 300 min, after which the process decelerates and fully stops in 350 min. Acid–base catalysts can accelerate phosphorylation of grafted PGMA chains. However, reactions of organophosphorus acids with epoxy compounds can also occur in the absence of catalyst [8]. Pyridine tested as catalyst had no appreciable effect on the phosphorus content in GPC. The phosphorus content was 2.9% at a pyridine content of 1 wt % relative to the polymer weight and 2.4% without pyridine; therefore, phosphorylation was performed without a catalyst.

Table 1. Influence of HEDP concentration on the amount of phosphorus in GPC C_P and on the conversion of epoxy groups*

[HEDP], M	C_P, %	Conversion, %
0.81	0.70	46.5
1.62	0.87	49.8
2.43	1.2	54.5
3.24	2.0	63.7
4.04	2.9	67.9
4.86	2.93	78.5

* PGMA concentration 43%, τ = 300 min, bath ratio 30, 90°C.

Table 2. Kinetic parameters of phosphorylation*

[HEDP], M	C_P, %	$V_{in} \times 10^4$	$V_{max} \times 10^4$
		mol l^{-1} s^{-1}	
0.81	1.4	0.28	0.4
1.62	1.9	0.5	1.0
4.04	2.7	0.83	1.6

* Reaction order $n = 1.92$.

Table 3. Effect of phosphorylation temperature T_P on the phosphorus content in GPC*

T_P, °C	C_P, %, at indicated reaction time, min						$V_{max} \times 10^4$, mol l^{-1} s^{-1}
	50	100	150	200	250	300	
70	0.8	0.9	1.0	1.3	1.5	1.5	1.4
80	1.25	1.6	1.9	2.0	2.3	2.5	2.0
90	1.5	1.7	2.0	2.3	2.5	2.98	2.6

* HEDP concentration 4.04 M.

Modification of PCA by graft polymerization was performed in an emulsion of HMA monomer (2.35 M) at 70°C for 60 min. The content of PGMA in the graft copolymer was 43–50 wt %. Subsequent polymer-analogous transformations of grafted PGMA chains allowed preparation of an ion-exchange fiber with the following characteristics: SEC 3.96 mg-equiv g^{-1}, relative breaking tensile load 24.3 cN tex^{-1}, breaking elongation 34.8%. The proposed procedure for chemical modification of PCA–PGMA allows preparation of new polymeric materials based on PCA.

EXPERIMENTAL

Modification of GPC was performed by its treatment with a 0.84–4.86 M HEDP solution at 70–90°C for 50–300 min in a flask equipped with a reflux con-

denser. After phosphorylation completion, the resulting copolymer was thoroughly washed with distilled water and dried to constant weight. The phosphorus content in the fiber was determined according to [9]. The total activation energy was calculated from the temperature dependence of K.

CONCLUSION

Incorporation of the P–OH group into the side chain of a macromolecule allows preparation of a fibrous sorbent capable of ion exchange and complexation.

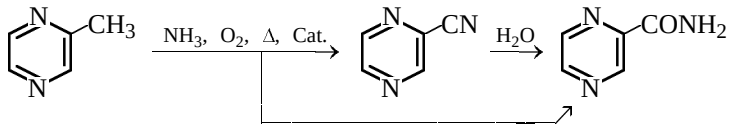
Abstract—A series of binary catalysts based on oxides of zinc and variable-valence metals were tested in synthesis of 2-methylpyrazine by catalytic dehydrocyclization of 1,2-propylene glycol with ethylenediamine.

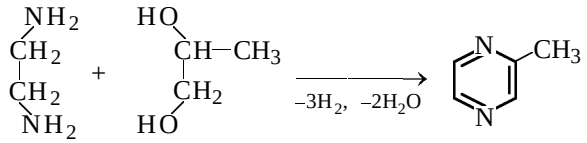
The growing incidence of tubercular diseases calls for improving the synthesis processes and increasing the production of tuberculostatic means. One of the most important antitubercular preparations is Pyrazinamide. Its active agent, which is also the starting compound for preparing low-toxic bacteriostatics [1], is pyrazine-2-carboxamide, prepared by oxidative ammonolysis of 2-methylpyrazine (MP) [2].



By now, fairly selective catalysts have been developed for oxidative ammonolysis of MP, allowing preparation, depending on reaction conditions, of either 2-cyanopyrazine [3] or 2-pyrazinamide [4] in yields of 80% and higher; however, there are no commercially acceptable procedures for synthesis of the starting compound.

The existing routes to MP, involving synthesis and subsequent dehydrogenation of 2-methylpiperazine [5] or reaction of propylene oxide with ethylenediamine at elevated pressure [6], are of no promise for commercial production of MP.

One of efficient routes to MP can be catalytic dehydrocyclization of ethylenediamine with 1,2-propylene glycol.



At present, the most frequently used cyclizing and dehydrogenating catalysts for this reaction are those based on oxides of Zn [7–9], Cu, or Cr(III) [10]; in their presence, the yield of MP reaches 60–70%. The best results are obtained with catalysts prepared by mixing the components to a pasty state, with subsequent extrusion and drying [8].

In this study, we tested MoO_3-modified zinc oxide catalysts prepared by such a procedure. The dependence of the MP yield on the catalyst composition and reaction temperature is illustrated by Fig. 1. We found that the catalyst containing ZnO and MoO_3 in 1 : 0.3 molar ratio ensures a yield of the target product as high as 75–80% in the temperature range 420–460°C.

However, we found that the catalysts prepared by extrusion are rapidly coked and require frequent regeneration, which results in the loss of mechanical strength and, finally, in decreased yield of the target product. The service life of such catalysts does not exceed 10 h.

To prolong the service life of the zinc–molybdenum catalysts and enhance their mechanical strength, the catalysts were prepared by pelletizing with sub-

sequent calcination. The results obtained with pelletized catalysts were similar to those obtained with the catalysts prepared by extrusion (see table). Although the mechanical strength increased considerably, the service life between regenerations decreased to 6 h, probably owing to a decrease in the specific surface area in the course of pelletizing.

1 : 0.2	27	33	38	43	52	50

* Molar ratio of the components is given.

Data in the table also show that we failed to improve the properties of zinc oxide catalysts by their modification with vanadium and tungsten oxides.

The results obtained in dehydrocyclization of 1,2-propylene glycol with ethylenediamine in the presence of $ZnO–MoO_3$ catalyst of the composition $ZnO : MoO_3$ = 1.0 : 0.3, prepared by granulation, deserve attention. The service life of this catalyst between regenerations, 20 h, is twice that of the catalyst prepared by extrusion. It should be noted that the optimal selectivity of this catalyst noticeably depends on the grain size (Fig. 2).

EXPERIMENTAL

Extrudates were prepared according to [11]. To obtain catalysts as pellets, the oxides were thoroughly mixed to uniform state and pressed at 100 atm (catalyst with WO_3, at 500 atm) in plunger dies with cell size of 4 × 4 mm. Pellets were dried at 105°C for 2 h, promoted with 1% $MnSO_4$ and 3% H_3PO_4 solutions [11], and again dried under the same conditions, with subsequent calcination in a muffle furnace at 650°C for 1 h.

For granulation, we used ZnO and MoO_3 with particle size of 10–40 and 40–60 μm, respectively. The oxides were mixed to uniform state and pelletized in a cup granulator by spraying a 5% NaOH solution in amount of 5–20% of the mixture weight. The resulting pellets were dried successively at 50–80 (2 h) and 100–150°C (2 h). The dried grains were sieved to obtain 0–1-, 1–2-, and 2–3-mm fractions and promoted similarly to the pellets prepared by pressing. Then the grains were dried for 2 h at 250°C.

The catalyst (extrudates, pellets, or grains) was charged in an amount of 150 cm^3 into a straight-flow reactor with a stainless steel tube (400 mm long, 20 mm i.d.), into which an equimolar mixture of ethylenediamine and 1,2-propylene glycol, diluted with 40 vol % water and preheated in a steam heater to 280–300°C, was fed at a space velocity of 120 h^{-1}. The reaction temperature was adjusted within 420–470°C; the reaction products were cooled in the trapping system.

MP was isolated from the reaction mixture as an azeotrope with water {bp 97°C (737 mm Hg), MP content 45% [12]}, from which the target product was recovered by extraction with chloroform or diethyl ether.

The reaction course was monitored by GLC (Chrom-5 chromatograph, flame-ionization detector, 2500 × 3-mm glass column, stationary phase 5% SE-30 on Chromaton N-AW-HMDS, column temperature 100°C, vaporizer temperature 180°C, detector temperature 190°C, carrier gas argon, flow rate 20 ml min^{-1}).

The constants of the isolated MP after distillation (bp 135°C, n_D^{20} 1.4967, d_4^{20} 1.030) were consistent with published data [13].

The mass spectrum of MP, taken on an MKh-1300 spectrometer (*m*/*z* 94, 67, 26, 39, 40, 53, 38, 42, 28, 41) confirms the structure of the synthesized MP [14].

CONCLUSIONS

(1) New zinc oxide catalysts modified with Mo, V, and W oxides were developed and tested in synthesis of 2-methylpyrazine from 1,2-propylene glycol and ethylenediamine.

(2) The selectivity of the mixed oxide catalyst $ZnO–MoO_3$ (molar ratio 1 : 0.3) with respect to 2-methylpyrazine is as high as 75–82% under the optimal conditions (420–460°C).

(3) The Zn–Mo–O catalyst produced by granulation has a considerably longer service life between regenerations than the catalysts prepared by pelletizing and extrusion.

ANNIVERSARIES

Mikhail Grigor'evich Voronkov (To the 80th of his anniversary birthday)

On December 6, 2001, Academician Mikhail Grigor'evich Voronkov was 80. In the same year of 2001, 50 years elapsed since his first paper appeared in *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry) (*Zh. Prikl. Khim.*, 1951, vol. 24, no. 1, p. 93). During the last 50 years he has published in this journal exactly 100 papers.

Mikhail Grigor'evich Voronkov is a well-known scientist, a specialist in chemistry of organoelement compounds, organic, and physical organic chemistry.

From 1970 till 1994, Voronkov headed the Irkutsk Institute of Organic Chemistry, Siberian Division, Russian Academy of Sciences. Since 1995, he has been an advisor of the Russian Academy of Sciences and headed the Laboratory of organoelement compounds of the same institute.

Voronkov's scientific life has been very successful. A disciple of three prominent chemical schools headed by academicians A.E. Favorsky, N.D. Zelinsky, and V.N. Ipatyev, Mikhail Grigor'evich has carried out fundamental investigations in the field of chemistry of organosilicon and other organoelement compounds, organic derivatives of sulfur (one of reactions involving these compounds is named after him), and unsaturated and heteroatomic organic compounds. He has created a new field of the chemistry of silicon—bioorganic chemistry.

Voronkov's basic research in the field of chemistry, physical chemistry, biology and pharmacology of silatranes, and other compounds of hypervalent silicon has received particularly wide recognition in the USSR and abroad. Silatranes proved to be a new class of physiologically active substances and have already found wide use in agriculture and medicine. In 1997, Voronkov was awarded the State Prize of the Russian Federation for the creation and development of the chemistry of pentacoordinated silicon.

Voronkov was the first in the USSR to commence extensive studies of hydrophobization of various materials with organosilicon monomers and oligomers. In 1952–1958, he developed methods for hydrophobization of building materials, metals, glass, paper, woven fabrics, leather, and Circulite. In 1952, as a result of these investigations, the facade of the Marble Palace, the sculptural frieze of the Russian Museum, and a number of other sculptures and architectural decorations, and, later, facades of many other buildings in Leningrad, were treated with water-proofing agents. This was the beginning of water-proofing organosilicon coatings in building practice.

Voronkov developed methods for paper sizing with organosilicon compounds (Goznak factory, Leningrad, 1957); proposed an original organosilicon water-repellent agent and developed effective water-proofing agents MN and EN, which were manufactured at the pilot plant of the Institute of Organic Synthesis, Academy of Sciences of the Latvian SSR. He studied the stability of water-proofing organosilicon coatings against aggressive media, hydrothermal treatment, and thermal-oxidative breakdown.

In 1981, Voronkov was awarded State Prize of the USSR for the development and introduction of polymolecular organosilicon coatings.

Voronkov and his co-workers were the first to create dirt-repellent organosilicon coatings.

Organosilicon sorbents and ion-exchange resins were for the first time synthesized on the basis of carbofunctional organosilicon monomers of the $R(CH_2)_nSi(OR)_3$ type. Some of these sorbents are used to recover from strongly diluted solutions and

1070-4272/01/7412-2128 $25.00 © 2001 MAIK "Nauka/Interperiodica"

separate mercury, silver, gold, platinum metals and rare-earth elements. Plasmochemical methods for depositing doped films of silicon dioxide or silicon nitride onto the surface of semiconductor materials and circuits have been developed. Other ways have been found for using organosilicon monomers and oligomers in microelectronics. For these developments, Voronkov was awarded the Prize of the Council of Ministers of the USSR in 1991.

Voronkov developed and introduced a number of sulfide break-in, antiwear, and antiseizure lubricant oil and motor fuel additives.

A versatile aqueous quenching medium, which replaced the previously used mineral oils, was put in practice at the largest plants of the country.

Voronkov's original designs were introduced into practice in industry, agriculture, and medicine (biostimulants, adaptogens, catalysts for microbiological synthesis, water-repellent and bioprotective organosilicon coatings, sorbents and ion-exchangers, special materials for microelectronics. Versatile aqueous quenching medium, lubricant oil additives, hydrodynamic resistance–reducing polymers, materials for special technologies, etc.). A number of original medical products having no analogues world medicine (feracryl, argacryl, acizole, trecrezan, silakist, silimine, dibutyrine, cobasole, sibusole, etc.) have been created under his supervision.

In 1983, Voronkov was given the rank of "Honorary Chemist of the USSR" and his name was put into the Book of Honor of the Ministry of Chemical Industry of the USSR.

The results of sixty years of Voronkov's investigations are reflected in more than 2000 scientific papers, of which 200 have been published abroad, in 45 monographs (of which 15 have been published in the US, UK, Japan, GDR, Poland, Romania), and also in 60 reviews published in national and foreign editions and in wide variety of popular-science articles. He received about 500 USSR Inventor's Certificates and more than 50 foreign patents.

Voronkov combined his intensive scientific work with extensive scientific-organizational and public activities. In 1970–1994, he headed the Institute of Organic Chemistry, Siberian Division, Russian Academy of Sciences; from 1973 till 1984, he was deputy chairman of the Presidium of the Eastern-Siberian Branch (later, Irkutsk Scientific Center, Siberian Division, Academy of Sciences of the USSR); in 1982–1989, he was director general of Khimiya research-and-production association. In 1965, he became deputy chairman, and in 1986, chairman of the Scientific Council for "Chemistry and Technology of Organic Compounds of Sulfur" of the State Committee for Science and Technology of the USSR (later, Ministry of Industry, Science, and Technology of the Russian Federation). He is also an expert for science and technology of this ministry. Voronkov was elected a corresponding member of the Academy of Sciences of Latvian SSR in 1966, a corresponding member of the Academy of Sciences of the USSR in 1970, and full member of the Academy of Sciences of the USSR in 1990. He is a member of the editorial boards of *Zhurnal Obshchei Khimii* (Russian Journal of General Chemistry) and a number of international journals.

The international recognition of Voronkov's scientific merits was manifested in that he was elected a foreign member of the Latvian Academy of Sciences (1992), corresponding member of Braunschweig scientific society (FRG, 1976), *honoris causa* doctor (Poland, 1975), member of the international society for environmental research and health protection SIRES (France), honorary member of Florida Institute of Heterocyclic Chemistry (USA, 1998), and member of the chemical societies of Japan and Latvia. He was awarded a medal of the Academy of Sciences of the Mongolian People's Republic, Polar Star Order and Friendship medal (Mongolia).

Mikhail Grigor'evich is a veteran of the Great Patriotic War, participant of the defense of Leningrad; he was awarded Orders of Great Patriotic War, Red Banner of Labor, Peoples' Friendship, For Services to Motherland, and 18 medals.

Voronkov still demonstrates high capacity for work, wide variety of original scientific ideas, broad scope of scientific interests, great erudition, benevolent attitude toward colleagues, and inexhaustible humor. Voronkov continues his scientific activities at Irkutsk Institute of Chemistry, Siberian Division, Russian Academy of Sciences. He is advisor of the Russian Academy of Sciences and consultant of a number of chemical plants, scientific centers, and institutes in Russia, Ukraine, China, and Mongolia. Only during the year of 1997, he reported on his most recent investigations at three international conferences, and in 1998 and 2001, at two conferences each year.

The Editorial Board and Editorial staff of *Zhurnal Prikladnoi Khimii* heartily congratulate Mikhail Grigor'evich Voronkov, Doctor of chemical sciences, professor, and academician, on his eightieth birthday and wish him sound health, happiness, and further success.

INFORMATION

IV Scientific Conference "Development of Russia's Rare-Earth Industry on the Basis of Loparite"

IV Scientific Conference "Development of Russia's Rare-Earth Industry on the Basis of Loparite" with more than 110 participants from Russia, Ukraine, Kazakhstan, Estonia, and Austria was held in St. Petersburg on May, 22–24, 2001. This event was initiated by the Institute of Chemistry, Kola Scientific Center, Russian Academy of Sciences; Rosredmet AO (St. Petersburg), and Administration of Murmansk Oblast on whose territory lies a unique deposit of loparite ores. The main effort in organizing the conference was made by Rosredmet AO, a company that expressed most earnest intention to create a plant for manufacturing of tantalum, niobium, titanium, and rare-earth products on the basis of this deposit.

The preceding "loparite" conference was held more than ten years ago, when the USSR was one of the largest world's manufacturers of rare-earths, and the Lovozero deposit of loparite stably provided its raw materials to satisfy country's demand for tantalum, niobium, rare-earths and, in part, titanium. Cooperation of the Lovozero ore mining and processing combine, Solikamsk magnesium plant, Slantsekhimicheskii plant (Estonia), Ul'binsk metallurgical and Irtysh chemical-metallurgical plants (Kazakhstan) enabled manufacture of a wide assortment of products for electronics and electrical engineering, ferrous and nonferrous metallurgy, nuclear power engineering, petrochemistry, optics, and many other industries.

After 1991, stable connections between the plants were disrupted, part of the plants is out of action, and loparite manufacturer—Sevredmet AO is going bankrupt. Here, the largest Russia's tantalum reserve is concentrated: the Karnasurt mine is to serve during 30 years, and the Umbozero mine is provided with resources for 50 years. The loparite concentrate from Lovozero has been and still is the main source of niobium in the country. It contains 25% of the total Russia's reserve of rare earths. The titanium component of the loparite concentrate is also of vital importance.

Possessing the necessary raw material resources and substantial scientific potential, we virtually do not produce tantalum, and, as regards such a fundamentally important parameter as niobium consumption per ton of steel, Russia is exceeded by a factor of 6 by the European Community, 9-fold by the US, and by a factor of 11 by Japan. Rare-earths are virtually not produced at all. All this leads to a pronounced dependence of the country from foreign markets and, undoubtedly, could serve to exert pressure on the country in a complicated situation.

The conference program included 40 oral and 17 poster presentations. Three reports concerned with the basic problems considered at the conference were delivered at plenary sessions.

V.E. Kalinnikov's report (Apatity), opening the scientific part of the conference, made a brief historical review of the chemical technology of loparite. It emphasized that the complex nature of the raw material containing more than 80% valuable components required a combined approach to its processing and was a real challenge to chemists-technologists and specialists in closely related fields. Solving this problem required many years' effort of scientists headed by Ya.G. Goroshchenko, who laid foundation of acid methods for loparite concentrate processing. Then, during decades, technological schemes have been under development, which employed a wide variety of mineral acids, depending on plant location, economic situation, and necessity for manufacture of one or another product. The report compared the advantages and disadvantages of these schemes and the constituent operations and mentioned important scientific advances made in their development. The author formulated basic principles of construction of the optimal schemes for processing of complex titanium–rare-earth raw materials, having emphasized that the schemes must be combined to ensure the necessary and readily reshaped assortment, product quality, and environmental safety.

As the most efficient way to exploit the mineral resources of the Kola peninsula, the report considered the possibility of creating a regional ore mining and processing combine intended for maximum intensification of processing of conventional and new types of rare-earth raw materials.

A.V. Elutin (Moscow) considered in his report the state and prospects of the market of processed loparite

1070-4272/01/7412-2130 $25.00 © 2001 MAIK "Nauka/Interperiodica"

concentrate and the economy of their manufacture by various technological schemes. He noted that the ores of the Lovozero loparite deposit have been and still remain the main source of niobium, tantalum, and rare-earth products in the country, but only Lovozero mining company (LGK) and Solikamsk magnesium plant (SMZ), processing loparite by the chlorine method, remained in the chain from the previously existing, well-developed system of plant cooperation. A study of prospects for development of the market of finished products of the technology indicates an unlimited demand on the foreign markets for the tantalum and niobium components, excess of demand for rare-earths over their supply, and the expected increase in the domestic demand for tantalum, niobium, and rare earths by 2005.

The report proposed a scheme for meeting the demand with account of the capacity of reserves of these metals. The scheme is based on raising the manufacture of loparite, use of the production capacity of Silmet AO (Estonia), and creation of a new plant for concentrate processing in Russia. According to the author's estimates, the nitric acid–chloride technology seems to be the most promising in this regard. The report presented the results of economic calculations confirming the efficiency of the future enterprise.

The problem of the present state of the analytical facilities of the rare-metal industry and, in particular, of the analytical monitoring of the quality of the loparite concentrate and products of its processing were considered in the report presented by Yu.A. Karpov (Moscow). Analyzing the general trends in the development of analytical chemistry—transition from labor-consuming and slow classical chemical methods to high-performance instrumental techniques, he noted that the leading research institute of the industry and a number of plants participating in loparite processing were equipped with modern precision analytical instruments. In the author's opinion, the simultaneous presence in loparite of a wide variety of elements imposes quite a number of stringent and specific requirements on the analytical monitoring and makes more important atomic emission, atomic absorption, and X-ray fluorescence techniques. A prominent place is occupied by the atomic emission analysis with inductively coupled plasma, determining separately simultaneously present rare-earth elements by means of modern software. Analysis of high-purity objects, whose share in products obtained by processing rare-earth-metal raw materials is growing all over the world, is made by mass-spectrometric techniques. A specific feature of plasma mass-spectrometry is its versatility enabling quantitative analysis for a wide variety of elements with large to ultrasmall content and determining the isotopic composition of samples. A separate problem mentioned by the author is fabrication of reference composition samples, updating of the regulating documents, and accreditation of laboratories.

T.Yu. Usova (Moscow) analyzed the state of the world market of tantalum, niobium, and rare-earth elements of the cerium group and considered the reasons for a dramatic increase in prices of tantalum-containing ores and final products. Of particular interest was the report by L.Z. Bykhovskii (Moscow), concerned with the importance of loparite ores in the mineral resources and manufacture of rare metals.

Undoubtedly, manufacturers of tantalum and niobium products are working at improving their quality in order to reduce their cost and use them in new fields of technology. The influence exerted by the market of final products on the technology of tantalum and niobium was revealed in a report by E.G. Polyakov (St. Petersburg). M.A. Polyakova (Moscow) considered in her communication new fields of use of rare-earth metals of the cerium group. One of, undoubtedly, the most important issues concerning the technological and economic prerequisites for efficient work of a plant for loparite concentrate processing was discussed in a report by Z.D. Gritsai (St. Petersburg).

An objective assessment of investments in the development of mineral resources of the Lovozero deposit for obtaining titanium, tantalum, niobium, and rare-earth products is impossible without analyzing the state of the mining facilities for manufacture of the loparite concentrate. The problems and prospects of the mining facilities of the Lovozero deposit were considered in a detailed report by I.I. Bessonov (Apatity). The report of A.I. Rakaev (Apatity) was concerned with pretreatment of loparite ores before gravitational dressing, aimed at the maximum possible recovery of valuable components at their minimum possible disintegration.

New trends in creation of promising technological materials on the basis of chemical compounds of tantalum and niobium were the subject of the report by A.A. Titov (Moscow). The development of high-capacity tantalum capacitor powders, conditions of sodium-reduction of potassium heptafluorotantalate, effect of subsequent treatment on the physical, physicomechanical, and electrical characteristics of powders and sintered capacitor anodes were considered in a report by V.M. Orlov (Apatity).

Various methods for loparite concentrate decomposition were reflected in a considerable number of reports and gave rise to lively discussion. The main ways of development, unused possibilities, and prospects of the sulfuric acid technology of loparite and its chemical and technological foundations were discussed in their reports by L.I. Sklokin and D.L. Molotov (Apatity); nitric acid decomposition of the loparite concentrate, by A.N. Sviridov (Moscow); nitric acid–hydrofluoride processing of loparite, by S.V. Shestakov (St. Petersburg); nitric acid–hydrochloride technology, by V.A. Krokhin; chlorine technology, by A.V. Chub (Soikamsk); hydrochloride technology, by A.I. Nikolaev (Apatity); hydrofluoride technology, by L.I. Sklokin (Apatity); combined processing of loparite, including nitric acid decomposition, chlorine technology (fractionation and condensation) or hydrofluoride processing of the hydrated cake, by S.A. Pirkovskii (Moscow); and autoclave method of recovery with unconventional chlorine-containing agents, by Yu.L. Garmazov (Irkutsk).

Despite the wide variety of the presented technological schemes for decomposition of the loparite concentrate, each having its own advantages and disadvantages, the nitric acid scheme is, not counting the sulfuric acid and chlorine techniques, the best-developed and well-tried on the industrial scale. One of its indisputable advantages is the reliable separation of the rare-earth and rare-metal parts of the concentrate. This, together with the high recovery of valuable components, is a prerequisite for setting-up a plant for processing of industrial products formed upon decomposition to well-marketable commercial compounds of tantalum, niobium, titanium, and rare-earth elements, satisfying the requirements of the present-day market.

The conference participants paid close attention to the report by F.H. Bayerhold, a representative of Andritz AG Ruthner (Wien, Austria), "Pyrohydrolysis: Basic Principles and Use in Non-Ferrous and ferrous Metallurgy since the approaches used in his technique are applicable to a HNO_3/HF mixture and to fluoride media formed in selective leaching of Nb, Ti, and Ta. The report presented new developments of the company, intended for regeneration of a mixture of acids (PYROMARS) or HCl.

Five interesting reports concerned with extraction technology were presented by Institute of Rare Element and Mineral Chemistry and Technology, Kola Research Center, Russian Academy of Sciences (IKhTREMS KNTs RAN), (Apatity). The extraction recovery of tantalum and niobium compounds in hydrated cake processing in the technology of loparite and joint tests of the proposed extraction technology by Rosredmet AO and IKhTREMS KNTs RAN on a pilot installation created by Rosredmwet AO at Sevredmet AO (Revda settl., Murmansk Province) were discussed in two reports by A.I. Nikolaev; extraction purification of fluorotitanium solutions for loparite concentrate processing, by V.A. Tyuremnov; fundamental aspects of extraction of niobium, tantalum, and titanium extraction with octanol, by I.V. Baklanova; and extraction recovery of metals from solutions for hydrochloric acid leaching of the loparite concentrate, by N.I. Kasikova. The extraction technology of processing of rare-earth metal solutions obtained from the loparite concentrate was considered by E.B. Mikhlin (FGUP Giredmet, Moscow).

Among poster reports, mention should be made of a study of the crystal structure of loparite from the Lovozero alkaline deposit (A.V. Arakcheeva, Moscow) and the development of schemes for monitoring analytically the processing of loparite concentrate and the quality of final products (T.G. Kashulina, Apatity).

The reports on "Manufacture and Use of Nonsiliceous Ligatures in Industry" were delivered in a special section. M.M. Verklov (Moscow), A. A. Kosilov (St. Petersburg), and M.D. Lyubalin (St. Petersburg) considered in their reports the state and problems of manufacture of various alloys containing rare-earth metals for creating new brands of construction steels. Examples of successful use of products obtained in loparite concentrate processing in manufacture of nickel- and iron-based rare-earth ligatures were given in a report by B.M. Freidin (Apatity). The prospects for use of industrial products and wastes of the Severonikel' combine in manufacture of complex rare-earth ligatures were covered by A.G. Kasikov (Apatity). Much attention was attracted by the report by A.A. Vasil'ev (St. Petersburg) on the resumption of manufacture of nonsiliceous complex ligatures on nickel base and analysis of the state of their market in Russia and CIS countries. The author demonstrated that nonsiliceous complex ligatures, including rare-earth metals, titanium, and niobium obtained from loparite, ensure deep deoxidation and modification of steel. As a result, the strength characteristics, impact elasticity, wear resistance, cold-resistance of steel are enhanced, its grain size becomes smaller, and casting properties are improved.

During the conference, a round-table discussion was organized, including more than 20 representatives of industrial enterprises; it was recommended to expand the assortment of ligatures with account of customers' demand, pay attention to the quality of the

starting raw materials, search ways to make lower the ligature cost, analyze and generalize the comments of plants using ligatures. The participants of the section considered the first experience of discussion and opinion exchange, involving specialists from the industry, a success and proposed to use this form of conference work in the future.

The discussion of the delivered reports on the final day of the conference took, in fact, the shape of a general discussion of the state of affairs in Russia as regards the self-sufficiency of the country with respect to such strategically important metals as tantalum, niobium, titanium, and rare-earth metals. The speakers noted that the recent decade resulted in substantial changes in the market of rare metals—it increasingly belongs to high-tech products with wide variety of stringent and markedly different requirements to the chemical and physical characteristics of materials on rare metals. The participants spoke with anxiety about the disruption of customary connections between those who produce raw materials, process them, and manufacture final products, such as tantalum capacitor powders, and emphasized the necessity for coordination among them and activation of scientific research in this direction.

The resolution of the conference proposes that the Kola Scientific Center, Russian Academy of Sciences, and a number of other institutions should initiate setting a State program of interbranch research into the problem of loparite mining and processing, and efficient use of tantalum, niobium, and rare earths in high-tech fields of industry. To assess the proposed technological schemes of loparite processing, it is advisable to use the services of a specialized designing institute. The conference participants consider it necessary to ensure state and financial support of research and design work aimed to create a rare-metal plant working on loparite from the Lovozero deposit.

A decision was made to request the Ministry of Economic Development and the Ministry Industry and Science of the Russian Federation to support the efforts of plants that mine and process loparite at the Lovozero deposit, which is presently the main source of tantalum, niobium, and rare-earth metals in the country, including Solikamskii magnievyi zavod AO, Rossiiskie redkie metally AO, and Sevredmet AO.

E. G. Polyakov and L. P. Polyakova
